Software

The procedures in SAS/ETS software were implemented by members of the Advanced Analytics Division. Program development includes design, programming, debugging, support, documentation, and technical review. In the following list, the name of the developer who currently has principal support responsibility for the procedure is given first.

ARIMA  Rajesh Selukar, Michael J. Leonard, Terry Woodfield

AUTOREG  Xilong Chen, Jan Chvosta, Richard Potter, John P. Sall

COMPUTAB  Michael J. Leonard, Alan R. Eaton

COPULA  Hao Chen, Jan Chvosta, Jason Qiao

Overview

This chapter summarizes the new features available in SAS/ETS 13.1 software.

If you have used SAS/ETS procedures in the past, you can review this chapter to learn about the new features that have been added. When you see a new feature that might be useful for your work, turn to the appropriate chapter to read about the feature in detail.
Highlights of Changes and Enhancements

The following procedures and interface engine have been added to SAS/ETS software:

- HPCDM procedure
- HPCOPULA procedure
- HPPANEL procedure
- SASEFRED interface engine

New features have been added to the following SAS/ETS components:

- AUTOREG procedure
- COPULA procedure
- COUNTREG procedure
- HPCOUNTREG procedure
- HPQLIM procedure
- HPSEVERITY procedure
- PANEL procedure
- QLIM procedure
- SASECRSP interface engine
- SASEXCCM interface engine
- SASEXFSD interface engine
- SEVERITY procedure
- SSM procedure
- UCM procedure
- VARMAX procedure

Highlights of Enhancements in SAS/ETS 12.1

Users who are updating directly to SAS/ETS 13.1 from a release prior can find information about the SAS/ETS 12.1 changes and enhancements in the chapter “What’s New in SAS/ETS” in the SAS/ETS 12.1 User’s Guide (see support.sas.com/whatsnewets121).
**AUTOREG Procedure**

The following features have been added to the AUTOREG procedure:

- The status of multiple structural change tests proposed by Bai and Perron (1998) has changed from experimental to production.
- The GARCH=(TYPE=NOCONSTRAINT) option is supported. You can estimate GARCH models without constraints on parameters by using this option. In particular, you can mimic the long-memory behavior of volatility in component GARCH models proposed by Ding and Granger (1996) and Engle and Lee (1999) by specifying this option on GARCH(2,2) model.

**COPULA Procedure**

The following features have been added to the COPULA procedure:

- The COPULA procedure now supports the tail dependence plot (chi-plot) in the PLOTS option. You can use this plot to visually examine the tail dependence of fitted and simulated copulas.

**COUNTREG Procedure**

The following features have been added to the COUNTREG procedure:

- Support for item stores. You can now use the STORE statement to save your COUNTREG model, parameter estimates, and other statistics in an item store and use the RESTORE option to restore them from your item store. You can use the new SHOW statement to view the contents of your item store and the new SCORE statement to score a data set using the estimates preserved in your item store.
- Support for new options in the CLASS statement. These new options allow you to control parameterization method, reference levels, and sort order for your classification variables.

**HPCDM Procedure (Experimental)**

The HPCDM procedure is a new, experimental high-performance procedure in SAS/ETS. The HPCDM procedure estimates a compound distribution model (CDM), which is the distribution of an aggregate loss that you expect to see in a given period of time. The aggregate loss depends on the number of loss events that occur in a given period of time and the severity (magnitude) of each loss event.
If you have estimated the probability distribution model of the frequency of loss events by using the COUNTREG procedure in SAS/ETS, and if you have estimated the probability distribution model of the severity of each loss by using the SEVERITY procedure in SAS/ETS, then PROC HPCDM combines the frequency and severity models to estimate the distribution of an aggregate loss. The probability distribution model of the aggregate loss is referred to as the compound distribution model (CDM).

At its core, PROC HPCDM uses the Monte Carlo simulation method to generate a random sample of the aggregate loss. The random sample is used to compute empirical estimates of various summary statistics and percentiles of the compound distribution. The HPCDM procedure also has the following features:

- PROC HPCDM performs a scenario or what-if analysis when the distributions of severity and count depend on a set of exogenous variables. You can simulate a scenario for one entity that is subject to loss events. For example, you can estimate the distribution of the aggregate loss that one insurance policyholder might incur by using the policyholder’s characteristics. You can also simulate a scenario that consists of multiple entities that are subject to the loss events. For example, you can estimate the distribution of the aggregate loss that is incurred together by a portfolio of financial instruments by using the characteristics of each instrument as well as the macroeconomic factors that affect each of them.

- PROC HPCDM can perform a parameter perturbation analysis to assess the effect of the uncertainty in the estimates of severity and frequency model parameters on the uncertainty of various statistics of the compound distribution. For example, if you are interested in computing the value-at-risk (VaR), which is usually the 97.5th or the 99.5th percentile of the aggregate loss distribution, then by using perturbation analysis of PROC HPCDM, you can get an estimate of not only the mean expected VaR but also the standard error that is associated with VaR. Both estimates can help you maintain an adequate amount of capital for regulatory compliance as well as a healthy, solvent business.

- PROC HPCDM estimates the compound distribution of an aggregate adjusted loss when you specify SAS programming statements to adjust the magnitude of each simulated loss. For example, this is helpful in estimating the distribution of the total amount paid by an insurance company to its policyholders in a given period of time. The amount paid for each loss depends on the magnitude of the loss as well as the various provisions in the insurance policy, such as the deductible and policy limit.

---

**HPCOPULA Procedure (Experimental)**

The new HPCOPULA procedure is a high-performance version of the COPULA procedure in SAS/ETS software, which enables you to simulate realizations of multivariate distributions by using the copula approach.

The HPCOPULA procedure supports simulation of multivariate distributions for the following types of copulas:

- normal copula
- $t$ copula
- Clayton copula
• Gumbel copula
• Frank copula

HPCOUNTREG Procedure

The following features have been added to the HPCOUNTREG procedure:

• support for the BY statement

HPPANEL Procedure (Experimental)

The new HPPANEL procedure is a high-performance version of the PANEL procedure in SAS/ETS software, which analyzes a class of linear econometric panel data models.

The HPPANEL procedure provides the following four models:

• one-way fixed-effects model
• two-way fixed-effects model
• one-way random-effects model
• two-way random-effects model

The following features have been added:

• The TEST statement performs Wald, Lagrange multiplier, and likelihood ratio tests of linear hypotheses about the regression parameters.
• You can request the restricted estimator by using the RESTRICT statement.
• You can request the Hausman (1978) specification test for random effects.
• For random-effects models, variance components are calculated by using methods described by Fuller and Battese (1974); Wansbeek and Kapteyn (1989); Wallace and Hussain (1969); Nerlove (1971).
Chapter 1: What's New in SAS/ETS 13.1

**HPQLIM Procedure**

The following features have been added to the HPQLIM procedure:

- Discrete choice models. Most of the discrete choice models available in the QLIM procedure are now available in the HPQLIM procedure. The HPQLIM procedure also support the BY statement. The main features are as follows:
  - support for binary models: probit and logit models
  - support for ordinal models: ordered probit and ordered logit models
  - support for the BY statement

**HPSEVERITY Procedure**

The following features have been added to the HPSEVERITY procedure:

- The HPSEVERITY procedure now supports the BY statement in the single-machine mode of execution. For the distributed mode, the BY statement is supported only in the client-data (or local-data) mode of the distributed computing model.

- The HPSEVERITY procedure now supports a new OFFSET= option in the SCALEMODEL statement to specify an offset variable in the scale regression model. An offset variable is a regressor that has a fixed regression coefficient of 1. An offset variable is useful for modeling the scale parameter per unit of some measure of exposure and for correcting the omitted variable bias.

- The HPSEVERITY procedure now supports a new OUTSCORELIB statement to create scoring functions. A scoring function is derived from a distribution function such that the parameter estimates of a fitted severity model are encoded inside the scoring function. You can use a scoring function to evaluate the corresponding distribution function without having to write a potentially complex SAS program to extract the parameter estimates. If you have specified a scale regression model, then you can use the scoring functions to score new observations by easily computing various statistics of interest, such as the mean and quantiles that depend on the regressor data. **NOTE:** This is an experimental feature.

The specification of custom objective function was an experimental feature in previous releases. It is now production.

**PANEL Procedure**

The following features have been added to the PANEL procedure:
• The status of panel unit root tests changed from experimental to production.

• The system GMM estimator proposed by Blundell and Bond (1998) is supported. The default changed to system GMM. The DEPVAR option has been modified. It can take the form of DEPVAR(LEVEL), DEPVAR(DIFF), and DEPVAR(ALL), depending on whether the level or the differenced variables are used as instruments.

---

### QLIM Procedure

The following features have been added to the QLIM procedure:

• Bayesian estimation features. Most of the multivariate models available in the QLIM procedure can now be estimated in a Bayesian framework by using the BAYES statement.

• Endogeneity issues can now be addressed in most of the models available in the QLIM procedure:
  – Parameters of a single structural model, such as a discrete choice model or limited dependent variable model with endogenous explanatory variables, along with the parameters of the reduced form models can be estimated consistently. There is no restriction on the nature of the endogenous explanatory variables; they can be discrete, censored, or truncated.
  – A new endogeneity test for the explanatory variables is available.
  – An overidentifying restrictions type test is available to test the validity of the instruments.

• For Heckman’s two-step procedure, a new option is available. This option enables the model for the selected sample to be a discrete choice or limited dependent variable model.

---

### SASECRSP Interface Engine

The SASECRSP interface engine for SAS/ETS 13.1 supports Linux X64 (64-bit), Solaris Sun Ultra Sparc, Solaris on Intel x86, and Windows.

CRSP/Compustat Merged Databases are no longer supported by SASECRSP because the CRSP API no longer supports the legacy access routines for the CCM legacy database.

The SASEXCCM interface should be used instead of the SASECRSP interface to access Xpressfeed CCM data. The SASEXCCM interface provides data item handling access methods by using CRSPAccess, version 3.23. For a detailed description of this new ETS interface engine, see Chapter 40, “The SASEXCCM Interface Engine.”

Because CRSPAccess, version 3.23, does not support CPZ data (legacy Compustat data format for SETID 200), the SASECRSP engine issues the following error messages when the SETID=200 option or CR-SPLINKPATH= option is used:
Chapter 1: What's New in SAS/ETS 13.1

**ERROR:** Use the SASEXCCM engine instead of the SASECRSP engine for CCM access. The CPZ data format needed for SETID=200 and the CRSPLINKPATH= options was last shipped in July 2011, and is no longer supported by CRSP. Use of the SASECRSP engine for this purpose is not allowed: Depreciated calendar configurations may result in fatal errors, corrupted memory, tracebacks, exceptions, or incorrect results for all libname assignments that follow the deassignment of a CCM/CRSPLINKPATH libref.

**ERROR:** Engine is unable to open crspdb CPZ200606 with setid 200. Check that your CRSP database contains crsp_ca_ref_2.bin file.

---

**SASEFRED Interface Engine**

The new SASEFRED interface engine enables SAS users to retrieve economic data from the FRED website, which is hosted by the Economic Research Division of the Federal Reserve Bank of St. Louis. FRED stands for Federal Reserve Economic Data. The FRED databases contain more than 61,000 economic data time series from 48 national and international sources, both public and private. These time series are updated at annual, quarterly, monthly, weekly, and daily intervals. The economic time series on the FRED website contain observation or measurement periods that are associated with data values. The SASEFRED interface engine uses the LIBNAME statement to enable you to specify how to subset your FRED data and how to aggregate the selected time series to the same update frequency. You can then use the SAS DATA step to perform further subsetting and to store the resulting time series in a SAS data set. You can perform more analysis (if desired) either in the same SAS session or in a later session. The SASEFRED interface engine supports Windows.

---

**SASEXCCM Interface Engine**

The SASEXCCM engine should be used instead of the SASECRSP engine for accessing the CCM database (SETID=250). The SASEXCCM interface engine is now production for CCM, STK, and IND access. The TRS access is an experimental feature and should be used at your own risk. CRSP supplies SAS data sets for US Treasury data in its TFZ product. The SASEXCCM interface engine supports Linux X64 (LAX), Solaris X64 (SAX), Solaris SPARC (S64), and Windows.

---

**SASEXFSD Interface Engine**

The new SASEXFSD interface engine enables SAS users to access FactSet data that are provided by the FactSet FASTFetch Web service. This service provides access to a number of data libraries from economic and financial data sources such as Aspect Huntley Fundamentals, Compustat, Dun and Bradstreet Corporation, FactSet, Ford Equity Research, Reuters, SEDAR, Toyo Keizai, Value Line, Worldscope, CEIC, EuroStat, Global Insight, IMF International Financial Statistics, INDB Main Economic Indicators, Markit Economics,
OECD, ONS (UK Office for National Statistics), U.S. Consumer Confidence Survey, Thomson Analytics Insider Trading, Trucost Environmental, SIC, and WM/Reuters. The ExtractBenchmarkDetail factlet is now supported by the SASEXFSD interface, and the ExtractEconData factlet can use FQL (Factset Query Language) syntax and functions. The SASEXFSD interface is now production and supports Windows.

SEVERITY Procedure

The following features have been added to the SEVERITY procedure:

- The SEVERITY procedure now supports a new OFFSET= option in the SCALEMODEL statement to specify an offset variable in the scale regression model. An offset variable is a regressor that has a fixed regression coefficient of 1. An offset variable is useful for modeling the scale parameter per unit of some measure of exposure and for correcting the omitted variable bias.

- The SEVERITY procedure now supports a new OUTSCORELIB statement to create scoring functions. A scoring function is derived from a distribution function such that the parameter estimates of a fitted severity model are encoded inside the scoring function. You can use a scoring function to evaluate the corresponding distribution function without having to write a potentially complex SAS program to extract the parameter estimates. If you have specified a scale regression model, then you can use the scoring functions to score new observations by easily computing various statistics of interest such as the mean and quantiles that depend on the regressor data. **NOTE:** This is an experimental feature.

The following two features, which were experimental in previous releases, are now production:

- specification of custom objective functions

- estimation of the empirical distribution function (EDF) with Turnbull’s estimator when you specify left-censoring or right-truncation in addition to right-censoring or left-truncation

SSM Procedure

The SSM procedure, which was experimental before this release, is now production and adds the following new features:

- The SSM procedure now supports a more general state transition equation. The new state transition equation permits inclusion of regression effects. You can use the new W= option in the STATE statement to specify the regression variables that affect the corresponding state subsection. Several examples in the documentation illustrate this functionality: one example shows how to formulate a transfer function model as a state space model by using this feature, and another example shows how to account for a structural break in a component by specifying a dummy regressor in the corresponding state equation.
• You can now search for structural breaks in any model component. The new CHECKBREAK option in the STATE and TREND statements generates a summary of the most likely break locations during the time evolution of the associated state subsection. For example, you can use the CHECKBREAK option in a TREND statement to generate a summary table of sudden shifts in the level (or slope) of the corresponding trend component.

---

**UCM Procedure**

The following experimental feature has been added to the UCM procedure:

• In the UCM procedure, by default, the standard errors of the series and component forecasts are computed by assuming that the estimated parameters are in fact the true parameters. Rodriguez and Ruiz (2010) describe a bootstrap-based procedure for computing the standard errors of the series and component forecasts that takes into account the uncertainty of the parameter estimation. By using this experimental feature in this release, you can request the computation of the standard errors based on this procedure by specifying the BOOTSTRAP option in the FORECAST statement. Subsequently, the confidence intervals for the series and component forecasts are based on these bootstrap standard errors. Note that this bootstrap algorithm is computationally expensive. The computational burden increases with the number of bootstrap replications and is comparable to fitting the specified model as many times as the number of replications. Fortunately these replications can be executed in parallel, and the UCM procedure can use multiple cores and multiple grid nodes (if they are available) to complete these calculations faster.

---

**VARMAX Procedure**

The following features have been added to the VARMAX procedure:

• Huge performance and scalability improvements are achieved for VARMAX and VARMAX-GARCH models that are estimated through the method of maximum likelihood. In some test cases, the estimation speed is thousands of times faster than in previous versions.

• The BOUND statement is supported. That is, you can specify inequality constraints on parameters to be estimated.

• The INITIAL statement is supported. Hence, you can set up the initial values for parameters to be estimated.

• The matrix expressions, operators, and functions are supported in the BOUND, INITIAL, RESTRICT, and TEST statements.

• The multivariate DCC GARCH model is supported.
• Four new forms of univariate GARCH models, namely the exponential GARCH (or EGARCH) model, the power GARCH (or PGARCH) model, the quadratic GARCH (or QGARCH) model, and the threshold GARCH (or TGARCH) model, are supported through the new SUBFORM= option in the GARCH statement for CCC and DCC GARCH models.

• The concentrated likelihood estimation (that is, estimating the constant correlation matrix through the standardized residuals by specifying CORRCONSTANT=EXPECT) is supported for CCC and DCC GARCH models.

Overview of SAS/ETS Software

SAS/ETS software, a component of the SAS System, provides SAS procedures for:

- econometric analysis
- time series analysis
- time series forecasting
- systems modeling and simulation
- discrete choice analysis
- analysis of qualitative and limited dependent variable models
- seasonal adjustment of time series data
- financial analysis and reporting
- access to economic and financial databases
- time series data management

In addition to SAS procedures, SAS/ETS software also includes seamless access to economic and financial databases and interactive environments for time series forecasting and investment analysis.
Uses of SAS/ETS Software

SAS/ETS software provides tools for a wide variety of applications in business, government, and academia. Major uses of SAS/ETS procedures are economic analysis, forecasting, economic and financial modeling, time series analysis, financial reporting, and manipulation of time series data.

The common theme relating the many applications of the software is time series data: SAS/ETS software is useful whenever it is necessary to analyze or predict processes that take place over time or to analyze models that involve simultaneous relationships.

Although SAS/ETS software is most closely associated with business, finance and economics, time series data also arise in many other fields. SAS/ETS software is useful whenever time dependencies, simultaneous relationships, or dynamic processes complicate data analysis. For example, an environmental quality study might use SAS/ETS software’s time series analysis tools to analyze pollution emissions data. A pharmacokinetic study might use SAS/ETS software’s features for nonlinear systems to model the dynamics of drug metabolism in different tissues.

The diversity of problems for which econometrics and time series analysis tools are needed is reflected in the applications reported by SAS users. The following listed items are some applications of SAS/ETS software presented by SAS users at past annual conferences of the SAS Users Group International (SUGI).

• forecasting college enrollment (Calise and Earley 1997)
• fitting a pharmacokinetic model (Morelock et al. 1995)
• testing interaction effect in reducing sudden infant death syndrome (Fleming, Gibson, and Fleming 1996)
• forecasting operational indices to measure productivity changes (McCarty 1994)
• spectral decomposition and reconstruction of nuclear plant signals (Hoyer and Gross 1993)
• estimating parameters for the constant-elasticity-of-substitution translog model (Hisnanick 1993)
• applying econometric analysis for mass appraisal of real property (Amal and Weselowski 1993)
• forecasting telephone usage data (Fischetti, Heathcote, and Perry 1993)
• forecasting demand and utilization of inpatient hospital services (Hisnanick 1992)
• using conditional demand estimation to determine electricity demand (Keshani and Taylor 1992)
• estimating tree biomass for measurement of forestry yields (Parresol and Thomas 1991)
• evaluating the theory of input separability in the production function of U.S. manufacturing (Hisnanick 1991)
• forecasting dairy milk yields and composition (Benseman 1990)
• predicting the gloss of coated aluminum products subject to weathering (Khan 1990)
• learning curve analysis for predicting manufacturing costs of aircraft (Le Bouton 1989)
• analyzing Dow Jones stock index trends (Early, Sweeney, and Zekavat 1989)
- analyzing the usefulness of the composite index of leading economic indicators for forecasting the economy (Lin and Myers 1988)

## Contents of SAS/ETS Software

### Procedures

SAS/ETS software includes the following SAS procedures:

<table>
<thead>
<tr>
<th>Procedure</th>
<th>Description</th>

X11 seasonal adjustment (Census X-11 and X-11 ARIMA)
X12 seasonal adjustment (Census X-12 ARIMA)

Macros

SAS/ETS software includes the following SAS macros:

%AR generates statements to define autoregressive error models for the MODEL procedure
%BOXCOXAR investigates Box-Cox transformations useful for modeling and forecasting a time series
%DFPVALUE computes probabilities for Dickey-Fuller test statistics
%DFTEST performs Dickey-Fuller tests for unit roots in a time series process
%LOGTEST tests to determine whether a log transformation is appropriate for modeling and forecasting a time series
%MA generates statements to define moving-average error models for the MODEL procedure
%PDL generates statements to define polynomial distributed lag models for the MODEL procedure

These macros are part of the SAS AUTOCALL facility and are automatically available for use in your SAS program. Refer to SAS Macro Language: Reference for information about the SAS macro facility.

Access Interfaces to Economic and Financial Databases

In addition to PROC DATASOURCE, these SAS/ETS access interfaces provide seamless access to financial and economic databases:

SASECRSP LIBNAME engine for accessing time series and event data residing in CRSPAccess database.
SASEFAME LIBNAME engine for accessing time or case series data residing in a FAME database.
SASEHAVR LIBNAME engine for accessing time series residing in a HAVER ANALYTICS Data Link Express (DLX) database.
SASEXCCM LIBNAME engine (experimental) for accessing data items residing in the CRSP US Stock (STK) Database, the CRSP US Stock and Indices (IND) Database, the CRSP US Treasury (TRS) Database, or the CRSP/Compustat Merged (CCM) Database, which is created from data delivered via Standard and Poor’s Compustat Xpressfeed product.

The Time Series Forecasting System

SAS/ETS software includes an interactive forecasting system, described in Part IV. This graphical user interface to SAS/ETS forecasting features was developed with SAS/AF software and uses PROC ARIMA and other internal routines to perform time series forecasting. The Time Series Forecasting System makes it easy to forecast time series and provides many features for graphical data exploration and graphical comparisons of forecasting models and forecasts. (You must have SAS/GRAPH® installed to use the graphical features of the system.)
Chapter 2: Introduction

The Investment Analysis System

The Investment Analysis System, described in Part V, is an interactive environment for analyzing the time-value of money in a variety of investments. Various analyses are provided to help analyze the value of investment alternatives: time value, periodic equivalent, internal rate of return, benefit-cost ratio, and break-even analysis.

About This Book

This book is a user’s guide to SAS/ETS software. Since SAS/ETS software is a part of the SAS System, this book assumes that you are familiar with Base SAS software and have the books SAS Language Reference: Dictionary and Base SAS Procedures Guide available for reference. It also assumes that you are familiar with SAS data sets, the SAS DATA step, and with basic SAS procedures such as PROC PRINT and PROC SORT. Chapter 3, “Working with Time Series Data,” in this book summarizes the aspects of Base SAS software that are most relevant to the use of SAS/ETS software.

Chapter Organization

Following a brief What’s New, this book is divided into five major parts. Part I contains general information to aid you in working with SAS/ETS Software. Part II explains the SAS procedures of SAS/ETS software. Part III describes the available data access interfaces for economic and financial databases. Part IV is the reference for the Time Series Forecasting System, an interactive forecasting menu system that uses PROC ARIMA and other routines to perform time series forecasting. Finally, Part V is the reference for the Investment Analysis System.

The new features added to SAS/ETS software since the publication of SAS/ETS Software: Changes and Enhancements for Release 8.2 are summarized in Chapter 1, “What’s New in SAS/ETS 13.1.” If you have used SAS/ETS software in the past, you may want to skim this chapter to see what’s new.

Part I contains the following chapters.

Chapter 2, the current chapter, provides an overview of SAS/ETS software and summarizes related SAS publications, products, and services.

Chapter 3, “Working with Time Series Data,” discusses the use of SAS data management and programming features for time series data.

Chapter 4, “Date Intervals, Formats, and Functions,” summarizes the time intervals, date and datetime informat, date and datetime formats, and date and datetime functions available in the SAS System.

Chapter 5, “SAS Macros and Functions,” documents SAS macros and DATA step financial functions provided with SAS/ETS software. The macros use SAS/ETS procedures to perform Dickey-Fuller tests, test for the need for log transformations, or select optimal Box-Cox transformation parameters for time series data.

Chapter 6, “Nonlinear Optimization Methods,” documents the NonLinear Optimization subsystem used by some ETS procedures to perform nonlinear optimization tasks.

Part II contains chapters that explain the SAS procedures that make up SAS/ETS software. These chapters appear in alphabetical order by procedure name.
Part III contains chapters that document the ETS access interfaces to economic and financial databases. Each of the chapters that document the SAS/ETS procedures (Part II) and the SAS/ETS access interfaces (Part III) is organized as follows:

1. The “Overview” section gives a brief description of the procedure.
2. The “Getting Started” section provides a tutorial introduction on how to use the procedure.
3. The “Syntax” section is a reference to the SAS statements and options that control the procedure.
4. The “Details” section discusses various technical details.
5. The “Examples” section contains examples of the use of the procedure.
6. The “References” section contains technical references on methodology.

Part IV contains the chapters that document the features of the Time Series Forecasting System.

Part V contains chapters that document the features of the Investment Analysis System.

---

**Typographical Conventions**

This book uses several type styles for presenting information. The following list explains the meaning of the typographical conventions used in this book:

- **roman** is the standard type style used for most text.
- **UPPERCASE ROMAN** is used for SAS statements, options, and other SAS language elements when they appear in the text. However, you can enter these elements in your own SAS programs in lowercase, uppercase, or a mixture of the two.
- **UPPERCASE BOLD** is used in the “Syntax” sections’ initial lists of SAS statements and options.
- **oblique** is used for user-supplied values for options in the syntax definitions. In the text, these values are written in italic.
- **helvetica** is used for the names of variables and data sets when they appear in the text.
- **bold** is used to refer to matrices and vectors and to refer to commands.
- **italic** is used for terms that are defined in the text, for emphasis, and for references to publications.
- **bold monospace** is used for example code. In most cases, this book uses lowercase type for SAS statements.

---

**Where to Turn for More Information**

This section describes other sources of information about SAS/ETS software.
Chapter 2: Introduction

Accessing the SAS/ETS Sample Library

The SAS/ETS Sample Library includes many examples that illustrate the use of SAS/ETS software, including the examples used in this documentation. To access these sample programs, select Help from the menu and then select SAS Help and Documentation. From the Contents list, select the section Sample SAS Programs under Learning to Use SAS.

Online Help System

You can access online help information about SAS/ETS software in two ways, depending on whether you are using the SAS windowing environment in the command line mode or the pull-down menu mode.

If you are using a command line, you can access the SAS/ETS help menus by typing help on the SAS windowing environment command line. Or you can issue the command help ARIMA (or another procedure name) to display the help for that particular procedure.

If you are using the SAS windowing environment pull-down menus, you can pull-down the Help menu and make the following selections:

- SAS Help and Documentation
- Learning to Use SAS in the Contents list
- SAS Products
- SAS/ETS

The content of the Online Help System follows closely that of this book.

SAS Short Courses

The SAS Education Division offers a number of training courses that might be of interest to SAS/ETS users. Please check the SAS web site for the current list of available training courses.

SAS Technical Support Services

As with all SAS products, the SAS Technical Support staff is available to respond to problems and answer technical questions regarding the use of SAS/ETS software.

Major Features of SAS/ETS Software

The following sections briefly summarize major features of SAS/ETS software. See the chapters on individual procedures for more detailed information.
The MDC procedure provides maximum likelihood (ML) or simulated maximum likelihood estimates of multinomial discrete choice models in which the choice set consists of unordered multiple alternatives. The MDC procedure supports the following models and features:

- conditional logit
- nested logit
- heteroscedastic extreme value
- multinomial probit
- mixed logit
- pseudo-random or quasi-random numbers for simulated maximum likelihood estimation
- bounds imposed on the parameter estimates
- linear restrictions imposed on the parameter estimates
- SAS data set containing predicted probabilities and linear predictor \((x'\beta)\) values
- decision tree and nested logit
- model fit and goodness-of-fit measures including
  - likelihood ratio
  - Aldrich-Nelson
  - Cragg-Uhler 1
  - Cragg-Uhler 2
  - Estrella
  - Adjusted Estrella
  - McFadden’s LRI
  - Veall-Zimmermann
  - Akaike Information Criterion (AIC)
  - Schwarz Criterion or Bayesian Information Criterion (BIC)

The QLIM procedure analyzes univariate and multivariate limited dependent variable models where dependent variables take discrete values or dependent variables are observed only in a limited range of values. This procedure includes logit, probit, Tobit, and general simultaneous equations models. The QLIM procedure supports the following models:
The COUNTREG procedure provides regression models in which the dependent variable takes nonnegative integer count values. The COUNTREG procedure supports the following models:

- Poisson regression
- negative binomial regression with quadratic and linear variance functions
- zero inflated Poisson (ZIP) model
- zero inflated negative binomial (ZINB) model
- fixed and random effect Poisson panel data models
- fixed and random effect NB (negative binomial) panel data models

The PANEL procedure deals with panel data sets that consist of time series observations on each of several cross-sectional units.

The models and methods the PANEL procedure uses to analyze are as follows:

- one-way and two-way models
- fixed and random effects
- autoregressive models
  - the Parks method
  - dynamic panel estimator
  - the Da Silva method for moving-average disturbances
Regression with Autocorrelated and Heteroscedastic Errors

The AUTOREG procedure provides regression analysis and forecasting of linear models with autocorrelated or heteroscedastic errors. The AUTOREG procedure includes the following features:

- estimation and prediction of linear regression models with autoregressive errors
- any order autoregressive or subset autoregressive process
- optional stepwise selection of autoregressive parameters
- choice of the following estimation methods:
  - exact maximum likelihood
  - exact nonlinear least squares
  - Yule-Walker
  - iterated Yule-Walker
- tests for any linear hypothesis that involves the structural coefficients
- restrictions for any linear combination of the structural coefficients
- forecasts with confidence limits
- estimation and forecasting of ARCH (autoregressive conditional heteroscedasticity), GARCH (generalized autoregressive conditional heteroscedasticity), I-GARCH (integrated GARCH), E-GARCH (exponential GARCH), and GARCH-M (GARCH in mean) models
- combination of ARCH and GARCH models with autoregressive models, with or without regressors
- estimation and testing of general heteroscedasticity models
- variety of model diagnostic information including the following:
  - autocorrelation plots
  - partial autocorrelation plots
  - Durbin-Watson test statistic and generalized Durbin-Watson tests to any order
  - Durbin $h$ and Durbin $t$ statistics
  - Akaike information criterion
  - Schwarz information criterion
  - tests for ARCH errors
  - Ramsey’s RESET test
  - Chow and PChow tests
  - Phillips-Perron stationarity test
  - CUSUM and CUMSUMSQ statistics
- exact significance levels ($p$-values) for the Durbin-Watson statistic
- embedded missing values
Simultaneous Systems Linear Regression

The SYSLIN and ENTROPY procedures provide regression analysis of a simultaneous system of linear equations.

The SYSLIN procedure includes the following features:

- estimation of parameters in simultaneous systems of linear equations
- full range of estimation methods including the following:
  - ordinary least squares (OLS)
  - two-stage least squares (2SLS)
  - three-stage least squares (3SLS)
  - iterated 3SLS (IT3SLS)
  - seemingly unrelated regression (SUR)
  - iterated SUR (ITSUR)
  - limited-information maximum likelihood (LIML)
  - full-information maximum likelihood (FIML)
  - minimum expected loss (MELO)
  - general K-class estimators
- weighted regression
- any number of restrictions for any linear combination of coefficients, within a single model or across equations
- tests for any linear hypothesis, for the parameters of a single model or across equations
- wide range of model diagnostics and statistics including the following:
  - usual ANOVA tables and R-square statistics
  - Durbin-Watson statistics
  - standardized coefficients
  - test for overidentifying restrictions
  - residual plots
  - standard errors and t tests
  - covariance and correlation matrices of parameter estimates and equation errors
- predicted values, residuals, parameter estimates, and variance-covariance matrices saved in output SAS data sets
- other features of the SYSLIN procedure that enable you to do the following:
  - impose linear restrictions on the parameter estimates
  - test linear hypotheses about the parameters
– write predicted and residual values to an output SAS data set
– write parameter estimates to an output SAS data set
– write the crossproducts matrix (SSCP) to an output SAS data set
– use raw data, correlations, covariances, or cross products as input

The **ENTROPY** procedure supports the following models and features:

- generalized maximum entropy (GME) estimation
- generalized cross entropy (GCE) estimation
- normed moment generalized maximum entropy
- maximum entropy-based seemingly unrelated regression (MESUR) estimation
- pure inverse estimation
- estimation of parameters in simultaneous systems of linear equations
- Markov models
- unordered multinomial choice problems
- weighted regression
- any number of restrictions for any linear combination of coefficients, within a single model or across equations
- tests for any linear hypothesis, for the parameters of a single model or across equations

---

**Linear Systems Simulation**

The **SIMLIN** procedure performs simulation and multiplier analysis for simultaneous systems of linear regression models. The SIMLIN procedure includes the following features:

- reduced form coefficients
- interim multipliers
- total multipliers
- dynamic multipliers
- multipliers for higher order lags
- dynamic forecasts and simulations
- goodness-of-fit statistics
- acceptance of the equation system coefficients estimated by the SYSLIN procedure as input
Polynomial Distributed Lag Regression

The PDLREG procedure provides regression analysis for linear models with polynomial distributed (Almon) lags. The PDLREG procedure includes the following features:

- entry of any number of regressors as a polynomial lag distribution and the use of any number of covariates
- use of any order lag length and degree polynomial for lag distribution
- optional upper and lower endpoint restrictions
- specification of any number of linear restrictions on covariates
- option to repeat analysis over a range of degrees for the lag distribution polynomials
- support for autoregressive errors to any lag
- forecasts with confidence limits

Nonlinear Systems Regression and Simulation

The MODEL procedure provides parameter estimation, simulation, and forecasting of dynamic nonlinear simultaneous equation models. The MODEL procedure includes the following features:

- nonlinear regression analysis for systems of simultaneous equations, including weighted nonlinear regression
- full range of parameter estimation methods including the following:
  - nonlinear ordinary least squares (OLS)
  - nonlinear seemingly unrelated regression (SUR)
  - nonlinear two-stage least squares (2SLS)
  - nonlinear three-stage least squares (3SLS)
  - iterated SUR
  - iterated 3SLS
  - generalized method of moments (GMM)
  - nonlinear full-information maximum likelihood (FIML)
  - simulated method of moments (SMM)
- supports dynamic multi-equation nonlinear models of any size or complexity
- uses the full power of the SAS programming language for model definition, including left-hand-side expressions
• hypothesis tests of nonlinear functions of the parameter estimates
• linear and nonlinear restrictions of the parameter estimates
• bounds imposed on the parameter estimates
• computation of estimates and standard errors of nonlinear functions of the parameter estimates
• estimation and simulation of ordinary differential equations (ODE’s)
• vector autoregressive error processes and polynomial lag distributions easily specified for the nonlinear equations
• variance modeling (ARCH, GARCH, and others)
• computation of goal-seeking solutions of nonlinear systems to find input values needed to produce target outputs
• dynamic, static, or n-period-ahead-forecast simulation modes
• simultaneous solution or single equation solution modes
• Monte Carlo simulation using parameter estimate covariance and across-equation residuals covariance matrices or user-specified random functions
• a variety of diagnostic statistics including the following
  – model R-square statistics
  – general Durbin-Watson statistics and exact p-values
  – asymptotic standard errors and t tests
  – first-stage R-square statistics
  – covariance estimates
  – collinearity diagnostics
  – simulation goodness-of-fit statistics
  – Theil inequality coefficient decompositions
  – Theil relative change forecast error measures
  – heteroscedasticity tests
  – Godfrey test for serial correlation
  – Hausman specification test
  – Chow tests
• block structure and dependency structure analysis for the nonlinear system
• listing and cross-reference of fitted model
• automatic calculation of needed derivatives by using exact analytic formula
• efficient sparse matrix methods used for model solution; choice of other solution methods

Model definition, parameter estimation, simulation, and forecasting can be performed interactively in a single SAS session or models can also be stored in files and reused and combined in later runs.
ARIMA (Box-Jenkins) and ARIMAX (Box-Tiao) Modeling and Forecasting

The ARIMA procedure provides the identification, parameter estimation, and forecasting of autoregressive integrated moving-average (Box-Jenkins) models, seasonal ARIMA models, transfer function models, and intervention models. The ARIMA procedure includes the following features:

- complete ARIMA (Box-Jenkins) modeling with no limits on the order of autoregressive or moving-average processes
- model identification diagnostics including the following:
  - autocorrelation function
  - partial autocorrelation function
  - inverse autocorrelation function
  - cross-correlation function
  - extended sample autocorrelation function
  - minimum information criterion for model identification
  - squared canonical correlations
- stationarity tests
- outlier detection
- intervention analysis
- regression with ARMA errors
- transfer function modeling with fully general rational transfer functions
- seasonal ARIMA models
- ARIMA model-based interpolation of missing values
- several parameter estimation methods including the following:
  - exact maximum likelihood
  - conditional least squares
  - exact nonlinear unconditional least squares (ELS or ULS)
- prewhitening transformations
- forecasts and confidence limits for all models
- forecasting tied to parameter estimation methods: finite memory forecasts for models estimated by maximum likelihood or exact nonlinear least squares methods and infinite memory forecasts for models estimated by conditional least squares
- diagnostic statistics to help judge the adequacy of the model including the following:
  - Akaike’s information criterion (AIC)
Vector Time Series Analysis

The VARMAX procedure enables you to model the dynamic relationship both between the dependent variables and between the dependent and independent variables. The VARMAX procedure includes the following features:

• several modeling features:
  – vector autoregressive model
  – vector autoregressive model with exogenous variables
  – vector autoregressive and moving-average model
  – Bayesian vector autoregressive model
  – vector error correction model
  – Bayesian vector error correction model
  – GARCH-type multivariate conditional heteroscedasticity models

• criteria for automatically determining AR and MA orders:
  – Akaike information criterion (AIC)
  – corrected AIC (AICC)
  – Hannan-Quinn (HQ) criterion
  – final prediction error (FPE)
  – Schwarz Bayesian criterion (SBC), also known as Bayesian information criterion (BIC)

• AR order identification aids:
  – partial cross-correlations
  – Yule-Walker estimates
  – partial autoregressive coefficients
  – partial canonical correlations

• testing the presence of unit roots and cointegration:
  – Dickey-Fuller tests
  – Johansen cointegration test for nonstationary vector processes of integrated order one

- Schwarz’s Bayesian criterion (SBC or BIC)
- Box-Ljung chi-square test statistics for white-noise residuals
- autocorrelation function of residuals
- partial autocorrelation function of residuals
- inverse autocorrelation function of residuals
- automatic outlier detection
– Stock-Watson common trends test for the possibility of cointegration among nonstationary vector processes of integrated order one
– Johansen cointegration test for nonstationary vector processes of integrated order two

• model parameter estimation methods:
  – least squares (LS)
  – maximum likelihood (ML)

• model checks and residual analysis using the following tests:
  – Durbin-Watson (DW) statistics
  – $F$ test for autoregressive conditional heteroscedastic (ARCH) disturbance
  – $F$ test for AR disturbance
  – Jarque-Bera normality test
  – Portmanteau test

• seasonal deterministic terms
• subset models
• multiple regression with distributed lags
• dead-start model that does not have present values of the exogenous variables
• Granger-causal relationships between two distinct groups of variables
• infinite order AR representation
• impulse response function (or infinite order MA representation)
• decomposition of the predicted error covariances
• roots of the characteristic functions for both the AR and MA parts to evaluate the proximity of the roots to the unit circle
• contemporaneous relationships among the components of the vector time series
• forecasts
• conditional covariances for GARCH models

State Space Modeling and Forecasting

The STATESPACE procedure provides automatic model selection, parameter estimation, and forecasting of state space models. (State space models encompass an alternative general formulation of multivariate ARIMA models.) The STATESPACE procedure includes the following features:
• multivariate ARIMA modeling by using the general state space representation of the stochastic process
• automatic model selection using Akaike’s information criterion (AIC)
• user-specified state space models including restrictions
• transfer function models with random inputs
• any combination of simple and seasonal differencing; input series can be differenced to any order for any lag lengths
• forecasts with confidence limits
• ability to save selected and fitted model in a data set and reuse for forecasting
• wide range of output options including the ability to print any statistics concerning the data and their covariance structure, the model selection process, and the final model fit

Spectral Analysis

The SPECTRA procedure provides spectral analysis and cross-spectral analysis of time series. The SPECTRA procedure includes the following features:

• efficient calculation of periodogram and smoothed periodogram using fast finite Fourier transform and Chirp-Z algorithms
• multiple spectral analysis, including raw and smoothed spectral and cross-spectral function estimates, with user-specified window weights
• choice of kernel for smoothing
• output of the following spectral estimates to a SAS data set:
  – Fourier sine and cosine coefficients
  – periodogram
  – smoothed periodogram
  – cospectrum
  – quadrature spectrum
  – amplitude
  – phase spectrum
  – squared coherency
• Fisher’s Kappa and Bartlett’s Kolmogorov-Smirnov test statistic for testing a null hypothesis of white noise
Chapter 2: Introduction

Seasonal Adjustment

The X11 procedure provides seasonal adjustment of time series by using the Census X-11 or X-11 ARIMA method. The X11 procedure is based on the U.S. Bureau of the Census X-11 seasonal adjustment program and also supports the X-11 ARIMA method developed by Statistics Canada. The X11 procedure includes the following features:

- decomposition of monthly or quarterly series into seasonal, trend, trading day, and irregular components
- both multiplicative and additive form of the decomposition
- all the features of the Census Bureau program
- support of the X-11 ARIMA method
- support of sliding spans analysis
- processing of any number of variables at once with no maximum length for a series
- computation of tests for stable, moving, and combined seasonality
- optional printing or storing in SAS data sets of the individual X11 tables that show the various components at different stages of the computation; full control over what is printed or output
- ability to project seasonal component one year ahead, which enables reintroduction of seasonal factors for an extrapolated series

The X12 procedure provides seasonal adjustment of time series using the X-12 ARIMA method. The X12 procedure is based on the U.S. Bureau of the Census X-12 ARIMA seasonal adjustment program (version 0.3). It also supports the X-11 ARIMA method developed by Statistics Canada and the previous X-11 method of the U.S. Census Bureau. The X12 procedure includes the following features:

- decomposition of monthly or quarterly series into seasonal, trend, trading day, and irregular components
- support of multiplicative, additive, pseudo-additive, and log additive forms of decomposition
- support of the X-12 ARIMA method
- support of regARIMA modeling
- automatic identification of outliers
- support of TRAMO-based automatic model selection
- use of regressors to process missing values within the span of the series
- processing of any number of variables at once with no maximum length for a series
- computation of tests for stable, moving, and combined seasonality
- spectral analysis of original, seasonally adjusted, and irregular series
• optional printing or storing in a SAS data set of the individual X11 tables that show the various components at different stages of the decomposition; full control over what is printed or output
• optional projection of seasonal component one year ahead, which enables reintroduction of seasonal factors for an extrapolated series

### Structural Time Series Modeling and Forecasting

The **UCM** procedure provides a flexible environment for analyzing time series data using structural time series models, also called unobserved components models (UCM). These models represent the observed series as a sum of suitably chosen components such as trend, seasonal, cyclical, and regression effects. You can use the UCM procedure to formulate comprehensive models that bring out all the salient features of the series under consideration. Structural models are applicable in the same situations where Box-Jenkins ARIMA models are applicable; however, the structural models tend to be more informative about the underlying stochastic structure of the series. The UCM procedure includes the following features:

• general unobserved components modeling where the models can include trend, multiple seasons and cycles, and regression effects
• maximum-likelihood estimation of the model parameters
• model diagnostics that include a variety of goodness-of-fit statistics, and extensive graphical diagnosis of the model residuals
• forecasts and confidence limits for the series and all the model components
• Model-based seasonal decomposition
• extensive plotting capability that includes the following:
  – forecast and confidence interval plots for the series and model components such as trend, cycles, and seasons
  – diagnostic plots such as residual plot, residual autocorrelation plots, and so on
  – seasonal decomposition plots such as trend, trend plus cycles, trend plus cycles plus seasons, and so on
• model-based interpolation of series missing values
• full sample (also called smoothed) estimates of the model components

### Time Series Cross-Sectional Regression Analysis

The **TSCSREG** procedure provides combined time series cross-sectional regression analysis. The TSCSREG procedure includes the following features:
estimation of the regression parameters under several common error structures:

- Fuller and Battese method (variance component model)
- Wansbeek-Kapteyn method
- Parks method (autoregressive model)
- Da Silva method (mixed variance component moving-average model)
- one-way fixed effects
- two-way fixed effects
- one-way random effects
- two-way random effects

- any number of model specifications

- unbalanced panel data for the fixed or random-effects models

- variety of estimates and statistics including the following:

  - underlying error components estimates
  - regression parameter estimates
  - standard errors of estimates
  - $t$-tests
  - R-square statistic
  - correlation matrix of estimates
  - covariance matrix of estimates
  - autoregressive parameter estimate
  - cross-sectional components estimates
  - autocovariance estimates
  - $F$ tests of linear hypotheses about the regression parameters
  - specification tests

**Automatic Time Series Forecasting**

The ESM procedure provides a quick way to generate forecasts for many time series or transactional data in one step by using exponential smoothing methods. All parameters associated with the forecasting model are optimized based on the data.

You can use the following smoothing models:

- simple
- double
- linear
• damped trend
• seasonal
• Winters method (additive and multiplicative)

Additionally, PROC ESM can transform the data before applying the smoothing methods using any of these transformations:

• log
• square root
• logistic
• Box-Cox

In addition to forecasting, the ESM procedure can also produce graphic output.

The ESM procedure can forecast both time series data, whose observations are equally spaced at a specific time interval (for example, monthly, weekly), or transactional data, whose observations are not spaced with respect to any particular time interval. (Internet, inventory, sales, and similar data are typical examples of transactional data. For transactional data, the data are accumulated based on a specified time interval to form a time series.)

The ESM procedure is a replacement for the older FORECAST procedure. ESM is often more convenient to use than PROC FORECAST but it supports only exponential smoothing models.

The FORECAST procedure provides forecasting of univariate time series using automatic trend extrapolation. PROC FORECAST is an easy-to-use procedure for automatic forecasting and uses simple popular methods that do not require statistical modeling of the time series, such as exponential smoothing, time trend with autoregressive errors, and the Holt-Winters method.

The FORECAST procedure supplements the powerful forecasting capabilities of the econometric and time series analysis procedures described previously. You can use PROC FORECAST when you have many series to forecast and you want to extrapolate trends without developing a model for each series.

The FORECAST procedure includes the following features:

• choice of the following forecasting methods:
  – EXPO method—exponential smoothing: single, double, triple, or Holt two-parameter smoothing
  – exponential smoothing as an ARIMA Model
  – WINTERS method—using updating equations similar to exponential smoothing to fit model parameters
  – ADDWINTERS method—like the WINTERS method except that the seasonal parameters are added to the trend instead of multiplied with the trend
  – STEPAR method—stepwise autoregressive models with constant, linear, or quadratic trend and autoregressive errors to any order
  – Holt-Winters forecasting method with constant, linear, or quadratic trend
– additive variant of the Holt-Winters method

• support for up to three levels of seasonality for Holt-Winters method: time-of-year, day-of-week, or time-of-day

• ability to forecast any number of variables at once

• forecast confidence limits for all methods

---

**Time Series Interpolation and Frequency Conversion**

The EXPAND procedure provides time interval conversion and missing value interpolation for time series. The EXPAND procedure includes the following features:

• conversion of time series frequency; for example, constructing quarterly estimates from annual series or aggregating quarterly values to annual values

• conversion of irregular observations to periodic observations

• interpolation of missing values in time series

• conversion of observation types; for example, estimate stocks from flows and vice versa. All possible conversions are supported between any of the following:
  – beginning of period
  – end of period
  – period midpoint
  – period total
  – period average

• conversion of time series phase shift; for example, conversion between fiscal years and calendar years

• identifying observations including the following:
  – identification of the time interval of the input values
  – validation of the input data set observations
  – computation of the ID values for the observations in the output data set

• choice of four interpolation methods:
  – cubic splines
  – linear splines
  – step functions
  – simple aggregation

• ability to perform extrapolation by a linear projection of the trend of the cubic spline curve fit to the input data
• ability to transform series before and after interpolation (or without interpolation) by using any of the following:
  – constant shift or scale
  – sign change or absolute value
  – logarithm, exponential, square root, square, logistic, inverse logistic
  – lags, leads, differences
  – classical decomposition
  – bounds, trims, reverse series
  – centered moving, cumulative, or backward moving average
  – centered moving, cumulative, or backward moving range
  – centered moving, cumulative, or backward moving geometric mean
  – centered moving, cumulative, or backward moving maximum
  – centered moving, cumulative, or backward moving median
  – centered moving, cumulative, or backward moving minimum
  – centered moving, cumulative, or backward moving product
  – centered moving, cumulative, or backward moving corrected sum of squares
  – centered moving, cumulative, or backward moving uncorrected sum of squares
  – centered moving, cumulative, or backward moving rank
  – centered moving, cumulative, or backward moving standard deviation
  – centered moving, cumulative, or backward moving sum
  – centered moving, cumulative, or backward moving median
  – centered moving, cumulative, or backward moving $t$-value
  – centered moving, cumulative, or backward moving variance

• support for a wide range of time series frequencies:
  – YEAR
  – SEMIYEAR
  – QUARTER
  – MONTH
  – SEMIMONTH
  – TENDAY
  – WEEKDAY
  – DAY
  – HOUR
  – MINUTE
  – SECOND
• support for repeating of shifting the basic interval types to define a great variety of different frequencies, such as fiscal years, biennial periods, work shifts, and so forth

Refer to Chapter 3, “Working with Time Series Data,” and Chapter 4, “Date Intervals, Formats, and Functions,” for more information about time series data transformations.

---

**Trend and Seasonal Analysis on Transaction Databases**

The TIMESERIES procedure can accumulate transactional data to time series and perform trend and seasonal analysis on the accumulated time series.

Time series analyses performed by the TIMESERIES procedure include the follows:

• descriptive statistics relevant for time series data
• seasonal decomposition and seasonal adjustment analysis
• correlation analysis
• cross-correlation analysis

The TIMESERIES procedure includes the following features:

• ability to process large amounts of time-stamped transactional data
• statistical methods useful for large-scale time series analysis or (temporal) data mining
• output data sets stored in either a time series format (default) or a coordinate format (transposed)

The TIMESERIES procedure is normally used to prepare data for subsequent analysis that uses other SAS/ETS procedures or other parts of the SAS system. The time series format is most useful when the data are to be analyzed with SAS/ETS procedures. The coordinate format is most useful when the data are to be analyzed with SAS/STAT® procedures or SAS Enterprise Miner™. (For example, clustering time-stamped transactional data can be achieved by using the results of TIMESERIES procedure with the clustering procedures of SAS/STAT and the nodes of SAS Enterprise Miner.)

---

**Access to Financial and Economic Databases**

The DATASOURCE procedure and the SAS/ETS data access interface LIBNAME Engines (SASECRSP, SASEFAME, SASEHAVR and SASEXCCM) provide seamless, efficient access to time series data from data files supplied by a variety of commercial and governmental data vendors.

The DATASOURCE procedure includes the following features:

• support for data files distributed by the following data vendors:
  – DRI/McGraw-Hill
Access to Financial and Economic Databases

- FAME Information Services
- HAVER ANALYTICS
- Standard & Poors Compustat Service
- Center for Research in Security Prices (CRSP)
- International Monetary Fund
- U.S. Bureau of Labor Statistics
- U.S. Bureau of Economic Analysis
- Organization for Economic Cooperation and Development (OECD)

- ability to select the series, frequency, time range, and cross sections of extracted data
- ability to create an output data set containing descriptive information on the series available in the data file
- ability to read EBCDIC data on ASCII systems and vice versa

The **SASECRSP** interface LIBNAME engine includes the following features:

- enables random access to time series data residing in CRSPAccess databases
- provides a seamless interface between CRSP and SAS data processing
- uses the LIBNAME statement to enable you to specify which time series you would like to read from the CRSPAccess database, and how you would like to perform selection
- enables you access to CRSP Stock, CRSP/COMPUSTAT Merged (CCM) or CRSP Indices Data.
- provides convenient formats, informats, and functions for CRSP and SAS datetime conversions

The **SASEFAME** interface LIBNAME engine includes the following features:

- provides SAS and FAME users flexibility in accessing and processing time series data, case series, and formulas that reside in either a FAME database or a SAS data set
- provides a seamless interface between FAME and SAS data processing
- uses the LIBNAME statement to enable you to specify which time series you would like to read from the FAME database
- enables you to convert the selected time series to the same time scale
- works with the SAS DATA step to perform further subsetting and to store the resulting time series into a SAS data set
- performs more analysis if desired either in the same SAS session or in another session at a later time
- supports the FAME CROSSLIST function for subsetting via BYGROUPS using the CROSSLIST= option
– you can use a FAME namelist that contains your BY variables for selection in the CROSSLIST
– you can use a SAS input dataset, INSET, that contains the BY selection variables along with the WHERE= option in your SASEFAME libref

• supports the use of FAME in a client/server environment that uses the FAME CHLI capability on your FAME server

• enables access to your FAME remote data when you specify the port number of the TCP/IP service that is defined for your FAME server and the node name of your FAME master server in your SASEFAME libref’s physical path

The SASEHAV interface LIBNAME engine includes the following features:

• enables Windows users random access to economic and financial data residing in a HAVER ANALYTICS Data Link Express (DLX) database

• the following types of HAVER data sets are available:
  – United States Economic Indicators
  – Specialized Databases
  – Financial Indicators
  – Industry
  – Industrial Countries
  – Emerging Markets
  – International Organizations
  – Forecasts and As Reported Data
  – United States Regional

• enables you to limit the range of data that is read from the time series

• enables you to specify a desired conversion frequency. Start dates are recommended on the LIBNAME statement to help you save resources when processing large databases or when processing a large number of observations.

• enables you to use the WHERE, KEEP, or DROP statements in your DATA step to further subset your data

• supports use of the SQL procedure to create a view of your resulting SAS data set

The SASEXCCM interface LIBNAME engine includes the following experimental features:

• enables random access to time series data residing in CRSPAccess databases

• provides a seamless interface between CRSP, Compustat XpressFeed and SAS data processing

• uses the LIBNAME statement to enable you to specify which data items, data groups and time series you would like to read from the CRSPAccess database, and how you would like to perform selection
• supports data-item-handling access methods to CRSP Stock (STK), CRSP/COMPUSTAT Merged (CCM), CRSP Indices (IND) or CRSP Treasury (TRS) Data.

• provides selection based on keys such as GVKEY, PERMNO, INDNO, TREASNO, and TCUSIP for efficient access to data items.

Spreadsheet Calculations and Financial Report Generation

The COMPUTAB procedure generates tabular reports using a programmable data table.

The COMPUTAB procedure is especially useful when you need both the power of a programmable spreadsheet and a report-generation system and you want to set up a program to run in batch mode and generate routine reports. The COMPUTAB procedure includes the following features:

• report generation facility for creating tabular reports such as income statements, balance sheets, and other row and column reports for analyzing business or time series data

• ability to tailor report format to almost any desired specification

• use of the SAS programming language to provide complete control of the calculation and format of each item of the report

• ability to report definition in terms of a data table on which programming statements operate

• ability for a single reference to a row or column to bring the entire row or column into a calculation

• ability to create new rows and columns (such as totals, subtotals, and ratios) with a single programming statement

• access to individual table values when needed

• built-in features to provide consolidation reports over summarization variables

Loan Analysis, Comparison, and Amortization

The LOAN procedure provides analysis and comparison of mortgages and other installment loans; it includes the following features:

• ability to specify contract terms for any number of different loans and ability to analyze and compare various financing alternatives

• analysis of four different types of loan contracts including the following:
  – fixed rate
  – adjustable rate
  – buy-down rate
– balloon payment

• full control over adjustment terms for adjustable rate loans: life caps, adjustment frequency, and maximum and minimum rates

• support for a wide variety of payment and compounding intervals

• ability to incorporate initialization costs, discount points, down payments, and prepayments (uniform or lump-sum) in loan calculations

• analysis of different rate adjustment scenarios for variable rate loans including the following:
  – worst case
  – best case
  – fixed rate case
  – estimated case

• ability to make loan comparisons at different points in time

• ability to make loan comparisons at each analysis date on the basis of five different economic criteria:
  – present worth of cost (net present value of all payments to date)
  – true interest rate (internal rate of return to date)
  – current periodic payment
  – total interest paid to date
  – outstanding balance

• ability to base loan comparisons on either after-tax or before-tax analysis

• report of the best alternative when loans of equal amount are compared

• amortization schedules for each loan contract

• output that shows payment dates, rather than just payment sequence numbers, when starting date is specified

• optional printing or output of the amortization schedules, loan summaries, and loan comparison information to SAS data sets

• ability to specify rounding of payments to any number of decimal places

---

**Time Series Forecasting System**

SAS/ETS software includes the Time Series Forecasting System, a point-and-click application for exploring and analyzing univariate time series data. You can use the automatic model selection facility to select the best-fitting model for each time series, or you can use the system’s diagnostic features and time series modeling tools interactively to develop forecasting models customized to best predict your time series. The system provides both graphical and statistical features to help you choose the best forecasting method for each series.
The system can be invoked by selecting **Analysis ➤ Solutions**, by the FORECAST command, and by clicking the **Forecasting** icon in the Data Analysis folder of the SAS Desktop.

The following is a brief summary of the features of the Time Series Forecasting system. With the system you can:

- use a wide variety of forecasting methods, including several kinds of exponential smoothing models, Winters method, and ARIMA (Box-Jenkins) models. You can also produce forecasts by combining the forecasts from several models.
- use predictor variables in forecasting models. Forecasting models can include time trend curves, regressors, intervention effects (dummy variables), adjustments you specify, and dynamic regression (transfer function) models.
- view plots of the data, predicted versus actual values, prediction errors, and forecasts with confidence limits. You can plot changes or transformations of series, zoom in on parts of the graphs, or plot autocorrelations.
- use hold-out samples to select the best forecasting method
- compare goodness-of-fit measures for any two forecasting models side-by-side or list all models sorted by a particular fit statistic
- view the predictions and errors for each model in a spreadsheet or view and compare the forecasts from any two models in a spreadsheet
- examine the fitted parameters of each forecasting model and their statistical significance
- control the automatic model selection process: the set of forecasting models considered, the goodness-of-fit measure used to select the best model, and the time period used to fit and evaluate models
- customize the system by adding forecasting models for the automatic model selection process and for point-and-click manual selection
- save your work in a project catalog
- print an audit trail of the forecasting process
- save and print system output including spreadsheets and graphs

---

**Investment Analysis System**

The **Investment Analysis System** is an interactive environment for analyzing the time-value of money for a variety of investments:

- loans
- savings
- depreciations
• bonds
• generic cash flows

Various tools are provided to help analyze the value of investment alternatives: time value, periodic equivalent, internal rate of return, benefit-cost ratio, and breakeven analysis.

These analyses can help answer a number of questions you might have about your investments:

• Which option is more profitable or less costly?
• Is it better to buy or rent?
• Are the extra fees for refinancing at a lower interest rate justified?
• What is the balance of this account after saving this amount periodically for so many years?
• How much is legally tax-deductible?
• Is this a reasonable price?

Investment Analysis can be beneficial to users in many industries for a variety of decisions:

• manufacturing: cost justification of automation or any capital investment, replacement analysis of major equipment, or economic comparison of alternative designs
• government: setting funds for services
• finance: investment analysis and portfolio management for fixed-income securities

**ODS Graphics**

Many SAS/ETS procedures produce graphical output using the SAS Output Delivery System (ODS). The ODS Graphics system provides several advantages:

• Plots and graphs are output objects in the Output Delivery System (ODS) and can be manipulated with ODS commands.
• There is no need to write SAS/GRAF statements or use special plotting macros.
• There are multiple formats to choose from: html, gif, and rtf.
• Templates control the appearance of plots.
• Styles control the color scheme.
• You can edit or create templates and styles for all graphs.

To enable graphical output from SAS/ETS procedures, you must use the following statement in your SAS program.
ods graphics on;
The graphical output produced by many SAS/ETS procedures can be controlled using the PLOTS= option on the PROC statement.

For more information about the features of the ODS Graphics system, including the many ways that you can control or customize the plots produced by SAS procedures, refer to Chapter 21, “Statistical Graphics Using ODS” (SAS/STAT User’s Guide). For more information about the SAS Output Delivery system, refer to the SAS Output Delivery System: User’s Guide.

Related SAS Software

Many features not found in SAS/ETS software are available in other parts of the SAS System, such as Base SAS®, SAS® Forecast Server, SAS/STAT® software, SAS/OR® software, SAS/QC® software, SAS® Stat Studio, and SAS/IML® software.

If you do not find something you need in SAS/ETS software, you might be able to find it in SAS/STAT software and in Base SAS software. If you still do not find it, look in other SAS software products or contact SAS Technical Support staff.

The following subsections summarize the features of other SAS products that might be of interest to users of SAS/ETS software.

Base SAS Software

The features provided by SAS/ETS software are extensions to the features provided by Base SAS software. Many data management and reporting capabilities you need are part of Base SAS software. Refer to SAS Language Reference: Dictionary and Base SAS Procedures Guide for documentation of Base SAS software. In particular, refer to Base SAS Procedures Guide: Statistical Procedures for information about statistical analysis features included with Base SAS.

The following sections summarize Base SAS software features of interest to users of SAS/ETS software. See Chapter 3, “Working with Time Series Data,” for further discussion of some of these topics as they relate to time series data and SAS/ETS software.

SAS DATA Step

The DATA step is your primary tool for reading and processing data in the SAS System. The DATA step provides a powerful general purpose programming language that enables you to perform all kinds of data processing tasks. The DATA step is documented in SAS Language Reference: Dictionary.

Base SAS Procedures

Base SAS software includes many useful SAS procedures, which are documented in Base SAS Procedures Guide and Base SAS Procedures Guide: Statistical Procedures. The following is a list of Base SAS procedures you might find useful:
CATALOG for managing SAS catalogs
CHART for printing charts and histograms
COMPARE for comparing SAS data sets
CONTENTS for displaying the contents of SAS data sets
COPY for copying SAS data sets
CORR for computing correlations
CPORT for moving SAS data libraries between computer systems
DATASETS for deleting or renaming SAS data sets
FCMP for compiling functions for use in SAS programs. The SAS Function Compiler Procedure (FCMP) enables you to create, test, and store SAS functions and subroutines before you use them in other SAS procedures. PROC FCMP accepts slight variations of DATA step statements, and most features of the SAS programing language can be used in functions and subroutines that are processed by PROC FCMP.
FREQ for computing frequency crosstabulations
MEANS for computing descriptive statistics and summarizing or collapsing data over cross sections
PLOT for printing scatter plots
PRINT for printing SAS data sets
PROTO for accessing external functions from the SAS system. The PROTO procedure enables you to register external functions that are written in the C or C++ programming languages. You can use these functions in SAS as well as in C-language structures and types. After the C-language functions are registered in PROC PROTO, they can be called from any SAS function or subroutine that is declared in the FCMP procedure, as well as from any SAS function, subroutine, or method block that is declared in the COMPILE procedure.
RANK for computing rankings or order statistics
SORT for sorting SAS data sets
SQL for processing SAS data sets with Structured Query Language
STANDARD for standardizing variables to a fixed mean and variance
TABULATE for printing descriptive statistics in tabular format
TIMEPLOT for plotting variables over time
TRANSPOSE for transposing SAS data sets
UNIVARIATE for computing descriptive statistics

Global Statements

Global statements can be specified anywhere in your SAS program, and they remain in effect until changed. Global statements are documented in SAS Language Reference: Dictionary. You may find the following SAS global statements useful:
FILENAME for accessing data files
FOOTNOTE for printing footnote lines at the bottom of each page
%INCLUDE for including files of SAS statements
LIBNAME for accessing SAS data libraries
OPTIONS for setting various SAS system options
QUIT for ending an interactive procedure step
RUN for executing the preceding SAS statements
TITLE for printing title lines at the top of each page
X for issuing host operating system commands from within your SAS session

Some Base SAS statements can be used with any SAS procedure, including SAS/ETS procedures. These statements are not global, and they affect only the SAS procedure they are used with. These statements are documented in *SAS Language Reference: Dictionary*.

The following Base SAS statements are useful with SAS/ETS procedures:

BY for computing separate analyses for groups of observations
FORMAT for assigning formats to variables
LABEL for assigning descriptive labels to variables
WHERE for subsetting data to restrict the range of data processed or to select or exclude observations from the analysis

**SAS Functions**

SAS functions can be used in DATA step programs and in the COMPUTAB and MODEL procedures. The following kinds of functions are available:

- character functions for manipulating character strings
- date and time functions for performing date and calendar calculations
- financial functions for performing financial calculations such as depreciation, net present value, periodic savings, and internal rate of return
- lagging and differencing functions for computing lags and differences
- mathematical functions for computing data transformations and other mathematical calculations
- probability functions for computing quantiles of statistical distributions and the significance of test statistics
- random number functions for simulation experiments
- sample statistics functions for computing means, standard deviations, kurtosis, and so forth

Formats, Informats, and Time Intervals

Base SAS software provides formats to control the printing of data values, informats to read data values, and time intervals to define the frequency of time series. See Chapter 4, “Date Intervals, Formats, and Functions,” for more information.

SAS Forecast Studio

SAS Forecast Studio is part of the SAS Forecast Server product. It provides an interactive environment for modeling and forecasting very large collections of hierarchically organized time series, such as SKUs in product lines and sales regions of a retail business. Forecast Studio greatly extends the capabilities provided by the Time Series Forecasting System included with SAS/ETS and described in Part IV.

Forecast Studio is documented in SAS Forecast Studio User’s Guide.

SAS High-Performance Forecasting

SAS High-Performance Forecasting (HPF) software provides a system of SAS procedures for large-scale automatic forecasting in business, government, and academic applications. Major uses of High-Performance Forecasting procedures include: forecasting, forecast scoring, market response modeling, and time series data mining.

The software includes the following automatic forecasting process:

- accumulates the time-stamped data to form a fixed-interval time series
- diagnoses the time series using time series analysis techniques
- creates a list of candidate model specifications based on the diagnostics
- fits each candidate model specification to the time series
- generates forecasts for each candidate fitted model
- selects the most appropriate model specification based on either in-sample or holdout-sample evaluation using a model selection criterion
- refits the selected model specification to the entire range of the time series
- creates a forecast score from the selected fitted model
- generate forecasts from the forecast score
- evaluates the forecast using in-sample analysis
- provides for out-of-sample forecast performance analysis
- performs top-down, middle-out, or bottom-up reconciliations of forecasts in the hierarchy
SAS/GRAPH Software

SAS/GRAPH software includes procedures that create two- and three-dimensional high resolution color graphics plots and charts. You can generate output that graphs the relationship of data values to one another, enhance existing graphs, or simply create graphics output that is not tied to data.

With the addition of ODS Graphics features to SAS/ETS procedures, there is now less need for the use of SAS/GRAPH procedures with SAS/ETS. However, SAS/GRAPH procedures allow you to create additional graphical displays of your results.

SAS/GRAPH software can produce the following types of output:

- charts
- plots
- maps
- text
- three-dimensional graphs

With SAS/GRAPH software you can produce high-resolution color graphics plots of time series data.

SAS/STAT Software

SAS/STAT software is of interest to users of SAS/ETS software because many econometric and other statistical methods not included in SAS/ETS software are provided in SAS/STAT software.

SAS/STAT software includes procedures for a wide range of statistical methodologies including the following:

- logistic regression
- censored regression
- principal component analysis
- structural equation models using covariance structure analysis
- factor analysis
- survival analysis
- discriminant analysis
- cluster analysis
- categorical data analysis; log-linear and conditional logistic models
- general linear models
• mixed linear and nonlinear models
• generalized linear models
• response surface analysis
• kernel density estimation
• LOESS regression
• spline regression
• two-dimensional kriging
• multiple imputation for missing values
• survey data analysis

SAS/IML Software

SAS/IML software gives you access to a powerful and flexible programming language (Interactive Matrix Language) in a dynamic, interactive environment. The fundamental object of the language is a data matrix. You can use SAS/IML software interactively (at the statement level) to see results immediately, or you can store statements in a module and execute them later. The programming is dynamic because necessary activities such as memory allocation and dimensioning of matrices are done automatically.

You can access built-in operators and call routines to perform complex tasks such as matrix inversion or eigenvector generation. You can define your own functions and subroutines using SAS/IML modules. You can perform operations on an entire data matrix. You have access to a wide choice of data management commands. You can read, create, and update SAS data sets from inside SAS/IML software without ever using the DATA step.

SAS/IML software is of interest to users of SAS/ETS software because it enables you to program your own econometric and time series methods in the SAS System. It contains subroutines for time series operators and for general function optimization. If you need to perform a statistical calculation not provided as an automated feature by SAS/ETS or other SAS software, you can use SAS/IML software to program the matrix equations for the calculation.

Kalman Filtering and Time Series Analysis in SAS/IML

SAS/IML software includes CALL routines and functions for Kalman filtering and time series analysis, which perform the following:

• generate univariate, multivariate, and fractional time series
• compute likelihood function of ARMA, VARMA, and ARFIMA models
• compute an autocovariance function of ARMA, VARMA, and ARFIMA models
• check the stationarity of ARMA and VARMA models
• filter and smooth time series models using Kalman method
• fit AR, periodic AR, time-varying coefficient AR, VAR, and ARFIMA models
• handle Bayesian seasonal adjustment models

SAS/IML Stat Studio

SAS/IML Studio is a highly interactive tool for data exploration and analysis. SAS/IML Studio runs on a PC in the Microsoft Windows operating environment. You can use SAS/IML Studio to do the following:

• explore data through graphs linked across multiple windows
• transform data
• subset data
• analyze univariate distributions
• discover structure and features in multivariate data
• fit and evaluate explanatory models
• create your own customized statistical graphics
• add legends, curves, maps, or other custom features to statistical graphics
• develop interactive programs that use dialog boxes
• extend the built-in analyses by calling SAS procedures
• create custom analyses
• repeat an analysis on different data
• extend the results of SAS procedures by using IML
• share analyses with colleagues who also use SAS/IML Studio
• call functions from libraries written in R, C/C++, FORTRAN, or Java

SAS/OR Software

SAS/OR software provides SAS procedures for operations research and project planning and includes a menu driven system for project management. SAS/OR software has features for the following:

- solving transportation problems
- linear, integer, and mixed-integer programming
- nonlinear programming and optimization
- scheduling projects
- plotting Gantt charts
- drawing network diagrams
- solving optimal assignment problems
- network flow programming

SAS/OR software might be of interest to users of SAS/ETS software for its mathematical programming features. In particular, the NLP and OPTMODEL procedures in SAS/OR software solve nonlinear programming problems and can be used for constrained and unconstrained maximization of user-defined likelihood functions.

SAS/QC Software

SAS/QC software provides a variety of procedures for statistical quality control and quality improvement. SAS/QC software includes procedures for the following:

- Shewhart control charts
- cumulative sum control charts
- moving average control charts
- process capability analysis
- Ishikawa diagrams
- Pareto charts
- experimental design

SAS/QC software also includes the SQC menu system for interactive application of statistical quality control methods and the ADX Interface for experimental design.
MLE for User-Defined Likelihood Functions

There are several SAS procedures that enable you to do maximum likelihood estimation of parameters in an arbitrary model with a likelihood function that you define: PROC MODEL, PROC NLP, PROC OPTMODEL and PROC IML.

The MODEL procedure in SAS/ETS software enables you to minimize general log-likelihood functions for the error term of a model.

The NLP and OPTMODEL procedures in SAS/OR software are general nonlinear programming procedures that can maximize a general function subject to linear equality or inequality constraints. You can use PROC NLP or OPTMODEL to maximize a user-defined nonlinear likelihood function.

You can use the IML procedure in SAS/IML software for maximum likelihood problems. The optimization routines used by PROC NLP are available through IML subroutines. You can write the likelihood function in the SAS/IML matrix language and call the constrained and unconstrained nonlinear programming subroutines to maximize the likelihood function with respect to the parameter vector.

JMP® Software

JMP software uses a flexible graphical interface to display and analyze data. JMP dynamically links statistics and graphics so you can easily explore data, make discoveries, and gain the knowledge you need to make better decisions. JMP provides a comprehensive set of statistical tools as well as design of experiments (DOE) and advanced quality control (QC and SPC) tools for Six Sigma in a single package. JMP is software for interactive statistical graphics and includes:

- a data table window for editing, entering, and manipulating data
- a broad range of graphical and statistical methods for data analysis
- a facility for grouping data and computing summary statistics
- JMP scripting language (JSL)—a scripting language for saving and creating frequently used routines
- JMP automation
- Formula Editor—a formula editor for each table column to compute values as needed
- linear models, correlations, and multivariate
- design of experiments module
- options to highlight and display subsets of data
- statistical quality control and variability charts—special plots, charts, and communication capability for quality-improvement techniques
- survival analysis
- time series analysis, which includes the following:
– Box-Jenkins ARIMA forecasting
– seasonal ARIMA forecasting
– transfer function modeling
– smoothing models: Winters method, single, double, linear, damped trend linear, and seasonal exponential smoothing
– diagnostic charts (autocorrelation, partial autocorrelation, and variogram) and statistics of fit
– a model comparison table to compare all forecasts generated
– spectral density plots and white noise tests

• tools for printing and for moving analyses results between applications

SAS Enterprise Guide®

SAS Enterprise Guide has the following features:

• integration with the SAS9 platform:
  – open metadata repository (OMR) integration
  – SAS report integration
    * create report interface
    * ODS support
    * Web report studio integration
  – access to information maps
  – ETL studio impact analysis
  – ESRI integration within the OLAP analyzer
  – data mining scoring task

• the user interface and workflow
  – process flow
  – ability to create stored processes from process flows
  – SAS folders window
  – project parameters
  – query builder interface
  – code node
With Enterprise Guide, you can perform time series analysis with the following EG procedures:

• prepare time series data—the Prepare Time Series Data task can be used to make data more suitable for analysis by other time series tasks.

• create time series data—the Create Time Series Data wizard helps you convert transactional data into fixed-interval time series. Transactional data are time-stamped data collected over time with irregular or varied frequency.

• ARIMA Modeling and Forecasting task

• Basic Forecasting task

• Regression Analysis with Autoregressive Errors

• Regression Analysis of Panel Data
SAS Enterprise Miner™—Time Series Node

SAS Enterprise Miner™ is the SAS solution for data mining, streamlining the data mining process to create highly accurate predictive and descriptive models. Enterprise Miner’s process flow diagram eliminates the need for manual coding and reduces the model development time for both business analysts and statisticians. The system is customizable and extensible; users can integrate their code and build new nodes for redistribution.

The Time Series node is a method of investigating time series data. It belongs to the Modify category of the SAS SEMMA (sample, explore, modify, model, assess) data mining process. The Time Series node enables you to understand trends and seasonal variation in large amounts of time series and transactional data.

The Time Series node in SAS Enterprise Miner enables you to do the following:

• perform time series analysis
• perform forecasting
• work with transactional data

SAS Risk Products

The analytical methods of SAS Risk Dimensions measure market risk and credit risk. SAS Risk Dimensions creates an environment where market and position data are staged for analysis using SAS data access and warehousing methodologies. SAS Risk Dimensions delivers a full range of modern credit, market and operational risk analysis techniques including:

• mark-to-market
• scenario analysis
• profit/loss curves and surfaces
• sensitivity analysis
• delta normal VaR
• historical simulation VaR
• Monte Carlo VaR
• current exposure
• potential exposure
• credit VaR
• optimization

SAS Credit Risk Management for Banking is a complete end-to-end application for measuring, exploring, managing, and reporting credit risk. SAS Credit Risk Management for Banking integrates data access, mapping, enrichment, and aggregation with advanced analytics and flexible reporting, all in an open, extensible, client-server framework.

SAS Credit Risk Management for Banking enables you to do the following:

• access and aggregate credit risk data across disparate operating systems and sources
• seamlessly integrate credit scoring/internal rating with credit portfolio risk assessment
• accurately measure, monitor, and report potential credit risk exposures within entities of an organization and aggregated across the entire organization, both on the counterparty level and the portfolio level
• evaluate alternative strategies for pricing, hedging, or transferring credit risk
• optimize the allocation of credit risk mitigants or assign the mitigants to lower the regulatory capital requirement
• optimize the allocation of regulatory capital and economic capital
• facilitate regulatory compliance and risk disclosure requirements for a wide variety of regulations such as Basel I, Basel II, and the Capital Requirements Directive (CAD III)

Overview

This chapter discusses working with time series data in the SAS System. The following topics are included:

- dating time series and working with SAS date and datetime values
- subsetting data and selecting observations
- storing time series data in SAS data sets
- specifying time series periodicity and time intervals
- plotting time series
• using calendar and time interval functions
• computing lags and other functions across time
• transforming time series
• transposing time series data sets
• interpolating time series
• reading time series data recorded in different ways

In general, this chapter focuses on using features of the SAS programming language and not on features of SAS/ETS software. However, since SAS/ETS procedures are used to analyze time series, understanding how to use the SAS programming language to work with time series data is important for the effective use of SAS/ETS software.

You do not need to read this chapter to use SAS/ETS procedures. If you are already familiar with SAS programming you might want to skip this chapter, or you can refer to sections of this chapter for help on specific time series data processing questions.

Time Series and SAS Data Sets

Introduction

To analyze data with the SAS System, data values must be stored in a SAS data set. A SAS data set is a matrix (or table) of data values organized into variables and observations.

The variables in a SAS data set label the columns of the data matrix, and the observations in a SAS data set are the rows of the data matrix. You can also think of a SAS data set as a kind of file, with the observations representing records in the file and the variables representing fields in the records. (See SAS Language Reference: Concepts for more information about SAS data sets.)

Usually, each observation represents the measurement of one or more variables for the individual subject or item observed. Often, the values of some of the variables in the data set are used to identify the individual subjects or items that the observations measure. These identifying variables are referred to as ID variables.

For many kinds of statistical analysis, only relationships among the variables are of interest, and the identity of the observations does not matter. ID variables might not be relevant in such a case.

However, for time series data the identity and order of the observations are crucial. A time series is a set of observations made at a succession of equally spaced points in time.

For example, if the data are monthly sales of a company’s product, the variable measured is sales of the product and the unit observed is the operation of the company during each month. These observations can be identified by year and month. If the data are quarterly gross national product, the variable measured is final goods production and the unit observed is the economy during each quarter. These observations can be identified by year and quarter.
For time series data, the observations are identified and related to each other by their position in time. Since SAS does not assume any particular structure to the observations in a SAS data set, there are some special considerations needed when storing time series in a SAS data set.

The main considerations are how to associate dates with the observations and how to structure the data set so that SAS/ETS procedures and other SAS procedures recognize the observations of the data set as constituting time series. These issues are discussed in following sections.

### Reading a Simple Time Series

Time series data can be recorded in many different ways. The section “Reading Time Series Data” on page 117 discusses some of the possibilities. The example below shows a simple case.

The following SAS statements read monthly values of the U.S. Consumer Price Index for June 1990 through July 1991. The data set USCPI is shown in Figure 3.1.

```sas
data uscpi;
  input year  month cpi;
datalines;
1990 6  129.9
1990 7  130.4
1990 8  131.6
... more lines ...
proc print data=uscpi;
run;
```

</table>

When a time series is stored in the manner shown by this example, the terms *series* and *variable* can be used interchangeably. There is one observation per row and one series/variable per column.
Dating Observations

The SAS System supports special date, datetime, and time values, which make it easy to represent dates, perform calendar calculations, and identify the time period of observations in a data set.

The preceding example uses the ID variables YEAR and MONTH to identify the time periods of the observations. For a quarterly data set, you might use YEAR and QTR as ID variables. A daily data set might have the ID variables YEAR, MONTH, and DAY. Clearly, it would be more convenient to have a single ID variable that could be used to identify the time period of observations, regardless of their frequency.

The following section, “SAS Date, Datetime, and Time Values” on page 65, discusses how the SAS System represents dates and times internally and how to specify date, datetime, and time values in a SAS program. The section “Reading Date and Datetime Values with Informats” on page 67 discusses how to read in date and time values from data records and how to control the display of date and datetime values in SAS output. Later sections discuss other issues concerning date and datetime values, specifying time intervals, data periodicity, and calendar calculations.

SAS date and datetime values and the other features discussed in the following sections are also described in SAS Language Reference: Dictionary. Reference documentation on these features is also provided in Chapter 4, “Date Intervals, Formats, and Functions.”

SAS Date, Datetime, and Time Values

SAS Date Values

SAS software represents dates as the number of days since a reference date. The reference date, or date zero, used for SAS date values is 1 January 1960. For example, 3 February 1960 is represented by SAS as 33. The SAS date for 17 October 1991 is 11612.

SAS software correctly represents dates from the year 1582 to the year 20,000.

Dates represented in this way are called SAS date values. Any numeric variable in a SAS data set whose values represent dates in this way is called a SAS date variable.

Representing dates as the number of days from a reference date makes it easy for the computer to store them and perform calendar calculations, but these numbers are not meaningful to users. However, you never have to use SAS date values directly, since SAS automatically converts between this internal representation and ordinary ways of expressing dates, provided that you indicate the format with which you want the date values to be displayed. (Formatting of date values is explained in the section “Formatting Date and Datetime Values” on page 67.)

Century of Dates Represented with Two-Digit Year Values

SAS software informats, functions, and formats can process dates that are represented with two-digit year values. The century assumed for a two-digit year value can be controlled with the YEARCUTOFF= option in the OPTIONS statement. The YEARCUTOFF= system option controls how dates with two-digit year values are interpreted by specifying the first year of a 100-year span. The default value for the YEARCUTOFF= option is 1920. Thus by default the year ‘17’ is interpreted as 2017, while the year ‘25’ is interpreted as 1925. (See SAS Language Reference: Dictionary for more information about YEARCUTOFF=.)
SAS Date Constants

SAS date values are written in a SAS program by placing the dates in single quotes followed by a D. The date is represented by the day of the month, the three letter abbreviation of the month name, and the year.

For example, SAS reads the value ‘17OCT1991’D the same as 11612, the SAS date value for 17 October 1991. Thus, the following SAS statements print DATE=11612:

```sas
data _null_;
  date = '17oct1991'd;
  put date=;
run;
```

The year value can be given with two or four digits, so ‘17OCT91’D is the same as ‘17OCT1991’D.

SAS Datetime Values and Datetime Constants

To represent both the time of day and the date, SAS uses datetime values. SAS datetime values represent the date and time as the number of seconds the time is from a reference time. The reference time, or time zero, used for SAS datetime values is midnight, 1 January 1960. Thus, for example, the SAS datetime value for 17 October 1991 at 2:45 in the afternoon is 1003329900.

To specify datetime constants in a SAS program, write the date and time in single quotes followed by DT. To write the date and time in a SAS datetime constant, write the date part using the same syntax as for date constants, and follow the date part with the hours, the minutes, and the seconds, separating the parts with colons. The seconds are optional.

For example, in a SAS program you would write 17 October 1991 at 2:45 in the afternoon as ‘17OCT91:14:45’DT. SAS reads this as 1003329900. Table 3.1 shows some other examples of datetime constants.

<table>
<thead>
<tr>
<th>Datetime Constant</th>
<th>Time</th>
</tr>
</thead>
<tbody>
<tr>
<td>‘17OCT1991:14:45:32’DT</td>
<td>32 seconds past 2:45 p.m., 17 October 1991</td>
</tr>
<tr>
<td>‘17OCT1991:12:5’DT</td>
<td>12:05 p.m., 17 October 1991</td>
</tr>
<tr>
<td>‘17OCT1991:2:0’DT</td>
<td>2:00 a.m., 17 October 1991</td>
</tr>
<tr>
<td>‘17OCT1991:0:0’DT</td>
<td>midnight, 17 October 1991</td>
</tr>
</tbody>
</table>

SAS Time Values

The SAS System also supports time values. SAS time values are just like datetime values, except that the date part is not given. To write a time value in a SAS program, write the time the same as for a datetime constant, but use T instead of DT. For example, 2:45:32 p.m. is written ‘14:45:32’T. Time values are represented by a number of seconds since midnight, so SAS reads ‘14:45:32’T as 53132.

SAS time values are not very useful for identifying time series, since usually both the date and the time of day are needed. Time values are not discussed further in this book.
Reading Date and Datetime Values with Informs

SAS provides a selection of *informs* for reading SAS date and datetime values from date and time values recorded in ordinary notations.

A SAS informat is an instruction that converts the values from a character-string representation into the internal numerical value of a SAS variable. Date informats convert dates from ordinary notations used to enter them to SAS date values; datetime informats convert date and time from ordinary notation to SAS datetime values.

For example, the following SAS statements read monthly values of the U.S. Consumer Price Index. Since the data are monthly, you could identify the date with the variables YEAR and MONTH, as in the previous example. Instead, in this example the time periods are coded as a three-letter month abbreviation followed by the year. The informat MONYY. is used to read month-year dates coded this way and to express them as SAS date values for the first day of the month, as follows:

```
data uscpi;
  input date : monyy7. cpi;
  format date monyy7.;
  label cpi = "US Consumer Price Index";
datalines;
jun1990 129.9
jul1990 130.4
aug1990 131.6
... more lines ...
```

The SAS System provides informats for most common notations for dates and times. See Chapter 4 for more information about the date and datetime informats available.

Formatting Date and Datetime Values

SAS provides *formats* to convert the internal representation of date and datetime values used by SAS to ordinary notations for dates and times. Several different formats are available for displaying dates and datetime values in most of the commonly used notations.

A SAS format is an instruction that converts the internal numerical value of a SAS variable to a character string that can be printed or displayed. Date formats convert SAS date values to a readable form; datetime formats convert SAS datetime values to a readable form.

In the preceding example, the variable DATE was set to the SAS date value for the first day of the month for each observation. If the data set USCPI were printed or otherwise displayed, the values shown for DATE would be the number of days since 1 January 1960. (See the “DATE with no format” column in Figure 3.2.) To display date values appropriately, use the FORMAT statement.

The following example processes the data set USCPI to make several copies of the variable DATE and uses a FORMAT statement to give different formats to these copies. The format cases shown are the MONYY7. format (for the DATE variable), the DATE9. format (for the DATE1 variable), and no format (for the DATE0 variable). The PROC PRINT output in Figure 3.2 shows the effect of the different formats on how the date values are printed.
data fmttest;
    set uscpi;
    date0 = date;
    date1 = date;
    label date = "DATE with MONYY7. format"
    date1 = "DATE with DATE9. format"
    date0 = "DATE with no format"
    ;
    format date monyy7. date1 date9.;
run;

proc print data=fmttest label;
run;

The appropriate format to use for SAS date or datetime valued ID variables depends on the sampling frequency or periodicity of the time series. Table 3.2 shows recommended formats for common data sampling frequencies and shows how the date '17OCT1991'D or the datetime value '17OCT1991:14:45:32'DT is displayed by these formats.

The Variables DATE and DATETIME

SAS/ETS procedures enable you to identify time series observations in many different ways to suit your needs. As discussed in preceding sections, you can use a combination of several ID variables, such as YEAR and MONTH for monthly data.

However, using a single SAS date or datetime ID variable is more convenient and enables you to take advantage of some features SAS/ETS procedures provide for processing ID variables. One such feature is automatic extrapolation of the ID variable to identify forecast observations. These features are discussed in following sections.

Thus, it is a good practice to include a SAS date or datetime ID variable in all the time series SAS data sets you create. It is also a good practice to always give the date or datetime ID variable a format appropriate for the data periodicity. (For information about creating SAS date and datetime values from multiple ID variables, see the section “Computing Dates from Calendar Variables” on page 89.)

You can assign a SAS date- or datetime-valued ID variable any name that conforms to SAS variable name requirements. However, you might find working with time series data in SAS easier and less confusing if you adopt the practice of always using the same name for the SAS date or datetime ID variable.

This book always names the date- or datetime-values ID variable DATE if it contains SAS date values or DATETIME if it contains SAS datetime values. This makes it easy to recognize the ID variable and also makes it easy to recognize whether this ID variable uses SAS date or datetime values.

Sorting by Time

Many SAS/ETS procedures assume the data are in chronological order. If the data are not in time order, you can use the SORT procedure to sort the data set. For example,

```sas
proc sort data=a;
  by date;
run;
```

There are many ways of coding the time ID variable or variables, and some ways do not sort correctly. If you use SAS date or datetime ID values as suggested in the preceding section, you do not need to be concerned with this issue. But if you encode date values in nonstandard ways, you need to consider whether your ID variables will sort.

SAS date and datetime values always sort correctly, as do combinations of numeric variables such as YEAR, MONTH, and DAY used together. Julian dates also sort correctly. (Julian dates are numbers of the form yyddd, where yy is the year and ddd is the day of the year. For example, 17 October 1991 has the Julian date value 91290.)

Calendar dates such as numeric values coded as mmddyy or ddmmyy do not sort correctly. Character variables that contain display values of dates, such as dates in the notation produced by SAS date formats, generally do not sort correctly.
Subsetting Data and Selecting Observations

It is often necessary to subset data for analysis. You might need to subset data to do the following:

- restrict the time range. For example, you want to perform a time series analysis using only recent data and ignoring observations from the distant past.

- select cross sections of the data. (See the section “Cross-Sectional Dimensions and BY Groups” on page 75.) For example, you have a data set with observations over time for each of several states, and you want to analyze the data for a single state.

- select particular kinds of time series from an interleaved-form data set. (See the section “Interleaved Time Series” on page 77.) For example, you have an output data set produced by the FORECAST procedure that contains both forecast and confidence limits observations, and you want to extract only the forecast observations.

- exclude particular observations. For example, you have an outlier in your time series, and you want to exclude this observation from the analysis.

You can subset data either by using the DATA step to create a subset data set or by using a WHERE statement with the SAS procedure that analyzes the data.

A typical WHERE statement used in a procedure has the following form:

```sas
proc arima data=full;
   where '31dec1993'd < date < '26mar1994'd;
   identify var=close;
run;
```

For complete reference documentation on the WHERE statement, see SAS Language Reference: Dictionary.

Subsetting SAS Data Sets

To create a subset data set, specify the name of the subset data set in the DATA statement, bring in the full data set with a SET statement, and specify the subsetting criteria with either subsetting IF statements or WHERE statements.

For example, suppose you have a data set that contains time series observations for each of several states. The following DATA step uses a WHERE statement to exclude observations with dates before 1970 and uses a subsetting IF statement to select observations for the state NC:

```sas
data subset;
   set full;
   where date >= '1jan1970'd;
   if state = 'NC';
run;
```

In this case, it makes no difference logically whether the WHERE statement or the IF statement is used, and you can combine several conditions in one subsetting statement. The following statements produce the same results as the previous example:
data subset;
set full;
  if date >= '1jan1970'd & state = 'NC';
run;

The WHERE statement acts on the input data sets specified in the SET statement before observations are processed by the DATA step program, whereas the IF statement is executed as part of the DATA step program. If the input data set is indexed, using the WHERE statement can be more efficient than using the IF statement. However, the WHERE statement can refer only to variables in the input data set, not to variables computed by the DATA step program.

To subset the variables of a data set, use KEEP or DROP statements or use KEEP= or DROP= data set options. See *SAS Language Reference: Dictionary* for information about KEEP and DROP statements and SAS data set options.

For example, suppose you want to subset the data set as in the preceding example, but you want to include in the subset data set only the variables DATE, X, and Y. You could use the following statements:

data subset;
set full;
  if date >= '1jan1970'd & state = 'NC';
  keep date x y;
run;

---

**Using the WHERE Statement with SAS Procedures**

Use the WHERE statement with SAS procedures to process only a subset of the input data set. For example, suppose you have a data set that contains monthly observations for each of several states, and you want to use the AUTOREG procedure to analyze data since 1970 for the state NC. You could use the following statements:

```sas
proc autoreg data=full;
  where date >= '1jan1970'd & state = 'NC';
  ... additional statements ...
run;
```

You can specify any number of conditions in the WHERE statement. For example, suppose that a strike created an outlier in May 1975, and you want to exclude that observation. You could use the following statements:

```sas
proc autoreg data=full;
  where date >= '1jan1970'd & state = 'NC'
  & date ^= '1may1975'd;
  ... additional statements ...
run;
```
Using SAS Data Set Options

You can use the OBS= and FIRSTOBS= data set options to subset the input data set.

For example, the following statements print observations 20 through 25 of the data set FULL:

```sas
proc print data=full(firstobs=20 obs=25);
run;
```

**Figure 3.3** Partial Listing of Data Set FULL

You can use KEEP= and DROP= data set options to exclude variables from the input data set. See SAS Language Reference: Dictionary for information about SAS data set options.

Storing Time Series in a SAS Data Set

This section discusses aspects of storing time series in SAS data sets. The topics discussed are the standard form of a time series data set, storing several series with different time ranges in the same data set, omitted observations, cross-sectional dimensions and BY groups, and interleaved time series.

Any number of time series can be stored in a SAS data set. Normally, each time series is stored in a separate variable. For example, the following statements augment the USCPI data set read in the previous example with values for the producer price index:

```sas
data usprice;
  input date : monyy7. cpi ppi;
  format date monyy7.;
  label cpi = "Consumer Price Index"
          ppi = "Producer Price Index";
datalines;
jun1990 129.9 114.3
jul1990 130.4 114.5
aug1990 131.6 116.5
... more lines ...
```

... more lines ...
The simple way the CPI and PPI time series are stored in the USPRICE data set in the preceding example is termed the standard form of a time series data set. A time series data set in standard form has the following characteristics:

- The data set contains one variable for each time series.
- The data set contains exactly one observation for each time period.
- The data set contains an ID variable or variables that identify the time period of each observation.
- The data set is sorted by the ID variables associated with date time values, so the observations are in time sequence.
- The data are equally spaced in time. That is, successive observations are a fixed time interval apart, so the data set can be described by a single sampling interval such as hourly, daily, monthly, quarterly, yearly, and so forth. This means that time series with different sampling frequencies are not mixed in the same SAS data set.

Most SAS/ETS procedures that process time series expect the input data set to contain time series in this standard form, and this is the simplest way to store time series in SAS data sets. (The EXPAND and TIMESERIES procedures can be helpful in converting your data to this standard form.) There are more complex ways to represent time series in SAS data sets.
You can incorporate cross-sectional dimensions with BY groups, so that each BY group is like a standard form time series data set. This method is discussed in the section “Cross-Sectional Dimensions and BY Groups” on page 75.

You can interleave time series, with several observations for each time period identified by another ID variable. Interleaved time series data sets are used to store several series in the same SAS variable. Interleaved time series data sets are often used to store series of actual values, predicted values, and residuals, or series of forecast values and confidence limits for the forecasts. This is discussed in the section “Interleaved Time Series” on page 77.

### Several Series with Different Ranges

Different time series can have values recorded over different time ranges. Since a SAS data set must have the same observations for all variables, when time series with different ranges are stored in the same data set, missing values must be used for the periods in which a series is not available.

Suppose that in the previous example you did not record values for CPI before August 1990 and did not record values for PPI after June 1991. The USPRICE data set could be read with the following statements:

```sas
data usprice;
  input date : monyy7. cpi ppi;
  format date monyy7. ;
datalines;
  jun1990 . 114.3
  jul1990 . 114.5
  aug1990 131.6 116.5
  sep1990 132.7 118.4
  oct1990 133.5 120.8
  nov1990 133.8 120.1
  dec1990 133.8 118.7
  jan1991 134.6 119.0
  feb1991 134.8 117.2
  mar1991 135.0 116.2
  apr1991 135.2 116.0
  may1991 135.6 116.5
  jun1991 136.0 116.3
  jul1991 136.2 .
;
```

The decimal points with no digits in the data records represent missing data and are read by SAS as missing value codes.

In this example, the time range of the USPRICE data set is June 1990 through July 1991, but the time range of the CPI variable is August 1990 through July 1991, and the time range of the PPI variable is June 1990 through June 1991.

SAS/ETS procedures ignore missing values at the beginning or end of a series. That is, the series is considered to begin with the first nonmissing value and end with the last nonmissing value.
Missing Values and Omitted Observations

Missing data can also occur within a series. Missing values that appear after the beginning of a time series and before the end of the time series are called embedded missing values.

Suppose that in the preceding example you did not record values for CPI for November 1990 and did not record values for PPI for both November 1990 and March 1991. The USPRICE data set could be read with the following statements:

```sas
data usprice;
  input date : monyy. cpi ppi;
  format date monyy.;
data lines;
  jun1990 . 114.3
  jul1990 . 114.5
  aug1990 131.6 116.5
  sep1990 132.7 118.4
  oct1990 133.5 120.8
  nov1990 . .
  dec1990 133.8 118.7
  jan1991 134.6 119.0
  feb1991 134.8 117.2
  mar1991 135.0 .
  apr1991 135.2 116.0
  may1991 135.6 116.5
  jun1991 136.0 116.3
  jul1991 136.2 .
;
```

In this example, the series CPI has one embedded missing value, and the series PPI has two embedded missing values. The ranges of the two series are the same as before.

Note that the observation for November 1990 has missing values for both CPI and PPI; there is no data for this period. This is an example of a missing observation.

You might ask why the data record for this period is included in the example at all, since the data record contains no data. However, deleting the data record for November 1990 from the example would cause an omitted observation in the USPRICE data set. SAS/ETS procedures expect input data sets to contain observations for a contiguous time sequence. If you omit observations from a time series data set and then try to analyze the data set with SAS/ETS procedures, the omitted observations will cause errors. When all data are missing for a period, a missing observation should be included in the data set to preserve the time sequence of the series.

If observations are omitted from the data set, the EXPAND procedure can be used to fill in the gaps with missing values (or to interpolate nonmissing values) for the time series variables and with the appropriate date or datetime values for the ID variable.

Cross-Sectional Dimensions and BY Groups

Often, time series in a collection are related by a cross sectional dimension. For example, the national average U.S. consumer price index data shown in the previous example can be disaggregated to show price indexes.
Chapter 3: Working with Time Series Data

for major cities. In this case, there are several related time series: CPI for New York, CPI for Chicago, CPI for Los Angeles, and so forth. When these time series are considered as one data set, the city whose price level is measured is a cross sectional dimension of the data.

There are two basic ways to store such related time series in a SAS data set. The first way is to use a standard form time series data set with a different variable for each series.

For example, the following statements read CPI series for three major U.S. cities:

```sas
data citycpi;
  input date : monyy7. cpiny cpichi cpila;
  format date monyy7.;
datalines;
nov1989 133.200 126.700 130.000
dec1989 133.300 126.500 130.600
jan1990 135.100 128.100 132.100
... more lines ...
```

The second way is to store the data in a time series cross-sectional form. In this form, the series for all cross sections are stored in one variable and a cross section ID variable is used to identify observations for the different series. The observations are sorted by the cross section ID variable and by time within each cross section.

The following statements indicate how to read the CPI series for U.S. cities in time series cross-sectional form:

```sas
data cpicity;
  length city $11;
  input city $11. date : monyy. cpi;
  format date monyy.;
datalines;
New York JAN1990 135.100
New York FEB1990 135.300
New York MAR1990 136.600
... more lines ...
```

When processing a time series cross sectional form data set with most SAS/ETS procedures, use the cross section ID variable in a BY statement to process the time series separately. The data set must be sorted by the cross section ID variable and sorted by date within each cross section. The PROC SORT step in the preceding example ensures that the CPICITY data set is correctly sorted.

When the cross section ID variable is used in a BY statement, each BY group in the data set is like a standard form time series data set. Thus, SAS/ETS procedures that expect a standard form time series data set can process time series cross sectional data sets when a BY statement is used, producing an independent analysis for each cross section.

It is also possible to analyze time series cross-sectional data jointly. The PANEL procedure (and the older
TSCSREG procedure) expects the input data to be in the time series cross-sectional form described here. See Chapter 20, “The PANEL Procedure,” for more information.

# Interleaved Time Series

Normally, a time series data set has only one observation for each time period, or one observation for each time period within a cross section for a time series cross-sectional-form data set. However, it is sometimes useful to store several related time series in the same variable when the different series do not correspond to levels of a cross-sectional dimension of the data.

In this case, the different time series can be interleaved. An interleaved time series data set is similar to a time series cross-sectional data set, except that the observations are sorted differently and the ID variable that distinguishes the different time series does not represent a cross-sectional dimension.

Some SAS/ETS procedures produce interleaved output data sets. The interleaved time series form is a convenient way to store procedure output when the results consist of several different kinds of series for each of several input series. (Interleaved time series are also easy to process with plotting procedures. See the section “Plotting Time Series” on page 82.)

For example, the FORECAST procedure fits a model to each input time series and computes predicted values and residuals from the model. The FORECAST procedure then uses the model to compute forecast values beyond the range of the input data and also to compute upper and lower confidence limits for the forecast values.

Thus, the output from PROC FORECAST consists of up to five related time series for each variable forecast. The five resulting time series for each input series are stored in a single output variable with the same name as the series that is being forecast. The observations for the five resulting series are identified by values of the variable _TYPE_. These observations are interleaved in the output data set with observations for the same date grouped together.

The following statements show how to use PROC FORECAST to forecast the variable CPI in the USCPI data set. Figure 3.5 shows part of the output data set produced by PROC FORECAST and illustrates the interleaved structure of this data set.

```sas
proc forecast data=uscpi interval=month lead=12
   out=foreout outfull outresid;
   var cpi;
   id date;
run;

proc print data=foreout(obs=6);
run;
```
Chapter 3: Working with Time Series Data

Figure 3.5  Partial Listing of Output Data Set Produced by PROC FORECAST

<table>
<thead>
<tr>
<th>Obs</th>
<th>date</th>
<th><em>TYPE</em></th>
<th><em>LEAD</em></th>
<th>cpi</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>JUN1990</td>
<td>ACTUAL</td>
<td>0</td>
<td>129.900</td>
</tr>
<tr>
<td>2</td>
<td>JUN1990</td>
<td>FORECAST</td>
<td>0</td>
<td>130.817</td>
</tr>
<tr>
<td>3</td>
<td>JUN1990</td>
<td>RESIDUAL</td>
<td>0</td>
<td>-0.917</td>
</tr>
<tr>
<td>4</td>
<td>JUL1990</td>
<td>ACTUAL</td>

<td>130.678</td>
</tr>
<tr>
<td>6</td>
<td>JUL1990</td>
<td>RESIDUAL</td>
<td>0</td>
<td>-0.278</td>
</tr>
</tbody>
</table>

Observations with _TYPE_=_ACTUAL contain the values of CPI read from the input data set. Observations with _TYPE_=_FORECAST contain one-step-ahead predicted values for observations with dates in the range of the input series and contain forecast values for observations for dates beyond the range of the input series. Observations with _TYPE_=_RESIDUAL contain the difference between the actual and one-step-ahead predicted values. Observations with _TYPE_=_U95 and _TYPE_=_L95 contain the upper and lower bounds, respectively, of the 95% confidence interval for the forecasts.

Using Interleaved Data Sets as Input to SAS/ETS Procedures

Interleaved time series data sets are not directly accepted as input by SAS/ETS procedures. However, it is easy to use a WHERE statement with any procedure to subset the input data and select one of the interleaved time series as the input.

For example, to analyze the residual series contained in the PROC FORECAST output data set with another SAS/ETS procedure, include a WHERE _TYPE_='RESIDUAL' statement. The following statements perform a spectral analysis of the residuals produced by PROC FORECAST in the preceding example:

```sas
proc spectra data=foreout out=spectout;
   var cpi;
   where _type_='RESIDUAL';
run;
```

Combined Cross Sections and Interleaved Time Series Data Sets

Interleaved time series output data sets produced from BY-group processing of time series cross-sectional input data sets have a complex structure that combines a cross-sectional dimension, a time dimension, and the values of the _TYPE_ variable. For example, consider the PROC FORECAST output data set produced by the following statements:

```sas
title "FORECAST Output Data Set with BY Groups";

proc forecast data=cpicity interval=month
   method=expo lead=2
   out=foreout outfull outresid;
   var cpi;
   id date;
   by city;
run;
```
The output data set FOREOUT contains many different time series in the single variable CPI. (The first few observations of FOREOUT are shown in Figure 3.6.) BY groups that are identified by the variable CITY contain the result series for the different cities. Within each value of CITY, the actual, forecast, residual, and confidence limits series are stored in interleaved form, with the observations for the different series identified by the values of '_TYPE_'.

**Output Data Sets of SAS/ETS Procedures**

Some SAS/ETS procedures (such as PROC FORECAST) produce interleaved output data sets, and other SAS/ETS procedures produce standard form time series data sets. The form a procedure uses depends on whether the procedure is normally used to produce multiple result series for each of many input series in one step (as PROC FORECAST does).

For example, the ARIMA procedure can output actual series, forecast series, residual series, and confidence limit series just as the FORECAST procedure does. The PROC ARIMA output data set uses the standard form because PROC ARIMA is designed for the detailed analysis of one series at a time and so forecasts only one series at a time.

The following statements show the use of the ARIMA procedure to produce a forecast of the USCPI data set. Figure 3.7 shows part of the output data set that is produced by the ARIMA procedure’s FORECAST statement. (The printed output from PROC ARIMA is not shown.) Compare the PROC ARIMA output data set shown in Figure 3.7 with the PROC FORECAST output data set shown in Figure 3.6.

```
title "PROC ARIMA Output Data Set";

proc arima data=uscpi;
   identify var=cpi(1);
   estimate q=1;
   forecast id=date interval=month
      lead=12 out=arimaout;
run;
```
The output data set produced by the ARIMA procedure’s FORECAST statement stores the actual values in a variable with the same name as the response series, stores the forecast series in a variable named FORECAST, stores the residuals in a variable named RESIDUAL, stores the 95% confidence limits in variables named L95 and U95, and stores the standard error of the forecast in the variable STD.

This method of storing several different result series as a standard form time series data set is simple and convenient. However, it works well only for a single input series. The forecast of a single series can be stored in the variable FORECAST. But if two series are forecast, two different FORECAST variables are needed.

The STATESPACE procedure handles this problem by generating forecast variable names FOR1, FOR2, and so forth. The SPECTRA procedure uses a similar method. Names such as FOR1, FOR2, RES1, RES2, and so forth require you to remember the order in which the input series are listed. This is why PROC FORECAST, which is designed to forecast a whole list of input series at once, stores its results in interleaved form.

Other SAS/ETS procedures are often used for a single input series but can also be used to process several series in a single step. Thus, they are not clearly like PROC FORECAST nor clearly like PROC ARIMA in the number of input series they are designed to work with. These procedures use a third method for storing multiple result series in an output data set. These procedures store output time series in standard form (as PROC ARIMA does) but require an OUTPUT statement to give names to the result series.

---

**Time Series Periodicity and Time Intervals**

A fundamental characteristic of time series data is how frequently the observations are spaced in time. How often the observations of a time series occur is called the sampling frequency or the periodicity of the series. For example, a time series with one observation each month has a monthly sampling frequency or monthly periodicity and so is called a monthly time series.

In SAS, data periodicity is described by specifying periodic time intervals into which the dates of the observations fall. For example, the SAS time interval MONTH divides time into calendar months.

Many SAS/ETS procedures enable you to specify the periodicity of the input data set with the INTERVAL= option. For example, specifying INTERVAL=MONTH indicates that the procedure should expect the ID
variable to contain SAS date values, and that the date value for each observation should fall in a separate calendar month. The EXPAND procedure uses interval name values with the FROM= and TO= options to control the interpolation of time series from one periodicity to another.

SAS also uses time intervals in several other ways. In addition to indicating the periodicity of time series data sets, time intervals are used with the interval functions INTNX and INTCK and for controlling the plot axis and reference lines for plots of data over time.

### Specifying Time Intervals

Intervals are specified in SAS by using *interval names* such as YEAR, QTR, MONTH, DAY, and so forth. Table 3.3 summarizes the basic types of intervals.

<table>
<thead>
<tr>
<th>Name</th>
<th>Periodicity</th>
</tr>
</thead>
<tbody>
<tr>
<td>YEAR</td>
<td>yearly</td>
</tr>
<tr>
<td>SEMIYEAR</td>
<td>semiannual</td>
</tr>
<tr>
<td>QTR</td>
<td>quarterly</td>
</tr>
<tr>
<td>MONTH</td>
<td>monthly</td>
</tr>
<tr>
<td>SEMIMONTH</td>
<td>1st and 16th of each month</td>
</tr>
<tr>
<td>TENDAY</td>
<td>1st, 11th, and 21st of each month</td>
</tr>
<tr>
<td>WEEK</td>
<td>weekly</td>
</tr>
<tr>
<td>WEEKDAY</td>
<td>daily ignoring weekend days</td>
</tr>
<tr>
<td>DAY</td>
<td>daily</td>
</tr>
<tr>
<td>HOUR</td>
<td>hourly</td>
</tr>
<tr>
<td>MINUTE</td>
<td>every minute</td>
</tr>
<tr>
<td>SECOND</td>
<td>every second</td>
</tr>
</tbody>
</table>

Interval names can be abbreviated in various ways. For example, you could specify monthly intervals as MONTH, MONTHS, MONTHLY, or just MON. SAS accepts all these forms as equivalent.

Interval names can also be qualified with a multiplier to indicate multi-period intervals. For example, biennial intervals are specified as YEAR2.

Interval names can also be qualified with a shift index to indicate intervals with different starting points. For example, fiscal years starting in July are specified as YEAR.7.

Intervals are classified as either date or datetime intervals. Date intervals are used with SAS date values, while datetime intervals are used with SAS datetime values. The interval types YEAR, SEMIYEAR, QTR, MONTH, SEMIMONTH, TENDAY, WEEK, WEEKDAY, and DAY are date intervals. HOUR, MINUTE, and SECOND are datetime intervals. Date intervals can be turned into datetime intervals for use with datetime values by prefixing the interval name with ‘DT’. Thus DTMONTH intervals are like MONTH intervals but are used with datetime ID values instead of date ID values.

See Chapter 4, “Date Intervals, Formats, and Functions,” for more information about specifying time intervals and for a detailed reference to the different kinds of intervals available.
Using Intervals with SAS/ETS Procedures

SAS/ETS procedures use the date or datetime interval and the ID variable in the following ways:

• to validate the data periodicity. The ID variable is used to check the data and verify that successive observations have valid ID values that correspond to successive time intervals.

• to check for gaps in the input observations. For example, if INTERVAL=MONTH and an input observation for January 1990 is followed by an observation for April 1990, there is a gap in the input data with two omitted observations.

• to label forecast observations in the output data set. The values of the ID variable for the forecast observations after the end of the input data set are extrapolated according to the frequency specifications of the INTERVAL= option.

Time Intervals, the Time Series Forecasting System, and the Time Series Viewer

Time intervals are used in the Time Series Forecasting System and Time Series Viewer to identify the number of seasonal cycles or seasonality associated with a DATE, DATETIME, or TIME ID variable. For example, monthly time series have a seasonality of 12 because there are 12 months in a year; quarterly time series have a seasonality of 4 because there are four quarters in a year. The seasonality is used to analyze seasonal properties of time series data and to estimate seasonal forecasting methods.

Plotting Time Series

This section discusses SAS procedures that are available for plotting time series data, but it covers only certain aspects of the use of these procedures with time series data.

The Time Series Viewer displays and analyzes time series plots for time series data sets that do not contain cross sections. See Chapter 45, “Getting Started with Time Series Forecasting.”

Using the Time Series Viewer

The following command starts the Time Series Viewer to display the plot of CPI in the USCPI data set against DATE. (The USCPI data set was shown in the previous example; the time series used in the following example contains more observations than previously shown.)

tsvview data=uscpi var=cpi timeid=date
The TSVIEW DATA= option specifies the data set to be viewed; the VAR= option specifies the variable that contains the time series observations; the TIMEID= option specifies the time series ID variable.

The Time Series Viewer can also be invoked by selecting Solutions►Analyze►Time Series Viewer from the menu in the SAS Display Manager.

---

**Using PROC SGPLOT**

The following statements use the SGPLOT procedure to plot CPI in the USCPI data set against DATE. (The USCPI data set was shown in a previous example; the data set plotted in the following example contains more observations than shown previously.)

```sas
title "Plot of USCPI Data";
proc sgplot data=uscpi;
   series x=date y=cpi / markers;
run;
```

The plot is shown in **Figure 3.8**.

**Figure 3.8** Plot of Monthly CPI Over Time
Controlling the Time Axis: Tick Marks and Reference Lines

It is possible to control the spacing of the tick marks on the time axis. The following statements use the XAXIS statement to tell PROC SGPLOT to mark the axis at the start of each quarter:

```sas
proc sgplot data=uscpi;
    series x=date y=cpi / markers;
    format date yyqc.;
    xaxis values=('1jan90'd to '1jul91'd by qtr);
run;
```

The plot is shown in Figure 3.9.

**Figure 3.9** Plot of Monthly CPI Over Time

Overlay Plots of Different Variables

You can plot two or more series stored in different variables on the same graph by specifying multiple plot requests in one SGPLOT statement.

For example, the following statements plot the CPI, FORECAST, L95, and U95 variables produced by PROC ARIMA in a previous example. A reference line is drawn to mark the start of the forecast period. Quarterly tick marks with YYQC format date values are used.
title "ARIMA Forecasts of CPI";

proc arima data=uscpi;
   identify var=cpi(1);
   estimate q=1;
   forecast id=date interval=month lead=12 out=arimaout;
run;

title "ARIMA forecasts of CPI";
proc sgplot data=arimaout noautolegend;
  scatter x=date y=cpi;
  scatter x=date y=forecast / markerattrs=(symbol=asterisk);
  scatter x=date y=l95 / markerattrs=(symbol=asterisk color=green);
  scatter x=date y=u95 / markerattrs=(symbol=asterisk color=green);
format date yyqc4.;
xaxis values=('1jan90'd to '1jul92'd by qtr);
refline '15jul91'd / axis=x;
run;

The plot is shown in Figure 3.10.

**Figure 3.10** Plot of ARIMA Forecast

![Plot of ARIMA Forecast](image-url)
Overlay Plots of Interleaved Series

You can also plot several series on the same graph when the different series are stored in the same variable in interleaved form. Plot interleaved time series by using the values of the ID variable in GROUP= option to distinguish the different series.

The following example plots the output data set produced by PROC FORECAST in a previous example. Since the residual series has a different scale than the other series, it is excluded from the plot with a WHERE statement.

The _TYPE_ variable is used in the PLOT statement to identify the different series and to select the SCATTER statements to use for each plot.

```plaintext
title "Plot of Forecasts of US CPI Data";

proc forecast data=uscpi interval=month lead=12
   out=foreout outfull outresid;
   var cpi;
   id date;
run;

proc sgplot data=foreout;
   where _type_ ^= 'RESIDUAL';
   scatter x=date y=cpi / group=_type_ markerattrs=(symbol=asterisk);
   format date yyqc4.;
   xaxis values=('1jan90'd to '1jul92'd by qtr);
   refline '15jul91'd / axis=x;
run;
```

The plot is shown in Figure 3.11.
The following example plots the residuals series that was excluded from the plot in the previous example. The NEEDLE statement specifies a needle plot, so that each residual point is plotted as a vertical line showing deviation from zero.

```plaintext
   title "Plot of Residuals for USCPI Data";
   proc sgplot data=foreout;
      where _type_ = 'RESIDUAL';
      needle x=date y=cpi / markers;
      format date yyqc4.;
      xaxis values=('1jan90'd to '1jul91'd by qtr);
   run;
```

The plot is shown in Figure 3.12.
Using PROC GPLOT

The GPLOT procedure in SAS/GRAPH software can also be used to plot time series data, although the newer SGPLOT procedure is easier to use.

The following is an example of how GPLOT can be used to produce a plot similar to the graph produced by PROC SGPLOT in the preceding section.

```sas
title "Plot of USCPI Data";
proc gplot data=uscpi;
  symbol i=spline v=circle h=2;
  plot cpi * date;
run;
```

The plot is shown in Figure 3.13.
Calendar and Time Functions

Calendar and time functions convert calendar and time variables such as YEAR, MONTH, DAY, and HOUR, MINUTE, SECOND into SAS date or datetime values, and vice versa.

The SAS calendar and time functions are DATEJUL, DATEPART, DAY, DHMS, HMS, HOUR, JULDATE, MDY, MINUTE, MONTH, QTR, SECOND, TIMEPART, WEEKDAY, YEAR, and YYQ. See SAS Language Reference: Dictionary for more details about these functions.

Computing Dates from Calendar Variables

The MDY function converts MONTH, DAY, and YEAR values to a SAS date value. For example, MDY(2010,17,91) returns the SAS date value '17OCT2010'D.

For more information about the GPLOT procedure, see SAS/GRAPH: Reference.
The YYQ function computes the SAS date for the first day of a quarter. For example, YYQ(2010,4) returns the SAS date value '1OCT2010'D.

The DATEJUL function computes the SAS date for a Julian date. For example, DATEJUL(91290) returns the SAS date '17OCT2010'D.

The YYQ and MDY functions are useful for creating SAS date variables when the ID values recorded in the data are year and quarter; year and month; or year, month, and day.

For example, the following statements read quarterly data from records in which dates are coded as separate year and quarter values. The YYQ function is used to compute the variable DATE.

```sas
data usecon;
  input year qtr gnp;
  date = yyq( year, qtr );
  format date yyqc.;
datalines;
1990 1 5375.4
1990 2 5443.3
1990 3 5514.6
...
```

The monthly USCPI data shown in a previous example contained time ID values represented in the MONYY format. If the data records instead contain separate year and month values, the data can be read in and the DATE variable computed with the following statements:

```sas
data uscpi;
  input month year cpi;
  date = mdy( month, 1, year );
  format date monyy.;
datalines;
6 90 129.9
7 90 130.4
8 90 131.6
...
```

---

### Computing Calendar Variables from Dates

The functions YEAR, MONTH, DAY, WEEKDAY, and JULDATE compute calendar variables from SAS date values.

Returning to the example of reading the USCPI data from records that contain date values represented in the MONYY format, you can find the month and year of each observation from the SAS dates of the observations by using the following statements:

```sas
data uscpi;
  input date monyy7. cpi;
  format date monyy7.;
  year = year( date );
```
Converting between Date, Datetime, and Time Values

The DATEPART function computes the SAS date value for the date part of a SAS datetime value. The TIMEPART function computes the SAS time value for the time part of a SAS datetime value.

The HMS function computes SAS time values from HOUR, MINUTE, and SECOND time variables. The DHMS function computes a SAS datetime value from a SAS date value and HOUR, MINUTE, and SECOND time variables.

See the section “SAS Date, Time, and Datetime Functions” on page 141 for more information about these functions.

Computing Datetime Values

To compute datetime ID values from calendar and time variables, first compute the date and then compute the datetime with DHMS.

For example, suppose you read tri-hourly temperature data with time recorded as YEAR, MONTH, DAY, and HOUR. The following statements show how to compute the ID variable DATETIME:

```sas
  data weather;
    input year month day hour temp;
    datetime = dhms( mdy( month, day, year ), hour, 0, 0 );
    format datetime datetime10.;
  datalines;
  91 10 16 21 61
  91 10 17 0 56
  91 10 17 3 53
  91 10 17 6 54
  ... more lines ...
```

Computing Calendar and Time Variables

The functions HOUR, MINUTE, and SECOND compute time variables from SAS datetime values. The DATEPART function and the date-to-calendar variables functions can be combined to compute calendar variables from datetime values.
Chapter 3: Working with Time Series Data

For example, suppose the date and time of the tri-hourly temperature data in the preceding example were recorded as datetime values in the datetime format. The following statements show how to compute the YEAR, MONTH, DAY, and HOUR of each observation and include these variables in the SAS data set:

```sas
data weather;
  input datetime : datetime13. temp;
  format datetime datetime10.;
  hour = hour( datetime );
  date = datepart( datetime );
  year = year( date );
  month = month( date );
  day = day( date );
datalines;
  16oct91:21:00 61
  17oct91:00:00 56
  17oct91:03:00 53
  17oct91:06:00 54
  ... more lines ...
```

Interval Functions INTNX and INTCK

The SAS interval functions INTNX and INTCK perform calculations with date values, datetime values, and time intervals. They can be used for calendar calculations with SAS date values to increment date values or datetime values by intervals and to count time intervals between dates.

The INTNX function increments dates by intervals. INTNX computes the date or datetime of the start of the interval a specified number of intervals from the interval that contains a given date or datetime value.

The form of the INTNX function is

```
INTNX ( interval, from, n < , alignment > ) ;
```

The arguments to the INTNX function are as follows:

- `interval`
  is a character constant or variable that contains an interval name

- `from`
  is a SAS date value (for date intervals) or datetime value (for datetime intervals)

- `n`
  is the number of intervals to increment from the interval that contains the `from` value

- `alignment`
  controls the alignment of SAS dates, within the interval, used to identify output observations. Allowed values are BEGINNING, MIDDLE, END, and SAMEDAY.

The number of intervals to increment, `n`, can be positive, negative, or zero.
For example, the statement NEXTMON=INTNX(‘MONTH’,DATE,1) assigns to the variable NEXTMON the date of the first day of the month following the month that contains the value of DATE. Thus INTNX(‘MONTH’,’21OCT2007’D,1) returns the date 1 November 2007.

The INTCK function counts the number of interval boundaries between two date values or between two datetime values.

The form of the INTCK function is

\[ \text{INTCK} \left( \text{interval, from, to} \right) \];

The arguments of the INTCK function are as follows:

- **interval**
  - is a character constant or variable that contains an interval name

- **from**
  - is the starting date value (for date intervals) or datetime value (for datetime intervals)

- **to**
  - is the ending date value (for date intervals) or datetime value (for datetime intervals)

For example, the statement NEWYEARS=INTCK(‘YEAR’,DATE1,DATE2) assigns to the variable NEWYEARS the number of New Year’s Days between the two dates.

**Incrementing Dates by Intervals**

Use the INTNX function to increment dates by intervals. For example, suppose you want to know the date of the start of the week that is six weeks from the week of 17 October 1991. The function INTNX(‘WEEK’,’17OCT91’D,6) returns the SAS date value ’24NOV1991’D.

One practical use of the INTNX function is to generate periodic date values. For example, suppose the monthly U.S. Consumer Price Index data in a previous example were recorded without any time identifier on the data records. Given that you know the first observation is for June 1990, the following statements use the INTNX function to compute the ID variable DATE for each observation:

```sas
data uscpi;
  input cpi;
  date = intnx( 'month', '1jun1990'd, _n_-1 );
  format date monyy7.;
datalines;
129.9
130.4
131.6
... more lines ...
```

The automatic variable _N_ counts the number of times the DATA step program has executed; in this case _N_ contains the observation number. Thus _N_–1 is the increment needed from the first observation date. Alternatively, you could increment from the month before the first observation, in which case the INTNX function in this example would be written INTNX(‘MONTH’,’1MAY1990’D,_N_).
Alignment of SAS Dates

Any date within the time interval that corresponds to an observation of a periodic time series can serve as an ID value for the observation. For example, the USCPI data in a previous example might have been recorded with dates at the 15th of each month. The person recording the data might reason that since the CPI values are monthly averages, midpoints of the months might be the appropriate ID values.

However, as far as SAS/ETS procedures are concerned, what is important about monthly data is the month of each observation, not the exact date of the ID value. If you indicate that the data are monthly (with an INTERVAL=MONTH) option, SAS/ETS procedures ignore the day of the month in processing the ID variable. The MONYY format also ignores the day of the month.

Thus, you could read in the monthly USCPI data with mid-month DATE values by using the following statements:

```sas
data uscpi;
  input date : date9. cpi;
  format date monyy7.;
datalines;
  15jun1990 129.9
  15jul1990 130.4
  15aug1990 131.6
  ... more lines ...
```

The results of using this version of the USCPI data set for analysis with SAS/ETS procedures would be the same as with first-of-month values for DATE. Although you can use any date within the interval as an ID value for the interval, you might find working with time series in SAS less confusing if you always use date ID values normalized to the start of the interval.

For some applications it might be preferable to use end of period dates, such as 31Jan1994, 28Feb1994, 31Mar1994, ..., 31Dec1994. For other applications, such as plotting time series, it might be more convenient to use interval midpoint dates to identify the observations.

(Some SAS/ETS procedures provide an ALIGN= option to control the alignment of dates for output time series observations. In addition, the INTNX library function supports an optional argument to specify the alignment of the returned date value.)

To normalize date values to the start of intervals, use the INTNX function with a 0 increment. The INTNX function with an increment of 0 computes the date of the first day of the interval (or the first second of the interval for datetime values).

For example, INTNX('MONTH','17OCT1991'D,0,'BEG') returns the date '1OCT1991'D.

The following statements show how the preceding example can be changed to normalize the mid-month DATE values to first-of-month and end-of-month values. For exposition, the first-of-month value is transformed back into a middle-of-month value.

```sas
data uscpi;
  input date : date9. cpi;
  format date monyy7.;
  monthbeg = intnx('month', date, 0, 'beg');
  midmonth = intnx('month', monthbeg, 0, 'mid');
  monthend = intnx('month', date, 0, 'end');
```
If you want to compute the date of a particular day within an interval, you can use calendar functions, or you can increment the starting date of the interval by a number of days. The following example shows three ways to compute the seventh day of the month:

```sas
data test;
  set uscpi;
  mon07_1 = mdy( month(date), 7, year(date) );
  mon07_2 = intnx( 'month', date, 0, 'beg' ) + 6;
  mon07_3 = intnx( 'day', date, 6 );
run;
```

Computing the Width of a Time Interval

To compute the width of a time interval, subtract the ID value of the start of the next interval from the ID value of the start of the current interval. If the ID values are SAS dates, the width is in days. If the ID values are SAS datetime values, the width is in seconds.

For example, the following statements show how to add a variable WIDTH to the USCPI data set that contains the number of days in the month for each observation:

```sas
data uscpi;
  input date : date9. cpi;
  format date monyy7.;
  width = intnx( 'month', date, 1 ) - intnx( 'month', date, 0 );
datalines;
15jun1990 129.9
15jul1990 130.4
15aug1990 131.6
15sep1990 132.7
... more lines ...
```

Computing the Ceiling of an Interval

To shift a date to the start of the next interval if it is not already at the start of an interval, subtract 1 from the date and use INTNX to increment the date by 1 interval.

For example, the following statements add the variable NEWYEAR to the monthly USCPI data set. The variable NEWYEAR contains the date of the next New Year’s Day. NEWYEAR contains the same value as DATE when the DATE value is the start of year and otherwise contains the date of the start of the next year.
data test;
set uscpi;
newyear = intnx( 'year', date - 1, 1 );
format newyear date.;
run;

Counting Time Intervals

Use the INTCK function to count the number of interval boundaries between two dates.

Note that the INTCK function counts the number of times the beginning of an interval is reached in moving from the first date to the second. It does not count the number of complete intervals between two dates. Following are two examples:

- The function INTCK(‘MONTH’,’1JAN1991’D,’31JAN1991’D) returns 0, since the two dates are within the same month.
- The function INTCK(‘MONTH’,’31JAN1991’D,’1FEB1991’D) returns 1, since the two dates lie in different months that are one month apart.

When the first date is later than the second date, INTCK returns a negative count. For example, the function INTCK(‘MONTH’,’1FEB1991’D,’31JAN1991’D) returns –1.

The following example shows how to use the INTCK function with shifted interval specifications to count the number of Sundays, Mondays, Tuesdays, and so forth, in each month. The variables NSUNDAY, NMONDAY, NTUESDAY, and so forth, are added to the USCPI data set.

data uscpi;
set uscpi;
d0 = intnx( 'month', date, 0 ) - 1;
d1 = intnx( 'month', date, 1 ) - 1;
nSunday = intck( 'week.1', d0, d1 );
nMonday = intck( 'week.2', d0, d1 );
nTuesday = intck( 'week.3', d0, d1 );
nWednesday = intck( 'week.4', d0, d1 );
nThursday = intck( 'week.5', d0, d1 );
nFriday = intck( 'week.6', d0, d1 );
nSaturday = intck( 'week.7', d0, d1 );
drop d0 d1;
run;

Since the INTCK function counts the number of interval beginning dates between two dates, the number of Sundays is computed by counting the number of week boundaries between the last day of the previous month and the last day of the current month. To count Mondays, Tuesdays, and so forth, shifted week intervals are used. The interval type WEEK.2 specifies weekly intervals starting on Mondays, WEEK.3 specifies weeks starting on Tuesdays, and so forth.
Checking Data Periodicity

Suppose you have a time series data set and you want to verify that the data periodicity is correct, the observations are dated correctly, and the data set is sorted by date. You can use the INTCK function to compare the date of the current observation with the date of the previous observation and verify that the dates fall into consecutive time intervals.

For example, the following statements verify that the data set USCPI is a correctly dated monthly data set. The RETAIN statement is used to hold the date of the previous observation, and the automatic variable _N_ is used to start the verification process with the second observation.

```sas
data _null_;  
  set uscpi;  
  retain prevdate;  
  if _n_ > 1 then  
    if intck( 'month', prevdate, date ) ^= 1 then  
      put "Bad date sequence at observation number " _n_;  
  prevdate = date;  
run;
```

Filling In Omitted Observations in a Time Series Data Set

Most SAS/ETS procedures expect input data to be in the standard form, with no omitted observations in the sequence of time periods. When data are missing for a time period, the data set should contain a missing observation, in which all variables except the ID variables have missing values.

You can replace omitted observations in a time series data set with missing observations with the EXPAND procedure.

The following statements create a monthly data set, OMITTED, from data lines that contain records for an intermittent sample of months. (Data values are not shown.) The OMITTED data set is sorted to make sure it is in time order.

```sas
data omitted;  
  input date : monyy7. x y z;  
  format date monyy7.;  
  datalines;  
  jan1991 ...  
  mar1991 ...  
  apr1991 ...  
  jun1991 ...  
  ... etc. ...  
;  
  proc sort data=omitted;  
  by date;  
  run;
```

This data set is converted to a standard form time series data set by the following PROC EXPAND step. The TO= option specifies that monthly data is to be output, while the METHOD=NONE option specifies that no
interpolation is to be performed, so that the variables X, Y, and Z in the output data set STANDARD will have missing values for the omitted time periods that are filled in by the EXPAND procedure.

```sas
proc expand data=omitted
   out=standard
   to=month
   method=none;
   id date;
run;
```

---

**Using Interval Functions for Calendar Calculations**

With a little thought, you can come up with a formula that involves INTNX and INTCK functions and different interval types to perform almost any calendar calculation.

For example, suppose you want to know the date of the third Wednesday in the month of October 1991. The answer can be computed as

```sas
intnx( 'week.4', '1oct91'd - 1, 3 )
```

which returns the SAS date value ’16OCT91’D.

Consider this more complex example: how many weekdays are there between 17 October 1991 and the second Friday in November 1991, inclusive? The following formula computes the number of weekdays between the date value contained in the variable DATE and the second Friday of the following month (including the ending dates of this period):

```sas
n = intck( 'weekday', date - 1,
            intnx( 'week.6', intnx( 'month', date, 1 ) - 1, 2 ) + 1 );
```

Setting DATE to ’17OCT91’D and applying this formula produces the answer, N=17.

---

**Lags, Leads, Differences, and Summations**

When working with time series data, you sometimes need to refer to the values of a series in previous or future periods. For example, the usual interest in the consumer price index series shown in previous examples is how fast the index is changing, rather than the actual level of the index. To compute a percent change, you need both the current and the previous values of the series. When you model a time series, you might want to use the previous values of other series as explanatory variables.

This section discusses how to use the DATA step to perform operations over time: lags, differences, leads, summations over time, and percent changes.

The EXPAND procedure can also be used to perform many of these operations; see Chapter 15, “The EXPAND Procedure,” for more information. See also the section “Transforming Time Series” on page 107.
The LAG and DIF Functions

The DATA step provides two functions, LAG and DIF, for accessing previous values of a variable or expression. These functions are useful for computing lags and differences of series.

For example, the following statements add the variables CPILAG and CPIDIF to the USCPI data set. The variable CPILAG contains lagged values of the CPI series. The variable CPIDIF contains the changes of the CPI series from the previous period; that is, CPIDIF is CPI minus CPILAG. The new data set is shown in part in Figure 3.14.

```sas
data uscpi;
  set uscpi;
  cpilag = lag( cpi );
  cpidif = dif( cpi );
run;
```

```sas
proc print data=uscpi;
run;
```

Understanding the DATA Step LAG and DIF Functions

When used in this simple way, LAG and DIF act as lag and difference functions. However, it is important to keep in mind that, despite their names, the LAG and DIF functions available in the DATA step are not true lag and difference functions.

Rather, LAG and DIF are queuing functions that remember and return argument values from previous calls. The LAG function remembers the value you pass to it and returns as its result the value you passed to it on the previous call. The DIF function works the same way but returns the difference between the current argument and the remembered value. (LAG and DIF return a missing value the first time the function is called.)
A true lag function does not return the value of the argument for the “previous call,” as do the DATA step LAG and DIF functions. Instead, a true lag function returns the value of its argument for the “previous observation,” regardless of the sequence of previous calls to the function. Thus, for a true lag function to be possible, it must be clear what the “previous observation” is.

If the data are sorted chronologically, then LAG and DIF act as true lag and difference functions. If in doubt, use PROC SORT to sort your data before using the LAG and DIF functions. Beware of missing observations, which can cause LAG and DIF to return values that are not the actual lag and difference values.

The DATA step is a powerful tool that can read any number of observations from any number of input files or data sets, can create any number of output data sets, and can write any number of output observations to any of the output data sets, all in the same program. Thus, in general, it is not clear what “previous observation” means in a DATA step program. In a DATA step program, the “previous observation” exists only if you write the program in a simple way that makes this concept meaningful.

Since, in general, the previous observation is not clearly defined, it is not possible to make true lag or difference functions for the DATA step. Instead, the DATA step provides queuing functions that make it easy to compute lags and differences.

**Pitfalls of DATA Step LAG and DIF Functions**

The LAG and DIF functions compute lags and differences provided that the sequence of calls to the function corresponds to the sequence of observations in the output data set. However, any complexity in the DATA step that breaks this correspondence causes the LAG and DIF functions to produce unexpected results.

For example, suppose you want to add the variable CPILAG to the USCPI data set, as in the previous example, and you also want to subset the series to 1991 and later years. You might use the following statements:

```sas
data subset;
  set uscpi;
  if date >= '1jan1991'd;
  cpilag = lag( cpi );  /* WRONG PLACEMENT! */
run;
```

If the subsetting IF statement comes before the LAG function call, the value of CPILAG will be missing for January 1991, even though a value for December 1990 is available in the USCPI data set. To avoid losing this value, you must rearrange the statements to ensure that the LAG function is actually executed for the December 1990 observation.

```sas
data subset;
  set uscpi;
  cpilag = lag( cpi );
  if date >= '1jan1991'd;
run;
```

In other cases, the subsetting statement should come before the LAG and DIF functions. For example, the following statements subset the FOREOUT data set shown in a previous example to select only _TYPE_=RESIDUAL observations and also to compute the variable LAGRESID:

```sas
data residual;
  set foreout;
  if _type_ = "RESIDUAL";
  lagresid = lag( cpi );
```
Another pitfall of LAG and DIF functions arises when they are used to process time series cross-sectional data sets. For example, suppose you want to add the variable CPILAG to the CPICITY data set shown in a previous example. You might use the following statements:

```plaintext
data cpicity;
  set cpicity;
  cpilag = lag( cpi );
run;
```

However, these statements do not yield the desired result. In the data set produced by these statements, the value of CPILAG for the first observation for the first city is missing (as it should be), but in the first observation for all later cities, CPILAG contains the last value for the previous city. To correct this, set the lagged variable to missing at the start of each cross section, as follows:

```plaintext
data cpicity;
  set cpicity;
  by city date;
  cpilag = lag( cpi );
  if first.city then cpilag = .;
run;
```

### Alternatives to LAG and DIF Functions

You can also use the EXPAND procedure to compute lags and differences. For example, the following statements compute lag and difference variables for CPI:

```plaintext
proc expand data=uscpi out=uscpi method=none;
  id date;
  convert cpi=cpilag / transform=( lag 1 );
  convert cpi=cpidif / transform=( dif 1 );
run;
```

You can also calculate lags and differences in the DATA step without using LAG and DIF functions. For example, the following statements add the variables CPILAG and CPIDIF to the USCPI data set:

```plaintext
data uscpi;
  set uscpi;
  retain cpilag;
  cpidif = cpi - cpilag;
  output;
  cpilag = cpi;
run;
```

The RETAIN statement prevents the DATA step from reinitializing CPILAG to a missing value at the start of each iteration and thus allows CPILAG to retain the value of CPI assigned to it in the last statement. The OUTPUT statement causes the output observation to contain values of the variables before CPILAG is reassigned the current value of CPI in the last statement. This is the approach that must be used if you want to build a variable that is a function of its previous lags.
LAG and DIF Functions in PROC MODEL

The preceding discussion of LAG and DIF functions applies to LAG and DIF functions available in the DATA step. However, LAG and DIF functions are also used in the MODEL procedure.

The MODEL procedure LAG and DIF functions do not work like the DATA step LAG and DIF functions. The LAG and DIF functions supported by PROC MODEL are true lag and difference functions, not queuing functions.

Unlike the DATA step, the MODEL procedure processes observations from a single input data set, so the “previous observation” is always clearly defined in a PROC MODEL program. Therefore, PROC MODEL is able to define LAG and DIF as true lagging functions that operate on values from the previous observation. See Chapter 19, “The MODEL Procedure,” for more information about LAG and DIF functions in the MODEL procedure.

Multiperiod Lags and Higher-Order Differencing

To compute lags at a lagging period greater than 1, add the lag length to the end of the LAG keyword to specify the lagging function needed. For example, the LAG2 function returns the value of its argument two calls ago, the LAG3 function returns the value of its argument three calls ago, and so forth.

To compute differences at a lagging period greater than 1, add the lag length to the end of the DIF keyword. For example, the DIF2 function computes the differences between the value of its argument and the value of its argument two calls ago. (The maximum lagging period is 100.)

The following statements add the variables CPILAG12 and CPIDIF12 to the USCPI data set. CPILAG12 contains the value of CPI from the same month one year ago. CPIDIF12 contains the change in CPI from the same month one year ago. (In this case, the first 12 values of CPILAG12 and CPIDIF12 are missing.)

```sas
data uscpi;
set uscpi;
cpilag12 = lag12( cpi );
cpidif12 = dif12( cpi );
run;
```

To compute second differences, take the difference of the difference. To compute higher-order differences, nest DIF functions to the order needed. For example, the following statements compute the second difference of CPI:

```sas
data uscpi;
set uscpi;
cpi2dif = dif( dif( cpi ) );
run;
```

Multiperiod lags and higher-order differencing can be combined. For example, the following statements compute monthly changes in the inflation rate, with inflation rate computed as percent change in CPI from the same month one year ago:

```sas
data uscpi;
set uscpi;
infchng = dif( 100 * dif12( cpi ) / lag12( cpi ) );
run;
```
Percent Change Calculations

There are several common ways to compute the percent change in a time series. This section illustrates the use of LAG and DIF functions by showing SAS statements for various kinds of percent change calculations.

Computing Period-to-Period Change

To compute percent change from the previous period, divide the difference of the series by the lagged value of the series and multiply by 100.

```sas
data uscpi;
  set uscpi;
  pctchng = dif( cpi ) / lag( cpi ) * 100;
  label pctchng = "Monthly Percent Change, At Monthly Rates";
run;
```

Often, changes from the previous period are expressed at annual rates. This is done by exponentiation of the current-to-previous period ratio to the number of periods in a year and expressing the result as a percent change. For example, the following statements compute the month-over-month change in CPI as a percent change at annual rates:

```sas
data uscpi;
  set uscpi;
  pctchng = ( ( cpi / lag( cpi ) ) ** 12 - 1 ) * 100;
  label pctchng = "Monthly Percent Change, At Annual Rates";
run;
```

Computing Year-over-Year Change

To compute percent change from the same period in the previous year, use LAG and DIF functions with a lagging period equal to the number of periods in a year. (For quarterly data, use LAG4 and DIF4. For monthly data, use LAG12 and DIF12.)

For example, the following statements compute monthly percent change in CPI from the same month one year ago:

```sas
data uscpi;
  set uscpi;
  pctchng = dif12( cpi ) / lag12( cpi ) * 100;
  label pctchng = "Percent Change from One Year Ago";
run;
```

To compute year-over-year percent change measured at a given period within the year, subset the series of percent changes from the same period in the previous year to form a yearly data set. Use an IF or WHERE statement to select observations for the period within each year on which the year-over-year changes are based.

For example, the following statements compute year-over-year percent change in CPI from December of the previous year to December of the current year:

```sas
data annual;
  set uscpi;
  pctchng = dif12( cpi ) / lag12( cpi ) * 100;
  label pctchng = "Percent Change: December to December";
```
Computing Percent Change in Yearly Averages

To compute changes in yearly averages, first aggregate the series to an annual series by using the EXPAND procedure, and then compute the percent change of the annual series. (See Chapter 15, “The EXPAND Procedure,” for more information about PROC EXPAND.)

For example, the following statements compute percent changes in the annual averages of CPI:

```sas
proc expand data=uscpi out=annual from=month to=year;
  convert cpi / observed=average method=aggregate;
run;

data annual;
  set annual;
  pctchng = dif( cpi ) / lag( cpi ) * 100;
  label pctchng = "Percent Change in Yearly Averages";
run;
```

It is also possible to compute percent change in the average over the most recent yearly span. For example, the following statements compute monthly percent change in the average of CPI over the most recent 12 months from the average over the previous 12 months:

```sas
data uscpi;
  retain sum12 0;
  drop sum12 ave12 cpilag12;
  set uscpi;
  sum12 = sum12 + cpi;
  cpilag12 = lag12( cpi );
  if cpilag12 ^= . then sum12 = sum12 - cpilag12;
  if lag11( cpi ) ^= . then ave12 = sum12 / 12;
  pctchng = dif12( ave12 ) / lag12( ave12 ) * 100;
  label pctchng = "Percent Change in 12 Month Moving Ave.";
run;
```

This example is a complex use of LAG and DIF functions that requires care in handling the initialization of the moving-window averaging process. The LAG12 of CPI is checked for missing values to determine when more than 12 values have been accumulated, and older values must be removed from the moving sum. The LAG11 of CPI is checked for missing values to determine when at least 12 values have been accumulated; AVE12 will be missing when LAG11 of CPI is missing. The DROP statement prevents temporary variables from being added to the data set.

Note that the DIF and LAG functions must execute for every observation, or the queues of remembered values will not operate correctly. The CPILAG12 calculation must be separate from the IF statement. The PCTCHNG calculation must not be conditional on the IF statement.

The EXPAND procedure provides an alternative way to compute moving averages.
Leading Series

Although the SAS System does not provide a function to look ahead at the “next” value of a series, there are a couple of ways to perform this task.

The most direct way to compute leads is to use the EXPAND procedure. For example:

```sas
proc expand data=uscpi out=uscpi method=none;
  id date;
  convert cpi=cpilead1 / transform=( lead 1 );
  convert cpi=cpilead2 / transform=( lead 2 );
run;
```

Another way to compute lead series in SAS software is by lagging the time ID variable, renaming the series, and merging the result data set back with the original data set.

For example, the following statements add the variable CPILEAD to the USCPI data set. The variable CPILEAD contains the value of CPI in the following month. (The value of CPILEAD is missing for the last observation, of course.)

```sas
data temp;
  set uscpi;
  keep date cpi;
  rename cpi = cpilead;
  date = lag( date );
  if date ^= .;
run;

data uscpi;
  merge uscpi temp;
  by date;
run;
```

To compute leads at different lead lengths, you must create one temporary data set for each lead length. For example, the following statements compute CPILEAD1 and CPILEAD2, which contain leads of CPI for 1 and 2 periods, respectively:

```sas
data temp1(rename=(cpi=cpilead1)) temp2(rename=(cpi=cpilead2));
  set uscpi;
  keep date cpi;
  date = lag( date );
  if date ^= . then output temp1;
  date = lag( date );
  if date ^= . then output temp2;
run;

data uscpi;
  merge uscpi temp1 temp2;
  by date;
run;
```
Summing Series

Simple cumulative sums are easy to compute using SAS sum statements. The following statements show how to compute the running sum of variable X in data set A, adding XSUM to the data set.

```sas
data a;
  set a;
  xsum + x;
run;
```

The SAS sum statement automatically retains the variable XSUM and initializes it to 0, and the sum statement treats missing values as 0. The sum statement is equivalent to using a RETAIN statement and the SUM function. The previous example could also be written as follows:

```sas
data a;
  set a;
  retain xsum;
  xsum = sum( xsum, x );
run;
```

You can also use the EXPAND procedure to compute summations. For example:

```sas
proc expand data=a out=a method=none;
  convert x=xsum / transform=( sum );
run;
```

Like differencing, summation can be done at different lags and can be repeated to produce higher-order sums. To compute sums over observations separated by lags greater than 1, use the LAG and SUM functions together, and use a RETAIN statement that initializes the summation variable to zero.

For example, the following statements add the variable XSUM2 to data set A. XSUM2 contains the sum of every other observation, with even-numbered observations containing a cumulative sum of values of X from even observations, and odd-numbered observations containing a cumulative sum of values of X from odd observations.

```sas
data a;
  set a;
  retain xsum2 0;
  xsum2 = sum( lag( xsum2 ), x );
run;
```

Assuming that A is a quarterly data set, the following statements compute running sums of X for each quarter. XSUM4 contains the cumulative sum of X for all observations for the same quarter as the current quarter. Thus, for a first-quarter observation, XSUM4 contains a cumulative sum of current and past first-quarter values.

```sas
data a;
  set a;
  retain xsum4 0;
  xsum4 = sum( lag3( xsum4 ), x );
run;
```
To compute higher-order sums, repeat the preceding process and sum the summation variable. For example, the following statements compute the first and second summations of X:

```plaintext
data a;
  set a;
  xsum + x;
  x2sum + xsum;
run;
```

The following statements compute the second order four-period sum of X:

```plaintext
data a;
  set a;
  retain xsum4 x2sum4 0;
  xsum4 = sum( lag3( xsum4 ), x );
  x2sum4 = sum( lag3( x2sum4 ), xsum4 );
run;
```

You can also use PROC EXPAND to compute cumulative statistics and moving window statistics. See Chapter 15, "The EXPAND Procedure," for details.

---

**Transforming Time Series**

It is often useful to transform time series for analysis or forecasting. Many time series analysis and forecasting methods are most appropriate for time series with an unrestricted range, a linear trend, and a constant variance. Series that do not conform to these assumptions can often be transformed to series for which the methods are appropriate.

Transformations can be useful for the following:

- **range restrictions.** Many time series cannot have negative values or can be limited to a maximum possible value. You can often create a transformed series with an unbounded range.
- **nonlinear trends.** Many economic time series grow exponentially. Exponential growth corresponds to linear growth in the logarithms of the series.
- **series variability that changes over time.** Various transformations can be used to stabilize the variance.
- **nonstationarity.** The %DFTEST macro can be used to test a series for nonstationarity which can then be removed by differencing.

---

**Log Transformation**

The logarithmic transformation is often useful for series that must be greater than zero and that grow exponentially. For example, Figure 3.15 shows a plot of an airline passenger miles series. Notice that the series has exponential growth and the variability of the series increases over time. Airline passenger miles must also be zero or greater.
The following statements compute the logarithms of the airline series:

```sas
data lair;
  set sashelp.air;
  logair = log( air );
run;
```

Figure 3.16 shows a plot of the log-transformed airline series. Notice that the log series has a linear trend and constant variance.
Other Transformations

The %LOGTEST macro can help you decide if a log transformation is appropriate for a series. See Chapter 5, “SAS Macros and Functions,” for more information about the %LOGTEST macro.

Other Transformations

The Box-Cox transformation is a general class of transformations that includes the logarithm as a special case. The %BOXCOXAR macro can be used to find an optimal Box-Cox transformation for a time series. See Chapter 5 for more information about the %BOXCOXAR macro.

The logistic transformation is useful for variables with both an upper and a lower bound, such as market shares. The logistic transformation is useful for proportions, percent values, relative frequencies, or probabilities. The logistic function transforms values between 0 and 1 to values that can range from $-\infty$ to $+\infty$.

For example, the following statements transform the variable SHARE from percent values to an unbounded range:

```sas
data a;
set a;
```
\[ lshare = \log \left( \frac{\text{share}}{100 - \text{share}} \right); \]
run;

Many other data transformation can be used. You can create virtually any desired data transformation using DATA step statements.

---

**The EXPAND Procedure and Data Transformations**

The EXPAND procedure provides a convenient way to transform series. For example, the following statements add variables for the logarithm of AIR and the logistic of SHARE to data set A:

```plaintext
proc expand data=a out=a method=none;
   convert air=logair / transform=( log );
   convert share=lshare / transform=( / 100 logit );
run;
```

See Table 15.2 in Chapter 15, “The EXPAND Procedure,” for a complete list of transformations supported by PROC EXPAND.

---

**Manipulating Time Series Data Sets**

This section discusses merging, splitting, and transposing time series data sets and interpolating time series data to a higher or lower sampling frequency.

---

**Splitting and Merging Data Sets**

In some cases, you might want to separate several time series that are contained in one data set into different data sets. In other cases, you might want to combine time series from different data sets into one data set.

To split a time series data set into two or more data sets that contain subsets of the series, use a DATA step to create the new data sets and use the KEEP= data set option to control which series are included in each new data set. The following statements split the USPRICE data set shown in a previous example into two data sets, USCPI and USPPI:

```plaintext
data uscpi(keep=date cpi)
   usppi(keep=date ppi);
   set usprice;
run;
```

If the series have different time ranges, you can subset the time ranges of the output data sets accordingly. For example, if you know that CPI in USPRICE has the range August 1990 through the end of the data set, while PPI has the range from the beginning of the data set through June 1991, you could write the previous example as follows:
To combine time series from different data sets into one data set, list the data sets to be combined in a MERGE statement and specify the dating variable in a BY statement. The following statements show how to combine the USCPI and USPPI data sets to produce the USPRICE data set. It is important to use the BY DATE statement so that observations are matched by time before merging.

```sas
data usprice;
  merge uscpi usppi;
  by date;
run;
```

Transposing Data Sets

The TRANSPOSE procedure is used to transpose data sets from one form to another. The TRANSPOSE procedure can transpose variables and observations, or transpose variables and observations within BY groups. This section discusses some applications of the TRANSPOSE procedure relevant to time series data sets. See the *Base SAS Procedures Guide* for more information about PROC TRANSPOSE.

Transposing from Interleaved to Standard Time Series Form

The following statements transpose part of the interleaved-form output data set FOREOUT, produced by PROC FORECAST in a previous example, to a standard form time series data set. To reduce the volume of output produced by the example, a WHERE statement is used to subset the input data set.

Observations with _TYPE_=ACTUAL are stored in the new variable ACTUAL; observations with _TYPE_=FORECAST are stored in the new variable FORECAST; and so forth. Note that the method used in this example works only for a single variable.

```sas
title "Original Data Set";
proc print data=foreout(obs=10);
  where date > '1may1991'd & date < '1oct1991'd;
run;

proc transpose data=foreout out=trans(drop=_name_);
  var cpi;
  id _type_;  
  by date;
  where date > '1may1991'd & date < '1oct1991'd;
run;
```
title "Transposed Data Set";
proc print data=trans(obs=10);
run;

The TRANSPOSE procedure adds the variables _NAME_ and _LABEL_ to the output data set. These variables contain the names and labels of the variables that were transposed. In this example, there is only one transposed variable, so _NAME_ has the value CPI for all observations. Thus, _NAME_ and _LABEL_ are of no interest and are dropped from the output data set by using the DROP= data set option. (If none of the variables transposed have a label, PROC TRANSPOSE does not output the _LABEL_ variable and the DROP=_LABEL_ option produces a warning message. You can ignore this message, or you can prevent the message by omitting _LABEL_ from the DROP= list.)

The original and transposed data sets are shown in Figure 3.17 and Figure 3.18. (The observation numbers shown for the original data set reflect the operation of the WHERE statement.)

**Transposing Cross-Sectional Dimensions**

The following statements transpose the variable CPI in the CPICITY data set shown in a previous example from time series cross-sectional form to a standard form time series data set. (Only a subset of the data shown in the previous example is used here.) Note that the method shown in this example works only for a single variable.
title "Original Data Set";
proc print data=cpicity;
run;

proc sort data=cpicity out=temp;
   by date city;
run;

proc transpose data=temp out=citycpi(drop=_name_);
   var cpi;
   id city;
   by date;
run;

title "Transposed Data Set";
proc print data=citycpi;
run;

The names of the variables in the transposed data sets are taken from the city names in the ID variable CITY. The original and the transposed data sets are shown in Figure 3.19 and Figure 3.20.

</tbody>
</table>
The following statements transpose the CITYCPI data set back to the original form of the CPICITY data set. The variable _NAME_ is added to the data set to tell PROC TRANSPOSE the name of the variable in which to store the observations in the transposed data set. (If the (DROP=_NAME_ _LABEL_) option were omitted from the first PROC TRANSPOSE step, this would not be necessary. PROC TRANSPOSE assumes ID _NAME_ by default.)

The NAME=CITY option in the PROC TRANSPOSE statement causes PROC TRANSPOSE to store the names of the transposed variables in the variable CITY. Because PROC TRANSPOSE recodes the values of the CITY variable to create valid SAS variable names in the transposed data set, the values of the variable CITY in the retransposed data set are not the same as in the original. The retransposed data set is shown in Figure 3.21.

```
data temp;
  set citycpi;
  _name_ = 'CPI';
run;

proc transpose data=temp out=retrans name=city;
  by date;
run;

proc sort data=retrans;
  by city date;
run;

title "Retransposed Data Set";
proc print data=retrans;
run;
```
Time Series Interpolation

The EXPAND procedure interpolates time series. This section provides a brief summary of the use of PROC EXPAND for different kinds of time series interpolation problems. Most of the issues discussed in this section are explained in greater detail in Chapter 15.

By default, the EXPAND procedure performs interpolation by first fitting cubic spline curves to the available data and then computing needed interpolating values from the fitted spline curves. Other interpolation methods can be requested.

Note that interpolating values of a time series does not add any real information to the data because the interpolation process is not the same process that generated the other (nonmissing) values in the series. While time series interpolation can sometimes be useful, great care is needed in analyzing time series that contain interpolated values.

Interpolating Missing Values

To use the EXPAND procedure to interpolate missing values in a time series, specify the input and output data sets in the PROC EXPAND statement, and specify the time ID variable in an ID statement. For example, the
following statements cause PROC EXPAND to interpolate values for missing values of all numeric variables in the data set USPRICE:

```
proc expand data=usprice out=interpl;
  id date;
run;
```

Interpolated values are computed only for embedded missing values in the input time series. Missing values before or after the range of a series are ignored by the EXPAND procedure.

In the preceding example, PROC EXPAND assumes that all series are measured at points in time given by the value of the ID variable. In fact, the series in the USPRICE data set are monthly averages. PROC EXPAND can produce a better interpolation if this is taken into account. The following example uses the FROM=MONTH option to tell PROC EXPAND that the series is monthly and uses the CONVERT statement with the OBSERVED=AVERAGE to specify that the series values are averages over each month:

```
proc expand data=usprice out=interpl from=month;
  id date;
  convert cpi ppi / observed=average;
run;
```

**Interpolating to a Higher or Lower Frequency**

You can use PROC EXPAND to interpolate values of time series at a higher or lower sampling frequency than the input time series. To change the periodicity of time series, specify the time interval of the input data set with the FROM= option, and specify the time interval for the desired output frequency with the TO= option. For example, the following statements compute interpolated weekly values of the monthly CPI and PPI series:

```
proc expand data=usprice out=interpl from=month to=week;
  id date;
  convert cpi ppi / observed=average;
run;
```

**Interpolating between Stocks and Flows, Levels and Rates**

A distinction is made between variables that are measured at points in time and variables that represent totals or averages over an interval. Point-in-time values are often called **stocks** or **levels**. Variables that represent totals or averages over an interval are often called **flows** or **rates**.

For example, the annual series Gross National Product represents the final goods production of over the year and also the yearly average rate of that production. However, the monthly variable Inventory represents the cost of a stock of goods at the end of the month.

The EXPAND procedure can convert between point-in-time values and period average or total values. To convert observation characteristics, specify the input and output characteristics with the OBSERVED= option in the CONVERT statement. For example, the following statements use the monthly average price index values in USPRICE to compute interpolated estimates of the price index levels at the midpoint of each month.
Reading Time Series Data

Time series data can be coded in many different ways. The SAS System can read time series data recorded in almost any form. Earlier sections of this chapter show how to read time series data coded in several commonly used ways. This section shows how to read time series data from data records coded in two other commonly used ways not previously introduced.

Several time series databases distributed by major data vendors can be read into SAS data sets by the DATASOURCE procedure. See Chapter 12, “The DATASOURCE Procedure,” for more information.

Reading a Simple List of Values

Time series data can be coded as a simple list of values without dating information and with an arbitrary number of observations on each data record. In this case, the INPUT statement must use the trailing “@@” option to retain the current data record after reading the values for each observation, and the time ID variable must be generated with programming statements.

For example, the following statements read the USPRICE data set from data records that contain pairs of values for CPI and PPI. This example assumes you know that the first pair of values is for June 1990.

```
data usprice;
  input cpi ppi @@;
  date = intnx( 'month', '1jun1990'd, _n_-1 );
  format date monyy7.;
datalines;
129.9 114.3 130.4 114.5 131.6 116.5  
132.7 118.4 133.5 120.8 133.8 120.1 133.8 118.7 
134.6 119.0 134.8 117.2 135.0 116.2 135.2 116.0 
135.6 116.5 136.0 116.3 136.2 116.0
;```

Reading Fully Described Time Series in Transposed Form

Data for several time series can be coded with separate groups of records for each time series. Data files coded this way are transposed from the form required by SAS procedures. Time series data can also be coded
with descriptive information about the series included with the data records.

The following example reads time series data for the USPRICE data set coded with separate groups of records for each series. The data records for each series consist of a series description record and one or more value records. The series description record gives the series name, starting month and year of the series, number of values in the series, and a series label. The value records contain the observations of the time series.

The data are first read into a temporary data set that contains one observation for each value of each series.

```sas
data temp;
  length _name_ $8 _label_ $40;
  keep _name_ _label_ date value;
  format date monyy.;
  input _name_ month year nval _label_ &;
  date = mdy( month, 1, year );
  do i = 1 to nval;
    input value @;
    output;
    date = intnx( 'month', date, 1 );
  end;
datalines;
cpi  8 90 12  Consumer Price Index
131.6 132.7 133.5 133.8 134.6 134.8 135.0
135.2 135.6 136.0 136.2
ppi  6 90 13  Producer Price Index
114.3 114.5 116.5 118.4 120.8 120.1 118.7 119.0
117.2 116.2 116.0 116.5 116.3
;"}

The following statements sort the data set by date and series name, and the TRANSPOSE procedure is used to transpose the data into a standard form time series data set.

```sas
proc sort data=temp;
  by date _name_;
run;

proc transpose data=temp out=usprice(drop=_name_);
  by date;
  var value;
run;

proc contents data=usprice;
run;

proc print data=usprice;
run;
```

The final data set is shown in Figure 3.23.

Overview

This chapter summarizes the time intervals, date and datetime informats, date and datetime formats, and date, time, and datetime functions available in SAS software. The use of these features is explained in Chapter 3, “Working with Time Series Data.” The material in this chapter is also contained in SAS Language Reference: Concepts and SAS Language Reference: Dictionary. Because these features are useful for work with time series data, documentation of these features is consolidated and repeated here for easy reference.
**Time Intervals**

This section provides a reference for the different kinds of time intervals supported by SAS software, but it does not cover how they are used. For an introduction to the use of time intervals, see Chapter 3, “Working with Time Series Data.”

Some interval names are used with SAS date values, while other interval names are used with SAS datetime values. The interval names used with SAS date values are YEAR, SEMIYEAR, QTR, MONTH, SEMIMONTH, TENDAY, WEEK, WEEKDAY, DAY, YEARV, R445YR, R454YR, R544YR, R445QTR, R454QTR, R544QTR, R445MON, R454MON, R544MON, and WEEKV. The interval names used with SAS datetime or time values are HOUR, MINUTE, and SECOND. Various abbreviations of these names are also allowed, as described in the section “Summary of Interval Types” on page 125.

Interval names for use with SAS date values can be prefixed with ‘DT’ to construct interval names for use with SAS datetime values. The interval names DTYEAR, DTSEMIYEAR, DTQTR, DTMONTH, DTSEMIMONTH, DTTENDAY, DTWEEK, DTWEEKDAY, DTDAY, DTYEARV, DTR445YR, DTR454YR, DTR544YR, DTR445QTR, DTR454QTR, DTR544QTR, DTR445MON, DTR454MON, DTR544MON, and DTWEEKV are used with SAS datetime values.

**Constructing Interval Names**

Multipliers and shift indexes can be used with the basic interval names to construct more complex interval specifications. The general form of an interval name is as follows:

\[
\text{NAME}n.s
\]

The three parts of the interval name are shown below:

- **NAME** the name of the basic interval type. For example, YEAR specifies yearly intervals.
- **n** an optional multiplier that specifies that the interval is a multiple of the period of the basic interval type. For example, the interval YEAR2 consists of two-year (biennial) periods.
- **s** an optional starting subperiod index that specifies that the intervals are shifted to later starting points. For example, YEAR.3 specifies yearly periods shifted to start on the first of March of each calendar year and to end in February of the following year.

Both the multiplier \(n\) and the shift index \(s\) are optional and default to 1. For example, YEAR, YEAR1, YEAR.1, and YEAR1.1 are all equivalent ways of specifying ordinary calendar years.
To test for a valid interval specification, use the INTTEST function:

```sas
interval = 'MONTH3.2';
valid = INTTEST( interval );
valid = INTTEST( 'YEAR4');
```

INTTEST returns a value of 0 if the argument is not a valid interval specification and 1 if the argument is a valid interval specification. The INTTEST function can also be used in a DATA step to test an interval before calling an interval function:

```sas
valid = INTTEST( interval );
if ( valid = 1 ) then do;
   end_date = INTNX( interval, date, 0, 'E' );
   Status = 'Success';
end;
if ( valid = 0 ) then Status = 'Failure';
```

For more information about the INTTEST function, see the SAS Language Reference: Dictionary.

---

**Shifted Intervals**

Different kinds of intervals are shifted by different subperiods:

- YEAR, SEMIYEAR, QTR, and MONTH intervals are shifted by calendar months.
- WEEK and DAY intervals are shifted by days.
- SEMIMONTH intervals are shifted by semimonthly periods.
- TENDAY intervals are shifted by 10-day periods.
- YEARV intervals are shifted by WEEKV intervals.
- R445YR, R445QTR, and R445MON intervals are shifted by R445MON intervals.
- R454YR, R454QTR, and R454MON intervals are shifted by R454MON intervals.
- R544YR, R544QTR, and R544MON intervals are shifted by R544MON intervals.
- WEEKV intervals are shifted by days.
- WEEKDAY intervals are shifted by weekdays.
- HOUR intervals are shifted by hours.
- MINUTE intervals are shifted by minutes.
- SECOND intervals are shifted by seconds.
The INTSHIFT function returns the shift interval:

```
interval = 'MONTH3.2';
shift_interval = INTSHIFT( interval );
```

In this example, the value of shift_interval is ‘MONTH’. For more information about the INTSHIFT function, see the SAS Language Reference: Dictionary.

If a subperiod is specified, the shift index cannot be greater than the number of subperiods in the whole interval. For example, you can use YEAR2.24, but YEAR2.25 is an error because there is no 25th month in a two-year interval.

For interval types that shift by subperiods that are the same as the basic interval type, only multiperiod intervals can be shifted. For example, MONTH type intervals shift by MONTH subintervals; thus, monthly intervals cannot be shifted because there is only one month in MONTH. However, bimonthly intervals can be shifted because there are two MONTH intervals in each MONTH2 interval. The interval name MONTH2.2 specifies bimonthly periods that start on the first day of even-numbered months.

### Beginning Dates and Datetimess of Intervals

Intervals that represent divisions of a year begin with the start of the year (1 January). YEARV, R445YR, R454YR, and R544YR intervals begin with the first week of the International Organization for Standardization (ISO) year, the Monday on or immediately preceding January 4th. R445QTR, R454QTR, and R544QTR intervals begin with the 1st, 14th, 27th, and 40th weeks of the ISO year. MONTH2 periods begin with odd-numbered months (January, March, May, and so on).

Likewise, intervals that represent divisions of a day begin with the start of the day (midnight). Thus, HOUR8.7 intervals divide the day into the periods 06:00 to 14:00, 14:00 to 22:00, and 22:00 to 06:00.

Intervals that do not nest within years or days begin relative to the SAS date or datetime value 0. The arbitrary reference time of midnight on January 1, 1960, is used as the origin for nonshifted intervals, and shifted intervals are defined relative to that reference point. For example, MONTH13 defines the intervals January 1, 1960, February 1, 1961, March 1, 1962, and so forth, and the intervals December 1, 1959, November 1, 1958, and so on before the base date January 1, 1960.

Similarly, the WEEK2 interval begins relative to the Sunday of the week of January 1, 1960. The interval specification WEEK6.13 defines six-week periods that start on second Fridays, and the convention of counting relative to the period that contains January 1, 1960, indicates the starting date or datetime of the interval closest to January 1, 1960, that corresponds to the second Fridays of six-week intervals.

Intervals always begin on the date or datetime defined by the base interval name, the multiplier, and the shift value. The end of the interval immediately precedes the beginning of the next interval. However, an interval can be identified by any date or datetime value between its starting and ending values, inclusive. See the section “Alignment of SAS Dates” on page 141 for more information about generating identifying dates for intervals.
Summary of Interval Types

The interval types are summarized as follows:

**YEAR**

specifies yearly intervals. Abbreviations are YEAR, YEARS, YEARLY, YR, ANNUAL, ANNUALLY, and ANNUALS. The starting subperiod is in months (MONTH).

**YEARV**

specifies ISO 8601 yearly intervals. The ISO 8601 year starts on the Monday on or immediately preceding January 4th. Note that it is possible for the ISO 8601 year to start in December of the preceding year. Also, some ISO 8601 years contain a leap week. For further discussion of ISO weeks, see Technical Committee ISO/TC 154 (Processes, Data Elements, and Documents in Commerce, Industry, and Administration) (2004). The starting subperiod is in ISO 8601 weeks (WEEKV).

R445YR

is the same as YEARV except that the starting subperiod is in retail 4-4-5 months (R445MON).

R454YR

is the same as YEARV except that the starting subperiod is in retail 4-5-4 months (R454MON). For a discussion of the retail 4-5-4 calendar, see National Retail Federation (2007).

R544YR

is the same as YEARV except that the starting subperiod is in retail 5-4-4 months (R544MON).

**SEMIYEAR**

specifies semiannual intervals (every six months). Abbreviations are SEMIYEAR, SEMIYEARS, SEMIYEARLY, SEMIYR, SEMIANNUAL, and SEMIANN.

The starting subperiod is in months (MONTH). For example, SEMIYEAR.3 intervals are March–August and September–February.

**QTR**

specifies quarterly intervals (every three months). Abbreviations are QTR, QUARTER, QUARTERS, QUARTERLY, QTRLY, and QTRS. The starting subperiod is in months (MONTH).

R445QTR

specifies retail 4-4-5 quarterly intervals (every 13 ISO 8601 weeks). Some fourth quarters contain a leap week. The starting subperiod is in retail 4-4-5 months (R445MON).

R454QTR

specifies retail 4-5-4 quarterly intervals (every 13 ISO 8601 weeks). Some fourth quarters contain a leap week. For a discussion of the retail 4-5-4 calendar, see National Retail Federation (2007). The starting subperiod is in retail 4-5-4 months (R454MON).

R544QTR

specifies retail 5-4-4 quarterly intervals (every 13 ISO 8601 weeks). Some fourth quarters contain a leap week. The starting subperiod is in retail 5-4-4 months (R544MON).
MONTH specifies monthly intervals. Abbreviations are MONTH, MONTHS, MONTHLY, and MON. The starting subperiod $s$ is in months (MONTH). For example, MONTH2.2 intervals are February–March, April–May, June–July, August–September, October–November, and December–January of the following year.

R445MON specifies retail 4-4-5 monthly intervals. The 3rd, 6th, 9th, and 12th months are five ISO 8601 weeks long with the exception that some 12th months contain leap weeks. All other months are four ISO 8601 weeks long. R445MON intervals begin with the 1st, 5th, 9th, 14th, 18th, 22nd, 27th, 31st, 35th, 40th, 44th, and 48th weeks of the ISO year. The starting subperiod $s$ is in retail 4-4-5 months (R445MON).

R454MON specifies retail 4-5-4 monthly intervals. The 2nd, 5th, 8th, and 11th months are five ISO 8601 weeks long. All other months are four ISO 8601 weeks long with the exception that some 12th months contain leap weeks. R454MON intervals begin with the 1st, 5th, 10th, 14th, 18th, 23rd, 27th, 31st, 36th, 40th, 44th, and 49th weeks of the ISO year. For a discussion of the retail 4-5-4 calendar, see National Retail Federation (2007). The starting subperiod $s$ is in retail 4-5-4 months (R454MON).

R544MON specifies retail 5-4-4 monthly intervals. The 1st, 4th, 7th, and 10th months are five ISO 8601 weeks long. All other months are four ISO 8601 weeks long with the exception that some 12th months contain leap weeks. R544MON intervals begin with the 1st, 6th, 10th, 14th, 19th, 23rd, 27th, 32nd, 36th, 40th, 45th, and 49th weeks of the ISO year. The starting subperiod $s$ is in retail 5-4-4 months (R544MON).

SEMIMONTH specifies semimonthly intervals. SEMIMONTH breaks each month into two periods, starting on the 1st and 16th days. Abbreviations are SEMIMONTH, SEMIMONTHS, SEMIMONTHLY, and SEMIMON. The starting subperiod $s$ is in SEMIMONTH periods. For example, SEMIMONTH2.2 specifies intervals from the 16th of one month through the 15th of the next month.

TENDAY specifies 10-day intervals. TENDAY breaks the month into three periods, the 1st through the 10th day of the month, the 11th through the 20th day of the month, and the remainder of the month. (TENDAY is a special interval typically used for reporting automobile sales data.) The starting subperiod $s$ is in TENDAY periods. For example, TENDAY4.2 defines 40-day periods that start at the second TENDAY period.

WEEK specifies weekly intervals of seven days. Abbreviations are WEEK, WEEKS, and WEEKLY. The starting subperiod $s$ is in days (DAY), with the days of the week numbered as 1=Sunday, 2=Monday, 3=Tuesday, 4=Wednesday, 5=Thursday, 6=Friday, and 7=Saturday. For example, WEEK.7 means weekly with Saturday as the first day of the week.
WEEKV

specifies ISO 8601 weekly intervals of seven days. Each week starts on Monday. The starting subperiod \( s \) is in days (DAY). Note that WEEKV differs from WEEK in that WEEKV.1 starts on Monday, WEEKV.2 starts on Tuesday, and so forth.

WEEKDAY
WEEKDAY\( dW \)
WEEKDAY\( ddW \)
WEEKDAY\( dddW \)

specifies daily intervals with weekend days included in the preceding weekday. Note that for a five-day work week that starts on Monday, the appropriate interval is WEEKDAY5.2. Abbreviations are WEEKDAY and WEEKDAYS. The starting subperiod \( s \) is in weekdays (WEEKDAY).

The WEEKDAY interval is the same as DAY except that weekend days are absorbed into the preceding weekday. Thus, there are five WEEKDAY intervals in a calendar week: Monday, Tuesday, Wednesday, Thursday, and the three-day period Friday-Saturday-Sunday.

The default weekend days are Saturday and Sunday, but any one to six weekend days can be listed after the WEEKDAY string and followed by a W. Weekend days are specified as ‘1’ for Sunday, ‘2’ for Monday, and so forth. For example, WEEKDAY67W specifies a Friday-Saturday weekend. WEEKDAY1W specifies a six-day work week with a Sunday weekend. WEEKDAY17W is the same as WEEKDAY.

DAY

specifies daily intervals. Abbreviations are DAY, DAYS, and DAILY. The starting subperiod \( s \) is in days (DAY).

HOUR

specifies hourly intervals. Aliases are HOUR, DTHOUR, HOURS, DTHOURS, HOURLY, DTHOURLY, HR, and DTHR. The starting subperiod \( s \) is in hours (HOUR).

MINUTE

specifies minute intervals. Aliases are MINUTE, DTMINUTE, MINUTES, DTMINUTES, MIN, and DTMIN. The starting subperiod \( s \) is in minutes (MINUTE).

SECOND

specifies second intervals. Aliases are SECOND, DTSECOND, SECONDS, DTSECONDS, SEC and DTSEC. The starting subperiod \( s \) is in seconds (SECOND).
Examples of Interval Specifications

Table 4.1 shows examples of different kinds of interval specifications.

</tbody>
</table>
Custom Time Intervals

The standard time intervals described in the previous sections do not always fit the data. For example, you might want to use fiscal months that begin on the 10th of each month, but the MONTH interval begins on the 1st of each month. Or you might collect data hourly for a business that is closed at night, but using the DTHOUR interval results in gaps in the data that can cause problems in standard time series analysis. In another case, you might wish to calculate the number of business days between dates, excluding holidays and weekends, but holidays are counted when you use the INTCK function with the WEEKDAY interval. For more information about the INTCK function, see “Interval Functions INTNX and INTCK” on page 92.

Time series can be analyzed using observation numbers as the identifying reference. However, it is often desirable to maintain the time stamp for other types of modeling such as regression variables based on time or reconciliation.

To address these issues, you can define custom intervals within a given SAS program. The use of custom intervals requires the following two steps for each interval:

1. Associate a data set name with a custom interval name by using the INTERVALDS= system option. For more information about the INTERVALDS= option, see the SAS Language Reference: Dictionary. The following example associates the data set StoreHoursDS with the custom interval StoreHours.

   ```sas
   options intervalds=(StoreHours=StoreHoursDS);
   ```

2. Create a data set that describes the custom interval. The data set must contain a BEGIN variable. It can also contain an END and a SEASON variable. It should contain a FORMAT statement for the BEGIN variable that specifies a SAS date, SAS datetime, or numeric format that matches the BEGIN variable data. If the END variable is present, it should also be included in the FORMAT statement. A numeric format that is not a SAS date or SAS datetime format indicates that the values are observation numbers. If the END variable is not present, then the implied value of END at each observation is one less than the value of BEGIN at the next observation.

   The span of the custom interval data set should include any dates or times that are necessary for performing calculations on the time series, including backcasting, forecasting, and other operations that might extend beyond the series (such as filters).

   ```sas
   options intervalds=(StoreHours=StoreHoursDS);
   ```

After the two preceding steps have been completed, the custom interval can be specified in SAS procedures and functions where a standard time interval can be specified.
The following DATA step creates the StoreHoursDS data set, which is appropriate for a business that is open 9AM to 6PM Monday through Friday and Saturday 9AM to 1PM:

``` Sas
options intervalds=(StoreHours=StoreHoursDS);
data StoreHoursDS(keep=BEGIN END);
  start = '01JAN2009'D;
  stop = '31DEC2009'D;
  do date = start to stop;
    dow = WEEKDAY(date);

</table>
The following DATA step creates the FMDS data set to define a custom interval FiscalMonth, which is appropriate for a business that uses fiscal months that start on the 10th of each month. The SAME alignment option of the INTNX function specifies that the dates generated by the INTNX function are the same day of the month as the date in the start variable. For more information about the INTNX function, see “SAS Date, Time, and Datetime Functions” on page 141. The MONTH function assigns the month of the BEGIN variable to the SEASON variable. This specifies monthly seasonality.

```sas
options intervalds=(FiscalMonth=FMDS);
data FMDS(keep=BEGIN SEASON);
  start = '10JAN1999'D;
  stop = '10JAN2001'D;
  nmonths = INTCK('MONTH',start,stop);
  do i=0 to nmonths;
    BEGIN = INTNX('MONTH',start,i,'S');
    SEASON = MONTH(BEGIN);
    output;
  end;
  format BEGIN DATE.;
run;
```

The difference between the custom FiscalMonth interval and a standard interval can be seen in the following example. The output shown in Figure 4.2 compares how the data are accumulated. For the FiscalMonth interval, values in the first nine days of the month are accumulated with the interval that begins in the previous month. For the standard MONTH interval, values in the first nine days of the month are accumulated with the calendar month.

```sas
data sales(keep=DATE sales);
do date = '01JAN2000'D to '31DEC2000'D;
  month = MONTH(date);
  dayofmonth = DAY(date);
  sales = 0;
  if ( dayofmonth lt 10 ) then sales = month/9;
  output;
end;
  format date monyy.;
run;
```

```sas
proc timeseries data=sales out=dataInFiscalMonths;
  id DATE interval=FiscalMonth accumulate=total;
  var sales;
run;
```

```sas
proc timeseries data=sales out=dataInStdMonths;
  id DATE interval=Month accumulate=total;
  var sales;
run;
```

```sas
data compare;
  merge dataInFiscalMonths(rename=(sales=FM_sales))
    dataInStdMonths(rename=(sales=SM_sales));
  by DATE;
run;
```
title 'Standard Monthly Data vs. Fiscal Month Data';
proc print data=compare;
run;

The next example uses custom intervals in the time function INTCK to omit holidays when counting business days. The result is shown in Figure 4.3.

```sas
options intervals=(BankingDays=BankDayDS);
data BankDayDS(keep=BEGIN);
  start = '15DEC1998'D;
  stop = '15JAN2002'D;
  nwkdays = INTCK('WEEKDAY',start,stop);
do i = 0 to nwkdays;
  BEGIN = INTNX('WEEKDAY',start,i);
  year = YEAR(BEGIN);
  if BEGIN ne HOLIDAY("NEWYEAR",year) and
     BEGIN ne HOLIDAY("MLK",year) and
     BEGIN ne HOLIDAY("USPRESIDENTS",year) and
     BEGIN ne HOLIDAY("MEMORIAL",year) and
     BEGIN ne HOLIDAY("USINDEPENDENCE",year) and
     BEGIN ne HOLIDAY("LABOR",year) and
     BEGIN ne HOLIDAY("COLUMBUS",year) and
     BEGIN ne HOLIDAY("VETERANS",year) and
     BEGIN ne HOLIDAY("THANKSGIVING",year) and
     BEGIN ne HOLIDAY("CHRISTMAS",year) then
    output;
  end;
format BEGIN DATE.;
run;

data CountDays;
  start = '01JAN1999'D;
  stop = '31DEC2001'D;
  ActualDays = INTCK('DAYS',start,stop);
  Weekdays = INTCK('WEEKDAYS',start,stop);
  BankDays = INTCK('BankingDays',start,stop);
format start stop DATE.;
run;
title 'Methods of Counting Days';
proc print data=CountDays;
run;

Date and Datetime Informats

Table 4.2 lists some of the SAS date and datetime informats available to read date, time, and datetime values. See Chapter 3, “Working with Time Series Data,” for a discussion of the use of date and datetime informats. See SAS Language Reference: Concepts for a complete description of these informats.

For each informat, Table 4.2 shows an example of a date or datetime value written in the style that the informat is designed to read. You can specify the width of each informat by adding \( w \). For informats that include second values, you can specify the number of decimal digits for seconds by adding \( d \). Table 4.2 shows the width range allowed by the informat and the default width. The date 17 October 1991 and the time 2:25:32 p.m. are used for the example in all cases.

<table>
<thead>
<tr>

<td>Day, month, year: ( ddmmyy, dd/mm/yyyy, dd-mm-yy, or dd mm yy )</td>
<td>6–32</td>
<td>6</td>
</tr>
</tbody>
</table>
Some of the commonly used SAS date and datetime formats are listed in Table 4.3 and Table 4.4. You can specify the width value for each format by adding w. The tables list the range of width values allowed and the default width value for each format.

The notation used by a format is abbreviated in different ways depending on the width option used. For example, the format MMDDYY8. writes the date 17 October 1991 as 10/17/91, while the format MMDDYY6. writes this date as 101791. In particular, formats that display the year show two-digit or four-digit year values depending on the width option. The examples shown in the tables use the default width.

The interval function INTFMT returns a recommended format for time ID values based on the interval that describes the frequency of the values. The following example uses INTFMT to select a format to display the quarterly time ID variable qtrDate. In this example, INTFMT returns the format YYQC6., which displays the year in four digits and the quarter in a single digit. This selected format is stored in a macro variable that is created by the CALL SYMPUT statement. The second argument to INTFMT controls the width of the year for date formats; it can take the value ‘long’ or ‘l’ to indicate 4 for the year width or the value ‘short’ or ‘s’ to indicate 2 for the year width. For more information about the INTFMT function, see the SAS Language
Reference: Dictionary. For more information about the CALL SYMPUT statement, see the SAS Language Reference: Dictionary.

The macro variable &FMT is then used in the FORMAT statement in the PROC PRINT step as follows:

```sas
data b(keep=qtrDate);
  interval = 'QTR';
  form = INTFMT( interval, 'long' );
  call symput('fmt',form);
  do i=1 to 4;
    qtrDate = INTNX( interval, '01jan00'd, i-1 );
    output;
  end;
run;
```

```sas
proc print;
  format qtrDate &fmt;
run;
```

It is also possible to display date and datetime values as strings by using the format that is identified by INTFMT. In the following example, INTFIT is used to identify the intervals of the sashelp.citiwk and sashelp.air data sets. Then INTFMT is used to identify formats that are based on the intervals. The formats are then used to convert the first SAS date value of each data set to a string. The START variable displays the date of the first observation of each data set. This method assumes that the interval of the data set can be identified by examining the first two observations. This is often the case for output data sets and data sets that have been properly prepared for input by using a procedure such as the TIMESERIES procedure. More than two observations might be required to identify the difference between a DAY interval and a WEEKDAY interval. This example would need to be modified if the DATE variable contained SAS datetime values.

```sas
data a(keep=DATE0 DATE INTERVAL FMT START);
  length START INTERVAL FMT $32;
  format date0 date DATE.;
  set sashelp.citiwk(obs=2) sashelp.air(obs=2);
  DATE0 = lag(date);
  if ( mod(_n_,2) eq 1 ) then delete;
  if ( mod(_n_,2) eq 0 ) then INTERVAL = intfit( DATE0, date, 'D' );
  if ( mod(_n_,2) eq 0 ) then FMT = INTFMT( interval, 'l' );
  START = putn( DATE0, FMT );
run;
```

```sas
proc print;
run;
```

Table 4.3 lists some of the available SAS date formats. For each format, an example is shown of a date value in the notation produced by the format. The date ‘17OCT91’D is used as the example.

Datetime and Time Formats

Table 4.4 lists some of the available SAS datetime and time formats. For each format, the example shows the formatted value. The value of the variable dt is ‘17OCT91:14:25:32’ DT. You can specify the width of each format by adding w. For formats that allow a decimal value, you can specify the number of decimal digits by adding d.

Alignment of SAS Dates

SAS date values that are used to identify time series observations produced by SAS/ETS and SAS High-Performance Forecasting procedures are normally aligned with the beginning of the time intervals that correspond to the observations. For example, for monthly data for 1994, the date values that identify the observations are 1Jan94, 1Feb94, 1Mar94, . . . , 1Dec94.

However, for some applications it might be preferable to use end-of-period dates, such as 31Jan94, 28Feb94, 31Mar94, . . . , 31Dec94. For other applications, such as plotting time series, it might be more convenient to use interval midpoint dates to identify the observations.

Many SAS/ETS and SAS High-Performance Forecasting procedures provide an ALIGN= option to control the alignment of dates for outputting time series observations. SAS/ETS procedures that support the ALIGN= option are ARIMA, DATASOURCE, ESM, EXPAND, FORECAST, SIMILARITY, TIMESERIES, UCM, and VARMAX. SAS High-Performance Forecasting procedures that support the ALIGN= option are HPFRECONCILE, HPF, HPFDIAGNOSE, HPFENGINE, and HPFEVENTS.

ALIGN=
The ALIGN= option can have the following values:

BEGINNING specifies that dates be aligned to the start of the interval. This is the default. BEGINNING can be abbreviated as BEGIN, BEG, or B.

MIDDLE specifies that dates be aligned to the interval midpoint, the average of the beginning and ending values. MIDDLE can be abbreviated as MID or M.

ENDING specifies that dates be aligned to the end of the interval. ENDING can be abbreviated as END or E.

For information about the calculation of the beginning and ending values of intervals, see the section “Beginning Dates and Datetimes of Intervals” on page 124.

SAS Date, Time, and Datetime Functions

SAS date, time, and datetime functions are used to perform the following tasks:

• compute date, time, and datetime values from calendar and time-of-day values
• compute calendar and time-of-day values from date and datetime values
• convert between date, time, and datetime values
• perform calculations that involve time intervals
• provide information about time intervals
• provide information about seasonality
For all interval functions, you can supply the intervals and other character arguments either directly as a quoted string or as a SAS character variable. When you use a character variable, you should set the length of the character variable to at least the length of the longest string for that variable that is used in the DATA step.

Also, to ensure correct results when using interval functions, use date intervals with date values and datetime intervals with datetime values.

See SAS Language Reference: Dictionary for a complete description of these functions.

The following list shows SAS date, time, and datetime functions in alphabetical order.

**DATE()**

returns today’s date as a SAS date value.

**DATEJUL( yyddd )**

returns the SAS date value when given the Julian date in yyddd or yyyyddd format. For example, `DATE = DATEJUL(99001)`; assigns the SAS date value ‘01JAN99’D to DATE, and `DATE = DATEJUL(1999365)`; assigns the SAS date value ‘31DEC1999’D to DATE.

**DATEPART( datetime )**

returns the date part of a SAS datetime value as a date value.

**DATETIME()**

returns the current date and time of day as a SAS datetime value.

**DAY( date )**

returns the day of the month from a SAS date value.

**DHMS( date, hour, minute, second )**

returns a SAS datetime value for date, hour, minute, and second values.

**HMS( hour, minute, second )**

returns a SAS time value for hour, minute, and second values.

**HOLIDAY( 'holiday', year )**

**HOUR( datetime )**

returns the hour from a SAS datetime or time value.

**INTCINDEX( 'date-interval', date )**

returns the index of the seasonal cycle when given an interval and an appropriate SAS date, dateint, or time value. For example, the seasonal cycle for INTERVAL='DAY' is 'WEEK', so `INTCINDEX('DAY', '01SEP78'D)`; returns 35 because September 1, 1978, is the sixth day of the 35th week of the year. For correct results, date intervals should be used with date values, and datetime intervals should be used with datetime values.
INTCK(‘date-interval’, date1, date2<,’method’>)

INTCK(‘datetime-interval’, datetime1, datetime2<,’method’>)

returns the number of boundaries of intervals of the given kind that lie between the two date or datetime values. The optional method argument specifies that the intervals are counted using either a discrete or a continuous method. The default DISCRETE (or DISC or D) method uses discrete time intervals. For the DISCRETE method, the distance in MONTHS between January 31, 2000, and February 1, 2000, is one month. The CONTINUOUS (or CONT or C) method uses continuous time intervals. For the CONTINUOUS method, the distance in MONTHS between January 15, 2000, and February 14, 2000, is zero, but the distance in MONTHS between January 15, 2000, and February 15, 2000, is one month.

INTCYCLE(‘interval’<,’seasonality’)>

returns the interval of the seasonal cycle, given a date, time, or datetime interval. For example, INTCYCLE(‘MONTH’) returns ‘YEAR’ because the months January, February, . . . , December constitute a yearly cycle. INTCYCLE(‘DAY’) returns ‘WEEK’ because Sunday, Monday, . . . , Saturday constitute a weekly cycle.

You can specify the optional seasonality argument to construct a cycle other than the default seasonal cycle. For example, INTCYCLE(‘MONTH’, 3) returns ‘QTR’. The optional second argument is the seasonal frequency.

INTFIT( date1, date2, ‘D’ )

INTFIT( datetime1, datetime2, ‘DT’ )

INTFIT( obs1, obs2, ‘OBS’ )

returns an interval that fits exactly between two SAS date, datetime, or observation values. That is, if the interval result of the INTFIT function is used with date1, 1, and SAMEDAY alignment in the INTNX function, then the result is date2. This concept is illustrated in the following example, where result1 is the same as date1 and result2 is the same as date2.

```
FitInterval = INTFIT( date1, date2, 'D' );
result1 = INTNX( FitInterval, date1, 0, 'SAMEDAY');
result2 = INTNX( FitInterval, date1, 1, 'SAMEDAY');
```

More than one interval can fit the preceding definition. For example, two SAS date values that are seven days apart could be fit with either ‘DAY7’ or ‘WEEK’. The INTFIT function chooses the more common interval, so ‘WEEK’ is the result when the dates are seven days apart. The INTFIT function can be used to detect the possible frequency of the time series or to analyze frequencies of other events in a time series, such as outliers or missing values.

INTFMT(‘interval’, ‘size’)

returns a recommended format when given a date, time, or datetime interval for displaying the time ID values associated with a time series of the given interval. The second argument to INTFMT controls the width of the year for date formats; it can take the value ‘long’ or ‘l’ to specify that the returned format display a four-digit year or the value ‘short’ or ‘s’ to specify that the returned format display a two-digit year.
INTGET( date1, date2, date3 )

INTGET( datetime1, datetime2, datetime3 )

returns an interval that fits three consecutive SAS date or datetime values. The INTGET function examines two intervals: the first interval between date1 and date2, and the second interval between date2 and date3. In order for an interval to be detected, either the two intervals must be the same or one interval must be an integer multiple of the other interval. That is, INTGET assumes that at least two of the dates are consecutive points in the time series, and that the other two dates are also consecutive or represent the points before and after missing observations. The INTGET function assumes that large values are SAS datetime values, which are measured in seconds, and that smaller values are SAS date values, which are measured in days. The INTGET function can be used to detect the possible frequency of the time series or to analyze frequencies of other events in a time series, such as outliers or missing values.

INTINDEX( 'date-interval', date <, seasonality > )

INTINDEX( 'datetime-interval', datetime <, seasonality > )

returns the seasonal index for the specified date or datetime interval and an appropriate date or datetime value. The seasonal index is a number that represents the position of the date or datetime value in the seasonal cycle of the specified interval. For example, INTINDEX( 'MONTH', '01DEC2000'D ); returns 12 because monthly data is yearly periodic and DECEMBER is the 12th month of the year. However, INTINDEX( 'DAY', '01DEC2000'D ); returns 6 because daily data is weekly periodic and December 01, 2000, is a Friday, the sixth day of the week. To correctly identify the seasonal index, the interval specification should agree with the date or datetime value. For example, INTINDEX( 'DMONTH', '01DEC2000'D ); and INTINDEX( 'MONTH', '01DEC2000:00:00:00'DT ); do not return the expected value of 12. However, both INTINDEX( 'MONTH', '01DEC2000'D ); and INTINDEX( 'DMONTH', '01DEC2000:00:00:00'DT ); return the expected value of 12.

You can specify the optional seasonality argument to use a seasonal cycle other than the default seasonal cycle. For example, INTINDEX( 'MONTH', '01APR2000'D ); returns the value 4, to indicate the fourth month of the year. However, INTINDEX( 'DAY', '01APR2000'D ); returns 6 because daily data is yearly periodic and April 01, 2000, is another Friday, the sixth day of the month. To correctly identify the seasonal index, the interval specification should agree with the date or datetime value. For example, INTINDEX( 'DMONTH', '01APR2000'D ); and INTINDEX( 'MONTH', '01APR2000:00:00:00'DT ); do not return the expected value of 12. However, both INTINDEX( 'MONTH', '01APR2000'D ); and INTINDEX( 'DMONTH', '01APR2000:00:00:00'DT ); return the expected value of 12.

INTNX( 'date-interval', date, n <, 'alignment' > )

INTNX( 'datetime-interval', datetime, n <, 'alignment' > )

returns the date or datetime value of the beginning of the interval that is n intervals from the interval that contains the given date or datetime value. The optional alignment argument specifies that the returned date is aligned to the beginning, middle, or end of the interval. Beginning is the default. In addition, you can specify SAME (S) alignment. The SAME alignment bases the alignment of the calculated date or datetime value on the alignment of the input date or datetime value. As illustrated in the following example, the SAME alignment can be used to calculate the meaning of “same day next year” or “same day two weeks from now.”

nextYear = INTNX( 'YEAR', '15Apr2007'D, 1, 'S' );
TwoWeeks = INTNX( 'WEEK', '15Apr2007'D, 2, 'S' );

The preceding example returns ‘15Apr2008’D for nextYear and ‘29Apr2007’D for TwoWeeks.

For all values of alignment, the number of discrete intervals n between the input date and the resulting date agrees with the input value. In the following example, the result is always that n2 = n1:
date2 = INTNX( interval, date1, n1, align );
n2 = INTCK( interval, date1, date2 );

The preceding example uses the DISCRETE method of the INTCK function by default. The result n2 = n1 does not always apply when the CONTINUOUS method of the INTCK function is specified.

INTSEAS( ‘interval’ < , seasonality > )
returns the length of the seasonal cycle for the specified date or datetime interval. The length of a seasonal cycle is the number of intervals in a seasonal cycle. For example, when the interval for a time series is described as monthly, many procedures use the option INTERVAL=MONTH to indicate that each observation in the data corresponds to a particular month. Monthly data are considered to be periodic for a one-year seasonal cycle. There are 12 months in one year, so the number of intervals (months) in a seasonal cycle (year) is 12. For quarterly data, there are 4 quarters in one year, so the number of intervals in a seasonal cycle is 4. The periodicity is not always one year. For example, INTERVAL=DAY is considered to have a seasonal cycle of one week, and because there are 7 days in a week, the number of intervals in a seasonal cycle is 7.

You can specify the optional seasonality argument to use a seasonal cycle other than the default seasonal cycle. For example, INTSEAS(‘MONTH’, 3) and INTSEAS(‘MONTH’, ‘QTR’) both specify a quarterly seasonal cycle and return the value 3. If the optional seasonality argument is numeric, it is the seasonal frequency. If the optional seasonality argument is character, it is the seasonal cycle.

INTSHIFT( ‘interval’ )
returns the shift interval that applies to the shift index if a subperiod is specified. For example, YEAR intervals are shifted by MONTH, so INTSHIFT(‘YEAR’) returns ‘MONTH’.

INTTEST( ‘interval’ )
returns 1 if the interval name is valid, 0 otherwise. For example, VALID = INTTEST(‘MONTH’); should set VALID to 1, while VALID = INTTEST(‘NOTANINTERVAL’); should set VALID to 0. The INTTEST function can be useful in verifying which values of multiplier n and the shift index s are valid in constructing an interval name.

JULDATE( date )
returns the Julian date from a SAS date value. The format of the Julian date is either yyddd or yyyyddd depending on the value of the system option YEARCUTOFF=. For example, using the default system option values, JULDATE( ‘31DEC1999’D ); returns 99365, while JULDATE( ‘31DEC1899’D ); returns 1899365.

MDY( month, day, year )
returns a SAS date value for month, day, and year values.

MINUTE( datetime )
returns the minute from a SAS time or datetime value.

MONTH( date )
returns the numerical value for the month of the year from a SAS date value. For example, MONTH=MONTH(‘01JAN2000’D); returns 1, the numerical value for January.
NWKDOM( n, weekday, month, year )
returns a SAS date value for the nth weekday of the month and year specified. For example, Thanksgiving is always the fourth (n=4) Thursday (weekday=5) in November (month=11). Thus THANKS2000 = NWKDOM( 4, 5, 11, 2000 ); returns the SAS date value for Thanksgiving in the year 2000. The last weekday of a month can be specified by using n=5. Memorial Day in the United States is the last (n=5) Monday (weekday=2) in May (month=5), and so MEMORIAL2002 = NWKDOM( 5, 2, 5, 2002 ); returns the SAS date value for Memorial Day in 2002. Because n = 5 always specifies the last occurrence of the month and most months have only 4 instances of each day, the result for n = 5 is often the same as the result for n = 4. NWKDOM is useful for calculating the SAS date values of holidays that are defined in this manner.

QTR( date )
returns the quarter of the year from a SAS date value.

SECOND( date )
returns the second from a SAS time or datetime value.

TIME()
returns the current time of day.

TIMEPART( datetime )
returns the time part of a SAS datetime value.

TODAY()
returns the current date as a SAS date value. (TODAY is another name for the DATE function.)

WEEK( date <, 'descriptor'> )
returns the week of year from a SAS date value. The algorithm used to calculate the week depends on the descriptor, which can take the value ‘U’, ‘V’, or ‘W’.
If the descriptor is ‘U,’ weeks start on Sunday and the range is 0 to 53. If weeks 0 and 53 exist, they are only partial weeks. Week 52 can be a partial week.
If the descriptor is ‘V’, the result is equivalent to the ISO 8601 week of year definition. The range is 1 to 53. Week 53 is a leap week. The first week of the year, Week 1, and the last week of the year, Week 52 or 53, can include days in another Gregorian calendar year.
If the descriptor is ‘W’, weeks start on Monday and the range is 0 to 53. If weeks 0 and 53 exist, they are only partial weeks. Week 52 can be a partial week.

WEEKDAY( date )
returns the day of the week from a SAS date value. For example WEEKDAY=WEEKDAY(’17OCT1991’D); returns 5, the numerical value for Thursday.

YEAR( date )
returns the year from a SAS date value.

YYQ( year, quarter )
returns a SAS date value for year and quarter values.

SAS Macros

This chapter describes several SAS macros and the SAS function PROBDF that are provided with SAS/ETS software. A SAS macro is a program that generates SAS statements. Macros make it easy to produce and execute complex SAS programs that would be time-consuming to write yourself.

SAS/ETS software includes the following macros:

- %AR generates statements to define autoregressive error models for the MODEL procedure.
- %BOXCOXAR investigates Box-Cox transformations useful for modeling and forecasting a time series.
- %DFPVALUE computes probabilities for Dickey-Fuller test statistics.
- %DFTEST performs Dickey-Fuller tests for unit roots in a time series process.
- %LOGTEST tests to see if a log transformation is appropriate for modeling and forecasting a time series.
- %MA generates statements to define moving-average error models for the MODEL procedure.
- %PDL generates statements to define polynomial-distributed lag models for the MODEL procedure.

These macros are part of the SAS AUTOCALL facility and are automatically available for use in your SAS program. See SAS Macro Language: Reference for information about the SAS macro facility.

Since the %AR, %MA, and %PDL macros are used only with PROC MODEL, they are documented with the MODEL procedure. See the sections on the %AR, %MA, and %PDL macros in Chapter 19, “The MODEL Procedure,” for more information about these macros. The %BOXCOXAR, %DFPVALUE, %DFTEST, and %LOGTEST macros are described in the following sections.
The %BOXCOXAR macro finds the optimal Box-Cox transformation for a time series.

Transformations of the dependent variable are a useful way of dealing with nonlinear relationships or heteroscedasticity. For example, the logarithmic transformation is often used for modeling and forecasting time series that show exponential growth or that show variability proportional to the level of the series.

The Box-Cox transformation is a general class of power transformations that include the log transformation and no transformation as special cases. The Box-Cox transformation is

\[
Y_t = \begin{cases} 
(X_t + c)^{\lambda} - 1 & \text{for } \lambda \neq 0 \\
\ln(X_t + c) & \text{for } \lambda = 0 
\end{cases}
\]

The parameter \(\lambda\) controls the shape of the transformation. For example, \(\lambda=0\) produces a log transformation, while \(\lambda=0.5\) results in a square root transformation. When \(\lambda=1\), the transformed series differs from the original series by \(c - 1\).

The constant \(c\) is optional. It can be used when some \(X_t\) values are negative or 0. You choose \(c\) so that the series \(X_t\) is always greater than \(-c\).

The %BOXCOXAR macro tries a range of \(\lambda\) values and reports which of the values tried produces the optimal Box-Cox transformation. To evaluate different \(\lambda\) values, the %BOXCOXAR macro transforms the series with each \(\lambda\) value and fits an autoregressive model to the transformed series. It is assumed that this autoregressive model is a reasonably good approximation to the true time series model appropriate for the transformed series. The likelihood of the data under each autoregressive model is computed, and the \(\lambda\) value that produces the maximum likelihood over the values tried is reported as the optimal Box-Cox transformation for the series.

The %BOXCOXAR macro prints and optionally writes to a SAS data set all of the \(\lambda\) values tried, the corresponding log-likelihood value, and related statistics for the autoregressive model.

You can control the range and number of \(\lambda\) values tried. You can also control the order of the autoregressive models fit to the transformed series. You can difference the transformed series before the autoregressive model is fit.

Note that the Box-Cox transformation might be appropriate when the data have a common distribution (apart from heteroscedasticity) but not when groups of observations for the variable are quite different. Thus the %BOXCOXAR macro is more often appropriate for time series data than for cross-sectional data.

**Syntax**

The form of the %BOXCOXAR macro is

```sas
%BOXCOXAR ( SAS-data-set, variable < , options > ) ;
```

The first argument, *SAS-data-set*, specifies the name of the SAS data set that contains the time series to be analyzed. The second argument, *variable*, specifies the time series variable name to be analyzed. The first two arguments are required.

The following options can be used with the %BOXCOXAR macro. Options must follow the required arguments and are separated by commas.
AR=n

specifies the order of the autoregressive model fit to the transformed series. The default is AR=5.

CONST=value

specifies a constant $c$ to be added to the series before transformation. Use the CONST= option when some values of the series are 0 or negative. The default is CONST=0.

DIF=( differencing-list )

specifies the degrees of differencing to apply to the transformed series before the autoregressive model is fit. The differencing-list is a list of positive integers separated by commas and enclosed in parentheses. For example, DIF=(1,12) specifies that the transformed series be differenced once at lag 1 and once at lag 12. For more details, see the section “IDENTIFY Statement” on page 224 in Chapter 7, “The ARIMA Procedure.”

LAMBDALO=value

specifies the minimum value of lambda for the grid search. The default is LAMBDALO=0. A large (in magnitude) LAMBDALO= value can result in problems with floating point arithmetic.

NLAMBS=value

specifies the maximum value of lambda for the grid search. The default is LAMBDALO=1. A large (in magnitude) LAMBDAH= value can result in problems with floating point arithmetic.

NLAMBDA=value

specifies the number of lambda values considered, including the LAMBDALO= and LAMBDAH= option values. The default is NLAMBDA=2.

OUT=SAS-data-set

writes the results to an output data set. The output data set includes the lambda values tried (LAMBDA), and for each lambda value, the log likelihood (LOGLIK), residual mean squared error (RMSE), Akaike Information Criterion (AIC), and Schwarz’s Bayesian Criterion (SBC).

PRINT=YES | NO

specifies whether results are printed. The default is PRINT=YES. The printed output contains the lambda values, log likelihoods, residual mean square errors, Akaike Information Criterion (AIC), and Schwarz’s Bayesian Criterion (SBC).

Results

The value of $\lambda$ that produces the maximum log likelihood is returned in the macro variable &BOXCOXAR. The value of the variable &BOXCOXAR is “ERROR” if the %BOXCOXAR macro is unable to compute the best transformation due to errors. This might be the result of large lambda values. The Box-Cox transformation parameter involves exponentiation of the data, so that large lambda values can cause floating-point overflow.

Results are printed unless the PRINT=NO option is specified. Results are also stored in SAS data sets when the OUT= option is specified.

Details

Assume that the transformed series $Y_t$ is a stationary $p$th order autoregressive process generated by independent normally distributed innovations.

\[
(1 - \Theta(B))(Y_t - \mu) = \epsilon_t
\]
\[ \epsilon_t \sim \text{iid } N(0, \sigma^2) \]

Given these assumptions, the log-likelihood function of the transformed data \( Y_t \) is

\[
l_Y(\cdot) = - \frac{n}{2} \ln(2\pi) - \frac{1}{2} \ln(|\Sigma|) - \frac{n}{2} \ln(\sigma^2) - \frac{1}{2\sigma^2} (Y - 1\mu)'\Sigma^{-1}(Y - 1\mu)
\]

In this equation, \( n \) is the number of observations, \( \mu \) is the mean of \( Y_t \), \( 1 \) is the \( n \)-dimensional column vector of 1s, \( \sigma^2 \) is the innovation variance, \( Y = (Y_1, \ldots, Y_n)' \), and \( \Sigma \) is the covariance matrix of \( Y \).

The log-likelihood function of the original data \( X_1, \ldots, X_n \) is

\[
l_X(\cdot) = l_Y(\cdot) + (\lambda - 1) \sum_{t=1}^{n} \ln(X_t + c)
\]

where \( c \) is the value of the \text{CONST=} option.

For each value of \( \lambda \), the maximum log-likelihood of the original data is obtained from the maximum log-likelihood of the transformed data given the maximum likelihood estimate of the autoregressive model.

The maximum log-likelihood values are used to compute the Akaike Information Criterion (AIC) and Schwarz’s Bayesian Criterion (SBC) for each \( \lambda \) value. The residual mean squared error based on the maximum likelihood estimator is also produced. To compute the mean squared error, the predicted values from the model are transformed again to the original scale (Pankratz 1983, pp. 256–258; Taylor 1986).

After differencing as specified by the \text{DIF=} option, the process is assumed to be a stationary autoregressive process. You can check for stationarity of the series with the \%DFTEST macro. If the process is not stationary, differencing with the \text{DIF=} option is recommended. For a process with moving-average terms, a large value for the \text{AR=} option might be appropriate.

---

**DFPVALUE Macro**

The \%DFPVALUE macro computes the significance of the Dickey-Fuller test. The \%DFPVALUE macro evaluates the \( p \)-value for the Dickey-Fuller test statistic \( \tau \) for the test of \( H_0: \) “The time series has a unit root” versus \( H_a: \) “The time series is stationary” using tables published by Dickey (1976); Dickey, Hasza, and Fuller (1984).

The \%DFPVALUE macro can compute \( p \)-values for tests of a simple unit root with lag 1 or for seasonal unit roots at lags 2, 4, or 12. The \%DFPVALUE macro takes into account whether an intercept or deterministic time trend is assumed for the series.

The \%DFPVALUE macro is used by the \%DFTEST macro described later in this chapter.

Note that the \%DFPVALUE macro has been superseded by the \text{PROBD}F function described later in this chapter. It remains for compatibility with past releases of SAS/ETS.
Syntax

The `%DFPVVALUE` macro has the following form:

```
%DFPVVALUE ( tau, nobs < , options > ) ;
```

The first argument, `tau`, specifies the value of the Dickey-Fuller test statistic.

The second argument, `nobs`, specifies the number of observations on which the test statistic is based.

The first two arguments are required. The following options can be used with the `%DFPVVALUE` macro. Options must follow the required arguments and are separated by commas.

- **DLAG=1 | 2 | 4 | 12**
  - specifies the lag period of the unit root to be tested. DLAG=1 specifies a one-period unit root test. DLAG=2 specifies a test for a seasonal unit root with lag 2. DLAG=4 specifies a test for a seasonal unit root with lag 4. DLAG=12 specifies a test for a seasonal unit root with lag 12. The default is DLAG=1.

- **TREND=0 | 1 | 2**
  - specifies the degree of deterministic time trend included in the model. TREND=0 specifies no trend and assumes the series has a zero mean. TREND=1 includes an intercept term. TREND=2 specifies both an intercept and a deterministic linear time trend term. The default is TREND=1. TREND=2 is not allowed with DLAG=2, 4, or 12.

Results

The computed $p$-value is returned in the macro variable &DFPVALUE. If the $p$-value is less than 0.01 or larger than 0.99, the macro variable &DFPVALUE is set to 0.01 or 0.99, respectively.

Minimum Observations

The minimum number of observations required by the `%DFPVVALUE` macro depends on the value of the DLAG= option. The minimum observations are as follows:

<table>
<thead>
<tr>
<th>DLAG=</th>
<th>Minimum Observations</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>9</td>
</tr>
<tr>
<td>2</td>
<td>6</td>
</tr>
<tr>
<td>4</td>
<td>4</td>
</tr>
<tr>
<td>12</td>
<td>12</td>
</tr>
</tbody>
</table>

DFTEST Macro

The `%DFTEST` macro performs the Dickey-Fuller unit root test. You can use the `%DFTEST` macro to decide whether a time series is stationary and to determine the order of differencing required for the time series analysis of a nonstationary series.

Most time series analysis methods require that the series to be analyzed is stationary. However, many economic time series are nonstationary processes. The usual approach to this problem is to difference the series. A time series that can be made stationary by differencing is said to have a *unit root*. For more information, see the discussion of this issue in the section “Getting Started: ARIMA Procedure” on page 189 of Chapter 7, “The ARIMA Procedure.”
The Dickey-Fuller test is a method for testing whether a time series has a unit root. The %DFTEST macro tests the hypothesis $H_0$: “The time series has a unit root” versus $H_a$: “The time series is stationary” based on tables provided in Dickey (1976); Dickey, Hasza, and Fuller (1984). The test can be applied for a simple unit root with lag 1, or for seasonal unit roots at lag 2, 4, or 12.

Note that the %DFTEST macro has been superseded by the PROC ARIMA stationarity tests. See Chapter 7, “The ARIMA Procedure,” for details.

**Syntax**

The %DFTEST macro has the following form:

```
%DFTEST ( SAS-data-set, variable <, options > ) ;
```

The first argument, SAS-data-set, specifies the name of the SAS data set that contains the time series variable to be analyzed.

The second argument, variable, specifies the time series variable name to be analyzed.

The first two arguments are required. The following options can be used with the %DFTEST macro. Options must follow the required arguments and are separated by commas.

**AR=** specifies the order of autoregressive model fit after any differencing specified by the DIF= and DLAG= options. The default is AR=3.

**DIF=( differencing-list )** specifies the degrees of differencing to be applied to the series. The differencing list is a list of positive integers separated by commas and enclosed in parentheses. For example, DIF=(1,12) specifies that the series be differenced once at lag 1 and once at lag 12. For more details, see the section “IDENTIFY Statement” on page 224 in Chapter 7, “The ARIMA Procedure.”

If the option DIF=( $d_1, \cdots, d_k$ ) is specified, the series analyzed is $(1 - B^{d_1}) \cdots (1 - B^{d_k}) Y_t$, where $Y_t$ is the variable specified, and $B$ is the backshift operator defined by $BY_t = Y_{t-1}$.

**DLAG=1 | 2 | 4 | 12** specifies the lag to be tested for a unit root. The default is DLAG=1.

**OUT=SAS-data-set** writes residuals to an output data set.

**OUTSTAT=SAS-data-set** writes the test statistic, parameter estimates, and other statistics to an output data set.

**TREND=0 | 1 | 2** specifies the degree of deterministic time trend included in the model. TREND=0 includes no deterministic term and assumes the series has a zero mean. TREND=1 includes an intercept term. TREND=2 specifies an intercept and a linear time trend term. The default is TREND=1. TREND=2 is not allowed with DLAG=2, 4, or 12.
Results

The computed $p$-value is returned in the macro variable &DFTEST. If the $p$-value is less than 0.01 or larger than 0.99, the macro variable &DFTEST is set to 0.01 or 0.99, respectively. (The same value is given in the macro variable &DFPVALUE returned by the %DFPVALUE macro, which is used by the %DFTEST macro to compute the $p$-value.)

Results can be stored in SAS data sets with the OUT= and OUTSTAT= options.

Minimum Observations

The minimum number of observations required by the %DFTEST macro depends on the value of the DLAG= option. Let $s$ be the sum of the differencing orders specified by the DIF= option, let $t$ be the value of the TREND= option, and let $p$ be the value of the AR= option. The minimum number of observations required is as follows:

<table>
<thead>
<tr>
<th>DLAG=</th>
<th>Minimum Observations</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>$1 + p + s + \max(9, p + t + 2)$</td>
</tr>
<tr>
<td>2</td>
<td>$2 + p + s + \max(6, p + t + 2)$</td>
</tr>
<tr>
<td>4</td>
<td>$4 + p + s + \max(4, p + t + 2)$</td>
</tr>
<tr>
<td>12</td>
<td>$12 + p + s + \max(12, p + t + 2)$</td>
</tr>
</tbody>
</table>

Observations are not used if they have missing values for the series or for any lag or difference used in the autoregressive model.

LOGTEST Macro

The %LOGTEST macro tests whether a logarithmic transformation is appropriate for modeling and forecasting a time series. The logarithmic transformation is often used for time series that show exponential growth or variability proportional to the level of the series.

The %LOGTEST macro fits an autoregressive model to a series and fits the same model to the log of the series. Both models are estimated by the maximum-likelihood method, and the maximum log-likelihood values for both autoregressive models are computed. These log-likelihood values are then expressed in terms of the original data and compared.

You can control the order of the autoregressive models. You can also difference the series and the log-transformed series before the autoregressive model is fit.

You can print the log-likelihood values and related statistics (AIC, SBC, and MSE) for the autoregressive models for the series and the log-transformed series. You can also output these statistics to a SAS data set.

Syntax

The %LOGTEST macro has the following form:

```
%LOGTEST ( SAS-data-set, variable, < options > )
```

The first argument, SAS-data-set, specifies the name of the SAS data set that contains the time series variable to be analyzed. The second argument, variable, specifies the time series variable name to be analyzed.

The first two arguments are required. The following options can be used with the %LOGTEST macro. Options must follow the required arguments and are separated by commas.
AR=n
specifies the order of the autoregressive model fit to the series and the log-transformed series. The
default is AR=5.

CONST=value
specifies a constant to be added to the series before transformation. Use the CONST= option when
some values of the series are 0 or negative. The series analyzed must be greater than the negative of
the CONST= value. The default is CONST=0.

DIF=( differencing-list )
specifies the degrees of differencing applied to the original and log-transformed series before fitting
the autoregressive model. The differencing-list is a list of positive integers separated by commas and
enclosed in parentheses. For example, DIF=(1,12) specifies that the transformed series be differenced
once at lag 1 and once at lag 12. For more details, see the section “IDENTIFY Statement” on page 224
in Chapter 7, “The ARIMA Procedure.”

OUT=SAS-data-set
writes the results to an output data set. The output data set includes a variable TRANS that identifies
the transformation (LOG or NONE), the log-likelihood value (LOGLIK), residual mean squared
error (RMSE), Akaike Information Criterion (AIC), and Schwarz’s Bayesian Criterion (SBC) for the
log-transformed and untransformed cases.

PRINT=YES | NO
specifies whether the results are printed. The default is PRINT=NO. The printed output shows the
log-likelihood value, residual mean squared error, Akaike Information Criterion (AIC), and Schwarz’s
Bayesian Criterion (SBC) for the log-transformed and untransformed cases.

Results
The result of the test is returned in the macro variable &LOGTEST. The value of the &LOGTEST variable
is ‘LOG’ if the model fit to the log-transformed data has a larger log likelihood than the model fit to the
untransformed series. The value of the &LOGTEST variable is ‘NONE’ if the model fit to the untransformed
data has a larger log likelihood. The variable &LOGTEST is set to ‘ERROR’ if the %LOGTEST macro is
unable to compute the test due to errors.

Results are printed when the PRINT=YES option is specified. Results are stored in SAS data sets when the
OUT= option is specified.

Details
Assume that a time series \( X_t \) is a stationary \( p \)th order autoregressive process with normally distributed white
noise innovations. That is,

\[
(1 - \Theta(B))(X_t - \mu_x) = \epsilon_t
\]

where \( \mu_x \) is the mean of \( X_t \).

The log likelihood function of \( X_t \) is

\[
l_1() = -\frac{n}{2} \ln(2\pi) - \frac{1}{2} \ln(\Sigma_{xx}) - \frac{n}{2} \ln(\sigma^2) \\
- \frac{1}{2\sigma^2} (X - 1\mu_x)' \Sigma_{xx}^{-1} (X - 1\mu_x)
\]
where \( n \) is the number of observations, \( \mathbf{1} \) is the \( n \)-dimensional column vector of 1s, \( \sigma^2 \) is the variance of the white noise, \( \mathbf{X} = (X_1, \ldots, X_n)' \), and \( \Sigma_{XX} \) is the covariance matrix of \( \mathbf{X} \).

On the other hand, if the log-transformed time series \( Y_t = \ln(X_t + c) \) is a stationary \( p \)th order autoregressive process, the log-likelihood function of \( X_t \) is

\[
l_0(\cdot) = -\frac{n}{2}\ln(2\pi) - \frac{1}{2}\ln(|\Sigma_{YY}|) - \frac{n}{2}\ln(\sigma_e^2)
- \frac{1}{2\sigma_e^2}(\mathbf{Y} - \mathbf{1}\mu_y)'\Sigma_{YY}^{-1}(\mathbf{Y} - \mathbf{1}\mu_y) - \sum_{t=1}^{n}\ln(X_t + c)
\]

where \( \mu_y \) is the mean of \( Y_t \), \( \mathbf{Y} = (Y_1, \ldots, Y_n)' \), and \( \Sigma_{YY} \) is the covariance matrix of \( \mathbf{Y} \).

The %LOGTEST macro compares the maximum values of \( l_1(\cdot) \) and \( l_0(\cdot) \) and determines which is larger.

The %LOGTEST macro also computes the Akaike Information Criterion (AIC), Schwarz’s Bayesian Criterion (SBC), and residual mean squared error based on the maximum likelihood estimator for the autoregressive model. For the mean squared error, retransformation of forecasts is based on Pankratz (1983, pp. 256–258).

After differencing as specified by the DIF= option, the process is assumed to be a stationary autoregressive process. You might want to check for stationarity of the series using the %DFTEST macro. If the process is not stationary, differencing with the DIF= option is recommended. For a process with moving average terms, a large value for the AR= option might be appropriate.

---

## Functions

### PROBDF Function for Dickey-Fuller Tests

The PROBDF function calculates significance probabilities for Dickey-Fuller tests for unit roots in time series. The PROBDF function can be used wherever SAS library functions can be used, including DATA step programs, SCL programs, and PROC MODEL programs.

#### Syntax

\[
\text{PROBDF}( x, n < , d < , type > )
\]

- \( x \) is the test statistic.
- \( n \) is the sample size. The minimum value of \( n \) allowed depends on the value specified for the third argument \( d \). For \( d \) in the set \( \{1,2,4,6,12\} \), \( n \) must be an integer greater than or equal to \( \max(2d, 5) \); for other values of \( d \) the minimum value of \( n \) is 24.
- \( d \) is an optional integer giving the degree of the unit root tested for. Specify \( d = 1 \) for tests of a simple unit root \( (1 - B) \). Specify \( d \) equal to the seasonal cycle length for tests for a seasonal unit root \( (1 - B^d) \). The default value of \( d \) is 1; that is, a test for a simple unit root \( (1 - B) \) is assumed if \( d \) is not specified. The maximum value of \( d \) allowed is 12.
- \( type \) is an optional character argument that specifies the type of test statistic used. The values of \( type \) are the following:
SZM  studentized test statistic for the zero mean (no intercept) case
RZM  regression test statistic for the zero mean (no intercept) case
SSM  studentized test statistic for the single mean (intercept) case
RSM  regression test statistic for the single mean (intercept) case
STR  studentized test statistic for the deterministic time trend case
RTR  regression test statistic for the deterministic time trend case

The values STR and RTR are allowed only when $d = 1$. The default value of type is SZM.

Details

Theoretical Background

When a time series has a unit root, the series is nonstationary and the ordinary least squares (OLS) estimator is not normally distributed. The limiting distribution of the OLS estimator of autoregressive models for time series with a simple unit root was studied by Dickey (1976); Dickey and Fuller (1979). Dickey, Hasza, and Fuller (1984) obtained the limiting distribution for time series with seasonal unit roots. We will mainly introduce the nonseasonal tests in the following and list references for the nonseasonal tests.

Consider the Dickey-Fuller regression first. The null hypothesis is that there is an autoregressive unit root $H_0 : \alpha = 1$, and the alternative is $H_a : |\alpha| < 1$, where $\alpha$ is the autoregressive coefficient of the time series

$$y_t = \alpha y_{t-1} + \epsilon_t$$

This is referred to as the zero mean (ZM) model. The standard Dickey-Fuller (DF) test assumes that errors $\epsilon_t$ are white noise. There are two other types of regression models that include a constant or a time trend as follows:

$$y_t = \mu + \alpha y_{t-1} + \epsilon_t$$
$$y_t = \mu + \beta t + \alpha y_{t-1} + \epsilon_t$$

These two models are referred to as the constant mean model (SM) and the trend model (TR), respectively. The constant mean model includes a constant mean $\mu$ of the time series. However, the interpretation of $\mu$ depends on the stationarity in the following sense: the mean in the stationary case when $\alpha < 1$ is the trend in the integrated case when $\alpha = 1$. Therefore, the null hypothesis should be the joint hypothesis that $\alpha = 1$ and $\mu = 0$. However for the unit root tests, the test statistics are concerned with the null hypothesis of $\alpha = 1$. The joint null hypothesis is not commonly used. This issue is address in Bhargava (1986) with a different nesting model.

Under the null of I(1) of the Dickey-Fuller test, the differenced process is not serially correlated. There is a great need for the generalization of this specification. The augmented Dickey-Fuller (ADF) test, originally proposed in Dickey and Fuller (1979), adjusts for the serial correlation in the time series by adding lagged first differences to the autoregressive model as follows. Consider the $(p + 1)$th order autoregressive time series

$$y_t = \alpha_1 y_{t-1} + \alpha_2 y_{t-2} + \cdots + \alpha_{p+1} y_{t-p-1} + \epsilon_t$$

and its characteristic equation

$$m^{p+1} - \alpha_1 m^p - \alpha_2 m^{p-1} - \cdots - \alpha_{p+1} = 0$$
If all the characteristic roots are less than 1 in absolute value, \( y_t \) is stationary. \( y_t \) is nonstationary if there is a unit root. If there is a unit root, the sum of the autoregressive parameters is 1, and hence you can test for a unit root by testing whether the sum of the autoregressive parameters is 1 or not. The no-intercept model is parameterized as

\[
\nabla y_t = \delta y_{t-1} + \theta_1 \nabla y_{t-1} + \cdots + \theta_p \nabla y_{t-p} + e_t
\]

where \( \nabla y_t = y_t - y_{t-1} \) and

\[
\delta = \alpha_1 + \cdots + \alpha_{p+1} - 1
\]

\[
\theta_k = -\alpha_{k+1} - \cdots - \alpha_{p+1}
\]

The estimators are obtained by regressing \( \nabla y_t \) on \( y_{t-1}, \nabla y_{t-1}, \cdots, \nabla y_{t-p} \). The \( t \) statistic of the ordinary least squares estimator of \( \delta \) is the test statistic for the unit root test.

If the \textit{type} argument value specifies a test for a nonzero mean (intercept case), the autoregressive model includes a mean term \( \alpha_0 \). If the \textit{type} argument value specifies a test for a time trend, the model also includes a time trend term and the model is as follows:

\[
\nabla y_t = \alpha_0 + \gamma t + \delta y_{t-1} + \theta_1 \nabla y_{t-1} + \cdots + \theta_p \nabla y_{t-p} + e_t
\]

For testing for a seasonal unit root, consider the multiplicative model

\[
(1 - \alpha_d B^d)(1 - \theta_1 B - \cdots - \theta_p B^p) y_t = e_t
\]

Let \( \nabla^d y_t \equiv y_t - y_{t-d} \). The test statistic is calculated in the following steps:

1. Regress \( \nabla^d y_t \) on \( \nabla^d y_{t-1}, \nabla^d y_{t-2}, \cdots, \nabla^d y_{t-p} \) to obtain the initial estimators \( \hat{\theta}_i \) and compute residuals \( \hat{e}_t \).
   Under the null hypothesis that \( \alpha_d = 1 \), \( \hat{\theta}_i \) are consistent estimators of \( \theta_i \).

2. Regress \( \hat{e}_t \) on \( (1 - \hat{\theta}_1 B - \cdots - \hat{\theta}_p B^p) \nabla^d y_{t-d}, \nabla^d y_{t-1}, \cdots, \nabla^d y_{t-p} \) to obtain estimates of \( \delta = \alpha_d - 1 \) and \( \theta_i - \hat{\theta}_i \).

The \( t \) ratio for the estimate of \( \delta \) produced by the second step is used as a test statistic for testing for a seasonal unit root. The estimates of \( \theta_i \) are obtained by adding the estimates of \( \theta_i - \hat{\theta}_i \) from the second step to \( \hat{\theta}_i \) from the first step.

The series \( (1 - B^d) y_t \) is assumed to be stationary, where \( d \) is the value of the third argument to the \textsc{PROBDF} function.

If the series is an ARMA process, a large value of \( p \) might be desirable in order to obtain a reliable test statistic. To determine an appropriate value for \( p \), see Said and Dickey (1984).

\textbf{Test Statistics}

The Dickey-Fuller test is used to test the null hypothesis that the time series exhibits a lag \( d \) unit root against the alternative of stationarity. The \textsc{PROBDF} function computes the probability of observing a test statistic more extreme than \( x \) under the assumption that the null hypothesis is true. You should reject the unit root hypothesis when \textsc{PROBDF} returns a small (significant) probability value.
Consider the Dickey-Fuller regression first. There are several different versions of the Dickey-Fuller test. The PROBDF function supports six versions, as selected by the type argument. Specify the type value that corresponds to the way that you calculated the test statistic $x$.

The last two characters of the type value specify the kind of regression model used to compute the Dickey-Fuller test statistic. The meaning of the last two characters of the type value are as follows:

**ZM** zero mean or no-intercept case. The test statistic $x$ is assumed to be computed from the regression model

\[ y_t = \alpha y_{t-1} + e_t \]

**SM** single mean or intercept case. The test statistic $x$ is assumed to be computed from the regression model

\[ y_t = \mu + \alpha y_{t-1} + e_t \]

**TR** intercept and deterministic time trend case. The test statistic $x$ is assumed to be computed from the regression model

\[ y_t = \mu + \gamma t + \alpha y_{t-1} + e_t \]

The first character of the type value specifies whether the regression test statistic or the studentized test statistic is used. Let $\hat{\alpha}$ be the estimated regression coefficient for the lag of the series, and let $se_{\hat{\alpha}}$ be the standard error of $\hat{\alpha}$. The meaning of the first character of the type value is as follows:

**R** the regression-coefficient-based test statistic. The test statistic is

\[ \rho = n(\hat{\alpha} - 1) \]

**S** the studentized test statistic. The test statistic is

\[ DF_{\tau} = \frac{(\hat{\alpha} - 1)}{se_{\hat{\alpha}}} \]

The first one is also called $\rho$-test and the second is called $\tau$-test. For the zero mean model, the asymptotic distributions of the Dickey-Fuller test statistics are

\[ n(\hat{\alpha} - 1) \Rightarrow \left( \int_0^1 W(r) dW(r) \right) \left( \int_0^1 W(r)^2 dr \right)^{-1} \]

\[ DF_{\tau} \Rightarrow \left( \int_0^1 W(r) dW(r) \right) \left( \int_0^1 W(r)^2 dr \right)^{-1/2} \]

For the constant mean model, the asymptotic distributions are

\[ n(\hat{\alpha} - 1) \Rightarrow \left( [W(1)^2 - 1]/2 - W(1) \int_0^1 W(r) dr \right) \left( \int_0^1 W(r)^2 dr - \left( \int_0^1 W(r) dr \right)^2 \right)^{-1} \]

\[ DF_{\tau} \Rightarrow \left( [W(1)^2 - 1]/2 - W(1) \int_0^1 W(r) dr \right) \left( \int_0^1 W(r)^2 dr - \left( \int_0^1 W(r) dr \right)^2 \right)^{-1/2} \]
For the trend model, the asymptotic distributions are

\[ n(\hat{\alpha} - 1) \Rightarrow \left[ W(r)dr + 12 \left( \int_0^1 rW(r)dr - \frac{1}{2} \int_0^1 W(r)dr \right) \left( \int_0^1 W(r)dr - \frac{1}{2} W(1) \right) \right. \]
\[ \left. - W(1) \int_0^1 W(r)dr \right] D^{-1} \]
\[ DF_t \Rightarrow \left[ W(r)dr + 12 \left( \int_0^1 rW(r)dr - \frac{1}{2} \int_0^1 W(r)dr \right) \left( \int_0^1 W(r)dr - \frac{1}{2} W(1) \right) \right. \]
\[ \left. - W(1) \int_0^1 W(r)dr \right] D^{1/2} \]

where

\[ D = \int_0^1 W(r)^2dr - 12 \left( \int_0^1 rW(r)dr \right)^2 + 12 \int_0^1 W(r)dr \int_0^1 rW(r)dr - 4 \left( \int_0^1 W(r)dr \right)^2 \]

For more information about the Dickey-Fuller test null distribution see: Dickey and Fuller (1979); Dickey, Hasza, and Fuller (1984); Hamilton (1994). The preceding formulas are for the basic Dickey-Fuller test. The PROBDF function can also be used for the augmented Dickey-Fuller test, in which the error term \( e_t \) is modeled as an autoregressive process; however, the test statistic is computed somewhat differently for the augmented Dickey-Fuller test. For the nonseasonal augmented Dickey-Fuller test, the test statistics can take one of the two forms similar to Dickey-Fuller test. One is the OLS \( t \) value

\[ \frac{\hat{\alpha} - 1}{sd(\hat{\alpha})} \]

and the other is given by

\[ \frac{n(\hat{\alpha} - 1)}{1 - \hat{\alpha}_1 - \ldots - \hat{\alpha}_p} \]

The asymptotic distributions of the test statistics are the same as those of the standard Dickey-Fuller test statistics. For information about seasonal and nonseasonal augmented Dickey-Fuller tests see: Dickey, Hasza, and Fuller (1984); Hamilton (1994).

The PROBDF function is calculated from approximating functions fit to empirical quantiles that are produced by a Monte Carlo simulation that employs \( 10^8 \) replications for each simulation. Separate simulations were performed for selected values of \( n \) and for \( d = 1, 2, 4, 6, 12 \) (where \( n \) and \( d \) are the second and third arguments to the PROBDF function).

The maximum error of the PROBDF function is approximately \( \pm 10^{-3} \) for \( d \) in the set \( 1,2,4,6,12 \) and can be slightly larger for other \( d \) values. Because the number of simulation replications used to produce the PROBDF function is much greater than the 60,000 replications used by Dickey and colleagues (Dickey and Fuller 1979; Dickey, Hasza, and Fuller 1984), the PROBDF function can be expected to produce results that are substantially more accurate than the critical values reported in those papers.
Examples

Suppose the data set TEST contains 104 observations of the time series variable Y, and you want to test the null hypothesis that there exists a lag 4 seasonal unit root in the Y series. The following statements illustrate how to perform the single-mean Dickey-Fuller regression coefficient test using PROC REG and PROBDF.

```sas
data test1;
   set test;
   y4 = lag4(y);
run;

proc reg data=test1 outest=alpha;
   model y = y4 / noprint;
run;

data _null_; 
   set alpha;
   x = 100 * ( y4 - 1 );
   p = probdf( x, 100, 4, "RSM" );
   put p= pvalue5.3;
run;
```

To perform the augmented Dickey-Fuller test, regress the differences of the series on lagged differences and on the lagged value of the series, and compute the test statistic from the regression coefficient for the lagged series. The following statements illustrate how to perform the single-mean augmented Dickey-Fuller studentized test for a simple unit root using PROC REG and PROBDF:

```sas
data test1;
   set test;
   yl = lag(y);
   yd = dif(y);
   yd1 = lag1(yd); yd2 = lag2(yd);
   yd3 = lag3(yd); yd4 = lag4(yd);
run;

proc reg data=test1 outest=alpha covout;
   model yd = yl yd1-yd4 / noprint;
run;

data _null_; 
   set alpha;
   retain a ;
   if _type_ = 'PARMS' then a = yl ;
   if _type_ = 'COV' & _NAME_ = 'Y1' then do;
      x = a / sqrt(yl);
      p = probdf( x, 99, 1, "SSM" );
      put p= pvalue5.3;
   end;
run;
```
The %DFTEST macro provides an easier way to perform Dickey-Fuller tests. The following statements perform the same tests as the preceding example:

```latex
%dfptest(test, y, ar=4);
%put p=%dfptest;
```

Overview

Several SAS/ETS procedures (COUNTREG, ENTROPY, MDC, QLIM, UCM, and VARMAX) use the nonlinear optimization (NLO) subsystem to perform nonlinear optimization. This chapter describes the options of the NLO system and some technical details of the available optimization methods. Note that not all options have been implemented for all procedures that use the NLO subsystem. You should check each procedure chapter for more details about which options are available.

Options

The following table summarizes the options available in the NLO system.

Table 6.1 NLO options

These options are described in alphabetical order.

**ABSCONV=\( r \)**

**ABSTOL=\( r \)**

specifies an absolute function convergence criterion. For minimization, termination requires \( f(\theta^{(k)}) \leq r \). The default value of \( r \) is the negative square root of the largest double-precision value, which serves only as a protection against overflows.

**ABSFCONV=\( r[n] \)**

**ABSFTOL=\( r[n] \)**

specifies an absolute function convergence criterion. For all techniques except NMSIMP, termination requires a small change of the function value in successive iterations:

\[ |f(\theta^{(k-1)}) - f(\theta^{(k)})| \leq r \]
The same formula is used for the NMSIMP technique, but \( \theta^{(k)} \) is defined as the vertex with the lowest function value, and \( \theta^{(k-1)} \) is defined as the vertex with the highest function value in the simplex. The default value is \( r = 0 \). The optional integer value \( n \) specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

**ABSGCONV**\( = r[n] \)

**ABSGTOL**\( = r[n] \)

specifies an absolute gradient convergence criterion. Termination requires the maximum absolute gradient element to be small:

\[
\max_j |g_j(\theta^{(k)})| \leq r
\]

This criterion is not used by the NMSIMP technique. The default value is \( r = 1E-5 \). The optional integer value \( n \) specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

**ABSXCONV**\( = r[n] \)

**ABSXTOl**\( = r[n] \)

specifies an absolute parameter convergence criterion. For all techniques except NMSIMP, termination requires a small Euclidean distance between successive parameter vectors,

\[
\| \theta^{(k)} - \theta^{(k-1)} \|_2 \leq r
\]

For the NMSIMP technique, termination requires either a small length \( \alpha^{(k)} \) of the vertices of a restart simplex,

\[
\alpha^{(k)} \leq r
\]

or a small simplex size,

\[
\delta^{(k)} \leq r
\]

where the simplex size \( \delta^{(k)} \) is defined as the L1 distance from the simplex vertex \( \xi^{(k)} \) with the smallest function value to the other \( n \) simplex points \( \theta_l^{(k)} \neq \xi^{(k)} \):

\[
\delta^{(k)} = \sum_{\theta_l \neq \xi} \| \theta_l^{(k)} - \xi^{(k)} \|_1
\]

The default is \( r = 1E-8 \) for the NMSIMP technique and \( r = 0 \) otherwise. The optional integer value \( n \) specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

**DAMPSTEP**\( = r \)

specifies that the initial step length value \( \alpha^{(0)} \) for each line search (used by the QUANEW, HYQUAN, CONGRA, or NEWRAP technique) cannot be larger than \( r \) times the step length value used in the former iteration. If the DAMPSTEP option is specified but \( r \) is not specified, the default is \( r = 2 \). The DAMPSTEP\( = r \) option can prevent the line-search algorithm from repeatedly stepping into regions where some objective functions are difficult to compute or where they could lead to floating point overflows during the computation of objective functions and their derivatives. The DAMPSTEP\( = r \) option can save time-costly function calls during the line searches of objective functions that result in very small steps.
\[ \frac{|f(\theta(k)) - f(\theta(k-1))|}{\max(|f(\theta(k-1))|, \text{FSIZE})} \leq r \]

where FSIZE is defined by the FSIZE= option. The same formula is used for the NMSIMP technique, but \( \theta(k) \) is defined as the vertex with the lowest function value, and \( \theta(k-1) \) is defined as the vertex with the highest function value in the simplex. The default value may depend on the procedure. In most cases, you can use the PALL option to find it.

\[ FCONV2=r[n] \]
\[ FTOL2=r[n] \]

specifies another function convergence criterion.

For all techniques except NMSIMP, termination requires a small predicted reduction

\[ df(k) \approx f(\theta(k)) - f(\theta(k) + s(k)) \]

of the objective function. The predicted reduction

\[
\begin{align*}
  df(k) &= -g(k)^T s(k) - \frac{1}{2} s(k)^T H(k) s(k) \\
  &= -\frac{1}{2} s(k)^T g(k) \\
  &\leq r
\end{align*}
\]

is computed by approximating the objective function \( f \) by the first two terms of the Taylor series and substituting the Newton step

\[ s(k) = -[H(k)]^{-1} g(k) \]

For the NMSIMP technique, termination requires a small standard deviation of the function values of the \( n + 1 \) simplex vertices \( \theta_l^{(k)} \), \( l = 0, \ldots, n \),

\[
\sqrt{\frac{1}{n+1} \sum_l \left[ f(\theta_l^{(k)}) - \overline{f}(\theta^{(k)}) \right]^2} \leq r
\]

where \( \overline{f}(\theta^{(k)}) = \frac{1}{n+1} \sum_l f(\theta_l^{(k)}) \). If there are \( n_{act} \) boundary constraints active at \( \theta^{(k)} \), the mean and standard deviation are computed only for the \( n + 1 - n_{act} \) unconstrained vertices.

The default value is \( r = 1E-6 \) for the NMSIMP technique and \( r = 0 \) otherwise. The optional integer value \( n \) specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

\[ FSIZE=r \]

specifies the FSIZE parameter of the relative function and relative gradient termination criteria. The default value is \( r = 0 \). For more details, see the FCONV= and GCONV= options.
**GCONV=**\(r[n]\)

**GTOL=**\(r[n]\)

specifies a relative gradient convergence criterion. For all techniques except CONGRA and NMSIMP, termination requires that the normalized predicted function reduction is small,

\[
\frac{g(\theta^{(k)})^T [H^{(k)}]^{-1} g(\theta^{(k)}) \max(|f(\theta^{(k)})|, \text{FSIZE})}{\text{FSIZE}} \leq r
\]

where FSIZE is defined by the FSIZE= option. For the CONGRA technique (where a reliable Hessian estimate \(H\) is not available), the following criterion is used:

\[
\frac{\|g(\theta^{(k)})\|^2_2}{\|g(\theta^{(k)}) - g(\theta^{(k-1)})\|^2_2} \leq r
\]

This criterion is not used by the NMSIMP technique. The default value is \(r = 1E - 8\). The optional integer value \(n\) specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

**HESCAL=**0|1|2|3

**HS=**0|1|2|3

specifies the scaling version of the Hessian matrix used in NRRIDG, TRUREG, NEWRAP, or DBLDOG optimization.

If HS is not equal to 0, the first iteration and each restart iteration sets the diagonal scaling matrix \(D^{(0)} = \text{diag}(d_i^{(0)})\):

\[
d_i^{(0)} = \sqrt{\max(|H_{i,i}^{(0)}|, \epsilon)}
\]

where \(H_{i,i}^{(0)}\) are the diagonal elements of the Hessian. In every other iteration, the diagonal scaling matrix \(D^{(0)} = \text{diag}(d_i^{(0)})\) is updated depending on the HS option:

- **HS=0** specifies that no scaling is done.
- **HS=1** specifies the Moré (1978) scaling update:

\[
d_i^{(k+1)} = \max\left[d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)}\right]
\]

- **HS=2** specifies the Dennis, Gay, and Welsch (1981) scaling update:

\[
d_i^{(k+1)} = \max\left[0.6 \cdot d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)}\right]
\]

- **HS=3** specifies that \(d_i\) is reset in each iteration:

\[
d_i^{(k+1)} = \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)}
\]

In each scaling update, \(\epsilon\) is the relative machine precision. The default value is HS=0. Scaling of the Hessian can be time consuming in the case where general linear constraints are active.
INHESSIAN\[= r \]

INHESS\[= r \]
specifies how the initial estimate of the approximate Hessian is defined for the quasi-Newton techniques QUANEW and DBLDOG. There are two alternatives:

- If you do not use the \( r \) specification, the initial estimate of the approximate Hessian is set to the Hessian at \( \theta^{(0)} \).
- If you do use the \( r \) specification, the initial estimate of the approximate Hessian is set to the multiple of the identity matrix \( rI \).

By default, if you do not specify the option INHESSIAN\(=r \), the initial estimate of the approximate Hessian is set to the multiple of the identity matrix \( rI \), where the scalar \( r \) is computed from the magnitude of the initial gradient.

INSTEP\[=r \]

reduces the length of the first trial step during the line search of the first iterations. For highly nonlinear objective functions, such as the EXP function, the default initial radius of the trust-region algorithm TRUREG or DBLDOG or the default step length of the line-search algorithms can result in arithmetic overflows. If this occurs, you should specify decreasing values of \( 0 < r < 1 \) such as INSTEP\(=1E-1 \), INSTEP\(=1E-2 \), INSTEP\(=1E-4 \), and so on, until the iteration starts successfully.

- For trust-region algorithms (TRUREG, DBLDOG), the INSTEP\(= \) option specifies a factor \( r > 0 \) for the initial radius \( \Delta^{(0)} \) of the trust region. The default initial trust-region radius is the length of the scaled gradient. This step corresponds to the default radius factor of \( r = 1 \).
- For line-search algorithms (NEWRAP, CONGRA, QUANEW), the INSTEP\(= \) option specifies an upper bound for the initial step length for the line search during the first five iterations. The default initial step length is \( r = 1 \).
- For the Nelder-Mead simplex algorithm, using TECH=NMSIMP, the INSTEP\(=r \) option defines the size of the start simplex.

LINESEARCH\[=i \]

LIS\[=i \]
specifies the line-search method for the CONGRA, QUANEW, and NEWRAP optimization techniques. See Fletcher (1987) for an introduction to line-search techniques. The value of \( i \) can be \( 1, \ldots, 8 \). For CONGRA, QUANEW and NEWRAP, the default value is \( i = 2 \).

- LIS\(=1 \) specifies a line-search method that needs the same number of function and gradient calls for cubic interpolation and cubic extrapolation; this method is similar to one used by the Harwell subroutine library.
- LIS\(=2 \) specifies a line-search method that needs more function than gradient calls for quadratic and cubic interpolation and cubic extrapolation; this method is implemented as shown in Fletcher (1987) and can be modified to an exact line search by using the LSPRECISION\(= \) option.
- LIS\(=3 \) specifies a line-search method that needs the same number of function and gradient calls for cubic interpolation and cubic extrapolation; this method is implemented as shown in Fletcher (1987) and can be modified to an exact line search by using the LSPRECISION\(= \) option.
LIS=4 specifies a line-search method that needs the same number of function and gradient calls for stepwise extrapolation and cubic interpolation.

LIS=5 specifies a line-search method that is a modified version of LIS=4.

LIS=6 specifies golden section line search (Polak 1971), which uses only function values for linear approximation.

LIS=7 specifies bisection line search (Polak 1971), which uses only function values for linear approximation.

LIS=8 specifies the Armijo line-search technique (Polak 1971), which uses only function values for linear approximation.

LSPRECISION=r

LSP=r specifies the degree of accuracy that should be obtained by the line-search algorithms LIS=2 and LIS=3. Usually an imprecise line search is inexpensive and successful. For more difficult optimization problems, a more precise and expensive line search may be necessary (Fletcher 1987). The second line-search method (which is the default for the NEWRAP, QUANEW, and CONGRA techniques) and the third line-search method approach exact line search for small LSPRECISION= values. If you have numerical problems, you should try to decrease the LSPRECISION= value to obtain a more precise line search. The default values are shown in the following table.

<table>
<thead>
<tr>
<th>TECH=</th>
<th>UPDATE=</th>

<tr>
<td>QUANEW</td>
<td>DDFP, DFP</td>
<td>r = 0.06</td>
</tr>
<tr>
<td>CONGRA</td>
<td>all</td>
<td>r = 0.1</td>
</tr>
<tr>
<td>NEWRAP</td>
<td>no update</td>
<td>r = 0.9</td>
</tr>
</tbody>
</table>

For more details, see Fletcher (1987).

MAXFUNC=i

MAXFU=i specifies the maximum number i of function calls in the optimization process. The default values are

- TRUREG, NRRIDG, NEWRAP: 125
- QUANEW, DBLDOG: 500
- CONGRA: 1000
- NMSIMP: 3000

Note that the optimization can terminate only after completing a full iteration. Therefore, the number of function calls that is actually performed can exceed the number that is specified by the MAXFUNC= option.
MAXITER= specifies the maximum number \( i \) of iterations in the optimization process. The default values are

- TRUREG, NRRIDG, NEWRAP: 50
- QUANEW, DBLDOG: 200
- CONGRA: 400
- NMSIMP: 1000

These default values are also valid when \( i \) is specified as a missing value.

MAXSTEP= specifies an upper bound for the step length of the line-search algorithms during the first \( n \) iterations. By default, \( r \) is the largest double-precision value and \( n \) is the largest integer available. Setting this option can improve the speed of convergence for the CONGRA, QUANEW, and NEWRAP techniques.

MAXTIME= specifies an upper limit of \( r \) seconds of CPU time for the optimization process. The default value is the largest floating-point double representation of your computer. Note that the time specified by the MAXTIME= option is checked only once at the end of each iteration. Therefore, the actual running time can be much longer than that specified by the MAXTIME= option. The actual running time includes the rest of the time needed to finish the iteration and the time needed to generate the output of the results.

MINITER= specifies the minimum number of iterations. The default value is 0. If you request more iterations than are actually needed for convergence to a stationary point, the optimization algorithms can behave strangely. For example, the effect of rounding errors can prevent the algorithm from continuing for the required number of iterations.

NOPRINT suppresses the output. (See procedure documentation for availability of this option.)

PALL displays all optional output for optimization. (See procedure documentation for availability of this option.)

PHISTORY displays the optimization history. (See procedure documentation for availability of this option.)

PHISTPARMS display parameter estimates in each iteration. (See procedure documentation for availability of this option.)

PINIT displays the initial values and derivatives (if available). (See procedure documentation for availability of this option.)
PSHORT
restricts the amount of default output. (See procedure documentation for availability of this option.)

PSUMMARY
restricts the amount of default displayed output to a short form of iteration history and notes, warnings, and errors. (See procedure documentation for availability of this option.)

RESTART=i > 0

REST=i > 0

specifies that the QUANEW or CONGRA algorithm is restarted with a steepest descent/ascent search direction after, at most, \( i \) iterations. Default values are as follows:

- **CONGRA**
  UPDATE=PB: restart is performed automatically, \( i \) is not used.

- **CONGRA**
  UPDATE\(\neq PB\): \( i = \min(10n, 80) \), where \( n \) is the number of parameters.

- **QUANEW**
  \( i \) is the largest integer available.

SOCKET=fileref
Specifies the fileref that contains the information needed for remote monitoring. See the section “Remote Monitoring” on page 180 for more details.

TECHNIQUE=value
TECH=value
specifies the optimization technique. Valid values are as follows:

- **CONGRA**
  performs a conjugate-gradient optimization, which can be more precisely specified with the UPDATE= option and modified with the LINESEARCH= option. When you specify this option, UPDATE=PB by default.

- **DBLDOG**
  performs a version of double-dogleg optimization, which can be more precisely specified with the UPDATE= option. When you specify this option, UPDATE=DBFGS by default.

- **NMSIMP**
  performs a Nelder-Mead simplex optimization.

- **NONE**
  does not perform any optimization. This option can be used as follows:
    
    - to perform a grid search without optimization
    - to compute estimates and predictions that cannot be obtained efficiently with any of the optimization techniques

- **NEWRAP**
  performs a Newton-Raphson optimization that combines a line-search algorithm with ridging. The line-search algorithm LIS=2 is the default method.

- **NRRIDG**
  performs a Newton-Raphson optimization with ridging.
Chapter 6: Nonlinear Optimization Methods

- **QUANEW**
  performs a quasi-Newton optimization, which can be defined more precisely with the UPDATE= option and modified with the LINESEARCH= option. This is the default estimation method.
- **TRUREG**
  performs a trust region optimization.

**UPDATE= method**

**UPD= method**
specifies the update method for the QUANEW, DBLDOG, or CONGRA optimization technique. Not every update method can be used with each optimizer.

Valid methods are as follows:

- **BFGS**
  performs the original Broyden, Fletcher, Goldfarb, and Shanno (BFGS) update of the inverse Hessian matrix.
- **DBFGS**
  performs the dual BFGS update of the Cholesky factor of the Hessian matrix. This is the default update method.
- **DDFP**
  performs the dual Davidon, Fletcher, and Powell (DFP) update of the Cholesky factor of the Hessian matrix.
- **DFP**
  performs the original DFP update of the inverse Hessian matrix.
- **PB**
  performs the automatic restart update method of Powell (1977); Beale (1972).
- **FR**
  performs the Fletcher-Reeves update (Fletcher 1987).
- **PR**
  performs the Polak-Ribiere update (Fletcher 1987).
- **CD**

**XCONV= r\[n\]**

**XTOL= r\[n\]**
specifies the relative parameter convergence criterion. For all techniques except NMSIMP, termination requires a small relative parameter change in subsequent iterations.

\[
\frac{\max_j |\theta_j^{(k)} - \theta_j^{(k-1)}|}{\max(|\theta_j^{(k)}|, |\theta_j^{(k-1)}|, \text{XSIZE})} \leq r
\]

For the NMSIMP technique, the same formula is used, but \(\theta_j^{(k)}\) is defined as the vertex with the lowest function value and \(\theta_j^{(k-1)}\) is defined as the vertex with the highest function value in the simplex. The default value is \(r = 1E-8\) for the NMSIMP technique and \(r = 0\) otherwise. The optional integer value \(n\) specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.
XSIZE=r > 0

specifies the XSIZE parameter of the relative parameter termination criterion. The default value is \( r = 0 \). For more detail, see the XCONV= option.

---

**Details of Optimization Algorithms**

**Overview**

There are several optimization techniques available. You can choose a particular optimizer with the TECH=name option in the PROC statement or NLOPTIONS statement.

No algorithm for optimizing general nonlinear functions exists that always finds the global optimum for a general nonlinear minimization problem in a reasonable amount of time. Since no single optimization technique is invariably superior to others, NLO provides a variety of optimization techniques that work well in various circumstances. However, you can devise problems for which none of the techniques in NLO can find the correct solution. Moreover, nonlinear optimization can be computationally expensive in terms of time and memory, so you must be careful when matching an algorithm to a problem.

All optimization techniques in NLO use \( O(n^2) \) memory except the conjugate gradient methods, which use only \( O(n) \) of memory and are designed to optimize problems with many parameters. These iterative techniques require repeated computation of the following:

- the function value (optimization criterion)
- the gradient vector (first-order partial derivatives)
- for some techniques, the (approximate) Hessian matrix (second-order partial derivatives)

However, since each of the optimizers requires different derivatives, some computational efficiencies can be gained. Table 6.4 shows, for each optimization technique, which derivatives are required. (FOD means that first-order derivatives or the gradient is computed; SOD means that second-order derivatives or the Hessian is computed.)

Each optimization method employs one or more convergence criteria that determine when it has converged. The various termination criteria are listed and described in the previous section. An algorithm is considered to have converged when any one of the convergence criterion is satisfied. For example, under the default settings, the QUANEW algorithm will converge if $ABSGCONV < 1E-5$, $FCONV < 10^{-FDIGITS}$, or $GCONV < 1E-8$.

Choosing an Optimization Algorithm

The factors that go into choosing a particular optimization technique for a particular problem are complex and might involve trial and error.

For many optimization problems, computing the gradient takes more computer time than computing the function value, and computing the Hessian sometimes takes much more computer time and memory than computing the gradient, especially when there are many decision variables. Unfortunately, optimization techniques that do not use some kind of Hessian approximation usually require many more iterations than techniques that do use a Hessian matrix, and as a result the total run time of these techniques is often longer. Techniques that do not use the Hessian also tend to be less reliable. For example, they can more easily terminate at stationary points rather than at global optima.

A few general remarks about the various optimization techniques follow.

- The second-derivative methods TRUREG, NEWRAP, and NRRIDG are best for small problems where the Hessian matrix is not expensive to compute. Sometimes the NRRIDG algorithm can be faster than the TRUREG algorithm, but TRUREG can be more stable. The NRRIDG algorithm requires only one matrix with $n(n + 1)/2$ double words; TRUREG and NEWRAP require two such matrices.

- The first-derivative methods QUANEW and DBLDOG are best for medium-sized problems where the objective function and the gradient are much faster to evaluate than the Hessian. The QUANEW and DBLDOG algorithms, in general, require more iterations than TRUREG, NRRIDG, and NEWRAP, but each iteration can be much faster. The QUANEW and DBLDOG algorithms require only the gradient to update an approximate Hessian, and they require slightly less memory than TRUREG or NEWRAP (essentially one matrix with $n(n + 1)/2$ double words). QUANEW is the default optimization method.

- The first-derivative method CONGRA is best for large problems where the objective function and the gradient can be computed much faster than the Hessian and where too much memory is required to store the (approximate) Hessian. The CONGRA algorithm, in general, requires more iterations than
QUANEW or DBLDOG, but each iteration can be much faster. Since CONGRA requires only a factor of \( n \) double-word memory, many large applications can be solved only by CONGRA.

- The no-derivative method NMSIMP is best for small problems where derivatives are not continuous or are very difficult to compute.

---

**Algorithm Descriptions**

Some details about the optimization techniques are as follows.

**Trust Region Optimization (TRUREG)**

The trust region method uses the gradient \( g(\theta_k) \) and the Hessian matrix \( H(\theta_k) \); thus, it requires that the objective function \( f(\theta) \) have continuous first- and second-order derivatives inside the feasible region. The trust region method iteratively optimizes a quadratic approximation to the nonlinear objective function within a hyperelliptic trust region with radius \( \Delta \) that constrains the step size that corresponds to the quality of the quadratic approximation. The trust region method is implemented using Dennis, Gay, and Welsch (1981); Gay (1983); Moré and Sorensen (1983).

The trust region method performs well for small- to medium-sized problems, and it does not need many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the (dual) quasi-Newton or conjugate gradient algorithms may be more efficient.

**Newton-Raphson Optimization with Line Search (NEWRAP)**

The NEWRAP technique uses the gradient \( g(\theta_k) \) and the Hessian matrix \( H(\theta_k) \); thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region. If second-order derivatives are computed efficiently and precisely, the NEWRAP method can perform well for medium-sized to large problems, and it does not need many function, gradient, and Hessian calls.

This algorithm uses a pure Newton step when the Hessian is positive definite and when the Newton step reduces the value of the objective function successfully. Otherwise, a combination of ridging and line search is performed to compute successful steps. If the Hessian is not positive definite, a multiple of the identity matrix is added to the Hessian matrix to make it positive definite.

In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The default line-search method uses quadratic interpolation and cubic extrapolation (LIS=2).

**Newton-Raphson Ridge Optimization (NRRIDG)**

The NRRIDG technique uses the gradient \( g(\theta_k) \) and the Hessian matrix \( H(\theta_k) \); thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region.

This algorithm uses a pure Newton step when the Hessian is positive definite and when the Newton step reduces the value of the objective function successfully. If at least one of these two conditions is not satisfied, a multiple of the identity matrix is added to the Hessian matrix.

The NRRIDG method performs well for small- to medium-sized problems, and it does not require many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the (dual) quasi-Newton or conjugate gradient algorithms might be more efficient.
Since the NRRIDG technique uses an orthogonal decomposition of the approximate Hessian, each iteration of NRRIDG can be slower than that of the NEWRAP technique, which works with Cholesky decomposition. Usually, however, NRRIDG requires fewer iterations than NEWRAP.

**Quasi-Newton Optimization (QUANEW)**

The (dual) quasi-Newton method uses the gradient $g(\theta_k)$, and it does not need to compute second-order derivatives since they are approximated. It works well for medium to moderately large optimization problems where the objective function and the gradient are much faster to compute than the Hessian; but, in general, it requires more iterations than the TRUREG, NEWRAP, and NRRIDG techniques, which compute second-order derivatives. QUANEW is the default optimization algorithm because it provides an appropriate balance between the speed and stability required for most nonlinear mixed model applications.

The QUANEW technique is one of the following, depending upon the value of the UPDATE= option.

- the original quasi-Newton algorithm, which updates an approximation of the inverse Hessian
- the dual quasi-Newton algorithm, which updates the Cholesky factor of an approximate Hessian (default)

You can specify four update formulas with the UPDATE= option:

- DBFGS performs the dual Broyden, Fletcher, Goldfarb, and Shanno (BFGS) update of the Cholesky factor of the Hessian matrix. This is the default.
- DDFP performs the dual Davidon, Fletcher, and Powell (DFP) update of the Cholesky factor of the Hessian matrix.
- BFGS performs the original BFGS update of the inverse Hessian matrix.
- DFP performs the original DFP update of the inverse Hessian matrix.

In each iteration, a line search is performed along the search direction to find an approximate optimum. The default line-search method uses quadratic interpolation and cubic extrapolation to obtain a step size $\alpha$ satisfying the Goldstein conditions. One of the Goldstein conditions can be violated if the feasible region defines an upper limit of the step size. Violating the left-side Goldstein condition can affect the positive definiteness of the quasi-Newton update. In that case, either the update is skipped or the iterations are restarted with an identity matrix, resulting in the steepest descent or ascent search direction. You can specify line-search algorithms other than the default with the LIS= option.

The QUANEW algorithm performs its own line-search technique. All options and parameters (except the INSTEP= option) that control the line search in the other algorithms do not apply here. In several applications, large steps in the first iterations are troublesome. You can use the INSTEP= option to impose an upper bound for the step size $\alpha$ during the first five iterations. You can also use the INHESSIAN[=r] option to specify a different starting approximation for the Hessian. If you specify only the INHESSIAN option, the Cholesky factor of a (possibly ridged) finite difference approximation of the Hessian is used to initialize the quasi-Newton update process. The values of the LCSINGULAR=, LCEPSILON=, and LCDEACT= options, which control the processing of linear and boundary constraints, are valid only for the quadratic programming subroutine used in each iteration of the QUANEW algorithm.
**Double-Dogleg Optimization (DBLDOG)**

The double-dogleg optimization method combines the ideas of the quasi-Newton and trust region methods. In each iteration, the double-dogleg algorithm computes the step \( s^{(k)} \) as the linear combination of the steepest descent or ascent search direction \( s_1^{(k)} \) and a quasi-Newton search direction \( s_2^{(k)} \).

\[
s^{(k)} = \alpha_1 s_1^{(k)} + \alpha_2 s_2^{(k)}
\]

The step is requested to remain within a prespecified trust region radius; see Fletcher (1987, p. 107). Thus, the DBLDOG subroutine uses the dual quasi-Newton update but does not perform a line search. You can specify two update formulas with the UPDATE= option:

- **DBFGS** performs the dual Broyden, Fletcher, Goldfarb, and Shanno update of the Cholesky factor of the Hessian matrix. This is the default.
- **DDFP** performs the dual Davidon, Fletcher, and Powell update of the Cholesky factor of the Hessian matrix.

The double-dogleg optimization technique works well for medium to moderately large optimization problems where the objective function and the gradient are much faster to compute than the Hessian. The implementation is based on Dennis and Mei (1979); Gay (1983). However, this implementation is extended to deal with boundary and linear constraints. The DBLDOG technique generally requires more iterations than the TRUREG, NEWRAP, or NRRIDG technique, which requires second-order derivatives; however, each of the DBLDOG iterations is computationally cheap. Furthermore, the DBLDOG technique requires only gradient calls for the update of the Cholesky factor of an approximate Hessian.

**Conjugate Gradient Optimization (CONGRA)**

Second-order derivatives are not required by the CONGRA algorithm and are not even approximated. The CONGRA algorithm can be expensive in function and gradient calls, but it requires only \( O(n) \) memory for unconstrained optimization. In general, many iterations are required to obtain a precise solution, but each of the CONGRA iterations is computationally cheap. You can specify four different update formulas for generating the conjugate directions by using the UPDATE= option:

- **PB** performs the automatic restart update method of Powell (1977); Beale (1972). This is the default.
- **FR** performs the Fletcher-Reeves update (Fletcher 1987).
- **PR** performs the Polak-Ribiere update (Fletcher 1987).
- **CD** performs a conjugate-descent update of Fletcher (1987).

The default, UPDATE=PB, behaved best in most test examples. You are advised to avoid the option UPDATE=CD, which behaved worst in most test examples.

The CONGRA subroutine should be used for optimization problems with large \( n \). For the unconstrained or boundary constrained case, CONGRA requires only \( O(n) \) bytes of working memory, whereas all other optimization methods require order \( O(n^2) \) bytes of working memory. During \( n \) successive iterations, uninterrupted by restarts or changes in the working set, the conjugate gradient algorithm computes a cycle of \( n \) conjugate search directions. In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The default line-search method uses quadratic
interpolation and cubic extrapolation to obtain a step size \( \alpha \) satisfying the Goldstein conditions. One of the Goldstein conditions can be violated if the feasible region defines an upper limit for the step size. Other line-search algorithms can be specified with the LIS= option.

**Nelder-Mead Simplex Optimization (NMSIMP)**

The Nelder-Mead simplex method does not use any derivatives and does not assume that the objective function has continuous derivatives. The objective function itself needs to be continuous. This technique is quite expensive in the number of function calls, and it might be unable to generate precise results for \( n \) much greater than 40.

The original Nelder-Mead simplex algorithm is implemented and extended to boundary constraints. This algorithm does not compute the objective for infeasible points, but it changes the shape of the simplex by adapting to the nonlinearities of the objective function, which contributes to an increased speed of convergence. It uses a special termination criteria.

---

**Remote Monitoring**

The SAS/EmMonitor is an application for Windows that enables you to monitor and stop from your PC a CPU-intensive application performed by the NLO subsystem that runs on a remote server.

On the server side, a `FILENAME` statement assigns a fileref to a SOCKET-type device that defines the IP address of the client and the port number for listening. The fileref is then specified in the SOCKET= option in the PROC statement to control the EmMonitor. The following statements show an example of server-side statements for PROC ENTROPY.

```plaintext
data one;
  do t = 1 to 10;
    x1 = 5 * ranuni(456);
    x2 = 10 * ranuni(456);
    x3 = 2 * rannor(1456);
    e1 = rannor(1456);
    e2 = rannor(4560);
    tmp1 = 0.5 * e1 - 0.1 * e2;
    tmp2 = -0.1 * e1 - 0.3 * e2;
    y1 = 7 + 8.5*x1 + 2*x2 + tmp1;
    y2 = -3 + -2*x1 + x2 + 3*x3 + tmp2;
  output;
  end;
run;

filename sock socket 'your.pc.address.com:6943';

proc entropy data=one tech=tr gmenm gconv=2.e-5 socket=sock;
  model y1 = x1 x2 x3;
run;
```

On the client side, the EmMonitor application is started with the following syntax:

**EmMonitor options**

The options are:
-p port_number defines the port number
-t title defines the title of the EmMonitor window
-k keeps the monitor alive when the iteration is completed

The default port number is 6943.

The server does not need to be running when you start the EmMonitor, and you can start or dismiss the server at any time during the iteration process. You only need to remember the port number.

Starting the PC client, or closing it prematurely, does not have any effect on the server side. In other words, the iteration process continues until one of the criteria for termination is met.

Figure 6.1 through Figure 6.4 show screenshots of the application on the client side.

**ODS Table Names**

The NLO subsystem assigns a name to each table it creates. You can use these names when using the Output Delivery System (ODS) to select tables and create output data sets. Not all tables are created by all SAS/ETS procedures that use the NLO subsystem. You should check the procedure chapter for more details. The names are listed in the following table.

Overview: ARIMA Procedure

The ARIMA procedure analyzes and forecasts equally spaced univariate time series data, transfer function data, and intervention data by using the autoregressive integrated moving-average (ARIMA) or autoregressive moving-average (ARMA) model. An ARIMA model predicts a value in a response time series as a linear combination of its own past values, past errors (also called shocks or innovations), and current and past values of other time series.

The ARIMA approach was first popularized by Box and Jenkins, and ARIMA models are often referred to as Box-Jenkins models. The general transfer function model employed by the ARIMA procedure was discussed by Box and Tiao (1975). When an ARIMA model includes other time series as input variables, the model is sometimes referred to as an ARIMAX model. Pankratz (1991) refers to the ARIMAX model as *dynamic regression*.

The ARIMA procedure provides a comprehensive set of tools for univariate time series model identification, parameter estimation, and forecasting, and it offers great flexibility in the kinds of ARIMA or ARIMAX
models that can be analyzed. The ARIMA procedure supports seasonal, subset, and factored ARIMA models; intervention or interrupted time series models; multiple regression analysis with ARMA errors; and rational transfer function models of any complexity.

The design of PROC ARIMA closely follows the Box-Jenkins strategy for time series modeling with features for the identification, estimation and diagnostic checking, and forecasting steps of the Box-Jenkins method.

Before you use PROC ARIMA, you should be familiar with Box-Jenkins methods, and you should exercise care and judgment when you use the ARIMA procedure. The ARIMA class of time series models is complex and powerful, and some degree of expertise is needed to use them correctly.

---

**Getting Started: ARIMA Procedure**

This section outlines the use of the ARIMA procedure and gives a cursory description of the ARIMA modeling process for readers who are less familiar with these methods.

---

**The Three Stages of ARIMA Modeling**

The analysis performed by PROC ARIMA is divided into three stages, corresponding to the stages described by Box and Jenkins (1976).

1. In the **identification** stage, you use the IDENTIFY statement to specify the response series and identify candidate ARIMA models for it. The IDENTIFY statement reads time series that are to be used in later statements, possibly differencing them, and computes autocorrelations, inverse autocorrelations, partial autocorrelations, and cross-correlations. Stationarity tests can be performed to determine if differencing is necessary. The analysis of the IDENTIFY statement output usually suggests one or more ARIMA models that could be fit. Options enable you to test for stationarity and tentative ARMA order identification.

2. In the **estimation and diagnostic checking** stage, you use the ESTIMATE statement to specify the ARIMA model to fit to the variable specified in the previous IDENTIFY statement and to estimate the parameters of that model. The ESTIMATE statement also produces diagnostic statistics to help you judge the adequacy of the model.

   Significance tests for parameter estimates indicate whether some terms in the model might be unnecessary. Goodness-of-fit statistics aid in comparing this model to others. Tests for white noise residuals indicate whether the residual series contains additional information that might be used by a more complex model. The OUTLIER statement provides another useful tool to check whether the currently estimated model accounts for all the variation in the series. If the diagnostic tests indicate problems with the model, you try another model and then repeat the estimation and diagnostic checking stage.

3. In the **forecasting** stage, you use the FORECAST statement to forecast future values of the time series and to generate confidence intervals for these forecasts from the ARIMA model produced by the preceding ESTIMATE statement.

These three steps are explained further and illustrated through an extended example in the following sections.
Identification Stage

Suppose you have a variable called SALES that you want to forecast. The following example illustrates ARIMA modeling and forecasting by using a simulated data set TEST that contains a time series SALES generated by an ARIMA(1,1,1) model. The output produced by this example is explained in the following sections. The simulated SALES series is shown in Figure 7.1.

```sas
proc sgplot data=test;
  scatter y=sales x=date;
run;
```

**Figure 7.1** Simulated ARIMA(1,1,1) Series SALES
Using the IDENTIFY Statement

You first specify the input data set in the PROC ARIMA statement. Then, you use an IDENTIFY statement to read in the SALES series and analyze its correlation properties. You do this by using the following statements:

```proc arima data=test ;
   identify var=sales nlag=24;
run;```

Descriptive Statistics

The IDENTIFY statement first prints descriptive statistics for the SALES series. This part of the IDENTIFY statement output is shown in Figure 7.2.

![Figure 7.2 IDENTIFY Statement Descriptive Statistics Output](image)

Autocorrelation Function Plots

The IDENTIFY statement next produces a panel of plots used for its autocorrelation and trend analysis. The panel contains the following plots:

- the time series plot of the series
- the sample autocorrelation function plot (ACF)
- the sample inverse autocorrelation function plot (IACF)
- the sample partial autocorrelation function plot (PACF)

This correlation analysis panel is shown in Figure 7.3.
These autocorrelation function plots show the degree of correlation with past values of the series as a function of the number of periods in the past (that is, the lag) at which the correlation is computed.

The NLAG= option controls the number of lags for which the autocorrelations are shown. By default, the autocorrelation functions are plotted to lag 24.

Most books on time series analysis explain how to interpret the autocorrelation and the partial autocorrelation plots. See the section “The Inverse Autocorrelation Function” on page 234 for a discussion of the inverse autocorrelation plots.

By examining these plots, you can judge whether the series is stationary or nonstationary. In this case, a visual inspection of the autocorrelation function plot indicates that the SALES series is nonstationary, since the ACF decays very slowly. For more formal stationarity tests, use the STATIONARITY= option. (See the section “Stationarity” on page 207.)

**White Noise Test**
The last part of the default IDENTIFY statement output is the check for white noise. This is an approximate statistical test of the hypothesis that none of the autocorrelations of the series up to a given lag are significantly different from 0. If this is true for all lags, then there is no information in the series to model, and no ARIMA model is needed for the series.
The autocorrelations are checked in groups of six, and the number of lags checked depends on the NLAG= option. The check for white noise output is shown in Figure 7.4.

Figure 7.4 IDENTIFY Statement Check for White Noise

<table>
<thead>
<tr>
<th>Lag</th>
<th>Chi-Square</th>

</tr>
<tr>
<td>18</td>
<td>554.70</td>
<td>18</td>
<td>&lt;.0001</td>
<td>0.174 0.112 0.052 -0.004 -0.054 -0.098</td>
</tr>
<tr>
<td>24</td>
<td>585.73</td>
<td>24</td>
<td>&lt;.0001</td>
<td>-0.135 -0.167 -0.192 -0.211 -0.227 -0.240</td>
</tr>
</tbody>
</table>

In this case, the white noise hypothesis is rejected very strongly, which is expected since the series is nonstationary. The $p$-value for the test of the first six autocorrelations is printed as <0.0001, which means the $p$-value is less than 0.0001.

Identification of the Differenced Series

Since the series is nonstationary, the next step is to transform it to a stationary series by differencing. That is, instead of modeling the SALES series itself, you model the change in SALES from one period to the next. To difference the SALES series, use another IDENTIFY statement and specify that the first difference of SALES be analyzed, as shown in the following statements:

```plaintext
proc arima data=test;
   identify var=sales(1);
run;
```

The second IDENTIFY statement produces the same information as the first, but for the change in SALES from one period to the next rather than for the total SALES in each period. The summary statistics output from this IDENTIFY statement is shown in Figure 7.5. Note that the period of differencing is given as 1, and one observation was lost through the differencing operation.

Figure 7.5 IDENTIFY Statement Output for Differenced Series

<table>
<thead>
<tr>
<th>The ARIMA Procedure</th>

<td>Standard Deviation = 2.011543</td>
</tr>
<tr>
<td>Number of Observations = 99</td>
</tr>
<tr>
<td>Observation(s) eliminated by differencing = 1</td>
</tr>
</tbody>
</table>

The autocorrelation plots for the differenced series are shown in Figure 7.6.
The autocorrelations decrease rapidly in this plot, indicating that the change in SALES is a stationary time series.

The next step in the Box-Jenkins methodology is to examine the patterns in the autocorrelation plot to choose candidate ARMA models for the series. The partial and inverse autocorrelation function plots are also useful aids in identifying appropriate ARMA models for the series.

In the usual Box-Jenkins approach to ARIMA modeling, the sample autocorrelation function, inverse autocorrelation function, and partial autocorrelation function are compared with the theoretical correlation functions expected from different kinds of ARMA models. This matching of theoretical autocorrelation functions of different ARMA models to the sample autocorrelation functions computed from the response series is the heart of the identification stage of Box-Jenkins modeling. Most textbooks on time series analysis, such as Pankratz (1983), discuss the theoretical autocorrelation functions for different kinds of ARMA models.

Since the input data are only a limited sample of the series, the sample autocorrelation functions computed from the input series only approximate the true autocorrelation function of the process that generates the series. This means that the sample autocorrelation functions do not exactly match the theoretical autocorrelation functions for any ARMA model and can have a pattern similar to that of several different ARMA models. If the series is white noise (a purely random process), then there is no need to fit a model. The check for
Estimation and Diagnostic Checking Stage

The autocorrelation plots for this series, as shown in the previous section, suggest an AR(1) model for the change in SALES. You should check the diagnostic statistics to see if the AR(1) model is adequate. Other candidate models include an MA(1) model and low-order mixed ARMA models. In this example, the AR(1) model is tried first.

Estimating an AR(1) Model

The following statements fit an AR(1) model (an autoregressive model of order 1), which predicts the change in SALES as an average change, plus some fraction of the previous change, plus a random error. To estimate an AR model, you specify the order of the autoregressive model with the P= option in an ESTIMATE statement:

```
estimate p=1;
run;
```

The ESTIMATE statement fits the model to the data and prints parameter estimates and various diagnostic statistics that indicate how well the model fits the data. The first part of the ESTIMATE statement output, the table of parameter estimates, is shown in Figure 7.8.

![Parameter Estimates for AR(1) Model](image)
The table of parameter estimates is titled “Conditional Least Squares Estimation,” which indicates the estimation method used. You can request different estimation methods with the METHOD= option.

The table of parameter estimates lists the parameters in the model; for each parameter, the table shows the estimated value and the standard error and \( t \) value for the estimate. The table also indicates the lag at which the parameter appears in the model.

In this case, there are two parameters in the model. The mean term is labeled MU; its estimated value is 0.90280. The autoregressive parameter is labeled AR1.1; this is the coefficient of the lagged value of the change in SALES, and its estimate is 0.86847.

The \( t \) values provide significance tests for the parameter estimates and indicate whether some terms in the model might be unnecessary. In this case, the \( t \) value for the autoregressive parameter is 15.83, so this term is highly significant. The \( t \) value for MU indicates that the mean term adds little to the model.

The standard error estimates are based on large sample theory. Thus, the standard errors are labeled as approximate, and the standard errors and \( t \) values might not be reliable in small samples.

The next part of the ESTIMATE statement output is a table of goodness-of-fit statistics, which aid in comparing this model to other models. This output is shown in Figure 7.9.

**Figure 7.9** Goodness-of-Fit Statistics for AR(1) Model

<table>
<thead>

</tr>
<tr>
<td>SBC</td>
<td>302.6372</td>
</tr>
<tr>
<td>Number of Residuals</td>
<td>99</td>
</tr>
</tbody>
</table>

The “Constant Estimate” is a function of the mean term MU and the autoregressive parameters. This estimate is computed only for AR or ARMA models, but not for strictly MA models. See the section “General Notation for ARIMA Models” on page 204 for an explanation of the constant estimate.

The “Variance Estimate” is the variance of the residual series, which estimates the innovation variance. The item labeled “Std Error Estimate” is the square root of the variance estimate. In general, when you are comparing candidate models, smaller AIC and SBC statistics indicate the better fitting model. The section “Estimation Details” on page 242 explains the AIC and SBC statistics.

The ESTIMATE statement next prints a table of correlations of the parameter estimates, as shown in Figure 7.10. This table can help you assess the extent to which collinearity might have influenced the results. If two parameter estimates are very highly correlated, you might consider dropping one of them from the model.
Figure 7.10 Correlations of the Estimates for AR(1) Model

<thead>
<tr>
<th>Correlations of Parameter Estimates</th>
</tr>
</thead>
<tbody>
<tr>
<td>Parameter</td>
</tr>
<tr>
<td>MU</td>
</tr>
<tr>
<td>AR1,1</td>
</tr>
</tbody>
</table>

The next part of the ESTIMATE statement output is a check of the autocorrelations of the residuals. This output has the same form as the autocorrelation check for white noise that the IDENTIFY statement prints for the response series. The autocorrelation check of residuals is shown in Figure 7.11.

Figure 7.11 Check for White Noise Residuals for AR(1) Model

<table>
<thead>

<tr>
<td>18</td>
</tr>
<tr>
<td>24</td>
</tr>
</tbody>
</table>

The $\chi^2$ test statistics for the residuals series indicate whether the residuals are uncorrelated (white noise) or contain additional information that might be used by a more complex model. In this case, the test statistics reject the no-autocorrelation hypothesis at a high level of significance ($p = 0.0019$ for the first six lags.) This means that the residuals are not white noise, and so the AR(1) model is not a fully adequate model for this series. The ESTIMATE statement output also includes graphical analysis of the residuals. It is not shown here. The graphical analysis also reveals the inadequacy of the AR(1) model.

The final part of the ESTIMATE statement output is a listing of the estimated model, using the backshift notation. This output is shown in Figure 7.12.

Figure 7.12 Estimated ARIMA(1, 1, 0) Model for SALES

Model for variable sales

Estimated Mean 0.902799
Period(s) of Differencing 1

Autoregressive Factors

Factor 1: 1 - 0.86847 B**1
This listing combines the differencing specification given in the IDENTIFY statement with the parameter estimates of the model for the change in SALES. Since the AR(1) model is for the change in SALES, the final model for SALES is an ARIMA(1,1,0) model. Using $B$, the backshift operator, the mathematical form of the estimated model shown in this output is as follows:

$$(1 - B)_{\text{sales}} t = 0.902799 + \frac{1}{(1 - 0.86847B)} a_t$$

See the section “General Notation for ARIMA Models” on page 204 for further explanation of this notation.

### Estimating an ARMA(1,1) Model

The IDENTIFY statement plots suggest a mixed autoregressive and moving-average model, and the previous ESTIMATE statement check of residuals indicates that an AR(1) model is not sufficient. You now try estimating an ARMA(1,1) model for the change in SALES.

An ARMA(1,1) model predicts the change in SALES as an average change, plus some fraction of the previous change, plus a random error, plus some fraction of the random error in the preceding period. An ARMA(1,1) model for the change in SALES is the same as an ARIMA(1,1,1) model for the level of SALES.

To estimate a mixed autoregressive moving-average model, you specify the order of the moving-average part of the model with the Q= option in an ESTIMATE statement in addition to specifying the order of the autoregressive part with the P= option. The following statements fit an ARMA(1,1) model to the differenced SALES series:

```plaintext
estimate p=1 q=1;
run;
```

The parameter estimates table and goodness-of-fit statistics for this model are shown in Figure 7.13.

#### Figure 7.13 Estimated ARMA(1, 1) Model for Change in SALES

| Parameter | Estimate | Standard Error | t Value | Pr > |t| | Lag |
|-----------|----------|----------------|---------|------|---|-----|
| MU        | 0.89288  | 0.49391        | 1.81    | 0.0738 | 0 |
| MA1,1     | -0.58935 | 0.08988        | -6.56   | <.0001 | 1 |
| AR1,1     | 0.74755  | 0.07785        | 9.60    | <.0001 | 1 |

The moving-average parameter estimate, labeled “MA1,1”, is –0.58935. Both the moving-average and the autoregressive parameters have significant $t$ values. Note that the variance estimate, AIC, and SBC are all smaller than they were for the AR(1) model, indicating that the ARMA(1,1) model fits the data better without over-parameterizing.

The graphical check of the residuals from this model is shown in Figure 7.14 and Figure 7.15. The residual correlation and white noise test plots show that you cannot reject the hypothesis that the residuals are uncorrelated. The normality plots also show no departure from normality. Thus, you conclude that the ARMA(1,1) model is adequate for the change in SALES series, and there is no point in trying more complex models.

**Figure 7.14** White Noise Check of Residuals for the ARMA(1,1) Model
The form of the estimated ARIMA(1,1,1) model for SALES is shown in Figure 7.16.

Factor 1: 1 + 0.58935 B**(1)

The estimated model shown in this output is

\[(1 - B)sales_t = 0.892875 + \frac{(1 + 0.58935B)}{(1 - 0.74755B)}a_t\]
In addition to the residual analysis of a model, it is often useful to check whether there are any changes in the time series that are not accounted for by the currently estimated model. The OUTLIER statement enables you to detect such changes. For a long series, this task can be computationally burdensome. Therefore, in general, it is better done after a model that fits the data reasonably well has been found. Figure 7.17 shows the output of the simplest form of the OUTLIER statement:

```
outlier;
run;
```

Two possible outliers have been found for the model in question. See the section “Detecting Outliers” on page 253, and the examples Example 7.6 and Example 7.7, for more details about modeling in the presence of outliers. In this illustration these outliers are not discussed any further.

**Figure 7.17** Outliers for the ARIMA(1,1,1) Model for SALES

Since the model diagnostic tests show that all the parameter estimates are significant and the residual series is white noise, the estimation and diagnostic checking stage is complete. You can now proceed to forecasting the SALES series with this ARIMA(1,1,1) model.

**Forecasting Stage**

To produce the forecast, use a FORECAST statement after the ESTIMATE statement for the model you decide is best. If the last model fit is not the best, then repeat the ESTIMATE statement for the best model before you use the FORECAST statement.

Suppose that the SALES series is monthly, that you want to forecast one year ahead from the most recently available SALES figure, and that the dates for the observations are given by a variable DATE in the input data set TEST. You use the following FORECAST statement:

```
forecast lead=12 interval=month id=date out=results;
run;
```
The LEAD= option specifies how many periods ahead to forecast (12 months, in this case). The ID= option specifies the ID variable, which is typically a SAS date, time, or datetime variable, used to date the observations of the SALES time series. The INTERVAL= option indicates that data are monthly and enables PROC ARIMA to extrapolate DATE values for forecast periods. The OUT= option writes the forecasts to the output data set RESULTS. See the section “OUT= Data Set” on page 255 for information about the contents of the output data set.

By default, the FORECAST statement also prints and plots the forecast values, as shown in Figure 7.18 and Figure 7.19. The forecast table shows for each forecast period the observation number, forecast value, standard error estimate for the forecast value, and lower and upper limits for a 95% confidence interval for the forecast.

Normally, you want the forecast values stored in an output data set, and you are not interested in seeing this printed list of the forecast. You can use the NOPRINT option in the FORECAST statement to suppress this output.

Using ARIMA Procedure Statements

The IDENTIFY, ESTIMATE, and FORECAST statements are related in a hierarchy. An IDENTIFY statement brings in a time series to be modeled; several ESTIMATE statements can follow to estimate different ARIMA models for the series; for each model estimated, several FORECAST statements can be used. Thus, a FORECAST statement must be preceded at some point by an ESTIMATE statement, and an ESTIMATE statement must be preceded at some point by an IDENTIFY statement. Additional IDENTIFY statements can be used to switch to modeling a different response series or to change the degree of differencing used.

The ARIMA procedure can be used interactively in the sense that all ARIMA procedure statements can be executed any number of times without reinvoking PROC ARIMA. You can execute ARIMA procedure statements singly or in groups by following the single statement or group of statements with a RUN statement. The output for each statement or group of statements is produced when the RUN statement is entered.
A RUN statement does not terminate the PROC ARIMA step but tells the procedure to execute the statements given so far. You can end PROC ARIMA by submitting a QUIT statement, a DATA step, another PROC step, or an ENDSAS statement.

The example in the preceding section illustrates the interactive use of ARIMA procedure statements. The complete PROC ARIMA program for that example is as follows:

```plaintext
proc arima data=test;
   identify var=sales nlag=24;
   run;
   identify var=sales(1);
   run;
   estimate p=1;
   run;
   estimate p=1 q=1;
   run;
   outlier;
   run;
   forecast lead=12 interval=month id=date out=results;
   run;
quit;
```

---

**General Notation for ARIMA Models**

The order of an ARIMA (autoregressive integrated moving-average) model is usually denoted by the notation ARIMA($p,d,q$), where

- $p$ is the order of the autoregressive part
- $d$ is the order of the differencing
- $q$ is the order of the moving-average process

If no differencing is done ($d = 0$), the models are usually referred to as ARMA($p,q$) models. The final model in the preceding example is an ARIMA($1,1,1$) model since the IDENTIFY statement specified $d = 1$, and the final ESTIMATE statement specified $p = 1$ and $q = 1$.

**Notation for Pure ARIMA Models**

Mathematically the pure ARIMA model is written as

$$W_t = \mu + \frac{\theta(B)}{\phi(B)}a_t$$

where

- $t$ indexes time
- $W_t$ is the response series $Y_t$ or a difference of the response series
- $\mu$ is the mean term
- $B$ is the backshift operator; that is, $BX_t = X_{t-1}$
\( \phi(B) \) is the autoregressive operator, represented as a polynomial in the backshift operator: 
\[
\phi(B) = 1 - \phi_1 B - \ldots - \phi_p B^p
\]

\( \theta(B) \) is the moving-average operator, represented as a polynomial in the backshift operator: 
\[
\theta(B) = 1 - \theta_1 B - \ldots - \theta_q B^q
\]

\( \epsilon_t \) is the independent disturbance, also called the random error

The series \( W_t \) is computed by the IDENTIFY statement and is the series processed by the ESTIMATE statement. Thus, \( W_t \) is either the response series \( Y_t \) or a difference of \( Y_t \) specified by the differencing operators in the IDENTIFY statement.

For simple (nonseasonal) differencing, \( W_t = (1 - B)^d Y_t \). For seasonal differencing \( W_t = (1 - B)^d (1 - B^s)^D Y_t \), where \( d \) is the degree of nonseasonal differencing, \( D \) is the degree of seasonal differencing, and \( s \) is the length of the seasonal cycle.

For example, the mathematical form of the ARIMA(1,1,1) model estimated in the preceding example is
\[
(1 - B)Y_t = \mu + \frac{(1 - \theta_1 B)}{(1 - \phi_1 B)} \epsilon_t
\]

**Model Constant Term**

The ARIMA model can also be written as
\[
\phi(B)(W_t - \mu) = \theta(B) \epsilon_t
\]
or
\[
\phi(B)W_t = \text{const} + \theta(B) \epsilon_t
\]

where
\[
\text{const} = \phi(B) \mu = \mu - \phi_1 \mu - \phi_2 \mu - \ldots - \phi_p \mu
\]

Thus, when an autoregressive operator and a mean term are both included in the model, the constant term for the model can be represented as \( \phi(B) \mu \). This value is printed with the label “Constant Estimate” in the ESTIMATE statement output.

**Notation for Transfer Function Models**

The general ARIMA model with input series, also called the ARIMAX model, is written as
\[
W_t = \mu + \sum_i \frac{\omega_i(B)}{\delta_i(B)} B^{k_i} X_{i,t} + \frac{\theta(B)}{\phi(B)} \epsilon_t
\]

where
\[
X_{i,t} \quad \text{is the } i\text{th input time series or a difference of the } i\text{th input series at time } t
\]
\[
k_i \quad \text{is the pure time delay for the effect of the } i\text{th input series}
\]
\[
\omega_i(B) \quad \text{is the numerator polynomial of the transfer function for the } i\text{th input series}
\]
\( \delta_i(B) \) is the denominator polynomial of the transfer function for the \( i \)th input series.

The model can also be written more compactly as

\[
W_t = \mu + \sum_i \Psi_i(B)X_{i,t} + n_t
\]

where

\[
\Psi_i(B) \quad \text{is the transfer function for the } i \text{th input series modeled as a ratio of the } \omega \text{ and } \delta \text{ polynomials:}
\]

\[
\Psi_i(B) = (\omega_i(B)/\delta_i(B))B^{k_i}
\]

\( n_t \) is the noise series: \( n_t = (\theta(B)/\phi(B))\alpha_t \)

This model expresses the response series as a combination of past values of the random shocks and past values of other input series. The response series is also called the dependent series or output series. An input time series is also referred to as an independent series or a predictor series. Response variable, dependent variable, independent variable, or predictor variable are other terms often used.

**Notation for Factored Models**

ARIMA models are sometimes expressed in a factored form. This means that the \( \phi \), \( \theta \), \( \omega \), or \( \delta \) polynomials are expressed as products of simpler polynomials. For example, you could express the pure ARIMA model as

\[
W_t = \mu + \frac{\theta_1(B)\theta_2(B)}{\phi_1(B)\phi_2(B)}\alpha_t
\]

where \( \phi_1(B)\phi_2(B) = \phi(B) \) and \( \theta_1(B)\theta_2(B) = \theta(B) \).

When an ARIMA model is expressed in factored form, the order of the model is usually expressed by using a factored notation also. The order of an ARIMA model expressed as the product of two factors is denoted as ARIMA\((p,d,q)_{(PD,Q)}\).

**Notation for Seasonal Models**

ARIMA models for time series with regular seasonal fluctuations often use differencing operators and autoregressive and moving-average parameters at lags that are multiples of the length of the seasonal cycle. When all the terms in an ARIMA model factor refer to lags that are a multiple of a constant \( s \), the constant is factored out and suffixed to the ARIMA\((p,d,q)\) notation.

Thus, the general notation for the order of a seasonal ARIMA model with both seasonal and nonseasonal factors is ARIMA\((p,d,q)_{(PD,Q)}\). The term \((p,d,q)\) gives the order of the nonseasonal part of the ARIMA model; the term \((PD,Q)\) gives the order of the seasonal part. The value of \( s \) is the number of observations in a seasonal cycle: 12 for monthly series, 4 for quarterly series, 7 for daily series with day-of-week effects, and so forth.

For example, the notation ARIMA\((0,1,2)_{(0,1,1)}\) describes a seasonal ARIMA model for monthly data with the following mathematical form:

\[
(1 - B)(1 - B^{12})Y_t = \mu + (1 - \theta_{1,1}B - \theta_{1,2}B^2)(1 - \theta_{2,1}B^{12})\alpha_t
\]
Stationarity

The noise (or residual) series for an ARMA model must be stationary, which means that both the expected values of the series and its autocovariance function are independent of time.

The standard way to check for nonstationarity is to plot the series and its autocorrelation function. You can visually examine a graph of the series over time to see if it has a visible trend or if its variability changes noticeably over time. If the series is nonstationary, its autocorrelation function will usually decay slowly.

Another way of checking for stationarity is to use the stationarity tests described in the section “Stationarity Tests” on page 241.

Most time series are nonstationary and must be transformed to a stationary series before the ARIMA modeling process can proceed. If the series has a nonstationary variance, taking the log of the series can help. You can compute the log values in a DATA step and then analyze the log values with PROC ARIMA.

If the series has a trend over time, seasonality, or some other nonstationary pattern, the usual solution is to take the difference of the series from one period to the next and then analyze this differenced series. Sometimes a series might need to be differenced more than once or differenced at lags greater than one period. (If the trend or seasonal effects are very regular, the introduction of explanatory variables can be an appropriate alternative to differencing.)

Differencing

Differencing of the response series is specified with the VAR= option of the IDENTIFY statement by placing a list of differencing periods in parentheses after the variable name. For example, to take a simple first difference of the series SALES, use the statement

    identify var=sales(1);

In this example, the change in SALES from one period to the next is analyzed.

A deterministic seasonal pattern also causes the series to be nonstationary, since the expected value of the series is not the same for all time periods but is higher or lower depending on the season. When the series has a seasonal pattern, you might want to difference the series at a lag that corresponds to the length of the seasonal cycle. For example, if SALES is a monthly series, the statement

    identify var=sales(12);

takes a seasonal difference of SALES, so that the series analyzed is the change in SALES from its value in the same month one year ago.

To take a second difference, add another differencing period to the list. For example, the following statement takes the second difference of SALES:

    identify var=sales(1,1);

That is, SALES is differenced once at lag 1 and then differenced again, also at lag 1. The statement
Chapter 7: The ARIMA Procedure

`identify var=sales(2);`

creates a 2-span difference—that is, current period SALES minus SALES from two periods ago. The statement

`identify var=sales(1,12);`

takes a second-order difference of SALES, so that the series analyzed is the difference between the current period-to-period change in SALES and the change 12 periods ago. You might want to do this if the series had both a trend over time and a seasonal pattern.

There is no limit to the order of differencing and the degree of lagging for each difference.

Differencing not only affects the series used for the IDENTIFY statement output but also applies to any following ESTIMATE and FORECAST statements. ESTIMATE statements fit ARMA models to the differenced series. FORECAST statements forecast the differences and automatically sum these differences back to undo the differencing operation specified by the IDENTIFY statement, thus producing the final forecast result.

Differencing of input series is specified by the CROSSCORR= option and works just like differencing of the response series. For example, the statement

`identify var=y(1) crosscorr=(x1(1) x2(1));`

takes the first difference of Y, the first difference of X1, and the first difference of X2. Whenever X1 and X2 are used in INPUT= options in following ESTIMATE statements, these names refer to the differenced series.

---

**Subset, Seasonal, and Factored ARMA Models**

The simplest way to specify an ARMA model is to give the order of the AR and MA parts with the P= and Q= options. When you do this, the model has parameters for the AR and MA parts for all lags through the order specified. However, you can control the form of the ARIMA model exactly as shown in the following section.

**Subset Models**

You can control which lags have parameters by specifying the P= or Q= option as a list of lags in parentheses. A model that includes parameters for only some lags is sometimes called a *subset* or *additive model*. For example, consider the following two ESTIMATE statements:

```plaintext
identify var=sales;
estimate p=4;
estimate p=(1 4);
```

Both specify AR(4) models, but the first has parameters for lags 1, 2, 3, and 4, while the second has parameters for lags 1 and 4, with the coefficients for lags 2 and 3 constrained to 0. The mathematical form of the autoregressive models produced by these two specifications is shown in Table 7.1.
Subset, Seasonal, and Factored ARMA Models

### Table 7.1  Saturated versus Subset Models

<table>
<thead>
<tr>
<th>Option</th>
<th>Autoregressive Operator</th>
</tr>
</thead>
<tbody>
<tr>
<td>P=4</td>
<td>((1 - \phi_1 B - \phi_2 B^2 - \phi_3 B^3 - \phi_4 B^4))</td>
</tr>
<tr>
<td>P=(1 4)</td>
<td>((1 - \phi_1 B - \phi_4 B^4))</td>
</tr>
</tbody>
</table>

### Seasonal Models

One particularly useful kind of subset model is a *seasonal model*. When the response series has a seasonal pattern, the values of the series at the same time of year in previous years can be important for modeling the series. For example, if the series `SALES` is observed monthly, the statements

```plaintext
identify var=sales;
estimate p=(12);
```

model `SALES` as an average value plus some fraction of its deviation from this average value a year ago, plus a random error. Although this is an AR(12) model, it has only one autoregressive parameter.

### Factored Models

A factored model (also referred to as a multiplicative model) represents the ARIMA model as a product of simpler ARIMA models. For example, you might model `SALES` as a combination of an AR(1) process that reflects short term dependencies and an AR(12) model that reflects the seasonal pattern.

It might seem that the way to do this is with the option `P=(1 12)`, but the AR(1) process also operates in past years; you really need autoregressive parameters at lags 1, 12, and 13. You can specify a subset model with separate parameters at these lags, or you can specify a factored model that represents the model as the product of an AR(1) model and an AR(12) model. Consider the following two ESTIMATE statements:

```plaintext
identify var=sales;
estimate p=(1 12 13);
estimate p=(1)(12);
```

The mathematical form of the autoregressive models produced by these two specifications are shown in Table 7.2.

### Table 7.2  Subset versus Factored Models

<table>
<thead>
<tr>
<th>Option</th>
<th>Autoregressive Operator</th>
</tr>
</thead>
<tbody>
<tr>
<td>P=(1 12 13)</td>
<td>((1 - \phi_1 B - \phi_{12} B^{12} - \phi_{13} B^{13}))</td>
</tr>
<tr>
<td>P=(1)(12)</td>
<td>((1 - \phi_1 B)(1 - \phi_{12} B^{12}))</td>
</tr>
</tbody>
</table>

Both models fit by these two ESTIMATE statements predict `SALES` from its values 1, 12, and 13 periods ago, but they use different parameterizations. The first model has three parameters, whose meanings may be hard to interpret.

The factored specification `P=(1)(12)` represents the model as the product of two different AR models. It has only two parameters: one that corresponds to recent effects and one that represents seasonal effects. Thus the factored model is more parsimonious, and its parameter estimates are more clearly interpretable.
**Input Variables and Regression with ARMA Errors**

In addition to past values of the response series and past errors, you can also model the response series using the current and past values of other series, called *input series*.

Several different names are used to describe ARIMA models with input series. *Transfer function model, intervention model, interrupted time series model, regression model with ARMA errors, Box-Tiao model, and ARIMAX model* are all different names for ARIMA models with input series. Pankratz (1991) refers to these models as *dynamic regression* models.

**Using Input Series**

To use input series, list the input series in a CROSSCORR= option on the IDENTIFY statement and specify how they enter the model with an INPUT= option on the ESTIMATE statement. For example, you might use a series called *PRICE* to help model *SALES*, as shown in the following statements:

```sas
proc arima data=a;
   identify var=sales crosscorr=price;
   estimate input=price;
run;
```

This example performs a simple linear regression of *SALES* on *PRICE*; it produces the same results as PROC REG or another SAS regression procedure. The mathematical form of the model estimated by these statements is

\[
Y_t = \mu + \omega_0 X_t + a_t
\]

The parameter estimates table for this example (using simulated data) is shown in Figure 7.20. The intercept parameter is labeled MU. The regression coefficient for *PRICE* is labeled NUM1. (See the section “Naming of Model Parameters” on page 249 for information about how parameters for input series are named.)

**Figure 7.20 Parameter Estimates Table for Regression Model**

| Parameter | Estimate | Standard Error | t Value | Pr > |t| | Lag | Variable | Shift |
|-----------|----------|----------------|---------|-------|-----|-----|---------|-------|
| MU        | 199.83602 | 2.99463        | 66.73   | <.0001 | 0   | sales | 0       |
| NUM1      | -9.99299 | 0.02885        | -346.38 | <.0001 | 0   | price | 0       |

Any number of input variables can be used in a model. For example, the following statements fit a multiple regression of *SALES* on *PRICE* and *INCOME*:

```sas
proc arima data=a;
   identify var=sales crosscorr=(price income);
   estimate input=(price income);
run;
```
The mathematical form of the regression model estimated by these statements is

\[ Y_t = \mu + \omega_1 X_{1,t} + \omega_2 X_{2,t} + a_t \]

**Lagging and Differencing Input Series**

You can also difference and lag the input series. For example, the following statements regress the change in SALES on the change in PRICE lagged by one period. The difference of PRICE is specified with the CROSSCORR= option and the lag of the change in PRICE is specified by the 1 $ in the INPUT= option.

```
proc arima data=a;
  identify var=sales(1) crosscorr=price(1);
  estimate input=( 1 $ price );
run;
```

These statements estimate the model

\[ (1 - B)Y_t = \mu + \omega_0 (1 - B)X_{t-1} + a_t \]

**Regression with ARMA Errors**

You can combine input series with ARMA models for the errors. For example, the following statements regress SALES on INCOME and PRICE but with the error term of the regression model (called the noise series in ARIMA modeling terminology) assumed to be an ARMA(1,1) process.

```
proc arima data=a;
  identify var=sales crosscorr=(price income);
  estimate p=1 q=1 input=(price income);
run;
```

These statements estimate the model

\[ Y_t = \mu + \omega_1 X_{1,t} + \omega_2 X_{2,t} + \frac{(1 - \theta_1 B)}{(1 - \phi_1 B)} a_t \]

**Stationarity and Input Series**

Note that the requirement of stationarity applies to the noise series. If there are no input variables, the response series (after differencing and minus the mean term) and the noise series are the same. However, if there are inputs, the noise series is the residual after the effect of the inputs is removed.

There is no requirement that the input series be stationary. If the inputs are nonstationary, the response series will be nonstationary, even though the noise process might be stationary.

When nonstationary input series are used, you can fit the input variables first with no ARMA model for the errors and then consider the stationarity of the residuals before identifying an ARMA model for the noise part.
Identifying Regression Models with ARMA Errors

Previous sections described the ARIMA modeling identification process that uses the autocorrelation function plots produced by the IDENTIFY statement. This identification process does not apply when the response series depends on input variables. This is because it is the noise process for which you need to identify an ARIMA model, and when input series are involved the response series adjusted for the mean is no longer an estimate of the noise series.

However, if the input series are independent of the noise series, you can use the residuals from the regression model as an estimate of the noise series, then apply the ARIMA modeling identification process to this residual series. This assumes that the noise process is stationary.

The PLOT option in the ESTIMATE statement produces similar plots for the model residuals as the IDENTIFY statement produces for the response series. The PLOT option prints an autocorrelation function plot, an inverse autocorrelation function plot, and a partial autocorrelation function plot for the residual series. Note that these residual correlation plots are produced by default.

The following statements show how the PLOT option is used to identify the ARMA(1,1) model for the noise process used in the preceding example of regression with ARMA errors:

```plaintext
proc arima data=a;
   identify var=sales crosscorr=(price income) noprint;
   estimate input=(price income) plot;
   run;
   estimate p=1 q=1 input=(price income);
run;
```

In this example, the IDENTIFY statement includes the NOPRINT option since the autocorrelation plots for the response series are not useful when you know that the response series depends on input series.

The first ESTIMATE statement fits the regression model with no model for the noise process. The PLOT option produces plots of the autocorrelation function, inverse autocorrelation function, and partial autocorrelation function for the residual series of the regression on PRICE and INCOME.

By examining the PLOT option output for the residual series, you verify that the residual series is stationary and identify an ARMA(1,1) model for the noise process. The second ESTIMATE statement fits the final model.

Although this discussion addresses regression models, the same remarks apply to identifying an ARIMA model for the noise process in models that include input series with complex transfer functions.

---

**Intervention Models and Interrupted Time Series**

One special kind of ARIMA model with input series is called an *intervention model* or *interrupted time series* model. In an intervention model, the input series is an indicator variable that contains discrete values that flag the occurrence of an event affecting the response series. This event is an intervention in or an interruption of the normal evolution of the response time series, which, in the absence of the intervention, is usually assumed to be a pure ARIMA process.
Intervention models can be used both to model and forecast the response series and also to analyze the impact of the intervention. When the focus is on estimating the effect of the intervention, the process is often called *intervention analysis* or *interrupted time series analysis*.

**Impulse Interventions**

The intervention can be a one-time event. For example, you might want to study the effect of a short-term advertising campaign on the sales of a product. In this case, the input variable has the value of 1 for the period during which the advertising campaign took place and the value 0 for all other periods. Intervention variables of this kind are sometimes called *impulse functions* or *pulse functions*.

Suppose that `SALES` is a monthly series, and a special advertising effort was made during the month of March 1992. The following statements estimate the effect of this intervention by assuming an ARMA(1,1) model for `SALES`. The model is specified just like the regression model, but the intervention variable `AD` is constructed in the DATA step as a zero-one indicator for the month of the advertising effort.

```plaintext
data a;
  set a;
  ad = (date = '1mar1992'd);
run;

proc arima data=a;
  identify var=sales crosscorr=ad;
  estimate p=1 q=1 input=ad;
run;
```

**Continuing Interventions**

Other interventions can be continuing, in which case the input variable flags periods before and after the intervention. For example, you might want to study the effect of a change in tax rates on some economic measure. Another example is a study of the effect of a change in speed limits on the rate of traffic fatalities. In this case, the input variable has the value 1 after the new speed limit went into effect and the value 0 before. Intervention variables of this kind are called *step functions*.

Another example is the effect of news on product demand. Suppose it was reported in July 1996 that consumption of the product prevents heart disease (or causes cancer), and `SALES` is consistently higher (or lower) thereafter. The following statements model the effect of this news intervention:

```plaintext
data a;
  set a;
  news = (date >= '1jul1996'd);
run;

proc arima data=a;
  identify var=sales crosscorr=news;
  estimate p=1 q=1 input=news;
run;
```
Interaction Effects

You can include any number of intervention variables in the model. Intervention variables can have any pattern—impulse and continuing interventions are just two possible cases. You can mix discrete valued intervention variables and continuous regressor variables in the same model.

You can also form interaction effects by multiplying input variables and including the product variable as another input. Indeed, as long as the dependent measure is continuous and forms a regular time series, you can use PROC ARIMA to fit any general linear model in conjunction with an ARMA model for the error process by using input variables that correspond to the columns of the design matrix of the linear model.

Rational Transfer Functions and Distributed Lag Models

How an input series enters the model is called its transfer function. Thus, ARIMA models with input series are sometimes referred to as transfer function models.

In the preceding regression and intervention model examples, the transfer function is a single scale parameter. However, you can also specify complex transfer functions composed of numerator and denominator polynomials in the backshift operator. These transfer functions operate on the input series in the same way that the ARMA specification operates on the error term.

Numerator Factors

For example, suppose you want to model the effect of PRICE on SALES as taking place gradually with the impact distributed over several past lags of PRICE. This is illustrated by the following statements:

```plaintext
proc arima data=a;
   identify var=sales crosscorr=price;
   estimate input=( (1 2 3) price );
run;
```

These statements estimate the model

\[ Y_t = \mu + (\omega_0 - \omega_1 B - \omega_2 B^2 - \omega_3 B^3) X_t + a_t \]

This example models the effect of PRICE on SALES as a linear function of the current and three most recent values of PRICE. It is equivalent to a multiple linear regression of SALES on PRICE, LAG(PRICE), LAG2(PRICE), and LAG3(PRICE).

This is an example of a transfer function with one numerator factor. The numerator factors for a transfer function for an input series are like the MA part of the ARMA model for the noise series.

Denominator Factors

You can also use transfer functions with denominator factors. The denominator factors for a transfer function for an input series are like the AR part of the ARMA model for the noise series. Denominator factors introduce exponentially weighted, infinite distributed lags into the transfer function.
To specify transfer functions with denominator factors, place the denominator factors after a slash (/) in the INPUT= option. For example, the following statements estimate the \textit{PRICE} effect as an infinite distributed lag model with exponentially declining weights:

```plaintext
proc arima data=a;
   identify var=sales crosscorr=price;
   estimate input=( / (1) price );
run;
```

The transfer function specified by these statements is as follows:

$$\frac{\omega_0}{(1 - \delta_1 B)} X_t$$

This transfer function also can be written in the following equivalent form:

$$\omega_0 \left( 1 + \sum_{i=1}^{\infty} \delta_i B^i \right) X_t$$

This transfer function can be used with intervention inputs. When it is used with a pulse function input, the result is an intervention effect that dies out gradually over time. When it is used with a step function input, the result is an intervention effect that increases gradually to a limiting value.

\textbf{Rational Transfer Functions}

By combining various numerator and denominator factors in the INPUT= option, you can specify \textit{rational transfer functions} of any complexity. To specify an input with a general rational transfer function of the form

$$\frac{\omega(B)}{\delta(B)} B^k X_t$$

use an INPUT= option in the ESTIMATE statement of the form

\texttt{input=\{ k \$ ( \omega-lags ) / ( \delta-lags ) \ x \}}

See the section “Specifying Inputs and Transfer Functions” on page 247 for more information.

\textbf{Identifying Transfer Function Models}

The CROSSCORR= option of the IDENTIFY statement prints sample cross-correlation functions that show the correlation between the response series and the input series at different lags. The sample cross-correlation function can be used to help identify the form of the transfer function appropriate for an input series. See textbooks on time series analysis for information about using cross-correlation functions to identify transfer function models.

For the cross-correlation function to be meaningful, the input and response series must be filtered with a prewhitening model for the input series. See the section “Prewhitening” on page 241 for more information about this issue.
### Forecasting with Input Variables

To forecast a response series by using an ARIMA model with inputs, you need values of the input series for the forecast periods. You can supply values for the input variables for the forecast periods in the DATA= data set, or you can have PROC ARIMA forecast the input variables.

If you do not have future values of the input variables in the input data set used by the FORECAST statement, the input series must be forecast before the ARIMA procedure can forecast the response series. If you fit an ARIMA model to each of the input series for which you need forecasts before fitting the model for the response series, the FORECAST statement automatically uses the ARIMA models for the input series to generate the needed forecasts of the inputs.

For example, suppose you want to forecast SALES for the next 12 months. In this example, the change in SALES is predicted as a function of the change in PRICE, plus an ARMA(1,1) noise process. To forecast SALES by using PRICE as an input, you also need to fit an ARIMA model for PRICE.

The following statements fit an AR(2) model to the change in PRICE before fitting and forecasting the model for SALES. The FORECAST statement automatically forecasts PRICE using this AR(2) model to get the future inputs needed to produce the forecast of SALES.

```plaintext
proc arima data=a;
   identify var=price(1);
   estimate p=2;
   identify var=sales(1) crosscorr=price(1);
   estimate p=1 q=1 input=price;
   forecast lead=12 interval=month id=date out=results;
run;
```

Fitting a model to the input series is also important for identifying transfer functions. (See the section “Prewhitening” on page 241 for more information.)

Input values from the DATA= data set and input values forecast by PROC ARIMA can be combined. For example, a model for SALES might have three input series: PRICE, INCOME, and TAXRATE. For the forecast, you assume that the tax rate will be unchanged. You have a forecast for INCOME from another source but only for the first few periods of the SALES forecast you want to make. You have no future values for PRICE, which needs to be forecast as in the preceding example.
In this situation, you include observations in the input data set for all forecast periods, with \textsc{sales} and \textsc{price} set to a missing value, with \textsc{taxrate} set to its last actual value, and with \textsc{income} set to forecast values for the periods you have forecasts for and set to missing values for later periods. In the PROC ARIMA step, you estimate ARIMA models for \textsc{price} and \textsc{income} before you estimate the model for \textsc{sales}, as shown in the following statements:

```
proc arima data=a;
  identify var=price(1);
  estimate p=2;
  identify var=income(1);
  estimate p=2;
  identify var=sales(1) crosscorr=( price(1) income(1) taxrate );
  estimate p=1 q=1 input=( price income taxrate );
  forecast lead=12 interval=month id=date out=results;
run;
```

In forecasting \textsc{sales}, the ARIMA procedure uses as inputs the value of \textsc{price} forecast by its ARIMA model, the value of \textsc{taxrate} found in the DATA= data set, and the value of \textsc{income} found in the DATA= data set, or, when the \textsc{income} variable is missing, the value of \textsc{income} forecast by its ARIMA model. (Because \textsc{sales} is missing for future time periods, the estimation of model parameters is not affected by the forecast values for \textsc{price}, \textsc{income}, or \textsc{taxrate}.)

---

**Data Requirements**

PROC ARIMA can handle time series of moderate size; there should be at least 30 observations. With fewer than 30 observations, the parameter estimates might be poor. With thousands of observations, the method requires considerable computer time and memory.

---

**Syntax: ARIMA Procedure**

The ARIMA procedure uses the following statements:

- **PROC ARIMA** \textit{options} ;
- \textbf{BY} \textit{variables} ;
- **IDENTIFY** \textit{VAR=variable options} ;
- **ESTIMATE** \textit{options} ;
- **OUTLIER** \textit{options} ;
- **FORECAST** \textit{options} ;

The \textbf{PROC ARIMA} and \textbf{IDENTIFY} statements are required.
### Functional Summary

The statements and options that control the ARIMA procedure are summarized in Table 7.3.

**PROC ARIMA Statement**

PROC ARIMA options;

The following options can be used in the PROC ARIMA statement.
DATA=SAS-data-set

specifies the name of the SAS data set that contains the time series. If different DATA= specifications appear in the PROC ARIMA and IDENTIFY statements, the one in the IDENTIFY statement is used. If the DATA= option is not specified in either the PROC ARIMA or IDENTIFY statement, the most recently created SAS data set is used.

PLOTS<(global-plot-options)> <= plot-request <(options) >>

controls the plots produced through ODS Graphics. When you specify only one plot request, you can omit the parentheses around the plot request.

Here are some examples:

plots=none
plots=all
plots(unpack)=series(corr crosscorr)
plots(only)=(series(corr crosscorr) residual(normal smooth))

Global Plot Options:

The global-plot-options apply to all relevant plots generated by the ARIMA procedure. The following global-plot-options are supported:

ONLY
 suppresses the default plots. Only the plots specifically requested are produced.

UNPACK
 displays each graph separately. (By default, some graphs can appear together in a single panel.)

Specific Plot Options

The following list describes the specific plots and their options.

ALL
 produces all plots appropriate for the particular analysis.

NONE
 suppresses all plots.

SERIES(<series-plot-options>)
 produces plots associated with the identification stage of the modeling. The panel plots corresponding to the CORR and CROSSCORR options are produced by default. The following series-plot-options are available:

ACF
 produces the plot of autocorrelations.

ALL
 produces all the plots associated with the identification stage.
Chapter 7: The ARIMA Procedure

**CORR**
produces a panel of plots that are useful in the trend and correlation analysis of the series. The panel consists of the following:

- the time series plot
- the series-autocorrelation plot
- the series-partial-autocorrelation plot
- the series-inverse-autocorrelation plot

**CROSSCORR**
produces panels of cross-correlation plots.

**IACF**
produces the plot of inverse-autocorrelations.

**PACF**
produces the plot of partial-autocorrelations.

**RESIDUAL(<residual-plot-options>)**
produces the residuals plots. The residual correlation and normality diagnostic panels are produced by default. The following *residual-plot-options* are available:

**ACF**
produces the plot of residual autocorrelations.

**ALL**
produces all the residual diagnostics plots appropriate for the particular analysis.

**CORR**
produces a summary panel of the residual correlation diagnostics that consists of the following:

- the residual-autocorrelation plot
- the residual-partial-autocorrelation plot
- the residual-inverse-autocorrelation plot
- a plot of Ljung-Box white-noise test *p*-values at different lags

**HIST**
produces the histogram of the residuals.

**IACF**
produces the plot of residual inverse-autocorrelations.

**NORMAL**
produces a summary panel of the residual normality diagnostics that consists of the following:

- histogram of the residuals
- normal quantile plot of the residuals
BY Statement

BY variables;

A BY statement can be used in the ARIMA procedure to process a data set in groups of observations defined by the BY variables. Note that all IDENTIFY, ESTIMATE, and FORECAST statements specified are applied to all BY groups.

Because of the need to make data-based model selections, BY-group processing is not usually done with PROC ARIMA. You usually want to use different models for the different series contained in different BY groups, and the PROC ARIMA BY statement does not let you do this.

Using a BY statement imposes certain restrictions. The BY statement must appear before the first RUN statement. If a BY statement is used, the input data must come from the data set specified in the PROC statement; that is, no input data sets can be specified in IDENTIFY statements.

When a BY statement is used with PROC ARIMA, interactive processing applies only to the first BY group. Once the end of the PROC ARIMA step is reached, all ARIMA statements specified are executed again for each of the remaining BY groups in the input data set.

PACF
produces the plot of residual partial-autocorrelations.

QQ
produces the normal quantile plot of the residuals.

SMOOTH
produces a scatter plot of the residuals against time, which has an overlaid smooth fit.

WN
produces the plot of Ljung-Box white-noise test $p$-values at different lags.

FORECAST(< forecast-plot-options >)
produces the forecast plots in the forecasting stage. The forecast-only plot that shows the multistep forecasts in the forecast region is produced by default.

The following forecast-plot-options are available:

ALL
produces the forecast-only plot as well as the forecast plot.

FORECAST
produces a plot that shows the one-step-ahead forecasts as well as the multistep-ahead forecasts.

FORECASTONLY
produces a plot that shows only the multistep-ahead forecasts in the forecast region.

OUT=SAS-data-set
specifies a SAS data set to which the forecasts are output. If different OUT= specifications appear in the PROC ARIMA and FORECAST statements, the one in the FORECAST statement is used.
IDENTIFY Statement

**IDENTIFY** VAR=variable options;

The IDENTIFY statement specifies the time series to be modeled, differences the series if desired, and computes statistics to help identify models to fit. Use an IDENTIFY statement for each time series that you want to model.

If other time series are to be used as inputs in a subsequent ESTIMATE statement, they must be listed in a CROSSCORR= list in the IDENTIFY statement.

The following options are used in the IDENTIFY statement. The VAR= option is required.

**ALPHA=** significance-level

The ALPHA= option specifies the significance level for tests in the IDENTIFY statement. The default is 0.05.

**CENTER**

centers each time series by subtracting its sample mean. The analysis is done on the centered data. Later, when forecasts are generated, the mean is added back. Note that centering is done after differencing. The CENTER option is normally used in conjunction with the NOCONSTANT option of the ESTIMATE statement.

**CLEAR**

deletes all old models. This option is useful when you want to delete old models so that the input variables are not prewhitened. (See the section “Prewhitening” on page 241 for more information.)

**CROSSCORR=** variable (d11, d12, . . . , d1k)

**CROSSCORR=** (variable (d11, d12, . . . , d1k) ... variable (d21, d22, . . . , d2k))

names the variables cross-correlated with the response variable given by the VAR= specification.

Each variable name can be followed by a list of differencing lags in parentheses, the same as for the VAR= specification. If differencing is specified for a variable in the CROSSCORR= list, the differenced series is cross-correlated with the VAR= option series, and the differenced series is used when the ESTIMATE statement INPUT= option refers to the variable.

**DATA=** SAS-data-set

specifies the input SAS data set that contains the time series. If the DATA= option is omitted, the DATA= data set specified in the PROC ARIMA statement is used; if the DATA= option is omitted from the PROC ARIMA statement as well, the most recently created data set is used.

**ESACF**

computes the extended sample autocorrelation function and uses these estimates to tentatively identify the autoregressive and moving-average orders of mixed models.

The ESACF option generates two tables. The first table displays extended sample autocorrelation estimates, and the second table displays probability values that can be used to test the significance of these estimates. The P=(pmin : pmax) and Q=(qmin : qmax) options determine the size of the table.

The autoregressive and moving-average orders are tentatively identified by finding a triangular pattern in which all values are insignificant. The ARIMA procedure finds these patterns based on the IDENTIFY statement ALPHA= option and displays possible recommendations for the orders.
The following code generates an ESACF table with dimensions of p=(0:7) and q=(0:8).

```sas
proc arima data=test;
   identify var=x esacf p=(0:7) q=(0:8);
run;
```

See the section “The ESACF Method” on page 236 for more information.

**MINIC**

uses information criteria or penalty functions to provide tentative ARMA order identification. The MINIC option generates a table that contains the computed information criterion associated with various ARMA model orders. The PERROR=(\(p_{e,\text{min}} : p_{e,\text{max}}\)) option determines the range of the autoregressive model orders used to estimate the error series. The P=(\(p_{\text{min}} : p_{\text{max}}\)) and Q=(\(q_{\text{min}} : q_{\text{max}}\)) options determine the size of the table. The ARMA orders are tentatively identified by those orders that minimize the information criterion.

The following statements generate a MINIC table with default dimensions of p=(0:5) and q=(0:5) and with the error series estimated by an autoregressive model with an order, \(p_e\), that minimizes the AIC in the range from 8 to 11.

```sas
proc arima data=test;
   identify var=x minic perror=(8:11);
run;
```

See the section “The MINIC Method” on page 238 for more information.

**NLAG=number**

indicates the number of lags to consider in computing the autocorrelations and cross-correlations. To obtain preliminary estimates of an ARIMA\((p, d, q)\) model, the NLAG= value must be at least \(p + q + d\). The number of observations must be greater than or equal to the NLAG= value. The default value for NLAG= is 24 or one-fourth the number of observations, whichever is less. Even though the NLAG= value is specified, the NLAG= value can be changed according to the data set.

**NOMISS**

uses only the first continuous sequence of data with no missing values. By default, all observations are used.

**NOPRINT**

suppresses the normal printout (including the correlation plots) generated by the IDENTIFY statement.

**OUTCOV=SAS-data-set**

writes the autocovariances, autocorrelations, inverse autocorrelations, partial autocorrelations, and cross covariances to an output SAS data set. If the OUTCOV= option is not specified, no covariance output data set is created. See the section “OUTCOV= Data Set” on page 256 for more information.

**P=(p_{\text{min}} : p_{\text{max}})**

see the ESACF, MINIC, and SCAN options for details.
Chapter 7: The ARIMA Procedure

**PERROR=(p_{e,min} : p_{e,max})**
determines the range of the autoregressive model orders used to estimate the error series in MINIC, a tentative ARMA order identification method. See the section “The MINIC Method” on page 238 for more information. By default, $p_{e,min}$ is set to $p_{max}$ and $p_{e,max}$ is set to $p_{max} + q_{max}$, where $p_{max}$ and $q_{max}$ are the maximum settings of the P= and Q= options on the IDENTIFY statement.

**Q=(q_{min} : q_{max})**
see the ESACF, MINIC, and SCAN options for details.

**SCAN**
computes estimates of the squared canonical correlations and uses these estimates to tentatively identify the autoregressive and moving-average orders of mixed models.

The SCAN option generates two tables. The first table displays squared canonical correlation estimates, and the second table displays probability values that can be used to test the significance of these estimates. The P=(p_{min} : p_{max}) and Q=(q_{min} : q_{max}) options determine the size of each table.

The autoregressive and moving-average orders are tentatively identified by finding a rectangular pattern in which all values are insignificant. The ARIMA procedure finds these patterns based on the IDENTIFY statement ALPHA= option and displays possible recommendations for the orders.

The following code generates a SCAN table with default dimensions of p=(0:5) and q=(0:5). The recommended orders are based on a significance level of 0.1.

```sql
proc arima data=test;
identify var=x scan alpha=0.1;
run;
```

See the section “The SCAN Method” on page 239 for more information.

**STATIONARITY=**
performs stationarity tests. Stationarity tests can be used to determine whether differencing terms should be included in the model specification. In each stationarity test, the autoregressive orders can be specified by a range, test= $ar_{max}$, or as a list of values, test= $(ar_1, ..., ar_n)$, where test is ADF, PP, or RW. The default is (0,1,2).

See the section “Stationarity Tests” on page 241 for more information.

**STATIONARITY=(ADF= AR orders DLAG= s )**

**STATIONARITY=(DICKEY= AR orders DLAG= s )**
performs augmented Dickey-Fuller tests. If the DLAG=s option is specified with s is greater than one, seasonal Dickey-Fuller tests are performed. The maximum allowable value of s is 12. The default value of s is 1. The following code performs augmented Dickey-Fuller tests with autoregressive orders 2 and 5.

```sql
proc arima data=test;
    identify var=x stationarity=(adf=(2,5));
run;
```
**ESTIMATE Statement**

< label:>ESTIMATE options ;

The ESTIMATE statement specifies an ARMA model or transfer function model for the response variable specified in the previous IDENTIFY statement, and produces estimates of its parameters. The ESTIMATE statement also prints diagnostic information by which to check the model. The label in the ESTIMATE statement is optional. Include an ESTIMATE statement for each model that you want to estimate.

Options used in the ESTIMATE statement are described in the following sections.

**STATIONARITY=(PP=AR orders)**

**STATIONARITY=(PHILLIPS=AR orders)**

performs Phillips-Perron tests. The following statements perform augmented Phillips-Perron tests with autoregressive orders ranging from 0 to 6.

```plaintext
proc arima data=test;
   identify var=x stationarity=(pp=6);
run;
```

**STATIONARITY=(RW=AR orders)**

**STATIONARITY=(RANDOMWALK=AR orders)**

performs random-walk-with-drift tests. The following statements perform random-walk-with-drift tests with autoregressive orders ranging from 0 to 2.

```plaintext
proc arima data=test;
   identify var=x stationarity=(rw);
run;
```

**VAR=variable**

**VAR= variable (d1, d2, ..., dk)**

names the variable that contains the time series to analyze. The VAR= option is required.

A list of differencing lags can be placed in parentheses after the variable name to request that the series be differenced at these lags. For example, VAR=X(1) takes the first differences of X. VAR=X(1,1) requests that X be differenced twice, both times with lag 1, producing a second difference series, which is

\[(X_t - X_{t-1}) - (X_{t-1} - X_{t-2}) = X_t - 2X_{t-1} + X_{t-2}.\]

VAR=X(2) differences X once at lag two \((X_t - X_{t-2}).\)

If differencing is specified, it is the differenced series that is processed by any subsequent ESTIMATE statement.

**WHITENOISE=ST | IGNOREMISS**

specifies the type of test statistic that is used in the white noise test of the series when the series contains missing values. If WHITENOISE=IGNOREMISS, the standard Ljung-Box test statistic is used. If WHITENOISE=ST, a modification of this statistic suggested by Stoffer and Toloi (1992) is used. The default is WHITENOISE=ST.
Options for Defining the Model and Controlling Diagnostic Statistics

The following options are used to define the model to be estimated and to control the output that is printed.

**ALTPARM**
specifies the alternative parameterization of the overall scale of transfer functions in the model. See the section “Alternative Model Parameterization” on page 247 for details.

**INPUT=** `variable`
**INPUT=**( transfer-function variable . . . )
specifies input variables and their transfer functions.

The variables used on the INPUT= option must be included in the CROSSCORR= list in the previous IDENTIFY statement. If any differencing is specified in the CROSSCORR= list, then the differenced series is used as the input to the transfer function.

The transfer function specification for an input variable is optional. If no transfer function is specified, the input variable enters the model as a simple regressor. If specified, the transfer function specification has the following syntax:

\[ S(L_{1,1}, L_{1,2}, \ldots)(L_{2,1}, \ldots) \ldots / (L_{j,1}, \ldots) \ldots \]

Here, \( S \) is a shift or lag of the input variable, the terms before the slash (/) are numerator factors, and the terms after the slash (/) are denominator factors of the transfer function. All three parts are optional. See the section “Specifying Inputs and Transfer Functions” on page 247 for details.

**METHOD=** `value`
specifies the estimation method to use. METHOD=ML specifies the maximum likelihood method. METHOD=ULS specifies the unconditional least squares method. METHOD=CLS specifies the conditional least squares method. METHOD=CLS is the default. See the section “Estimation Details” on page 242 for more information.

**NOCONSTANT**
suppresses the fitting of a constant (or intercept) parameter in the model. (That is, the parameter \( \mu \) is omitted.)

**NOINT**

**NODF**
estimates the variance by dividing the error sum of squares (SSE) by the number of residuals. The default is to divide the SSE by the number of residuals minus the number of free parameters in the model.

**NOPRINT**
suppresses the normal printout generated by the ESTIMATE statement. If the NOPRINT option is specified for the ESTIMATE statement, then any error and warning messages are printed to the SAS log.

**P=** `order`
**P=**( `lag`, \ldots, \( l_k \)) \ldots ( `lag`, \ldots, `lag` )
specifies the autoregressive part of the model. By default, no autoregressive parameters are fit.

\( P=(l_1, l_2, \ldots, l_k) \) defines a model with autoregressive parameters at the specified lags. **P= order** is equivalent to **P=(1, 2, \ldots, order)**.
A concatenation of parenthesized lists specifies a factored model. For example, \( P=(1,2,5)(6,12) \) specifies the autoregressive model

\[
(1 - \phi_{1,1} B - \phi_{1,2} B^2 - \phi_{1,3} B^5)(1 - \phi_{2,1} B^6 - \phi_{2,2} B^{12})
\]

**PLOT**

plots the residual autocorrelation functions. The sample autocorrelation, the sample inverse autocorrelation, and the sample partial autocorrelation functions of the model residuals are plotted.

**Q=** order

**Q=(lag, ..., lag) ... (lag, ..., lag)**

specifies the moving-average part of the model. By default, no moving-average part is included in the model.

\( Q=(l_1, l_2, ..., l_k) \) defines a model with moving-average parameters at the specified lags. **Q= order** is equivalent to **Q=(1, 2, ..., order)**. A concatenation of parenthesized lists specifies a factored model. The interpretation of factors and lags is the same as for the **P=** option.

**WHITENOISE=ST | IGNOREMISS**

specifies the type of test statistic that is used in the white noise test of the series when the series contains missing values. If **WHITENOISE=IGNOREMISS**, the standard Ljung-Box test statistic is used. If **WHITENOISE=ST**, a modification of this statistic suggested by Stoffer and Toloi (1992) is used. The default is **WHITENOISE=ST**.

**Options for Output Data Sets**

The following options are used to store results in SAS data sets:

**OUTEST=SAS-data-set**

writes the parameter estimates to an output data set. If the OUTCORR or OUTCOV option is used, the correlations or covariances of the estimates are also written to the OUTEST= data set. See the section “**OUTEST= Data Set**” on page 257 for a description of the OUTEST= output data set.

**OUTCORR**

writes the correlations of the parameter estimates to the OUTEST= data set.

**OUTCOV**

writes the covariances of the parameter estimates to the OUTEST= data set.

**OUTMODEL=SAS-data-set**

writes the model and parameter estimates to an output data set. If OUTMODEL= is not specified, no model output data set is created. See the section “**OUTMODEL= SAS Data Set**” on page 259 for a description of the OUTMODEL= output data set.

**OUTSTAT=SAS-data-set**

writes the model diagnostic statistics to an output data set. If OUTSTAT= is not specified, no statistics output data set is created. See the section “**OUTSTAT= Data Set**” on page 261 for a description of the OUTSTAT= output data set.
Options to Specify Parameter Values

The following options enable you to specify values for the model parameters. These options can provide starting values for the estimation process, or you can specify fixed parameters for use in the FORECAST stage and suppress the estimation process with the NOEST option. By default, the ARIMA procedure finds initial parameter estimates and uses these estimates as starting values in the iterative estimation process.

If values for any parameters are specified, values for all parameters should be given. The number of values given must agree with the model specifications.

\textbf{AR=}\textit{value} \ldots

lists starting values for the autoregressive parameters. See the section “Initial Values” on page 248 for more information.

\textbf{INITVAL=}\textit{(initializer-spec variable} \ldots \textit{)}

specifies starting values for the parameters in the transfer function parts of the model. See the section “Initial Values” on page 248 for more information.

\textbf{MA=}\textit{value} \ldots

lists starting values for the moving-average parameters. See the section “Initial Values” on page 248 for more information.

\textbf{MU=}\textit{value}

specifies the MU parameter.

\textbf{NOEST}

uses the values specified with the AR=, MA=, INITVAL=, and MU= options as final parameter values. The estimation process is suppressed except for estimation of the residual variance. The specified parameter values are used directly by the next FORECAST statement. When NOEST is specified, standard errors, t values, and the correlations between estimates are displayed as 0 or missing. (The NOEST option is useful, for example, when you want to generate forecasts that correspond to a published model.)

Options to Control the Iterative Estimation Process

The following options can be used to control the iterative process of minimizing the error sum of squares or maximizing the log-likelihood function. These tuning options are not usually needed but can be useful if convergence problems arise.

\textbf{BACKLIM=}\textit{\textit{-}\textit{n}}

omits the specified number of initial residuals from the sum of squares or likelihood function. Omitting values can be useful for suppressing transients in transfer function models that are sensitive to start-up values.

\textbf{CONVERGE=}\textit{\textit{value}}

specifies the convergence criterion. Convergence is assumed when the largest change in the estimate for any parameter is less that the CONVERGE= option value. If the absolute value of the parameter estimate is greater than 0.01, the relative change is used; otherwise, the absolute change in the estimate is used. The default is CONVERGE=0.001.
DELTA=value
specifies the perturbation value for computing numerical derivatives. The default is DELTA=0.001.

GRID
prints the error sum of squares (SSE) or concentrated log-likelihood surface in a small grid of the parameter space around the final estimates. For each pair of parameters, the SSE is printed for the nine parameter-value combinations formed by the grid, with a center at the final estimates and with spacing given by the GRIDVAL= specification. The GRID option can help you judge whether the estimates are truly at the optimum, since the estimation process does not always converge. For models with a large number of parameters, the GRID option produces voluminous output.

GRIDVAL=number
controls the spacing in the grid printed by the GRID option. The default is GRIDVAL=0.005.

MAXITER=n
MAXIT=n
specifies the maximum number of iterations allowed. The default is MAXITER=50.

NOLS
begins the maximum likelihood or unconditional least squares iterations from the preliminary estimates rather than from the conditional least squares estimates that are produced after four iterations. See the section “Estimation Details” on page 242 for more information.

NOSTABLE
specifies that the autoregressive and moving-average parameter estimates for the noise part of the model not be restricted to the stationary and invertible regions, respectively. See the section “Stationarity and Invertibility” on page 249 for more information.

PRINTALL
prints preliminary estimation results and the iterations in the final estimation process.

NOTFSTABLE
specifies that the parameter estimates for the denominator polynomial of the transfer function part of the model not be restricted to the stability region. See the section “Stationarity and Invertibility” on page 249 for more information.

SINGULAR=value
specifies the criterion for checking singularity. If a pivot of a sweep operation is less than the SINGULAR= value, the matrix is deemed singular. Sweep operations are performed on the Jacobian matrix during final estimation and on the covariance matrix when preliminary estimates are obtained. The default is SINGULAR=1E–7.

OUTLIER Statement

OUTLIER options;

The OUTLIER statement can be used to detect shifts in the level of the response series that are not accounted for by the previously estimated model. An ESTIMATE statement must precede the OUTLIER statement. The following options are used in the OUTLIER statement:
Chapter 7: The ARIMA Procedure

TYPE=ADDITIVE
TYPE=SHIFT
TYPE=TEMP (d_1, ..., d_k)

`TYPE=(< ADDITIVE > < SHIFT > < TEMP (d_1, ..., d_k) >)`
specifies the types of level shifts to search for. The default is `TYPE=(ADDITIVE SHIFT)`, which requests searching for additive outliers and permanent level shifts. The option `TEMP( d_1, ..., d_k)` requests searching for temporary changes in the level of durations d_1, ..., d_k. These options can also be abbreviated as AO, LS, and TC.

`ALPHA=significance-level`
specifies the significance level for tests in the OUTLIER statement. The default is 0.05.

`SIGMA=ROBUST | MSE`
specifies the type of error variance estimate to use in the statistical tests performed during the outlier detection. `SIGMA=MSE` corresponds to the usual mean squared error (MSE) estimate, and `SIGMA=ROBUST` corresponds to a robust estimate of the error variance. The default is `SIGMA=ROBUST`.

`MAXNUM=number`
limits the number of outliers to search. The default is `MAXNUM=5`.

`MAXPCT=number`
limits the number of outliers to search for according to a percentage of the series length. The default is `MAXPCT=2`. When both the `MAXNUM= and MAXPCT= options are specified, the minimum of the two search numbers is used.

`ID=Date-Time ID variable`
specifies a SAS date, time, or datetime identification variable to label the detected outliers. This variable must be present in the input data set.

The following examples illustrate a few possibilities for the OUTLIER statement.

The most basic usage, shown as follows, sets all the options to their default values.

```
outlier;
```

That is, it is equivalent to

```
outlier type=(ao ls) alpha=0.05 sigma=robust maxnum=5 maxpct=2;
```

The following statement requests a search for permanent level shifts and for temporary level changes of durations 6 and 12. The search is limited to at most three changes and the significance level of the underlying tests is 0.001. MSE is used as the estimate of error variance. It also requests labeling of the detected shifts using an ID variable `date`.

```
outlier type=(ls tc(6 12)) alpha=0.001 sigma=mse maxnum=3 ID=date;
```
FORECAST Statement

FORECAST options;

The FORECAST statement generates forecast values for a time series by using the parameter estimates produced by the previous ESTIMATE statement. See the section “Forecasting Details” on page 250 for more information about calculating forecasts.

The following options can be used in the FORECAST statement:

ALIGN=option
controls the alignment of SAS dates used to identify output observations. The ALIGN= option allows the following values: BEGINNING|BEG|B, MIDDLE|MID|M, and ENDING|END|E. BEGINNING is the default.

ALPHA=n
sets the size of the forecast confidence limits. The ALPHA= value must be between 0 and 1. When you specify ALPHA=α, the upper and lower confidence limits have a 1 − α confidence level. The default is ALPHA=0.05, which produces 95% confidence intervals. ALPHA values are rounded to the nearest hundredth.

BACK=n
specifies the number of observations before the end of the data where the multistep forecasts are to begin. The BACK= option value must be less than or equal to the number of observations minus the number of parameters.

The default is BACK=0, which means that the forecast starts at the end of the available data. The end of the data is the last observation for which a noise value can be calculated. If there are no input series, the end of the data is the last nonmissing value of the response time series. If there are input series, this observation can precede the last nonmissing value of the response variable, since there may be missing values for some of the input series.

ID=variable
names a variable in the input data set that identifies the time periods associated with the observations. The ID= variable is used in conjunction with the INTERVAL= option to extrapolate ID values from the end of the input data to identify forecast periods in the OUT= data set.

If the INTERVAL= option specifies an interval type, the ID variable must be a SAS date or datetime variable with the spacing between observations indicated by the INTERVAL= value. If the INTERVAL= option is not used, the last input value of the ID= variable is incremented by one for each forecast period to extrapolate the ID values for forecast observations.

INTERVAL=interval
INTERVAL=n
specifies the time interval between observations. See Chapter 4, “Date Intervals, Formats, and Functions,” for information about valid INTERVAL= values.

The value of the INTERVAL= option is used by PROC ARIMA to extrapolate the ID values for forecast observations and to check that the input data are in order with no missing periods. See the section “Specifying Series Periodicity” on page 252 for more details.
**LEAD=n**
specifies the number of multistep forecast values to compute. For example, if LEAD=10, PROC ARIMA forecasts for ten periods beginning with the end of the input series (or earlier if BACK= is specified). It is possible to obtain fewer than the requested number of forecasts if a transfer function model is specified and insufficient data are available to compute the forecast. The default is LEAD=24.

**NOOUTALL**
includes only the final forecast observations in the OUT= output data set, not the one-step forecasts for the data before the forecast period.

**NOPRINT**
suppresses the normal printout of the forecast and associated values.

**OUT=SAS-data-set**
writes the forecast (and other values) to an output data set. If OUT= is not specified, the OUT= data set specified in the PROC ARIMA statement is used. If OUT= is also not specified in the PROC ARIMA statement, no output data set is created. See the section “OUT= Data Set” on page 255 for more information.

**PRINTALL**
prints the FORECAST computation throughout the whole data set. The forecast values for the data before the forecast period (specified by the BACK= option) are one-step forecasts.

**SIGSQ=value**
specifies the variance term used in the formula for computing forecast standard errors and confidence limits. The default value is the variance estimate computed by the preceding ESTIMATE statement. This option is useful when you wish to generate forecast standard errors and confidence limits based on a published model. It would often be used in conjunction with the NOEST option in the preceding ESTIMATE statement.

---

**Details: ARIMA Procedure**

**The Inverse Autocorrelation Function**

The sample inverse autocorrelation function (SIACF) plays much the same role in ARIMA modeling as the sample partial autocorrelation function (SPACF), but it generally indicates subset and seasonal autoregressive models better than the SPACF.

Additionally, the SIACF can be useful for detecting over-differencing. If the data come from a nonstationary or nearly nonstationary model, the SIACF has the characteristics of a noninvertible moving-average. Likewise, if the data come from a model with a noninvertible moving average, then the SIACF has nonstationary characteristics and therefore decays slowly. In particular, if the data have been over-differenced, the SIACF looks like a SACF from a nonstationary process.

The inverse autocorrelation function is not often discussed in textbooks, so a brief description is given here. For more complete discussions, see: Cleveland (1972); Chatfield (1980); Priestley (1981).
Let $W_t$ be generated by the ARMA($p, q$) process
\[ \phi(B)W_t = \theta(B)a_t \]
where $a_t$ is a white noise sequence. If $\theta(B)$ is invertible (that is, if $\theta$ considered as a polynomial in $B$ has no roots less than or equal to 1 in magnitude), then the model
\[ \theta(B)Z_t = \phi(B)a_t \]
is also a valid ARMA($q, p$) model. This model is sometimes referred to as the dual model. The autocorrelation function (ACF) of this dual model is called the inverse autocorrelation function (IACF) of the original model.

Notice that if the original model is a pure autoregressive model, then the IACF is an ACF that corresponds to a pure moving-average model. Thus, it cuts off sharply when the lag is greater than $p$; this behavior is similar to the behavior of the partial autocorrelation function (PACF).

The sample inverse autocorrelation function (SIACF) is estimated in the ARIMA procedure by the following steps. A high-order autoregressive model is fit to the data by means of the Yule-Walker equations. The order of the autoregressive model used to calculate the SIACF is the minimum of the NLAG= value and one-half the number of observations after differencing. The SIACF is then calculated as the autocorrelation function that corresponds to this autoregressive operator when treated as a moving-average operator. That is, the autoregressive coefficients are convolved with themselves and treated as autocovariances.

Under certain conditions, the sampling distribution of the SIACF can be approximated by the sampling distribution of the SACF of the dual model (Bhansali 1980). In the plots generated by ARIMA, the confidence limit marks (.) are located at $\pm 2/\sqrt{n}$. These limits bound an approximate 95% confidence interval for the hypothesis that the data are from a white noise process.

---

### The Partial Autocorrelation Function

The approximation for a standard error for the estimated partial autocorrelation function at lag $k$ is based on a null hypothesis that a pure autoregressive Gaussian process of order $k-1$ generated the time series. This standard error is $1/\sqrt{n}$ and is used to produce the approximate 95% confidence intervals depicted by the dots in the plot.

### The Cross-Correlation Function

The autocorrelation and partial and inverse autocorrelation functions described in the preceding sections help when you want to model a series as a function of its past values and past random errors. When you want to include the effects of past and current values of other series in the model, the correlations of the response series and the other series must be considered.

The CROSSCORR= option in the IDENTIFY statement computes cross-correlations of the VAR= series with other series and makes these series available for use as inputs in models specified by later ESTIMATE statements.

When the CROSSCORR= option is used, PROC ARIMA prints a plot of the cross-correlation function for each variable in the CROSSCORR= list. This plot is similar in format to the other correlation plots, but it shows the correlation between the two series at both lags and leads. For example,
**Chapter 7: The ARIMA Procedure**

```plaintext
identify var=y crosscorr=x ...;
```

plots the cross-correlation function of Y and X, Cor($y_t, x_{t-s}$), for $s = -L$ to $L$, where $L$ is the value of the NLAG= option. Study of the cross-correlation functions can indicate the transfer functions through which the input series should enter the model for the response series.

The cross-correlation function is computed after any specified differencing has been done. If differencing is specified for the VAR= variable or for a variable in the CROSSCORR= list, it is the differenced series that is cross-correlated (and the differenced series is processed by any following ESTIMATE statement).

For example,

```plaintext
identify var=y(1) crosscorr=x(1);
```

computes the cross-correlations of the changes in Y with the changes in X. When differencing is specified, the subsequent ESTIMATE statement models changes in the variables rather than the variables themselves.

---

**The ESACF Method**

The extended sample autocorrelation function (ESACF) method can tentatively identify the orders of a stationary or nonstationary ARMA process based on iterated least squares estimates of the autoregressive parameters. Tsay and Tiao (1984) proposed the technique, and Choi (1992) provides useful descriptions of the algorithm.

Given a stationary or nonstationary time series \( \{z_t : 1 \leq t \leq n\} \) with mean corrected form \( \bar{z}_t = z_t - \mu_z \) with a true autoregressive order of \( p + d \) and with a true moving-average order of \( q \), you can use the ESACF method to estimate the unknown orders \( p + d \) and \( q \) by analyzing the autocorrelation functions associated with filtered series of the form

\[
w_t^{(m,j)} = \hat{\Phi}_{(m,j)}(B)\bar{z}_t = \bar{z}_t - \sum_{i=1}^{m} \hat{\phi}_{i}^{(m,j)}\bar{z}_{t-i}
\]

where \( B \) represents the backshift operator, where \( m = p_{\text{min}}, \ldots, p_{\text{max}} \) are the autoregressive test orders, where \( j = q_{\text{min}} + 1, \ldots, q_{\text{max}} + 1 \) are the moving-average test orders, and where \( \hat{\phi}_{i}^{(m,j)} \) are the autoregressive parameter estimates under the assumption that the series is an ARMA\((m, j)\) process.

For purely autoregressive models \((j = 0)\), ordinary least squares (OLS) is used to consistently estimate \( \hat{\phi}_{i}^{(m,0)} \). For ARMA models, consistent estimates are obtained by the iterated least squares recursion formula, which is initiated by the pure autoregressive estimates:

\[
\hat{\phi}_{i}^{(m,j)} = \hat{\phi}_{i}^{(m+1,j-1)} - \hat{\phi}_{i-1}^{(m,j-1)} \frac{\hat{\gamma}^{(m+1,j-1)}_{i}}{\hat{\gamma}^{(m,j-1)}_{i}}
\]

The \( j \)th lag of the sample autocorrelation function of the filtered series \( w_t^{(m,j)} \) is the extended sample autocorrelation function, and it is denoted as \( r_{j(m)} = r_{j}(w_{(m,j)}) \).

The standard errors of \( r_{j(m)} \) are computed in the usual way by using Bartlett’s approximation of the variance of the sample autocorrelation function, \( \text{var}(r_{j(m)}) \approx (1 + \sum_{t=1}^{j-1} r_{j}^{2}(w_{(m,j)})) \).
If the true model is an ARMA \((p + d, q)\) process, the filtered series \(w_t^{(m,j)}\) follows an MA\((q)\) model for \(j \geq q\) so that

\[
\begin{align*}
    r_{j(p+d)} &\approx 0 & j > q \\
    r_{j(p+d)} &\neq 0 & j = q
\end{align*}
\]

Additionally, Tsay and Tiao (1984) show that the extended sample autocorrelation satisfies

\[
\begin{align*}
    r_{j(m)} &\approx 0 & j - q > m - p - d \leq 0 \\
    r_{j(m)} &\neq c(m - p - d, j - q) & 0 \leq j - q \leq m - p - d 
\end{align*}
\]

where \(c(m - p - d, j - q)\) is a nonzero constant or a continuous random variable bounded by \(-1\) and \(1\).

An ESACF table is then constructed by using the \(r_{j(m)}\) for \(m = p_{min}, \ldots, p_{max}\) and \(j = q_{min} + 1, \ldots, q_{max} + 1\) to identify the ARMA orders (see Table 7.4). The orders are tentatively identified by finding a right (maximal) triangular pattern with vertices located at \((p + d, q)\) and \((p + d, q_{max})\) and in which all elements are insignificant (based on asymptotic normality of the autocorrelation function). The vertex \((p + d, q)\) identifies the order. Table 7.5 depicts the theoretical pattern associated with an ARMA\((1,2)\) series.

The MINIC Method

The minimum information criterion (MINIC) method can tentatively identify the order of a stationary and invertible ARMA process. Note that Hannan and Rissanen (1982) proposed this method; for useful descriptions of the algorithm, see: Box, Jenkins, and Reinsel (1994); Choi (1992).

Given a stationary and invertible time series \( \{z_t: 1 \leq t \leq n\} \) with mean corrected form \( \tilde{z}_t = z_t - \mu_z \) with a true autoregressive order of \( p \) and with a true moving-average order of \( q \), you can use the MINIC method to compute information criteria (or penalty functions) for various autoregressive and moving average orders. The following paragraphs provide a brief description of the algorithm.

If the series is a stationary and invertible ARMA(\( p, q \)) process of the form

\[
\Phi(p, q)(B)\tilde{z}_t = \Theta(p, q)(B)\epsilon_t
\]

the error series can be approximated by a high-order AR process

\[
\hat{\epsilon}_t = \hat{\Phi}(p_e, q)(B)\tilde{z}_t \approx \epsilon_t
\]

where the parameter estimates \( \hat{\Phi}(p_e, q) \) are obtained from the Yule-Walker estimates. The choice of the autoregressive order \( p_e \) is determined by the order that minimizes the Akaike information criterion (AIC) in the range \( p_{e, \text{min}} \leq p_e \leq p_{e, \text{max}} \)

\[
AIC(p_e, 0) = \ln(\hat{\sigma}^2(p_e, 0)) + 2(p_e + 0)/n
\]

where

\[
\hat{\sigma}^2(p_e, 0) = \frac{1}{n} \sum_{t=p_e+1}^{n} \hat{\epsilon}_t^2
\]

Note that Hannan and Rissanen (1982) use the Bayesian information criterion (BIC) to determine the autoregressive order used to estimate the error series while others recommend the AIC (Box, Jenkins, and Reinsel 1994; Choi 1992).

Once the error series has been estimated for autoregressive test order \( m = p_{\text{min}}, \ldots, p_{\text{max}} \) and for moving-average test order \( j = q_{\text{min}}, \ldots, q_{\text{max}} \), the OLS estimates \( \hat{\Phi}(m, j) \) and \( \hat{\Theta}(m, j) \) are computed from the regression model

\[
\tilde{z}_t = \sum_{i=1}^{m} \phi_i^{(m, j)} \tilde{z}_{t-i} + \sum_{k=1}^{j} \theta_k^{(m, j)} \hat{\epsilon}_{t-k} + \text{error}
\]

From the preceding parameter estimates, the BIC is then computed

\[
BIC(m, j) = \ln(\hat{\sigma}^2(m, j)) + 2(m + j)\ln(n)/n
\]

where

\[
\hat{\sigma}^2(m, j) = \frac{1}{n} \sum_{t=t_0}^{n} \left( \tilde{z}_t - \sum_{i=1}^{m} \phi_i^{(m, j)} \tilde{z}_{t-i} + \sum_{k=1}^{j} \theta_k^{(m, j)} \hat{\epsilon}_{t-k} \right)^2
\]
The SCAN Method

The smallest canonical (SCAN) correlation method can tentatively identify the orders of a stationary or nonstationary ARMA process. Tsay and Tiao (1985) proposed the technique, and for useful descriptions of the algorithm, see: Box, Jenkins, and Reinsel (1994); Choi (1992).

Given a stationary or nonstationary time series \( \{z_t : 1 \leq t \leq n\} \) with mean corrected form \( \tilde{z}_t = z_t - \mu_z \) with a true autoregressive order of \( p + d \) and with a true moving-average order of \( q \), you can use the SCAN method to analyze eigenvalues of the correlation matrix of the ARMA process. The following paragraphs provide a brief description of the algorithm.

For autoregressive test order \( m = p_{\text{min}} \ldots p_{\text{max}} \) and for moving-average test order \( j = q_{\text{min}} \ldots q_{\text{max}} \), perform the following steps.

1. Let \( Y_{m,t} = (\tilde{z}_t, \tilde{z}_{t-1}, \ldots, \tilde{z}_{t-m})' \). Compute the following \( (m+1) \times (m+1) \) matrix

\[
\hat{\beta}(m, j + 1) = \left( \sum_t Y_{m,t-j-1}Y_{m,t-j-1}' \right)^{-1} \left( \sum_t Y_{m,t-j-1}Y_{m,t}' \right)
\]

\[
\hat{\beta}^*(m, j + 1) = \left( \sum_t Y_{m,t}Y_{m,t}' \right)^{-1} \left( \sum_t Y_{m,t}Y_{m,t,j-1}' \right)
\]

\[
\hat{A}^*(m, j) = \hat{\beta}^*(m, j + 1)\hat{\beta}(m, j + 1)
\]

where \( t \) ranges from \( j + m + 2 \) to \( n \).

2. Find the smallest eigenvalue, \( \hat{\lambda}^*(m, j) \), of \( \hat{A}^*(m, j) \) and its corresponding normalized eigenvector, \( \Phi_{m,j} = (1, -\phi_1^{(m,j)}, -\phi_2^{(m,j)}, \ldots, -\phi_m^{(m,j)}) \). The squared canonical correlation estimate is \( \hat{\lambda}^*(m, j) \).

A MINIC table is then constructed using \( BIC(m, j) \); see Table 7.6. If \( p_{\text{max}} > p_{\text{err}, \text{min}} \), the preceding regression might fail due to linear dependence on the estimated error series and the mean-corrected series. Values of \( BIC(m, j) \) that cannot be computed are set to missing. For large autoregressive and moving-average test orders with relatively few observations, a nearly perfect fit can result. This condition can be identified by a large negative \( BIC(m, j) \) value.

</table>

where \( t \) ranges from \( 0 \) to \( n \).
3. Using the $\Phi_{m,j}$ as AR($m$) coefficients, obtain the residuals for $t = j + m + 1$ to $n$, by following the formula: $w_{t}^{(m,j)} = \hat{z}_{t} - \phi_{1}^{(m,j)}\hat{z}_{t-1} - \phi_{2}^{(m,j)}\hat{z}_{t-2} - \ldots - \phi_{m}^{(m,j)}\hat{z}_{t-m}$.

4. From the sample autocorrelations of the residuals, $r_{k}(w)$, approximate the standard error of the squared canonical correlation estimate by

$$\text{var}(\hat{\lambda}^{*}(m, j)^{1/2}) \approx d(m, j)/(n - m - j)$$

where $d(m, j) = (1 + 2 \sum_{j=1}^{j} r_{k}(w^{(m,j)}))$.

The test statistic to be used as an identification criterion is

$$c(m, j) = -(n - m - j)\ln(1 - \hat{\lambda}^{*}(m, j)/d(m, j))$$

which is asymptotically $\chi_{1}^{2}$ if $m = p + d$ and $j \geq q$ or if $m \geq p + d$ and $j = q$. For $m > p$ and $j < q$, there is more than one theoretical zero canonical correlation between $Y_{m,t}$ and $Y_{m,t-j-1}$. Since the $\hat{\lambda}^{*}(m, j)$ are the smallest canonical correlations for each $(m, j)$, the percentiles of $c(m, j)$ are less than those of a $\chi_{1}^{2}$; therefore, Tsay and Tiao (1985) state that it is safe to assume a $\chi_{1}^{2}$. For $m < p$ and $j < q$, no conclusions about the distribution of $c(m, j)$ are made.

A SCAN table is then constructed using $c(m, j)$ to determine which of the $\hat{\lambda}^{*}(m, j)$ are significantly different from zero (see Table 7.7). The ARMA orders are tentatively identified by finding a (maximal) rectangular pattern in which the $\hat{\lambda}^{*}(m, j)$ are insignificant for all test orders $m \geq p + d$ and $j \geq q$. There may be more than one pair of values $(p + d, q)$ that permit such a rectangular pattern. In this case, parsimony and the number of insignificant items in the rectangular pattern should help determine the model order. Table 7.8 depicts the theoretical pattern associated with an ARMA(2,2) series.

Stationarity Tests

When a time series has a unit root, the series is nonstationary and the ordinary least squares (OLS) estimator is not normally distributed. Dickey and Fuller studied the limiting distribution of the OLS estimator of autoregressive models for time series with a simple unit root (Dickey 1976; Dickey and Fuller 1979). Dickey, Hasza, and Fuller obtained the limiting distribution for time series with seasonal unit roots (Dickey, Hasza, and Fuller 1984). Hamilton (1994) discusses the various types of unit root testing.

For a description of Dickey-Fuller tests, see the section “PROBDF Function for Dickey-Fuller Tests” on page 157 in Chapter 5. See Chapter 8, “The AUTOREG Procedure,” for a description of Phillips-Perron tests.

The random-walk-with-drift test recommends whether or not an integrated times series has a drift term. Hamilton (1994) discusses this test.

Prewhitening

If, as is usually the case, an input series is autocorrelated, the direct cross-correlation function between the input and response series gives a misleading indication of the relation between the input and response series.

One solution to this problem is called prewhitening. You first fit an ARIMA model for the input series sufficient to reduce the residuals to white noise; then, filter the input series with this model to get the white noise residual series. You then filter the response series with the same model and cross-correlate the filtered response with the filtered input series.

The ARIMA procedure performs this prewhitening process automatically when you precede the IDENTIFY statement for the response series with IDENTIFY and ESTIMATE statements to fit a model for the input series. If a model with no inputs was previously fit to a variable specified by the CROSSCORR= option, then that model is used to prewhiten both the input series and the response series before the cross-correlations are computed for the input series.

For example,

```
proc arima data=in;
   identify var=x;
   estimate p=1 q=1;
   identify var=y crosscorr=x;
run;
```

Both X and Y are filtered by the ARMA(1,1) model fit to X before the cross-correlations are computed.

Note that prewhitening is done to estimate the cross-correlation function; the unfiltered series are used in any subsequent ESTIMATE or FORECAST statements, and the correlation functions of Y with its own lags are computed from the unfiltered Y series. But initial values in the ESTIMATE statement are obtained with prewhitened data; therefore, the result with prewhitening can be different from the result without prewhitening.

To suppress prewhitening for all input variables, use the CLEAR option in the IDENTIFY statement to make PROC ARIMA disregard all previous models.
Prewhitening and Differencing

If the VAR= and CROSSCORR= options specify differencing, the series are differenced before the prewhitening filter is applied. When the differencing lists specified in the VAR= option for an input and in the CROSSCORR= option for that input are not the same, PROC ARIMA combines the two lists so that the differencing operators used for prewhitening include all differences in either list (in the least common multiple sense).

Identifying Transfer Function Models

When identifying a transfer function model with multiple input variables, the cross-correlation functions can be misleading if the input series are correlated with each other. Any dependencies among two or more input series will confound their cross-correlations with the response series.

The prewhitening technique assumes that the input variables do not depend on past values of the response variable. If there is feedback from the response variable to an input variable, as evidenced by significant cross-correlation at negative lags, both the input and the response variables need to be prewhitened before meaningful cross-correlations can be computed.

PROC ARIMA cannot handle feedback models. The STATESPACE and VARMAX procedures are more appropriate for models with feedback.

Missing Values and Autocorrelations

To compute the sample autocorrelation function when missing values are present, PROC ARIMA uses only crossproducts that do not involve missing values and employs divisors that reflect the number of crossproducts used rather than the total length of the series. Sample partial autocorrelations and inverse autocorrelations are then computed by using the sample autocorrelation function. If necessary, a taper is employed to transform the sample autocorrelations into a positive definite sequence before calculating the partial autocorrelation and inverse correlation functions. The confidence intervals produced for these functions might not be valid when there are missing values. The distributional properties for sample correlation functions are not clear for finite samples. See Dunsmuir (1984) for some asymptotic properties of the sample correlation functions.

Estimation Details

The ARIMA procedure primarily uses the computational methods outlined by Box and Jenkins. Marquardt’s method is used for the nonlinear least squares iterations. Numerical approximations of the derivatives of the sum-of-squares function are taken by using a fixed delta (controlled by the DELTA= option).

The methods do not always converge successfully for a given set of data, particularly if the starting values for the parameters are not close to the least squares estimates.

Back-Forecasting

The unconditional sum of squares is computed exactly; thus, back-forecasting is not performed. Early versions of SAS/ETS software used the back-forecasting approximation and allowed a positive value of the
BACKLIM= option to control the extent of the back-forecasting. In the current version, requesting a positive number of back-forecasting steps with the BACKLIM= option has no effect.

**Preliminary Estimation**

If an autoregressive or moving-average operator is specified with no missing lags, preliminary estimates of the parameters are computed by using the autocorrelations computed in the IDENTIFY stage. Otherwise, the preliminary estimates are arbitrarily set to values that produce stable polynomials.

When preliminary estimation is not performed by PROC ARIMA, then initial values of the coefficients for any given autoregressive or moving-average factor are set to 0.1 if the degree of the polynomial associated with the factor is 9 or less. Otherwise, the coefficients are determined by expanding the polynomial \((1 - 0.1B)\) to an appropriate power by using a recursive algorithm.

These preliminary estimates are the starting values in an iterative algorithm to compute estimates of the parameters.

**Estimation Methods**

**Maximum Likelihood**

The METHOD= ML option produces maximum likelihood estimates. The likelihood function is maximized via nonlinear least squares using Marquardt’s method. Maximum likelihood estimates are more expensive to compute than the conditional least squares estimates; however, they may be preferable in some cases (Ansley and Newbold 1980; Davidson 1981).

The maximum likelihood estimates are computed as follows. Let the univariate ARMA model be

\[
\phi(B)(W_t - \mu_t) = \theta(B)a_t
\]

where \(a_t\) is an independent sequence of normally distributed innovations with mean 0 and variance \(\sigma^2\). Here \(\mu_t\) is the mean parameter \(\mu\) plus the transfer function inputs. The log-likelihood function can be written as follows:

\[
-\frac{1}{2\sigma^2}x'\Omega^{-1}x - \frac{1}{2}\ln(|\Omega|) - \frac{n}{2}\ln(\sigma^2)
\]

In this equation, \(n\) is the number of observations, \(\sigma^2\Omega\) is the variance of \(x\) as a function of the \(\phi\) and \(\theta\) parameters, and \(|\Omega|\) denotes the determinant. The vector \(x\) is the time series \(W_t\) minus the structural part of the model \(\mu_t\), written as a column vector, as follows:

\[
x = \begin{bmatrix} W_1 \\ W_2 \\ \vdots \\ W_n \end{bmatrix} - \begin{bmatrix} \mu_1 \\ \mu_2 \\ \vdots \\ \mu_n \end{bmatrix}
\]

The maximum likelihood estimate (MLE) of \(\sigma^2\) is

\[
\hat{\sigma}^2 = \frac{1}{n}x'\Omega^{-1}x
\]

Note that the default estimator of the variance divides by \(n - r\), where \(r\) is the number of parameters in the model, instead of by \(n\). Specifying the NODF option causes a divisor of \(n\) to be used.
The log-likelihood concentrated with respect to $\sigma^2$ can be taken up to additive constants as

$$\frac{-n}{2} \ln(x' \Omega^{-1} x) - \frac{1}{2} \ln(|\Omega|)$$

Let $H$ be the lower triangular matrix with positive elements on the diagonal such that $HH' = \Omega$. Let $e$ be the vector $H^{-1}x$. The concentrated log-likelihood with respect to $\sigma^2$ can now be written as

$$\frac{-n}{2} \ln(e'e) - \ln(|H|)$$

or

$$\frac{-n}{2} \ln(|H|^{1/n} e|H|^{1/n})$$

The MLE is produced by using a Marquardt algorithm to minimize the following sum of squares:

$$|H|^{1/n} e|H|^{1/n}$$

The subsequent analysis of the residuals is done by using $e$ as the vector of residuals.

**Unconditional Least Squares**

The METHOD=ULS option produces unconditional least squares estimates. The ULS method is also referred to as the exact least squares (ELS) method. For METHOD=ULS, the estimates minimize

$$\sum_{t=1}^{n} \hat{a}_t^2 = \sum_{t=1}^{n} (x_t - C_t V_t^{-1} (x_1, \ldots, x_{t-1})')^2$$

where $C_t$ is the covariance matrix of $x_t$ and $(x_1, \ldots, x_{t-1})$, and $V_t$ is the variance matrix of $(x_1, \ldots, x_{t-1})$. In fact, $\sum_{t=1}^{n} \hat{a}_t^2$ is the same as $x' \Omega^{-1} x$, and hence $e'e$. Therefore, the unconditional least squares estimates are obtained by minimizing the sum of squared residuals rather than using the log-likelihood as the criterion function.

**Conditional Least Squares**

The METHOD=CLS option produces conditional least squares estimates. The CLS estimates are conditional on the assumption that the past unobserved errors are equal to 0. The series $x_t$ can be represented in terms of the previous observations, as follows:

$$x_t = a_t + \sum_{i=1}^{\infty} \pi_i x_{t-i}$$

The $\pi$ weights are computed from the ratio of the $\phi$ and $\theta$ polynomials, as follows:

$$\frac{\phi(B)}{\theta(B)} = 1 - \sum_{i=1}^{\infty} \pi_i B^i$$

The CLS method produces estimates minimizing

$$\sum_{t=1}^{n} \hat{a}_t^2 = \sum_{t=1}^{n} \left(x_t - \sum_{i=1}^{\infty} \hat{\pi}_i x_{t-i}\right)^2$$

where the unobserved past values of $x_t$ are set to 0 and $\hat{\pi}_i$ are computed from the estimates of $\phi$ and $\theta$ at each iteration.

For METHOD=ULS and METHOD=ML, initial estimates are computed using the METHOD=CLS algorithm.
Start-up for Transfer Functions

When computing the noise series for transfer function and intervention models, the start-up for the transferred variable is done by assuming that past values of the input series are equal to the first value of the series. The estimates are then obtained by applying least squares or maximum likelihood to the noise series. Thus, for transfer function models, the ML option does not generate the full (multivariate ARMA) maximum likelihood estimates, but it uses only the univariate likelihood function applied to the noise series.

Because PROC ARIMA uses all of the available data for the input series to generate the noise series, other start-up options for the transferred series can be implemented by prefixing an observation to the beginning of the real data. For example, if you fit a transfer function model to the variable Y with the single input X, then you can employ a start-up using 0 for the past values by prefixing to the actual data an observation with a missing value for Y and a value of 0 for X.

Information Criteria

PROC ARIMA computes and prints two information criteria, Akaike’s information criterion (AIC) (Akaike 1974; Harvey 1981) and Schwarz’s Bayesian criterion (SBC) (Schwarz 1978). The AIC and SBC are used to compare competing models fit to the same series. The model with the smaller information criteria is said to fit the data better. The AIC is computed as

$$-2 \ln(L) + 2k$$

where \(L\) is the likelihood function and \(k\) is the number of free parameters. The SBC is computed as

$$-2 \ln(L) + \ln(n)k$$

where \(n\) is the number of residuals that can be computed for the time series. Sometimes Schwarz’s Bayesian criterion is called the Bayesian information criterion (BIC).

If METHOD=CLS is used to do the estimation, an approximation value of \(L\) is used, where \(L\) is based on the conditional sum of squares instead of the exact sum of squares, and a Jacobian factor is left out.

Tests of Residuals

A table of test statistics for the hypothesis that the model residuals are white noise is printed as part of the ESTIMATE statement output. The chi-square statistics used in the test for lack of fit are computed using the Ljung-Box formula

$$\chi^2_m = n(n + 2) \sum_{k=1}^{m} \frac{r_k^2}{(n - k)}$$

where

$$r_k = \frac{\sum_{t=1}^{n-k} a_t a_{t+k}}{\sum_{t=1}^{n} a_t^2}$$

and \(a_t\) is the residual series.

This formula has been suggested by Ljung and Box (1978) as yielding a better fit to the asymptotic chi-square distribution than the Box-Pierce Q statistic. Some simulation studies of the finite sample properties of this statistic are given by Davies, Triggs, and Newbold (1977); Ljung and Box (1978). When the time series
has missing values, Stoffer and Toloi (1992) suggest a modification of this test statistic that has improved
distributional properties over the standard Ljung-Box formula given above. When the series contains missing
values, this modified test statistic is used by default.

Each chi-square statistic is computed for all lags up to the indicated lag value and is not independent of the
preceding chi-square values. The null hypotheses tested is that the current set of autocorrelations is white
noise.

$t$-values

The $t$ values reported in the table of parameter estimates are approximations whose accuracy depends on the
validity of the model, the nature of the model, and the length of the observed series. When the length of the
observed series is short and the number of estimated parameters is large with respect to the series length, the
$t$ approximation is usually poor. Probability values that correspond to a $t$ distribution should be interpreted
carefully because they may be misleading.

Cautions during Estimation

The ARIMA procedure uses a general nonlinear least squares estimation method that can yield problematic
results if your data do not fit the model. Output should be examined carefully. The GRID option can be used
to ensure the validity and quality of the results. Problems you might encounter include the following:

- Preliminary moving-average estimates might not converge. If this occurs, preliminary estimates are
derived as described previously in "Preliminary Estimation" on page 243. You can supply your own
preliminary estimates with the ESTIMATE statement options.

- The estimates can lead to an unstable time series process, which can cause extreme forecast values or
overflows in the forecast.

- The Jacobian matrix of partial derivatives might be singular; usually, this happens because not all the
parameters are identifiable. Removing some of the parameters or using a longer time series might help.

- The iterative process might not converge. PROC ARIMA's estimation method stops after $n$ iterations,
where $n$ is the value of the MAXITER= option. If an iteration does not improve the SSE, the Marquardt
parameter is increased by a factor of ten until parameters that have a smaller SSE are obtained or until
the limit value of the Marquardt parameter is exceeded.

- For METHOD=CLS, the estimates might converge but not to least squares estimates. The estimates
might converge to a local minimum, the numerical calculations might be distorted by data whose
sum-of-squares surface is not smooth, or the minimum might lie outside the region of invertibility or
stationarity.

- If the data are differenced and a moving-average model is fit, the parameter estimates might try to
converge exactly on the invertibility boundary. In this case, the standard error estimates that are based
on derivatives might be inaccurate.
Specifying Inputs and Transfer Functions

Input variables and transfer functions for them can be specified using the INPUT= option in the ESTIMATE statement. The variables used in the INPUT= option must be included in the CROSSCORR= list in the previous IDENTIFY statement. If any differencing is specified in the CROSSCORR= list, then the differenced variable is used as the input to the transfer function.

General Syntax of the INPUT= Option

The general syntax of the INPUT= option is

\[ \text{ESTIMATE \ldots INPUT} = (\text{transfer-function variable \ldots}) \]

The transfer function for an input variable is optional. The name of a variable by itself can be used to specify a pure regression term for the variable.

If specified, the syntax of the transfer function is

\[ S \cdot (L_{1,1}, L_{1,2}, \ldots) (L_{2,1}, \ldots) / (L_{i,1}, L_{i,2}, \ldots) (L_{i+1,1}, \ldots) \ldots \]

\( S \) is the number of periods of time delay (lag) for this input series. Each term in parentheses specifies a polynomial factor with parameters at the lags specified by the \( L_{i,j} \) values. The terms before the slash (/) are numerator factors. The terms after the slash (/) are denominator factors. All three parts are optional.

Commas can optionally be used between input specifications to make the INPUT= option more readable. The $ sign after the shift is also optional.

Except for the first numerator factor, each of the terms \( L_{i,1}, L_{i,2}, \ldots, L_{i,k} \) indicates a factor of the form

\[ (1 - \omega_{i,1}B^{L_{i,1}} - \omega_{i,2}B^{L_{i,2}} - \ldots - \omega_{i,k}B^{L_{i,k}}) \]

The form of the first numerator factor depends on the ALTPARM option. By default, the constant 1 in the first numerator factor is replaced with a free parameter \( \omega_0 \).

Alternative Model Parameterization

When the ALTPARM option is specified, the \( \omega_0 \) parameter is factored out so that it multiplies the entire transfer function, and the first numerator factor has the same form as the other factors.

The ALTPARM option does not materially affect the results; it just presents the results differently. Some people prefer to see the model written one way, while others prefer the alternative representation. Table 7.9 illustrates the effect of the ALTPARM option.

<table>
<thead>
<tr>
<th>INPUT= Option</th>
<th>ALTPARM</th>
<th>Model</th>
</tr>
</thead>
<tbody>
<tr>
<td>INPUT=((1 2)(12)/(1)X);</td>
<td>No</td>
<td>( (\omega_0 - \omega_1 B - \omega_2 B^2)(1 - \omega_3 B^{12})/(1 - \delta_1 B)X_t )</td>
</tr>
<tr>
<td></td>
<td>Yes</td>
<td>( \omega_0(1 - \omega_1 B - \omega_2 B^2)(1 - \omega_3 B^{12})/(1 - \delta_1 B)X_t )</td>
</tr>
</tbody>
</table>
### Differencing and Input Variables

If you difference the response series and use input variables, take care that the differencing operations do not change the meaning of the model. For example, if you want to fit the model

\[
Y_t = \frac{\omega_0}{(1 - \delta_1 B)} X_t + \frac{(1 - \theta_1 B)}{(1 - B)(1 - B^{12})} a_t
\]

then the IDENTIFY statement must read

```plaintext
identify var=y(1,12) crosscorr=x(1,12);
estimate q=1 input=(/(1)x) noconstant;
```

If instead you specify the differencing as

```plaintext
identify var=y(1,12) crosscorr=x;
estimate q=1 input=(/(1)x) noconstant;
```

then the model being requested is

\[
Y_t = \frac{\omega_0}{(1 - \delta_1 B)} X_t + \frac{(1 - \theta_1 B)}{(1 - B)(1 - B^{12})} a_t
\]

which is a very different model.

The point to remember is that a differencing operation requested for the response variable specified by the VAR= option is applied only to that variable and not to the noise term of the model.

### Initial Values

The syntax for giving initial values to transfer function parameters in the INITVAL= option parallels the syntax of the INPUT= option. For each transfer function in the INPUT= option, the INITVAL= option should give an initialization specification followed by the input series name. The initialization specification for each transfer function has the form

\[
C \times (V_{i,1}, V_{i,2}, \ldots)(V_{2,1}, \ldots)\ldots/(V_{i,1}, \ldots)\ldots
\]

where \(C\) is the lag 0 term in the first numerator factor of the transfer function (or the overall scale factor if the ALTPARM option is specified) and \(V_{i,j}\) is the coefficient of the \(L_{i,j}\) element in the transfer function.

To illustrate, suppose you want to fit the model

\[
Y_t = \mu + \frac{(\omega_0 - \omega_1 B - \omega_2 B^2)}{(1 - \delta_1 B - \delta_2 B^2 - \delta_3 B^3)} X_{t-3} + \frac{1}{(1 - \phi_1 B - \phi_2 B^2)} a_t
\]

and start the estimation process with the initial values \(\mu=10, \omega_0=1, \omega_1=0.5, \omega_2=0.03, \delta_1=0.8, \delta_2=-0.1, \delta_3=0.002, \phi_1=0.1, \phi_2=0.01\). (These are arbitrary values for illustration only.) You would use the following statements:
identify var=y crosscorr=x;
estimate p=(1,3) input=(3$(1,2)/(1,2,3)x)
mu=10 ar=.1 .01
initval=(1$(.5,.03)/(.8,-.1,.002)x);

Note that the lags specified for a particular factor are sorted, so initial values should be given in sorted order. For example, if the P= option had been entered as P=(3,1) instead of P=(1,3), the model would be the same and so would the AR= option. Sorting is done within all factors, including transfer function factors, so initial values should always be given in order of increasing lags.

Here is another illustration, showing initialization for a factored model with multiple inputs. The model is

\[ Y_t = \mu + \frac{\omega_{1,0}}{(1 - \delta_{1,1} B)} W_t + (\omega_{2,0} - \omega_{2,1} B) X_{t-3} + \frac{1}{(1 - \phi_1 B)(1 - \phi_2 B^6 - \phi_3 B^{12})} a_t \]

and the initial values are \( \mu=10, \omega_{1,0}=5, \delta_{1,1}=0.8, \omega_{2,0}=1, \omega_{2,1}=0.5, \phi_1=0.1, \phi_2=0.05, \) and \( \phi_3=0.01. \) You would use the following statements:

identify var=y crosscorr=(w x);
estimate p=(1)(6,12) input=/(1)w, 3$(1)x)
mu=10 ar=.1 .05 .01
initval=(5$/(.8)w 1$(.5)x);

**Stationarity and Invertibility**

By default, PROC ARIMA requires that the parameter estimates for the AR and MA parts of the model always remain in the stationary and invertible regions, respectively. The NOSTABLE option removes this restriction and for high-order models can save some computer time. Note that using the NOSTABLE option does not necessarily result in an unstable model being fit, since the estimates can leave the stable region for some iterations but still ultimately converge to stable values. Similarly, by default, the parameter estimates for the denominator polynomial of the transfer function part of the model are also restricted to be stable. The NOTFSTABLE option can be used to remove this restriction.

**Naming of Model Parameters**

In the table of parameter estimates produced by the ESTIMATE statement, model parameters are referred to by using the naming convention described in this section.

The parameters in the noise part of the model are named as \( \text{AR}i,j \) or \( \text{MA}i,j \), where AR refers to autoregressive parameters and MA to moving-average parameters. The subscript \( i \) refers to the particular polynomial factor, and the subscript \( j \) refers to the \( j \)th term within the \( i \)th factor. These terms are sorted in order of increasing lag within factors, so the subscript \( j \) refers to the \( j \)th term after sorting.
When inputs are used in the model, the parameters of each transfer function are named NUM\textsubscript{i,j} and DEN\textsubscript{i,j}. The \textit{j}th term in the \textit{i}th factor of a numerator polynomial is named NUM\textsubscript{i,j}. The \textit{j}th term in the \textit{i}th factor of a denominator polynomial is named DEN\textsubscript{i,j}.

This naming process is repeated for each input variable, so if there are multiple inputs, parameters in transfer functions for different input series have the same name. The table of parameter estimates shows in the “Variable” column the input with which each parameter is associated. The parameter name shown in the “Parameter” column and the input variable name shown in the “Variable” column must be combined to fully identify transfer function parameters.

The lag 0 parameter in the first numerator factor for the first input variable is named NUM1. For subsequent input variables, the lag 0 parameter in the first numerator factor is named NUM\textsubscript{k}, where \textit{k} is the position of the input variable in the INPUT= option list. If the ALTPARM option is specified, the NUM\textsubscript{k} parameter is replaced by an overall scale parameter named SCALE\textsubscript{k}.

For the mean and noise process parameters, the response series name is shown in the “Variable” column. The lag and shift for each parameter are also shown in the table of parameter estimates when inputs are used.

### Missing Values and Estimation and Forecasting

Estimation and forecasting are carried out in the presence of missing values by forecasting the missing values with the current set of parameter estimates. The maximum likelihood algorithm employed was suggested by Jones (1980) and is used for both unconditional least squares (ULS) and maximum likelihood (ML) estimation.

The CLS algorithm simply fills in missing values with infinite memory forecast values, computed by forecasting ahead from the nonmissing past values as far as required by the structure of the missing values. These artificial values are then employed in the nonmissing value CLS algorithm. Artificial values are updated at each iteration along with parameter estimates.

For models with input variables, embedded missing values (that is, missing values other than at the beginning or end of the series) are not generally supported. Embedded missing values in input variables are supported for the special case of a multiple regression model that has ARIMA errors. A multiple regression model is specified by an INPUT= option that simply lists the input variables (possibly with lag shifts) without any numerator or denominator transfer function factors. One-step-ahead forecasts are not available for the response variable when one or more of the input variables have missing values.

When embedded missing values are present for a model with complex transfer functions, PROC ARIMA uses the first continuous nonmissing piece of each series to do the analysis. That is, PROC ARIMA skips observations at the beginning of each series until it encounters a nonmissing value and then uses the data from there until it encounters another missing value or until the end of the data is reached. This makes the current version of PROC ARIMA compatible with earlier releases that did not allow embedded missing values.

### Forecasting Details

If the model has input variables, a forecast beyond the end of the data for the input variables is possible only if univariate ARIMA models have previously been fit to the input variables or future values for the input variables are included in the DATA= data set.
If input variables are used, the forecast standard errors and confidence limits of the response depend on the estimated forecast error variance of the predicted inputs. If several input series are used, the forecast errors for the inputs should be independent; otherwise, the standard errors and confidence limits for the response series will not be accurate. If future values for the input variables are included in the DATA= data set, the standard errors of the forecasts will be underestimated since these values are assumed to be known with certainty.

The forecasts are generated using forecasting equations consistent with the method used to estimate the model parameters. Thus, the estimation method specified in the ESTIMATE statement also controls the way forecasts are produced by the FORECAST statement. If METHOD=CLS is used, the forecasts are infinite memory forecasts, also called conditional forecasts. If METHOD=ULS or METHOD=ML, the forecasts are finite memory forecasts, also called unconditional forecasts. A complete description of the steps to produce the series forecasts and their standard errors by using either of these methods is quite involved, and only a brief explanation of the algorithm is given in the next two sections. Additional details about the finite and infinite memory forecasts can be found in Brockwell and Davis (1991). The prediction of stationary ARMA processes is explained in Chapter 5, and the prediction of nonstationary ARMA processes is given in Chapter 9 of Brockwell and Davis (1991).

**Infinite Memory Forecasts**

If METHOD=CLS is used, the forecasts are infinite memory forecasts, also called conditional forecasts. The term conditional is used because the forecasts are computed by assuming that the unknown values of the response series before the start of the data are equal to the mean of the series. Thus, the forecasts are conditional on this assumption.

The series $x_t$ can be represented as

$$x_t = a_t + \sum_{i=1}^{\infty} \pi_i x_{t-i}$$

where $\phi(B) / \theta(B) = 1 - \sum_{i=1}^{\infty} \pi_i B^i$.

The $k$-step forecast of $x_{t+k}$ is computed as

$$\hat{x}_{t+k} = \sum_{i=1}^{k-1} \hat{\pi}_i \hat{x}_{t+k-i} + \sum_{i=k}^{\infty} \hat{\pi}_i x_{t+k-i}$$

where unobserved past values of $x_t$ are set to zero and $\hat{\pi}_i$ is obtained from the estimated parameters $\hat{\phi}$ and $\hat{\theta}$.

**Finite Memory Forecasts**

For METHOD=ULS or METHOD=ML, the forecasts are finite memory forecasts, also called unconditional forecasts. For finite memory forecasts, the covariance function of the ARMA model is used to derive the best linear prediction equation.

That is, the $k$-step forecast of $x_{t+k}$, given $(x_1, \cdots, x_{t-1})$, is

$$\bar{x}_{t+k} = C_{k,t} V_t^{-1} (x_1, \cdots, x_{t-1})'$$

where $C_{k,t}$ is the covariance of $x_{t+k}$ and $(x_1, \cdots, x_{t-1})$ and $V_t$ is the covariance matrix of the vector $(x_1, \cdots, x_{t-1})$. $C_{k,t}$ and $V_t$ are derived from the estimated parameters.
Finite memory forecasts minimize the mean squared error of prediction if the parameters of the ARMA model are known exactly. (In most cases, the parameters of the ARMA model are estimated, so the predictors are not true best linear forecasts.)

If the response series is differenced, the final forecast is produced by summing the forecast of the differenced series. This summation and the forecast are conditional on the initial values of the series. Thus, when the response series is differenced, the final forecasts are not true finite memory forecasts because they are derived by assuming that the differenced series begins in a steady-state condition. Thus, they fall somewhere between finite memory and infinite memory forecasts. In practice, there is seldom any practical difference between these forecasts and true finite memory forecasts.

Forecasting Log Transformed Data

The log transformation is often used to convert time series that are nonstationary with respect to the innovation variance into stationary time series. The usual approach is to take the log of the series in a DATA step and then apply PROC ARIMA to the transformed data. A DATA step is then used to transform the forecasts of the logs back to the original units of measurement. The confidence limits are also transformed by using the exponential function.

As one alternative, you can simply exponentiate the forecast series. This procedure gives a forecast for the median of the series, but the antilog of the forecast log series underpredicts the mean of the original series. If you want to predict the expected value of the series, you need to take into account the standard error of the forecast, as shown in the following example, which uses an AR(2) model to forecast the log of a series Y:

```plaintext
data in;
  set in;
  ylog = log( y );
run;

proc arima data=in;
  identify var=ylog;
  estimate p=2;
  forecast lead=10 out=out;
run;

data out;
  set out;
  y = exp( ylog );
  l95 = exp( l95 );
  u95 = exp( u95 );
  forecast = exp( forecast + std*std/2 );
run;
```

Specifying Series Periodicity

The INTERVAL= option is used together with the ID= variable to describe the observations that make up the time series. For example, INTERVAL=MONTH specifies a monthly time series in which each observation represents one month. See Chapter 4, “Date Intervals, Formats, and Functions,” for details about the interval values supported.
Detecting Outliers

The variable specified by the ID= option in the PROC ARIMA statement identifies the time periods associated with the observations. Usually, SAS date, time, or datetime values are used for this variable. PROC ARIMA uses the ID= variable in the following ways:

- to validate the data periodicity. When the INTERVAL= option is specified, PROC ARIMA uses the ID variable to check the data and verify that successive observations have valid ID values that correspond to successive time intervals. When the INTERVAL= option is not used, PROC ARIMA verifies that the ID values are nonmissing and in ascending order.

- to check for gaps in the input observations. For example, if INTERVAL=MONTH and an input observation for April 1970 follows an observation for January 1970, there is a gap in the input data with two omitted observations (namely February and March 1970). A warning message is printed when a gap in the input data is found.

- to label the forecast observations in the output data set. PROC ARIMA extrapolates the values of the ID variable for the forecast observations from the ID value at the end of the input data according to the frequency specifications of the INTERVAL= option. If the INTERVAL= option is not specified, PROC ARIMA extrapolates the ID variable by incrementing the ID variable value for the last observation in the input data by 1 for each forecast period. Values of the ID variable over the range of the input data are copied to the output data set.

The ALIGN= option is used to align the ID variable to the beginning, middle, or end of the time ID interval specified by the INTERVAL= option.

Detecting Outliers

You can use the OUTLIER statement to detect changes in the level of the response series that are not accounted for by the estimated model. The types of changes considered are additive outliers (AO), level shifts (LS), and temporary changes (TC).

Let \( \eta_t \) be a regression variable that describes some type of change in the mean response. In time series literature \( \eta_t \) is called a shock signature. An additive outlier at some time point \( s \) corresponds to a shock signature \( \eta_t \) such that \( \eta_s = 1.0 \) and \( \eta_t = 0.0 \) at all other points. Similarly a permanent level shift that originates at time \( s \) has a shock signature such that \( \eta_t \) is 0.0 for \( t < s \) and 1.0 for \( t \geq s \). A temporary level shift of duration \( d \) that originates at time \( s \) has \( \eta_t \) equal to 1.0 between \( s \) and \( s + d \) and 0.0 otherwise.

Suppose that you are estimating the ARIMA model

\[
D(B)Y_t = \mu_t + \frac{\theta(B)}{\phi(B)}a_t
\]

where \( Y_t \) is the response series, \( D(B) \) is the differencing polynomial in the backward shift operator \( B \) (possibly identity), \( \mu_t \) is the transfer function input, \( \phi(B) \) and \( \theta(B) \) are the AR and MA polynomials, respectively, and \( a_t \) is the Gaussian white noise series.

The problem of detection of level shifts in the OUTLIER statement is formulated as a problem of sequential selection of shock signatures that improve the model in the ESTIMATE statement. This is similar to the forward selection process in the stepwise regression procedure. The selection process starts with considering
shock signatures of the type specified in the TYPE= option, originating at each nonmissing measurement. This involves testing $H_0: \beta = 0$ versus $H_a: \beta \neq 0$ in the model

$$D(B)(Y_t - \beta \eta_t) = \mu_t + \frac{\theta(B)}{\phi(B)} a_t$$

for each of these shock signatures. The most significant shock signature, if it also satisfies the significance criterion in ALPHA= option, is included in the model. If no significant shock signature is found, then the outlier detection process stops; otherwise this augmented model, which incorporates the selected shock signature in its transfer function input, becomes the null model for the subsequent selection process. This iterative process stops if at any stage no more significant shock signatures are found or if the number of iterations exceeds the maximum search number that results due to the MAXNUM= and MAXPCT= settings. In all these iterations, the parameters of the ARIMA model in the ESTIMATE statement are held fixed.

The precise details of the testing procedure for a given shock signature $\eta_t$ are as follows:

The preceding testing problem is equivalent to testing $H_0: \beta = 0$ versus $H_a: \beta \neq 0$ in the following “regression with ARMA errors” model

$$N_t = \beta \xi_t + \frac{\theta(B)}{\phi(B)} a_t$$

where $N_t = (D(B)Y_t - \mu_t)$ is the “noise” process and $\xi_t = D(B)\eta_t$ is the “effective” shock signature.

In this setting, under $H_0$, $N = (N_1, N_2, \ldots, N_n)^T$ is a mean zero Gaussian vector with variance covariance matrix $\sigma^2 \Omega$. Here $\sigma^2$ is the variance of the white noise process $a_t$ and $\Omega$ is the variance-covariance matrix associated with the ARMA model. Moreover, under $H_a$, $N$ has $\beta \xi$ as the mean vector where $\xi = (\xi_1, \xi_2, \ldots, \xi_n)^T$. Additionally, the generalized least squares estimate of $\beta$ and its variance is given by

$$\hat{\beta} = \frac{\delta}{\kappa}$$

$$\text{Var}(\hat{\beta}) = \frac{\sigma^2}{\kappa}$$

where $\delta = \xi^T \Omega^{-1} N$ and $\kappa = \xi^T \Omega^{-1} \xi$. The test statistic $\tau^2 = \delta^2 / (\sigma^2 \kappa)$ is used to test the significance of $\beta$, which has an approximate chi-squared distribution with 1 degree of freedom under $H_0$. The type of estimate of $\sigma^2$ used in the calculation of $\tau^2$ can be specified by the SIGMA= option. The default setting is SIGMA=ROBUST, which corresponds to a robust estimate suggested in an outlier detection procedure in X-12-ARIMA, the Census Bureau’s time series analysis program; see Findley et al. (1998) for additional information. The robust estimate of $\sigma^2$ is computed by the formula

$$\hat{\sigma}^2 = (1.49 \times \text{Median}(|\hat{a}_t|))^2$$

where $\hat{a}_t$ are the standardized residuals of the null ARIMA model. The setting SIGMA=MSE corresponds to the usual mean squared error estimate (MSE) computed the same way as in the ESTIMATE statement with the NODF option.

The quantities $\delta$ and $\kappa$ are efficiently computed by a method described in de Jong and Penzer (1998); see also Kohn and Ansley (1985).
Modeling in the Presence of Outliers

In practice, modeling and forecasting time series data in the presence of outliers is a difficult problem for several reasons. The presence of outliers can adversely affect the model identification and estimation steps. Their presence close to the end of the observation period can have a serious impact on the forecasting performance of the model. In some cases, level shifts are associated with changes in the mechanism that drives the observation process, and separate models might be appropriate to different sections of the data. In view of all these difficulties, diagnostic tools such as outlier detection and residual analysis are essential in any modeling process.

The following modeling strategy, which incorporates level shift detection in the familiar Box-Jenkins modeling methodology, seems to work in many cases:

1. Proceed with model identification and estimation as usual. Suppose this results in a tentative ARIMA model, say M.
2. Check for additive and permanent level shifts unaccounted for by the model M by using the OUTLIER statement. In this step, unless there is evidence to justify it, the number of level shifts searched should be kept small.
3. Augment the original dataset with the regression variables that correspond to the detected outliers.
4. Include the first few of these regression variables in M, and call this model M1. Reestimate all the parameters of M1. It is important not to include too many of these outlier variables in the model in order to avoid the danger of over-fitting.
5. Check the adequacy of M1 by examining the parameter estimates, residual analysis, and outlier detection. Refine it more if necessary.

OUT= Data Set

The output data set produced by the OUT= option of the PROC ARIMA or FORECAST statements contains the following:

- the BY variables
- the ID variable
- the variable specified by the VAR= option in the IDENTIFY statement, which contains the actual values of the response series
- FORECAST, a numeric variable that contains the one-step-ahead predicted values and the multistep forecasts
- STD, a numeric variable that contains the standard errors of the forecasts
- a numeric variable that contains the lower confidence limits of the forecast. This variable is named L95 by default but has a different name if the ALPHA= option specifies a different size for the confidence limits.
• RESIDUAL, a numeric variable that contains the differences between actual and forecast values

• a numeric variable that contains the upper confidence limits of the forecast. This variable is named U95 by default but has a different name if the ALPHA= option specifies a different size for the confidence limits.

The ID variable, the BY variables, and the response variable are the only ones copied from the input to the output data set. In particular, the input variables are not copied to the OUT= data set.

Unless the NOOUTALL option is specified, the data set contains the whole time series. The FORECAST variable has the one-step forecasts (predicted values) for the input periods, followed by n forecast values, where n is the LEAD= value. The actual and RESIDUAL values are missing beyond the end of the series.

If you specify the same OUT= data set in different FORECAST statements, the latter FORECAST statements overwrite the output from the previous FORECAST statements. If you want to combine the forecasts from different FORECAST statements in the same output data set, specify the OUT= option once in the PROC ARIMA statement and omit the OUT= option in the FORECAST statements.

When a global output data set is created by the OUT= option in the PROC ARIMA statement, the variables in the OUT= data set are defined by the first FORECAST statement that is executed. The results of subsequent FORECAST statements are vertically concatenated onto the OUT= data set. Thus, if no ID variable is specified in the first FORECAST statement that is executed, no ID variable appears in the output data set, even if one is specified in a later FORECAST statement. If an ID variable is specified in the first FORECAST statement that is executed but not in a later FORECAST statement, the value of the ID variable is the same as the last value processed for the ID variable for all observations created by the later FORECAST statement. Furthermore, even if the response variable changes in subsequent FORECAST statements, the response variable name in the output data set is that of the first response variable analyzed.

OUTCOV= Data Set

The output data set produced by the OUTCOV= option of the IDENTIFY statement contains the following variables:

• LAG, a numeric variable that contains the lags that correspond to the values of the covariance variables. The values of LAG range from 0 to N for covariance functions and from –N to N for cross-covariance functions, where N is the value of the NLAG= option.

• VAR, a character variable that contains the name of the variable specified by the VAR= option.

• CROSSVAR, a character variable that contains the name of the variable specified in the CROSSTEST= option, which labels the different cross-covariance functions. The CROSSVAR variable is blank for the autocovariance observations. When there is no CROSSTEST= option, this variable is not created.

• N, a numeric variable that contains the number of observations used to calculate the current value of the covariance or cross-covariance function.

• COV, a numeric variable that contains the autocovariance or cross-covariance function values. COV contains the autocovariances of the VAR= variable when the value of the CROSSVAR variable is blank. Otherwise COV contains the cross covariances between the VAR= variable and the variable named by the CROSSVAR variable.
• CORR, a numeric variable that contains the autocorrelation or cross-correlation function values. CORR contains the autocorrelations of the VAR= variable when the value of the CROSSVAR variable is blank. Otherwise CORR contains the cross-correlations between the VAR= variable and the variable named by the CROSSVAR variable.

• STDERR, a numeric variable that contains the standard errors of the autocorrelations. The standard error estimate is based on the hypothesis that the process that generates the time series is a pure moving-average process of order LAG–1. For the cross-correlations, STDERR contains the value $1/\sqrt{n}$, which approximates the standard error under the hypothesis that the two series are uncorrelated.

• INVCORR, a numeric variable that contains the inverse autocorrelation function values of the VAR= variable. For cross-correlation observations (that is, when the value of the CROSSVAR variable is not blank), INVCORR contains missing values.

• PARTCORR, a numeric variable that contains the partial autocorrelation function values of the VAR= variable. For cross-correlation observations (that is, when the value of the CROSSVAR variable is not blank), PARTCORR contains missing values.

OUTEST= Data Set

PROC ARIMA writes the parameter estimates for a model to an output data set when the OUTEST= option is specified in the ESTIMATE statement. The OUTEST= data set contains the following:

• the BY variables

• _MODLABEL_, a character variable that contains the model label, if it is provided by using the label option in the ESTIMATE statement (otherwise this variable is not created).

• _NAME_, a character variable that contains the name of the parameter for the covariance or correlation observations or is blank for the observations that contain the parameter estimates. (This variable is not created if neither OUTCOV nor OUTCORR is specified.)

• _TYPE_, a character variable that identifies the type of observation. A description of the _TYPE_ variable values is given below.

• variables for model parameters

The variables for the model parameters are named as follows:

<table>
<thead>
<tr>
<th>Variable</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ERRORVAR</td>
<td>This numeric variable contains the variance estimate. The <em>TYPE</em>=EST observation for this variable contains the estimated error variance, and the remaining observations are missing.</td>
</tr>
<tr>
<td>MU</td>
<td>This numeric variable contains values for the mean parameter for the model. (This variable is not created if NOCONSTANT is specified.)</td>
</tr>
<tr>
<td>MAj _k</td>
<td>These numeric variables contain values for the moving-average parameters. The variables for moving-average parameters are named MAj _k, where j is the factor-number and k is the index of the parameter within a factor.</td>
</tr>
</tbody>
</table>
AR_j_k These numeric variables contain values for the autoregressive parameters. The variables for autoregressive parameters are named AR_j_k, where j is the factor number and k is the index of the parameter within a factor.

I_j_k These variables contain values for the transfer function parameters. Variables for transfer function parameters are named I_j_k, where j is the number of the INPUT variable associated with the transfer function component and k is the number of the parameter for the particular INPUT variable. INPUT variables are numbered according to the order in which they appear in the INPUT= list.

_STATUS_ This variable describes the convergence status of the model. A value of 0_CONVERGED indicates that the model converged.

The value of the _TYPE_ variable for each observation indicates the kind of value contained in the variables for model parameters for the observation. The OUTEST= data set contains observations with the following _TYPE_ values:

EST The observation contains parameter estimates.
STD The observation contains approximate standard errors of the estimates.
CORR The observation contains correlations of the estimates. OUTCORR must be specified to get these observations.
COV The observation contains covariances of the estimates. OUTCOV must be specified to get these observations.
FACTOR The observation contains values that identify for each parameter the factor that contains it. Negative values indicate denominator factors in transfer function models.
LAG The observation contains values that identify the lag associated with each parameter.
SHIFT The observation contains values that identify the shift associated with the input series for the parameter.

The values given for _TYPE_ =FACTOR, _TYPE_ =LAG, or _TYPE_ =SHIFT observations enable you to reconstruct the model employed when provided with only the OUTEST= data set.

OUTEST= Examples

This section clarifies how model parameters are stored in the OUTEST= data set with two examples.

Consider the following example:

```plaintext
proc arima data=input;
   identify var=y cross=(x1 x2);
   estimate p=(1)(6) q=(1,3)(12) input=(x1 x2) outest=est;
run;

proc print data=est;
run;
```

The model specified by these statements is

\[ Y_t = \mu + \omega_{1.0}X_{1,t} + \omega_{2.0}X_{2,t} + \frac{(1 - \theta_{11}B - \theta_{12}B^3)(1 - \theta_{21}B^{12})}{(1 - \phi_{11}B)(1 - \phi_{21}B^6)} \delta_t \]
The OUTTEST= data set contains the values shown in Table 7.10.

**Table 7.10** OUTTEST= Data Set for First Example

<table>
<thead>
<tr>
<th>Obs</th>
<th><em>TYPE</em></th>
<th>Y</th>
<th>MU</th>
<th>MA1_1</th>
<th>MA1_2</th>
<th>MA2_1</th>
<th>AR1_1</th>
<th>AR2_1</th>
<th>I1_1</th>
<th>I2_1</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>EST</td>
<td></td>
<td></td>
<td>0</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>2</td>
<td>STD</td>
<td></td>
<td></td>
<td>10</td>
<td>11</td>
<td>12</td>
<td>21</td>
<td>11</td>
<td>21</td>
<td>1;0</td>
</tr>
<tr>
<td>3</td>
<td>FACTOR</td>
<td></td>
<td></td>
<td>0</td>
<td>1</td>
<td>1</td>
<td>2</td>
<td>1</td>
<td>2</td>
<td>1</td>
</tr>
<tr>
<td>4</td>
<td>LAG</td>
<td></td>
<td></td>
<td>0</td>
<td>1</td>
<td>3</td>
<td>12</td>
<td>1</td>
<td>6</td>
<td>0</td>
</tr>
<tr>
<td>5</td>
<td>SHIFT</td>
<td></td>
<td></td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

Note that the symbols in the rows for _TYPE_=EST and _TYPE_=STD in Table 7.10 would be numeric values in a real data set.

Next, consider the following example:

```sas
proc arima data=input;
    identify var=y cross=(x1 x2);
    estimate p=1 q=1 input=(2 $ (1)/(1,2)x1 1 $ /(1)x2) outest=est;
run;

proc print data=est;
run;
```

The OUTTEST= data set contains the values shown in Table 7.11.

**Table 7.11** OUTTEST= Data Set for Second Example

<table>
<thead>

</tr>
</tbody>
</table>

**OUTMODEL= SAS Data Set**

The OUTMODEL= option in the ESTIMATE statement writes an output data set that enables you to reconstruct the model. The OUTMODEL= data set contains much the same information as the OUTTEST= data set but in a transposed form that might be more useful for some purposes. In addition, the OUTMODEL= data set includes the differencing operators.
The OUTMODEL data set contains the following:

- the BY variables
- _MODLABEL_, a character variable that contains the model label, if it is provided by using the label option in the ESTIMATE statement (otherwise this variable is not created).
- _NAME_, a character variable that contains the name of the response or input variable for the observation.
- _TYPE_, a character variable that contains the estimation method that was employed. The value of _TYPE_ can be CLS, ULS, or ML.
- _STATUS_, a character variable that describes the convergence status of the model. A value of 0_CONVERGED indicates that the model converged.
- _PARM_, a character variable that contains the name of the parameter given by the observation. _PARM_ takes on the values ERRORVAR, MU, AR, MA, NUM, DEN, and DIF.
- _VALUE_, a numeric variable that contains the value of the estimate defined by the _PARM_ variable.
- _STD_, a numeric variable that contains the standard error of the estimate.
- _FACTOR_, a numeric variable that indicates the number of the factor to which the parameter belongs.
- _LAG_, a numeric variable that contains the number of the term within the factor that contains the parameter.
- _SHIFT_, a numeric variable that contains the shift value for the input variable associated with the current parameter.

The values of _FACTOR_ and _LAG_ identify which particular MA, AR, NUM, or DEN parameter estimate is given by the _VALUE_ variable. The _NAME_ variable contains the response variable name for the MU, AR, or MA parameters. Otherwise, _NAME_ contains the input variable name associated with NUM or DEN parameter estimates. The _NAME_ variable contains the appropriate variable name associated with the current DIF observation as well. The _VALUE_ variable is 1 for all DIF observations, and the _LAG_ variable indicates the degree of differencing employed.

The observations contained in the OUTMODEL= data set are identified by the _PARM_ variable. A description of the values of the _PARM_ variable follows:

NUMRESID _VALUE_ contains the number of residuals.
NPARMS _VALUE_ contains the number of parameters in the model.
NDIFS _VALUE_ contains the sum of the differencing lags employed for the response variable.
ERRORVAR _VALUE_ contains the estimate of the innovation variance.
MU _VALUE_ contains the estimate of the mean term.
AR _VALUE_ contains the estimate of the autoregressive parameter indexed by the _FACTOR_ and _LAG_ variable values.
OUTSTAT= Data Set

PROC ARIMA writes the diagnostic statistics for a model to an output data set when the OUTSTAT= option is specified in the ESTIMATE statement. The OUTSTAT data set contains the following:

- the BY variables.
- _MODLABEL_, a character variable that contains the model label, if it is provided by using the label option in the ESTIMATE statement (otherwise this variable is not created).
- _TYPE_, a character variable that contains the estimation method used. _TYPE_ can have the value CLS, ULS, or ML.
- _STAT_, a character variable that contains the name of the statistic given by the _VALUE_ variable in this observation. _STAT_ takes on the values AIC, SBC, LOGLIK, SSE, NUMRESID, NPARMS, NDIFS, ERRORVAR, MU, CONV, and NITER.
- _VALUE_, a numeric variable that contains the value of the statistic named by the _STAT_ variable.

The observations contained in the OUTSTAT= data set are identified by the _STAT_ variable. A description of the values of the _STAT_ variable follows:

AIC    Akaike’s information criterion
SBC    Schwarz’s Bayesian criterion
LOGLIK the log-likelihood, if METHOD=ML or METHOD=ULS is specified
SSE    the sum of the squared residuals
NUMRESID the number of residuals
NPARMS the number of parameters in the model
NDIFS the sum of the differencing lags employed for the response variable
ERRORVAR the estimate of the innovation variance
MU     the estimate of the mean term
CONV tells if the estimation converged. The value of 0 signifies that estimation converged. Nonzero values reflect convergence problems.

NITER the number of iterations

Remark. CONV takes an integer value that corresponds to the error condition of the parameter estimation process. The value of 0 signifies that estimation process has converged. The higher values signify convergence problems of increasing severity. Specifically:

- CONV = 0 indicates that the estimation process has converged.
- CONV = 1 or 2 indicates that the estimation process has run into numerical problems (such as encountering an unstable model or a ridge) during the iterations.
- CONV >= 3 indicates that the estimation process has failed to converge.

Printed Output
The ARIMA procedure produces printed output for each of the IDENTIFY, ESTIMATE, and FORECAST statements. The output produced by each ARIMA statement is described in the following sections.

IDENTIFY Statement Printed Output
The printed output of the IDENTIFY statement consists of the following:

- a table of summary statistics, including the name of the response variable, any specified periods of differencing, the mean and standard deviation of the response series after differencing, and the number of observations after differencing
- a plot of the sample autocorrelation function for lags up to and including the NLAG= option value. Standard errors of the autocorrelations also appear to the right of the autocorrelation plot if the value of LINESIZE= option is sufficiently large. The standard errors are derived using Bartlett’s approximation (Box and Jenkins 1976, p. 177). The approximation for a standard error for the estimated autocorrelation function at lag k is based on a null hypothesis that a pure moving-average Gaussian process of order k–1 generated the time series. The relative position of an approximate 95% confidence interval under this null hypothesis is indicated by the dots in the plot, while the asterisks represent the relative magnitude of the autocorrelation value.
- a plot of the sample inverse autocorrelation function. See the section “The Inverse Autocorrelation Function” on page 234 for more information about the inverse autocorrelation function.
- a plot of the sample partial autocorrelation function
- a table of test statistics for the hypothesis that the series is white noise. These test statistics are the same as the tests for white noise residuals produced by the ESTIMATE statement and are described in the section “Estimation Details” on page 242.
• a plot of the sample cross-correlation function for each series specified in the CROSSCORR= option. If a model was previously estimated for a variable in the CROSSCORR= list, the cross-correlations for that series are computed for the prewhitened input and response series. For each input variable with a prewhitening filter, the cross-correlation report for the input series includes the following:

  – a table of test statistics for the hypothesis of no cross-correlation between the input and response series
  – the prewhitening filter used for the prewhitening transformation of the predictor and response variables

• ESACF tables if the ESACF option is used

• MINIC table if the MINIC option is used

• SCAN table if the SCAN option is used

• STATIONARITY test results if the STATIONARITY option is used

ESTIMATE Statement Printed Output

The printed output of the ESTIMATE statement consists of the following:

• if the PRINTALL option is specified, the preliminary parameter estimates and an iteration history that shows the sequence of parameter estimates tried during the fitting process

• a table of parameter estimates that show the following for each parameter: the parameter name, the parameter estimate, the approximate standard error, t value, approximate probability (Pr > |t|), the lag for the parameter, the input variable name for the parameter, and the lag or “Shift” for the input variable

• the estimates of the constant term, the innovation variance (variance estimate), the innovation standard deviation (Std Error Estimate), Akaike’s information criterion (AIC), Schwarz’s Bayesian criterion (SBC), and the number of residuals

• the correlation matrix of the parameter estimates

• a table of test statistics for hypothesis that the residuals of the model are white noise. The table is titled “Autocorrelation Check of Residuals.”

• if the PLOT option is specified, autocorrelation, inverse autocorrelation, and partial autocorrelation function plots of the residuals

• if an INPUT variable has been modeled in such a way that prewhitening is performed in the IDENTIFY step, a table of test statistics titled “Crosscorrelation Check of Residuals.” The test statistic is based on the chi-square approximation suggested by Box and Jenkins (1976, pp. 395–396). The cross-correlation function is computed by using the residuals from the model as one series and the prewhitened input variable as the other series.

• if the GRID option is specified, the sum-of-squares or likelihood surface over a grid of parameter values near the final estimates
• a summary of the estimated model that shows the autoregressive factors, moving-average factors, and transfer function factors in backshift notation with the estimated parameter values.

OUTLIER Statement Printed Output

The printed output of the OUTLIER statement consists of the following:

• a summary that contains the information about the maximum number of outliers searched, the number of outliers actually detected, and the significance level used in the outlier detection.

• a table that contains the results of the outlier detection process. The outliers are listed in the order in which they are found. This table contains the following columns:

  – The Obs column contains the observation number of the start of the level shift.
  – If an ID= option is specified, then the Time ID column contains the time identification labels of the start of the outlier.
  – The Type column lists the type of the outlier.
  – The Estimate column contains \( \hat{\beta} \), the estimate of the regression coefficient of the shock signature.
  – The Chi-Square column lists the value of the test statistic \( \tau^2 \).
  – The Approx Prob > ChiSq column lists the approximate p-value of the test statistic.

FORECAST Statement Printed Output

The printed output of the FORECAST statement consists of the following:

• a summary of the estimated model

• a table of forecasts with following columns:

  – The Obs column contains the observation number.
  – The Forecast column contains the forecast values.
  – The Std Error column contains the forecast standard errors.
  – The Lower and Uppers columns contain the approximate 95% confidence limits. The ALPHA= option can be used to change the confidence interval for forecasts.
  – If the PRINTALL option is specified, the forecast table also includes columns for the actual values of the response series (Actual) and the residual values (Residual).

ODS Table Names

PROC ARIMA assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 7.12.

### Statistical Graphics

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section provides information about the graphics produced by the ARIMA procedure. (See Chapter 21, “Statistical Graphics Using ODS” (SAS/STAT User’s Guide), for more information about ODS statistical graphics.) The main types of plots available are as follows:

- plots useful in the trend and correlation analysis of the dependent and input series
- plots useful for the residual analysis of an estimated model
- forecast plots

You can obtain most plots relevant to the specified model by default. For finer control of the graphics, you can use the PLOTS= option in the PROC ARIMA statement. The following example is a simple illustration of how to use the PLOTS= option.

### Airline Series: Illustration of ODS Graphics

The series in this example, the monthly airline passenger series, is also discussed later, in Example 7.2.

The following statements specify an ARIMA(0,1,1)(0,1,1)_{12} model without a mean term to the logarithms of the airline passengers series, xlog. Notice the use of the global plot option ONLY in the PLOTS= option of the PROC ARIMA statement. It suppresses the production of default graphics and produces only the plots specified by the subsequent RESIDUAL and FORECAST plot options. The RESIDUAL(SMOOTH) plot specification produces a time series plot of residuals that has an overlaid loess fit; see Figure 7.21. The FORECAST(FORECAST) option produces a plot that shows the one-step-ahead forecasts, as well as the multistep-ahead forecasts; see Figure 7.22.
proc arima data=seriesg
   plots(only)=(residual(smooth) forecast(forecasts));
   identify var=xlog(1,12);
   estimate q=(1)(12) noint method=ml;
   forecast id=date interval=month;
run;

### ODS Graph Names

PROC ARIMA assigns a name to each graph it creates by using ODS. You can use these names to reference the graphs when you use ODS. The names are listed in Table 7.13.

Examples: ARIMA Procedure

Example 7.1: Simulated IMA Model

This example illustrates the ARIMA procedure results for a case where the true model is known. An integrated moving-average model is used for this illustration.

The following DATA step generates a pseudo-random sample of 100 periods from the ARIMA(0,1,1) process $u_t = u_{t-1} + a_t - 0.8a_{t-1}$, $a_t$ iid N(0, 1):

```plaintext
title1 'Simulated IMA(1,1) Series';
data a;
    u1 = 0.9; a1 = 0;
    do i = -50 to 100;
        a = rannor( 32565 );
        u = u1 + a - 0.8 * a1;
        if i > 0 then output;
        a1 = a;
        u1 = u;
    end;
run;
```

The following ARIMA procedure statements identify and estimate the model:

```plaintext
/*-- Simulated IMA Model --*/
proc arima data=a;
    identify var=u;
    run;
    identify var=u(1);
    run;
    estimate q=1 ;
    run;
quit;
```

The graphical series correlation analysis output of the first IDENTIFY statement is shown in Output 7.1.1. The output shows the behavior of the sample autocorrelation function when the process is nonstationary. Note that in this case the estimated autocorrelations are not very high, even at small lags. Nonstationarity is reflected in a pattern of significant autocorrelations that do not decline quickly with increasing lag, not in the size of the autocorrelations.
Output 7.1.1 Correlation Analysis from the First IDENTIFY Statement

The second IDENTIFY statement differences the series. The results of the second IDENTIFY statement are shown in Output 7.1.2. This output shows autocorrelation, inverse autocorrelation, and partial autocorrelation functions typical of MA(1) processes.
Chapter 7: The ARIMA Procedure

Output 7.1.2 Correlation Analysis from the Second IDENTIFY Statement

The ESTIMATE statement fits an ARIMA(0,1,1) model to the simulated data. Note that in this case the parameter estimates are reasonably close to the values used to generate the simulated data. \((\mu = 0, \mu = 0.02; \theta_1 = 0.8, \hat{\theta}_1 = 0.79; \sigma^2 = 1, \hat{\sigma}^2 = 0.82)\). Moreover, the graphical analysis of the residuals shows no model inadequacies (see Output 7.1.4 and Output 7.1.5).

The ESTIMATE statement results are shown in Output 7.1.3.

Output 7.1.3 Output from Fitting ARIMA(0,1,1) Model

Output 7.1.4  Residual Correlation Analysis of the ARIMA(0,1,1) Model
Example 7.2: Seasonal Model for the Airline Series

The airline passenger data, given as Series G in Box and Jenkins (1976), have been used in time series analysis literature as an example of a nonstationary seasonal time series. This example uses PROC ARIMA to fit the airline model, ARIMA(0,1,1)×(0,1,1)_{12}, to Box and Jenkins' Series G. The following statements read the data and log-transform the series:

```plaintext
title1 'International Airline Passengers';
title2 '(Box and Jenkins Series-G)';
data seriesg;
   input x @@;
xlog = log( x );
date = intnx( 'month', '31dec1948'd, _n_ );
   format date monyy.;
datalines;
112 118 132 129 121 135 148 148 136 119 104 118
...

The following PROC TIMESERIES step plots the series, as shown in Output 7.2.1:

```plaintext
proc timeseries data=seriesg plot=series;
   id date interval=month;
   var x;
run;
```
The following statements specify an ARIMA$(0,1,1) \times (0,1,1)_12$ model without a mean term to the logarithms of the airline passengers series, $x\log$. The model is forecast, and the results are stored in the data set B.

```sas
/*--- Seasonal Model for the Airline Series ---*/
proc arima data=seriesg;
  identify var=xlog(1,12);
  estimate q=(1)(12) noint method=ml;
  forecast id=date interval=month printall out=b;
run;
```

The output from the IDENTIFY statement is shown in Output 7.2.2. The autocorrelation plots shown are for the twice differenced series $(1 - B)(1 - B^{12})XLOG$. Note that the autocorrelation functions have the pattern characteristic of a first-order moving-average process combined with a seasonal moving-average process with lag 12.

### Output 7.2.3 Trend and Correlation Analysis for the Twice Differenced Series

Trend and Correlation Analysis for xlog(1 12)
The results of the ESTIMATE statement are shown in Output 7.2.4, Output 7.2.5, and Output 7.2.6. The model appears to fit the data quite well.

**Output 7.2.4** ESTIMATE Statement Output

| Parameter | Estimate | Standard Error | t Value | Pr > |t| | Lag |

Factor 2: 1 - 0.55686 B**(12)
Output 7.2.5  Residual Analysis of the Airline Model: Correlation
Output 7.2.6 Residual Analysis of the Airline Model: Normality

The forecasts and their confidence limits for the transformed series are shown in Output 7.2.7.
The following statements retransform the forecast values to get forecasts in the original scales. See the section “Forecasting Log Transformed Data” on page 252 for more information.

```plaintext
data c;
  set b;
  x     = exp( xlog );
  forecast = exp( forecast + std*std/2 );
  l95 = exp( l95 );
  u95 = exp( u95 );
run;
```

The forecasts and their confidence limits are plotted by using the following PROC SGPLOT step. The plot is shown in Output 7.2.8.

```plaintext
proc sgplot data=c;
  where date >= '1jan58'd;
  band Upper=u95 Lower=l95 x=date / LegendLabel="95% Confidence Limits";
  scatter x=date y=x;
  series x=date y=forecast;
run;
```
This example uses the Series J data from Box and Jenkins (1976). First, the input series \( X \) is modeled with a univariate ARMA model. Next, the dependent series \( Y \) is cross-correlated with the input series. Since a model has been fit to \( X \), both \( Y \) and \( X \) are prewhitened by this model before the sample cross-correlations are computed. Next, a transfer function model is fit with no structure on the noise term. The residuals from this model are analyzed; then, the full model, transfer function and noise, is fit to the data.

The following statements read 'Input Gas Rate' and 'Output CO\(_2\)' from a gas furnace. (Data values are not shown. The full example including data is in the SAS/ETS sample library.)

```sas
title1 'Gas Furnace Data';
title2 '(Box and Jenkins, Series J)';
data seriesj;
  input x y @@;
  label x = 'Input Gas Rate'
       y = 'Output CO2';
datalines;
```
The results of the first IDENTIFY statement for the input series \( X \) are shown in Output 7.3.1. The correlation analysis suggests an AR(3) model.

Example 7.4: An Intervention Model for Ozone Data

This example fits an intervention model to ozone data as suggested by Box and Tiao (1975). Notice that the response variable, OZONE, and the innovation, X1, are seasonally differenced. The final model for the differenced data is a multiple regression model with a moving-average structure assumed for the residuals.

The model is fit by maximum likelihood. The seasonal moving-average parameter and its standard error are fairly sensitive to which method is chosen to fit the model (Ansley and Newbold 1980; Davidson 1981); thus, fitting the model by the unconditional or conditional least squares method produces somewhat different estimates for these parameters.

Some missing values are appended to the end of the input data to generate additional values for the independent variables. Since the independent variables are not modeled, values for them must be available for any times at which predicted values are desired. In this case, predicted values are requested for 12 periods beyond the end of the data. Thus, values for X1, WINTER, and SUMMER must be given for 12 periods ahead.

The following statements read in the data and compute dummy variables for use as intervention inputs:

```plaintext
title1 'Intervention Data for Ozone Concentration';
title2 '(Box and Tiao, JASA 1975 P.70)';
data air;
  input ozone @@;
  label ozone = 'Ozone Concentration'
    x1   = 'Intervention for post 1960 period'
    summer = 'Summer Months Intervention'
    winter = 'Winter Months Intervention';
  date = intnx( 'month', '31dec1954'd, _n_ );
  format date monyy.;
  month = month( date );
  year = year( date );
```
Example 7.4: An Intervention Model for Ozone Data

\[
x_1 = \text{year} \geq 1960;
\text{summer} = (5 < \text{month} < 11) \ast (\text{year} > 1965);
\text{winter} = (\text{year} > 1965) - \text{summer};
\]
datalines;
2.7 2.0 3.6 5.0 6.5 6.1 5.9 5.0 6.4 7.4 8.2 3.9
4.1 4.5 5.5 3.8 4.8 5.6 6.3 5.9 8.7 5.3 5.7 5.7
3.0 3.4 4.9 4.5 4.0 5.7 6.3 7.1 8.0 5.2 5.0 4.7
3.7 3.1 2.5 4.0 4.1 4.6 4.4 4.2 5.1 4.6 4.4 4.0
... more lines ...

The following statements produce Output 7.4.1 through Output 7.4.3:

```sas
proc arima data=air;
/* Identify and seasonally difference ozone series */
identify var=ozone(12)
crosscorr=( x1(12) summer winter ) noprint;
/* Fit a multiple regression with a seasonal MA model */
/* by the maximum likelihood method */
estimate q=(1)(12) input=( x1 summer winter )
   noconstant method=ml;
/* Forecast */
forecast lead=12 id=date interval=month;
run;
```

The ESTIMATE statement results are shown in Output 7.4.1 and Output 7.4.2.

Example 7.5: Using Diagnostics to Identify ARIMA Models

Fitting ARIMA models is as much an art as it is a science. The ARIMA procedure has diagnostic options to help tentatively identify the orders of both stationary and nonstationary ARIMA processes.

Consider the Series A in Box, Jenkins, and Reinsel (1994), which consists of 197 concentration readings taken every two hours from a chemical process. Let Series A be a data set that contains these readings in a variable named X. The following SAS statements use the SCAN option of the IDENTIFY statement to generate Output 7.5.1 and Output 7.5.2. See “The SCAN Method” on page 239 for details of the SCAN method.
Example 7.5: Using Diagnostics to Identify ARIMA Models

/**-- Order Identification Diagnostic with SCAN Method --*/
proc arima data=SeriesA;
  identify var=x scan;
run;

**Output 7.5.1** Example of SCAN Tables

<table>

In **Output 7.5.3**, there are three right-triangular regions in which all elements are insignificant at the 5% level. The triangles have vertices (1,1), (3,1), and (4,1). Since the triangle at (1,1) covers more insignificant terms, it is recommended first. Similarly, the remaining recommendations are ordered by the number of insignificant terms contained in the triangle. **Output 7.5.4** gives recommendations based on the significance level specified by the ALPHA=siglevel option.
Example 7.5: Using Diagnostics to Identify ARIMA Models

Output 7.5.4  Example of ESACF Option Tentative Order Selection

<table>
<thead>

<tr>
<td>p+d q p+d q</td>
</tr>
<tr>
<td>1 1 1 1</td>
</tr>
<tr>
<td>3 1</td>
</tr>
<tr>
<td>4 1</td>
</tr>
</tbody>
</table>

(5% Significance Level)

From Output 7.5.5, the autoregressive and moving-average orders are tentatively identified by both SCAN and ESACF tables to be \((p + d, q) = (1, 1)\). Because both the SCAN and ESACF indicate a \(p + d\) term of 1, a unit root test should be used to determine whether this autoregressive term is a unit root. Since a moving-average term appears to be present, a large autoregressive term is appropriate for the augmented Dickey-Fuller test for a unit root.
Submitting the following statements generates Output 7.5.6:

```plaintext
/*-- Augmented Dickey-Fuller Unit Root Tests --*/
proc arima data=SeriesA;
   identify var=x stationarity=(adf=(5,6,7,8));
run;
```

Output 7.5.6 Example of STATIONARITY Option Output

The preceding test results show that a unit root is very likely given that none of the \( p \)-values are small enough to cause you to reject the null hypothesis that the series has a unit root. Based on this test and the previous results, the series should be differenced, and an ARIMA(0,1,1) would be a good choice for a tentative model for Series A.

Using the recommendation that the series be differenced, the following statements generate Output 7.5.7:

```plaintext
/*-- Minimum Information Criterion --*/
proc arima data=SeriesA;
   identify var=x(1) minic;
run;
```

</table>

The error series is estimated by using an AR(7) model, and the minimum of this MINIC table is $BIC(0, 1)$. This diagnostic confirms the previous result which indicates that an ARIMA(0,1,1) is a tentative model for Series A.

If you also specify the SCAN or MINIC option in the same IDENTIFY statement as follows, the BIC associated with the SCAN table and ESACF table recommendations is listed. Output 7.5.8 shows the results.

```sas
/*--- Combination of MINIC, SCAN and ESACF Options ---*/
proc arima data=SeriesA;
  identify var=x(1) minic scan esacf;
run;
```

(5% Significance Level)
Example 7.6: Detection of Level Changes in the Nile River Data

This example shows how to use the OUTLIER statement to detect changes in the dynamics of the time series being modeled. The time series used here is discussed in de Jong and Penzer (1998). The data consist of readings of the annual flow volume of the Nile River at Aswan from 1871 to 1970. These data have also been studied by Cobb (1978). These studies indicate that river flow levels in the years 1877 and 1913 are strong candidates for additive outliers and that there was a shift in the flow levels starting from the year 1899. This shift in 1899 is attributed partly to the weather changes and partly to the start of construction work for a new dam at Aswan. The following DATA step statements create the input data set.

```plaintext
data nile;
  input level @@;
  year = intnx('year', '1jan1871'd, _n_-1);
  format year year4.;
datalines;
1120 1160 963 1210 1160 1160 813 1230 1370 1140
995 935 1110 994 1020 960 1180 799 958 1140
1100 1210 1150 1250 1260 1220 1030 1100 774 840
... more lines ...
```

The following program fits an ARIMA model, ARIMA(0,1,1), similar to the structural model suggested in de Jong and Penzer (1998). This model is also suggested by the usual correlation analysis of the series. By default, the OUTLIER statement requests detection of additive outliers and level shifts, assuming that the series follows the estimated model.

```plaintext
/*** ARIMA(0, 1, 1) Model —*/
proc arima data=nile;
  identify var=level(1);
  estimate q=1 noint method=ml;
  outlier maxnum= 5 id=year;
run;
```

The outlier detection output is shown in Output 7.6.1.

<td>6.00</td>
<td>0.0143</td>
</tr>
</tbody>
</table>

Note that the first three outliers detected are indeed the ones discussed earlier. You can include the shock signatures that correspond to these three outliers in the Nile data set as follows:

```latex
\begin{verbatim}
data nile;
set nile;
AO1877 = ( year = '1jan1877'd );
AO1913 = ( year = '1jan1913'd );
LS1899 = ( year >= '1jan1899'd );
run;
\end{verbatim}
```

Now you can refine the earlier model by including these outliers. After examining the parameter estimates and residuals (not shown) of the ARIMA(0,1,1) model with these regressors, the following stationary MA1 model (with regressors) appears to fit the data well:

```latex
\begin{verbatim}
/*-- MA1 Model with Outliers --*/
data nile;
set nile;
AO1877 = ( year = '1jan1877'd );
AO1913 = ( year = '1jan1913'd );
LS1899 = ( year >= '1jan1899'd );
run;
\end{verbatim}
```

The relevant outlier detection process output is shown in **Output 7.6.2**. No outliers, at significance level 0.01, were detected.

### Output 7.6.2 MA1 Model with Outliers

```latex
\begin{verbatim}
SERIES A: Chemical Process Concentration Readings

The ARIMA Procedure

Outlier Detection Summary

Maximum number searched 5
Number found 0
Significance used 0.01
\end{verbatim}
```
Example 7.7: Iterative Outlier Detection

This example illustrates the iterative nature of the outlier detection process. This is done by using a simple test example where an additive outlier at observation number 50 and a level shift at observation number 100 are artificially introduced in the international airline passenger data used in Example 7.2. The following DATA step shows the modifications introduced in the data set:

```plaintext
data airline;
   set sashelp.air;
   logair = log(air);
   if _n_ = 50 then logair = logair - 0.25;
   if _n_ >= 100 then logair = logair + 0.5;
run;
```

In Example 7.2 the airline model, ARIMA(0, 1, 1)(0, 1, 1)_12, was seen to be a good fit to the unmodified log-transformed airline passenger series. The preliminary identification steps (not shown) again suggest the airline model as a suitable initial model for the modified data. The following statements specify the airline model and request an outlier search.

```plaintext
/*-- Outlier Detection --*/
proc arima data=airline;
   identify var=logair( 1, 12 ) noprint;
   estimate q= (1)(12) noint method= ml;
   outlier maxnum=3 alpha=0.01;
run;
```

The outlier detection output is shown in Output 7.7.1.

### Output 7.7.1 Initial Model

<table>
<thead>
<tr>
<th>Obs</th>
<th>Type</th>

<td>-0.27508</td>
<td>104.78</td>
<td>&lt;.0001</td>
</tr>
<tr>
<td>135</td>
<td>Additive</td>
<td>-0.10488</td>
<td>13.08</td>
<td>0.0003</td>
</tr>
</tbody>
</table>
Example 7.7: Iterative Outlier Detection

Clearly the level shift at observation number 100 and the additive outlier at observation number 50 are the dominant outliers. Moreover, the corresponding regression coefficients seem to correctly estimate the size and sign of the change. You can augment the airline data with these two regressors, as follows:

```
data airline;
  set airline;
  if _n_ = 50 then AO = 1;
  else AO = 0.0;
  if _n_ >= 100 then LS = 1;
  else LS = 0.0;
run;
```

You can now refine the previous model by including these regressors, as follows. Note that the differencing order of the dependent series is matched to the differencing orders of the outlier regressors to get the correct “effective” outlier signatures.

```
/*-- Airline Model with Outliers --*/
proc arima data=airline;
  identify var=logair(1, 12)
  crosscorr=( AO(1, 12) LS(1, 12) )
  noprint;
  estimate q= (1)(12) noint
  input=( AO LS )
  method=ml plot;
  outlier maxnum=3 alpha=0.01;
run;
```

The outlier detection results are shown in Output 7.7.2.

**Output 7.7.2** Airline Model with Outliers

Overview: AUTOREG Procedure

The AUTOREG procedure estimates and forecasts linear regression models for time series data when the errors are autocorrelated or heteroscedastic. The autoregressive error model is used to correct for autocorrelation, and the generalized autoregressive conditional heteroscedasticity (GARCH) model and its variants are used to model and correct for heteroscedasticity.

When time series data are used in regression analysis, often the error term is not independent through time. Instead, the errors are serially correlated (autocorrelated). If the error term is autocorrelated, the efficiency of ordinary least squares (OLS) parameter estimates is adversely affected and standard error estimates are biased.

The autoregressive error model corrects for serial correlation. The AUTOREG procedure can fit autoregressive error models of any order and can fit subset autoregressive models. You can also specify stepwise autoregression to select the autoregressive error model automatically.

To diagnose autocorrelation, the AUTOREG procedure produces generalized Durbin-Watson (DW) statistics and their marginal probabilities. Exact p-values are reported for generalized DW tests to any specified order. For models with lagged dependent regressors, PROC AUTOREG performs the Durbin t test and the Durbin h test for first-order autocorrelation and reports their marginal significance levels.

Ordinary regression analysis assumes that the error variance is the same for all observations. When the error variance is not constant, the data are said to be heteroscedastic, and ordinary least squares estimates are inefficient. Heteroscedasticity also affects the accuracy of forecast confidence limits. More efficient use of the data and more accurate prediction error estimates can be made by models that take the heteroscedasticity into account.

To test for heteroscedasticity, the AUTOREG procedure uses the portmanteau Q test statistics (McLeod and Li 1983), Engle’s Lagrange multiplier tests (Engle 1982), tests from Lee and King (1993), and tests from Wong and Li (1995). Test statistics and significance p-values are reported for conditional heteroscedasticity at lags 1 through 12. The Bera-Jarque normality test statistic and its significance level are also reported to test for conditional nonnormality of residuals. The following tests for independence are also supported by the AUTOREG procedure for residual analysis and diagnostic checking: Brock-Dechert-Scheinkman (BDS) test, runs test, turning point test, and the rank version of the von Neumann ratio test.
The family of GARCH models provides a means of estimating and correcting for the changing variability of the data. The GARCH process assumes that the errors, although uncorrelated, are not independent, and it models the conditional error variance as a function of the past realizations of the series.

The AUTOREG procedure supports the following variations of the GARCH models:

- generalized ARCH (GARCH)
- integrated GARCH (IGARCH)
- exponential GARCH (EGARCH)
- quadratic GARCH (QGARCH)
- threshold GARCH (TGARCH)
- power GARCH (PGARCH)
- GARCH-in-mean (GARCH-M)

For GARCH-type models, the AUTOREG procedure produces the conditional prediction error variances in addition to parameter and covariance estimates.

The AUTOREG procedure can also analyze models that combine autoregressive errors and GARCH-type heteroscedasticity. PROC AUTOREG can output predictions of the conditional mean and variance for models with autocorrelated disturbances and changing conditional error variances over time.

Four estimation methods are supported for the autoregressive error model:

- Yule-Walker
- iterated Yule-Walker
- unconditional least squares
- exact maximum likelihood

The maximum likelihood method is used for GARCH models and for mixed AR-GARCH models.

The AUTOREG procedure produces forecasts and forecast confidence limits when future values of the independent variables are included in the input data set. PROC AUTOREG is a useful tool for forecasting because it uses the time series part of the model in addition to the systematic part in generating predicted values. The autoregressive error model takes into account recent departures from the trend in producing forecasts.

The AUTOREG procedure permits embedded missing values for the independent or dependent variables. The procedure should be used only for ordered and equally spaced time series data.
Getting Started: AUTOREG Procedure

Regression with Autocorrelated Errors

Ordinary regression analysis is based on several statistical assumptions. One key assumption is that the errors are independent of each other. However, with time series data, the ordinary regression residuals usually are correlated over time. It is not desirable to use ordinary regression analysis for time series data since the assumptions on which the classical linear regression model is based will usually be violated.

Violation of the independent errors assumption has three important consequences for ordinary regression. First, statistical tests of the significance of the parameters and the confidence limits for the predicted values are not correct. Second, the estimates of the regression coefficients are not as efficient as they would be if the autocorrelation were taken into account. Third, since the ordinary regression residuals are not independent, they contain information that can be used to improve the prediction of future values.

The AUTOREG procedure solves this problem by augmenting the regression model with an autoregressive model for the random error, thereby accounting for the autocorrelation of the errors. Instead of the usual regression model, the following autoregressive error model is used:

\[
y_t = x_t \beta + v_t \\
v_t = -\varphi_1 v_{t-1} - \varphi_2 v_{t-2} - \ldots - \varphi_m v_{t-m} + \epsilon_t \\
\epsilon_t \sim \text{IN}(0, \sigma^2)
\]

The notation \( \epsilon_t \sim \text{IN}(0, \sigma^2) \) indicates that each \( \epsilon_t \) is normally and independently distributed with mean 0 and variance \( \sigma^2 \).

By simultaneously estimating the regression coefficients \( \beta \) and the autoregressive error model parameters \( \varphi_i \), the AUTOREG procedure corrects the regression estimates for autocorrelation. Thus, this kind of regression analysis is often called autoregressive error correction or serial correlation correction.

Example of Autocorrelated Data

A simulated time series is used to introduce the AUTOREG procedure. The following statements generate a simulated time series \( Y \) with second-order autocorrelation:

```sas
/* Regression with Autocorrelated Errors */
data a;
  ul = 0; ull = 0;
  do time = -10 to 36;
    u = + 1.3 * ul - .5 * ull + 2 * rannor(12346);
    y = 10 + .5 * time + u;
    if time > 0 then output;
    ull = ul; ul = u;
  end;
run;
```
The series $Y$ is a time trend plus a second-order autoregressive error. The model simulated is

\[ y_t = 10 + 0.5t + \nu_t \]
\[ \nu_t = 1.3\nu_{t-1} - 0.5\nu_{t-2} + \epsilon_t \]
\[ \epsilon_t \sim \text{IN}(0, 4) \]

The following statements plot the simulated time series $Y$. A linear regression trend line is shown for reference.

```sas
title 'Autocorrelated Time Series';
proc sgplot data=a noautolegend;
  series x=time y=y / markers;
  reg x=time y=y / lineattrs=(color=black);
run;
```

The plot of series $Y$ and the regression line are shown in Figure 8.1.

**Figure 8.1** Autocorrelated Time Series

Note that when the series is above (or below) the OLS regression trend line, it tends to remain above (below) the trend for several periods. This pattern is an example of *positive autocorrelation*. 
Time series regression usually involves independent variables other than a time trend. However, the simple time trend model is convenient for illustrating regression with autocorrelated errors, and the series Y shown in Figure 8.1 is used in the following introductory examples.

**Ordinary Least Squares Regression**

To use the AUTOREG procedure, specify the input data set in the PROC AUTOREG statement and specify the regression model in a MODEL statement. Specify the model by first naming the dependent variable and then listing the regressors after an equal sign, as is done in other SAS regression procedures. The following statements regress Y on TIME by using ordinary least squares:

```
proc autoreg data=a;
  model y = time;
run;
```

The AUTOREG procedure output is shown in Figure 8.2.

**Parameter Estimates**

| Variable | DF | Estimate | Standard Error | t Value | Pr > |t| |
|----------|----|----------|----------------|---------|-------|---|
| Intercept| 1  | 8.2308   | 0.8559         | 9.62    | <.0001|
| time     | 1  | 0.5021   | 0.0403         | 12.45   | <.0001|
The output first shows statistics for the model residuals. The model root mean square error (Root MSE) is 2.51, and the model $R^2$ is 0.82. Notice that two $R^2$ statistics are shown, one for the regression model (Reg Rsq) and one for the full model (Total Rsq) that includes the autoregressive error process, if any. In this case, an autoregressive error model is not used, so the two $R^2$ statistics are the same.

Other statistics shown are the sum of square errors (SSE), mean square error (MSE), mean absolute error (MAE), mean absolute percentage error (MAPE), error degrees of freedom (DFE, the number of observations minus the number of parameters), the information criteria SBC, HQC, AIC, and AICC, and the Durbin-Watson statistic. (Durbin-Watson statistics, MAE, MAPE, SBC, HQC, AIC, and AICC are discussed in the section “Goodness-of-Fit Measures and Information Criteria” on page 376.)

The output then shows a table of regression coefficients, with standard errors and $t$ tests. The estimated model is

$$y_t = 8.23 + 0.502 t + \epsilon_t$$

$Est. Var(\epsilon_t) = 6.32$

The OLS parameter estimates are reasonably close to the true values, but the estimated error variance, 6.32, is much larger than the true value, 4.

**Autoregressive Error Model**

The following statements regress $Y$ on $TIME$ with the errors assumed to follow a second-order autoregressive process. The order of the autoregressive model is specified by the NLAG=2 option. The Yule-Walker estimation method is used by default. The example uses the METHOD=ML option to specify the exact maximum likelihood method instead.

```sas
proc autoreg data=a;
   model y = time / nlag=2 method=ml;
run;
```
The first part of the results is shown in Figure 8.3. The initial OLS results are produced first, followed by estimates of the autocorrelations computed from the OLS residuals. The autocorrelations are also displayed graphically.

The diagnostic statistics and parameter estimates tables in Figure 8.4 have the same form as in the OLS output, but the values shown are for the autoregressive error model. The MSE for the autoregressive model is 1.71, which is much smaller than the true value of 4. In small samples, the autoregressive error model tends to underestimate $\sigma^2$, while the OLS MSE overestimates $\sigma^2$.

Notice that the total $R^2$ statistic computed from the autoregressive model residuals is 0.954, reflecting the improved fit from the use of past residuals to help predict the next Y value. The Reg Rsq value 0.728 is the
The parameter estimates table shows the ML estimates of the regression coefficients and includes two additional rows for the estimates of the autoregressive parameters, labeled AR(1) and AR(2).

The estimated model is

\[ y_t = 7.88 + 0.5096t + \nu_t \]

\[ \nu_t = 1.25\nu_{t-1} - 0.628\nu_{t-2} + \epsilon_t \]

\[ Est. Var(\epsilon_t) = 1.71 \]

Note that the signs of the autoregressive parameters shown in this equation for \( \nu_t \) are the reverse of the estimates shown in the AUTOREG procedure output. Figure 8.4 also shows the estimates of the regression coefficients with the standard errors recomputed on the assumption that the autoregressive parameter estimates equal the true values.

### Predicted Values and Residuals

The AUTOREG procedure can produce two kinds of predicted values and corresponding residuals and confidence limits. The first kind of predicted value is obtained from only the structural part of the model, \( x'_t b \). This is an estimate of the unconditional mean of the response variable at time \( t \). For the time trend model, these predicted values trace the estimated trend. The second kind of predicted value includes both the structural part of the model and the predicted values of the autoregressive error process. The full model (conditional) predictions are used to forecast future values.

Use the OUTPUT statement to store predicted values and residuals in a SAS data set and to output other values such as confidence limits and variance estimates. The P= option specifies an output variable to contain the full model predicted values. The PM= option names an output variable for the predicted mean. The R= and RM= options specify output variables for the corresponding residuals, computed as the actual value minus the predicted value.

The following statements store both kinds of predicted values in the output data set. (The printed output is the same as previously shown in Figure 8.3 and Figure 8.4.)

```sas
proc autoreg data=a;
   model y = time / nlag=2 method=ml;
   output out=p p=yhat pm=trendhat;
run;
```

The following statements plot the predicted values from the regression trend line and from the full model together with the actual values:

```sas
title 'Predictions for Autocorrelation Model';
proc sgplot data=p;
   scatter x=time y=y / markerattrs=(color=blue);
   series x=time y=yhat / lineattrs=(color=blue);
   series x=time y=trendhat / lineattrs=(color=black);
run;
```
The plot of predicted values is shown in Figure 8.5.

In Figure 8.5 the straight line is the autocorrelation corrected regression line, traced out by the structural predicted values TRENDHAT. The jagged line traces the full model prediction values. The actual values are marked by asterisks. This plot graphically illustrates the improvement in fit provided by the autoregressive error process for highly autocorrelated data.

**Forecasting Autoregressive Error Models**

To produce forecasts for future periods, include observations for the forecast periods in the input data set. The forecast observations must provide values for the independent variables and have missing values for the response variable.

For the time trend model, the only regressor is time. The following statements add observations for time periods 37 through 46 to the data set A to produce an augmented data set B:
data b;
  y = .;
  do time = 37 to 46; output; end;
run;

data b;
  merge a b;
  by time;
run;

To produce the forecast, use the augmented data set as input to PROC AUTOREG, and specify the appropriate options in the OUTPUT statement. The following statements produce forecasts for the time trend with autoregressive error model. The output data set includes all the variables in the input data set, the forecast values (YHAT), the predicted trend (YTREND), and the upper (UCL) and lower (LCL) 95% confidence limits.

proc autoreg data=b;
  model y = time / nlag=2 method=ml;
  output out=p p=yhat pm=ytrend
     lcl=lcl ucl=ucl;
run;

The following statements plot the predicted values and confidence limits, and they also plot the trend line for reference. The actual observations are shown for periods 16 through 36, and a reference line is drawn at the start of the out-of-sample forecasts.

   title 'Forecasting Autocorrelated Time Series';
   proc sgplot data=p;
     band x=time upper=ucl lower=lcl;
     scatter x=time y=y;
     series x=time y=yhat;
     series x=time y=ytrend / lineattrs=(color=black);
   run;

The plot is shown in Figure 8.6. Notice that the forecasts take into account the recent departures from the trend but converge back to the trend line for longer forecast horizons.
In the preceding section, it is assumed that the order of the autoregressive process is known. In practice, you need to test for the presence of autocorrelation.

The Durbin-Watson test is a widely used method of testing for autocorrelation. The first-order Durbin-Watson statistic is printed by default. This statistic can be used to test for first-order autocorrelation. Use the DWPROB option to print the significance level (p-values) for the Durbin-Watson tests. Since the Durbin-Watson p-values are computationally expensive, they are not reported by default.

You can use the DW= option to request higher-order Durbin-Watson statistics. Since the ordinary Durbin-Watson statistic tests only for first-order autocorrelation, the Durbin-Watson statistics for higher-order autocorrelation are called generalized Durbin-Watson statistics.

The following statements perform the Durbin-Watson test for autocorrelation in the OLS residuals for orders 1 through 4. The DWPROB option prints the marginal significance levels (p-values) for the Durbin-Watson statistics.
/*-- Durbin-Watson test for autocorrelation --*/
proc autoreg data=a;
  model y = time / dw=4 dwprob;
run;

The AUTOREG procedure output is shown in Figure 8.7. In this case, the first-order Durbin-Watson test is highly significant, with $p < .0001$ for the hypothesis of no first-order autocorrelation. Thus, autocorrelation correction is needed.

Using the Durbin-Watson test, you can decide if autocorrelation correction is needed. However, generalized Durbin-Watson tests should not be used to decide on the autoregressive order. The higher-order tests assume the absence of lower-order autocorrelation. If the ordinary Durbin-Watson test indicates no first-order autocorrelation, you can use the second-order test to check for second-order autocorrelation. Once
Testing for Autocorrelation

When using Durbin-Watson tests to check for autocorrelation, you should specify an order at least as large as the order of any potential seasonality, since seasonality produces autocorrelation at the seasonal lag. For example, for quarterly data use DW=4, and for monthly data use DW=12.

Lagged Dependent Variables

The Durbin-Watson tests are not valid when the lagged dependent variable is used in the regression model. In this case, the Durbin \( h \) test or Durbin \( t \) test can be used to test for first-order autocorrelation.

For the Durbin \( h \) test, specify the name of the lagged dependent variable in the LAGDEP= option. For the Durbin \( t \) test, specify the LAGDEP option without giving the name of the lagged dependent variable.

For example, the following statements add the variable YLAG to the data set A and regress Y on YLAG instead of TIME:

```
data b;
set a;
ylag = lag1( y );
run;

proc autoreg data=b;
model y = ylag / lagdep=ylag;
run;
```

The results are shown in Figure 8.8. The Durbin \( h \) statistic 2.78 is significant with a \( p \)-value of 0.0027, indicating autocorrelation.

Stepwise Autoregression

Once you determine that autocorrelation correction is needed, you must select the order of the autoregressive error model to use. One way to select the order of the autoregressive error model is stepwise autoregression. The stepwise autoregression method initially fits a high-order model with many autoregressive lags and then sequentially removes autoregressive parameters until all remaining autoregressive parameters have significant t tests.

To use stepwise autoregression, specify the BACKSTEP option, and specify a large order with the NLAG= option. The following statements show the stepwise feature, using an initial order of 5:

```bash
/*-- stepwise autoregression --*/
proc autoreg data=a;
   model y = time / method=ml nlag=5 backstep;
run;
```

The results are shown in Figure 8.9.
**Stepwise Autoregression**

**Backward Elimination of Autoregressive Terms**

| Lag | Estimate | t Value | Pr > |t| |
|-----|----------|---------|------|---|
| 4   | -0.052908| -0.20   | 0.8442 |
| 3   | 0.115986 | 0.57    | 0.5698 |
| 5   | 0.131734 | 1.21    | 0.2340 |

The estimates of the autocorrelations are shown for 5 lags. The backward elimination of autoregressive terms report shows that the autoregressive parameters at lags 3, 4, and 5 were insignificant and eliminated, resulting in the second-order model shown previously in Figure 8.4. By default, retained autoregressive parameters must be significant at the 0.05 level, but you can control this with the SLSTAY= option. The remainder of the output from this example is the same as that in Figure 8.3 and Figure 8.4, and it is not repeated here.

The stepwise autoregressive process is performed using the Yule-Walker method. The maximum likelihood estimates are produced after the order of the model is determined from the significance tests of the preliminary Yule-Walker estimates.
When using stepwise autoregression, it is a good idea to specify an NLAG= option value larger than the order of any potential seasonality, since seasonality produces autocorrelation at the seasonal lag. For example, for monthly data use NLAG=13, and for quarterly data use NLAG=5.

Subset and Factored Models

In the previous example, the BACKSTEP option dropped lags 3, 4, and 5, leaving a second-order model. However, in other cases a parameter at a longer lag may be kept while some smaller lags are dropped. For example, the stepwise autoregression method might drop lags 2, 3, and 5 but keep lags 1 and 4. This is called a subset model, since the number of estimated autoregressive parameters is lower than the order of the model.

Subset models are common for seasonal data and often correspond to factored autoregressive models. A factored model is the product of simpler autoregressive models. For example, the best model for seasonal monthly data may be the combination of a first-order model for recent effects with a 12th-order subset model for the seasonality, with a single parameter at lag 12. This results in a 13th-order subset model with nonzero parameters at lags 1, 12, and 13. See Chapter 7, “The ARIMA Procedure,” for further discussion of subset and factored autoregressive models.

You can specify subset models with the NLAG= option. List the lags to include in the autoregressive model within parentheses. The following statements show an example of specifying the subset model resulting from the combination of a first-order process for recent effects with a fourth-order seasonal process:

```plaintext
/*--- specifying the lags ---*/
proc autoreg data=a;
   model y = time / nlag=(1 4 5);
run;
```

The MODEL statement specifies the following fifth-order autoregressive error model:

$$y_t = a + bt + v_t$$

$$v_t = -\phi_1 v_{t-1} - \phi_4 v_{t-4} - \phi_5 v_{t-5} + \epsilon_t$$

Testing for Heteroscedasticity

One of the key assumptions of the ordinary regression model is that the errors have the same variance throughout the sample. This is also called the homoscedasticity model. If the error variance is not constant, the data are said to be heteroscedastic.

Since ordinary least squares regression assumes constant error variance, heteroscedasticity causes the OLS estimates to be inefficient. Models that take into account the changing variance can make more efficient use of the data. Also, heteroscedasticity can make the OLS forecast error variance inaccurate because the predicted forecast variance is based on the average variance instead of on the variability at the end of the series.

To illustrate heteroscedastic time series, the following statements create the simulated series Y. The variable Y has an error variance that changes from 1 to 4 in the middle part of the series.
data a;
  do time = -10 to 120;
    s = 1 + (time >= 60 & time < 90);
    u = s*rannor(12346);
    y = 10 + .5 * time + u;
    if time > 0 then output;
  end;
run;

title 'Heteroscedastic Time Series';
proc sgplot data=a noautolegend;
  series x=time y=y / markers;
  reg x=time y=y / lineattrs=(color=black);
run;

The simulated series is plotted in Figure 8.10.

Figure 8.10 Heteroscedastic and Autocorrelated Series

To test for heteroscedasticity with PROC AUTOREG, specify the ARCHTEST option. The following statements regress Y on TIME and use the ARCHTEST= option to test for heteroscedastic OLS residuals:
/*--- test for heteroscedastic OLS residuals ---*/
proc autoreg data=a;
    model y = time / archtest;
    output out=r r=yresid;
run;

The PROC AUTOREG output is shown in Figure 8.11. The Q statistics test for changes in variance across time by using lag windows that range from 1 through 12. (See the section “Testing for Nonlinear Dependence: Heteroscedasticity Tests” on page 397 for details.) The p-values for the test statistics strongly indicate heteroscedasticity, with p < 0.0001 for all lag windows.

The Lagrange multiplier (LM) tests also indicate heteroscedasticity. These tests can also help determine the order of the ARCH model that is appropriate for modeling the heteroscedasticity, assuming that the changing variance follows an autoregressive conditional heteroscedasticity model.

Figure 8.11 Heteroscedasticity Tests
Testing for Heteroscedasticity

The tests of Lee and King (1993) and Wong and Li (1995) can also be applied to check the absence of ARCH effects. The following example shows that Wong and Li’s test is robust to detect the presence of ARCH effects with the existence of outliers.

```sas
/*-- data with outliers at observation 10 --*/
data b;
do time = -10 to 120;
s = 1 + (time >= 60 & time < 90);
u = s*rannor(12346);
y = 10 + .5 * time + u;
if time = 10 then
   do; y = 200; end;
if time > 0 then output;
end;
run;
/*-- test for heteroscedastic OLS residuals --*/
proc autoreg data=b;
   model y = time / archtest=(qlm) ;
   model y = time / archtest=(lk,wl) ;
run;
```

As shown in Figure 8.12, the $p$-values of Q or LM statistics for all lag windows are above 90%, which fails to reject the null hypothesis of the absence of ARCH effects. Lee and King’s test, which rejects the null hypothesis for lags more than 8 at 10% significance level, works better. Wong and Li’s test works best, rejecting the null hypothesis and detecting the presence of ARCH effects for all lag windows.

| Variable | DF | Estimate | Standard Error | t Value | Pr > |t| |
|----------|----|----------|----------------|---------|-------|---|
| Intercept| 1  | 9.8684   | 0.2529         | 39.02   | <.0001|
| time     | 1  | 0.5000   | 0.003628       | 137.82  | <.0001|
Heteroscedasticity and GARCH Models

There are several approaches to dealing with heteroscedasticity. If the error variance at different times is known, weighted regression is a good method. If, as is usually the case, the error variance is unknown and must be estimated from the data, you can model the changing error variance.

The generalized autoregressive conditional heteroscedasticity (GARCH) model is one approach to modeling time series with heteroscedastic errors. The GARCH regression model with autoregressive errors is

\[ y_t = x_t'\beta + \nu_t \]

\[ \nu_t = \epsilon_t - \varphi_1 \nu_{t-1} - \ldots - \varphi_m \nu_{t-m} \]
\[ \epsilon_t = \sqrt{h_t} \epsilon_t \]

\[ h_t = \omega + \sum_{i=1}^{q} \alpha_i \epsilon_{t-i}^2 + \sum_{j=1}^{p} \beta_j h_{t-j} \]

\[ \epsilon_t \sim \text{IN}(0, 1) \]

This model combines the \( m \)th-order autoregressive error model with the \( \text{GARCH}(p, q) \) variance model. It is denoted as the \( \text{AR}(m) \)-\( \text{GARCH}(p, q) \) regression model.

The tests for the presence of ARCH effects (namely, Q and LM tests, tests from Lee and King (1993) and tests from Wong and Li (1995)) can help determine the order of the \( \text{ARCH} \) model appropriate for the data. For example, the Lagrange multiplier (LM) tests shown in Figure 8.11 are significant \((p < 0.0001)\) through order 12, which indicates that a very high-order \( \text{ARCH} \) model is needed to model the heteroscedasticity.

The basic \( \text{ARCH}(q) \) model \((p = 0)\) is a short memory process in that only the most recent \( q \) squared residuals are used to estimate the changing variance. The \( \text{GARCH} \) model \((p > 0)\) allows long memory processes, which use all the past squared residuals to estimate the current variance. The LM tests in Figure 8.11 suggest the use of the \( \text{GARCH} \) model \((p > 0)\) instead of the \( \text{ARCH} \) model.

The \( \text{GARCH}(p, q) \) model is specified with the \( \text{GARCH}=(P=p, Q=q) \) option in the MODEL statement. The basic \( \text{ARCH}(q) \) model is the same as the \( \text{GARCH}(0, q) \) model and is specified with the \( \text{GARCH}=(Q=q) \) option.

The following statements fit an \( \text{AR}(2) \)-\( \text{GARCH}(1, 1) \) model for the Y series that is regressed on TIME. The \( \text{GARCH}=(P=1, Q=1) \) option specifies the \( \text{GARCH}(1, 1) \) conditional variance model. The \( \text{NLAG}=2 \) option specifies the \( \text{AR}(2) \) error process. Only the maximum likelihood method is supported for \( \text{GARCH} \) models; therefore, the \( \text{METHOD=} \) option is not needed. The \( \text{CEV=} \) option in the OUTPUT statement stores the estimated conditional error variance at each time period in the variable \( \text{VHAT} \) in an output data set named \( \text{OUT} \). The data set is the same as in the section “Testing for Heteroscedasticity” on page 322.

```plaintext
data c;
  ul=0; ull=0;
  do time = -10 to 120;
    s = 1 + (time >= 60 & time < 90);
    u = + 1.3 * ul - .5 * ull + s*rannor(12346);
    y = 10 + .5 * time + u;
    if time > 0 then output;
    ull = ul; ul = u;
  end;
run;
title 'AR(2)-GARCH(1,1) model for the Y series regressed on TIME';
proc autoreg data=c;
  model y = time / nlag=2 garch=(q=1,p=1) maxit=50;
  output out=out cev=vhat;
run;
```
The results for the GARCH model are shown in Figure 8.13. (The preliminary estimates are not shown.)

The normality test is not significant \( p = 0.959 \), which is consistent with the hypothesis that the residuals from the GARCH model, \( \varepsilon_t / \sqrt{h_t} \), are normally distributed. The parameter estimates table includes rows for the GARCH parameters. ARCH0 represents the estimate for the parameter \( \omega \), ARCH1 represents \( \alpha_1 \), and GARCH1 represents \( \gamma_1 \).

The following statements transform the estimated conditional error variance series \( \hat{V} \) to the estimated standard deviation series \( \hat{S} \). Then, they plot \( \hat{S} \) together with the true standard deviation \( S \) used to generate the simulated data.

```plaintext
data out;
set out;
shat = sqrt( vhat );
run;

title 'Predicted and Actual Standard Deviations';
proc sgplot data=out noautolegend;
scatter x=time y=s;
series x=time y=shat/ lineattrs=(color=black);
run;
```

The plot is shown in Figure 8.14.
In this example note that the form of heteroscedasticity used in generating the simulated series Y does not fit the GARCH model. The GARCH model assumes *conditional* heteroscedasticity, with homoscedastic unconditional error variance. That is, the GARCH model assumes that the changes in variance are a function of the realizations of preceding errors and that these changes represent temporary and random departures from a constant unconditional variance. The data-generating process used to simulate series Y, contrary to the GARCH model, has exogenous unconditional heteroscedasticity that is independent of past errors.

Nonetheless, as shown in Figure 8.14, the GARCH model does a reasonably good job of approximating the error variance in this example, and some improvement in the efficiency of the estimator of the regression parameters can be expected.
The GARCH model might perform better in cases where theory suggests that the data-generating process produces true autoregressive conditional heteroscedasticity. This is the case in some economic theories of asset returns, and GARCH-type models are often used for analysis of financial market data.

**GARCH Models**

The AUTOREG procedure supports several variations of GARCH models.

Using the `TYPE=` option along with the `GARCH=` option enables you to control the constraints placed on the estimated GARCH parameters. You can specify unconstrained, nonnegativity-constrained (default), stationarity-constrained, or integration-constrained models. The integration constraint produces the integrated GARCH (IGARCH) model.

You can also use the `TYPE=` option to specify the exponential form of the GARCH model, called the EGARCH model, or other types of GARCH models, namely the quadratic GARCH (QGARCH), threshold GARCH (TGARCH), and power GARCH (PGARCH) models. The `MEAN=` option along with the `GARCH=` option specifies the GARCH-in-mean (GARCH-M) model.

The following statements illustrate the use of the `TYPE=` option to fit an AR(2)-EGARCH(1, 1) model to the series Y. (Output is not shown.)

```sas
/*-- AR(2)-EGARCH(1,1) model --*/
proc autoreg data=a;
   model y = time / nlag=2 garch=(p=1,q=1,type=exp);
run;
```

See the section “GARCH Models” on page 367 for details.

---

**Syntax: AUTOREG Procedure**

The AUTOREG procedure is controlled by the following statements:

```
PROC AUTOREG options ;
   BY variables ;
   CLASS variables ;
   MODEL dependent = regressors / options ;
   HETERO variables / options ;
   NLOPTIONS options ;
   OUTPUT <OUT=SAS-data-set> <options> <keyword=name> ;
   RESTRICT equation , . . . , equation ;
   TEST equation , . . . , equation / option ;
```

At least one `MODEL` statement must be specified. One `OUTPUT` statement can follow each `MODEL` statement. One `HETERO` statement can follow each `MODEL` statement.
The statements and options used with the AUTOREG procedure are summarized in the following table.

### PROC AUTOREG Statement

**PROC AUTOREG** options;

The following options can be used in the PROC AUTOREG statement:

**DATA=SAS-data-set**

specifies the input SAS data set. If the DATA= option is not specified, PROC AUTOREG uses the most recently created SAS data set.

**OUTEST=SAS-data-set**

writes the parameter estimates to an output data set. See the section “OUTEST= Data Set” on page 406 for information on the contents of these data set.

**COVOUT**

writes the covariance matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.
PROC AUTOREG Statement  ♦  335

**PLOTS<**(global-plot-options)> < = (specific plot options)> **requests that the AUTOREG procedure produce statistical graphics via the Output Delivery System, provided that the ODS GRAPHICS statement has been specified. For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” (SAS/STAT User’s Guide). The global-plot-options apply to all relevant plots generated by the AUTOREG procedure. The global-plot-options supported by the AUTOREG procedure follow.**

**Global Plot Options**

- **ONLY** suppresses the default plots. Only the plots specifically requested are produced.
- **UNPACKPANEL | UNPACK** displays each graph separately. (By default, some graphs can appear together in a single panel.)

**Specific Plot Options**

- **ALL** requests that all plots appropriate for the particular analysis be produced.
- **ACF** produces the autocorrelation function plot.
- **IACF** produces the inverse autocorrelation function plot of residuals.
- **PACF** produces the partial autocorrelation function plot of residuals.
- **FITPLOT** plots the predicted and actual values.
- **COOKSD** produces the Cook’s $D$ plot.
- **QQ** Q-Q plot of residuals.
- **RESIDUAL | RES** plots the residuals.
- **STUDENTRESIDUAL** plots the studentized residuals. For the models with the NLAG= or GARCH= options in the MODEL statement or with the HETERO statement, this option is replaced by the STANDARDRESIDUAL option.
- **STANDARDRESIDUAL** plots the standardized residuals.
- **WHITENOISE** plots the white noise probabilities.
- **RESIDUALHISTOGRAM | RESIDHISTOGRAM** plots the histogram of residuals.
- **NONE** suppresses all plots.

In addition, any of the following MODEL statement options can be specified in the PROC AUTOREG statement, which is equivalent to specifying the option for every MODEL statement: **ALL, ARCHTEST, BACKSTEP, CENTER, COEF, CONVERGE=, CORRB, COVB, DW=, DWPROB, GINV, ITER, ITPRINT, MAXITER=, METHOD=, NOINT, NOMISS, NOPRINT, and PARTIAL.**
BY Statement

BY variables;

A BY statement can be used with PROC AUTOREG to obtain separate analyses on observations in groups defined by the BY variables.

CLASS Statement (Experimental)

CLASS variables;

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric.

In PROC AUTOREG, the CLASS statement enables you to output class variables to a data set that contains a copy of the original data.

Class levels are determined from the formatted values of the CLASS variables. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in *SAS Language Reference: Dictionary* for details.

MODEL Statement

MODEL dependent = regressors / options;

The MODEL statement specifies the dependent variable and independent regressor variables for the regression model. If no independent variables are specified in the MODEL statement, only the mean is fitted. (This is a way to obtain autocorrelations of a series.)

Models can be given labels of up to eight characters. Model labels are used in the printed output to identify the results for different models. The model label is specified as follows:

label : MODEL . . . ;

The following options can be used in the MODEL statement after a slash (/).

CENTER

centers the dependent variable by subtracting its mean and suppresses the intercept parameter from the model. This option is valid only when the model does not have regressors (explanatory variables).

NOINT

suppresses the intercept parameter.

Autoregressive Error Options

NLAG=number

NLAG=(number-list)

specifies the order of the autoregressive error process or the subset of autoregressive error lags to be fitted. Note that NLAG=3 is the same as NLAG=(1 2 3). If the NLAG= option is not specified, PROC AUTOREG does not fit an autoregressive model.
GARCH Estimation Options

\[ \text{DIST}= \text{value} \]

specifies the distribution assumed for the error term in GARCH-type estimation. If no GARCH= option is specified, the option is ignored. If EGARCH is specified, the distribution is always the normal distribution. The values of the DIST= option are as follows:

- T specifies Student’s t distribution.
- NORMAL specifies the standard normal distribution. The default is DIST=NORMAL.

\[ \text{GARCH}=(\text{option-list}) \]

specifies a GARCH-type conditional heteroscedasticity model. The GARCH= option in the MODEL statement specifies the family of ARCH models to be estimated. The GARCH(1, 1) regression model is specified in the following statement:

\[ \text{model } y = x_1 \ x_2 \ / \ garch=(q=1,p=1); \]

When you want to estimate the subset of ARCH terms, such as ARCH(1, 3), you can write the SAS statement as follows:

\[ \text{model } y = x_1 \ x_2 \ / \ garch=(q=(1 \ 3)); \]

With the TYPE= option, you can specify various GARCH models. The IGARCH(2, 1) model without trend in variance is estimated as follows:

\[ \text{model } y = / \ garch=(q=2,p=1,\text{type=integ, noint}); \]

The following options can be used in the GARCH=() option. The options are listed within parentheses and separated by commas.

- Q=number
- Q=(number-list)
  specifies the order of the process or the subset of ARCH terms to be fitted.

- P=number
- P=(number-list)
  specifies the order of the process or the subset of GARCH terms to be fitted. If only the P= option is specified, P= option is ignored and Q=1 is assumed.

\[ \text{TYPE}= \text{value} \]

specifies the type of GARCH model. The values of the TYPE= option are as follows:

- EXP | EGARCH specifies the exponential GARCH, or EGARCH, model.
- INTEGRATED | IGARCH specifies the integrated GARCH, or IGARCH, model.
- NELSON | NELSONCAO specifies the Nelson-Cao inequality constraints.
- NOCONSTRAINT specifies the GARCH model with no constraints.
NONNEG specifies the GARCH model with nonnegativity constraints.

POWER | PGARCH specifies the power GARCH, or PGARCH, model.

QUADR | QUADRATIC | QGARCH specifies the quadratic GARCH, or QGARCH, model.

STATIONARY constrains the sum of GARCH coefficients to be less than 1.

THRES | THRESHOLD | TGARCH | GJR | GJRGARCH specifies the threshold GARCH, or TGARCH, model.

The default is TYPE=NELSON.

**MEAN=value**

specifies the functional form of the GARCH-M model. You can specify the following values:

- **LINEAR** specifies the linear function:
  \[ y_t = x_t' \beta + \delta h_t + \epsilon_t \]

- **LOG** specifies the log function:
  \[ y_t = x_t' \beta + \delta \ln(h_t) + \epsilon_t \]

- **SQRT** specifies the square root function:
  \[ y_t = x_t' \beta + \delta \sqrt{h_t} + \epsilon_t \]

**NOINT** suppresses the intercept parameter in the conditional variance model. This option is valid only when you also specify the TYPE=INTEG option.

**STARTUP=MSE | ESTIMATE**

requests that the positive constant \( c \) for the start-up values of the GARCH conditional error variance process be estimated. By default, or if you specify STARTUP=MSE, the value of the mean squared error is used as the default constant.

**TR** uses the trust region method for GARCH estimation. This algorithm is numerically stable, although computation is expensive. The double quasi-Newton method is the default.

**Printing Options**

- **ALL** requests all printing options.

- **ARCHTEST**

  **ARCHTEST=(option-list)** specifies tests for the absence of ARCH effects. The following options can be used in the ARCHTEST=( ) option. The options are listed within parentheses and separated by commas.
QLM | QLMARCH
requests the Q and Engle’s LM tests.

LK | LKARCH
requests Lee and King’s ARCH tests.

WL | WLARCH
requests Wong and Li’s ARCH tests.

ALL
requests all ARCH tests, namely Q and Engle’s LM tests, Lee and King’s tests, and Wong and Li’s tests.

If ARCHTEST is defined without additional suboptions, it requests the Q and Engle’s LM tests. That is, the statement

```
model return = x1 x2 / archtest;
```

is equivalent to the statement

```
model return = x1 x2 / archtest=(qlm);
```
The following statement requests Lee and King’s tests and Wong and Li’s tests:

```
model return = / archtest=(lk, wl);
```

BDS

BDS=(option-list)
specifies Brock-Dechert-Scheinkman (BDS) tests for independence. The following options can be used in the BDS=( ) option. The options are listed within parentheses and separated by commas.

- **M=number**
  specifies the maximum number of the embedding dimension. The BDS tests with embedding dimension from 2 to M are calculated. M must be an integer between 2 and 20. The default value of the M= suboption is 20.

- **D=number**
  specifies the parameter to determine the radius for BDS test. The BDS test sets up the radius as 
  \[ r = D \times \sigma, \]
  where \( \sigma \) is the standard deviation of the time series to be tested. By default, D=1.5.

- **PVALUE=DIST | SIM**
  specifies the way to calculate the \( p \)-values. By default or if PVALUE=DIST is specified, the \( p \)-values are calculated according to the asymptotic distribution of BDS statistics (that is, the standard normal distribution). Otherwise, for samples of size less than 500, the \( p \)-values are obtained through Monte Carlo simulation.
Z=value

specifies the type of the time series (residuals) to be tested. You can specify the following values:

Y specifies the regressand.
RO specifies the OLS residuals.
R specifies the residuals of the final model.
RM specifies the structural residuals of the final model.
SR specifies the standardized residuals of the final model, defined by residuals over the square root of the conditional variance.

The default is Z=Y.

If BDS is defined without additional suboptions, all suboptions are set as default values. That is, the following two statements are equivalent:

```
model return = x1 x2 / nlag=1 BDS;
```

```
model return = x1 x2 / nlag=1 BDS=(M=20, D=1.5, PVALUE=DIST, Z=Y);
```

To do the specification check of a GARCH(1,1) model, you can write the SAS statement as follows:

```
model return = / garch=(p=1,q=1) BDS=(Z=SR);
```

BP
BP=(option-list)

specifies Bai-Perron (BP) tests for multiple structural changes, introduced in Bai and Perron (1998). You can specify the following options in the BP=( ) option, in parentheses and separated by commas.

EPS=number
specifies the minimum length of regime; that is, if EPS=\(\epsilon\), for any \(i, i = 1, \ldots, M, T_i - T_{i-1} \geq T \epsilon\), where \(T\) is the sample size; \((T_1 \ldots T_M)\) are the break dates; and \(T_0 = 0\) and \(T_{M+1} = T\). The default is EPS=0.05.

ETA=number
specifies that the second method is to be used in the calculation of the \(sup F(l+1/l)\) test, and the minimum length of regime for the new additional break date is \((T_i - T_{i-1})\epsilon\) if ETA=\(\eta\) and the new break date is in regime \(i\) for the given break dates \((T_1 \ldots T_I)\). The default value of the ETA= suboption is the missing value; i.e., the first method is to be used in the calculation of the \(sup F(l+1/l)\) test and, no matter which regime the new break date is in, the minimum length of regime for the new additional break date is \(T \epsilon\) when EPS=\(\epsilon\).

HAC<(option-list)>
specifies that the heteroscedasticity- and autocorrelation-consistent estimator be applied in the estimation of the variance covariance matrix and the confidence intervals of break dates. When the HAC option is specified, you can specify the following options within parentheses and separated by commas:
KERNEL=value
specifies the type of kernel function. You can specify the following values:

BARTLET specifies the Bartlett kernel function.
PARZEN specifies the Parzen kernel function.
QUADRATICSPECTRAL | QS specifies the quadratic spectral kernel function.
TRUNCATED specifies the truncated kernel function.
TUKEYHANNING | TUKEY | TH specifies the Tukey-Hanning kernel function.

The default is KERNEL=QUADRATICSPECTRAL.

KERNELLB=number
specifies the lower bound of the kernel weight value. Any kernel weight less than this lower bound is regarded as zero, which accelerates the calculation for big samples, especially for the quadratic spectral kernel. The default is KERNELLB=0.

BANDWIDTH=value
specifies the fixed bandwidth value or bandwidth selection method to use in the kernel function. You can specify the following values:

NEWEYWEST94 | NW94 <(C=number)> specifies the Newey and West (1994) bandwidth selection method. You can specify the C= option in parentheses to calculate the lag selection parameter; the default is C=12.
SAMPLESIZE | SS <(option-list)> specifies that the bandwidth be calculated according to the following equation, based on the sample size:

\[ b = \gamma T^r + c \]

where \( b \) is the bandwidth parameter and \( T \) is the sample size, and \( \gamma \), \( r \), and \( c \) are values specified by the following options within parentheses and separated by commas.

GAMMA=number
specifies the coefficient \( \gamma \) in the equation. The default is \( \gamma = 0.75 \).

RATE=number
specifies the growth rate \( r \) in the equation. The default is \( r = 0.3333 \).

CONSTANT=number
specifies the constant \( c \) in the equation. The default is \( c = 0.5 \).

INT
specifies that the bandwidth parameter must be integer; that is, \( b = \lfloor \gamma T^r + c \rfloor \), where \( \lfloor x \rfloor \) denotes the largest integer less than or equal to \( x \).

number specifies the fixed value of the bandwidth parameter.

The default is BANDWIDTH=ANDREWS91.
**PREWHITENING**

specifies that prewhitening is required in the calculation.

In the calculation of the HAC estimator, the adjustment for degrees of freedom is always applied. See the section “Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrix Estimator” on page 372 for more information about the HAC estimator.

**HE**

specifies that the errors are assumed to have heterogeneous distribution across regimes in the estimation of covariance matrix.

**HO**

specifies that $\Omega_i$s in the calculation of confidence intervals of break dates are different across regimes.

**HQ**

specifies that $Q_i$s in the calculation of confidence intervals of break dates are different across regimes.

**HR**

specifies that the regressors are assumed to have heterogeneous distribution across regimes in the estimation of covariance matrix.

**M=number**

specifies the number of breaks. For a given $M$, the following tests are to be performed: (1) the $sup F$ tests of no break versus the alternative hypothesis that there are $i$ breaks, $i = 1, ..., M$; (2) the $UD_{max}F$ and $WD_{max}F$ double maximum tests of no break versus the alternative hypothesis that there are unknown number of breaks up to $M$; and (3) the $sup F(l + 1|l)$ tests of $l$ versus $l + 1$ breaks, $l = 0, ..., M$. The default is $M=5$.

**NTHREADS=number**

specifies the number of threads to be used for parallel computing. The default is the number of CPUs available.

**P=number**

specifies the number of covariates that have coefficients unchanged over time in the partial structural change model. The first $P=p$ independent variables that are specified in the MODEL statement have unchanged coefficients; the rest of the independent variables have coefficients that change across regimes. The default is $P=0$; i.e., the pure structural change model is estimated.

**PRINTTEST=ALL | BIC | LWZ | NONE | SEQ<(<number>)> | number**

specifies in which structural change models the parameter estimates are to be printed. You can specify the following option values:

- **ALL**
 specifies that the parameter estimates in all structural change models with $m$ breaks, $m = 0, ..., M$, be printed.

- **BIC**
  specifies that the parameter estimates in the structural change model that minimizes the BIC information criterion be printed.

- **LWZ**
  specifies that the parameter estimates in the structural change model that minimizes the LWZ information criterion be printed.
NONE specifies that none of the parameter estimates be printed.

SEQ specifies that the parameter estimates in the structural change model that is chosen by sequentially applying $sup F(l + 1|l)$ tests, $l$ from 0 to $M$, be printed. If you specify the SEQ option, you can also specify the significance level in the parentheses, for example, SEQ(0.10). The first $l$ such that the $p$-value of $sup F(l + 1|l)$ test is greater than the significance level is selected as the number of breaks in the structural change model. By default, the significance level 5% is used for the SEQ option; i.e., specifying SEQ is equivalent to specifying SEQ(0.05).

number specifies that the parameter estimates in the structural change model with the specified number of breaks be printed. If the specified number is greater than the number specified in the M= option, none of the parameter estimates are printed; that is, it is equivalent to specifying the NONE option.

The default is PRINTEST=ALL.

If you define the BP option without additional suboptions, all suboptions are set as default values. That is, the following two statements are equivalent:

```
model y = z1 z2 / BP;
```

```
model y = z1 z2 / BP=(M=5, P=0, EPS=0.05, PRINTEST=ALL);
```

To apply the HAC estimator with the Bartlett kernel function and print only the parameter estimates in the structural change model selected by the LWZ information criterion, you can write the SAS statement as follows:

```
model y = z1 z2 / BP=(HAC(KERNEL=BARTLETT), PRINTEST=LWZ);
```

To specify a partial structural change model, you can write the SAS statement as follows:

```
model y = x1 x2 x3 z1 z2 / NOINT BP=(P=3);
```

CHOW=(obs₁ ... obsₙ) computes Chow tests to evaluate the stability of the regression coefficient. The Chow test is also called the analysis-of-variance test.

Each value $obs_i$ listed on the CHOW= option specifies a break point of the sample. The sample is divided into parts at the specified break point, with observations before $obs_i$ in the first part and $obs_i$ and later observations in the second part, and the fits of the model in the two parts are compared to whether both parts of the sample are consistent with the same model.

The break points $obs_i$ refer to observations within the time range of the dependent variable, ignoring missing values before the start of the dependent series. Thus, CHOW=20 specifies the 20th observation after the first nonmissing observation for the dependent variable. For example, if the dependent variable Y contains 10 missing values before the first observation with a nonmissing Y value, then CHOW=20 actually refers to the 30th observation in the data set.

When you specify the break point, you should note the number of presample missing values.
Chapter 8: The AUTOREG Procedure

**COEF** prints the transformation coefficients for the first $p$ observations. These coefficients are formed from a scalar multiplied by the inverse of the Cholesky root of the Toeplitz matrix of autocovariances.

**CORRB** prints the estimated correlations of the parameter estimates.

**COVB** prints the estimated covariances of the parameter estimates.

**COVEST= OP | HESSIAN | QML | HC0 | HC1 | HC2 | HC3 | HC4 | HAC<(. . . )> | NEWEYWEST<(. . . )>** specifies the type of covariance matrix.

When COVEST=OP is specified, the outer product matrix is used to compute the covariance matrix of the parameter estimates; by default, COVEST=OP. The COVEST=HESSIAN option produces the covariance matrix by using the Hessian matrix. The quasi–maximum likelihood estimates are computed with COVEST=QML, which is equivalent to COVEST=HC0. When the final model is an OLS or AR error model, COVEST=OP, HESSIAN, or QML is ignored; the method to calculate the estimate of covariance matrix is illustrated in the section “Variance Estimates and Standard Errors” on page 365.

When you specify COVEST=HC$n$, where $n = 0, 1, 2, 3, 4$, the corresponding heteroscedasticity-consistent covariance matrix estimator (HCCME) is calculated.

The HAC option specifies the heteroscedasticity- and autocorrelation-consistent (HAC) covariance matrix estimator. When you specify the HAC option, you can specify the following options in parentheses and separate them with commas:

**KERNEL=value** specifies the type of kernel function. You can specify the following values:

- **BARTLETT** specifies the Bartlett kernel function.
- **PARZEN** specifies the Parzen kernel function.
- **QUADRATIC SPECTRAL | QS** specifies the quadratic spectral kernel function.
- **TRUNCATED** specifies the truncated kernel function.
- **TUKEYHANNING | TUKEY | TH** specifies the Tukey-Hanning kernel function.

The default is KERNEL=QUADRATIC SPECTRAL.

**KERNELLB=number** specifies the lower bound of the kernel weight value. Any kernel weight less than this lower bound is regarded as zero, which accelerates the calculation for big samples, especially for the quadratic spectral kernel. The default is KERNELLB=0.

**BANDWIDTH=value** specifies the fixed bandwidth value or bandwidth selection method to use in the kernel function. You can specify the following values:

NEWEYWEST94 | NW94 <(C=number)> specifies the Newey and West (1994) bandwidth selection method. You can specify the C= option in the parentheses to calculate the lag selection parameter; the default is C=12.

SAMPLESIZE | SS <(option-list)> specifies that the bandwidth be calculated according to the following equation, based on the sample size:

\[ b = \gamma T^r + c \]

where \( b \) is the bandwidth parameter and \( T \) is the sample size, and \( \gamma, r, \) and \( c \) are values specified by the following options within parentheses and separated by commas.

**GAMMA=number**

specifies the coefficient \( \gamma \) in the equation. The default is \( \gamma = 0.75 \).

**RATE=number**

specifies the growth rate \( r \) in the equation. The default is \( r = 0.3333 \).

**CONSTANT=number**

specifies the constant \( c \) in the equation. The default is \( c = 0.5 \).

**INT**

specifies that the bandwidth parameter must be integer; that is, \( b = \lfloor \gamma T^r + c \rfloor \), where \( \lfloor x \rfloor \) denotes the largest integer less than or equal to \( x \).

**number** specifies the fixed value of the bandwidth parameter.

The default is BANDWIDTH=ANDREWS91.

**PREWHITENING**

specifies that prewhitening is required in the calculation.

**ADJUSTDF**

specifies that the adjustment for degrees of freedom be required in the calculation.

The COVEST=NEWEYWEST option specifies the well-known Newey-West estimator, a special HAC estimator with (1) the Bartlett kernel; (2) the bandwidth parameter determined by the equation based on the sample size, \( b = \lfloor \gamma T^r + c \rfloor \); and (3) no adjustment for degrees of freedom and no prewhitening. By default the bandwidth parameter for Newey-West estimator is \( 0.75T^{0.3333} + 0.5 \), as shown in equation (15.17) in Stock and Watson (2002). When you specify COVEST=NEWEYWEST, you can specify the following options in parentheses and separate them with commas:

**GAMMA= number**

specifies the coefficient \( \gamma \) in the equation. The default is \( \gamma = 0.75 \).

**RATE= number**

specifies the growth rate \( r \) in the equation. The default is \( r = 0.3333 \).
**CONSTANT=** *number*

specifies the constant $c$ in the equation. The default is $c = 0.5$.

The following two statements are equivalent:

```plaintext
model y = x / COVEST=NEWEYWEST;

model y = x / COVEST=HAC(KERNEL=BARTLETT, BANDWIDTH=SAMPLESIZE(GAMMA=0.75, RATE=0.3333, CONSTANT=0.5, INT));
```

Another popular sample-size-dependent bandwidth, $T^{1/4} + 1.5$, as mentioned in Newey and West (1987), can be specified by the following statement:

```plaintext
model y = x / COVEST=NEWEYWEST(GAMMA=1, RATE=0.25, CONSTANT=1.5);
```

See the section “Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrix Estimator” on page 372 for more information about HC0 to HC4, HAC, and Newey-West estimators.

**DW=n**

prints Durbin-Watson statistics up to the order $n$. The default is $DW=1$. When the LAGDEP option is specified, the Durbin-Watson statistic is not printed unless the DW= option is explicitly specified.

**DWPROB**

now produces $p$-values for the generalized Durbin-Watson test statistics for large sample sizes. Previously, the Durbin-Watson probabilities were calculated only for small sample sizes. The new method of calculating Durbin-Watson probabilities is based on the algorithm of Ansley, Kohn, and Shively (1992).

**GINV**

prints the inverse of the Toeplitz matrix of autocovariances for the Yule-Walker solution. See the section “Computational Methods” on page 364 later in this chapter for more information.

**GODFREY**

**GODFREY=r**

produces Godfrey’s general Lagrange multiplier test against ARMA errors.

**ITPRINT**

prints the objective function and parameter estimates at each iteration. The objective function is the full log likelihood function for the maximum likelihood method, while the error sum of squares is produced as the objective function of unconditional least squares. For the ML method, the ITPRINT option prints the value of the full log likelihood function, not the concentrated likelihood.
LAGDEP
LAGDV

prints the Durbin $t$ statistic, which is used to detect residual autocorrelation in the presence of lagged dependent variables. See the section “Generalized Durbin-Watson Tests” on page 393 for details.

**LAGDEP=** name
**LAGDV=** name

prints the Durbin $h$ statistic for testing the presence of first-order autocorrelation when regressors contain the lagged dependent variable whose name is specified as LAGDEP= **name**. If the Durbin $h$ statistic cannot be computed, the asymptotically equivalent $t$ statistic is printed instead. See the section “Generalized Durbin-Watson Tests” on page 393 for details.

When the regression model contains several lags of the dependent variable, specify the lagged dependent variable for the smallest lag in the LAGDEP= option. For example:

```
model y = x1 x2 ylag2 ylag3 / lagdep=ylag2;
```

LOGLIKEL

prints the log likelihood value of the regression model, assuming normally distributed errors.

NOPRINT

suppresses all printed output.

NORMAL

specifies the Jarque-Bera’s normality test statistic for regression residuals.

PARTIAL

prints partial autocorrelations.

**PCHOW=**( obs $1$ . . . obs $n$ )

computes the predictive Chow test. The form of the PCHOW= option is the same as the CHOW= option; see the discussion of the CHOW= option earlier in this chapter.

RESET

produces Ramsey’s RESET test statistics. The RESET option tests the null model

$$y_t = x_t \hat{\beta} + u_t$$

against the alternative

$$y_t = x_t \hat{\beta} + \sum_{j=2}^{p} \phi_j \hat{y}_t^j + u_t$$

where $\hat{y}_t$ is the predicted value from the OLS estimation of the null model. The RESET option produces three RESET test statistics for $p = 2$, 3, and 4.

RUNS

**RUNS=**(Z=value)

specifies the runs test for independence. The Z= suboption specifies the type of the time series or residuals to be tested. The values of the Z= suboption are as follows:
Y specifies the regressand. The default is Z=Y.

RO specifies the OLS residuals.

R specifies the residuals of the final model.

RM specifies the structural residuals of the final model.

SR specifies the standardized residuals of the final model, defined by residuals over the square root of the conditional variance.

STATIONARITY=( ADF)

STATIONARITY=( ADF=(value...value))

STATIONARITY=( KPSS)

STATIONARITY=( KPSS=(KERNEL=type))

STATIONARITY=( KPSS=(KERNEL=type TRUNCPOINTMETHOD))

STATIONARITY=( PHILLIPS)

STATIONARITY=( PHILLIPS=(value...value))

STATIONARITY=( ERS)

STATIONARITY=( ERS=(value))

STATIONARITY=( NP)

STATIONARITY=( NP=(value))

STATIONARITY=( ADF<=(...), ERS<=(...), KPSS<=(...), NP<=(...), PHILLIPS<=(...))

specifies tests of stationarity or unit roots. The STATIONARITY= option provides Phillips-Perron, Phillips-Ouliaris, augmented Dickey-Fuller, Engle-Granger, KPSS, Shin, ERS, and NP tests.

The PHILLIPS or PHILLIPS= suboption of the STATIONARITY= option produces the Phillips-Perron unit root test when there are no regressors in the MODEL statement. When the model includes regressors, the PHILLIPS option produces the Phillips-Ouliaris cointegration test. The PHILLIPS option can be abbreviated as PP.

The PHILLIPS option performs the Phillips-Perron test for three null hypothesis cases: zero mean, single mean, and deterministic trend. For each case, the PHILLIPS option computes two test statistics, \( \hat{Z}_p \) and \( \hat{Z}_t \) (in the original paper they are referred to as \( \hat{Z}_\alpha \) and \( \hat{Z}_t \)), and reports their \( p \)-values. These test statistics have the same limiting distributions as the corresponding Dickey-Fuller tests.

The three types of the Phillips-Perron unit root test reported by the PHILLIPS option are as follows:

**Zero mean**

computes the Phillips-Perron test statistic based on the zero mean autoregressive model:

\[
y_t = \rho y_{t-1} + u_t
\]

**Single mean**

computes the Phillips-Perron test statistic based on the autoregressive model with a constant term:

\[
y_t = \mu + \rho y_{t-1} + u_t
\]
Trend computes the Phillips-Perron test statistic based on the autoregressive model with constant and time trend terms:

\[ y_t = \mu + \rho y_{t-1} + \delta t + u_t \]

You can specify several truncation points \( l \) for weighted variance estimators by using the PHILLIPS=(\( l_1 \ldots l_n \)) specification. The statistic for each truncation point \( l \) is computed as

\[
\sigma^2_{(T \mid l)} = \frac{1}{T} \sum_{i=1}^{T} \hat{u}^2_i + \frac{2}{T} \sum_{s=1}^{l} w_{sl} \sum_{t=s+1}^{T} \hat{u}_t \hat{u}_{t-s}
\]

where \( w_{sl} = 1 - s/(l + 1) \) and \( \hat{u}_t \) are OLS residuals. If you specify the PHILLIPS option without specifying truncation points, the default truncation point is \( \max(1, \sqrt{T}/5) \), where \( T \) is the number of observations.

The Phillips-Perron test can be used in general time series models since its limiting distribution is derived in the context of a class of weakly dependent and heterogeneously distributed data. The marginal probability for the Phillips-Perron test is computed assuming that error disturbances are normally distributed.

When there are regressors in the MODEL statement, the PHILLIPS option computes the Phillips-Ouliaris cointegration test statistic by using the least squares residuals. The normalized cointegrating vector is estimated using OLS regression. Therefore, the cointegrating vector estimates might vary with the regressand (normalized element) unless the regression R-square is 1.

The marginal probabilities for cointegration testing are not produced. You can refer to Phillips and Ouliaris (1990) tables Ia–Ic for the \( \hat{Z}_\alpha \) test and tables IIa–IIc for the \( \hat{Z}_t \) test. The standard residual-based cointegration test can be obtained using the NOINT option in the MODEL statement, while the demeaned test is computed by including the intercept term. To obtain the demeaned and detrended cointegration tests, you should include the time trend variable in the regressors. Refer to Phillips and Ouliaris (1990) or Hamilton (1994, Tbl. 19.1) for information about the Phillips-Ouliaris cointegration test. Note that Hamilton (1994, Tbl. 19.1) uses \( Z_\rho \) and \( Z_t \) instead of the original Phillips and Ouliaris (1990) notation. We adopt the notation introduced in Hamilton. To distinguish from Student’s \( t \) distribution, these two statistics are named accordingly as \( \rho \) (rho) and \( \tau \) (tau).

The ADF or ADF= suboption produces the augmented Dickey-Fuller unit root test (Dickey and Fuller 1979). As in the Phillips-Perron test, three regression models can be specified for the null hypothesis for the augmented Dickey-Fuller test (zero mean, single mean, and trend). These models assume that the disturbances are distributed as white noise. The augmented Dickey-Fuller test can account for the serial correlation between the disturbances in some way. The model, with the time trend specification for example, is

\[ y_t = \mu + \rho y_{t-1} + \delta t + \gamma_1 \Delta y_{t-1} + \ldots + \gamma_p \Delta y_{t-p} + u_t \]

This formulation has the advantage that it can accommodate higher-order autoregressive processes in \( u_t \). The test statistic follows the same distribution as the Dickey-Fuller test statistic. For more information, see the section “PROBDF Function for Dickey-Fuller Tests” on page 157.

In the presence of regressors, the ADF option tests the cointegration relation between the dependent variable and the regressors. Following Engle and Granger (1987), a two-step estimation and testing procedure is carried out, in a fashion similar to the Phillips-Ouliaris test. The OLS residuals of the
regression in the MODEL statement are used to compute the \( t \) statistic of the augmented Dickey-Fuller regression in a second step. Three cases arise based on which type of deterministic terms are included in the first step of regression. Only the constant term and linear trend cases are practically useful (Davidson and MacKinnon 1993, page 721), and therefore are computed and reported. The test statistic, as shown in Phillips and Ouliaris (1990), follows the same distribution as the \( \hat{Z}_t \) statistic in the Phillips-Ouliaris cointegration test. The asymptotic distribution is tabulated in tables IIa–IIc of Phillips and Ouliaris (1990), and the finite sample distribution is obtained in Table 2 and Table 3 in Engle and Yoo (1987) by Monte Carlo simulation.

The ERS or ERS= suboption and the NP or NP= suboption provide a class of efficient unit root tests, because they reduce the size distortion and improve the power compared with traditional unit root tests such as the augmented Dickey-Fuller and Phillips-Perron tests. Two test statistics are reported with the ERS= suboption: the point optimal test and the DF-GLS test, which are originally proposed in Elliott, Rothenberg, and Stock (1996). Elliott, Rothenberg, and Stock suggest using the Schwarz Bayesian information criterion to select the optimal lag length in the augmented Dickey-Fuller regression. The maximum lag length can be specified by the ERS= suboption. The minimum lag length is 3 and the default maximum lag length is 8. Six tests, namely \( MZ_a, MSB, MZ_t \), the modified point optimal test, the point optimal test, and the DF-GLS test, discussed in Ng and Perron (2001), are reported with the NP= suboption. Ng and Perron suggest using the modified AIC to select the optimal lag length in the augmented Dickey-Fuller regression by using GLS detrended data. The maximum lag length can be specified by the NP= suboption. The default maximum lag length is 8. The maximum lag length in the ERS tests and Ng-Perron tests cannot exceed \( T/2 - 2 \), where \( T \) is the sample size.

The KPSS, KPSS=(KERNEL=TYPE), or KPSS=(KERNEL=TYPE TRUNCPOINTMETHOD) specifications of the STATIONARITY= option produce the Kwiatkowski, Phillips, Schmidt, and Shin (1992) (KPSS) unit root test or Shin (1994) cointegration test.

Unlike the null hypothesis of the Dickey-Fuller and Phillips-Perron tests, the null hypothesis of the KPSS states that the time series is stationary. As a result, it tends to reject a random walk more often. If the model does not have an intercept, the KPSS option performs the KPSS test for three null hypothesis cases: zero mean, single mean, and deterministic trend. Otherwise, it reports the single mean and deterministic trend only. It computes a test statistic and provides \( p \)-value (Hobijn, Franses, and Ooms 2004) for the hypothesis that the random walk component of the time series is equal to zero in the following cases (for more information, see “Kwiatkowski, Phillips, Schmidt, and Shin (KPSS) Unit Root Test and Shin Cointegration Test” on page 388):

1. **Zero mean** computes the KPSS test statistic based on the zero mean autoregressive model.
   
   \[
   y_t = u_t
   \]

2. **Single mean** computes the KPSS test statistic based on the autoregressive model with a constant term.
   
   \[
   y_t = \mu + u_t
   \]

3. **Trend** computes the KPSS test statistic based on the autoregressive model with constant and time trend terms.
   
   \[
   y_t = \mu + \delta t + u_t
   \]
This test depends on the long-run variance of the series being defined as

\[ \sigma^2_{T1} = \frac{1}{T} \sum_{i=1}^{T} \hat{u}_i^2 + \frac{2}{T} \sum_{s=1}^{l} w_{sl} \sum_{t=s+1}^{T} \hat{u}_t \hat{u}_{t-s} \]

where \( w_{sl} \) is a kernel, \( s \) is a maximum lag (truncation point), and \( \hat{u}_t \) are OLS residuals or original data series. You can specify two types of the kernel:

**KERNEL=NW | BART**  
Newey-West (or Bartlett) kernel

\[ w(s, l) = 1 - \frac{s}{l + 1} \]

**KERNEL=QS**  
Quadratic spectral kernel

\[ w(s/l) = w(x) = \frac{25}{12\pi^2 x^2} \left( \frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right) \]

You can set the truncation point \( l \) by using three different methods:

**SCHW=c**  
Schwert maximum lag formula

\[ l = \max \left\{ 1, \left\lfloor \frac{c}{100} \left( \frac{T}{100} \right)^{1/4} \right\rfloor \right\} \]

**LAG=l**  
LAG=l manually defined number of lags.

**AUTO**  
Automatic bandwidth selection (Hobijn, Franses, and Ooms 2004) (for details, see “Kwiatkowski, Phillips, Schmidt, and Shin (KPSS) Unit Root Test and Shin Cointegration Test” on page 388).

If **STATIONARITY=KPSS** is defined without additional parameters, the Newey-West kernel is used. For the Newey-West kernel the default is the Schwert truncation point method with \( c = 12 \). For the quadratic spectral kernel the default is AUTO.

The KPSS test can be used in general time series models because its limiting distribution is derived in the context of a class of weakly dependent and heterogeneously distributed data. The limiting probability for the KPSS test is computed assuming that error disturbances are normally distributed. The \( p \)-values that are reported are based on the simulation of the limiting probability for the KPSS test.

To test for stationarity of a variable, \( y \), by using default **KERNEL=NW** and **SCHW=12**, you can use the following statements:

```sas
/*-- test for stationarity of regression residuals --*/
proc autoreg data=a;
   model y= / stationarity=(KPSS);
run;
```

To test for stationarity of a variable, \( y \), by using quadratic spectral kernel and automatic bandwidth selection, you can use the following statements:

```sas
/*-- test for stationarity of regression residuals --*/
proc autoreg data=a;
   model y= / stationarity=(QS, AUTO);
run;
```
/*-- test for stationarity using quadratic spectral kernel and automatic bandwidth selection --*/
proc autoreg data=a;
  model y= /
    stationarity = (KPSS=(KERNEL=QS AUTO));
run;

If there are regressors in the MODEL statement except for the intercept, the Shin (1994) cointegration test, an extension of the KPSS test, is carried out. The limiting distribution of the tests, and then the reported $p$-values, are different from those in the KPSS tests. See “Kwiatkowski, Phillips, Schmidt, and Shin (KPSS) Unit Root Test and Shin Cointegration Test” on page 388 for more information.

TP

TP=(Z=value)
specifies the turning point test for independence. The $Z=$ suboption specifies the type of the time series or residuals to be tested. You can specify the following values:

Y specifies the regressand. The default is $Z=Y$.
RO specifies the OLS residuals.
R specifies the residuals of the final model.
RM specifies the structural residuals of the final model.
SR specifies the standardized residuals of the final model, defined by residuals over the square root of the conditional variance.

URSQ

prints the uncentered regression $R^2$. The uncentered regression $R^2$ is useful to compute Lagrange multiplier test statistics, since most LM test statistics are computed as $T \times URSQ$, where $T$ is the number of observations used in estimation.

VNRRANK

VNRRANK=(option-list)
specifies the rank version of the von Neumann ratio test for independence. You can specify the following options in the VNRRANK=( ) option. The options are listed within parentheses and separated by commas.

PVALUE=DIST | SIM

specifies the way to calculate the $p$-value. By default or if PVALUE=DIST is specified, the $p$-value is calculated according to the asymptotic distribution of the statistic (that is, the standard normal distribution). Otherwise, for samples of size less than 100, the $p$-value is obtained though Monte Carlo simulation.

Z=value

specifies the type of the time series or residuals to be tested. You can specify the following values:
Y specifies the regressand.
RO specifies the OLS residuals.
R specifies the residuals of the final model.
RM specifies the structural residuals of the final model.
SR specifies the standardized residuals of the final model, defined by residuals over the square root of the conditional variance.

By default, \( Z = Y \).

**Stepwise Selection Options**

**BACKSTEP**
removes insignificant autoregressive parameters. The parameters are removed in order of least significance. This backward elimination is done only once on the Yule-Walker estimates computed after the initial ordinary least squares estimation. You can use the BACKSTEP option with all estimation methods because the initial parameter values for other estimation methods are estimated by using the Yule-Walker method.

**SLSTAY=value**
specifies the significance level criterion to be used by the BACKSTEP option. By default, SLSTAY=.05.

**Estimation Control Options**

**CONVERGE=value**
specifies the convergence criterion. If the maximum absolute value of the change in the autoregressive parameter estimates between iterations is less than this criterion, then convergence is assumed. By default, CONVERGE=.001.

If you specify the GARCH= option or the HETERO statement, convergence is assumed when the absolute maximum gradient is smaller than the value specified by the CONVERGE= option or when the relative gradient is smaller than 1E–8. By default, CONVERGE=1E–5.

**INITIAL=( initial-values )**
**START=( initial-values )**
specifies initial values for some or all of the parameter estimates. This option is not applicable when the Yule-Walker method or iterative Yule-Walker method is used. The specified values are assigned to model parameters in the same order in which the parameter estimates are printed in the AUTOREG procedure output. The order of values in the INITIAL= or START= option is as follows: the intercept, the regressor coefficients, the autoregressive parameters, the ARCH parameters, the GARCH parameters, the inverted degrees of freedom for Student’s \( t \) distribution, the start-up value for conditional variance, and the heteroscedasticity model parameters \( \eta \) specified by the HETERO statement.

The following is an example of specifying initial values for an AR(1)-GARCH(1, 1) model with regressors X1 and X2:
The model that is specified by this MODEL statement is

\[ y_t = \beta_0 + \beta_1 w_t + \beta_2 x_t + v_t \]

\[ v_t = \epsilon_t - \phi_1 v_{t-1} \]

\[ \epsilon_t = \sqrt{h_t} \epsilon_t \]

\[ h_t = \omega + \alpha_1 \epsilon_{t-1}^2 + \gamma_1 h_{t-1} \]

\[ \epsilon_t \sim N(0, \sigma_t^2) \]

The initial values for the regression parameters, INTERCEPT (\(\beta_0\)), X1 (\(\beta_1\)), and X2 (\(\beta_2\)), are specified as 1. The initial value of the AR(1) coefficient (\(\phi_1\)) is specified as 0.5. The initial value of ARCH0 (\(\omega\)) is 0.8, the initial value of ARCH1 (\(\alpha_1\)) is 0.1, and the initial value of GARCH1 (\(\gamma_1\)) is 0.6.

When you use the RESTRICT statement, the initial values that you specify in the INITIAL= option should satisfy the restrictions specified for the parameter estimates. If they do not, these initial values are adjusted to satisfy the restrictions.

**LDW**

specifies that \(p\)-values for the Durbin-Watson test be computed by using a linearized approximation of the design matrix when the model is nonlinear because an autoregressive error process is present. (The Durbin-Watson tests of the OLS linear regression model residuals are not affected by the LDW option.) See White (1992) for information about Durbin-Watson testing of nonlinear models.

**MAXITER=number**

sets the maximum number of iterations allowed. The default is MAXITER=50. When you specify both the GARCH= option in the MODEL statement and the MAXITER= option in the NLOPTIONS statement, the MAXITER= option in the MODEL statement is ignored. This option is not applicable when the Yule-Walker method is used.

**METHOD=value**

requests the type of estimates to be computed. You can specify the following values:

- METHOD=ML specifies maximum likelihood estimates.
- METHOD=ULS specifies unconditional least squares estimates.
- METHOD=YW specifies Yule-Walker estimates.
- METHOD=ITYW specifies iterative Yule-Walker estimates.

If you specify the GARCH= or LAGDEP option, the default is METHOD=ML. Otherwise, the default is METHOD=YW.

**NOMISS**

requests the estimation to the first contiguous sequence of data with no missing values. Otherwise, all complete observations are used.
OPTMETHOD=QN | TR

specifies the optimization technique when the GARCH or heteroscedasticity model is estimated.

The OPTMETHOD=QN option specifies the quasi-Newton method. The OPTMETHOD=TR option specifies the trust region method. The default is OPTMETHOD=QN.

---

HETERO Statement

HETERO variables / options ;

The HETERO statement specifies variables that are related to the heteroscedasticity of the residuals and the way these variables are used to model the error variance of the regression.

The heteroscedastic regression model supported by the HETERO statement is

\[ y_t = x_t \beta + \epsilon_t \]
\[ \epsilon_t \sim N(0, \sigma_t^2) \]
\[ \sigma_t^2 = \sigma^2 h_t \]
\[ h_t = l(z_t^\prime \eta) \]

The HETERO statement specifies a model for the conditional variance \( h_t \). The vector \( z_t \) is composed of the variables listed in the HETERO statement, \( \eta \) is a parameter vector, and \( l(\cdot) \) is a link function that depends on the value of the LINK= option. In the printed output, \( HET0 \) represents the estimate of \( \sigma \), while \( HET1 - HETn \) are the estimates of parameters in the \( \eta \) vector.

The keyword XBETA can be used in the variables list to refer to the model predicted value \( x_t^\prime \beta \). If XBETA is specified in the variables list, other variables in the HETERO statement will be ignored. In addition, XBETA cannot be specified in the GARCH process.

For heteroscedastic regression models without GARCH effects, the errors \( \epsilon_t \) are assumed to be uncorrelated — the heteroscedasticity models specified by the HETERO statement cannot be combined with an autoregressive model for the errors. Thus, when a HETERO statement is used, the NLAG= option cannot be specified unless the GARCH= option is also specified.

You can specify the following options in the HETERO statement.

**LINK=value**

specifies the functional form of the heteroscedasticity model. By default, LINK=EXP. If you specify a GARCH model with the HETERO statement, the model is estimated using LINK=LINEAR only. For details, see the section “Using the HETERO Statement with GARCH Models” on page 369. Values of the LINK= option are as follows:

- **EXP** specifies the exponential link function. The following model is estimated when you specify LINK=EXP:
  \[ h_t = \exp(z_t^\prime \eta) \]

- **SQUARE** specifies the square link function. The following model is estimated when you specify LINK=SQUARE:
  \[ h_t = (1 + z_t^\prime \eta)^2 \]
Chapter 8: The AUTOREG Procedure

LINEAR specifies the linear function; that is, the HETERO statement variables predict the error variance linearly. The following model is estimated when you specify LINK=LINEAR:

\[ h_t = (1 + z'_t \eta) \]

**COEF=value**
imposes constraints on the estimated parameters \( \eta \) of the heteroscedasticity model. You can specify the following values:

- **NONNEG** specifies that the estimated heteroscedasticity parameters \( \eta \) must be nonnegative.
- **UNIT** constrains all heteroscedasticity parameters \( \eta \) to equal 1.
- **ZERO** constrains all heteroscedasticity parameters \( \eta \) to equal 0.
- **UNREST** specifies unrestricted estimation of \( \eta \).

If you specify the GARCH= option in the MODEL statement, the default is COEF=NONNEG. If you do not specify the GARCH= option in the MODEL statement, the default is COEF=UNREST.

**STD=value**
imposes constraints on the estimated standard deviation \( \sigma \) of the heteroscedasticity model. You can specify the following values:

- **NONNEG** specifies that the estimated standard deviation parameter \( \sigma \) must be nonnegative.
- **UNIT** constrains the standard deviation parameter \( \sigma \) to equal 1.
- **UNREST** specifies unrestricted estimation of \( \sigma \).

The default is STD=UNREST.

**TEST=LM**
produces a Lagrange multiplier test for heteroscedasticity. The null hypothesis is homoscedasticity; the alternative hypothesis is heteroscedasticity of the form specified by the HETERO statement. The power of the test depends on the variables specified in the HETERO statement.

The test may give different results depending on the functional form specified by the LINK= option. However, in many cases the test does not depend on the LINK= option. The test is invariant to the form of \( h_t \) when \( h_t(0) = 1 \) and \( h'_t(0) \neq 0 \). (The condition \( h_t(0) = 1 \) is satisfied except when the NOCONST option is specified with LINK=SQUARE or LINK=LINEAR.)

**NOCONST**
specifies that the heteroscedasticity model does not include the unit term for the LINK=SQUARE and LINK=LINEAR options. For example, the following model is estimated when you specify the options LINK=SQUARE NOCONST:

\[ h_t = (z'_t \eta)^2 \]
**NLOPTIONS Statement**

NLOPTIONS <options> ;

PROC AUTOREG uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks when the GARCH= option is specified. If the GARCH= option is not specified, the NLOPTIONS statement is ignored. For a list of all the options of the NLOPTIONS statement, see Chapter 6, “Nonlinear Optimization Methods.”

**OUTPUT Statement**

OUTPUT <OUT=SAS-data-set> <options> <keyword=name> ;

The OUTPUT statement creates an output SAS data set as specified by the following options.

**OUT=SAS-data-set**

names the output SAS data set to contain the predicted and transformed values. If the OUT= option is not specified, the new data set is named according to the DATA_{n} convention.

You can specify any of the following options.

**ALPHACLI=number**

sets the confidence limit size for the estimates of future values of the response time series. The ALPHACLI= value must be between 0 and 1. The resulting confidence interval has \(1 - \text{number}\) confidence. The default is ALPHACLI=0.05, which corresponds to a 95% confidence interval.

**ALPHACLM=number**

sets the confidence limit size for the estimates of the structural or regression part of the model. The ALPHACLM= value must be between 0 and 1. The resulting confidence interval has \(1 - \text{number}\) confidence. The default is ALPHACLM=0.05, which corresponds to a 95% confidence interval.

**ALPHACSM=0.01 | 0.05 | 0.10**

specifies the significance level for the upper and lower bounds of the CUSUM and CUSUMSQ statistics output by the CUSUMLB=, CUSUMUB=, CUSUMSQLB=, and CUSUMSQUB= options. The significance level specified by the ALPHACSM= option can be 0.01, 0.05, or 0.10. Other values are not supported.

You can specify the following values for keyword=name, where keyword specifies the statistic to include in the output data set and name gives the name of the variable in the OUT= data set to contain the statistic.

**BLUS=variable**

specifies the name of a variable to contain the values of the Theil’s BLUS residuals. Refer to Theil (1971) for more information on BLUS residuals.

**CEV=variable**

**HT=variable**

writes to the output data set the value of the error variance \(\sigma_t^2\) from the heteroscedasticity model specified by the HETERO statement or the value of the conditional error variance \(h_t\) by the GARCH= option in the MODEL statement.
**CPEV=** _variable_
writes the conditional prediction error variance to the output data set. The value of conditional prediction error variance is equal to that of the conditional error variance when there are no autoregressive parameters. See the section “Predicted Values” on page 402 for details.

**CONSTANT=** _variable_
writes the transformed intercept to the output data set. The details of the transformation are described in “Computational Methods” on page 364.

**CUSUM=** _variable_
specifies the name of a variable to contain the CUSUM statistics.

**CUSUMSQ=** _variable_
specifies the name of a variable to contain the CUSUMSQ statistics.

**CUSUMUB=** _variable_
specifies the name of a variable to contain the upper confidence bound for the CUSUM statistic.

**CUSUMLB=** _variable_
specifies the name of a variable to contain the lower confidence bound for the CUSUM statistic.

**CUSUMSQUB=** _variable_
specifies the name of a variable to contain the upper confidence bound for the CUSUMSQ statistic.

**CUSUMSQLB=** _variable_
specifies the name of a variable to contain the lower confidence bound for the CUSUMSQ statistic.

**LCL=** _name_
writes the lower confidence limit for the predicted value (specified in the PREDICTED= option) to the output data set. The size of the confidence interval is set by the ALPHACLI= option. See the section “Predicted Values” on page 402 for details.

**LCLM=** _name_
writes the lower confidence limit for the structural predicted value (specified in the PREDICTEDM= option) to the output data set under the name given. The size of the confidence interval is set by the ALPHACLIM= option.

**PREDICTED=** _name_
**P=** _name_
writes the predicted values to the output data set. These values are formed from both the structural and autoregressive parts of the model. See the section “Predicted Values” on page 402 for details.

**PREDICTEDM=** _name_
**PM=** _name_
writes the structural predicted values to the output data set. These values are formed from only the structural part of the model. See the section “Predicted Values” on page 402 for details.

**RECPEV=** _variable_
specifies the name of a variable to contain the part of the predictive error variance ($v_t$) that is used to compute the recursive residuals.
RECRES=variable
specifies the name of a variable to contain recursive residuals. The recursive residuals are used to compute the CUSUM and CUSUMSQ statistics.

RESIDUAL=name
R=name
writes the residuals from the predicted values based on both the structural and time series parts of the model to the output data set.

RESIDUALM=name
RM=name
writes the residuals from the structural prediction to the output data set.

TRANSFORM=variables
transforms the specified variables from the input data set by the autoregressive model and writes the transformed variables to the output data set. The details of the transformation are described in the section “Computational Methods” on page 364. If you need to reproduce the data suitable for re-estimation, you must also transform an intercept variable. To do this, transform a variable that is all 1s or use the CONSTANT= option.

UCL=name
writes the upper confidence limit for the predicted value (specified in the PREDICTED= option) to the output data set. The size of the confidence interval is set by the ALPHACLI= option. For more information, see the section “Predicted Values” on page 402.

UCLM=name
writes the upper confidence limit for the structural predicted value (specified in the PREDICTEDM= option) to the output data set. The size of the confidence interval is set by the ALPHACLM= option.

RESTRICT Statement

RESTRICT equation , ... , equation ;

The RESTRICT statement provides constrained estimation and places restrictions on the parameter estimates for covariates in the preceding MODEL statement. The AR, GARCH, and HETERO parameters are also supported in the RESTRICT statement when you specify the GARCH= option. Any number of RESTRICT statements can follow a MODEL statement. To specify more than one restriction in a single RESTRICT statement, separate them with commas.

Each restriction is written as a linear equation composed of constants and parameter names. Refer to model parameters by the name of the corresponding regressor variable. Each name that is used in the equation must be a regressor in the preceding MODEL statement. Use the keyword INTERCEPT to refer to the intercept parameter in the model. For the names of these parameters, see the section “OUTEST= Data Set” on page 406. Inequality constraints are supported only when you specify the GARCH= option. For non-GARCH models, if inequality signs are specified, they are treated as equality signs.

The following is an example of a RESTRICT statement:
model y = a b c d;
restrict a+b=0, 2*d-c=0;

When restricting a linear combination of parameters to be 0, you can omit the equal sign. For example, the following RESTRICT statement is equivalent to the preceding example:

restrict a+b, 2*d-c;

The following RESTRICT statement constrains the parameters estimates for three regressors (X1, X2, and X3) to be equal:

restrict x1 = x2, x2 = x3;

The preceding restriction can be abbreviated as follows:

restrict x1 = x2 = x3;

The following example shows how to specify AR, GARCH, and HETERO parameters in the RESTRICT statement:

model y = a b / nlag=2 garch=(p=2,q=3,mean=sqrt);
hetero c d;
restrict _A_1=0, _AH_2=0.2, _HET_2=1, _DELTA_ = 0.1;

You can specify only simple linear combinations of parameters in RESTRICT statement expressions. You cannot specify complex expressions that involve parentheses, division, functions, or complex products.

---

**TEST Statement**

The AUTOREG procedure supports a TEST statement for linear hypothesis tests. The syntax of the TEST statement is

```
TEST equation , . . . , equation / option ;
```

The TEST statement tests hypotheses about the covariates in the model that are estimated by the preceding MODEL statement. The AR, GARCH, and HETERO parameters are also supported in the TEST statement when you specify the GARCH= option. Each equation specifies a linear hypothesis to be tested. If you specify more than one equation, separate them with commas.

Each test is written as a linear equation composed of constants and parameter names. Refer to parameters by the name of the corresponding regressor variable. Each name that is used in the equation must be a regressor in the preceding MODEL statement. Use the keyword INTERCEPT to refer to the intercept parameter in the model. For the names of these parameters, see the section “OUTEST= Data Set” on page 406.

You can specify the following options in the TEST statement:

**TYPE=**\textit{value}

specifies the test statistics to use. The default is TYPE=F. The following values for TYPE= option are available:

\begin{itemize}
  \item \texttt{F} produces an \textit{F} test. This option is supported for all models specified in MODEL statement.
\end{itemize}
**TEST Statement**

WALD produces a Wald test. This option is supported for all models specified in MODEL statement.

LM produces a Lagrange multiplier test. This option is supported only when the GARCH= option is specified (for example, when there is a statement like MODEL Y = C D I / GARCH=(Q=2)).

LR produces a likelihood ratio test. This option is supported only when the GARCH= option is specified (for example, when there is a statement like MODEL Y = C D I / GARCH=(Q=2)).

ALL produces all tests applicable for a particular model. For non-GARCH-type models, only F and Wald tests are output. For all other models, all four tests (LR, LM, F, and Wald) are computed.

The following example of a TEST statement tests the hypothesis that the coefficients of two regressors A and B are equal:

```
model y = a b c d;
test a = b;
```

To test separate null hypotheses, use separate TEST statements. To test a joint hypothesis, specify the component hypotheses on the same TEST statement, separated by commas.

For example, consider the following linear model:

\[ y_t = \beta_0 + \beta_1 x_{1t} + \beta_2 x_{2t} + \epsilon_t \]

The following statements test the two hypotheses \( H_0 : \beta_0 = 1 \) and \( H_0 : \beta_1 + \beta_2 = 0 \):

```
model y = x1 x2;
test intercept = 1;
test x1 + x2 = 0;
```

The following statements test the joint hypothesis \( H_0 : \beta_0 = 1 \) and \( \beta_1 + \beta_2 = 0 \):

```
model y = x1 x2;
test intercept = 1, x1 + x2 = 0;
```

To illustrate the TYPE= option, consider the following examples.

```
model Y = C D I / garch=(q=2);
test C + D = 1;
```

The preceding statements produce only one default test, the \( F \) test.

```
model Y = C D I / garch=(q=2);
test C + D = 1 / type = LR;
```

The preceding statements produce one of four tests applicable for GARCH-type models, the likelihood ratio test.

```
model Y = C D I / nlag = 2;
test C + D = 1 / type = LM;
```

The preceding statements produce the warning and do not output any test because the Lagrange multiplier test is not applicable for non-GARCH models.
model Y = C D I / nlag=2;
test C + D = 1 / type = ALL;

The preceding statements produce all tests that are applicable for non-GARCH models (namely, the $F$ and Wald tests). The TYPE= prefix is optional. Thus the test statement in the previous example could also have been written as:

test C + D = 1 / ALL;

The following example shows how to test AR, GARCH, and HETERO parameters:

```plaintext
model y = a b / nlag=2 garch=(p=2,q=3,mean=sqrt);
hetero c d;
test _A_1=0,_AH_2=0.2,_HET_2=1,_DELTA_=0.1;
```

### Details: AUTOREG Procedure

#### Missing Values

PROC AUTOREG skips any missing values at the beginning of the data set. If the NOMISS option is specified, the first contiguous set of data with no missing values is used; otherwise, all data with nonmissing values for the independent and dependent variables are used. Note, however, that the observations containing missing values are still needed to maintain the correct spacing in the time series. PROC AUTOREG can generate predicted values when the dependent variable is missing.

#### Autoregressive Error Model

The regression model with autocorrelated disturbances is as follows:

$$
y_t = x_t' \beta + \nu_t
$$

$$
\nu_t = \epsilon_t - \varphi_1 \nu_{t-1} - \ldots - \varphi_m \nu_{t-m}
$$

$$
\epsilon_t \sim N(0, \sigma^2)
$$

In these equations, $y_t$ are the dependent values, $x_t$ is a column vector of regressor variables, $\beta$ is a column vector of structural parameters, and $\epsilon_t$ is normally and independently distributed with a mean of 0 and a variance of $\sigma^2$. Note that in this parameterization, the signs of the autoregressive parameters are reversed from the parameterization documented in most of the literature.

PROC AUTOREG offers four estimation methods for the autoregressive error model. The default method, Yule-Walker (YW) estimation, is the fastest computationally. The Yule-Walker method used by PROC AUTOREG is described in Gallant and Goebel (1976). Harvey (1981) calls this method the two-step full transform method. The other methods are iterated YW, unconditional least squares (ULS), and maximum likelihood (ML). The ULS method is also referred to as nonlinear least squares (NLS) or exact least squares (ELS).
You can use all of the methods with data containing missing values, but you should use ML estimation if the missing values are plentiful. See the section “Alternative Autocorrelation Correction Methods” on page 366 later in this chapter for further discussion of the advantages of different methods.

**The Yule-Walker Method**

Let $\varphi$ represent the vector of autoregressive parameters,

$$\varphi = (\varphi_1, \varphi_2, \ldots, \varphi_m)'$$

and let the variance matrix of the error vector $\mathbf{v} = (v_1, \ldots, v_N)'$ be $\mathbf{\Sigma}$,

$$E(\mathbf{vv}') = \mathbf{\Sigma} = \sigma^2 \mathbf{V}$$

If the vector of autoregressive parameters $\varphi$ is known, the matrix $\mathbf{V}$ can be computed from the autoregressive parameters. $\mathbf{\Sigma}$ is then $\sigma^2 \mathbf{V}$. Given $\mathbf{\Sigma}$, the efficient estimates of regression parameters $\beta$ can be computed using generalized least squares (GLS). The GLS estimates then yield the unbiased estimate of the variance $\sigma^2$.

The Yule-Walker method alternates estimation of $\beta$ using generalized least squares with estimation of $\varphi$ using the Yule-Walker equations applied to the sample autocorrelation function. The YW method starts by forming the OLS estimate of $\beta$. Next, $\varphi$ is estimated from the sample autocorrelation function of the OLS residuals by using the Yule-Walker equations. Then $\mathbf{V}$ is estimated from the estimate of $\varphi$, and $\mathbf{\Sigma}$ is estimated from $\mathbf{V}$ and the OLS estimate of $\sigma^2$. The autocorrelation corrected estimates of the regression parameters $\beta$ are then computed by GLS, using the estimated $\mathbf{\Sigma}$ matrix. These are the Yule-Walker estimates.

If the ITER option is specified, the Yule-Walker residuals are used to form a new sample autocorrelation function, the new autocorrelation function is used to form a new estimate of $\varphi$ and $\mathbf{V}$, and the GLS estimates are recomputed using the new variance matrix. This alternation of estimates continues until either the maximum change in the $\hat{\varphi}$ estimate between iterations is less than the value specified by the CONVERGE= option or the maximum number of allowed iterations is reached. This produces the iterated Yule-Walker estimates. Iteration of the estimates may not yield much improvement.

The Yule-Walker equations, solved to obtain $\hat{\varphi}$ and a preliminary estimate of $\sigma^2$, are

$$\mathbf{R}\hat{\varphi} = -\mathbf{r}$$

Here $\mathbf{r} = (r_1, \ldots, r_m)'$, where $r_i$ is the lag $i$ sample autocorrelation. The matrix $\mathbf{R}$ is the Toeplitz matrix whose $i,j$th element is $r_{|i-j|}$. If you specify a subset model, then only the rows and columns of $\mathbf{R}$ and $\mathbf{r}$ corresponding to the subset of lags specified are used.

If the BACKSTEP option is specified, for purposes of significance testing, the matrix $[\mathbf{R} \, \mathbf{r}]$ is treated as a sum-of-squares-and-crossproducts matrix arising from a simple regression with $N - k$ observations, where $k$ is the number of estimated parameters.

**The Unconditional Least Squares and Maximum Likelihood Methods**

Define the transformed error, $\mathbf{e}$, as

$$\mathbf{e} = \mathbf{L}^{-1}\mathbf{n}$$

where $\mathbf{n} = \mathbf{y} - \mathbf{X}\beta$. 

The unconditional sum of squares for the model, $S$, is

$$S = n'V^{-1}n = e'e$$

The ULS estimates are computed by minimizing $S$ with respect to the parameters $\beta$ and $\varphi_i$.

The full log likelihood function for the autoregressive error model is

$$l = -\frac{N}{2} \ln(2\pi) - \frac{N}{2} \ln(\sigma^2) - \frac{1}{2} \ln(|V|) - \frac{S}{2\sigma^2}$$

where $|V|$ denotes determinant of $V$. For the ML method, the likelihood function is maximized by minimizing an equivalent sum-of-squares function.

Maximizing $l$ with respect to $\sigma^2$ (and concentrating $\sigma^2$ out of the likelihood) and dropping the constant term $-\frac{N}{2} \ln(2\pi) + 1 - \ln(N)$ produces the concentrated log likelihood function

$$l_c = -\frac{N}{2} \ln(S|V|^{1/N})$$

Rewriting the variable term within the logarithm gives

$$S_{ml} = |L|^{1/N} e'e |L|^{1/N}$$

PROC AUTOREG computes the ML estimates by minimizing the objective function $S_{ml} = |L|^{1/N} e'e |L|^{1/N}$.

The maximum likelihood estimates may not exist for some data sets (Anderson and Mentz 1980). This is the case for very regular data sets, such as an exact linear trend.

**Computational Methods**

**Sample Autocorrelation Function**

The sample autocorrelation function is computed from the structural residuals or noise $n_t = y_t - x'_t b$, where $b$ is the current estimate of $\beta$. The sample autocorrelation function is the sum of all available lagged products of $n_t$ of order $j$ divided by $\ell + j$, where $\ell$ is the number of such products.

If there are no missing values, then $\ell + j = N$, the number of observations. In this case, the Toeplitz matrix of autocorrelations, $R$, is at least positive semidefinite. If there are missing values, these autocorrelation estimates of $r$ can yield an $R$ matrix that is not positive semidefinite. If such estimates occur, a warning message is printed, and the estimates are tapered by exponentially declining weights until $R$ is positive definite.

**Data Transformation and the Kalman Filter**

The calculation of $V$ from $\varphi$ for the general AR($m$) model is complicated, and the size of $V$ depends on the number of observations. Instead of actually calculating $V$ and performing GLS in the usual way, in practice a Kalman filter algorithm is used to transform the data and compute the GLS results through a recursive process.

In all of the estimation methods, the original data are transformed by the inverse of the Cholesky root of $V$. Let $L$ denote the Cholesky root of $V$ — that is, $V = LL'$ with $L$ lower triangular. For an AR($m$) model, $L^{-1}$ is a band diagonal matrix with $m$ anomalous rows at the beginning and the autoregressive parameters
along the remaining rows. Thus, if there are no missing values, after the first \( m - 1 \) observations the data are transformed as

\[
z_t = x_t + \hat{\phi}_1 x_{t-1} + \ldots + \hat{\phi}_m x_{t-m}
\]

The transformation is carried out using a Kalman filter, and the lower triangular matrix \( L \) is never directly computed. The Kalman filter algorithm, as it applies here, is described in Harvey and Phillips (1979) and Jones (1980). Although \( L \) is not computed explicitly, for ease of presentation the remaining discussion is in terms of \( L \). If there are missing values, then the submatrix of \( L \) consisting of the rows and columns with nonmissing values is used to generate the transformations.

**Gauss-Newton Algorithms**

The ULS and ML estimates employ a Gauss-Newton algorithm to minimize the sum of squares and maximize the log likelihood, respectively. The relevant optimization is performed simultaneously for both the regression and AR parameters. The OLS estimates of \( \beta \) and the Yule-Walker estimates of \( \varphi \) are used as starting values for these methods.

The Gauss-Newton algorithm requires the derivatives of \( e \) or \( |L|^{1/N} e \) with respect to the parameters. The derivatives with respect to the parameter vector \( \beta \) are

\[
\frac{\partial e}{\partial \beta'} = -L^{-1} X
\]

\[
\frac{\partial |L|^{1/N} e}{\partial \beta'} = -|L|^{1/N} L^{-1} X
\]

These derivatives are computed by the transformation described previously. The derivatives with respect to \( \varphi \) are computed by differentiating the Kalman filter recurrences and the equations for the initial conditions.

**Variance Estimates and Standard Errors**

For the Yule-Walker method, the estimate of the error variance, \( s^2 \), is the error sum of squares from the last application of GLS, divided by the error degrees of freedom (number of observations \( N \) minus the number of free parameters).

The variance-covariance matrix for the components of \( b \) is taken as \( s^2 (X'V^{-1}X)^{-1} \) for the Yule-Walker method. For the ULS and ML methods, the variance-covariance matrix of the parameter estimates is computed as \( s^2 (J'J)^{-1} \). For the ULS method, \( J \) is the matrix of derivatives of \( e \) with respect to the parameters. For the ML method, \( J \) is the matrix of derivatives of \( |L|^{1/N} e \) divided by \( |L|^{1/N} \). The estimate of the variance-covariance matrix of \( b \) assuming that \( \varphi \) is known is \( s^2 (X'V^{-1}X)^{-1} \). For OLS model, the estimate of the variance-covariance matrix is \( s^2 (X'X)^{-1} \).

Park and Mitchell (1980) investigated the small sample performance of the standard error estimates obtained from some of these methods. In particular, simulating an AR(1) model for the noise term, they found that the standard errors calculated using GLS with an estimated autoregressive parameter underestimated the true standard errors. These estimates of standard errors are the ones calculated by PROC AUTOREG with the Yule-Walker method.

The estimates of the standard errors calculated with the ULS or ML method take into account the joint estimation of the AR and the regression parameters and may give more accurate standard-error values than the YW method. At the same values of the autoregressive parameters, the ULS and ML standard errors
Autocorrelation correction in regression analysis has a long history, and various approaches have been suggested. Moreover, the same method may be referred to by different names.

Pioneering work in the field was done by Cochrane and Orcutt (1949). The Cochrane-Orcutt method refers to a more primitive version of the Yule-Walker method that drops the first observation. The Cochrane-Orcutt method is like the Yule-Walker method for first-order autoregression, except that the Yule-Walker method retains information from the first observation. The iterative Cochrane-Orcutt method is also in use.

The Yule-Walker method used by PROC AUTOREG is also known by other names. Harvey (1981) refers to the Yule-Walker method as the two-step full transform method. The Yule-Walker method can be considered as generalized least squares using the OLS residuals to estimate the covariances across observations, and Judge et al. (1985) use the term estimated generalized least squares (EGLS) for this method. For a first-order AR process, the Yule-Walker estimates are often termed Prais-Winsten estimates (Prais and Winsten 1954). There are variations to these methods that use different estimators of the autocorrelations or the autoregressive parameters.

The unconditional least squares (ULS) method, which minimizes the error sum of squares for all observations, is referred to as the nonlinear least squares (NLS) method by Spitzer (1979).

The Hildreth-Lu method (Hildreth and Lu 1960) uses nonlinear least squares to jointly estimate the parameters with an AR(1) model, but it omits the first transformed residual from the sum of squares. Thus, the Hildreth-Lu method is a more primitive version of the ULS method supported by PROC AUTOREG in the same way Cochrane-Orcutt is a more primitive version of Yule-Walker.

The maximum likelihood method is also widely cited in the literature. Although the maximum likelihood method is well defined, some early literature refers to estimators that are called maximum likelihood but are not full unconditional maximum likelihood estimates. The AUTOREG procedure produces full unconditional maximum likelihood estimates.
Harvey (1981) and Judge et al. (1985) summarize the literature on various estimators for the autoregressive error model. Although asymptotically efficient, the various methods have different small sample properties. Several Monte Carlo experiments have been conducted, although usually for the AR(1) model.

Harvey and McAvinishy (1978) found that for a one-variable model, when the independent variable is trending, methods similar to Cochrane-Orcutt are inefficient in estimating the structural parameter. This is not surprising since a pure trend model is well modeled by an autoregressive process with a parameter close to 1.

Harvey and McAvinishy (1978) also made the following conclusions:

- The Yule-Walker method appears to be about as efficient as the maximum likelihood method. Although Spitzer (1979) recommended ML and NLS, the Yule-Walker method (labeled Prais-Winsten) did as well or better in estimating the structural parameter in Spitzer’s Monte Carlo study (table A2 in their article) when the autoregressive parameter was not too large. Maximum likelihood tends to do better when the autoregressive parameter is large.

- For small samples, it is important to use a full transformation (Yule-Walker) rather than the Cochrane-Orcutt method, which loses the first observation. This was also demonstrated by Maeshiro (1976), Chipman (1979), and Park and Mitchell (1980).

- For large samples (Harvey and McAvinishy used 100), losing the first few observations does not make much difference.

GARCH Models

Consider the series \( y_t \), which follows the GARCH process. The conditional distribution of the series \( Y \) for time \( t \) is written

\[
y_t | \Psi_{t-1} \sim N(0, h_t)
\]

where \( \Psi_{t-1} \) denotes all available information at time \( t-1 \). The conditional variance \( h_t \) is

\[
h_t = \omega + \sum_{i=1}^{q} \alpha_i y_{t-i}^2 + \sum_{j=1}^{p} \gamma_j h_{t-j}
\]

where

\[
p \geq 0, q > 0
\]

\[
\omega > 0, \alpha_i \geq 0, \gamma_j \geq 0
\]

The GARCH\((p,q)\) model reduces to the ARCH\((q)\) process when \( p = 0 \). At least one of the ARCH parameters must be nonzero \((q > 0)\). The GARCH regression model can be written

\[
y_t = x_t' \beta + \epsilon_t
\]

\[
\epsilon_t = \sqrt{h_t} e_t
\]
where $e_t \sim \text{IN}(0,1)$.

In addition, you can consider the model with disturbances following an autoregressive process and with the GARCH errors. The AR$(m)$-GARCH$(p, q)$ regression model is denoted

$$y_t = x_t' \beta + \nu_t$$

$$\nu_t = \epsilon_t - \varphi_1 \nu_{t-1} - \ldots - \varphi_m \nu_{t-m}$$

$$\epsilon_t = \sqrt{h_t} \epsilon_t$$

$$h_t = \omega + \sum_{i=1}^{q} \alpha_i \epsilon_{t-i}^2 + \sum_{j=1}^{p} \gamma_j h_{t-j}$$

**GARCH Estimation with Nelson-Cao Inequality Constraints**

The GARCH$(p, q)$ model is written in ARCH$(\infty)$ form as

$$h_t = \left( 1 - \sum_{j=1}^{p} \gamma_j B^j \right)^{-1} \left[ \omega + \sum_{i=1}^{q} \alpha_i \epsilon_{t-i}^2 \right]$$

$$= \omega^* + \sum_{i=1}^{\infty} \phi_i \epsilon_{t-i}^2$$

where $B$ is a backshift operator. Therefore, $h_t \geq 0$ if $\omega^* \geq 0$ and $\phi_i \geq 0$, $\forall i$. Assume that the roots of the following polynomial equation are inside the unit circle:

$$\sum_{j=0}^{p} -\gamma_j Z^{p-j}$$

where $\gamma_0 = -1$ and $Z$ is a complex scalar. $-\sum_{j=0}^{p} \gamma_j Z^{p-j}$ and $\sum_{i=1}^{q} \alpha_i Z^{q-i}$ do not share common factors. Under these conditions, $|\omega^*| < \infty$, $|\phi_i| < \infty$, and these coefficients of the ARCH$(\infty)$ process are well defined.

Define $n = \max(p, q)$. The coefficient $\phi_i$ is written

$$\phi_0 = \alpha_1$$

$$\phi_1 = \gamma_1 \phi_0 + \alpha_2$$

$$\cdots$$

$$\phi_{n-1} = \gamma_1 \phi_{n-2} + \gamma_2 \phi_{n-3} + \cdots + \gamma_{n-1} \phi_0 + \alpha_n$$

$$\phi_k = \gamma_1 \phi_{k-1} + \gamma_2 \phi_{k-2} + \cdots + \gamma_n \phi_{k-n} \text{ for } k \geq n$$

where $\alpha_i = 0$ for $i > q$ and $\gamma_j = 0$ for $j > p$. 

$$h_t = \omega + \sum_{i=1}^{q} \alpha_i \epsilon_{t-i}^2 + \sum_{j=1}^{p} \gamma_j h_{t-j}$$
Nelson and Cao (1992) proposed the finite inequality constraints for GARCH(1, q) and GARCH(2, q) cases. However, it is not straightforward to derive the finite inequality constraints for the general GARCH(p, q) model.

For the GARCH(1, q) model, the nonlinear inequality constraints are

\[
\begin{align*}
\omega & \geq 0 \\
\gamma_1 & \geq 0 \\
\phi_k & \geq 0 \text{ for } k = 0, 1, \ldots, q - 1
\end{align*}
\]

For the GARCH(2, q) model, the nonlinear inequality constraints are

\[
\begin{align*}
\Delta_i & \in R \text{ for } i = 1, 2 \\
\omega^* & \geq 0 \\
\Delta_1 & > 0 \\
\sum_{j=0}^{q-1} \Delta_1^{-j} \alpha_{j+1} & > 0 \\
\phi_k & \geq 0 \text{ for } k = 0, 1, \ldots, q
\end{align*}
\]

where \(\Delta_1\) and \(\Delta_2\) are the roots of \((Z^2 - \gamma_1 Z - \gamma_2)\).

For the GARCH(p, q) model with \(p > 2\), only \(\max(q - 1, p) + 1\) nonlinear inequality constraints \(\phi_k \geq 0\) for \(k = 0\) to \(\max(q - 1, p)\) are imposed, together with the in-sample positivity constraints of the conditional variance \(h_t\).

**Using the HETERO Statement with GARCH Models**

The HETERO statement can be combined with the GARCH= option in the MODEL statement to include input variables in the GARCH conditional variance model. For example, the GARCH(1, 1) variance model with two dummy input variables D1 and D2 is

\[
\begin{align*}
\epsilon_t & = \sqrt{h_t} \epsilon_t \\
h_t & = \omega + \alpha_1 \epsilon_{t-1}^2 + \gamma_1 h_{t-1} + \eta_1 D1_t + \eta_2 D2_t
\end{align*}
\]

The following statements estimate this GARCH model:

```plaintext
proc autoreg data=one;
   model y = x z / garch=(p=1,q=1);
   hetero d1 d2;
run;
```

The parameters for the variables D1 and D2 can be constrained using the COEF= option. For example, the constraints \(\eta_1 = \eta_2 = 1\) are imposed by the following statements:

```plaintext
proc autoreg data=one;
   model y = x z / garch=(p=1,q=1);
   hetero d1 d2 / coef=unit;
run;
```
Limitations of GARCH and Heteroscedasticity Specifications

When you specify both the GARCH= option and the HETERO statement, the GARCH=(TYPE=EXP) option is not valid. The COVEST= option is not applicable to the EGARCH model.

IGARCH and Stationary GARCH Model

The condition $\sum_{i=1}^{q} \alpha_i + \sum_{j=1}^{p} \gamma_j < 1$ implies that the GARCH process is weakly stationary since the mean, variance, and autocovariance are finite and constant over time. When the GARCH process is stationary, the unconditional variance of $\epsilon_t$ is computed as

$$V(\epsilon_t) = \frac{\omega}{(1 - \sum_{i=1}^{q} \alpha_i - \sum_{j=1}^{p} \gamma_j)}$$

where $\epsilon_t = \sqrt{h_t} \epsilon_t$ and $h_t$ is the GARCH($p, q$) conditional variance.

Sometimes the multistep forecasts of the variance do not approach the unconditional variance when the model is integrated in variance; that is, $\sum_{i=1}^{q} \alpha_i + \sum_{j=1}^{p} \gamma_j = 1$.

The unconditional variance for the IGARCH model does not exist. However, it is interesting that the IGARCH model can be strongly stationary even though it is not weakly stationary. Refer to Nelson (1990) for details.

EGARCH Model

The EGARCH model was proposed by Nelson (1991). Nelson and Cao (1992) argue that the nonnegativity constraints in the linear GARCH model are too restrictive. The GARCH model imposes the nonnegative constraints on the parameters, $\alpha_i$ and $\gamma_j$, while there are no restrictions on these parameters in the EGARCH model. In the EGARCH model, the conditional variance, $h_t$, is an asymmetric function of lagged disturbances $\epsilon_{t-i}$:

$$\ln(h_t) = \omega + \sum_{i=1}^{q} \alpha_i g(z_{t-i}) + \sum_{j=1}^{p} \gamma_j \ln(h_{t-j})$$

where

$$g(z_t) = \theta z_t + \gamma (|z_t| - E|z_t|)$$

$$z_t = \epsilon_t / \sqrt{h_t}$$

The coefficient of the second term in $g(z_t)$ is set to be 1 ($\gamma=1$) in our formulation. Note that $E|z_t| = (2/\pi)^{1/2}$ if $z_t \sim N(0, 1)$. The properties of the EGARCH model are summarized as follows:

- The function $g(z_t)$ is linear in $z_t$ with slope coefficient $\theta + 1$ if $z_t$ is positive while $g(z_t)$ is linear in $z_t$ with slope coefficient $\theta - 1$ if $z_t$ is negative.
- Suppose that $\theta = 0$. Large innovations increase the conditional variance if $|z_t| - E|z_t| > 0$ and decrease the conditional variance if $|z_t| - E|z_t| < 0$.
- Suppose that $\theta < 1$. The innovation in variance, $g(z_t)$, is positive if the innovations $z_t$ are less than $(2/\pi)^{1/2} / (\theta - 1)$. Therefore, the negative innovations in returns, $\epsilon_t$, cause the innovation to the conditional variance to be positive if $\theta$ is much less than 1.
GARCH Models

QGARCH, TGARCH, and PGARCH Models

As shown in many empirical studies, positive and negative innovations have different impacts on future volatility. There is a long list of variations of GARCH models that consider the asymmetricity. Three typical variations are the quadratic GARCH (QGARCH) model (Engle and Ng 1993), the threshold GARCH (TGARCH) model (Glosten, Jaganathan, and Runkle 1993; Zakoian 1994), and the power GARCH (PGARCH) model (Ding, Granger, and Engle 1993). For more details about the asymmetric GARCH models, see Engle and Ng (1993).

In the QGARCH model, the lagged errors’ centers are shifted from zero to some constant values:

\[ h_t = \omega + \sum_{i=1}^{q} \alpha_i (\epsilon_{t-i} - \psi_i)^2 + \sum_{j=1}^{p} \gamma_j h_{t-j} \]

In the TGARCH model, there is an extra slope coefficient for each lagged squared error,

\[ h_t = \omega + \sum_{i=1}^{q} (\alpha_i + 1_{\epsilon_{t-i} < 0} \psi_i) \epsilon_{t-i}^2 + \sum_{j=1}^{p} \gamma_j h_{t-j} \]

where the indicator function \( 1_{\epsilon_{t-i} < 0} \) is one if \( \epsilon_{t-i} < 0 \); otherwise, zero.

The PGARCH model not only considers the asymmetric effect, but also provides another way to model the long memory property in the volatility,

\[ h_t^\lambda = \omega + \sum_{i=1}^{q} \alpha_i (|\epsilon_{t-i} - \psi_i \epsilon_{t-i}|)^{2\lambda} + \sum_{j=1}^{p} \gamma_j h_{t-j}^\lambda \]

where \( \lambda > 0 \) and \( |\psi_i| \leq 1, i = 1, \ldots, q \).

Note that the implemented TGARCH model is also well known as GJR-GARCH (Glosten, Jaganathan, and Runkle 1993), which is similar to the threshold GARCH model proposed by Zakoian (1994) but not exactly same. In Zakoian’s model, the conditional standard deviation is a linear function of the past values of the white noise. Zakoian’s version can be regarded as a special case of PGARCH model when \( \lambda = 1/2 \).

GARCH-in-Mean

The GARCH-M model has the added regressor that is the conditional standard deviation:

\[ y_t = x_t' \beta + \delta \sqrt{h_t} + \epsilon_t \]

\[ \epsilon_t = \sqrt{h_t} \eta_t \]

where \( h_t \) follows the ARCH or GARCH process.

Maximum Likelihood Estimation

The family of GARCH models are estimated using the maximum likelihood method. The log-likelihood function is computed from the product of all conditional densities of the prediction errors.
When \( e_t \) is assumed to have a standard normal distribution (\( e_t \sim N(0, 1) \)), the log-likelihood function is given by

\[
l = \sum_{t=1}^{N} \frac{1}{2} \left[ -\ln(2\pi) - \ln(h_t) - \frac{e_t^2}{h_t} \right]
\]

where \( e_t = y_t - x'_t \beta \) and \( h_t \) is the conditional variance. When the GARCH(p,q)-M model is estimated, \( e_t = y_t - x'_t \beta - \delta \sqrt{h_t} \). When there are no regressors, the residuals \( e_t \) are denoted as \( y_t \) or \( y_t - \delta \sqrt{h_t} \).

If \( e_t \) has the standardized Student’s \( t \) distribution, the log-likelihood function for the conditional \( t \) distribution is

\[
\ell = \sum_{t=1}^{N} \left[ \ln \left( \Gamma \left( \frac{\nu + 1}{2} \right) \right) - \ln \left( \Gamma \left( \frac{\nu}{2} \right) \right) - \frac{1}{2} \ln((\nu - 2)\pi h_t) \right.
\]

\[
-\frac{1}{2}(\nu + 1)\ln \left( 1 + \frac{e_t^2}{h_t(\nu - 2)} \right) \right]
\]

where \( \Gamma(\cdot) \) is the gamma function and \( \nu \) is the degree of freedom (\( \nu > 2 \)). Under the conditional \( t \) distribution, the additional parameter \( 1/\nu \) is estimated. The log-likelihood function for the conditional \( t \) distribution converges to the log-likelihood function of the conditional normal GARCH model as \( 1/\nu \to 0 \).

The likelihood function is maximized via either the dual quasi-Newton or the trust region algorithm. The default is the dual quasi-Newton algorithm. The starting values for the regression parameters \( \hat{\beta} \) are obtained from the OLS estimates. When there are autoregressive parameters in the model, the initial values are obtained from the Yule-Walker estimates. The starting value \( 1.0^{-6} \) is used for the GARCH process parameters.

The variance-covariance matrix is computed using the Hessian matrix. The dual quasi-Newton method approximates the Hessian matrix while the quasi-Newton method gets an approximation of the inverse of Hessian. The trust region method uses the Hessian matrix obtained using numerical differentiation. When there are active constraints, that is, \( q(\theta) = 0 \), the variance-covariance matrix is given by

\[
V(\hat{\theta}) = H^{-1}[I - Q'(QH^{-1}Q')^{-1}QH^{-1}]
\]

where \( H = -\partial^2 l/\partial \theta \partial \theta' \) and \( Q = \partial q(\theta)/\partial \theta' \). Therefore, the variance-covariance matrix without active constraints reduces to \( V(\hat{\theta}) = H^{-1} \).

### Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrix Estimator

The heteroscedasticity-consistent covariance matrix estimator (HCCME), also known as the sandwich (or robust or empirical) covariance matrix estimator, has been popular in recent years because it gives the consistent estimation of the covariance matrix of the parameter estimates even when the heteroscedasticity structure might be unknown or misspecified. White (1980) proposes the concept of HCCME, known as HC0. However, the small-sample performance of HC0 is not good in some cases. Davidson and MacKinnon (1993) introduce more improvements to HC0, namely HC1, HC2 and HC3, with the degrees-of-freedom or leverage adjustment. Cribari-Neto (2004) proposes HC4 for cases that have points of high leverage.
HCCME can be expressed in the following general “sandwich” form:

\[ \Sigma = B^{-1}MB^{-1} \]

where \( B \), which stands for “bread,” is the Hessian matrix and \( M \), which stands for “meat,” is the outer product of gradient (OPG) with or without adjustment. For HC0, \( M \) is the OPG without adjustment; that is,

\[ M_{HC0} = \sum_{t=1}^{T} g_t g_t' \]

where \( T \) is the sample size and \( g_t \) is the gradient vector of \( t \)th observation. For HC1, \( M \) is the OPG with the degrees-of-freedom correction; that is,

\[ M_{HC1} = \frac{T}{T-k} \sum_{t=1}^{T} g_t g_t' \]

where \( k \) is the number of parameters. For HC2, HC3, and HC4, the adjustment is related to leverage, namely,

\[ M_{HC2} = \sum_{t=1}^{T} \frac{g_t g_t'}{1-h_{tt}} \]
\[ M_{HC3} = \sum_{t=1}^{T} \frac{g_t g_t'}{(1-h_{tt})^2} \]
\[ M_{HC4} = \sum_{t=1}^{T} \frac{g_t g_t'}{(1-h_{tt})^{min(4,Th_{tt}/k)}} \]

The leverage \( h_{tt} \) is defined as \( h_{tt} = j_t' \left( \sum_{t=1}^{T} j_t j_t' \right)^{-1} j_t \), where \( j_t \) is defined as follows:

- For an OLS model, \( j_t \) is the \( t \)th observed regressors in column vector form.
- For an AR error model, \( j_t \) is the derivative vector of the \( t \)th residual with respect to the parameters.
- For a GARCH or heteroscedastic model, \( j_t \) is the gradient of the \( t \)th observation (that is, \( g_t \)).

The heteroscedasticity- and autocorrelation-consistent (HAC) covariance matrix estimator can also be expressed in “sandwich” form:

\[ \Sigma = B^{-1}MB^{-1} \]

where \( B \) is still the Hessian matrix, but \( M \) is the kernel estimator in the following form:

\[ M_{HAC} = a \left( \sum_{t=1}^{T} g_t g_t' + \sum_{j=1}^{T-1} k(\frac{j}{b}) \sum_{t=1}^{T-j} (g_t g_t'+j + g_t+j g_t') \right) \]

where \( T \) is the sample size, \( g_t \) is the gradient vector of \( t \)th observation, \( k(.) \) is the real-valued kernel function, \( b \) is the bandwidth parameter, and \( a \) is the adjustment factor of small-sample degrees of freedom (that is, \( a = 1 \) if ADJUSTDF option is not specified and otherwise \( a = T/(T-k) \), where \( k \) is the number of parameters). The types of kernel functions are listed in Table 8.2.

Let \( \{g_{at}\} \) denote each series in \( g_t \), and let \((\rho_a, \sigma_a^2)\) denote the corresponding estimates of the autoregressive and innovation variance parameters of the AR(1) model on \( g_{at} \), \( a = 1, \ldots, k \), where the AR(1) model is parameterized as \( g_{at} = \rho g_{at-1} + \epsilon_{at} \) with \( \text{Var}(\epsilon_{at}) = \sigma_a^2 \). The factors \( \alpha(1) \) and \( \alpha(2) \) are estimated with the following formulas:

\[
\alpha(1) = \frac{\sum_{a=1}^{k} \frac{4\rho_a^2\sigma_a^4}{(1-\rho_a)^2(1+\rho_a)^2}}{\sum_{a=1}^{k} \frac{\sigma_a^4}{(1-\rho_a)^2}}
\]

\[
\alpha(2) = \frac{\sum_{a=1}^{k} \frac{4\rho_a^2\sigma_a^2}{(1-\rho_a)^5}}{\sum_{a=1}^{k} \frac{\sigma_a^4}{(1-\rho_a)^4}}
\]

When you specify BANDWIDTH=NEWEYWEST94, according to Newey and West (1994) the bandwidth parameter is estimated as shown in Table 8.4.
Table 8.4  Bandwidth Parameter Estimation

<table>
<thead>
<tr>
<th>Kernel Name</th>
<th>Bandwidth Parameter</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bartlett</td>
<td>( b = 1.1447\left({s_1/s_0}^2 T\right)^{1/3} )</td>
</tr>
<tr>
<td>Parzen</td>
<td>( b = 2.6614\left({s_1/s_0}^2 T\right)^{1/5} )</td>
</tr>
<tr>
<td>Quadratic spectral</td>
<td>( b = 1.3221\left({s_1/s_0}^2 T\right)^{1/5} )</td>
</tr>
<tr>
<td>Truncated</td>
<td>( b = 0.6611\left({s_1/s_0}^2 T\right)^{1/5} )</td>
</tr>
<tr>
<td>Tukey-Hanning</td>
<td>( b = 1.7462\left({s_1/s_0}^2 T\right)^{1/5} )</td>
</tr>
</tbody>
</table>

The factors \( s_1 \) and \( s_0 \) are estimated with the following formulas:

\[
 s_1 = 2 \sum_{j=1}^{n} j \sigma_j \quad s_0 = \sigma_0 + 2 \sum_{j=1}^{n} \sigma_j
\]

where \( n \) is the lag selection parameter and is determined by kernels, as listed in Table 8.5.

Table 8.5  Lag Selection Parameter Estimation

<table>
<thead>
<tr>
<th>Kernel Name</th>
<th>Lag Selection Parameter</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bartlett</td>
<td>( n = c\left(T/100\right)^{2/9} )</td>
</tr>
<tr>
<td>Parzen</td>
<td>( n = c\left(T/100\right)^{4/25} )</td>
</tr>
<tr>
<td>Quadratic spectral</td>
<td>( n = c\left(T/100\right)^{2/25} )</td>
</tr>
<tr>
<td>Truncated</td>
<td>( n = c\left(T/100\right)^{1/5} )</td>
</tr>
<tr>
<td>Tukey-Hanning</td>
<td>( n = c\left(T/100\right)^{1/5} )</td>
</tr>
</tbody>
</table>

The factor \( c \) in Table 8.5 is specified by the C= option; by default it is 12.

The factor \( \sigma_j \) is estimated with the equation

\[
 \sigma_j = T^{-1} \sum_{t=j+1}^{T} \left( \sum_{a=i}^{k} g_{at} \sum_{a=i}^{k} g_{at-j} \right), \quad j = 0, ..., n
\]

where \( i \) is 1 if the NOINT option in the MODEL statement is specified (otherwise, it is 2), and \( g_{at} \) is the same as in the Andrews method.

If you specify BANDWIDTH=SAMPLESIZE, the bandwidth parameter is estimated with the equation

\[
 b = \begin{cases} 
 [\gamma T^r + c] & \text{if BANDWIDTH=SAMPLESIZE(INT) option is specified} \\
 \gamma T^r + c & \text{otherwise} 
\end{cases}
\]

where \( T \) is the sample size; \( [x] \) is the largest integer less than or equal to \( x \); and \( \gamma, r, \) and \( c \) are values specified by the BANDWIDTH=SAMPLESIZE(GAMMA=, RATE=, CONSTANT=) options, respectively.
If you specify the PREWHITENING option, \( g_t \) is prewhitened by the VAR(1) model,

\[
g_t = Ag_{t-1} + w_t
\]

Then \( M \) is calculated by

\[
M_{\text{HAC}} = a \left((I - A)^{-1}\right) \left( \sum_{t=1}^{T} w_tw'_t + \sum_{j=1}^{T-1} k\left(\frac{j}{b}\right) \sum_{i=1}^{T-j} (w_tw'_{t+j} + w_{t+j}w'_t) \right) (I - A)^{-1}
\]

The bandwidth calculation is also based on the prewhitened series \( w_t \).

---

**Goodness-of-Fit Measures and Information Criteria**

This section discusses various goodness-of-fit statistics produced by the AUTOREG procedure.

**Total R-Square Statistic**

The total R-Square statistic (Total Rsq) is computed as

\[
R^2_{\text{tot}} = 1 - \frac{\text{SSE}}{\text{SST}}
\]

where SST is the sum of squares for the original response variable corrected for the mean and SSE is the final error sum of squares. The Total Rsq is a measure of how well the next value can be predicted using the structural part of the model and the past values of the residuals. If the NOINT option is specified, SST is the uncorrected sum of squares.

**Regression R-Square Statistic**

The regression R-Square statistic (Reg RSQ) is computed as

\[
R^2_{\text{reg}} = 1 - \frac{\text{TSSE}}{\text{TSST}}
\]

where TSST is the total sum of squares of the transformed response variable corrected for the transformed intercept, and TSSE is the error sum of squares for this transformed regression problem. If the NOINT option is requested, no correction for the transformed intercept is made. The Reg RSQ is a measure of the fit of the structural part of the model after transforming for the autocorrelation and is the R-Square for the transformed regression.

The regression R-Square and the total R-Square should be the same when there is no autocorrelation correction (OLS regression).

**Mean Absolute Error and Mean Absolute Percentage Error**

The mean absolute error (MAE) is computed as

\[
\text{MAE} = \frac{1}{T} \sum_{t=1}^{T} |e_t|
\]
where $e_t$ are the estimated model residuals and $T$ is the number of observations.

The mean absolute percentage error (MAPE) is computed as

$$\text{MAPE} = \frac{1}{T} \sum_{t=1}^{T} \frac{|e_t|}{|y_t|}$$

where $e_t$ are the estimated model residuals, $y_t$ are the original response variable observations, $\delta_{y_t \neq 0} = 1$ if $y_t \neq 0$, $\delta_{y_t = 0}|e_t/y_t| = 0$ if $y_t = 0$, and $T'$ is the number of nonzero original response variable observations.

### Calculation of Recursive Residuals and CUSUM Statistics

The recursive residuals $w_t$ are computed as

$$w_t = \frac{e_t}{\sqrt{v_t}}$$

$$e_t = y_t - x_t' \hat{\beta}^{(t)}$$

$$\hat{\beta}^{(t)} = \left[ \sum_{i=1}^{t-1} x_i x_i' \right]^{-1} \left( \sum_{i=1}^{t-1} x_i y_i \right)$$

$$v_t = 1 + x_t' \left[ \sum_{i=1}^{t-1} x_i x_i' \right]^{-1} x_t$$

Note that the first $\hat{\beta}^{(t)}$ can be computed for $t = p + 1$, where $p$ is the number of regression coefficients. As a result, first $p$ recursive residuals are not defined. Note also that the forecast error variance of $e_t$ is the scalar multiple of $v_t$ such that $V(e_t) = \sigma^2 v_t$.

The CUSUM and CUSUMSQ statistics are computed using the preceding recursive residuals.

$$\text{CUSUM}_t = \sum_{i=k+1}^{t} \frac{w_i}{\sigma_w}$$

$$\text{CUSUMSQ}_t = \frac{\sum_{i=k+1}^{T} w_i^2}{\sum_{i=k+1}^{T} w_i^2}$$

where $w_i$ are the recursive residuals,

$$\sigma_w = \sqrt{\frac{\sum_{i=k+1}^{T} (w_i - \hat{w})^2}{(T - k - 1)}}$$

$$\hat{w} = \frac{1}{T - k} \sum_{i=k+1}^{T} w_i$$

and $k$ is the number of regressors.
The CUSUM statistics can be used to test for misspecification of the model. The upper and lower critical values for $\text{CUSUM}_t$ are

$$\pm a \left[ \sqrt{T - k} + 2 \frac{(t - k)}{(T - k)^{\frac{1}{2}}} \right]$$

where $a = 1.143$ for a significance level 0.01, 0.948 for 0.05, and 0.850 for 0.10. These critical values are output by the CUSUMLB= and CUSUMUB= options for the significance level specified by the ALPHACSM= option.

The upper and lower critical values of $\text{CUSUMSQ}_t$ are given by

$$\pm a \frac{(t - k)}{T - k}$$

where the value of $a$ is obtained from the table by Durbin (1969) if the $\frac{1}{2} (T - k) - 1 \leq 60$. Edgerton and Wells (1994) provided the method of obtaining the value of $a$ for large samples.

These critical values are output by the CUSUMSQLB= and CUSUMSQUB= options for the significance level specified by the ALPHACSM= option.

**Information Criteria AIC, AICC, SBC, and HQC**

Akaike’s information criterion (AIC), the corrected Akaike’s information criterion (AICC), Schwarz’s Bayesian information criterion (SBC), and the Hannan-Quinn information criterion (HQC), are computed as follows:

$$\text{AIC} = -2\ln(L) + 2k$$
$$\text{AICC} = \text{AIC} + \frac{k(k + 1)}{N - k - 1}$$
$$\text{SBC} = -2\ln(L) + \ln(N)k$$
$$\text{HQC} = -2\ln(L) + 2\ln(\ln(N))k$$

In these formulas, $L$ is the value of the likelihood function evaluated at the parameter estimates, $N$ is the number of observations, and $k$ is the number of estimated parameters. Refer to Judge et al. (1985), Hurvich and Tsai (1989), Schwarz (1978) and Hannan and Quinn (1979) for additional details.

**Testing**

The modeling process consists of four stages: identification, specification, estimation, and diagnostic checking (Cromwell, Labys, and Terraza 1994). The AUTOREG procedure supports tens of statistical tests for identification and diagnostic checking. Figure 8.15 illustrates how to incorporate these statistical tests into the modeling process.
Testing for Stationarity

Most of the theories of time series require stationarity; therefore, it is critical to determine whether a time series is stationary. Two nonstationary time series are fractionally integrated time series and autoregressive series with random coefficients. However, more often some time series are nonstationary due to an upward trend over time. The trend can be captured by either of the following two models.

- The difference stationary process

\[(1 - L)y_t = \delta + \psi(L)\epsilon_t\]
where \( L \) is the lag operator, \( \psi(1) \neq 0 \), and \( \epsilon_t \) is a white noise sequence with mean zero and variance \( \sigma^2 \). Hamilton (1994) also refers to this model the unit root process.

- The trend stationary process

\[
y_t = \alpha + \delta t + \psi(L)\epsilon_t
\]

When a process has a unit root, it is said to be integrated of order one or \( I(1) \). An \( I(1) \) process is stationary after differencing once. The trend stationary process and difference stationary process require different treatment to transform the process into stationary one for analysis. Therefore, it is important to distinguish the two processes. Bhargava (1986) nested the two processes into the following general model

\[
y_t = \gamma_0 + \gamma_1 t + \alpha(y_{t-1} - \gamma_0 - \gamma_1(t-1)) + \psi(L)\epsilon_t
\]

However, a difficulty is that the right-hand side is nonlinear in the parameters. Therefore, it is convenient to use a different parametrization

\[
y_t = \beta_0 + \beta_1 t + \alpha y_{t-1} + \psi(L)\epsilon_t
\]

The test of null hypothesis that \( \alpha = 1 \) against the one-sided alternative of \( \alpha < 1 \) is called a unit root test.

Dickey-Fuller unit root tests are based on regression models similar to the previous model

\[
y_t = \beta_0 + \beta_1 t + \alpha y_{t-1} + \epsilon_t
\]

where \( \epsilon_t \) is assumed to be white noise. The \( t \) statistic of the coefficient \( \alpha \) does not follow the normal distribution asymptotically. Instead, its distribution can be derived using the functional central limit theorem.

Three types of regression models including the preceding one are considered by the Dickey-Fuller test. The deterministic terms that are included in the other two types of regressions are either null or constant only.

An assumption in the Dickey-Fuller unit root test is that it requires the errors in the autoregressive model to be white noise, which is often not true. There are two popular ways to account for general serial correlation between the errors. One is the augmented Dickey-Fuller (ADF) test, which uses the lagged difference in the regression model. This was originally proposed by Dickey and Fuller (1979) and later studied by Said and Dickey (1984) and Phillips and Perron (1988). Another method is proposed by Phillips and Perron (1988); it is called Phillips-Perron (PP) test. The tests adopt the original Dickey-Fuller regression with intercept, but modify the test statistics to take account of the serial correlation and heteroscedasticity. It is called nonparametric because no specific form of the serial correlation of the errors is assumed.

A problem of the augmented Dickey-Fuller and Phillips-Perron unit root tests is that they are subject to size distortion and low power. It is reported in Schwert (1989) that the size distortion is significant when the series contains a large moving average (MA) parameter. DeJong et al. (1992) find that the ADF has power around one third and PP test has power less than 0.1 against the trend stationary alternative, in some common settings. Among some more recent unit root tests that improve upon the size distortion and the low power are the tests described by Elliott, Rothenberg, and Stock (1996) and Ng and Perron (2001). These tests involve a step of detrending before constructing the test statistics and are demonstrated to perform better than the traditional ADF and PP tests.

Most testing procedures specify the unit root processes as the null hypothesis. Tests of the null hypothesis of stationarity have also been studied, among which Kwiatkowski et al. (1992) is very popular.

Economic theories often dictate that a group of economic time series are linked together by some long-run equilibrium relationship. Statistically, this phenomenon can be modeled by cointegration. When several
nonstationary processes \( z_t = (z_{1t}, \cdots, z_{kt})' \) are cointegrated, there exists a \((k \times 1)\) cointegrating vector \( c \) such that \( c'z_t \) is stationary and \( c \) is a nonzero vector. One way to test the relationship of cointegration is the \textit{residual based cointegration test}, which assumes the regression model
\[
y_t = \beta_1 + X_t' \beta + u_t
\]
where \( y_t = z_{1t}, x_t = (z_{2t}, \cdots, z_{kt})' \), and \( \beta = (\beta_2, \cdots, \beta_k)' \). The OLS residuals from the regression model are used to test for the null hypothesis of no cointegration. Engle and Granger (1987) suggest using ADF on the residuals while Phillips and Ouliaris (1990) study the tests using PP and other related test statistics.

**Augmented Dickey-Fuller Unit Root and Engle-Granger Cointegration Testing**

Common unit root tests have the null hypothesis that there is an autoregressive unit root \( H_0 : \alpha = 1 \), and the alternative is \( H_a : |\alpha| < 1 \), where \( \alpha \) is the autoregressive coefficient of the time series
\[
y_t = \alpha y_{t-1} + \epsilon_t
\]
This is referred to as the zero mean model. The standard Dickey-Fuller (DF) test assumes that errors \( \epsilon_t \) are white noise. There are two other types of regression models that include a constant or a time trend as follows:
\[
y_t = \mu + \alpha y_{t-1} + \epsilon_t \\
y_t = \mu + \beta t + \alpha y_{t-1} + \epsilon_t
\]
These two models are referred to as the constant mean model and the trend model, respectively. The constant mean model includes a constant mean \( \mu \) of the time series. However, the interpretation of \( \mu \) depends on the stationarity in the following sense: the mean in the stationary case when \( \alpha < 1 \) is the trend in the integrated case when \( \alpha = 1 \). Therefore, the null hypothesis should be the joint hypothesis that \( \alpha = 1 \) and \( \mu = 0 \). However for the unit root tests, the test statistics are concerned with the null hypothesis of \( \alpha = 1 \). The joint null hypothesis is not commonly used. This issue is address in Bhargava (1986) with a different nesting model.

There are two types of test statistics. The conventional \( t \) ratio is
\[
DF_t = \frac{\hat{\alpha} - 1}{sd(\hat{\alpha})}
\]
and the second test statistic, called \( \rho \)-test, is
\[
T(\hat{\alpha} - 1)
\]
For the zero mean model, the asymptotic distributions of the Dickey-Fuller test statistics are
\[
T(\hat{\alpha} - 1) \Rightarrow \left( \int_0^1 W(r) dW(r) \right) \left( \int_0^1 W(r)^2 dr \right)^{-1/2}
\]
\[
DF_t \Rightarrow \left( \int_0^1 W(r) dW(r) \right) \left( \int_0^1 W(r)^2 dr \right)^{-1/2}
\]
For the constant mean model, the asymptotic distributions are
\[
T(\hat{\alpha} - 1) \Rightarrow \left( [W(1)^2 - 1]/2 - W(1) \int_0^1 W(r) dr \right) \left( \int_0^1 W(r)^2 dr - \left( \int_0^1 W(r) dr \right)^2 \right)^{-1}
\]
\[
DF_t \Rightarrow \left( [W(1)^2 - 1]/2 - W(1) \int_0^1 W(r) dr \right) \left( \int_0^1 W(r)^2 dr - \left( \int_0^1 W(r) dr \right)^2 \right)^{-1/2}
\]
For the trend model, the asymptotic distributions are

\[ T(\hat{\alpha} - 1) \Rightarrow \left[ W(r)dW + 12 \left( \int_0^1 rW(r)dr - \frac{1}{2} \int_0^1 W(r)dr \right) \left( \int_0^1 W(r)dr - \frac{1}{2} W(1) \right) \right. \]

\[ \left. -W(1) \int_0^1 W(r)dr \right] D^{-1} \]

\[ DF_t \Rightarrow \left[ W(r)dW + 12 \left( \int_0^1 rW(r)dr - \frac{1}{2} \int_0^1 W(r)dr \right) \left( \int_0^1 W(r)dr - \frac{1}{2} W(1) \right) \right. \]

\[ \left. -W(1) \int_0^1 W(r)dr \right] D^{1/2} \]

where

\[ D = \int_0^1 W(r)^2 dr - 12 \left( \int_0^1 r(W(r)dr \right)^2 + 12 \int_0^1 W(r)dr \int_0^1 rW(r)dr - 4 \left( \int_0^1 W(r)dr \right)^2 \]

One problem of the Dickey-Fuller and similar tests that employ three types of regressions is the difficulty in the specification of the deterministic trends. Campbell and Perron (1991) claimed that “the proper handling of deterministic trends is a vital prerequisite for dealing with unit roots”. However the “proper handling” is not obvious since the distribution theory of the relevant statistics about the deterministic trends is not available. Hayashi (2000) suggests to using the constant mean model when you think there is no trend, and using the trend model when you think otherwise. However no formal procedure is provided.

The null hypothesis of the Dickey-Fuller test is a random walk, possibly with drift. The differenced process is not serially correlated under the null of I(1). There is a great need for the generalization of this specification. The augmented Dickey-Fuller (ADF) test, originally proposed in Dickey and Fuller (1979), adjusts for the serial correlation in the time series by adding lagged first differences to the autoregressive model,

\[ y_t = x_0 + \delta t + \alpha y_{t-1} + \sum_{j=1}^{p} \alpha_j \Delta y_{t-j} + \epsilon_t \]

where the deterministic terms \( \delta t \) and \( \mu \) can be absent for the models without drift or linear trend. As previously, there are two types of test statistics. One is the OLS \( t \) value

\[ \frac{\hat{\alpha} - 1}{sd(\hat{\alpha})} \]

and the other is given by

\[ \frac{T(\hat{\alpha} - 1)}{1 - \hat{\alpha}_1 - \ldots - \hat{\alpha}_p} \]

The asymptotic distributions of the test statistics are the same as those of the standard Dickey-Fuller test statistics.

Nonstationary multivariate time series can be tested for cointegration, which means that a linear combination of these time series is stationary. Formally, denote the series by \( z_t = (z_{1t}, \ldots, z_{kt})' \). The null hypothesis of cointegration is that there exists a vector \( c \) such that \( c'z_t \) is stationary. Residual-based cointegration tests were studied in Engle and Granger (1987) and Phillips and Ouliaris (1990). The latter are described in the next subsection. The first step regression is

\[ y_t = x_0 + \beta + u_t \]
where \( y_t = z_{1t}, x_t = (z_{2t}, \cdots, z_{kt})', \) and \( \beta = (\beta_2, \cdots, \beta_k)' \). This regression can also include an intercept or an intercept with a linear trend. The residuals are used to test for the existence of an autoregressive unit root. Engle and Granger (1987) proposed augmented Dickey-Fuller type regression without an intercept on the residuals to test the unit root. When the first step OLS does not include an intercept, the asymptotic distribution of the ADF test statistic \( DF_t \) is given by

\[
DF_t \Rightarrow \int_0^1 \frac{Q(r)}{(f_0^1 Q^2)^{1/2}} dS \\
Q(r) = W_1(r) - \int_0^1 W_1 W_2' \left( \int_0^1 W_2 W_2' \right)^{-1} W_2(r) \\
S(r) = \frac{Q(r)}{(\kappa' \kappa)^{1/2}} \\
\kappa' = \left( 1, - \int_0^1 W_1 W_2' \left( \int_0^1 W_2 W_2' \right)^{-1} \right)
\]

where \( W(r) \) is a \( k \) vector standard Brownian motion and

\[
W(r) = \left( W_1(r), W_2(r) \right)
\]

is a partition such that \( W_1(r) \) is a scalar and \( W_2(r) \) is \( k - 1 \) dimensional. The asymptotic distributions of the test statistics in the other two cases have the same form as the preceding formula. If the first step regression includes an intercept, then \( W(r) \) is replaced by the demeaned Brownian motion \( \overline{W}(r) = W(r) - \int_0^1 W(r) d\ell \). If the first step regression includes a time trend, then \( W(r) \) is replaced by the detrended Brownian motion. The critical values of the asymptotic distributions are tabulated in Phillips and Ouliaris (1990) and MacKinnon (1991).

The residual based cointegration tests have a major shortcoming. Different choices of the dependent variable in the first step OLS might produce contradictory results. This can be explained theoretically. If the dependent variable is in the cointegration relationship, then the test is consistent against the alternative that there is cointegration. On the other hand, if the dependent variable is not in the cointegration system, the OLS residual \( y_t - x_t' \beta \) do not converge to a stationary process. Changing the dependent variable is more likely to produce conflicting results in finite samples.

**Phillips-Perron Unit Root and Cointegration Testing**

Besides the ADF test, there is another popular unit root test that is valid under general serial correlation and heteroscedasticity, developed by Phillips (1987) and Phillips and Perron (1988). The tests are constructed using the AR(1) type regressions, unlike ADF tests, with corrected estimation of the long run variance of \( \Delta y_t \). In the case without intercept, consider the driftless random walk process

\[
y_t = y_{t-1} + u_t
\]

where the disturbances might be serially correlated with possible heteroscedasticity. Phillips and Perron (1988) proposed the unit root test of the OLS regression model,

\[
y_t = \rho y_{t-1} + u_t
\]
Denote the OLS residual by \( \hat{u}_t \). The asymptotic variance of \( \frac{1}{T} \sum_{t=1}^{T} \hat{u}_t^2 \) can be estimated by using the truncation lag \( l \).

\[
\hat{\lambda} = \sum_{j=0}^{l} \kappa_j [1 - j/(l + 1)] \hat{\gamma}_j
\]

where \( \kappa_0 = 1, \kappa_j = 2 \) for \( j > 0 \), and \( \hat{\gamma}_j = \frac{1}{T} \sum_{t=j+1}^{T} \hat{u}_t \hat{u}_{t-j} \). This is a consistent estimator suggested by Newey and West (1987).

The variance of \( u_t \) can be estimated by \( s^2 = \frac{1}{T-k} \sum_{t=1}^{T} \hat{u}_t^2 \). Let \( \hat{\sigma}^2 \) be the variance estimate of the OLS estimator \( \hat{\rho} \). Then the Phillips-Perron \( \hat{Z}_p \) test (zero mean case) is written

\[
\hat{Z}_p = T(\hat{\rho} - 1) - \frac{1}{2} T^2 \hat{\sigma}^2 (\hat{\lambda} - \hat{\gamma}_0) / s^2
\]

The \( \hat{Z}_p \) statistic is just the ordinary Dickey-Fuller \( \hat{Z}_a \) statistic with a correction term that accounts for the serial correlation. The correction term goes to zero asymptotically if there is no serial correlation.

Note that \( P(\hat{\rho} < 1) \approx 0.68 \) as \( T \to \infty \), which shows that the limiting distribution is skewed to the left.

Let \( \tau_p \) be the \( \tau \) statistic for \( \hat{\rho} \). The Phillips-Perron \( \hat{Z}_t \) (defined here as \( \hat{Z}_t \)) test is written

\[
\hat{Z}_t = (\hat{\gamma}_0 / \hat{\lambda})^{1/2} \tau_p - \frac{1}{2} T \hat{\sigma} (\hat{\lambda} - \hat{\gamma}_0) / (s \hat{\lambda}^{1/2})
\]

To incorporate a constant intercept, the regression model \( y_t = \mu + \rho y_{t-1} + u_t \) is used (single mean case) and null hypothesis the series is a driftless random walk with nonzero unconditional mean. To incorporate a time trend, we used the regression model \( y_t = \mu + \delta t + \rho y_{t-1} + u_t \) and under the null the series is a random walk with drift.

The limiting distributions of the test statistics for the zero mean case are

\[
\hat{Z}_p \Rightarrow \frac{1}{2} \left\{ B(1)^2 - 1 \right\} / \oint_0^1 \left[ B(s) \right]^2 ds
\]

\[
\hat{Z}_t \Rightarrow \frac{1}{2} \left\{ B(1)^2 - 1 \right\} / \oint_0^1 \left[ B(x) \right]^2 dx \right\}^{1/2}
\]

where \( B(\cdot) \) is a standard Brownian motion.

The limiting distributions of the test statistics for the intercept case are

\[
\hat{Z}_p \Rightarrow \frac{1}{2} \left\{ B(1)^2 - 1 \right\} - B(1) \oint_0^1 B(x) dx / \oint_0^1 [B(x)]^2 dx - \left[ \oint_0^1 B(x) dx \right]^2
\]

\[
\hat{Z}_t \Rightarrow \frac{1}{2} \left\{ B(1)^2 - 1 \right\} - B(1) \oint_0^1 B(x) dx / \oint_0^1 [B(x)]^2 dx - \left[ \oint_0^1 B(x) dx \right]^2 \right\}^{1/2}
\]

Finally, The limiting distributions of the test statistics for the trend case are can be derived as

\[
\begin{bmatrix}
0 & c & 0
\end{bmatrix} V^{-1}
\begin{bmatrix}
\frac{B(1)}{B(1) - \oint_0^1 B(x) dx}
\frac{(B(1)^2 - 1)/2}{B(1) - \oint_0^1 B(x) dx}
\end{bmatrix}
\]
where \( c = 1 \) for \( \hat{Z}_p \) and \( c = \frac{1}{\sqrt{Q}} \) for \( \hat{Z}_r \),

\[
V = \begin{bmatrix}
1 & \int_0^1 B(x)dx & \int_0^1 B(x)^2 dx & \int_0^1 xB(x)dx \\
1/2 & \int_0^1 B(x)dx & \int_0^1 (x)_B(x)dx & \int_0^1 xB(x)dx \\
1/3 & \int_0^1 B(x)dx & \int_0^1 (x)_B(x)dx & \int_0^1 xB(x)dx
\end{bmatrix}
\]

\[
Q = \begin{bmatrix} 0 & c & 0 \end{bmatrix} V^{-1} \begin{bmatrix} 0 & c & 0 \end{bmatrix}^T
\]

The finite sample performance of the PP test is not satisfactory (see Hayashi (2000)).

When several variables \( z_t = (z_{1t}, \ldots, z_{kt})' \) are cointegrated, there exists a \((k \times 1)\) cointegrating vector \( c \) such that \( c'z_t \) is stationary and \( c \) is a nonzero vector. The residual based cointegration test assumes the following regression model:

\[
y_t = \beta_1 + x_t' \beta + u_t
\]

where \( y_t = z_{1t}, x_t = (z_{2t}, \ldots, z_{kt})' \), and \( \beta = (\beta_2, \ldots, \beta_k)' \). You can estimate the consistent cointegrating vector by using OLS if all variables are difference stationary — that is, I(1). The estimated cointegrating vector is \( \hat{c} = (1, -\hat{\beta}_2, \ldots, -\hat{\beta}_k)' \). The Phillips-Ouliaris test is computed using the OLS residuals from the preceding regression model, and it uses the PP unit root tests \( \hat{Z}_p \) and \( \hat{Z}_r \) developed in Phillips (1987), although in Phillips and Ouliaris (1990) the asymptotic distributions of some other leading unit root tests are also derived. The null hypothesis is no cointegration.

You need to refer to the tables by Phillips and Ouliaris (1990) to obtain the \( p \)-value of the cointegration test. Before you apply the cointegration test, you may want to perform the unit root test for each variable (see the option \texttt{STATIONARITY=}).

As in the Engle-Granger cointegration tests, the Phillips-Ouliaris test can give conflicting results for different choices of the regressand. There are other cointegration tests that are invariant to the order of the variables, including Johansen (1988), Johansen (1991), Stock and Watson (1988).

**ERS and Ng-Perron Unit Root Tests**

As mentioned earlier, ADF and PP both suffer severe size distortion and low power. There is a class of newer tests that improve both size and power. These are sometimes called efficient unit root tests, and among them tests by Elliott, Rothenberg, and Stock (1996) and Ng and Perron (2001) are prominent.

Elliott, Rothenberg, and Stock (1996) consider the data generating process

\[
y_t = \beta'z_t + u_t \\
u_t = \alpha u_{t-1} + v_t, t = 1, \ldots, T
\]

where \( \{z_t\} \) is either \( \{1\} \) or \( \{(1, t)\} \) and \( \{v_t\} \) is an unobserved stationary zero-mean process with positive spectral density at zero frequency. The null hypothesis is \( H_0 : \alpha = 1 \), and the alternative is \( H_a : |\alpha| < 1 \).

The key idea of Elliott, Rothenberg, and Stock (1996) is to study the asymptotic power and asymptotic power envelope of some new tests. Asymptotic power is defined with a sequence of local alternatives. For a fixed alternative hypothesis, the power of a test usually goes to one when sample size goes to infinity; however, this says nothing about the finite sample performance. On the other hand, when the data generating process under the alternative moves closer to the null hypothesis as the sample size increases, the power does not necessarily converge to one. The local-to-unity alternatives in ERS are

\[
\alpha = 1 + \frac{c}{T}
\]
and the power against the local alternatives has a limit as $T$ goes to infinity, which is called asymptotic power. This value is strictly between 0 and 1. Asymptotic power indicates the adequacy of a test to distinguish small deviations from the null hypothesis.

Define

$$y_{\alpha} = (y_1, (1 - \alpha L)y_2, \ldots, (1 - \alpha L)y_T)$$
$$z_{\alpha} = (z_1, (1 - \alpha L)z_2, \ldots, (1 - \alpha L)z_T)$$

Let $S(\alpha)$ be the sum of squared residuals from a least squares regression of $y_{\alpha}$ on $z_{\alpha}$. Then the point optimal test against the local alternative $\alpha = 1 + \tilde{c}/T$ has the form

$$P^{GLS}_T = \frac{S(\hat{\alpha}) - \hat{\alpha}S(1)}{\hat{\omega}^2}$$

where $\hat{\omega}^2$ is an estimator for $\omega^2 = \sum_{k=-\infty}^{\infty} E v_tv_{t-k}$. The test rejects the null when $P_T$ is small. The asymptotic power function for the point optimal test that is constructed with $N_c$ under local alternatives with $c$ is denoted by $c; N_c$. Then the power envelope is $c; c$ because the test formed with $N_c$ is the most powerful against the alternative $c = N_c$. In other words, the asymptotic function $c; N_c$ is always below the power envelope $c$ except that at one point, $c = \hat{c}$, they are tangent. Elliott, Rothenberg, and Stock (1996) show that choosing some specific values for $N_c$ can cause the asymptotic power function $c; N_c$ of the point optimal test to be very close to the power envelope. The optimal $N_c$ is 7 when $z_t = 1$, and 13.5 when $z_t = (1, t)'$. This choice of $N_c$ corresponds to the tangent point where $P_T$ is small. The DF-GLS test is indeed a superior unit root test, according to Stock (1994), Schwert (1989), and Elliott, Rothenberg, and Stock (1996). In terms of the size of the test, DF-GLS is almost as good as the ADF $t$ test DF and better
than the PP $\hat{Z}_p$ and $\hat{Z}_\tau$ test. In addition, the power of the DF-GLS test is greater than that of both the ADF $t$ test and the $\rho$-test.

Ng and Perron (2001) also apply GLS detrending to obtain the following M-tests:

$$MZ_\alpha = \left( \frac{1}{T-1} \sum_{t=1}^{T-1} (y_T^d)^2 - \hat{\omega}^2 \right) \left( \frac{2(T-1)^2}{\sum_{t=1}^{T-1} (y_T^d)^2} \right)^{-1}$$

$$MSB = \left( \frac{\sum_{t=1}^{T-1} (y_T^d)^2}{(T-1)^2 \hat{\omega}^2} \right)^{1/2}$$

$$MZ_t = MZ_\alpha \times MSB$$

The first one is a modified version of the Phillips-Perron $Z_\rho$ test,

$$MZ_\rho = Z_\rho + \frac{T}{2} (\hat{\omega} - 1)^2$$

where the detrended data $\{y_T^d\}$ is used. The second is a modified Bhargava (1986) $R_1$ test statistic. The third can be perceived as a modified Phillips-Perron $Z_\tau$ statistic because of the relationship $Z_\tau = MSB \times Z_\rho$.

The modified point optimal tests that use the GLS detrended data are

$$MP_{\alpha}^{GLS} = \frac{\hat{\omega}^2 (T-1) - 2 \sum_{t=1}^{T-1} (y_T^d)^2 - \hat{\epsilon} (T-1) - 1 (y_T^d)^2}{\hat{\omega}^2}$$

for $z_t = 1$

$$MP_{\alpha}^{GLS} = \frac{\hat{\omega}^2 (T-1) - 2 \sum_{t=1}^{T-1} (y_T^d)^2 (1-\hat{\epsilon}) (T-1) - 1 (y_T^d)^2}{\hat{\omega}^2}$$

for $z_t = (1, t)$

The DF-GLS test and the $MZ_t$ test have the same limiting distribution:

$$DF-GLS \approx MZ_t \Rightarrow 0.5 \left( \frac{J_c(1)^2 - 1}{\int_0^1 J_c(r)^2 dr} \right)^{1/2}$$

for $z_t = 1$

$$DF-GLS \approx MZ_t \Rightarrow 0.5 \left( \frac{V_{c,\hat{\epsilon}}(1)^2 - 1}{\int_0^1 V_{c,\hat{\epsilon}}(r)^2 dr} \right)^{1/2}$$

for $z_t = (1, t)$

The point optimal test and the modified point optimal test have the same limiting distribution:

$$P_{\alpha}^{GLS} \approx MP_{\alpha}^{GLS} \Rightarrow \hat{\epsilon}^2 \int_0^1 J_c(r)^2 dr - \hat{\epsilon} J_c(1)^2$$

for $z_t = 1$

$$P_{\alpha}^{GLS} \approx MP_{\alpha}^{GLS} \Rightarrow \hat{\epsilon}^2 \int_0^1 V_{c,\hat{\epsilon}}(r)^2 dr + (1 - \hat{\epsilon}) V_{c,\hat{\epsilon}}(1)^2$$

for $z_t = (1, t)$

where $W(r)$ is a standard Brownian motion and $J_c(r)$ is an Ornstein-Uhlenbeck process defined by $dJ_c(r) = \lambda J_c(r) dr + dW(r)$ with $J_c(0) = 0$, $V_{c,\hat{\epsilon}}(r) = J_c(r) - r [\lambda J_c(1) + 3(1 - \lambda) \int_0^1 sJ_c(s) ds]$, and $\lambda = (1 - \hat{\epsilon})/(1 - \hat{\epsilon} + \hat{\epsilon}^2/3)$.

Overall, the M-tests have the smallest size distortion, with the ADF $t$ test having the next smallest. The ADF $\rho$-test, $\hat{Z}_p$, and $\hat{Z}_\tau$ have the largest size distortion. In addition, the power of the DF-GLS and M-tests is greater than that of the ADF $t$ test and $\rho$-test. The ADF $\hat{Z}_p$ has more severe size distortion than the ADF $\hat{Z}_\tau$, but it has more power for a fixed lag length.
Kwiatkowski, Phillips, Schmidt, and Shin (KPSS) Unit Root Test and Shin Cointegration Test

There are fewer tests available for the null hypothesis of trend stationarity I(0). The main reason is the difficulty of theoretical development. The KPSS test was introduced in Kwiatkowski et al. (1992) to test the null hypothesis that an observable series is stationary around a deterministic trend. For consistency, the notation used here differs from the notation in the original paper. The setup of the problem is as follows: it is assumed that the series is expressed as the sum of the deterministic trend, random walk \( r_t \), and stationary error \( u_t \); that is,

\[
y_t = \mu + \delta t + r_t + u_t
\]

\[
r_t = r_{t-1} + e_t
\]

where \( e_t \sim \text{iid} (0, \sigma_e^2) \), and an intercept \( \mu \) (in the original paper, the authors use \( r_0 \) instead of \( \mu \); here we assume \( r_0 = 0 \)) The null hypothesis of trend stationarity is specified by \( H_0: \sigma_e^2 = 0 \), while the null of level stationarity is the same as above with the model restriction \( \delta = 0 \). Under the alternative that \( \sigma_e^2 \neq 0 \), there is a random walk component in the observed series \( y_t \).

Under stronger assumptions of normality and iid of \( u_t \) and \( e_t \), a one-sided LM test of the null that there is no random walk \( (e_t = 0, \forall t) \) can be constructed as follows:

\[
\hat{LM} = \frac{1}{T^2} \sum_{t=1}^{T} \frac{S_t^2}{s^2(l)}
\]

\[
s^2(l) = \frac{1}{T} \sum_{t=1}^{T} \hat{u}_t^2 + \frac{2}{T} \sum_{s=1}^{l} w(s, l) \sum_{t=s+1}^{T} \hat{u}_t \hat{u}_{t-s}
\]

\[
S_t = \sum_{t=1}^{T} \hat{u}_t
\]

Under the null hypothesis, \( \hat{u}_t \) can be estimated by ordinary least squares regression of \( y_t \) on an intercept and the time trend. Following the original work of Kwiatkowski et al. (1992), under the null \( (\sigma_e^2 = 0) \), the \( \hat{LM} \) statistic converges asymptotically to three different distributions depending on whether the model is trend-stationary, level-stationary \( (\delta = 0) \), or zero-mean stationary \( (\delta = 0, \mu = 0) \). The trend-stationary model is denoted by subscript \( \tau \) and the level-stationary model is denoted by subscript \( \mu \). The case when there is no trend and zero intercept is denoted as \( 0 \). The last case, although rarely used in practice, is considered in Hobijn, Franses, and Ooms (2004):

\[
y_t = u_t : \quad \hat{LM}_0 \xrightarrow{D} \int_0^1 B^2(r)dr
\]

\[
y_t = \mu + u_t : \quad \hat{LM}_\mu \xrightarrow{D} \int_0^1 V^2(r)dr
\]

\[
y_t = \mu + \delta t + u_t : \quad \hat{LM}_\tau \xrightarrow{D} \int_0^1 V_2^2(r)dr
\]

with

\[
V(r) = B(r) - rB(1)
\]

\[
V_2(r) = B(r) + (2r - 3r^2)B(1) + (-6r + 6r^2) \int_0^1 B(s)ds
\]
where $B(r)$ is a Brownian motion (Wiener process) and $\stackrel{D}{\longrightarrow}$ is convergence in distribution. $V(r)$ is a standard Brownian bridge, and $V_2(r)$ is a second-level Brownian bridge.

Using the notation of Kwiatkowski et al. (1992), the $\hat{L}M$ statistic is named as $\hat{\eta}$. This test depends on the computational method used to compute the long-run variance $s(l)$; that is, the window width $l$ and the kernel type $w(\cdot, \cdot)$. You can specify the kernel used in the test by using the KERNEL option:

- Newey-West/Bartlett (KERNEL=NW | BART) (this is the default)
  \[
  w(s, l) = 1 - \frac{s}{l + 1}
  \]

- quadratic spectral (KERNEL=QS)
  \[
  w(s, l) = \hat{w} \left( \frac{s}{l} \right) = \hat{w}(x) = \frac{25}{12\pi^2x^2} \left( \frac{\sin(6\pi x/5)}{6\pi x/5} - \cos \left( \frac{6}{5}\pi x \right) \right)
  \]

You can specify the number of lags, $l$, in three different ways:

- Schwert (SCHW = c) (default for NW, c=12)
  \[
  l = \max \left\{ 1, \text{floor} \left( c \left( \frac{T}{100} \right)^{1/4} \right) \right\}
  \]

- manual (LAG = l)

- automatic selection (AUTO) (default for QS), from Hobijn, Franses, and Ooms (2004). The number of lags, $l$, is calculated as in the following table:

<table>
<thead>
<tr>
<th>KERNEL=NW</th>
<th>KERNEL=QS</th>
</tr>
</thead>
<tbody>
<tr>
<td>$l = \min(T, \text{floor}(\hat{\tau} T^{1/3}))$</td>
<td>$l = \min(T, \text{floor}(\hat{\tau} T^{1/5}))$</td>
</tr>
<tr>
<td>$\hat{\tau} = 1.1447 \left{ \left( \frac{\hat{\omega}(1)}{\hat{\omega}(3)} \right)^2 \right}^{1/3}$</td>
<td>$\hat{\tau} = 1.3221 \left{ \left( \frac{\hat{\omega}(2)}{\hat{\omega}(4)} \right)^2 \right}^{1/5}$</td>
</tr>
<tr>
<td>$\hat{s}^{(j)} = \delta_{0,j} \hat{\tau} + 2 \sum_{i=1}^{n} i^j \hat{\tau}_i$</td>
<td>$\hat{s}^{(j)} = \delta_{0,j} \hat{\tau} + 2 \sum_{i=1}^{n} i^j \hat{\tau}_i$</td>
</tr>
<tr>
<td>$n = \text{floor}(T^{2/9})$</td>
<td>$n = \text{floor}(T^{2/25})$</td>
</tr>
</tbody>
</table>

where $T$ is the number of observations, $\delta_{0,j} = 1$ if $j = 0$ and 0 otherwise, and $\hat{\tau}_i = \frac{1}{T} \sum_{t=1}^{T-i} u_t u_{t+i}$.

Simulation evidence shows that the KPSS has size distortion in finite samples. For an example, see Caner and Kilian (2001). The power is reduced when the sample size is large; this can be derived theoretically (see Breitung (1995)). Another problem of the KPSS test is that the power depends on the truncation lag used in the Newey-West estimator of the long-run variance $s^2(l)$.
Shin (1994) extends the KPSS test to incorporate the regressors to be a cointegration test. The cointegrating regression becomes

\[ y_t = \mu + \delta t + X'_t \beta + r_t + u_t \]

\[ r_t = r_{t-1} + e_t \]

where \( y_t \) and \( X_t \) are scalar and \( m \)-vector \( I(1) \) variables. There are still three cases of cointegrating regressions: without intercept and trend, with intercept only, and with intercept and trend. The null hypothesis of the cointegration test is the same as that for the KPSS test, \( H_0 : \sigma^2 = 0 \). The test statistics for cointegration in the three cases of cointegrating regressions are exactly the same as those in the KPSS test; these test statistics are then ignored here. Under the null hypothesis, the statistics converge asymptotically to three different distributions:

\[ y_t = X'_t \beta + u_t : \quad \lim_{n \to \infty} \frac{1}{n} \sum_{t=1}^{n} Q_1(r) \xrightarrow{D} \int_0^1 Q_1(r) \, dr \]

\[ y_t = \mu + X'_t \beta + u_t : \quad \lim_{n \to \infty} \frac{1}{n} \sum_{t=1}^{n} Q_2(r) \xrightarrow{D} \int_0^1 Q_2(r) \, dr \]

\[ y_t = \mu + \delta t + X'_t \beta + u_t : \quad \lim_{n \to \infty} \frac{1}{n} \sum_{t=1}^{n} Q_3(r) \xrightarrow{D} \int_0^1 Q_3(r) \, dr \]

with

\[ Q_1(r) = B(r) - \left( \int_0^r B_m(x) \, dx \right) \left( \int_0^1 B_m(x) B_m'(x) \, dx \right)^{-1} \left( \int_0^1 B_m(x) \, dB(x) \right) \]

\[ Q_2(r) = V(r) - \left( \int_0^r B_m(x) \, dx \right) \left( \int_0^1 B_m(x) B_m'(x) \, dx \right)^{-1} \left( \int_0^1 B_m(x) \, dB(x) \right) \]

\[ Q_3(r) = V_2(r) - \left( \int_0^r B_m^*(x) \, dx \right) \left( \int_0^1 B_m^*(x) B_m^*(x) \, dx \right)^{-1} \left( \int_0^1 B_m^*(x) \, dB(x) \right) \]

where \( B(.) \) and \( B_m(.) \) are independent scalar and \( m \)-vector standard Brownian motion, and \( \xrightarrow{D} \) is convergence in distribution. \( V(r) \) is a standard Brownian bridge, \( V_2(r) \) is a Brownian bridge of a second-level, \( B_m(r) \) is an \( m \)-vector standard demeaned Brownian motion, and \( B_m^*(r) = B_m(r) - \int_0^r B_m(x) \, dx \) is an \( m \)-vector standard demeaned and detrended Brownian motion.

The \( p \)-values that are reported for the KPSS test and Shin test are calculated via a Monte Carlo simulation of the limiting distributions, using a sample size of 2,000 and 1,000,000 replications.

**Testing for Statistical Independence**

Independence tests are widely used in model selection, residual analysis, and model diagnostics because models are usually based on the assumption of independently distributed errors. If a given time series (for example, a series of residuals) is independent, then no deterministic model is necessary for this completely random process; otherwise, there must exist some relationship in the series to be addressed. In the following section, four independence tests are introduced: the BDS test, the runs test, the turning point test, and the rank version of von Neumann ratio test.
**BDS Test**

Brock, Dechter, and Scheinkman (1987) propose a test (BDS test) of independence based on the correlation dimension. Brock et al. (1996) show that the first-order asymptotic distribution of the test statistic is independent of the estimation error provided that the parameters of the model under test can be estimated \( \sqrt{n} \)-consistently. Hence, the BDS test can be used as a model selection tool and as a specification test.

Given the sample size \( T \), the embedding dimension \( m \), and the value of the radius \( r \), the BDS statistic is

\[
S_{\text{BDS}}(T, m, r) = \sqrt{T - m + 1} \frac{c_{m,m,T}(r) - c_{1,m,T}(r)}{\sigma_{m,T}(r)}
\]

where

\[
c_{m,n,N}(r) = \frac{2}{(N - n + 1)(N - n)} \sum_{s=n}^{N} \sum_{t=s+1}^{N} \prod_{j=0}^{m-1} I_r(z_{s-j}, z_{t-j})
\]

\[
I_r(z_s, z_t) = \begin{cases} 
1 & \text{if } |z_s - z_t| < r \\
0 & \text{otherwise}
\end{cases}
\]

\[
\sigma^2_{m,T}(r) = 4 \left( k^m + 2 \sum_{j=1}^{m-1} k^{m-j} c^{2j} + (m - 1)^2 c^{2m} - m^2 k c^{2m-2} \right)
\]

\[
c = c_{1,1,T}(r)
\]

\[
k = k_T(r) = \frac{6}{T(T - 1)(T - 2)} \sum_{t=1}^{T} \sum_{s=t+1}^{T} \sum_{l=s+1}^{T} h_r(z_t, z_s, z_l)
\]

\[
h_r(z_t, z_s, z_l) = \frac{1}{3} (I_r(z_t, z_s) I_r(z_s, z_l) + I_r(z_t, z_l) I_r(z_l, z_s) + I_r(z_s, z_l) I_r(z_t, z_l))
\]

The statistic has a standard normal distribution if the sample size is large enough. For small sample size, the distribution can be approximately obtained through simulation. Kanzler (1999) has a comprehensive discussion on the implementation and empirical performance of BDS test.

**Runs Test and Turning Point Test**

The runs test and turning point test are two widely used tests for independence (Cromwell, Labys, and Terraza 1994).

The runs test needs several steps. First, convert the original time series into the sequence of signs, \( \{+ - + - - \ldots \} \), that is, map \( \{z_t\} \) into \( \{\text{sign}(z_t - z_M)\} \) where \( z_M \) is the sample mean of \( z_t \) and \( \text{sign}(x) \) is “+” if \( x \) is nonnegative and “−” if \( x \) is negative. Second, count the number of runs, \( R \), in the sequence. A run of a sequence is a maximal non-empty segment of the sequence that consists of adjacent equal elements. For example, the following sequence contains \( R = 8 \) runs:

\[
++-+---++-++-+--
\]

Third, count the number of pluses and minuses in the sequence and denote them as \( N_+ \) and \( N_- \), respectively. In the preceding example sequence, \( N_+ = 11 \) and \( N_- = 8 \). Note that the sample size \( T = N_+ + N_- \). Finally, compute the statistic of runs test,

\[
S_{\text{runs}} = \frac{R - \mu}{\sigma}
\]
where
\[
\mu = \frac{2N_+N_-}{T} + 1
\]
\[
\sigma^2 = \frac{(\mu - 1)(\mu - 2)}{T - 1}
\]

The statistic of the turning point test is defined as follows:
\[
S_{TP} = \frac{\sum_{t=2}^{T-1} TP_t - 2(T-2)/3}{\sqrt{(16T^2 - 29)/90}}
\]

where the indicator function of the turning point \(TP_t\) is 1 if \(z_t > z_{t+1}\) or \(z_t < z_{t-1}\) (that is, both the previous and next values are greater or less than the current value); otherwise, 0.

The statistics of both the runs test and the turning point test have the standard normal distribution under the null hypothesis of independence.

**Rank Version of von Neumann Ratio Test**

Since the runs test completely ignores the magnitudes of the observations, Bartels (1982) proposes a rank version of the von Neumann Ratio test for independence:

\[
S_{RVN} = \sqrt{T} \left( \frac{\sum_{t=1}^{T-1} (R_{t+1} - R_t)^2}{(T(T^2 - 1)/12) - 2} \right)
\]

where \(R_t\) is the rank of \(t\)th observation in the sequence of \(T\) observations. For large sample, the statistic follows the standard normal distribution under the null hypothesis of independence. For small samples of size between 11 and 100, the critical values through simulation would be more precise; for samples of size no more than 10, the exact CDF is applied.

**Testing for Normality**

Based on skewness and kurtosis, Jarque and Bera (1980) calculated the test statistic
\[
T_N = \left[ \frac{N}{6} b_1^2 + \frac{N}{24} (b_2 - 3)^2 \right]
\]

where
\[
b_1 = \frac{\sqrt{N} \sum_{t=1}^N \hat{u}_t^3}{\left( \sum_{t=1}^N \hat{u}_t^2 \right)^{3/2}}
\]
\[
b_2 = \frac{N \sum_{t=1}^N \hat{u}_t^4}{\left( \sum_{t=1}^N \hat{u}_t^2 \right)^2}
\]

The \(\chi^2(2)\) distribution gives an approximation to the normality test \(T_N\).

When the GARCH model is estimated, the normality test is obtained using the standardized residuals \(\hat{u}_t = \hat{\epsilon}_t / \sqrt{h_t}\). The normality test can be used to detect misspecification of the family of ARCH models.
Testing for Linear Dependence

**Generalized Durbin-Watson Tests**

Consider the following linear regression model:

\[
Y = X\beta + \nu
\]

where \( X \) is an \( N \times k \) data matrix, \( \beta \) is a \( k \times 1 \) coefficient vector, and \( \nu \) is a \( N \times 1 \) disturbance vector. The error term \( \nu \) is assumed to be generated by the \( j \)th-order autoregressive process \( \nu_t = \epsilon_t - \varphi_j \nu_{t-j} \) where \( |\varphi_j| < 1 \), \( \epsilon_t \) is a sequence of independent normal error terms with mean 0 and variance \( \sigma^2 \). Usually, the Durbin-Watson statistic is used to test the null hypothesis \( H_0 : \varphi_1 = 0 \) against \( H_1 : \varphi_1 > 0 \). Vinod (1973) generalized the Durbin-Watson statistic:

\[
d_j = \frac{\sum_{t=j+1}^{N} (\hat{\nu}_t - \hat{\nu}_{t-j})^2}{\sum_{t=1}^{N} \hat{\nu}_t^2}
\]

where \( \hat{\nu} \) are OLS residuals. Using the matrix notation,

\[
d_j = \frac{Y'MA_j'MY}{Y'MY}
\]

where \( M = I_N - X(X'X)^{-1}X' \) and \( A_j \) is a \((N - j) \times N\) matrix:

\[
A_j = \begin{bmatrix}
-1 & 0 & \cdots & 0 & 1 & 0 & \cdots & 0 \\
0 & -1 & 0 & \cdots & 0 & 1 & 0 & \cdots \\
\vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \\
0 & \cdots & 0 & -1 & 0 & \cdots & 0 & 1 \\
\end{bmatrix}
\]

and there are \( j - 1 \) zeros between \(-1\) and \(1\) in each row of matrix \( A_j \).

The QR factorization of the design matrix \( X \) yields a \( N \times N \) orthogonal matrix \( Q \):

\[
X = QR
\]

where \( R \) is an \( N \times k \) upper triangular matrix. There exists an \( N \times (N - k) \) submatrix of \( Q \) such that \( Q_1Q_1' = M \) and \( Q_1Q_1 = I_{N-k} \). Consequently, the generalized Durbin-Watson statistic is stated as a ratio of two quadratic forms:

\[
d_j = \frac{\sum_{l=1}^{n} \lambda_{jl}\xi_l^2}{\sum_{l=1}^{n} \xi_l^2}
\]

where \( \lambda_{j1} \ldots \lambda_{jn} \) are upper \( n \) eigenvalues of \( MA_j'M \) and \( \xi_l \) is a standard normal variate, and \( n = \min(N - k, N - j) \). These eigenvalues are obtained by a singular value decomposition of \( Q_1A_j' \) (Golub and Van Loan 1989; Savin and White 1978).

The marginal probability (or \( p \)-value) for \( d_j \) given \( c_0 \) is

\[
\text{Prob}(\frac{\sum_{l=1}^{n} \lambda_{jl}\xi_l^2}{\sum_{l=1}^{n} \xi_l^2} < c_0) = \text{Prob}(q_j < 0)
\]

where

\[
q_j = \sum_{l=1}^{n} (\lambda_{jl} - c_0)\xi_l^2
\]
When the null hypothesis $H_0 : \varphi_j = 0$ holds, the quadratic form $q_j$ has the characteristic function

$$\phi_j(t) = \prod_{i=1}^{n} (1 - 2(\lambda_{jl} - c_0)it)^{-1/2}$$

The distribution function is uniquely determined by this characteristic function:

$$F(x) = \frac{1}{2} + \frac{1}{2\pi} \int_{0}^{\infty} \frac{e^{itx} \phi_j(-t) - e^{-itx} \phi_j(t)}{it} dt$$

For example, to test $H_0 : \varphi_4 = 0$ given $\varphi_1 = \varphi_2 = \varphi_3 = 0$ against $H_1 : -\varphi_4 > 0$, the marginal probability ($p$-value) can be used:

$$F(0) = \frac{1}{2} + \frac{1}{2\pi} \int_{0}^{\infty} \frac{(\phi_4(-t) - \phi_4(t))}{it} dt$$

where

$$\phi_4(t) = \prod_{i=1}^{n} (1 - 2(\lambda_{4l} - \hat{d}_4)it)^{-1/2}$$

and $\hat{d}_4$ is the calculated value of the fourth-order Durbin-Watson statistic.

In the Durbin-Watson test, the marginal probability indicates positive autocorrelation ($-\varphi_j > 0$) if it is less than the level of significance ($\alpha$), while you can conclude that a negative autocorrelation ($-\varphi_j < 0$) exists if the marginal probability based on the computed Durbin-Watson statistic is greater than $1 - \alpha$. Wallis (1972) presented tables for bounds tests of fourth-order autocorrelation, and Vinod (1973) has given tables for a 5% significance level for orders two to four. Using the AUTOREG procedure, you can calculate the exact $p$-values for the general order of Durbin-Watson test statistics. Tests for the absence of autocorrelation of order $p$ can be performed sequentially; at the $j$th step, test $H_0 : \varphi_j = 0$ given $\varphi_1 = \ldots = \varphi_{j-1} = 0$ against $\varphi_j \neq 0$. However, the size of the sequential test is not known.

The Durbin-Watson statistic is computed from the OLS residuals, while that of the autoregressive error model uses residuals that are the difference between the predicted values and the actual values. When you use the Durbin-Watson test from the residuals of the autoregressive error model, you must be aware that this test is only an approximation. See “Autoregressive Error Model” on page 362 earlier in this chapter. If there are missing values, the Durbin-Watson statistic is computed using all the nonmissing values and ignoring the gaps caused by missing residuals. This does not affect the significance level of the resulting test, although the power of the test against certain alternatives may be adversely affected. Savin and White (1978) have examined the use of the Durbin-Watson statistic with missing values.

The Durbin-Watson probability calculations have been enhanced to compute the $p$-value of the generalized Durbin-Watson statistic for large sample sizes. Previously, the Durbin-Watson probabilities were only calculated for small sample sizes.

Consider the following linear regression model:

$$Y = X\beta + u$$

$$u_t + \varphi_j u_{t-j} = \epsilon_t, \quad t = 1, \ldots, N$$
where $X$ is an $N \times k$ data matrix, $\beta$ is a $k \times 1$ coefficient vector, $u$ is a $N \times 1$ disturbance vector, and $\epsilon_t$ is a sequence of independent normal error terms with mean 0 and variance $\sigma^2$.

The generalized Durbin-Watson statistic is written as

$$DW_j = \frac{\hat{u}'A_j' A_j \hat{u}}{\hat{u}'\hat{u}}$$

where $\hat{u}$ is a vector of OLS residuals and $A_j$ is a $(T - j) \times T$ matrix. The generalized Durbin-Watson statistic $DW_j$ can be rewritten as

$$DW_j = \frac{Y'MA_j' A_j MY}{Y'MY} = \frac{\eta'(Q_1'A_j' A_j Q_1)\eta}{\eta'\eta}$$

where $Q_1 = I_{T-k}$, $Q_1X = 0$, and $\eta = Q_1u$.

The marginal probability for the Durbin-Watson statistic is

$$\Pr(DW_j < c) = \Pr(h < 0)$$

where $h = \eta'(Q_1'A_j' A_j Q_1 - cI)\eta$.

The $p$-value or the marginal probability for the generalized Durbin-Watson statistic is computed by numerical inversion of the characteristic function $\phi(u)$ of the quadratic form $h = \eta'(Q_1'A_j' A_j Q_1 - cI)\eta$. The trapezoidal rule approximation to the marginal probability $\Pr(h < 0)$ is

$$\Pr(h < 0) = \frac{1}{2} - \frac{1}{2} \sum_{k=0}^{K} \frac{\text{Im} \left[ \phi((k + \frac{1}{2})\Delta) \right]}{\pi(k + \frac{1}{2})} + E_I(\Delta) + E_T(K)$$

where $\text{Im} [\phi(\cdot)]$ is the imaginary part of the characteristic function, $E_I(\Delta)$ and $E_T(K)$ are integration and truncation errors, respectively. Refer to Davies (1973) for numerical inversion of the characteristic function.

Ansley, Kohn, and Shively (1992) proposed a numerically efficient algorithm that requires $O(N)$ operations for evaluation of the characteristic function $\phi(u)$. The characteristic function is denoted as

$$\phi(u) = \left| I - 2iu(Q_1'A_j' A_j Q_1 - cI_{N-k}) \right|^{-1/2}$$

$$= |V|^{-1/2} |X'V^{-1}X|^{-1/2} |X'X|^{1/2}$$

where $V = (1 + 2iu)I - 2iuA_j' A_j$ and $i = \sqrt{-1}$. By applying the Cholesky decomposition to the complex matrix $V$, you can obtain the lower triangular matrix $G$ that satisfies $V = GG'$. Therefore, the characteristic function can be evaluated in $O(N)$ operations by using the following formula:

$$\phi(u) = |G|^{-1} |X'^*X'^*|^{-1/2} |X'X|^{1/2}$$

where $X^* = G^{-1}X$. Refer to Ansley, Kohn, and Shively (1992) for more information on evaluation of the characteristic function.
**Tests for Serial Correlation with Lagged Dependent Variables**

When regressors contain lagged dependent variables, the Durbin-Watson statistic \( d_1 \) for the first-order autocorrelation is biased toward 2 and has reduced power. Wallis (1972) shows that the bias in the Durbin-Watson statistic \( d_4 \) for the fourth-order autocorrelation is smaller than the bias in \( d_1 \) in the presence of a first-order lagged dependent variable. Durbin (1970) proposes two alternative statistics (Durbin \( h \) and \( t \)) that are asymptotically equivalent. The \( h \) statistic is written as

\[
h = \hat{\rho} \sqrt{N/(1 - N \hat{V})}
\]

where \( \hat{\rho} = \frac{\sum_{t=2}^{N} \hat{\varepsilon}_t \hat{\varepsilon}_{t-1}}{\sum_{t=1}^{N} \hat{\varepsilon}_t^2} \) and \( \hat{V} \) is the least squares variance estimate for the coefficient of the lagged dependent variable. Durbin’s \( t \) test consists of regressing the OLS residuals \( \hat{\varepsilon}_t \) on explanatory variables and \( \hat{\varepsilon}_{t-1} \) and testing the significance of the estimate for coefficient of \( \hat{\varepsilon}_{t-1} \).

Inder (1984) shows that the Durbin-Watson test for the absence of first-order autocorrelation is generally more powerful than the \( h \) test in finite samples. Refer to Inder (1986) and King and Wu (1991) for the Durbin-Watson test in the presence of lagged dependent variables.

**Godfrey LM test**

The GODFREY= option in the MODEL statement produces the Godfrey Lagrange multiplier test for serially correlated residuals for each equation (Godfrey 1978b, a). \( r \) is the maximum autoregressive order, and specifies that Godfrey’s tests be computed for lags 1 through \( r \). The default number of lags is four.

**Testing for Nonlinear Dependence: Ramsey’s Reset Test**

Ramsey’s reset test is a misspecification test associated with the functional form of models to check whether power transforms need to be added to a model. The original linear model, henceforth called the restricted model, is

\[
y_t = x_t \beta + u_t
\]

To test for misspecification in the functional form, the unrestricted model is

\[
y_t = x_t \beta + \sum_{j=2}^{p} \phi_j \hat{y}_t^j + u_t
\]

where \( \hat{y}_t \) is the predicted value from the linear model and \( p \) is the power of \( \hat{y}_t \) in the unrestricted model equation starting from 2. The number of higher-ordered terms to be chosen depends on the discretion of the analyst. The RESET option produces test results for \( p = 2, 3, \) and 4.

The reset test is an \( F \) statistic for testing \( H_0 : \phi_j = 0, \) for all \( j = 2, \ldots, p, \) against \( H_1 : \phi_j \neq 0 \) for at least one \( j = 2, \ldots, p \) in the unrestricted model and is computed as follows:

\[
F_{(p-1,n-k-p+1)} = \frac{(SSE_R - SSE_U)/(p - 1)}{SSE_U/(n - k - p + 1)}
\]

where \( SSE_R \) is the sum of squared errors due to the restricted model, \( SSE_U \) is the sum of squared errors due to the unrestricted model, \( n \) is the total number of observations, and \( k \) is the number of parameters in the original linear model.

Ramsey’s test can be viewed as a linearity test that checks whether any nonlinear transformation of the specified independent variables has been omitted, but it need not help in identifying a new relevant variable other than those already specified in the current model.
Testing for Nonlinear Dependence: Heteroscedasticity Tests

**Portmanteau Q Test**
For nonlinear time series models, the portmanteau test statistic based on squared residuals is used to test for independence of the series (McLeod and Li 1983):

\[
Q(q) = N(N + 2) \sum_{i=1}^{q} \frac{r(i; \hat{\sigma}^2_i)}{(N - i)}
\]

where

\[
r(i; \hat{\sigma}^2_i) = \sum_{t=i+1}^{N} \frac{(\hat{\sigma}^2_t - \hat{\sigma}^2_i)(\hat{\sigma}^2_{t-i} - \hat{\sigma}^2_i)}{\sum_{t=1}^{N} (\hat{\sigma}^2_t - \hat{\sigma}^2)^2}
\]

\[
\hat{\sigma}^2 = \frac{1}{N} \sum_{t=1}^{N} \hat{\sigma}^2_t
\]

This Q statistic is used to test the nonlinear effects (for example, GARCH effects) present in the residuals. The GARCH\((p, q)\) process can be considered as an ARMA\(\max(p, q), p\) process. See the section “Predicting the Conditional Variance” on page 404. Therefore, the Q statistic calculated from the squared residuals can be used to identify the order of the GARCH process.

**Engle’s Lagrange Multiplier Test for ARCH Disturbances**
Engle (1982) proposed a Lagrange multiplier test for ARCH disturbances. The test statistic is asymptotically equivalent to the test used by Breusch and Pagan (1979). Engle’s Lagrange multiplier test for the \(q\)th order ARCH process is written

\[
LM(q) = NW'Z(Z'Z)^{-1}Z'W
\]

where

\[
W = \left( \frac{\hat{\sigma}^2_1}{\hat{\sigma}^2} - 1, \ldots, \frac{\hat{\sigma}^2_N}{\hat{\sigma}^2} - 1 \right)'
\]

and

\[
Z = \begin{bmatrix}
1 & \hat{\sigma}^2_0 & \cdots & \hat{\sigma}^2_{q+1} \\
\vdots & \vdots & \ddots & \vdots \\
\vdots & \vdots & \ddots & \vdots \\
1 & \hat{\sigma}^2_{N-1} & \cdots & \hat{\sigma}^2_{N-q}
\end{bmatrix}
\]

The presample values \((\hat{\sigma}^2_0, \ldots, \hat{\sigma}^2_{q+1})\) have been set to 0. Note that the \(LM(q)\) tests might have different finite-sample properties depending on the presample values, though they are asymptotically equivalent regardless of the presample values.
**Lee and King’s Test for ARCH Disturbances**

Engle’s Lagrange multiplier test for ARCH disturbances is a two-sided test; that is, it ignores the inequality constraints for the coefficients in ARCH models. Lee and King (1993) propose a one-sided test and prove that the test is locally most mean powerful. Let $\epsilon_t$, $t = 1, ..., T$, denote the residuals to be tested. Lee and King’s test checks

$H_0 : \alpha_i = 0, i = 1, ..., q$

$H_1 : \alpha_i > 0, i = 1, ..., q$

where $\alpha_i, i = 1, ..., q$, are in the following ARCH(q) model:

$$\epsilon_t = \sqrt{h_t} \epsilon_t, \epsilon_t \sim i.i.d.(0, 1)$$

$$h_t = \alpha_0 + \sum_{i=1}^{q} \alpha_i \epsilon_{t-i}^2$$

The statistic is written as

$$S = \frac{\sum_{t=q+1}^{T} \left( \frac{\epsilon_t^2}{h_t} - 1 \right) \sum_{i=1}^{q} \epsilon_{t-i}^2}{\left[ 2 \sum_{t=q+1}^{T} \left( \sum_{i=1}^{q} \epsilon_{t-i}^2 \right)^2 - 2 \left( \sum_{t=q+1}^{T} \sum_{i=1}^{q} \epsilon_{t-i}^2 \right)^2 \right]^{1/2}}$$

**Wong and Li’s Test for ARCH Disturbances**

Wong and Li (1995) propose a rank portmanteau statistic to minimize the effect of the existence of outliers in the test for ARCH disturbances. They first rank the squared residuals; that is, $R_t = rank(\epsilon_t^2)$. Then they calculate the rank portmanteau statistic

$$Q_R = \sum_{i=1}^{q} \frac{(r_i - \mu_i)^2}{\sigma_i^2}$$

where $r_i$, $\mu_i$, and $\sigma_i^2$ are defined as follows:

$$r_i = \frac{\sum_{t=i+1}^{T} (R_t - (T + 1)/2)(R_{t-i} - (T + 1)/2)}{T(T^2 - 1)/12}$$

$$\mu_i = -\frac{T - i}{T(T - 1)}$$

$$\sigma_i^2 = \frac{5T^4 - (5i + 9)T^3 + 9(i - 2)T^2 + 2i(5i + 8)T + 16i^2}{5(T - 1)^2T^2(T + 1)}$$

The Q, Engle’s LM, Lee and King’s, and Wong and Li’s statistics are computed from the OLS residuals, or residuals if the NLAG= option is specified, assuming that disturbances are white noise. The Q, Engle’s LM, and Wong and Li’s statistics have an approximate $\chi^2(q)$ distribution under the white-noise null hypothesis, while the Lee and King’s statistic has a standard normal distribution under the white-noise null hypothesis.
Testing for Structural Change

**Chow Test**
Consider the linear regression model
\[ y = X\beta + u \]
where the parameter vector \( \beta \) contains \( k \) elements.

Split the observations for this model into two subsets at the break point specified by the CHOW= option, so that
\[ y = (y', y'_2)' \]
\[ X = (X', X'_2)' \]
\[ u = (u', u'_2)' \]

Now consider the two linear regressions for the two subsets of the data modeled separately,
\[ y_1 = X_1\beta_1 + u_1 \]
\[ y_2 = X_2\beta_2 + u_2 \]
where the number of observations from the first set is \( n_1 \) and the number of observations from the second set is \( n_2 \).

The Chow test statistic is used to test the null hypothesis \( H_0 : \beta_1 = \beta_2 \) conditional on the same error variance \( V(u_1) = V(u_2) \). The Chow test is computed using three sums of square errors:
\[ F_{chow} = \frac{(\hat{u}'\hat{u} - \hat{u}_1'\hat{u}_1 - \hat{u}_2'\hat{u}_2)/k}{(\hat{u}_1'\hat{u}_1 + \hat{u}_2'\hat{u}_2)/(n_1 + n_2 - 2k)} \]
where \( \hat{u} \) is the regression residual vector from the full set model, \( \hat{u}_1 \) is the regression residual vector from the first set model, and \( \hat{u}_2 \) is the regression residual vector from the second set model. Under the null hypothesis, the Chow test statistic has an \( F \) distribution with \( k \) and \( (n_1 + n_2 - 2k) \) degrees of freedom, where \( k \) is the number of elements in \( \beta \).

Chow (1960) suggested another test statistic that tests the hypothesis that the mean of prediction errors is 0. The predictive Chow test can also be used when \( n_2 < k \).

The PCHOW= option computes the predictive Chow test statistic
\[ F_{pchow} = \frac{(\hat{u}'\hat{u} - \hat{u}_1'\hat{u}_1)/n_2}{\hat{u}_1'\hat{u}_1/(n_1 - k)} \]
The predictive Chow test has an \( F \) distribution with \( n_2 \) and \( (n_1 - k) \) degrees of freedom.

**Bai and Perron's Multiple Structural Change Tests**
Bai and Perron (1998) propose several kinds of multiple structural change tests: (1) the test of no break versus a fixed number of breaks (supF test), (2) the equal and unequal weighted versions of double maximum tests of no break versus an unknown number of breaks given some upper bound (UDmaxF test and WDmaxF test), and (3) the test of \( l \) versus \( l + 1 \) breaks (supF\(_{l+1}I\)_l test). Bai and Perron (2003a, b, 2006) also show how to implement these tests, the commonly used critical values, and the simulation analysis on these tests.
Consider the following partial structural change model with \( m \) breaks \((m + 1 \text{ regimes})\):

\[
y_t = x_t' \beta + z_t' \delta_j + u_t, \quad t = T_{j-1} + 1, ..., T_j, \ j = 1, ..., m
\]

Here, \( y_t \) is the dependent variable observed at time \( t \), \( x_t \) \((p \times 1)\) is a vector of covariates with coefficients \( \beta \) unchanged over time, and \( z_t \) \((q \times 1)\) is a vector of covariates with coefficients \( \delta_j \) at regime \( j \), \( j = 1, ..., m \). If \( p = 0 \) (that is, there are no \( x \) regressors), the regression model becomes the pure structural change model.

The indices \((T_1, ..., T_m)\) (that is, the break dates or break points) are unknown, and the convenient notation \( T_0 = 0 \) and \( T_{m+1} = T \) applies. For any given \( m \)-partition \((T_1, ..., T_m)\), the associated least squares estimates of \( \beta \) and \( \delta_j \), \( j = 1, ..., m \), are obtained by minimizing the sum of squared residuals (SSR),

\[
S_T(T_1, ..., T_m) = \sum_{i=1}^{m+1} \sum_{t=T_{i-1}+1}^{T_i} (y_t - x_t' \beta - z_t' \delta_i)^2
\]

Let \( \hat{S}_T(T_1, ..., T_m) \) denote the minimized SSR for a given \((T_1, ..., T_m)\). The estimated break dates \((\hat{T}_1, ..., \hat{T}_m)\) are such that

\[
(\hat{T}_1, ..., \hat{T}_m) = \arg\min_{T_1, ..., T_m} \hat{S}_T(T_1, ..., T_m)
\]

where the minimization is taken over all partitions \((T_1, ..., T_m)\) such that \( T_i - T_{i-1} \geq T \epsilon \). Bai and Perron (2003a) propose an efficient algorithm, based on the principle of dynamic programming, to estimate the preceding model.

In the case that the data are nontrending, as stated in Bai and Perron (1998), the limiting distribution of the break dates is as follows:

\[
\frac{(\Delta'_i Q_i \Delta_i)^2}{(\Delta'_i \Omega_i \Delta_i)} (\hat{T}_i - T_i^0) \Rightarrow \arg\max_s V^{(i)}(s), \quad i = 1, ..., m
\]

where

\[
V^{(i)}(s) = \begin{cases} 
W_1^{(i)}(-s) - |s|/2 & \text{if } s \leq 0 \\
\sqrt{n}(\phi_{s,2}/\phi_{s,1}) W_2^{(i)}(s) - \eta_i |s|/2 & \text{if } s > 0
\end{cases}
\]

and

\[
\Delta T_i^0 = T_i^0 - T_{i-1}^0 \quad \Delta_i = \delta_{i+1}^0 - \delta_i^0
\]

\[
Q_i = \lim (\Delta T_i^0)^{-1} \sum_{t=T_{i-1}^0+1}^{T_i^0} E(z_t z_t')
\]

\[
\Omega_i = \lim (\Delta T_i^0)^{-1} \sum_{r=T_{i-1}^0+1}^{T_i^0} \sum_{t=T_{i-1}^0+1}^{T_i^0} E(z_r z_t' u_r u_t)
\]

\[
\eta_i = \Delta'_i Q_i + 1 \Delta_i / \Delta'_i Q_i \Delta_i
\]

\[
\phi_{i,1}^2 = \Delta'_i \Omega_i \Delta_i / \Delta'_i Q_i \Delta_i
\]

\[
\phi_{i,2}^2 = \Delta'_i \Omega_i + 1 \Delta_i / \Delta'_i Q_i + 1 \Delta_i
\]
Also, \( W_1(s) \) and \( W_2(s) \) are independent standard Weiner processes that are defined on \([0, \infty)\), starting at the origin when \( s = 0 \); these processes are also independent across \( i \). The cumulative distribution function of \( \arg \max \ V(i) \) is shown in Bai (1997). Hence, with the estimates of \( \Delta_i, Q_i, \) and \( \Omega_i \), the relevant critical values for confidence interval of break dates \( T_i \) can be calculated. The estimate of \( Q_i \) is either

\[
\hat{Q}_i = (\Delta \hat{T}_i)^{-1} \sum_{t=\hat{T}_{i-1}+1}^{\hat{T}_i} z_t z_t'
\]

if the regressors are assumed to have heterogeneous distributions across regimes (that is, the HQ option is specified), or

\[
\hat{Q}_i = \hat{Q} = (T)^{-1} \sum_{t=1}^{T} z_t z_t'
\]

if the regressors are assumed to have identical distributions across regimes (that is, the HQ option is not specified). The estimate of \( \Omega_i \) can also be constructed with data over regime \( i \) only or the whole sample, depending on whether the vectors \( z_t \) are heterogeneously distributed across regimes (that is, the HO option is specified). If the HAC option is specified, \( \hat{Q}_i \) is estimated through the heteroscedasticity- and autocorrelation-consistent (HAC) covariance matrix estimator applied to vectors \( z_t \).

The \( supF \) test of no structural break \( (m = 0) \) versus the alternative hypothesis that there are a fixed number, \( m = k \), of breaks is defined as follows:

\[
supF(k) = \frac{1}{T} \left( \frac{T - (k + 1)q - p}{kq} \right) (R\hat{\theta})' (R\hat{V}(\hat{\theta}) R')^{-1} (R\hat{\theta})
\]

where

\[
R_{(kq) \times (p + (k + 1)q)} = \begin{pmatrix}
0_{q \times p} & I_q & -I_q & 0 & 0 & \ldots & 0 \\
0_{q \times p} & 0 & I_q & -I_q & 0 & \ldots & 0 \\
\vdots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\
0_{q \times p} & 0 & \ldots & \ldots & \ldots & 0 & I_q & -I_q
\end{pmatrix}
\]

and \( I_q \) is the \( q \times q \) identity matrix; \( \hat{\theta} \) is the coefficient vector \( (\hat{\theta}_1' \ldots \hat{\theta}_{k+1}') \), which together with the break dates \( (\hat{T}_1 \ldots \hat{T}_k) \) minimizes the global sum of squared residuals; and \( \hat{V}(\hat{\theta}) \) is an estimate of the variance-covariance matrix of \( \hat{\theta} \), which could be estimated by using the HAC estimator or another way, depending on how the HAC, HR, and HE options are specified. The output \( supF \) test statistics are scaled by \( q \), the number of regressors, to be consistent with the limiting distribution; Bai and Perron (2003b, 2006) take the same action.

There are two versions of double maximum tests of no break against an unknown number of breaks given some upper bound \( M \): the \( UD\max F \) test:

\[
UD\max F(M) = \max_{1 \leq m \leq M} supF(m)
\]

and the \( WD\max F \) test:

\[
WD\max F(M, \alpha) = \max_{1 \leq m \leq M} \frac{c_{\alpha}(1)}{c_{\alpha}(m)} supF(m)
\]

where \( c_{\alpha}(m) \) is the critical value for \( \alpha \) at the \( m \)-th maximum.
where $\alpha$ is the significance level and $c_\alpha(m)$ is the critical value of $supF(m)$ test given the significance level $\alpha$. Four kinds of $WD_{max}F$ tests that correspond to $\alpha = 0.100, 0.050, 0.025,$ and $0.010$ are implemented.

The $supF(l + 1|l)$ test of $l$ versus $l + 1$ breaks is calculated in two ways that are asymptotically the same. In the first calculation, the method amounts to the application of $(l + 1)$ tests of the null hypothesis of no structural change versus the alternative hypothesis of a single change. The test is applied to each segment that contains the observations $\hat{T}_{i-1}$ to $\hat{T}_i$ ($i = 1, ..., l + 1$). The $supF(l + 1|l)$ test statistics are the maximum of these $(l + 1)$ $supF$ test statistics. In the second calculation, for the given $l$ breaks $(\hat{T}_1, ..., \hat{T}_l)$, the new break $\hat{T}^{(N)}$ is to minimize the global SSR:

$$\hat{T}^{(N)} = \arg\min_{T^{(N)}} SSR(\hat{T}_1, ..., \hat{T}_l; T^{(N)})$$

Then,

$$supF(l + 1|l) = (T - (l + 1)q - p) \frac{SSR(\hat{T}_1, ..., \hat{T}_l) - SSR(\hat{T}_1, ..., \hat{T}_l; \hat{T}^{(N)})}{SSR(\hat{T}_1, ..., \hat{T}_l)}$$

The $p$-value of each test is based on the simulation of the limiting distribution of that test.

### Predicted Values

The AUTOREG procedure can produce two kinds of predicted values for the response series and corresponding residuals and confidence limits. The residuals in both cases are computed as the actual value minus the predicted value. In addition, when GARCH models are estimated, the AUTOREG procedure can output predictions of the conditional error variance.

#### Predicting the Unconditional Mean

The first type of predicted value is obtained from only the structural part of the model, $x'_t \beta$. These are useful in predicting values of new response time series, which are assumed to be described by the same model as the current response time series. The predicted values, residuals, and upper and lower confidence limits for the structural predictions are requested by specifying the PREDICTEDM=, RESIDUALM=, UCLM=, or LCLM= option in the OUTPUT statement. The ALPHACL= option controls the confidence level for UCLM= and LCLM=.

The predicted values are computed as

$$\hat{y}_t = x'_t \beta$$

and the upper and lower confidence limits as

$$\hat{u}_t = \hat{y}_t + t_{\alpha/2} \nu$$

$$\hat{l}_t = \hat{y}_t - t_{\alpha/2} \nu$$

where $\nu^2$ is an estimate of the variance of $\hat{y}_t$ and $t_{\alpha/2}$ is the upper $\alpha/2$ percentage point of the $t$ distribution.

$$\text{Prob}(T > t_{\alpha/2}) = \alpha/2$$
where $T$ is an observation from a $t$ distribution with $q$ degrees of freedom. The value of $\alpha$ can be set with the ALPHACLIM= option. The degrees of freedom parameter, $q$, is taken to be the number of observations minus the number of free parameters in the final model. For the YW estimation method, the value of $v$ is calculated as

$$v = \sqrt{s^2 x'_t (X'V^{-1}X)^{-1} x_t}$$

where $s^2$ is the error sum of squares divided by $q$. For the ULS and ML methods, it is calculated as

$$v = \sqrt{s^2 x'_t W x_t}$$

where $W$ is the $k \times k$ submatrix of $(J'J)^{-1}$ that corresponds to the regression parameters. For details, see the section “Computational Methods” on page 364 earlier in this chapter.

**Predicting Future Series Realizations**

The other predicted values use both the structural part of the model and the predicted values of the error process. These conditional mean values are useful in predicting future values of the current response time series. The predicted values, residuals, and upper and lower confidence limits for future observations conditional on past values are requested by the PREDICTED=, RESIDUAL=, UCL=, or LCL= option in the OUTPUT statement. The ALPHACLIM= option controls the confidence level for UCL= and LCL=. These confidence limits are for the predicted value,

$$\hat{y}_t = x'_t b + v_{t|t-1}$$

where $x_t$ is the vector of independent variables if all independent variables at time $t$ are nonmissing, and $v_{t|t-1}$ is the minimum variance linear predictor of the error term, which is defined in the following recursive way given the autoregressive model, AR($m$) model, for $y_t$:

$$v_{s|t} = \begin{cases} -\sum_{i=1}^{m} \hat{\phi}_i v_{s-i|t} & s > t \text{ or observation } s \text{ is missing} \\ y_s - x'_s b & 0 < s \leq t \text{ and observation } s \text{ is nonmissing} \\ 0 & s \leq 0 \end{cases}$$

where $\hat{\phi}_i, i = 1, \ldots, m$, are the estimated AR parameters. Observation $s$ is considered to be missing if the dependent variable or at least one independent variable is missing. If some of the independent variables at time $t$ are missing, the predicted $\hat{y}_t$ is also missing. With the same definition of $v_{s|t}$, the prediction method can be easily extended to the multistep forecast of $\hat{y}_{t+d}, d > 0$:

$$\hat{y}_{t+d} = x'_{t+d} b + v_{t+d|t-1}$$

The prediction method is implemented through the Kalman filter.

If $\hat{y}_t$ is not missing, the upper and lower confidence limits are computed as

$$\tilde{u}_t = \hat{y}_t + t_{\alpha/2}v$$

$$\tilde{l}_t = \hat{y}_t - t_{\alpha/2}v$$

where $v$, in this case, is computed as

$$v = \sqrt{z'_t V_{\beta} z_t + s^2 r}$$
where $\mathbf{V}_{\beta}$ is the variance-covariance matrix of the estimation of regression parameter $\beta$; $z_t$ is defined as

$$z_t = x_t + \sum_{i=1}^{m} \hat{\psi}_i x_{t-i|t-1}$$

and $x_{s|t}$ is defined in a similar way as $v_{s|t}$:

$$x_{s|t} = \begin{cases} 
-\sum_{i=1}^{m} \hat{\psi}_i x_{s-i|t} & s > t \text{ or observation } s \text{ is missing} \\
 x_t & 0 < s \leq t \text{ and observation } s \text{ is nonmissing} \\
 0 & s \leq 0 
\end{cases}$$

The formula for computing the prediction variance $v$ is deducted based on Baillie (1979).

The value $s^2 r$ is the estimate of the conditional prediction error variance. At the start of the series, and after missing values, $r$ is usually greater than 1. For the computational details of $r$, see the section “Predicting the Conditional Variance” on page 404. The plot of residuals and confidence limits in Example 8.4 illustrates this behavior.

Except to adjust the degrees of freedom for the error sum of squares, the preceding formulas do not account for the fact that the autoregressive parameters are estimated. In particular, the confidence limits are likely to be somewhat too narrow. In large samples, this is probably not an important effect, but it might be appreciable in small samples. For some discussion of this problem for AR(1) models, see Harvey (1981).

At the beginning of the series (the first $m$ observations, where $m$ is the value of the NLAG= option) and after missing values, these residuals do not match the residuals obtained by using OLS on the transformed variables. This is because, in these cases, the predicted noise values must be based on less than a complete set of past noise values and, thus, have larger variance. The GLS transformation for these observations includes a scale factor in addition to a linear combination of past values. Put another way, the $L^{-1}$ matrix defined in the section “Computational Methods” on page 364 has the value 1 along the diagonal, except for the first $m$ observations and after missing values.

### Predicting the Conditional Variance

The GARCH process can be written as

$$e_t^2 = \omega + \sum_{i=1}^{n} (\alpha_i + \gamma_i) e_{t-i}^2 - \sum_{j=1}^{p} \gamma_j \eta_{t-j} + \eta_t$$

where $\eta_t = \epsilon_t^2 - h_t$ and $n = \max(p, q)$. This representation shows that the squared residual $e_t^2$ follows an ARMA$(n, p)$ process. Then for any $d > 0$, the conditional expectations are as follows:

$$\text{E}(e_{t+d}^2 | \Psi_t) = \omega + \sum_{i=1}^{n} (\alpha_i + \gamma_i) \text{E}(e_{t+d-i}^2 | \Psi_t) - \sum_{j=1}^{p} \gamma_j \text{E}(\eta_{t+d-j} | \Psi_t)$$

The $d$-step-ahead prediction error, $\hat{\xi}_{t+d} = y_{t+d} - \hat{y}_{t+d|t}$, has the conditional variance

$$\text{V}(\hat{\xi}_{t+d} | \Psi_t) = \sum_{j=0}^{d-1} g_j^2 \sigma_{t+d-j|t}^2$$
where
\[ \sigma^2_{t+d-j|t} = E(\epsilon^2_{t+d-j}|\Psi_t) \]

Coefficients in the conditional \(d\)-step prediction error variance are calculated recursively using the formula
\[ g_j = -\varphi_1 g_{j-1} - \ldots - \varphi_m g_{j-m} \]

where \( g_0 = 1 \) and \( g_j = 0 \) if \( j < 0 \); \( \varphi_1, \ldots, \varphi_m \) are autoregressive parameters. Since the parameters are not known, the conditional variance is computed using the estimated autoregressive parameters. The \(d\)-step-ahead prediction error variance is simplified when there are no autoregressive terms:
\[ V(\xi_{t+d}|\Psi_t) = \sigma^2_{t+d|t} \]

Therefore, the one-step-ahead prediction error variance is equivalent to the conditional error variance defined in the GARCH process:
\[ h_t = E(\epsilon^2_t|\Psi_{t-1}) = \sigma^2_{t|t-1} \]

The multistep forecast of conditional error variance of the EGARCH, QGARCH, TGARCH, PGARCH, and GARCH-M models cannot be calculated using the preceding formula for the GARCH model. The following formulas are recursively implemented to obtain the multistep forecast of conditional error variance of these models:

• for the EGARCH\((p, q)\) model:

\[ \ln(\sigma^2_{t+d|t}) = \omega + \sum_{i=d}^{q} \alpha_i g(z_{t+d-i}) + \sum_{j=1}^{d-1} \gamma_j \ln(\sigma^2_{t+d-j|t}) + \sum_{j=d}^{p} \gamma_j \ln(h_{t+d-j}) \]

where
\[ g(z_t) = \theta z_t + |z_t| - E|z_t| \]
\[ z_t = \epsilon_t / \sqrt{h_t} \]

• for the QGARCH\((p, q)\) model:

\[ \sigma^2_{t+d|t} = \omega + \sum_{i=1}^{d-1} \alpha_i (\sigma^2_{t+d-i|t} + \psi^2_i) + \sum_{i=d}^{q} \alpha_i (\epsilon_{t+d-i} - \psi_i)^2 \]

\[ + \sum_{j=1}^{d-1} \gamma_j \sigma^2_{t+d-j|t} + \sum_{j=d}^{p} \gamma_j h_{t+d-j} \]

• for the TGARCH\((p, q)\) model:

\[ \sigma^2_{t+d|t} = \omega + \sum_{i=1}^{d-1} (\alpha_i + \psi_i / 2) \sigma^2_{t+d-i|t} + \sum_{i=d}^{q} (\alpha_i + 1 \epsilon_{t+d-i} < \psi_i) \epsilon^2_{t+d-i} \]

\[ + \sum_{j=1}^{d-1} \gamma_j \sigma^2_{t+d-j|t} + \sum_{j=d}^{p} \gamma_j h_{t+d-j} \]
• for the PGARCH\((p, q)\) model:

\[
\left(\sigma^2_{t+d|t}\right)^{\lambda} = \omega + \sum_{i=1}^{d-1} \alpha_i ((1 + \psi_i)^{2\lambda} + (1 - \psi_i)^{2\lambda})(\sigma^2_{t+d-i|t})^{\lambda} / 2 \\
+ \sum_{i=d}^{q} \alpha_i (|\epsilon_{t+d-i}| - \psi_i \epsilon_{t+d-i})^{2\lambda} \\
+ \sum_{j=1}^{d-1} \gamma_j (\sigma^2_{t+d-j|t})^{\lambda} + \sum_{j=d}^{p} \gamma_j h^\lambda_{t+d-j}
\]

• for the GARCH-M model: ignoring the mean effect and directly using the formula of the corresponding GARCH model.

If the conditional error variance is homoscedastic, the conditional prediction error variance is identical to the unconditional prediction error variance

\[
V(\xi_{t+d}|\Psi_t) = V(\xi_{t+d}) = \sigma^2 \sum_{j=0}^{d-1} g_j^2
\]

since \(\sigma^2_{t+d-j|t} = \sigma^2\). You can compute \(s^2 r\) (which is the second term of the variance for the predicted value \(\tilde{y}_t\) explained in the section “Predicting Future Series Realizations” on page 403) by using the formula \(\sigma^2 \sum_{j=0}^{d-1} g_j^2\), and \(r\) is estimated from \(\sum_{j=0}^{d-1} g_j^2\) by using the estimated autoregressive parameters.

Consider the following conditional prediction error variance:

\[
V(\xi_{t+d}|\Psi_t) = \sigma^2 \sum_{j=0}^{d-1} g_j^2 + \sum_{j=0}^{d-1} g_j^2 (\sigma^2_{t+d-j|t} - \sigma^2)
\]

The second term in the preceding equation can be interpreted as the noise from using the homoscedastic conditional variance when the errors follow the GARCH process. However, it is expected that if the GARCH process is covariance stationary, the difference between the conditional prediction error variance and the unconditional prediction error variance disappears as the forecast horizon \(d\) increases.

## OUT= Data Set

The output SAS data set produced by the OUTPUT statement contains all the variables in the input data set and the new variables specified by the OUTPUT statement options. See the section “OUTPUT Statement” on page 357 earlier in this chapter for information on the output variables that can be created. The output data set contains one observation for each observation in the input data set.

## OUTEST= Data Set

The OUTEST= data set contains all the variables used in any MODEL statement. Each regressor variable contains the estimate for the corresponding regression parameter in the corresponding model. In addition, the OUTEST= data set contains the following variables:
the \( i \)th order autoregressive parameter estimate. There are \( m \) such variables \(_A_i\) through \(_A_m\), where \( m \) is the value of the NLAG= option.

\(_AH_i\) the \( i \)th order ARCH parameter estimate, if the GARCH= option is specified. There are \( q \) such variables \(_AH_1\) through \(_AH_q\), where \( q \) is the value of the Q= option. The variable \(_AH_0\) contains the estimate of \( \omega \).

\(_AHP_i\) the estimate of the \( \psi_i \) parameter in the PGARCH model, if a PGARCH model is specified. There are \( q \) such variables \(_AHP_1\) through \(_AHP_q\), where \( q \) is the value of the Q= option.

\(_AHQ_i\) the estimate of the \( \psi_i \) parameter in the QGARCH model, if a QGARCH model is specified. There are \( q \) such variables \(_AHQ_1\) through \(_AHQ_q\), where \( q \) is the value of the Q= option.

\(_AHT_i\) the estimate of the \( \psi_i \) parameter in the TGARCH model, if a TGARCH model is specified. There are \( q \) such variables \(_AHT_1\) through \(_AHT_q\), where \( q \) is the value of the Q= option.

\(_DELT A_\) the estimated mean parameter for the GARCH-M model if a GARCH-in-mean model is specified

\(_DEPV AR_\) the name of the dependent variable

\(_GH_i\) the \( i \)th order GARCH parameter estimate, if the GARCH= option is specified. There are \( p \) such variables \(_GH_1\) through \(_GH_p\), where \( p \) is the value of the P= option.

\(_HET_i\) the \( i \)th heteroscedasticity model parameter specified by the HETERO statement

INTERCEPT the intercept estimate. INTERCEPT contains a missing value for models for which the NOINT option is specified.

\(_METHOD_\) the estimation method that is specified in the METHOD= option

\(_MODEL_\) the label of the MODEL statement if one is given, or blank otherwise

\(_MSE_\) the value of the mean square error for the model

\(_NAME_\) the name of the row of covariance matrix for the parameter estimate, if the COVOUT option is specified

\(_LAMBDA_\) the estimate of the power parameter \( \lambda \) in the PGARCH model, if a PGARCH model is specified.

\(_LIKLHD_\) the log-likelihood value of the GARCH model

\(_SSE_\) the value of the error sum of squares

\(_START_\) the estimated start-up value for the conditional variance when GARCH= (STARTUP=ESTIMATE) option is specified

\(_STATUS_\) This variable indicates the optimization status. \(_STATUS_ = 0\) indicates that there were no errors during the optimization and the algorithm converged. \(_STATUS_ = 1\) indicates that the optimization could not improve the function value and means that the results should be interpreted with caution. \(_STATUS_ = 2\) indicates that the optimization failed due to the number of iterations exceeding either the maximum default or the specified number of iterations or the number of function calls allowed. \(_STATUS_ = 3\) indicates that an error occurred during the optimization process. For example, this error message is obtained when a function or its derivatives cannot be calculated at the initial values or
during the iteration process, when an optimization step is outside of the feasible region or when active constraints are linearly dependent.

_STDERR_ standard error of the parameter estimate, if the COVOUT option is specified.

_TDFI_ the estimate of the inverted degrees of freedom for Student’s $t$ distribution, if DIST=T is specified.

_THETA_ the estimate of the $\theta$ parameter in the EGARCH model, if an EGARCH model is specified.

_TYPE_ PARM for observations containing parameter estimates, or COV for observations containing covariance matrix elements.

The OUTEST= data set contains one observation for each MODEL statement giving the parameter estimates for that model. If the COVOUT option is specified, the OUTEST= data set includes additional observations for each MODEL statement giving the rows of the covariance of parameter estimates matrix. For covariance observations, the value of the _TYPE_ variable is COV, and the _NAME_ variable identifies the parameter associated with that row of the covariance matrix.

Printed Output

The AUTOREG procedure prints the following items:

1. the name of the dependent variable
2. the ordinary least squares estimates
3. Estimates of autocorrelations, which include the estimates of the autocovariances, the autocorrelations, and (if there is sufficient space) a graph of the autocorrelation at each LAG
4. if the PARTIAL option is specified, the partial autocorrelations
5. the preliminary MSE, which results from solving the Yule-Walker equations. This is an estimate of the final MSE.
6. the estimates of the autoregressive parameters (Coefficient), their standard errors (Standard Error), and the ratio of estimate to standard error (t Value)
7. the statistics of fit for the final model. These include the error sum of squares (SSE), the degrees of freedom for error (DFE), the mean square error (MSE), the mean absolute error (MAE), the mean absolute percentage error (MAPE), the root mean square error (Root MSE), the Schwarz information criterion (SBC), the Hannan-Quinn information criterion (HQC), the Akaike information criterion (AIC), the corrected Akaike information criterion (AICC), the Durbin-Watson statistic (Durbin-Watson), the regression $R^2$ (Regress R-square), and the total $R^2$ (Total R-square). For GARCH models, the following additional items are printed:
   - the value of the log-likelihood function (Log Likelihood)
   - the number of observations that are used in estimation (Observations)
   - the unconditional variance (Uncond Var)
   - the normality test statistic and its $p$-value (Normality Test and Pr > ChiSq)
8. the parameter estimates for the structural model (Estimate), a standard error estimate (Standard Error),
the ratio of estimate to standard error (t Value), and an approximation to the significance probability
for the parameter being 0 (Approx Pr > |t|)

9. If the NLAG= option is specified with METHOD=ULS or METHOD=ML, the regression parameter
estimates are printed again, assuming that the autoregressive parameter estimates are known. In this
case, the Standard Error and related statistics for the regression estimates will, in general, be different
from the case when they are estimated. Note that from a standpoint of estimation, Yule-Walker
and iterated Yule-Walker methods (NLAG= with METHOD=YW, ITYW) generate only one table,
assuming AR parameters are given.

10. If you specify the NORMAL option, the Bera-Jarque normality test statistics are printed. If you specify
the LAGDEP option, Durbin’s $h$ or Durbin’s $t$ is printed.

### ODS Table Names

PROC AUTOREG assigns a name to each table it creates. You can use these names to reference the table
when using the Output Delivery System (ODS) to select tables and create output data sets. These names are
listed in the Table 8.6.

ODS Graphics

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.
This section describes the use of ODS for creating graphics with the AUTOREG procedure.

To request these graphs, you must specify the ODS GRAPHICS statement. By default, only the residual, predicted versus actual, and autocorrelation of residuals plots are produced. If, in addition to the ODS GRAPHICS statement, you also specify the ALL option in either the PROC AUTOREG statement or MODEL statement, all plots are created. For HETERO, GARCH, and AR models studentized residuals are replaced by standardized residuals. For the autoregressive models, the conditional variance of the residuals is computed as described in the section “Predicting Future Series Realizations” on page 403. For the GARCH and HETERO models, residuals are assumed to have $h_t$ conditional variance invoked by the HT= option of the OUTPUT statement. For all these cases, the Cook’s $D$ plot is not produced.

**ODS Graph Names**

PROC AUTOREG assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 8.7.

Example 8.1: Analysis of Real Output Series

In this example, the annual real output series is analyzed over the period 1901 to 1983 (Balke and Gordon 1986, pp. 581–583). With the following DATA step, the original data are transformed using the natural logarithm, and the differenced series DY is created for further analysis. The log of real output is plotted in Output 8.1.1.

```sas
title 'Analysis of Real GNP';
data gnp;
  date = intnx( 'year', '01jan1901'd, _n_-1 );
  format date year4.;
  input x @@;
  y = log(x);
  dy = dif(y);
  t = _n_;
  label y = 'Real GNP'
     dy = 'First Difference of Y'
     t = 'Time Trend';
datalines;
137.87 139.13 146.10 144.21 155.04 172.97 175.61 161.22
... more lines ...

proc sgplot data=gnp noautolegend;
  scatter x=date y=y;
  xaxis grid values=('01jan1901'd '01jan1911'd '01jan1921'd '01jan1931'd '01jan1941'd '01jan1951'd '01jan1961'd '01jan1971'd '01jan1981'd '01jan1991'd);
run;
```
The (linear) trend-stationary process is estimated using the following form:

\[ y_t = \beta_0 + \beta_1 t + \nu_t \]

where

\[ \nu_t = \epsilon_t - \phi_1 \nu_{t-1} - \phi_2 \nu_{t-2} \]

\[ \epsilon_t \sim \text{IN}(0, \sigma^2) \]

The preceding trend-stationary model assumes that uncertainty over future horizons is bounded since the error term, \( \nu_t \), has a finite variance. The maximum likelihood AR estimates from the statements that follow are shown in Output 8.1.2:

```plaintext
proc autoreg data=gnp;
   model y = t / nlag=2 method=ml;
run;
```

|----------|-------|----------|--------|---------|------|-------|
| Intercept | 1     | 4.8206   | 0.0661 | 72.88   | <.0001 |
| t        | 1     | 0.0302   | 0.001346 | 22.45 | <.0001 | Time Trend |

Nelson and Plosser (1982) failed to reject the hypothesis that macroeconomic time series are nonstationary and have no tendency to return to a trend line. In this context, the simple random walk process can be used as an alternative process:

\[ y_t = \beta_0 + y_{t-1} + \nu_t \]

where \( \nu_t = \epsilon_t \) and \( y_0 = 0 \). In general, the difference-stationary process is written as

\[ \phi(L)(1 - L)y_t = \beta_0 \phi(1) + \theta(L)\epsilon_t \]

where \( L \) is the lag operator. You can observe that the class of a difference-stationary process should have at least one unit root in the AR polynomial \( \phi(L)(1 - L) \).

The Dickey-Fuller procedure is used to test the null hypothesis that the series has a unit root in the AR polynomial. Consider the following equation for the augmented Dickey-Fuller test:

\[ \Delta y_t = \beta_0 + \delta t + \beta_1 y_{t-1} + \sum_{i=1}^{m} \gamma_i \Delta y_{t-i} + \epsilon_t \]
where $\Delta = 1 - L$. The test statistic $\tau_r$ is the usual $t$ ratio for the parameter estimate $\hat{\beta}_1$, but the $\tau_r$ does not follow a $t$ distribution.

The following code performs the augmented Dickey-Fuller test with $m = 3$ and we are interested in the test results in the linear time trend case since the previous plot reveals there is a linear trend.

```plaintext
proc autoreg data = gnp;
   model y = / stationarity =(adf =3);
run;
```

The augmented Dickey-Fuller test indicates that the output series may have a difference-stationary process. The statistic Tau with linear time trend has a value of $-2.6190$ and its $p$-value is $0.2732$. The statistic Rho has a $p$-value of $0.0817$ which also indicates the null of unit root is accepted at the 5% level. (See Output 8.1.3.)

The AR(1) model for the differenced series $DY$ is estimated using the maximum likelihood method for the period 1902 to 1983. The difference-stationary process is written

$$\Delta y_t = \beta_0 + \nu_t$$

$$\nu_t = \epsilon_t - \varphi_1 \nu_{t-1}$$

The estimated value of $\varphi_1$ is $-0.297$ and that of $\beta_0$ is $0.0293$. All estimated values are statistically significant. The PROC step follows:

```plaintext
proc autoreg data=gnp;
   model dy = / nlag=1 method=ml;
run;
```

The printed output produced by the PROC step is shown in Output 8.1.4.

Example 8.2: Comparing Estimates and Models

In this example, the Grunfeld series are estimated using different estimation methods. Refer to Maddala (1977) for details of the Grunfeld investment data set. For comparison, the Yule-Walker method, ULS method, and maximum likelihood method estimates are shown. With the DWPROB option, the $p$-value of the Durbin-Watson statistic is printed. The Durbin-Watson test indicates the positive autocorrelation of the regression residuals. The DATA and PROC steps follow:

```
title 'Grunfeld''s Investment Models Fit with Autoregressive Errors';
data grunfeld;
   input year gei gef gec;
   label gei = 'Gross investment GE'
      gec = 'Lagged Capital Stock GE'
         gef = 'Lagged Value of GE shares';
datalines;
1935   33.1   1170.6   97.8

  ... more lines ...

proc autoreg data=grunfeld;
   model gei = gef gec / nlag=1 dwprob;
   model gei = gef gec / nlag=1 method=uls;
   model gei = gef gec / nlag=1 method=ml;
run;
```

The printed output produced by each of the MODEL statements is shown in Output 8.2.1 through Output 8.2.4.

Example 8.3: Lack-of-Fit Study

Many time series exhibit high positive autocorrelation, having the smooth appearance of a random walk. This behavior can be explained by the partial adjustment and adaptive expectation hypotheses.

Short-term forecasting applications often use autoregressive models because these models absorb the behavior of this kind of data. In the case of a first-order AR process where the autoregressive parameter is exactly 1 (a random walk), the best prediction of the future is the immediate past.

PROC AUTOREG can often greatly improve the fit of models, not only by adding additional parameters but also by capturing the random walk tendencies. Thus, PROC AUTOREG can be expected to provide good short-term forecast predictions.

However, good forecasts do not necessarily mean that your structural model contributes anything worthwhile to the fit. In the following example, random noise is fit to part of a sine wave. Notice that the structural model does not fit at all, but the autoregressive process does quite well and is very nearly a first difference (AR(1) = −.976). The DATA step, PROC AUTOREG step, and PROC SGPLOT step follow:

```sas
ods listing; /* Optional: turn on the ODS settings */
title1 'Lack of Fit Study';
title2 'Fitting White Noise Plus Autoregressive Errors to a Sine Wave';

data a;
  pi=3.14159;
  do time = 1 to 75;
    if time > 75 then y = .;
    else y = sin( pi * ( time / 50 ) );
    x = ranuni( 1234567 );
    output;
  end;
run;

proc autoreg data=a plots;
  model y = x / nlag=1;
  output out=b p=pred pm=xbeta;
run;

proc sgplot data=b;
  scatter y=y x=time / markerattrs=(color=black);
  series y=pred x=time / lineattrs=(color=blue);
  series y=xbeta x=time / lineattrs=(color=red);
run;
```

The printed output produced by PROC AUTOREG is shown in Output 8.3.1 and Output 8.3.2. Plots of observed and predicted values are shown in Output 8.3.3 and Output 8.3.4. Note: the plot Output 8.3.3 can be viewed in the Autoreg.Model.FitDiagnosticPlots category by selecting View►Results.

Example 8.4: Missing Values

In this example, a pure autoregressive error model with no regressors is used to generate 50 values of a time series. Approximately 15% of the values are randomly chosen and set to missing. The following statements generate the data:

```sas
title 'Simulated Time Series with Roots';
title2 ' (X-1.25)(X**4-1.25)';
title3 'With 15% Missing Values';
data ar;
  do i=1 to 550;
    e = rannor(12345);
    n = sum( e, .8*n1, .8*n4, -.64*n5 ); /* ar process */
    y = n;
    if ranuni(12345) > .85 then y = .; /* 15% missing */
    n5=n4; n4=n3; n3=n2; n2=n1; n1=n; /* set lags */
    if i>500 then output;
  end;
run;
```

The model is estimated using maximum likelihood, and the residuals are plotted with 99% confidence limits. The PARTIAL option prints the partial autocorrelations. The following statements fit the model:

```sas
proc autoreg data=ar partial;
  model y = / nlag=(1 4 5) method=ml;
  output out=a predicted=p residual=r ucl=u lcl=l alphacli=.01;
run;
```

The printed output produced by the AUTOREG procedure is shown in Output 8.4.1 and Output 8.4.2. Note: the plot Output 8.4.2 can be viewed in the Autoreg.Model.FitDiagnosticPlots category by selecting View►Results.

Autoregressive parameters assumed given

| Variable | DF | Estimate | Standard Error | t Value | Pr > |t| |
|----------|----|----------|----------------|---------|------|---|
| Intercept| 1  |-2.2370   | 0.5225         | -4.28   | 0.0001 |
The following statements plot the residuals and confidence limits:

```sas
data reshapel;
  set a;
  miss = .;
  if r=. then do;
    miss = p;
    p = .;
  end;
run;

title 'Predicted Values and Confidence Limits';

proc sgplot data=reshapel NOAUTOLEGEND;
  band x=i upper=u lower=l;
  scatter y=miss x=i/ MARKERATTRS =(symbol=x color=red);
  series y=p x=i/markers MARKERATTRS = (color=blue) lineattrs=(color=blue);
run;
```

The plot of the predicted values and the upper and lower confidence limits is shown in Output 8.4.3. Note that the confidence interval is wider at the beginning of the series (when there are no past noise values to use in the forecast equation) and after missing values where, again, there is an incomplete set of past residuals.
Example 8.5: Money Demand Model

This example estimates the log-log money demand equation by using the maximum likelihood method. The money demand model contains four explanatory variables. The lagged nominal money stock M1 is divided by the current price level GDF to calculate a new variable M1CP since the money stock is assumed to follow the partial adjustment process. The variable M1CP is then used to estimate the coefficient of adjustment. All variables are transformed using the natural logarithm with a DATA step. Refer to Balke and Gordon (1986) for a data description.

The first eight observations are printed using the PRINT procedure and are shown in Output 8.5.1. Note that the first observation of the variables M1CP and INFR are missing. Therefore, the money demand equation is estimated for the period 1968:2 to 1983:4 since PROC AUTOREG ignores the first missing observation. The DATA step that follows generates the transformed variables.
data money;
  date = intnx( 'qtr', '01jan1968'd, _n_-1 );
  format date yyqc6.;
  input ml gnp gdf ycb @@;
  m = log( 100 * ml / gdf );
  mlcp = log( 100 * lag(ml) / gdf );
  y = log( gnp );
  intr = log( ycb );
  infr = 100 * log( gdf / lag(gdf) );
  label m = 'Real Money Stock (M1)';
  mlcp = 'Lagged M1/Current GDF'
  y = 'Real GNP'
  intr = 'Yield on Corporate Bonds'
  infr = 'Rate of Prices Changes';

The money demand equation is first estimated using OLS. The DW=4 option produces generalized Durbin-Watson statistics up to the fourth order. Their exact marginal probabilities (p-values) are also calculated with the DWPROB option. The Durbin-Watson test indicates positive first-order autocorrelation at, say, the 10% confidence level. You can use the Durbin-Watson table, which is available only for 1% and 5% significance points. The relevant upper ($d_U$) and lower ($d_L$) bounds are $d_U = 1.731$ and $d_L = 1.471$, respectively, at 5% significance level. However, the bounds test is inconvenient, since sometimes you may get the statistic in the inconclusive region while the interval between the upper and lower bounds becomes smaller with the increasing sample size. The PROC step follows:

```sas
    title 'Partial Adjustment Money Demand Equation';
    title2 'Quarterly Data - 1968:2 to 1983:4';

    proc autoreg data=money outest=est covout;
      model m = mlcp y intr infr / dw=4 dwprob;
    run;
```

</tbody>
</table>
The autoregressive model is estimated using the maximum likelihood method. Though the Durbin-Watson test statistic is calculated after correcting the autocorrelation, it should be used with care since the test based on this statistic is not justified theoretically. The PROC step follows:

```plaintext
proc autoreg data=money;
  model m = m1cp y intr infr / nlag=1 method=ml maxit=50;
  output out=a p=p pm=pm r=r rm=rm ucl=ucl lcl=lcl
  uclm=uclm lclm=lclm;
run;

proc print data=a(obs=8);
  var p pm r rm ucl lcl uclm lclm;
run;
```

A difference is shown between the OLS estimates in Output 8.5.2 and the AR(1)-ML estimates in Output 8.5.3. The estimated autocorrelation coefficient is significantly negative (−0.88345). Note that the negative coefficient of AR(1) should be interpreted as a positive autocorrelation.

Two predicted values are produced: predicted values computed for the structural model and predicted values computed for the full model. The full model includes both the structural and error-process parts. The predicted values and residuals are stored in the output data set A, as are the upper and lower 95% confidence limits for the predicted values. Part of the data set A is shown in Output 8.5.4. The first observation is missing since the explanatory variables, M1CP and INFR, are missing for the corresponding observation.

Example 8.6: Estimation of ARCH(2) Process

Stock returns show a tendency for small changes to be followed by small changes while large changes are followed by large changes. The plot of daily price changes of IBM common stock (Box and Jenkins 1976, p. 527) is shown in Output 8.6.1. The time series look serially uncorrelated, but the plot makes us skeptical of their independence.

With the following DATA step, the stock (capital) returns are computed from the closing prices. To forecast the conditional variance, an additional 46 observations with missing values are generated.

```sas
title 'IBM Stock Returns (daily)';
title2 '29jun1959 - 30jun1960';
data ibm;
  infile datalines eof=last;
  input x @@;
r = dif( log( x ) );
time = _n_-1;
  output;
  return;
last:
  do i = 1 to 46;
    r = .;
    time + 1;
    output;
  end;
  return;
datalines;
445 448 450 447 451 453 454 454 459 440 446 443 443 440
... more lines ...
proc sgplot data=ibm;
  series y=r x=time/lineattrs=(color=blue);
    repline 0/ axis = y LINEATTRS = (pattern=ShortDash);
run;
```
Example 8.6: Estimation of ARCH(2) Process

Output 8.6.1 IBM Stock Returns: Daily

The simple ARCH(2) model is estimated using the AUTOREG procedure. The MODEL statement option GARCH=(Q=2) specifies the ARCH(2) model. The OUTPUT statement with the CEV= option produces the conditional variances \( V \). The conditional variance and its forecast are calculated using parameter estimates:

\[
    h_t = \omega + \alpha_1 \epsilon_{t-1}^2 + \alpha_2 \epsilon_{t-2}^2
\]

\[
    E(\epsilon_{t+d}^2 | \Psi_t) = \omega + \sum_{i=1}^{2} \hat{\alpha}_i E(\epsilon_{t+d-i}^2 | \Psi_t)
\]

where \( d > 1 \). This model can be estimated as follows:

``` Sas
proc autoreg data=ibm maxit=50;
    model r = / noint garch=(q=2);
    output out=a cev=v;
run;
```

The parameter estimates for \( \omega, \alpha_1, \) and \( \alpha_2 \) are 0.00011, 0.04136, and 0.06976, respectively. The normality test indicates that the conditional normal distribution may not fully explain the leptokurtosis in the stock returns (Bollerslev 1987).

The ARCH model estimates are shown in Output 8.6.2, and conditional variances are also shown in Output 8.6.3. The code that generates Output 8.6.3 is shown below.
data b; set a;
    length type $ 8.;
    if r ^= . then do;
        type = 'ESTIMATE'; output; end;
    else do;
        type = 'FORECAST'; output; end;
run;
proc sgplot data=b;
    series x=time y=v/group=type;
    refline 254/ axis = x LINEATTRS = (pattern=ShortDash);
run;

The following statements perform estimation of different kinds of GARCH-type models. First, ODS listing output that contains fit summary tables for each single model is captured by using an ODS OUTPUT statement with the appropriate ODS table name assigned to a new SAS data set. Along with these new data sets, another one that contains parameter estimates is created by using the OUTEST= option in AUTOREG statement.

/* Capturing ODS tables into SAS data sets */
ods output Autoreg.ar_1.FinalModel.FitSummary = fitsum_ar_1;
ods output Autoreg.arch_2.FinalModel.Results.FitSummary = fitsum_arch_2;
ods output Autoreg.garch_1_1.FinalModel.Results.FitSummary = fitsum_garch_1_1;
ods output Autoreg.st_garch_1_1.FinalModel.Results.FitSummary = fitsum_st_garch_1_1;
ods output Autoreg.ar_1_garch_1_1.FinalModel.Results.FitSummary = fitsum_ar_1_garch_1_1;
ods output Autoreg.igarch_1_1.FinalModel.Results.FitSummary = fitsum_igarch_1_1;
ods output Autoreg.garchm_1_1.FinalModel.Results.FitSummary = fitsum_garchm_1_1;
ods output Autoreg.egarch_1_1.FinalModel.Results.FitSummary = fitsum_egarch_1_1;
ods output Autoreg.qgarch_1_1.FinalModel.Results.FitSummary = fitsum_qgarch_1_1;
ods output Autoreg.tgarch_1_1.FinalModel.Results.FitSummary = fitsum_tgarch_1_1;
ods output Autoreg.pgarch_1_1.FinalModel.Results.FitSummary = fitsum_pgarch_1_1;

/* Estimating multiple GARCH-type models */
title "GARCH family";
proc autoreg data=ibm_long outest=garch_family;
  ar_1 : model r = / noint nlag=1 method=ml;
  arch_2 : model r = / noint garch=(q=2);
  garch_1_1 : model r = / noint garch=(p=1,q=1);
  st_garch_1_1 : model r = / noint garch=(p=1,q=1,type=stationary);
  ar_1_garch_1_1 : model r = / noint nlag=1 garch=(p=1,q=1);
  igarch_1_1 : model r = / noint garch=(p=1,q=1,type=integ,noint);
  egarch_1_1 : model r = / noint garch=(p=1,q=1,type=egarch);
  garchm_1_1 : model r = / noint garch=(p=1,q=1,mean=log);
  qgarch_1_1 : model r = / noint garch=(p=1,q=1,type=qgarch);
  tgarch_1_1 : model r = / noint garch=(p=1,q=1,type=tgarch);
  pgarch_1_1 : model r = / noint garch=(p=1,q=1,type=pgarch);
run;
The following statements print partial contents of the data set GARCH_FAMILY. The columns of interest are explicitly specified in the VAR statement.

```sas
/* Printing summary table of parameter estimates */
title "Parameter Estimates for Different Models";
proc print data=garch_family;
  var _MODEL_ _A_1 _AH_0 _AH_1 _AH_2 _GH_1 _AHQ_1 _AHT_1 _AHP_1 _THETA_ _LAMBDA_ _DELTA_;
run;
```

These statements produce the results shown in Output 8.7.2.

The table shown in Output 8.7.2 is convenient for reporting the estimation result of multiple models and their comparison.

The following statements merge multiple tables that contain fit statistics for each estimated model, leaving only columns of interest, and rename them.

```sas
/* Merging ODS output tables and extracting AIC and SBC measures */
data sbc_aic;
  set fitsum_arch_2 fitsum_garch_1_1 fitsum_st_garch_1_1
    fitsum_ar_1 fitsum_ar_1_garch_1_1 fitsum_igarch_1_1
    fitsum_egarch_1_1 fitsum_garchm_1_1;
```
Example 8.7: Estimation of GARCH-Type Models

Example 8.7: Estimation of GARCH-Type Models

```
fitsum_tgarch_1_1 fitsum_pgarch_1_1 fitsum_qgarch_1_1;
keep Model SBC AIC;
if Label1="SBC" then do; SBC=input(cValue1,BEST12.4); end;
if Label2="SBC" then do; SBC=input(cValue2,BEST12.4); end;
if Label1="AIC" then do; AIC=input(cValue1,BEST12.4); end;
if Label2="AIC" then do; AIC=input(cValue2,BEST12.4); end;
if not (SBC=.) then output;
run;
```

Next, sort the models by one of the criteria, for example, by AIC:

```c
/* Sorting data by AIC criterion */
proc sort data=sbc_aic;
  by AIC;
run;
```

Finally, print the sorted data set:

```c
title "Selection Criteria for Different Models";
proc print data=sbc_aic;
  format _NUMERIC_ BEST12.4;
run;
```

The result is given in Output 8.7.3.

```

According to the smaller-is-better rule for the information criteria, the PGARCH(1,1) model is the leader by AIC while the EGARCH(1,1) is the model of choice according to SBC.

Next, check whether the power GARCH model is misspecified, especially, if dependence exists in the standardized residuals that correspond to the assumed independently and identically distributed (iid) disturbance. The following statements reestimate the power GARCH model and use the BDS test to check the independence of the standardized residuals.
The partial results listing of the preceding statements is given in Output 8.7.4.

**Output 8.7.4** Diagnostic Checking of the PGARCH(1,1) Model

The results in Output 8.7.4 indicate that when embedded size is greater than 9, you fail to reject the null hypothesis of independence at 1% significance level, which is a good indicator that the PGARCH model is not misspecified.
Example 8.8: Illustration of ODS Graphics

This example illustrates the use of ODS GRAPHICS. This is a continuation of the section “Forecasting Autoregressive Error Models” on page 315.

These graphical displays are requested by specifying the ODS GRAPHICS statement. For information about the graphs available in the AUTOREG procedure, see the section “ODS Graphics” on page 411.

The following statements show how to generate ODS GRAPHICS plots with the AUTOREG procedure. In this case, all plots are requested using the ALL option in the PROC AUTOREG statement, in addition to the ODS GRAPHICS statement. The plots are displayed in Output 8.8.1 through Output 8.8.8. Note: these plots can be viewed in the Autoreg.Model.FitDiagnosticPlots category by selecting View | Results.

  Example 9.7: Cash Flows .............................................. 510
Overview: COMPUTAB Procedure

The COMPUTAB (computing and tabular reporting) procedure produces tabular reports generated using a programmable data table.

The COMPUTAB procedure is especially useful when you need both the power of a programmable spreadsheet and a report generation system, but you want to set up a program to run in a batch mode and generate routine reports.

With PROC COMPUTAB, you can select a subset of observations from the input data set, define the format of a table, operate on its row and column values, and create new columns and rows. Access to individual table values is available when needed.

The COMPUTAB procedure can tailor reports to almost any desired specification and provide consolidation reports over summarization variables. The generated report values can be stored in an output data set. PROC COMPUTAB is especially useful in creating tabular reports such as income statements, balance sheets, and other row and column reports.

Getting Started: COMPUTAB Procedure

The following example shows the different types of reports that can be generated by PROC COMPUTAB.

Suppose a company has monthly expense data on three of its divisions and wants to produce the year-to-date expense report shown in Figure 9.1. This section starts out with the default report produced by the COMPUTAB procedure and modifies it until the desired report is achieved.

**Figure 9.1 Year-to-Date Expense Report**

```
<table>
<thead>
<tr>
<th>Year to Date Expenses</th>
</tr>
</thead>
<tbody>
<tr>
<td>Division</td>
</tr>
<tr>
<td>----------</td>
</tr>
<tr>
<td></td>
</tr>
<tr>
<td>Travel Expenses within U.S.</td>
</tr>
<tr>
<td>Advertising</td>
</tr>
<tr>
<td>Permanent Staff Salaries</td>
</tr>
<tr>
<td>Benefits Including Insurance</td>
</tr>
<tr>
<td>Total</td>
</tr>
</tbody>
</table>
```

Producing a Simple Report

Without any specifications, the COMPUTAB procedure transposes and prints the input data set. The variables in the input data set become rows in the report, and the observations in the input data set become columns. The variable names are used as the row titles. The column headings default to COL1 through COLn. For
example, the following input data set contains the monthly expenses reported by different divisions of the company:

```plaintext
data report;
  length compdiv $ 1;
  input compdiv $ date:date7. salary travel insure advrtise;
  format date date7.;
  label travel = 'Travel Expenses within U.S.'
                 advrtise = 'Advertising'
                 salary = 'Permanent Staff Salaries'
                 insure = 'Benefits Including Insurance';
datalines;
A 31JAN1989 95000 10500 2000 6500
B 31JAN1989 668000 112000 5600 90000
C 31JAN1989 105000 6800 9000 18500
A 28FEB1989 91000 8200 1900 12000
B 28FEB1989 602000 99000 5500 86000
C 28FEB1989 96000 6000 8500 16000
;
```

You can get a listing of the data set by using the PRINT procedure, as follows:

```plaintext
title 'Listing of Monthly Divisional Expense Data';
proc print data=report;
run;
```

Figure 9.2  Listing of Data Set by PROC PRINT

<table>
<thead>
<tr>
<th>Obs</th>
<th>compdiv</th>
<th>date</th>
<th>salary</th>
<th>travel</th>
<th>insure</th>
<th>advrtise</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>A</td>
<td>31JAN89</td>
<td>95000</td>
<td>10500</td>
<td>2000</td>
<td>6500</td>
</tr>
<tr>
<td>2</td>
<td>B</td>
<td>31JAN89</td>
<td>668000</td>
<td>112000</td>
<td>5600</td>
<td>90000</td>
</tr>
<tr>
<td>3</td>
<td>C</td>
<td>31JAN89</td>
<td>105000</td>
<td>6800</td>
<td>9000</td>
<td>18500</td>
</tr>
<tr>
<td>4</td>
<td>A</td>
<td>28FEB89</td>
<td>91000</td>
<td>8200</td>
<td>1900</td>
<td>12000</td>
</tr>
<tr>
<td>5</td>
<td>B</td>
<td>28FEB89</td>
<td>602000</td>
<td>99000</td>
<td>5500</td>
<td>86000</td>
</tr>
<tr>
<td>6</td>
<td>C</td>
<td>28FEB89</td>
<td>96000</td>
<td>6000</td>
<td>8500</td>
<td>16000</td>
</tr>
</tbody>
</table>

To get a simple, transposed report of the same data set, use the following PROC COMPUTAB statement:

```plaintext
title 'Monthly Divisional Expense Report';
proc computab data=report;
run;
```
Using PROC COMPUTAB

The COMPUTAB procedure is best understood by examining the following features:

- definition of the report layout with ROWS and COLUMNS statements
- input block
- row blocks
- column blocks

PROC COMPUTAB builds a table according to the specifications in the ROWS and COLUMNS statements. Row names and column names define the rows and columns of the table. Options in the ROWS and COLUMNS statements control titles, spacing, and formatting.

The input block places input observations into the appropriate columns of the report. It consists of programming statements used to select observations to be included in the report, to determine the column into which the observation should be placed, and to calculate row and column values that are not in the input data set.

Row blocks and column blocks perform operations on the values of rows and columns of the report after the input block has executed. Row blocks are a block of programming statements labeled ROWxxxx: that create or modify row values; column blocks are a block of programming statements labeled COLxxxx: that create or modify column values. Row and column blocks can make multiple passes through the report for final calculations.

For most reports, these features are sufficient. More complicated applications might require knowledge of the program data vector and the COMPUTAB data table. These topics are discussed in the section “Details: COMPUTAB Procedure” on page 478.

Defining Report Layout

ROWS and COLUMNS statements define the rows and columns of the report. The order of row and column names in these statements determines the order of rows and columns in the report. Additional ROWS and COLUMNS statements can be used to specify row and column formatting options.
The following statements select and order the variables from the input data set and produce the report in Figure 9.4:

```sas
proc computab data=report;
   rows travel advrtise salary;
run;
```

**Figure 9.4  Report Produced Using a ROWS Statement**

<table>
<thead>
<tr>
<th>Monthly Divisional Expense Report</th>
</tr>
</thead>
<tbody>
<tr>
<td>COL1</td>
</tr>
<tr>
<td>---------</td>
</tr>
<tr>
<td>TRAVEL</td>
</tr>
<tr>
<td>ADVRTISE</td>
</tr>
<tr>
<td>SALARY</td>
</tr>
</tbody>
</table>

When a COLUMNS statement is not specified, each observation becomes a new column. If you use a COLUMNS statement, you must specify to which column each observation belongs by using program statements for column selection. When more than one observation is selected for the same column, values are summed.

The following statements produce Figure 9.5:

```sas
proc computab data=report;
   rows travel advrtise salary insure;
   columns a b c;
   *-----select column for company division, based on value of compdiv-----*;
   a = compdiv = 'A';
   b = compdiv = 'B';
   c = compdiv = 'C';
run;
```

**Figure 9.5  Report Produced Using ROWS and COLUMNS Statements**

<table>
<thead>
<tr>
<th>Monthly Divisional Expense Report</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
</tr>
<tr>
<td>---------</td>
</tr>
<tr>
<td>TRAVEL</td>
</tr>
<tr>
<td>ADVRTISE</td>
</tr>
<tr>
<td>SALARY</td>
</tr>
<tr>
<td>INSURE</td>
</tr>
</tbody>
</table>

The statement A=COMPDIV='A'; illustrates the use of logical operators as a selection technique. If COMPDIV='A', then the current observation is added to the A column. See *SAS Language: Reference, Version 6, First Edition* for more information about logical operators.
Adding Computed Rows and Columns

In addition to the variables and observations in the input data set, you can create additional rows or columns by using SAS programming statements in PROC COMPUTAB. You can do the following:

- modify input data and select columns in the input block
- create or modify columns in column blocks
- create or modify rows in row blocks

The following statements add one computed row (SUM) and one computed column (TOTAL) to the report in Figure 9.5. In the input block the logical operators indicate the observations that correspond to each column of the report. After the input block reads in the values from the input data set, the column block creates the column variable TOTAL by summing the columns A, B, and C. The additional row variable, SUM, is calculated as the sum of the other rows. The result is shown in Figure 9.6.

```
proc computab data= report;
  rows travel advertise salary insure sum;
  columns a b c total;
  a = compdiv = 'A';
  b = compdiv = 'B';
  c = compdiv = 'C';
  colblk: total = a + b + c;
  rowblk: sum = travel + advertise + salary + insure;
run;
```

**Figure 9.6** Report Produced Using Row and Column Blocks

<table>
<thead>
<tr>
<th>Monthly Divisional Expense Report</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>A</strong></td>
</tr>
<tr>
<td>---------</td>
</tr>
<tr>
<td>TRAVEL</td>
</tr>
<tr>
<td>ADVRTISE</td>
</tr>
<tr>
<td>SALARY</td>
</tr>
<tr>
<td>INSURE</td>
</tr>
<tr>
<td>SUM</td>
</tr>
</tbody>
</table>

Enhancing the Report

To enhance the appearance of the final report, you can use the following:

- TITLE and LABEL statements
- column headings
The following example enhances the report in the previous example. The enhanced report is shown in Figure 9.7.

The TITLE statement assigns the report title. The column headings in Figure 9.7 (Division A, Division B, and Division C) are assigned in the first COLUMNS statement by “Division” _name_ specification. The second COLUMNS statement assigns the column heading (“All” “Divisions”), sets the spacing (+4), and formats the values in the TOTAL column.

Similarly, the first ROWS statement uses previously assigned variable labels for row labels by specifying the _LABEL_ option. The DUL option in the second ROWS statement double-underlines the INSURE row. The third ROWS statement assigns the row label TOTAL to the SUM row.

```plaintext
title 'Year to Date Expenses';
proc computab cwidth=8 cdec=0;
  columns a b c / 'Division' _name_;
  columns total / 'All' 'Divisions' +4 f=dollar10.0;
  rows travel advrtise salary insure / _label_;
  rows insure / dul;
  rows sum / 'Total';
  a = compdiv = 'A';
  b = compdiv = 'B';
  c = compdiv = 'C';
  colblk: total = a + b + c;
  rowblk: sum = travel + advrtise + salary + insure;
run;
```

**Figure 9.7** Report Produced by PROC COMPUTAB Using Enhancements

<table>
<thead>

<td>265800</td>
<td>$2,161,000</td>
</tr>
</tbody>
</table>
Syntax: COMPUTAB Procedure

The following statements are used with the COMPUTAB procedure:

```plaintext
PROC COMPUTAB options ;
   BY variables ;
   COLUMNS names / options ;
   ROWS names / options ;
   CELL names / FORMAT= format ;
   INIT anchor-name locator-name values locator-name values ;
   programming statements ;
   SUMBY variables ;
```

The PROC COMPUTAB statement is the only required statement. The COLUMNS, ROWS, and CELL statements define the COMPUTAB table. The INIT statement initializes the COMPUTAB table values. Programming statements process COMPUTAB table values. The BY and SUMBY statements provide BY-group processing and consolidation (roll up) tables.

Functional Summary

Table 9.1 summarizes the COMPUTAB procedure statements and options.

<table>
<thead>
<tr>
<th>Description</th>
<th>Statement</th>
<th>Option</th>
</tr>
</thead>
<tbody>
<tr>

</tbody>
</table>

**Report Formatting Options**

- specify number of decimal places to print: COMPUTAB CDEC=
- specify number of spaces between columns: COMPUTAB CSPACE=
- specify column width for the report: COMPUTAB CWIDTH=
- overline the listed rows with double lines: ROWS DOL
- underline the listed rows with double lines: ROWS DUL
- specify a format for printing the cell values: CELL FORMAT=
- specify a format for printing column values: COLUMNS FORMAT=
- specify a format for printing the row values: ROWS FORMAT=
- left-align the column headings: COLUMNS LJC
- left-justify character rows in each column: ROWS LJC
- specify indentation from the margin: ROWS +n
- suppress printing of row titles on later pages: COMPUTAB NORTR
- overline the listed rows with a single line: ROWS OL
- start a new page before printing the listed rows: ROWS _PAGE_
- specify number of spaces before row titles: COMPUTAB RTS=
- print a blank row: ROWS SKIP
- underline the listed rows with a single line: ROWS UL
- specify text to print if column is 0 or missing: COLUMNS ZERO=
- specify text to print if row is 0 or missing: ROWS ZERO=

**Row and Column Type Options**

- specify that columns contain character data: COLUMNS CHAR
- specify that rows contain character data: ROWS CHAR

**Options for Column Headings**

- specify literal column headings: COLUMNS ‘column heading’
- use variable labels in column headings: COLUMNS _LABEL_
- specify a master title centered over columns: COLUMNS MTITLE=
- use column names in column headings: COLUMNS _NAME_

**Options for Row Titling**

- use labels in row titles: ROWS _LABEL_
- use row names in row titles: ROWS _NAME_
- specify literal row titles: ROWS ‘row title’
PROC COMPUTAB Statement

PROC COMPUTAB options;

The following options can be used in the PROC COMPUTAB statement.

Input Options

DATA=SAS-data-set
names the SAS data set that contains the input data. If this option is not specified, the last created data set is used. If you are not reading a data set, use DATA=_NULL_.

FUZZ=value
specifies the criterion to use when testing for 0. If a number is within the FUZZ= value of 0, the number is set to 0.

INITMISS
initializes the COMPUTAB data table to missing rather than to 0. The COMPUTAB data table is discussed further in the section “Details: COMPUTAB Procedure” on page 478.

NOTRANSPOSE
NOTRANS
prevents the transposition of the input data set in building the COMPUTAB report tables. The NOTRANS option causes input data set variables to appear among the columns of the report rather than among the rows.

Report Formatting Options

The formatting options specify default values. Many of the formatting options can be modified for specific columns in COLUMNS statements and for rows in ROWS statements.

CDEC=d
specifies the default number of decimal places for printing. The default is CDEC=2. See the FORMAT= option in the sections on COLUMN, ROWS, and CELL statements later in this chapter.

CSPACE=n
specifies the default number of spaces to insert between columns. The value of the CSPACE= option is used as the default value for the +n option in the COLUMNS statement. The default is CSPACE=2.

CWIDTH=w
specifies a default column width for the report. The default is CWIDTH=9. The width must be in the range of 1–32.

NORTR
suppresses the printing of row titles on each page. The NORTR (no row-title repeat) option is useful to suppress row titles when report pages are to be joined together in a larger report.
RTS=n specifies the default number of spaces to be inserted before row titles when row titles appear after the first printed column. The default row-title spacing is RTS=2.

Output Options

NOPRINT suppresses all printed output. Use the NOPRINT option with the OUT= option to produce an output data set but no printed reports.

OPTIONS lists PROC COMPUTAB option values. The option values appear on a separate page preceding the procedure’s normal output.

OUT=SAS-data-set names the SAS data set to contain the output data. See the section “Details: COMPUTAB Procedure” on page 478 for a description of the structure of the output data set.

SUMONLY suppresses printing of detailed reports. When the SUMONLY option is used, PROC COMPUTAB generates and prints only consolidation tables as specified in the SUMBY statement.

COLUMNs Statement

COLUMNs column-list / options ;

COLUMNs statements define the columns of the report. The COLUMNs statement can be abbreviated COLUMN, COLS, or COL.

The specified column names must be valid SAS names. Abbreviated lists, as described in SAS Language: Reference, can also be used.

You can use as many COLUMNs statements as you need. A COLUMNs statement can describe more than one column, and one column of the report can be described with several different COLUMNs statements. The order of the columns on the report is determined by the order of appearance of column names in COLUMNs statements. The first occurrence of the name determines where in the sequence of columns a particular column is located.

The following options can be used in the COLUMNs statement.

Option for Column Type

CHAR indicates that the columns contain character data.

Options for Column Headings

You can specify as many lines of column headings as needed. If no options are specified, the column names from the COLUMNs statement are used as column headings. Any or all of the following options can be used in a column heading:
"column heading"
specifies that the characters enclosed in quotes are to be used in the column heading for the variable or variables listed in the COLUMNS statement. Each quoted string appears on a separate line of the heading.

_LABEL_
uses labels, if provided, in the heading for the column or columns listed in the COLUMNS statement. If a label has not been provided, the name of the column is used. See SAS Language: Reference for information about the LABEL statement.

_MTITLE= "text"
specifies that the string of characters enclosed in quotes is a master title to be centered over all the columns listed in the COLUMNS statement. The list of columns must be consecutive. Special characters ("+", "*", "="), and so forth) placed on either side of the text expand to fill the space. The _MTITLE= option can be abbreviated _M=.

_NAME_
uses column names in column headings for the columns listed in the COLUMNS statement. This option allows headings ("text") and names to be combined in a heading.

**Options for Column Print Control**

+_n_
inserts _n_ spaces before each column listed in the COLUMNS statement. The default spacing is given by the _CSPACE=_ option in the PROC COMPUTAB statement.

_NOPRINT_
suppresses printing of columns listed in the COLUMNS statement. This option enables you to create columns to be used for intermediate calculations without having those columns printed.

_NOZERO_
suppresses printing of columns when all the values in a column are 0 or missing. Numbers within the _FUZZ_= value of 0 are treated as 0.

_PAGE_
starts a new page of the report before printing each of the columns in the list that follows.

_TITLES_
prints row titles before each column in the list. The _TITLES_ option can be abbreviated as _TITLE_.

**Options for Column Formatting**

Column formats override row formats for particular table cells only when the input data set is not transposed (when the NOTRANS option is specified).

_FORMAT= format 
specifies a format for printing the values of the columns listed in the COLUMNS statement. The _FORMAT_= option can be abbreviated _F=.
LJC
left-justifies the column headings for the columns listed. By default, columns are right-justified. When the LJC (left-justify character) option is used, any character row values in the column are also left-justified rather than right-justified.

ZERO="text"
substitutes “text” when the value in the column is 0 or missing.

ROWS Statement

ROWS row-list / options ;
ROWS statements define the rows of the report. The ROWS statement can be abbreviated ROW.

The specified row names must be valid SAS names. Abbreviated lists, as described in SAS Language: Reference, can also be used.

You can use as many ROWS statements as you need. A ROWS statement can describe more than one row, and one row of the report can be described with several different ROWS statements. The order of the rows in the report is determined by the order of appearance of row names in ROWS statements. The first occurrence of the name determines where the row is located.

The following options can be used in the ROWS statement.

Option for Row Type

  CHAR
indicates that the rows contain character data.

Options for Row Titling

You can specify as many lines of row titles as needed. If no options are specified, the names from the ROWS statement are used as row titles. Any or all of the following options can be used in a row title:

  _LABEL_
uses labels as row titles for the row or rows listed in the ROWS statement. If a label is not provided, the name of the row is substituted. See SAS Language: Reference for more information about the LABEL statement.

  _NAME_
uses row names in row titles for the row or rows listed in the ROWS statement.

"row title"
specifies that the string of characters enclosed in quotes is to be used in the row title for the row or rows listed in the ROWS statement. Each quoted string appears on a separate line of the heading.
Options for Row Print Control

+n
indents n spaces from the margin for the rows in the ROWS statement.

DOL
overlines the rows listed in the ROWS statement with double lines. Overlines are printed on the line before any row titles or data for the row.

DUL
underlines the rows listed in the ROWS statement with double lines. Underlines are printed on the line after the data for the row. A row can have both an underline and an overline option.

NOPRINT
suppresses printing of the rows listed in the ROWS statement. This option enables you to create rows to be used for intermediate calculations without having those rows printed.

NOZERO
suppresses the printing of a row when all the values are 0 or missing.

OL
overlines the rows listed in the ROWS statement with a single line. Overlines are printed on the line before any row titles or data for the row.

OVERPRINT
overprints titles, values, overlining, and underlining associated with rows listed in the ROWS statement. The OVERPRINT option can be abbreviated OVP. This option is valid only when the system option OVP is in effect. See SAS Language: Reference for more information about the OVP option.

_PAGE_
starts a new page of the report before printing these rows.

SKIP
prints a blank line after the data lines for these rows.

UL
underlines the rows listed in the ROWS statement with a single line. Underlines are printed on the line after the data for the row. A row can have both an underline and an overline option.

Options for Row Formatting

Row formatting options take precedence over column-formatting options when the input data set is transposed. Row print width can never be wider than column width. Character values are truncated on the right.

FORMAT= format
specifies a format for printing the values of the rows listed in the ROWS statement. The FORMAT= option can be abbreviated as F=.

LJC
left-justifies character rows in each column.
ZERO="text"
substitutes text when the value in the row is 0 or missing.

---

**CELL Statement**

```sql
CELL cell_names / FORMAT= format ;
```

The CELL statement specifies the format for printing a particular cell in the COMPUTAB data table. Cell variable names are compound SAS names of the form `name1.name2`, where `name1` is the name of a row variable and `name2` is the name of a column variable. Formats specified with the FORMAT= option in CELL statements override formats specified in ROWS and COLUMNS statements.

---

**INIT Statement**

```sql
INIT anchor-name [locator-name] values [locator-name values] ;
```

The INIT statement initializes values in the COMPUTAB data table at the beginning of each execution of the procedure and at the beginning of each BY group if a BY statement is present.

The INIT statement in the COMPUTAB procedure is similar in function to the RETAIN statement in the DATA step, which initializes values in the program data vector. The INIT statement can be used at any point after the variable to which it refers has been defined in COLUMNS or ROWS statements. Each INIT statement initializes one row or column. Any number of INIT statements can be used.

The first term after the keyword INIT, `anchor-name`, anchors initialization to a row or column. If `anchor-name` is a row name, then all `locator-name` values in the statement are columns of that row. If `anchor-name` is a column name, then all `locator-name` values in the statement are rows of that column.

The following terms appear in the INIT statement:

- `anchor-name` names the row or column in which values are to be initialized. This term is required.
- `locator-name` identifies the starting column in the row (or starting row in the column) into which values are to be placed. For example, in a table with a row SALES and a column for each month of the year, the following statement initializes values for columns JAN, FEB, and JUN:

  ```sql
  init sales jan 500 feb 600 jun 800;
  ```

  If you do not specify `locator-name` values, the first value is placed into the first row or column, the second value into the second row or column, and so on. For example, the following statement assigns 500 to column JAN, 600 to FEB, and 450 to MAR:

  ```sql
  init sales 500 600 450;
  ```

- `+n` specifies the number of columns in a row (or rows in a column) that are to be skipped when initializing values. For example, the following statement assigns 500 to JAN and 900 to JUL:

  ```sql
  init sales jan 500 +5 900;
  ```
n*value assigns value to n columns in the row (or rows in the column). For example, both of the following statements assign 500 to columns JAN through JUN and 1000 to JUL through DEC:

```
init sales jan 6*500 jul 6*1000;
init sales 6*500 6*1000;
```

### Programming Statements

You can use most SAS programming statements the same way you use them in the DATA step. Also, all DATA step functions can be used in the COMPUTAB procedure.

Lines written by the PUT statement are not integrated with the COMPUTAB report. PUT statement output is written to the SAS log.

The automatic variable _N_ can be used; its value is the number of observations read or the number read in the current BY group, if a BY statement is used. FIRST:variable and LAST:variable references cannot be used.

The following statements are also available in PROC COMPUTAB:

- `ABORT`  
- `ARRAY`  
- `ATTRIB`  
- `assignment statement`  
- `CALL`  
- `DELETE`  
- `DO`  
- `iterative DO`  
- `DO UNTIL`  
- `DO WHILE`  
- `END`  
- `FOOTNOTE`  
- `FORMAT`

The programming statements can be assigned labels ROW:xxxxx: or COL:xxxxx: to indicate the start of a row and column block, respectively. Statements in a row block create or change values in all the columns in the specified rows. Similarly, statements in a column block create or change values in all the rows in the specified columns.

There is an implied RETURN statement before each new row or column block. Thus, the flow of execution does not leave the current row (column) block before the block repeats for all columns (rows.) Row and column variables and nonretained variables are initialized prior to each execution of the block.

The next COL:xxxxx: label, ROW:xxxxx: label, or the end of the PROC COMPUTAB step signals the end of a row (column) block. Column blocks and row blocks can be mixed in any order. In some cases, performing calculations in different orders can lead to different results.

See the sections “Program Flow Example” on page 478, “Order of Calculations” on page 481, and “Controlling Execution within Row and Column Blocks” on page 484 for more information.
BY Statement

BY variables;

A BY statement can be used with PROC COMPUTAB to obtain separate reports for observations in groups defined by the BY variables. At the beginning of each BY group, before PROC COMPUTAB reads any observations, all table values are set to 0 unless the INITMISS option or an INIT statement is specified.

SUMBY Statement

SUMBY variables;

The SUMBY statement produces consolidation tables for variables whose names are in the SUMBY list. Only one SUMBY statement can be used.

To use a SUMBY statement, you must use a BY statement. The SUMBY and BY variables must be in the same relative order in both statements. For example:

by a b c;
sumby a b;

This SUMBY statement produces tables that consolidate over values of C within levels of B and over values of B within levels of A. Suppose A has values 1, 2; B has values 1, 2; and C has values 1, 2, 3. Table 9.2 indicates the consolidation tables produced by the SUMBY statement.

\[
\begin{array}{|c|c|c|c|}
\hline
\text{SUMBY Consolations} & \text{Consolidated BY Groups} \\
\hline
A=1, B=1 & \text{C=1} & \text{C=2} & \text{C=3} \\
A=1, B=2 & \text{C=1} & \text{C=2} & \text{C=3} \\
A=1 & \text{B=1, C=1} & \text{B=1, C=2} & \text{B=1, C=3} \\
& \text{B=2, C=1} & \text{B=2, C=2} & \text{B=2, C=3} \\
A=2, B=1 & \text{C=1} & \text{C=2} & \text{C=3} \\
A=2, B=2 & \text{C=1} & \text{C=2} & \text{C=3} \\
A=2 & \text{B=1, C=1} & \text{B=1, C=2} & \text{B=1, C=3} \\
& \text{B=2, C=1} & \text{B=2, C=2} & \text{B=2, C=3} \\
\hline
\end{array}
\]

Two consolidation tables for B are produced for each value of A. The first table consolidates the three tables produced for the values of C while B is 1; the second table consolidates the three tables produced for C while B is 2.

Tables are similarly produced for values of A. Nested consolidation tables are produced for B (as described previously) for each value of A. Thus, this SUMBY statement produces a total of six consolidation tables in addition to the tables produced for each BY group.

To produce a table that consolidates the entire data set (the equivalent of using PROC COMPUTAB with neither BY nor SUMBY statements), use the special name _TOTAL_ as the first entry in the SUMBY variable list. For example,
Chapter 9: The COMPUTAB Procedure

PROC COMPUTAB then produces consolidation tables for SUMBY variables as well as a consolidation table for all observations.

To produce only consolidation tables, use the SUMONLY option in the PROC COMPUTAB statement.

---

**NOTRANS Option**

The NOTRANS option in the PROC COMPUTAB statement prevents the transposition of the input data set. NOTRANS affects the input block, the precedence of row and column options, and the structure of the output data set if the OUT= option is specified.

When the input data set is transposed, input variables are among the rows of the COMPUTAB report, and observations compose columns. The reverse is true if the data set is not transposed; therefore, the input block must select rows to receive data values, and input variables are among the columns.

Variables from the input data set dominate the format specification and data type. When the input data set is transposed, input variables are among the rows of the report, and row options take precedence over column options. When the input data set is not transposed, input variables are among the columns, and column options take precedence over row options.

Variables for the output data set are taken from the dimension (row or column) that contains variables from the input data set. When the input data set is transposed, this dimension is the row dimension; otherwise, the output variables come from the column dimension.

---

**Details: COMPUTAB Procedure**

**Program Flow Example**

This example shows how the COMPUTAB procedure processes observations in the program working storage and the COMPUTAB data table (CDT).

Assume you have three years of figures for sales and cost of goods sold (CGS), and you want to determine total sales and cost of goods sold and calculate gross profit and the profit margin.

```plaintext
   data example;
      input year sales cgs;
   datalines;
   1988   83   52
   1989   106  85
   1990   120  114
   ;
```

```plaintext
   sumby _total_ a b;
```

PROC COMPUTAB then produces consolidation tables for SUMBY variables as well as a consolidation table for all observations.

To produce only consolidation tables, use the SUMONLY option in the PROC COMPUTAB statement.
proc computab data=example;

    columns c88 c89 c90 total;
    rows sales cgs gprofit pctmarg;

    /* calculate gross profit */
    gprofit = sales - cgs;

    /* select a column */
    c88 = year = 1988;
    c89 = year = 1989;
    c90 = year = 1990;

    /* calculate row totals for sales */
    /* and cost of goods sold */
    col: total = c88 + c89 + c90;

    /* calculate profit margin */
    row: pctmarg = gprofit / cgs * 100;

run;

Table 9.3 shows the CDT before any observation is read in. All the columns and rows are defined with the values initialized to 0.

<table>
<thead>
<tr>
<th></th>
<th>C88</th>
<th>C89</th>
<th>C90</th>
<th>TOTAL</th>
</tr>
</thead>
<tbody>
<tr>
<td>SALES</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>CGS</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>GPROFIT</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>PCTMARG</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

When the first input is read in (year=1988, sales=83, and cgs=52), the input block puts the values for SALES and CGS in the C88 column since year=1988. Also the value for the gross profit for that year (GPROFIT) is calculated as indicated in the following statements:

    gprofit = sales-cgs;
    c88 = year = 1988;
    c89 = year = 1989;
    c90 = year = 1990;

Table 9.4 shows the CDT after the first observation is input.

<table>
<thead>
<tr>
<th></th>
<th>C88</th>
<th>C89</th>
<th>C90</th>
<th>TOTAL</th>
</tr>
</thead>
<tbody>
<tr>
<td>SALES</td>
<td>83</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>CGS</td>
<td>52</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>

<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>PCTMARG</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>
Similarly, the second observation (year=1989, sales=106, cgs=85) is put in the second column, and the GPROFIT is calculated to be 21. The third observation (year=1990, sales=120, cgs=114) is put in the third column, and the GPROFIT is calculated to be 6. Table 9.5 shows the CDT after all observations are input.

Table 9.5  CDT after All Observations Input

<table>
<thead>
<tr>

<td>PCTMARG</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

After the input block is executed for each observation in the input data set, the first row or column block is processed. In this case, the column block is

\[
\text{col: total} = \text{c88} + \text{c89} + \text{c90};
\]

The column block executes for each row, calculating the TOTAL column for each row. Table 9.6 shows the CDT after the column block has executed for the first row (total=83 + 106 + 120). The total sales for the three years is 309.

Table 9.6  CDT after Column Block Executed for First Row

<table>
<thead>
<tr>
<th></th>
<th>C88</th>
<th>C89</th>
<th>C90</th>
<th>TOTAL</th>
</tr>
</thead>
<tbody>

<td>6</td>
<td>58</td>
</tr>
<tr>
<td>PCTMARG</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

After the column block has been executed for all rows, the next block is processed. The row block is

\[
\text{row: pctmarg} = \text{gprofit} / \text{cgs} \times 100;
\]
The row block executes for each column, calculating the PCTMARG for each year and the total (TOTAL column) for three years. Table 9.8 shows the CDT after the row block has executed for all columns.

<table>
<thead>
<tr>

<td>23.11</td>
</tr>
</tbody>
</table>

Order of Calculations

The COMPUTAB procedure provides alternative programming methods for performing most calculations. New column and row values are formed by adding values from the input data set, directly or with modification, into existing columns or rows. New columns can be formed in the input block or in column blocks. New rows can be formed in the input block or in row blocks.

This example illustrates the different ways to collect totals. Table 9.9 is the total sales report for two products, SALES1 and SALES2, during the years 1988–1990. The values for SALES1 and SALES2 in columns C88, C89, and C90 come from the input data set.

<table>
<thead>
<tr>
<th></th>
<th>C88</th>
<th>C89</th>
<th>C90</th>
<th>SALESTOT</th>
</tr>
</thead>
<tbody>
<tr>
<td>SALES1</td>
<td>15</td>
<td>45</td>
<td>80</td>
<td>140</td>
</tr>
<tr>
<td>SALES2</td>
<td>30</td>
<td>40</td>
<td>50</td>
<td>120</td>
</tr>
<tr>
<td>YRTOT</td>
<td>45</td>
<td>85</td>
<td>130</td>
<td>260</td>
</tr>
</tbody>
</table>

The new column SALESTOT, which is the total sales for each product over three years, can be computed in several different ways:

- in the input block by selecting SALESTOT for each observation:
  
  salestot = 1;

- in a column block:
  
  coltot: salestot = c88 + c89 + c90;

In a similar fashion, the new row YRTOT, which is the total sales for each year, can be formed as follows:

- in the input block:
\[ yrtot = sales1 + sales2; \]

- in a row block:

\[ rowtot: yrtot = sales1 + sales2; \]

Performing some calculations in PROC COMPUTAB in different orders can yield different results, because many operations are not commutative. Be sure to perform calculations in the proper sequence. It might take several column and row blocks to produce the desired report values.

Notice that in the previous example, the grand total for all rows and columns is 260 and is the same whether it is calculated from row subtotals or column subtotals. It makes no difference in this case whether you compute the row block or the column block first.

However, consider the following example where a new column and a new row are formed:

<table>
<thead>
<tr>
<th>STORE1</th>
<th>STORE2</th>
<th>STORE3</th>
<th>MAX</th>
</tr>
</thead>
<tbody>
<tr>
<td>PRODUCT1</td>
<td>12</td>
<td>13</td>
<td>27</td>
</tr>
<tr>
<td>PRODUCT2</td>
<td>11</td>
<td>15</td>
<td>14</td>
</tr>
<tr>
<td>TOTAL</td>
<td>23</td>
<td>28</td>
<td>41</td>
</tr>
</tbody>
</table>

The new column MAX contains the maximum value in each row, and the new row TOTAL contains the column totals. MAX is calculated in a column block:

\[ col: \text{max} = \text{max}(store1, store2, store3); \]

TOTAL is calculated in a row block:

\[ row: \text{total} = \text{product1} + \text{product2}; \]
Notice that either of two values, 41 or 42, is possible for the element in column MAX and row TOTAL. If the row block is first, the value is the maximum of the column totals (41). If the column block is first, the value is the sum of the MAX values (42). Whether to compute a column block before a row block can be a critical decision.

Column Selection

The following discussion assumes that the NOTRANS option has not been specified. When NOTRANS is specified, this section applies to rows rather than columns.

If a COLUMNS statement appears in PROC COMPUTAB, a target column must be selected for the incoming observation. If there is no COLUMNS statement, a new column is added for each observation. When a COLUMNS statement is present and the selection criteria fail to designate a column, the current observation is ignored. Faulty column selection can result in columns or entire tables of 0s (or missing values if the INITMISS option is specified).

During execution of the input block, when an observation is read, its values are copied into row variables in the program data vector (PDV).

To select columns, use either the column variable names themselves or the special variable _COL_. Use the column names by setting a column variable equal to some nonzero value. The example in the section “Getting Started: COMPUTAB Procedure” on page 462 uses the logical expression COMPDIV= value, and the result is assigned to the corresponding column variable.

```plaintext
a = compdiv = 'A';
b = compdiv = 'B';
c = compdiv = 'C';
```

IF statements can also be used to select columns. The following statements are equivalent to the preceding example:

```plaintext
if compdiv = 'A' then a = 1;
else if compdiv = 'B' then b = 1;
else if compdiv = 'C' then c = 1;
```

At the end of the input block for each observation, PROC COMPUTAB multiplies numeric input values by any nonzero selector values and adds the result to selected columns. Character values simply overwrite the contents already in the table. If more than one column is selected, the values are added to each of the selected columns.

Use the _COL_ variable to select a column by assigning the column number to it. The COMPUTAB procedure automatically initializes column variables and sets the _COL_ variable to 0 at the start of each execution of the input block. At the end of the input block for each observation, PROC COMPUTAB examines the value of _COL_. If the value is nonzero and within range, the row variable values are added to the CDT cells of the _COL_th column, for example,
data rept;
   input div sales cgs;
datalines;
  2 106 85
  3 120 114
  1  83  52
;
   proc computab data=rept;
      row div sales cgs;
      columns div1 div2 div3;
      _col_ = div;
   run;

The code in this example places the first observation (DIV=2) in column 2 (DIV2), the second observation (DIV=3) in column 3 (DIV3), and the third observation (DIV=1) in column 1 (DIV1).

---

Controlling Execution within Row and Column Blocks

Row names, column names, and the special variables _ROW_ and _COL_ can be used to limit the execution of programming statements to selected rows or columns. A row block operates on all columns of the table for a specified row unless restricted in some way. Likewise, a column block operates on all rows for a specified column. Use column names or _COL_ in a row block to execute programming statements conditionally; use row names or _ROW_ in a column block.

For example, consider a simple column block that consists of only one statement:

```
col: total = qtr1 + qtr2 + qtr3 + qtr4;
```

This column block assigns a value to each row in the TOTAL column. As each row participates in the execution of a column block, the following changes occur:

- Its row variable in the program data vector is set to 1.
- The value of _ROW_ is the number of the participating row.
- The value from each column of the row is copied from the COMPUTAB data table to the program data vector.

To avoid calculating TOTAL on particular rows, use row names or _ROW_. For example,

```
col: if sales|cost then total = qtr1 + qtr2 + qtr3 + qtr4;
```

or

```
col: if _row_ < 3 then total = qtr1 + qtr2 + qtr3 + qtr4;
```

Row and column blocks can appear in any order, and rows and columns can be selected in each block.
Program Flow

This section describes in detail the different steps in PROC COMPUTAB execution.

Step 1: Define Report Organization and Set Up the COMPUTAB Data Table

Before the COMPUTAB procedure reads in data or executes programming statements, the columns list from the COLUMNS statements and the rows list from the ROWS statements are used to set up a matrix of all columns and rows in the report. This matrix is called the COMPUTAB data table (CDT). When you define columns and rows of the CDT, the COMPUTAB procedure also sets up corresponding variables in working storage called the program data vector (PDV) for programming statements. Data values reside in the CDT but are copied into the program data vector as they are needed for calculations.

Step 2: Select Input Data with Input Block Programming Statements

The input block copies input observations into rows or columns of the CDT. By default, observations go to columns; if the data set is not transposed (the NOTRANS option is specified), observations go to rows of the report table. The input block consists of all executable statements before any ROWxxxx: or COLxxxx: statement label. Use programming statements to perform calculations and select a given observation to be added into the report.

Input Block

The input block is executed once for each observation in the input data set. If there is no input data set, the input block is not executed. The program logic of the input block is as follows:

1. Determine which variables, row or column, are selector variables and which are data variables. Selector variables determine which rows or columns receive values at the end of the block. Data variables contain the values that the selected rows or columns receive. By default, column variables are selector variables and row variables are data variables. If the input data set is not transposed (the NOTRANS option is specified), the roles are reversed.

2. Initialize nonretained program variables (including selector variables) to 0 (or missing if the INITMISS option is specified). Selector variables are temporarily associated with a numeric data item supplied by the procedure. Using these variables to control row and column selection does not affect any other data values.

3. Transfer data from an observation in the data set to data variables in the PDV.

4. Execute the programming statements in the input block by using values from the PDV and storing results in the PDV.

5. Transfer data values from the PDV into the appropriate columns of the CDT. If a selector variable for a row or column has a nonmissing and nonzero value, multiply each PDV value for variables used in the report by the selector variable and add the results to the selected row or column of the CDT.
Step 3: Calculate Final Values by Using Column Blocks and Row Blocks

**Column Blocks**
A column block is executed once for each row of the CDT. The program logic of a column block is as follows:

1. Indicate the current row by setting the corresponding row variable in the PDV to 1 and the other row variables to missing. Assign the current row number to the special variable _ROW_.
2. Move values from the current row of the CDT to the respective column variables in the PDV.
3. Execute programming statements in the column block by using the column values in the PDV. Here new columns can be calculated and old ones adjusted.
4. Move the values back from the PDV to the current row of the CDT.

**Row Blocks**
A row block is executed once for each column of the CDT. The program logic of a row block is as follows:

1. Indicate the current column by setting the corresponding column variable in the PDV to 1 and the other column variables to missing. Assign the current column number to the special variable _COL_.
2. Move values from the current column of the CDT to the respective row variables in the PDV.
3. Execute programming statements in the row block by using the row values in the PDV. Here new rows can be calculated and old ones adjusted.
4. Move the values back from the PDV to the current column of the CDT.

See the section “Controlling Execution within Row and Column Blocks” on page 484.

Any number of column blocks and row blocks can be used. Each can include any number of programming statements.

The values of row variables and column variables are determined by the order in which different row-block and column-block programming statements are processed. These values can be modified throughout the COMPUTAB procedure, and final values are printed in the report.

---

**Direct Access to Table Cells**

You can insert or retrieve numeric values from specific table cells by using the special reserved name TABLE with row and column subscripts. References to the TABLE have the form

```
TABLE[ row-index, column-index ]
```

where row-index and column-index can be numbers, character literals, numeric variables, character variables, or expressions that produce a number or a name. If an index is numeric, it must be within range; if it is character, it must name a row or column.

References to TABLE elements can appear on either side of an equal sign in an assignment statement and can be used in a SAS expression.
Reserved Words

Certain words are reserved for special use by the COMPUTAB procedure, and using these words as variable names can lead to syntax errors or warnings. They are:

- COLUMN
- COLUMNS
- COL
- COLS
- _COL_
- ROW
- ROWS
- _ROW_
- INIT
- _N_
- TABLE

Missing Values

Missing values for variables in programming statements are treated in the same way that missing values are treated in the DATA step; that is, missing values used in expressions propagate missing values to the result. See *SAS Language: Reference* for more information about missing values.

Missing values in the input data are treated as follows in the COMPUTAB report table. At the end of the input block, either one or more rows or one or more columns can have been selected to receive values from the program data vector (PDV). Numeric data values from variables in the PDV are added into selected report table rows or columns. If a PDV value is missing, the values already in the selected rows or columns for that variable are unchanged by the current observation. Other values from the current observation are added to table values as usual.

OUT= Data Set

The output data set contains the following variables:

- BY variables
- a numeric variable _TYPE_
Chapter 9: The COMPUTAB Procedure

- a character variable _NAME_
- the column variables from the COMPUTAB data table

The BY variables contain values for the current BY group. For observations in the output data set from consolidation tables, the consolidated BY variables have missing values.

The special variable _TYPE_ is a numeric variable that can have one of three values: 1, 2, or 3. _TYPE_ = 1 indicates observations from the normal report table produced for each BY group; _TYPE_ = 2 indicates observations from the _TOTAL_ consolidation table; _TYPE_ = 3 indicates observations from other consolidation tables. _TYPE_ = 2 and _TYPE_ = 3 observations have one or more BY variables with missing values.

The special variable _NAME_ is a character variable of length 8 that contains the row or column name associated with the observation from the report table. If the input data set is transposed, _NAME_ contains column names; otherwise, _NAME_ contains row names.

If the input data set is transposed, the remaining variables in the output data set are row variables from the report table. They are column variables if the input data set is not transposed.

---

Examples: COMPUTAB Procedure

Example 9.1: Using Programming Statements

This example illustrates two ways of operating on the same input variables and producing the same tabular report. To simplify the example, no report enhancements are shown.

The manager of a hotel chain wants a report that shows the number of bookings at its hotels in each of four cities, the total number of bookings in the current quarter, and the percentage of the total coming from each location for each quarter of the year. Input observations contain the following variables: REPTDATE (report date), LA (number of bookings in Los Angeles), ATL (number of bookings in Atlanta), CH (number of bookings in Chicago), and NY (number of bookings in New York).

The following DATA step creates the SAS data set BOOKINGS:

```sas
data bookings;
  input reptdate date9. la atl ch ny;
datalines;
01JAN1989 100 110 120 130
01FEB1989 140 150 160 170
01MAR1989 180 190 200 210
01APR1989 220 230 240 250
01MAY1989 260 270 280 290
01JUN1989 300 310 320 330
01JUL1989 340 350 360 370
01AUG1989 380 390 400 410
01SEP1989 420 430 440 450
01OCT1989 460 470 480 490
01NOV1989 500 510 520 530
01DEC1989 540 550 560 570
```

---
Example 9.1: Using Programming Statements

The following PROC COMPUTAB statements select columns by setting _COL_ to an appropriate value. The PCT1, PCT2, PCT3, and PCT4 columns represent the percentage contributed by each city to the total for the quarter. These statements produce Output 9.1.1.

```
proc computab data=bookings cspace=1 cwidth=6;
  columns qtr1 pct1 qtr2 pct2 qtr3 pct3 qtr4 pct4;
  columns qtr1-qtr4 / format=6.;
  columns pct1-pct4 / format=6.2;
  rows la atl ch ny total;

  /* column selection */
  _col_ = qtr( reptdate ) * 2 - 1;

</table>
Using the same input data, the next set of statements shows the usefulness of arrays in allowing PROC COMPUTAB to work in two directions at once. Arrays in larger programs can both reduce the amount of program source code and simplify otherwise complex methods of referring to rows and columns. The same report as in Output 9.1.1 is produced.

```sas
proc computab data=bookings cspace=1 cwidth=6;
  columns qtr1 pct1 qtr2 pct2 qtr3 pct3 qtr4 pct4;
  columns qtr1-qtr4 / format=6.;
  columns pct1-pct4 / format=6.2;
  rows la atl ch ny total;
  array pct[4] pct1-pct4;
  array qt[4] qtr1-qtr4;
  array rowlist[5] la atl ch ny total;

  /* column selection */
  _col_ = qtr(reptdate) * 2 - 1;

  /* copy qtr column values temporarily into pct columns */
  colcopy:
    do i = 1 to 4;
      pct[i] = qt[i];
    end;

  /* calculate total row for all columns */
  rowcalc:
    total = la + atl + ch + ny;
    if mod(_col_,2) = 0 then
      do i = 1 to 5;
        rowlist[i] = rowlist[i] / total * 100;
      end;
    end;
run;
```

Example 9.2: Enhancing a Report

The following example shows how a report can be enhanced from a simple listing to a complex report. The simplest COMPUTAB report is a transposed listing of the data in the SAS data set INCOMREP shown in Output 9.2.1. To produce this output, nothing is specified except the PROC COMPUTAB statement and a TITLE statement.

```sas
data incomrep;
  length type $ 8;
  input type :$8. date :monyy7.
    sales retdis tcos selling randd
    general admin deprec other taxes;
  format date monyy7.;
datalines;
BUDGET JAN1989 4600 300 2200 480 110 500 210 14 -8 510
```
Example 9.2: Enhancing a Report

To complete the report, compute new rows from existing rows. This is done in a row block (although it can also be done in the input block). Add a new column (QTR1) that accumulates all the actual data. The NOZERO option suppresses the zero column for March. The output produced by these statements is shown in Output 9.2.3.

```plaintext
proc computab data=incomrep;
    /* add a new column to be selected */
    /* qtr1 column will be selected several times */
    columns actual1-actual3 qtr1 / nozero;

Example 9.3: Comparison of Actual and Budget

This example shows a more complex report that compares the actual data with the budgeted values. The same input data as in the previous example is used.

The report produced by these statements is shown in Output 9.3.1. The report shows the values for the current month and the year-to-date totals for budgeted amounts, actual amounts, and the actuals as a percentage of the budgeted amounts. The data have the values for January and February. Therefore, the CURMO variable (current month) in the RETAIN statement is set to 2. The values for the observations where the month of the year is 2 (February) are accumulated for the current month values. The year-to-date values are accumulated from those observations where the month of the year is less than or equal to 2 (January and February).

Example 9.4: Consolidations

This example consolidates product tables by region and region tables by corporate division. Output 9.4.1 shows the North Central and Northeast regional summaries for the Equipment division for the first quarter. Output 9.4.2 shows the profit summary for the Equipment division. Similar tables for the Publishing division are produced but not shown here.

```sas
data product;

Example 9.5: Creating an Output Data Set

This example uses data and reports similar to those in Example 9.3 to illustrate the creation of an output data set.

```plaintext
data product;
  input pcode div region month sold revenue recd cost;
datalines;
  1 1 1 1 56 5600 29 2465
  1 1 1 2 13 1300 30 2550
  1 1 1 3 17 1700 65 5525
  2 1 1 1 2 240 50 4900
  2 1 1 2 82 9840 17 1666
  1 1 1 1 37 3700 75 6375
  ... more lines ...

proc sort data=product out=sorted;
  by div region;
run;
```
Example 9.5: Creating an Output Data Set

/* create data set, profit */
proc computab data=sorted notrans out=profit noprint;
   by div region;
   sumby div;

   /* specify order of rows and row titles */
   row    jan feb mar qtr1;
   row    apr may jun qtr2;
   row    jul aug sep qtr3;
   row    oct nov dec qtr4;

   /* specify order of columns and column titles */
   columns sold revenue recd cost profit pctmarg;

   /* select row for appropriate month */
   _row_ = month + ceil( month / 3 ) - 1;

   /* calculate quarterly summary rows */
   rowlcalc:
      qtr1 = jan + feb + mar;
      qtr2 = apr + may + jun;
      qtr3 = jul + aug + sep;
      qtr4 = oct + nov + dec;

   /* calculate profit columns */
   colcalc:
      profit = revenue - cost;
      if cost > 0 then pctmarg = profit / cost * 100;
run;

   /* make a partial listing of the output data set */
   options linesize=96;
   proc print data=profit(obs=10) noobs;
   run;

Because the NOTRANS option is specified, column names become variables in the data set. REGION has missing values in the output data set for observations associated with consolidation tables. The output data set PROFIT, in conjunction with the option NOPRINT, illustrates how you can use the computational features of PROC COMPUTAB for creating additional rows and columns as in a spreadsheet without producing a report. Output 9.5.1 shows a partial listing of the output data set PROFIT.
Output 9.5.1 Partial Listing of the PROFIT Data Set

Example 9.6: A What-If Market Analysis

PROC COMPUTAB can be used with other SAS/ETS procedures and with macros to implement commonly needed decision support tools for financial and marketing analysis.

The following input data set reads quarterly sales figures:

```sas
data market;
  input date :yyq6. units @@;
datalines;
1980Q1 3608.9 1980Q2 5638.4 1980Q3 6017.9 1980Q4 4929.6
... more lines ...
```

The following statements illustrate how PROC FORECAST makes a total market forecast for the next four quarters:

```sas
/* forecast the total number of units to be */
/* sold in the next four quarters */
proc forecast out=outcome trend=2
  interval=qtr lead=4;
  id date;
  var units;
run;
```

The macros WHATIF and SHOW build a report table and provide the flexibility of examining alternate what-if situations. The row and column calculations of PROC COMPUTAB compute the income statement. With macros stored in a macro library, the only statements required with PROC COMPUTAB are macro invocations and TITLE statements.
Example 9.6: A What-If Market Analysis

/* set up rows and columns of report and initialize */
/* market share and program constants */
%macro whatif(mktshr=,price=,ucost=,taxrate=,numshar=,overhead=);

    columns mar / 'March';

Example 9.7: Cash Flows

The COMPUTAB procedure can be used to model cash flows from one time period to the next. The RETAIN statement is useful for enabling a row or column to contribute one of its values to its successor. Financial functions such as IRR (internal rate of return) and NPV (net present value) can be used on PROC COMPUTAB table values to provide a more comprehensive report. The following statements produce Output 9.7.1:

data cashflow;
  input date date9. netinc depr borrow invest tax div adv ;
datalines;

Overview: COPULA Procedure

A multivariate distribution for a random vector contains a description of both the marginal distributions and their dependence structure. A copula approach to formulating a multivariate distribution provides a way to isolate the description of the dependence structure from the marginal distributions. A copula is a function that combines marginal distributions of variables into a specific multivariate distribution. All of the one-dimensional marginals in the multivariate distribution are the cumulative distribution functions of the factors. Copulas help perform large-scale multivariate simulation from separate models, each of which can be fitted using different, even nonnormal, distributional specifications.

The COPULA procedure enables you to fit multivariate distributions or copulas from a given sample data set. You can do the following:

- estimate the parameters for a specified copula type
- simulate a given copula
- plot dependent relationships among the variables

The following types of copulas are supported:

- normal copula
- t copula
- Clayton copula
- Gumbel copula
- Frank copula

Getting Started: COPULA Procedure

The following example illustrates the use of PROC COPULA. The data used are daily returns on several major stocks. The main purpose of this example is to estimate the joint distribution of stock returns and then simulate from this distribution a new sample of specified size.

Figure 10.1 shows the first 10 observations of the daily stock return data set.
Figure 10.1 First 10 Observations of Daily Returns

</tbody>
</table>

The following statements fit a normal copula to the returns data (with the FIT statement) and create a new SAS data set that contains parameter estimates of the model. The VAR statement specifies the list of variables, which in this case are the daily returns of five large company stocks.

```sas
/* Copula estimation */
proc copula data = returns;
  var ret_ibm ret_msft ret_bp ret_ko ret_duk;
  fit normal / outcopula=estimates;
run;
```

The first table in Figure 10.2 shows some general information about the copula fitting procedure: the number of observations, the name of the input data set, the type of model and the correlation matrix.

**Figure 10.2** Copula Estimation: Fit Summary and Correlation Matrix

<table>
<thead>
<tr>
<th>The COPULA Procedure</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model Fit Summary</td>
</tr>
<tr>
<td>Number of Observations</td>
</tr>
<tr>
<td>Data Set</td>
</tr>
<tr>
<td>Copula Type</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Correlation Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>ret_ibm</td>
</tr>
<tr>
<td>ret_ibm</td>
</tr>
<tr>
<td>ret_msft</td>
</tr>
<tr>
<td>ret_bp</td>
</tr>
<tr>
<td>ret_ko</td>
</tr>
<tr>
<td>ret_duk</td>
</tr>
</tbody>
</table>
Next, the following statements restrict the data set to only those columns that contain correlation parameter estimates.

```sas
/* keep only correlation estimates */
data estimates;
    set estimates;
    keep ret_ibm ret_msft ret_bp ret_ko ret_duk;
run;
```

Then, in the following statements, the DEFINE statement specifies a normal copula named COP, and the CORR= option specifies that the data set Estimates be used as the source for the model parameters. The NDRAWS=500 option in the SIMULATE statement generates 500 observations from the normal copula. The OUTUNIFORM= option specifies the name of SAS data set to contain the simulated sample with uniform marginal distributions. Note that this syntax does not require the DATA= option.

```sas
/* Copula simulation of uniforms */
proc copula;
    var ret_ibm ret_msft ret_bp ret_ko ret_duk;
    define cop normal (corr = estimates);
    simulate cop / ndraws = 500
        seed = 1234
        outuniform = simulated_uniforms
        plots=(datatype=uniform);
run;
```

The simulated data is contained in the new SAS data set, Simulated_Uniforms. A scatter plot matrix of uniform marginals contained in the data set is shown in Output 10.3.
The preceding sequence of PROC COPULA usage—first fit, then simulate given estimated parameters—is a legitimate sequence but has a limitation in that the second COPULA call does not generate the sample according to the empirical distribution of the raw data. It generates only marginally uniform series.

In the following statements, the FIT statement fits a \( t \) copula to the returns data and at the same time simulates the sample according to empirical marginal distributions:
/* Copula estimation and simulation of returns */
proc copula data = returns;
  var ret_ibm ret_msft ret_bp ret_ko ret_duk;
  fit T;
  simulate / ndraws = 1000
    seed = 1234
    out = simulated_returns;
run;

The output of the statements is similar in structure to the output displayed in Figure 10.2 with the addition of parameter estimates and inference statistics that are specific to the copula model as shown in Figure 10.4. For a \( t \) copula, the degrees of freedom are displayed (as in Figure 10.4); for Archimedean copulas, the parameter “theta” is displayed; and for a normal copula, this table is not printed.

**Figure 10.4** Copula Estimation: Specific Parameter Estimates

| Parameter | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----------|----------------|---------|------|
| DF        | 3.659320 | 0.320729       | 11.41   | <.0001 |

The simulated data is contained in the new SAS data set, Simulated_Returns.

---

**Syntax: COPULA Procedure**

The COPULA procedure is controlled by the following statements:

```
PROC COPULA options ;
   VAR variables ;
   DEFINE name copula-type < ( parameter-value-options ... ) > ;
   FIT type <NAME=name > <INIT=(parameter-value-options)> / options ;
   BOUNDS bound1 < , bound2 ... > ;
   SIMULATE < copula-name-list > / options ;
   BY variables ;
```

---

**Functional Summary**

Table 10.1 summarizes the statements and options used with the COPULA procedure.

Chapter 10: The COPULA Procedure

### PROC COPULA Statement

**PROC COPULA** <option> ;

The PROC COPULA statement has the following option:

**DATA=** <libref.>SAS-data-set

specifies the input data set used to estimate parameters for the FIT statement. When the procedure is used for simulation only, the input data set is not required to run the procedure. If you do not specify *libref*, then the Work library is used. Work is the default temporary library that is automatically defined by SAS at the beginning of each SAS session or job.

### BOUNDS Statement

**BOUNDS** bound1 <, bound2 . . . > ;

The BOUNDS statement specifies the lower and upper bounds for the parameters. You can use this statement only when maximum likelihood estimation is used for the specified copula. Each bound is composed of parameters, constants, and inequality operators in the following format:

```
operator item < operator item < operator item . . . >>
```

Each item is a constant, parameter, or list of parameters. Parameters associated with a regressor variable are referred to by the name of the corresponding regressor variable. Each operator is <, >, <=, or >=. The following example indicates that the lower and upper bounds for the parameter THETA are -5 and 10, respectively.

```
bounds -5 < THETA < 10;
```
If you do not specify bounds, the internal default values are used; the default values are described in the section “Details: COPULA Procedure” on page 526. For the normal and $t$ copulas, the correlation matrix uses only the default parameter bounds, which are $-1$ and $1$ for lower bound and upper bound, respectively.

---

**BY Statement**

```
BY variables ;
```

The BY statement specifies groups in which separate FIT analyses for copula are performed. The `variables` must be present in the input data set and are excluded from the model fitting. The BY statement requires the VAR statement to be present.

---

**DEFINE Statement**

```
DEFINE name copula-type < ( parameter-value-options ... ) > ;
```

The DEFINE statement specifies the relevant information of the copula used for the simulation.

- `name` specifies the name of the copula definition, which can be used later in the SIMULATE statement.
- `copula-type` specifies one of the following types of the copula:
  - `NORMAL` specifies the normal copula.
  - `T` specifies the $t$ copula.
  - `CLAYTON` specifies the Clayton copula.
  - `GUMBEL` specifies the Gumbel copula.
  - `FRANK` specifies the Frank copula.

These copula models are also described in the section “Details: COPULA Procedure” on page 526.

- `parameter-value-options` specify the input parameters used to simulate the specified copula. These options must be appropriate for the type of copula specified. The following options are valid:
  - `CORR=SAS-data-set` specifies the data set that contains the correlation matrix to use for elliptical copulas. If the correlation matrix is valid but not submitted in order, then you must provide the variable names in the first column of the matrix and these names must match the variable names in the VAR statement. See Output 10.2.1 for an example of a correlation matrix input in this form. If the correlation matrix is submitted in order, the first column of variable names is not required. This option can be used for the normal and $t$ copulas.
KENDALL=SAS-data-set
specifies the data set that contains the correlation matrix defined in Kendall’s tau. If the correlation matrix is valid but not submitted in order, then you must provide the variable names in the first column of the matrix and these names must match the variable names in the VAR statement. If the correlation matrix is submitted in order, the first column of variable names is not required. This option can be used for the normal and t copulas.

SPEARMAN=SAS-data-set
specifies the data set that contains the correlation matrix defined in Spearman’s rho. If the correlation matrix is valid but not submitted in order, then you must provide the variable names in the first column of the matrix and these names must match the variable names in the VAR statement. If the correlation matrix is submitted in order, the first column of variable names is not required. This option can be used for the normal copula.

DF=value
specifies the degrees of freedom. This option can be used for the t copula.

THETA=value
specifies the parameter value for the Archimedean copulas.

The DEFINE statement is used with the SIMULATE statement. The FIT statement can also be used with the SIMULATE statement. The results of the FIT statement can be the input of the SIMULATE statement. Therefore, the SIMULATE statement can follow the FIT statement. If there is no FIT statement, then the DEFINE statement must precede SIMULATE statement. However, the FIT and DEFINE statements cannot both be used in the same procedure.

FIT Statement

FIT type < NAME=name >< INIT=(parameter-value-options) > /options ;

The FIT statement estimates the parameters for a specified copula type.

type
specifies the type of the copula to be estimated, which is one of the following:

NORMAL fits the normal copula
T fits the t copula
CLAYTON fits the Clayton copula
GUMBEL fits the Gumbel copula
FRANK fits the Frank copula

NAME=name
specifies an identifier for the fit, which is stored as an ID variable in the OUTCOPULA= data set.
**FIT Statement**  

**INIT=(parameter-value-options)**  
provides the initial values for the numerical optimization. For Archimedean copulas, the initial values of the parameter are computed using the calibration method. The initial value for the degrees-of-freedom parameter in the \(t\) copula is set to 2.0.

You can specify the following **options** after a slash (/):

**METHOD=MLE | CAL**  
specifies the method used to estimate parameters. MLE represents canonical maximum likelihood estimation (CMLE) or maximum likelihood estimation (MLE). CAL is the calibration method that uses the correlation matrix (only Kendall’s tau is implemented in this procedure). For the \(t\) copula, if METHOD=CAL, then the correlation matrix is estimated using the calibration method with Kendall’s tau and the degrees of freedom are estimated by the MLE. For the normal copula, only MLE is supported and METHOD=CAL is ignored. The default for all copula types is METHOD=MLE.

**OUTCOPULA=SAS-data-set**  
specifies the name of the output data set. Each fitted copula is written to the OUTCOPULA= data set. The data set is not created if this option is not specified.

**OUTPSEUDO=SAS-data-set**  
specifies the output data set for saving the pseudo-samples with uniform marginal distributions. The pseudo-samples are obtained by transforming the individual variables of the original data with the empirical cumulative distribution functions (CDFs). The data set is not created if this option is not specified.

**MARGINALS=UNIFORM | EMPIRICAL**  
specifies the marginal distribution of the individual variables. If MARGINALS=UNIFORM, then the copula is fitted with the input data without transformation. If MARGINALS=EMPIRICAL, the marginal empirical CDF is used to transform the data and the copula is fitted using the transformed data.

**PLOTS<(global-plot-options)> = (specific-plot-options)>**  
controls the plots that are produced by the COPULA procedure. By default, PROC COPULA produces a scatter plot matrix for variables (that is, it displays a symmetric matrix plot with the variables that are specified in the VAR statement).

You can specify the following **global-plot-options**:

**UNPACKPANEL | UNPACK**  
requests scatter plots for pairs of variables. If you specify this option, PROC COPULA displays a scatter plot for each applicable pair of distinct variables that are specified in the VAR statement.

**NVAR=ALL | n**  
specifies the maximum number of variables specified in the VAR statement to be displayed in the matrix plot. The NVAR=ALL option uses all variables that are specified in the VAR statement. By default, NVAR=5.

**TAIL | CHI**  
requests that tail dependence plots (chi-plots) be plotted. If you specify this option with the UNPACK option on, PROC COPULA displays a chi-plot for each applicable pair of distinct variables that are specified in the VAR statement. If you specify this option without the UNPACK
option, PROC COPULA displays a scatter plot matrix, the lower triangular section shows regular scatter plots between distinct pairs of variables that are specified in the VAR statement, the upper triangular section shows chi-plots for corresponding pairs of variables.

You can specify the following specific-plot-options:

**DATATYPE=**ORIGINAL | UNIFORM | BOTH
requests the data type to be plotted. DATA=ORIGINAL presents the data in its original marginal distribution; DATA=UNIFORM shows the transformed data with uniform marginal distribution; and DATA=BOTH plots both the original and uniform data types. If MARGINALS=UNIFORM, then the transformation is omitted and the DATA= option is ignored.

**NONE**
suppresses all plots.

### Printing Options

**ITPRINT**
prints a summary iteration listing.

**PRINTALL**
default option.

**NOCORR**
suppresses the correlation matrix.

**NOPRINT**
suppresses all output.

### SIMULATE Statement

**SIMULATE** < copula-name-list >/options ;

The SIMULATE statement simulates data from a specified copula model. The copula name specification can be either the name of a defined copula as specified by name in the DEFINE statement or the name of a fitted copula specified in the NAME= option in the FIT statement copula specification.

**MARGINALS=**UNIFORM | EMPIRICAL
specifies how the marginal distributions are computed. If MARGINALS=UNIFORM, then the samples are drawn from the copula distribution and marginal distributions are uniform.

MARGINALS=EMPIRICAL can be used to explicitly specify that the marginal distributions are empirical CDF computed from the DATA= option in the PROC COPULA statement.

If the MARGINALS= option is not specified in the SIMULATE statement, then the marginal distributions used in the simulation depend on whether a preceding FIT statement was used: If there is no FIT statement, the marginal distributions depend on whether the PROC COPULA statement includes a DATA= option. If there is a preceding FIT statement, then the marginal distributions from that fit are used. If there is no FIT statement and there is no DATA= option, then MARGINALS=UNIFORM.
OUT=SAS-data-set  
specifies the output data set for the random samples from the simulation. This data set is the SAS data set in the OUTUNIFORM= option transformed by the inverse empirical CDF. This option is useful only when an input data exists and MARGINALS=EMPIRICAL. The data set is not created if this option is not specified.

OUTUNIFORM=SAS-data-set  
specifies the output data set for the result of the simulation in uniforms. This option can be used when MARGINALS=UNIFORM or when MARGINALS=EMPIRICAL. If MARGINALS=EMPIRICAL, then this option enables you to obtain the samples simulated from the joint distribution specified by the copula, with all marginal distributions being uniform. The data is not created if this option is not specified.

NDRAWS=integer  
specifies the number of draws to generate for this simulation. The default is 100.

SEED=integer  
specifies the seed for generating random numbers for the simulation. If the seed is not provided, a random number is used as the seed.

PLOTS<(global-plot-options)> = (specific-plot-options)>
controls the plots that are produced by the COPULA procedure. By default, the PROC COPULA produces a scatter plot matrix for variables. You can specify any of the following global-plot-options:

UNPACKPANEL | UNPACK  
requests scatter plots for pairs of variables. If you specify this option, PROC COPULA displays a scatter plot for each applicable pair of distinct variables that are specified in the VAR statement.

NVAR=ALL | n  
specifies the maximum number of variables specified in the VAR statement to be displayed in the matrix plot. The NVAR=ALL option uses all variables that are specified in the VAR statement. By default, NVAR=5.

TAIL | CHI  
requests that tail dependence plots (chi-plots) be plotted. If you specify this option with the UNPACK option on, PROC COPULA displays a chi-plot for each applicable pair of distinct variables that are specified in the VAR statement. If you specify this option without the UNPACK option, PROC COPULA displays a scatter plot matrix, the lower triangular section shows regular scatter plots between distinct pairs of variables that are specified in the VAR statement, the upper triangular section shows chi-plots for corresponding pairs of variables.

You can specify the following specific-plot-options:

DATATYPE=ORIGINAL | UNIFORM | BOTH  
requests the data type to be plotted. DATA=ORIGINAL presents the data in its original marginal distribution; DATA=UNIFORM shows the transformed data with uniform marginal distribution; and DATA=BOTH plots both the original and uniform data types. If MARGINALS=UNIFORM, then the transformation is omitted and the DATA= option is ignored. If there is no input data, then the simulated data can only have uniform marginal distributions; in this case, the DATA= option is ignored.
DISTRIBUTION=PDF | CDF
requests distributional graphs for the case of two variables. DISTRIBUTION=PDF specifies that the theoretical probability density function is provided with both a contour plot and a surface plot. DISTRIBUTION=CDF requests the graph for the theoretical cumulative distribution function of the copula.

NONE
suppresses all plots.

VAR Statement

VAR variables ;

The VAR statement specifies the variable names in the input data set specified by the DATA= option in the PROC COPULA statement. The subset of variables in the data set is used for the copula models in the FIT statement. When there is no input data set, the VAR statement creates the names of the list of variables for the SIMULATE statement.

Details: COPULA Procedure

Sklar’s Theorem

The copula models are tools for studying the dependence structure of multivariate distributions. The usual joint distribution function contains the information both about the marginal behavior of the individual random variables and about the dependence structure between the variables. The copula is introduced to decouple the marginal properties of the random variables and the dependence structures. A \( m \)-dimensional copula is a joint distribution function on \([0, 1]^m\) with all marginal distributions being standard uniform. The common notation for a copula is \( C(u_1, \ldots, u_m) \).

The Sklar (1959) theorem shows the importance of copulas in modeling multivariate distributions. The first part claims that a copula can be derived from any joint distribution functions, and the second part asserts the opposite: that is, any copula can be combined with any set of marginal distributions to result in a multivariate distribution function.

- Let \( F \) be a joint distribution function and \( F_j, j = 1, \ldots, m \) be the marginal distributions. Then there exists a copula \( C : [0, 1]^m \to [0, 1] \) such that
  \[
  F(x_1, \ldots, x_m) = C(F_1(x_1), \ldots, F_m(x_m))
  \]
  for all \( x_1, \ldots, x_m \) in \([-\infty, \infty]\). Moreover, if the margins are continuous, then \( C \) is unique; otherwise \( C \) is uniquely determined on \( \text{Ran} F_1 \times \ldots \times \text{Ran} F_m \), where \( \text{Ran} F_j = F_j([\infty, \infty]) \) is the range of \( F_j \).

- The converse is also true. That is, if \( C \) is a copula and \( F_1, \ldots, F_m \) are univariate distribution functions, then the multivariate function defined in the preceding equation is a joint distribution function with marginal distributions \( F_j, j = 1, \ldots, m \).
Dependence Measures

There are three basic types of measures: linear correlation, rank correlation, and tail dependence. Linear correlation is given by

$$\rho \equiv \text{corr}(X, Y) = \frac{\text{cov}(X, Y)}{\sqrt{\text{var}(X)} \sqrt{\text{var}(Y)}}$$

The linear correlation coefficient carries very limited information about the joint properties of the variables. A well-known property is that uncorrelatedness does not imply independence, while independence implies noncorrelation. In addition, there exist distinct bivariate distributions that have the same marginal distribution and the same correlation coefficient. These results suggest that caution must be used when interpreting the linear correlation.

Another statistical measure of dependence is called rank correlation, which is nonparametric. Kendall’s tau, for example, is the covariance between the sign statistic $X_1 - \bar{X}_1$ and $X_2 - \bar{X}_2$, where $(\bar{X}_1, \bar{X}_2)$ is an independent copy of $(X_1, X_2)$:

$$\rho_\tau = E[\text{sign}(X_1 - \bar{X}_1)(X_2 - \bar{X}_2)]$$

The sign function (sometimes written as sgn) is defined by

$$\text{sign}(x) = \begin{cases} -1 & \text{if } x \leq 0 \\ 0 & \text{if } x = 0 \\ 1 & \text{if } x \geq 0 \end{cases}$$

Spearman’s rho is the correlation between the transformed random variables:

$$\rho_S(X_1, X_2) \equiv \rho(F_1(X_1), F_2(X_2))$$

The variables are transformed by their distribution functions so that the transformed variables are uniformly distributed on $[0, 1]$. The rank correlations depend only on the copula of the random variables and are indifferent to the marginal distributions. Like linear correlation, the rank correlations have their limitations. In particular, there are different copulas that result in the same rank correlation.

A third measure focuses on only part of the joint properties between the variables. Tail dependence measures the dependence when both variables are at extreme values. Formally, they can be defined as the conditional probabilities of quantile exceedances. There are two types of tail dependence:

- The upper tail dependence, denoted $\lambda_u$, is

$$\lambda_u(X_1, X_2) \equiv \lim_{q \to 1^-} P(X_2 > F_2^{-1}(q) | X_1 > F_1^{-1}(q))$$

when the limit exists $\lambda_u \in [0, 1]$. Here $F_j^{-1}$ is the quantile function (that is, the inverse of the CDF).

- The lower tail dependence is defined symmetrically.

Tail dependence is hard to detect by looking at a scatter plot of realizations of two random variables. One graphical way to detect tail dependence between two variables is by creating the chi plot of those two
variables. The chi plot, as defined in Fisher and Switzer (2001), has characteristic patterns that depend on the dependence structure between the variables. The chi plot for the random variables \(X\) and \(Y\) is a scatter plot of the pairs \((x_i, y_i)\) for each data point \((x_i, y_i)\). \(\lambda_i\) is a measure of the distance of the data point \((x_i, y_i)\) from the center of the data as measured by the median values of \((x_i, y_i)\), and \(\chi_i\) is a correlation coefficient between dichotomized values of \(X\) and \(Y\). A positive \(\lambda_i\) means that \(x_i\) and \(y_i\) are either both large with respect to their median values or both small. A negative \(\lambda_i\) means that \(x_i\) or \(y_i\) is large with respect to its median, whereas the other value is small. Signs of tail dependence manifest as clusters of points that are significantly far from the \(\chi\) axis around \(\lambda\) values of \(\pm 1\). If \(X\) and \(Y\) are uncorrelated, the \(\chi\) values cluster around the \(\lambda\) axis.

### Normal Copula

Let \(u_j \sim U(0, 1)\) for \(j = 1, \ldots, m\), where \(U(0, 1)\) represents the uniform distribution on the \([0, 1]\) interval. Let \(\Sigma\) be the correlation matrix with \(m(m-1)/2\) parameters satisfying the positive semidefiniteness constraint. The normal copula can be written as

\[
C_{\Sigma}(u_1, u_2, \ldots, u_m) = \Phi_{\Sigma}(\Phi^{-1}(u_1), \ldots, \Phi^{-1}(u_m))
\]

where \(\Phi\) is the distribution function of a standard normal random variable and \(\Phi_{\Sigma}\) is the \(m\)-variate standard normal distribution with mean vector \(0\) and covariance matrix \(\Sigma\). That is, the distribution \(\Phi_{\Sigma}\) is \(N_m(0, \Sigma)\).

### Simulation

For the normal copula, the input of the simulation is the correlation matrix \(\Sigma\). The normal copula can be simulated by the following steps in which \(U = (U_1, \ldots, U_m)\) denotes one random draw from the copula:

1. Generate a multivariate normal vector \(Z \sim N(0, \Sigma)\) where \(\Sigma\) is an \(m\)-dimensional correlation matrix.
2. Transform the vector \(Z\) into \(U = (\Phi(Z_1), \ldots, \Phi(Z_m))^T\), where \(\Phi\) is the distribution function of univariate standard normal.

The first step can be achieved by Cholesky decomposition of the correlation matrix \(\Sigma = LL^T\) where \(L\) is a lower triangular matrix with positive elements on the diagonal. If \(\tilde{Z} \sim N(0, I)\), then \(L \tilde{Z} \sim N(0, \Sigma)\).

### Fitting

To fit a normal copula is to estimate the covariance matrix \(\Sigma\) from an input sample data set. Given a random sample \(u_i = (u_{i,1}, \ldots, u_{i,m})^T\) where \(i = 1, \ldots, n\), the log-likelihood function is

\[
\log L(\Sigma; u_1, \ldots, u_n) = \sum_{i=1}^{n} \log f_{\Sigma}(\Phi^{-1}(u_{t,1}), \ldots, \Phi^{-1}(u_{t,m})) - \sum_{i=1}^{n} \sum_{j=1}^{m} \log \phi(\Phi^{-1}(u_{t,j}))
\]

Here \(f_{\Sigma}\) is the joint density of the multivariate normal with mean zero and variance \(\Sigma\), and \(\phi\) is the univariate density of the standard normal distribution. Note that the second term is not related to the parameters \(\Sigma\) and, therefore, can be ignored during the optimization. The restriction that \(\Sigma\) is a correlation matrix is
very inconvenient, and it is common practice to circumvent this problem by first assuming that $\Sigma$ has the covariance form. Therefore, $\Sigma$ can be estimated by

$$
\hat{\Sigma} = \frac{1}{n} \sum_{i=1}^{n} \xi_i \xi_i^T
$$

where

$$
\xi_i = \left( \Phi^{-1}(u_{i,1}), \Phi^{-1}(u_{i,2}), \ldots, \Phi^{-1}(u_{i,m}) \right)^T
$$

This estimate is consistent with the form of a covariance matrix but not necessarily with the form of a correlation matrix. The approximation to the original MLE problem can be obtained using the normalizing operator defined as follows:

$$
\Delta_i(\Sigma) = \text{diag}(\sigma_{11}^{1/2}, \ldots, \sigma_{mm}^{1/2})
$$

$$
P(\Sigma) = (\Delta(\Sigma))^{-1} \Sigma (\Delta(\Sigma))^{-1}
$$

**Student’s $t$ copula**

Let $\Theta = \{ (v, \Sigma) : v \in (1, \infty), \Sigma \in \mathbb{R}^{m \times m} \}$ and let $t_v$ be a univariate $t$ distribution with $v$ degrees of freedom. The Student’s $t$ copula can be written as

$$
C_\Theta(u_1, u_2, \ldots, u_m) = t_v, \Sigma \left( t_v^{-1}(u_1), t_v^{-1}(u_2), \ldots, t_v^{-1}(u_m) \right)
$$

where $t_v, \Sigma$ is the multivariate Student’s $t$ distribution with a correlation matrix $\Sigma$ with $v$ degrees of freedom.

**Simulation**

The input parameters for the simulation are $(v, \Sigma)$. The $t$ copula can be simulated by the following two steps:

1. Generate a multivariate vector $X \sim t_m(v, 0, \Sigma)$ following the centered $t$ distribution with $v$ degrees of freedom and correlation matrix $\Sigma$.
2. Transform the vector $X$ into $U = (t_v(X_1), \ldots, t_v(X_m))^T$, where $t_v$ is the distribution function of univariate $t$ distribution with $v$ degrees of freedom.

To simulate centered multivariate $t$ random variables, you can use the property that $X \sim t_m(v, 0, \Sigma)$ if $X = \sqrt{v/s} Z$, where $Z \sim N(0, \Sigma)$ and the univariate random variable $s \sim F_{\chi}^2$.

**Fitting**

To fit a $t$ copula is to estimate the covariance matrix $\Sigma$ and degrees of freedom $v$ from a given multivariate data set. Given a random sample $u_i = (u_{i,1}, \ldots, u_{i,m})^T$, $i = 1, \ldots, n$ that has uniform marginal distributions, the log likelihood is

$$
\log L(v, \Sigma; u_{i,1}, \ldots, u_{i,m})
$$

$$
= \sum_{i=1}^{n} \log g_{v, \Sigma}(t_v^{-1}(u_{i,1}), \ldots, t_v^{-1}(u_{i,m})) - \sum_{i=1}^{n} \sum_{j=1}^{m} \log g_v(t_v^{-1}(u_{i,j}))
$$
where \(v\) denotes the degrees of freedom of the \(t\) copula, \(g_{\nu, \Sigma}\) denotes the joint density function of the centered multivariate \(t\) distribution with parameters \((\nu, \Sigma)\), \(t_{\nu}\) is the distribution function of a univariate \(t\) distribution with \(v\) degrees of freedom, \(\Sigma\) is a correlation matrix, and \(g_{\nu}\) is the density function of univariate \(t\) distribution with \(v\) degrees of freedom.

The log likelihood can be maximized with respect to the parameters \(\theta = (\nu, \Sigma) \in \Theta\) using numerical optimization. If you allow the parameters in \(\Sigma\) to be such that \(\Sigma\) is symmetric and with ones on the diagonal, then the MLE estimate for \(\Sigma\) might not be positive semidefinite. In that case, you need to apply the adjustment to convert the estimated matrix to positive semidefinite, as shown by McNeil, Frey, and Embrechts (2005), Algorithm 5.55.

When the dimension of the data \(m\) increases, the numerical optimization quickly becomes infeasible. It is common practice to estimate the correlation matrix \(\Sigma\) by calibration using Kendall’s tau. Then, using this fixed \(\Sigma\), the single parameter \(v\) can be estimated by MLE. By proposition 5.37 in McNeil, Frey, and Embrechts (2005),

\[
\rho_t(U_i, U_j) = \frac{2}{\pi} \arcsin \rho_{ij}
\]

where \(\rho_t\) is the Kendall’s tau and \(\rho_{ij}\) is the off-diagonal elements of the correlation matrix \(\Sigma\) of the \(t\) copula. Therefore, an estimate for the correlation is

\[
\hat{\rho}_{ij} = \sin \left( \frac{1}{2} \hat{\rho}_{i,j}^\tau \right)
\]

where \(\hat{\rho}\) and \(\hat{\rho}^\tau\) are the estimates of the sample correlation matrix and Kendall’s tau, respectively. However, it is possible that the estimate of the correlation matrix \(\hat{\Sigma}\) is not positive definite. In this case, there is a standard procedure that uses the eigenvalue decomposition to transform the correlation matrix into one that is positive definite. Let \(\Sigma\) be a symmetric matrix with ones on the diagonal, with off-diagonal entries in \([-1, 1]\). If \(\Sigma\) is not positive semidefinite, use Algorithm 5.55 from McNeil, Frey, and Embrechts (2005):

1. Compute the eigenvalue decomposition \(\Sigma = E \Lambda E^T\), where \(E\) is a diagonal matrix that contains all the eigenvalues and \(E\) is an orthogonal matrix that contains the eigenvectors.
2. Construct a diagonal matrix \(D\) by replacing all negative eigenvalues in \(\Sigma\) by a small value \(\delta > 0\).
3. Compute \(\tilde{\Sigma} = E \tilde{D} E^T\), which is positive definite but not necessarily a correlation matrix.
4. Apply the normalizing operator \(P\) on the matrix \(\tilde{\Sigma}\) to obtain the correlation matrix desired.

The log likelihood function and its gradient function for a single observation are listed as follows, where \(\xi = (\xi_1, \ldots, \xi_m)\), with \(\xi_j = t^{-1}_\nu(u_j)\), and \(g\) is the derivative of the log \(\Gamma\) function:
Archimedean Copulas

Overview of Archimedean Copulas

Let function \( \phi : [0, 1] \rightarrow [0, \infty) \) be a strict Archimedean copula generator function and suppose its inverse \( \phi^{-1} \) is completely monotonic on \([0, \infty)\). A strict generator is a decreasing function \( \phi : [0, 1] \rightarrow [0, \infty) \) that satisfies \( \phi(0) = \infty \) and \( \phi(1) = 0 \). A decreasing function \( f(t) : [a, b] \rightarrow (-\infty, \infty) \) is completely monotonic if it satisfies

\[
(-1)^k \frac{d^k}{dt^k} f(t) \geq 0, \quad k \in \mathbb{N}, \quad t \in (a, b)
\]

An Archimedean copula is defined as follows:

\[
C(u_1, u_2, \ldots, u_m) = \phi^{-1} \left( \phi(u_1) + \cdots + \phi(u_m) \right)
\]

The Archimedean copulas available in the COPULA procedure are the Clayton copula, the Frank copula, and the Gumbel copula.
Clayton Copula

Let the generator function \( \phi(u) = \theta^{-1} \left( u^{-\theta} - 1 \right) \). A Clayton copula is defined as

\[
C_\theta(u_1, u_2, \ldots, u_m) = \left[ \sum_{i=1}^{m} u_i^{-\theta} - m + 1 \right]^{-1/\theta}
\]

with \( \theta > 0 \).

Frank Copula

Let the generator function be

\[
\phi(u) = -\log \left[ \frac{\exp(-\theta u) - 1}{\exp(-\theta) - 1} \right]
\]

A Frank copula is defined as

\[
C_\theta(u_1, u_2, \ldots, u_m) = \frac{1}{\theta} \log \left\{ 1 + \frac{\prod_{i=1}^{m} \left[ \exp(-\theta u_i) - 1 \right]}{\left[ \exp(-\theta) - 1 \right]^{m-1}} \right\}
\]

with \( \theta \in (-\infty, \infty) \setminus \{0\} \) for \( m = 2 \) and \( \theta > 0 \) for \( m \geq 3 \).

Gumbel Copula

Let the generator function \( \phi(u) = (-\log u)^\theta \). A Gumbel copula is defined as

\[
C_\theta(u_1, u_2, \ldots, u_m) = \exp \left\{ - \left[ \sum_{i=1}^{m} (-\log u_i)^\theta \right]^{1/\theta} \right\}
\]

with \( \theta > 1 \).

Simulation

Suppose the generator of the Archimedean copula is \( \phi \). Then the simulation method using Laplace-Stieltjes transformation of the distribution function is given by Marshall and Olkin (1988) where \( \tilde{F}(t) = \int_{0}^{\infty} e^{-tx} dF(x) \):

1. Generate a random variable \( V \) with the distribution function \( F \) such that \( \tilde{F}(t) = \phi^{-1}(t) \).
2. Draw samples from independent uniform random variables \( X_1, \ldots, X_m \).
3. Return \( U = (\tilde{F}(\log(X_1)/V), \ldots, \tilde{F}(\log(X_m)/V))^T \).

The Laplace-Stieltjes transformations are as follows:

- For the Clayton copula, \( \tilde{F} = (1 + t)^{-1/\theta} \), and the distribution function \( F \) is associated with a Gamma random variable with shape parameter \( \theta^{-1} \) and scale parameter one.
- For the Gumbel copula, \( \tilde{F} = \exp(-1^{1/\theta}) \), and \( F \) is the distribution function of the stable variable \( \text{St}(\theta^{-1}, 1, \gamma, 0) \) with \( \gamma = [\cos(\pi/(2\theta))]^{\theta} \).
• For the Frank copula with $\theta > 0$, $\tilde{F} = -\log\{1 - \exp(-t)[1 - \exp(-\theta)]\}/\theta$, and $F$ is a discrete probability function $P(V = k) = (1 - \exp(-\theta))^k/(k\theta)$. This probability function is related to a logarithmic random variable with parameter value $1 - e^{-\theta}$.

For details about simulating a random variable from a stable distribution, see Theorem 1.19 in Nolan (2010). For details about simulating a random variable from a logarithmic series, see Chapter 10.5 in Devroye (1986).

For a Frank copula with $m = 2$ and $\theta < 0$, the simulation can be done through conditional distributions as follows:

1. Draw independent $v_1, v_2$ from a uniform distribution.
2. Let $u_1 = v_1$.
3. Let $u_2 = -\frac{1}{\theta} \log \left( 1 + \frac{v_2(1 - e^{-\theta})}{v_2(1 - e^{-\theta} v_1) - e^{-\theta} v_1} \right)$.

**Fitting**

One method to estimate the parameters is to calibrate with Kendall’s tau. The relation between the parameter $\theta$ and Kendall’s tau is summarized in the following table for the three Archimedean copulas.

<table>
<thead>
<tr>
<th>Copula Type</th>
<th>Formula for $\tau$</th>
<th>Formula for $\theta$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Clayton</td>
<td>$\theta/(\theta + 2)$</td>
<td>$2\tau/(1 - \tau)$</td>
</tr>
<tr>
<td>Gumbel</td>
<td>$1 - 1/\theta$</td>
<td>$1/(1 - \tau)$</td>
</tr>
<tr>
<td>Frank</td>
<td>$1 - 4\theta^{-1}(1 - D_1(\theta))$</td>
<td>No closed form</td>
</tr>
</tbody>
</table>

In Table 10.2, $D_1(\theta) = \theta^{-1}\int_0^\theta t/(\exp(t) - 1)dt$ for $\theta > 0$, and $D_1(\theta) = D_1(\theta) + 0.5\theta$ for $\theta < 0$. In addition, for the Frank copula, the formula for $\theta$ has no closed form. The numerical algorithm for root finding can be used to invert the function $\tau(\theta)$ to obtain $\theta$ as a function of $\tau$.

Alternatively, you can use the MLE or the CMLE method to estimate the parameter $\theta$ given the data $u = \{u_{i,j}\}$ and $i = 1, \ldots, n$, $j = 1, \ldots, m$. The log-likelihood function for each type of Archimedean copula is provided in the following sections.

**Fitting the Clayton Copula**

For the Clayton copula, the log-likelihood function is as follows (Cherubini, Luciano, and Vecchiato 2004, Chapter 7):

$$
\begin{align*}
    l &= n \left[ m \log(\theta) + \log \left( \Gamma \left( \frac{1}{\theta} + m \right) \right) - \log \left( \Gamma \left( \frac{1}{\theta} \right) \right) \right] - (\theta + 1) \sum_{i,j} \log u_{ij} \\
    &\quad - \left( \frac{1}{\theta} + m \right) \sum_i \log \left( \sum_j u_{ij}^{-\theta} - m + 1 \right)
\end{align*}
$$
Let \( g(\cdot) \) be the derivative of \( \log(\Gamma(\cdot)) \). Then the first order derivative is

\[
\frac{dl}{d\theta} = n \left[ \frac{m}{\theta} + g\left(\frac{1}{\theta} + m\right) \frac{-1}{\theta^2} - g\left(\frac{1}{\theta}\right) \frac{-1}{\theta^2} \right] \\
- \sum_{i,j} \log(u_{ij}) + \frac{1}{\theta^2} \sum_i \log \left( \sum_j u_{ij}^{-\theta} - m + 1 \right) \\
- \left( \frac{1}{\theta} + m \right) \sum_i \frac{-\sum_j u_{ij}^{-\theta} \log(u_{ij})}{\sum_j u_{ij}^{-\theta} - m + 1}
\]

The second order derivative is

\[
\frac{d^2 l}{d\theta^2} = n \left\{ \frac{-m}{\theta^2} + g'(\frac{1}{\theta} + m) \frac{1}{\theta^4} + g\left(\frac{1}{\theta} + m\right) \frac{2}{\theta^3} - g'(\frac{1}{\theta}) \frac{1}{\theta^4} - g\left(\frac{1}{\theta}\right) \frac{2}{\theta^3} \right\} \\
- \frac{2}{\theta^3} \sum_i \log \left( \sum_j u_{ij}^{-\theta} - m + 1 \right) \\
+ \frac{2}{\theta^2} \sum_i \frac{-\sum_j u_{ij}^{-\theta} \log(u_{ij})}{\sum_j u_{ij}^{-\theta} - m + 1} \\
- \left( \frac{1}{\theta} + m \right) \sum_i \left\{ \frac{\sum_j u_{ij}^{-\theta} (\log(u_{ij}))^2}{\sum_j u_{ij}^{-\theta} - m + 1} - \left( \frac{\sum_j u_{ij}^{-\theta} \log(u_{ij})}{\sum_j u_{ij}^{-\theta} - m + 1} \right)^2 \right\}
\]

**Fitting the Gumbel Copula**

A different parameterization \( \alpha = \theta^{-1} \) is used for the following part, which is related to the fitting of the Gumbel copula. For Gumbel copula, you need to compute \( \phi^{-1}(m) \). It turns out that for \( k = 1, 2, \ldots, m \),

\[
\phi^{-1}(k)(u) = (-1)^k \alpha \exp(-u^\alpha) u^{-k + \alpha} \Psi_{k-1}(u^\alpha)
\]

where \( \Psi_{k-1} \) is a function that is described later. The copula density is given by

\[
c = \phi^{-1}(m) \left( x \right) \prod_k \phi'(u_k)
\]

\[
= (-1)^m \alpha \exp(-x^\alpha) x^{-k + \alpha} \Psi_{m-1}(x^\alpha) \prod_k \phi'(u_k)
\]

\[
= (-1)^m f_1 f_2 f_3 f_4 f_5
\]

where \( x = \sum_k \phi(u_k) \), \( f_1 = \alpha \), \( f_2 = \exp(-x^\alpha) \), \( f_3 = x^{-k + \alpha} \), \( f_4 = \Psi_{m-1}(x^\alpha) \), and \( f_5 = (-1)^m \prod_k \phi'(u_k) \).

The log density is

\[
l = \log(c)
\]

\[
= \log(f_1) + \log(f_2) + \log(f_3) + \log(f_4) + \log((-1)^m f_5)
\]
Now the first order derivative of the log density has the decomposition

$$
\frac{dl}{d\alpha} = \frac{1}{c} \frac{dc}{d\alpha} = \sum_{j=1}^{4} \frac{1}{f_j} \frac{df_j}{d\alpha} + d \sum_{k} \log (\phi'(u_k))
$$

Some of the terms are given by

$$
\frac{1}{f_1} \frac{df_1}{d\alpha} = \frac{1}{\alpha} \\
\frac{1}{f_2} \frac{df_2}{d\alpha} = -x^\alpha \log (x) - \alpha x^{\alpha-1} \frac{dx}{d\alpha} \\
\frac{1}{f_3} \frac{df_3}{d\alpha} = \log (x) + (-k + \alpha) x^{-1} \frac{dx}{d\alpha}
$$

where

$$
\frac{dx}{d\alpha} = \sum (-\log u_k)^{1/\alpha} \log (-\log u_k) \left( \frac{-1}{\alpha^2} \right)
$$

The last term in the derivative of the $dl/d\alpha$ is

$$
\log (\phi'(u_k)) = \log \left( \frac{1}{\alpha} (-\log u_k)^{1/\alpha-1} \frac{1}{u_k} \right) \\
= -\log \alpha - \log (u_k) + \left( \frac{1}{\alpha} - 1 \right) \log (-\log (u_k))
$$

$$
\frac{d}{d\alpha} \sum_k \log (\phi'(u_k)) = \sum_{k=1}^{m} \left( -\frac{1}{\alpha} - \frac{1}{\alpha^2} \right) \log (-\log (u_k)) \\
= \frac{-m}{\alpha} - \frac{1}{\alpha^2} \sum_{k=1}^{m} \log (-\log (u_k))
$$

Now the only remaining term is $f_4$, which is related to $\Psi_{m-1}$. Wu, Valdez, and Sherris (2007) show that $\Psi_k(x)$ satisfies a recursive equation

$$
\Psi_k(x) = [\alpha (x - 1) + k] \Psi_{k-1}(x) - \alpha x \Psi'_{k-1}(x)
$$

with $\Psi_0(x) = 1$.

The preceding equation implies that $\Psi_{k-1}(x)$ is a polynomial of $x$ and therefore can be represented as

$$
\Psi_{k-1}(x) = \sum_{j=0}^{k-1} a_j \left( k - 1, \alpha \right) x^j
$$

In addition, its coefficient, denoted by $a_j(k - 1, \alpha)$, is a polynomial of $\alpha$. For simplicity, use the notation $a_j(\alpha) \equiv a_j(m - 1, \alpha)$. Therefore,

$$
f_4 = \Psi_{m-1} (x^\alpha) = \sum_{j=0}^{m-1} a_j (\alpha) x^{j\alpha}
$$
\[
\frac{df_4}{d\alpha} = \frac{d\Psi_{m-1}(x^\alpha)}{d\alpha} \\
= \sum_{j=0}^{m-1} \left[ \frac{da_j(\alpha)}{d\alpha} x^{j\alpha} + a_j(\alpha) x^{j\alpha} \log(x) j + a_j(\alpha) j x^{j\alpha-1} \frac{dx}{d\alpha} \right]
\]

**Fitting the Frank copula**

For the Frank copula,

\[
\phi^{-1(k)}(u) = -\frac{1}{\theta} \Psi_{k-1} \left( (1 + e^{-u}(e^{-\theta} - 1))^{-1} \right)
\]

When \( \theta > 0 \), a Frank copula has a probability density function

\[
c = \varphi^{-1(m)}(x) \prod_k \varphi'(u_k)
\]

\[
= -\frac{1}{\theta} \Psi_{m-1} \left( \frac{1}{1 + e^{-x}(e^{-\theta} - 1)} \right) \prod_k \varphi'(u_k)
\]

where \( x = \sum_k \varphi(u_k) \).

The log likelihood is

\[
\log c = -\log(\theta) + \log \left( \Psi_{m-1} \left( \frac{1}{1 + e^{-x}(e^{-\theta} - 1)} \right) \right) + \sum \log(\varphi'(u_k))
\]

Denote

\[
y = \frac{1}{1 + e^{-x}(e^{-\theta} - 1)}
\]

Then the derivative of the log likelihood is

\[
\frac{d \log c}{d\theta} = -\frac{1}{\theta} + \frac{1}{\Psi_{m-1}(y)} \frac{d\Psi_{m-1}}{d\theta} + \sum_k \frac{1}{\varphi'(u_k)} \frac{d\varphi'(u_k)}{d\theta}
\]

The term in the last summation is

\[
\frac{1}{\varphi'(u_k)} \frac{d\varphi'(u_k)}{d\theta} = \frac{1}{\theta(1 - e^{\theta u_k})} \left[ 1 - e^{\theta u_k} + \theta u e^{\theta u_k} \right]
\]

The function \( \Psi_{m-1} \) satisfies a recursive relation

\[
\Psi_k(x) = x(x - 1) \Psi'_k(x)
\]
with \( \Psi_0(x) = x - 1 \). Note that \( \Psi_{m-1} \) is a polynomial whose coefficients do not depend on \( \theta \); therefore,

\[
\frac{d \Psi_{m-1}}{d \theta} = \frac{d \Psi_{m-1}}{dy} \frac{dy}{d \theta}
= \frac{d \Psi_{m-1}}{dy} \left[ \frac{dy}{d \theta} + \frac{dy}{dx} \frac{dx}{d \theta} \right]
= \frac{d \Psi_{m-1}}{dy} \left[ \frac{e^{-x} e^{-\theta}}{1 + e^{-x} (e^{-\theta} - 1)^2} + \frac{e^{-\theta} (e^{-\theta} - 1)}{1 + e^{-x} (e^{-\theta} - 1)^2} \right]
\]

where

\[
\frac{dx}{d \theta} = \sum_k \frac{d \varphi(u_k)}{d \theta} = \sum_k \left[ \frac{u_k e^{-\theta u_k}}{1 - e^{-\theta u_k}} + \frac{e^{-\theta}}{1 - e^\theta} \right]
= \sum_k \left[ -\frac{u_k}{e^{\theta u_k} - 1} + \frac{1}{e^\theta - 1} \right]
\]

For the case of \( m = 2 \) and \( \theta < 0 \), the bivariate density is

\[
\log c = \log(\theta(1 - e^{-\theta})) - \theta(u_1 + u_2) - \log((1 - e^{-\theta} - (1 - e^{-\theta u_1})(1 - e^{-\theta u_2})^2)
\]

Canonical Maximum Likelihood Estimation (CMLE)

In the canonical maximum likelihood estimation (CMLE) method, it is assumed that the sample data \( x_i = (x_{i1}, x_{i2}, \ldots, x_{im})^\top, i = 1, \ldots, n \) have been transformed into uniform variates \( \hat{u}_i = (\hat{u}_{i1}, \ldots, \hat{u}_{im}), i = 1, \ldots, n \). One commonly used transformation is the nonparametric estimation of the CDF of the marginal distributions, which is closely related to empirical CDF,

\[
\hat{u}_{i,j} = \hat{F}_{j,n}(x_{i,j})
\]

where

\[
\hat{F}_{j,n}(x) = \frac{1}{n+1} \sum_{i=1}^n I[x_{i,j} \leq x]
\]

The transformed data \( \hat{u}_{i,j} \) are used as if they had uniform marginal distributions; hence, they are called pseudo-samples. The function \( \hat{F}_{j,n} \) is different from the standard empirical CDF in the scalar \( 1/(n + 1) \), which is to ensure that the transformed data cannot be on the boundary of the unit interval \([0, 1]\). It is clear that

\[
\hat{u}_{i,j} = \frac{1}{n+1} \text{rank}(x_{i,j})
\]

where \( \text{rank}(x_{i,j}) \) is the rank among \( i = 1, \ldots, n \) in increasing order.

Let \( c(u_1, u_2, \ldots, u_m; \theta) \) be the density function of a copula \( C(u_1, u_2, \ldots, u_m; \theta) \), and let \( \theta \) be the parameter vector to be estimated. The parameter \( \theta \) is estimated by maximum likelihood:

\[
\hat{\theta} = \arg \max_{\theta \in \Theta} \sum_{i=1}^n \log c(\hat{u}_{i1}, \ldots, \hat{u}_{im}; \theta)
\]
Exact Maximum Likelihood Estimation (MLE)

Suppose that the marginal distributions of vector elements \( x_i = (x_{i1}, x_{i2}, \ldots, x_{im})^T, i = 1, \ldots, n \) are already known to be uniform. Then the parameter \( \theta \) is estimated by exact maximum likelihood:

\[
\hat{\theta} = \arg \max_{\theta \in \Theta} \sum_{i=1}^{n} \log c(x_{i1}, x_{i2}, \ldots, x_{im}; \theta)
\]

Calibration Estimation

Instead of fitting the whole distribution as in MLE methods, you can directly use empirical estimates of distribution parameters. The unknown parameter that you want to estimate can be obtained by calibration using Kendall’s tau. There exists a one-to-one map between the parameter at interest and Kendall’s tau. Therefore, after you estimate the Kendall’s tau, you can use the map to compute the parameter value. For example, the parameter matrix \( \Sigma \) in a \( t \) copula and the parameter \( \theta \) in Archimedean copulas can be estimated in this manner. The most frequently used estimator of Kendall’s tau is the rank correlation coefficient:

\[
\hat{\rho}_\tau (X_i, X_j) = \left( \frac{n}{2} \right)^{-1} \sum_{1 \leq i < j \leq n} \text{sign} \left( (x_{it,i} - x_{is,i}) (x_{jt,j} - x_{sj,j}) \right)
\]

The preceding formula is analogous to its population counterpart

\[
\rho_\tau (X_i, X_j) = E \left[ \text{sign} \left( (X_i - \tilde{X}_i) (X_j - \tilde{X}_j) \right) \right]
\]

where \((\tilde{X}_i, \tilde{X}_j)\) has the same distribution but is independent of \((X_i, X_j)\).

For Archimedean multivariate copulas there is only one parameter to estimate, \( \tau \) (or its function \( \theta \)), although for \( m \) variables there are \( m(m-1)/2 \) unique pairwise correlation coefficients. Denote the map from \( \rho_\tau \) to \( \theta \) by \( \theta = \hat{\theta}(\rho_\tau) \). To aggregate the map, take simple arithmetic average:

\[
\hat{\theta} = \frac{2}{m(m-1)} \sum_{1 \leq i < j \leq m} \hat{\theta} \left[ \hat{\rho}_\tau (X_i, X_j) \right]
\]

Nonlinear Optimization Options

PROC COPULA uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. In the PROC COPULA statement, you can specify nonlinear optimization options that are then passed to the NLO subsystem. For a list of all the nonlinear optimization options, see Chapter 6, “Nonlinear Optimization Methods.”
Displayed Output

PROC COPULA produces displayed output described in the following sections.

Optimization Start and Resulting Parameter Estimates

If you specify the ITPRINT option in the PROC COPULA statement, PROC COPULA displays two tables, “Optimization Start Parameter Estimates” and “Optimization Results Parameter Estimates.” Each table contains the following information for each model parameter:

- parameter number
- parameter name
- parameter estimate
- gradient of the objective function at the initial parameter values

In addition to this information, the table “Optimization Start Parameter Estimates” contains the following columns:

- lower-bound constraint
- upper-bound constraint

The value of the objective function at the parameter values is displayed below each table.

Iteration History for Parameter Estimates

If you specify the ITPRINT option in the PROC COPULA statement, PROC COPULA displays a table that contains the following information for each iteration. Note that some information is specific to the model-fitting method chosen (for example, Newton-Raphson, trust region, or quasi-Newton method).

- iteration number
- number of restarts since the fitting began
- number of function calls
- number of active constraints at the current solution
- value of the objective function (−1 times the log-likelihood value) at the current solution
- change in the objective function from previous iteration
- value of the maximum absolute gradient element
- step size (for Newton-Raphson and quasi-Newton methods)
- slope of the current search direction (for Newton-Raphson and quasi-Newton methods)
- lambda (for trust region method)
- radius value at current iteration (for trust region method)
Model Fit Summary

The “Model Fit Summary” table contains the following information:

- number of observations used
- number of missing values in data set, if any
- data set name
- type of model that was fit
- log-likelihood value at solution
- maximum absolute gradient at solution
- number of iterations
- optimization method
- value of Akaike’s information criterion (AIC) at the solution (a smaller value indicates better fit)
- value of Schwarz-Bayesian criterion (SBC) at the solution (a smaller value indicates better fit)

Under the “Model Fit Summary” is a statement about whether the algorithm successfully converged.

Parameter Estimates

The “Parameter Estimates” table contains the estimates of the model parameters. For the normal copula, this table is not displayed because the only parameters are in the correlation matrix, which is displayed in the “Correlation Matrix” table. For the t copula, the parameter is the number of degrees of freedom; in the table it is called “DF.” For Archimedean copulas such as Clayton, Frank, and Gumbel, the parameter is called “theta.”

Correlation Matrix

The “Correlation Matrix” table contains the estimates of the model correlation matrix. This table is displayed only for elliptical copulas such as the normal and t copulas. Row and column names come from the list of variables defined in VAR statement.

OUTCOPULA= Data Set

The OUTCOPULA= data set consists of several rows. The first row (with _TYPE_='PARM') contains the parameter estimates in the model. For a t copula, the estimate is the number of degrees of freedom; for Archimedean copulas, the estimate is “theta.” The second row (with _TYPE_='STD') contains the standard error for the parameter estimate in the model. These two rows do not appear for the normal copula.

If you use one of the elliptical copulas, t or normal, the rest of the data set contains the correlation matrix estimates. The correlation matrix appears in the observations with _TYPE_='CORR’, and the _VARIABLE_ column contains the parameter names.
If METHOD=MLE and the nonlinear optimization subsystem is used, a _STATUS_ column is created that contains a character variable that indicates whether the optimization process reached convergence or failed to converge:

- 0 indicates that the convergence was reached
- 1 indicates that the maximum number of iterations allowed was exceeded
- 2 indicates a failure to improve the function value
- 3 indicates a failure to converge for one of the following reasons:
  - The objective function or its derivatives could not be evaluated or improved.
  - Linear constraints are dependent.
  - The algorithm failed to return to feasible region.
  - The number of iterations is greater than prespecified.

OUTPSEUDO=, OUT=, and OUTUNIFORM= Data Sets

The OUTPSEUDO=, OUT=, and OUTUNIFORM= data sets contain the same number of columns as specified in VAR statement. The names of the columns are taken from the same VAR statement list.

**ODS Table Names**

PROC COPULA assigns a name to each table it creates. You can use these names to denote the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 10.3.

### ODS Graph Names

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

PROC COPULA assigns a name to each graph it creates by using ODS. You can use these names to refer to the graphs when you use ODS. The names are listed in Table 10.4.

Chapter 10: The COPULA Procedure

Example 10.1: Copula Based VaR Estimation

Value-at-risk (VaR) has become a de facto standard in financial risk management. The purpose of this measure is to give some quantitative insight to the riskiness of an asset portfolio. This measure is expressed generically in the following terms: What is the probability of losing no more than given percentage of a portfolio in a certain period of time? Or, what are the maximum possible losses at a given confidence level? The most simple and clearly wrong answer to this question is to compute the empirical quantile of past portfolio returns. The problem of this approach is that it does not take into account the dynamic nature of asset returns, the possibility of changing distribution, time memory, and, most importantly, cross-sectional dependence between individual assets in the portfolio.

This simple example of VaR computation takes into account at least cross-sectional dependence of the data. The end result is the prediction of the next-day maximum possible loss on the portfolio of stocks.

This example uses the daily returns on large stocks such as IBM, Microsoft, British Petroleum, Coca Cola, and Duke Energy. Output 10.1.1 shows the first 10 observations of the data.

```

</tbody>
</table>
```

The purpose of this exercise is to estimate one-day future losses of a stock portfolio. The simplest approach is to assume that the joint distribution of individual asset returns does not change with time. This might be close to the truth if only a small time interval is used. Then, a copula approach is used to estimate the joint distribution. Next, the new large sample of daily individual asset returns is simulated from the fitted joint distribution. These assets are then combined into a portfolio and its daily returns are computed. Finally, quantiles of simulated portfolio returns (which simply represent possible next-day losses of the portfolio) are examined.
So, the first step is to cut off a small number of past return observations as in the following SAS data step:

```sas
/* Keep only the last 250 observations of the data */
data returns;
   set returns nobs=observ;
   if (_N_ > observ-250);
run;
```

The following statements fit a $t$ copula to the returns data and at the same time simulate the sample from the fitted joint distribution:

```sas
/* Copula estimation and simulation of returns */
proc copula data = returns;
   var ret_ibm ret_msft ret_bp ret_ko ret_duk;
   * fit $T$-copula to stock returns;
   fit T /
      marginals = empirical
      method = MLE
      plots = (datatype = both);
   * simulate 10000 observations;
   * independent in time, dependent in cross-section;
   simulate /
      ndraws = 10000
      seed = 1234
      out = simulated_returns
      plots(unpack) = (datatype = original);
run;
```

The first line of COPULA procedure uses a VAR statement to specify the list of variables. In this example, these are daily returns of five large-company stocks. The next statement, FIT, requires some options. First, Student’s $t$ copula ($T$) is specified. After the slash, the MARGINALS=EMPIRICAL option specifies that an empirical distribution be fit. The choice of fitting method is MLE. The PLOTS=BOTH option requests that both original and transformed data graphs be organized into a symmetric panel.

Then, given the estimation results, the NDRAWS= option in the SIMULATE statement simulates 10,000 new observations for each asset return series. The SEED= option fixes the random number generator, the OUT= option specifies the name of SAS data set to contain the simulated sample, and the PLOT= option requests scatter plots of simulated returns in the original data scale.
The output of these statements is shown in Output 10.1.2.

</tbody>
</table>

The first table in Output 10.1.2, “Model Fit Summary,” provides some general description of copula model estimation. The second table, “Parameter Estimates,” provides point estimates and inference on copula parameters. In this example the only parameter in this table is the number of degrees of freedom in the multivariate \( t \) distribution. The last table, “Correlation Matrix,” contains estimates of copula model parameters.

The graphical output of the preceding statements is in Output 10.1.3 and in Output 10.1.4.
Output 10.1.3: Original Data
Chapter 10: The COPULA Procedure

Output 10.1.4 Original Data Transformed into Uniform Marginals

Note that in Output 10.1.3 the most elliptical scatter plot, between IBM and MSFT, indicates the strongest dependence. Similarly, in Output 10.1.4 those graphs that are denser along the diagonal indicate the same thing.

Now the equally weighted next day portfolio return is computed. Each individual return is transformed into nominal scale first, then all returns are added up with equal weights, and the result is transformed into a net return by subtracting one.
Example 10.1: Copula Based VaR Estimation

```sas
/* compute equally weighted portfolio return */
data port_ret (drop = i ret);
   set simulated_returns;
   array returns{5} ret_ibm ret_msft ret_bp ret_ko ret_duk;
   ret = 0;
   do i = 1 to 5;
      ret = ret + 0.2*exp(returns[i]);
   end;
   port_ret = ret - 1;
run;
```

The final step is to compute empirical quantiles of simulated daily portfolio return. This is done with the help of PROC UNIVARIATE in the following statements:

```sas
/* compute descriptive statistics */
/* quantile table will give Value-at-Risk estimates for the portfolio */
proc univariate data = port_ret;
   var port_ret;
run;
```

Output 10.1.5 shows that with 99\% confidence the potential loss on an equally weighted portfolio over the next day does not exceed 2.6\% (the number in table is multiplied by 100). You can also say that there is no more than 5\% chance of losing 1.5\% of the portfolio value. These percentage measures are exactly the value-at-risk.

Example 10.2: Simulating Default Times

Suppose the correlation structure required for a normal copula function is already given. For example, it can be estimated from the historic data on default times in some set of industries, but this stage is not in the scope of this example. The correlation structure is saved in a SAS data set called Inparm. The following statements and their output in Output 10.2.1 show that the correlation parameter is set at 0.8:

```sas
proc print data = inparm;
run;
```

<td>0.8</td>
<td>1.0</td>
</tr>
</tbody>
</table>

Now you use PROC COPULA to simulate the data. The VAR statement specifies the list of variables to contain simulated data. The DEFINE statement assigns the name COP and specifies a normal copula that reads the correlation matrix from the inparm data set.

The SIMULATE statement refers to the COP label defined in the VAR statement and specifies some options: the NDRAWS= option specifies a sample size, the SEED= option specifies 1234 as the random number generator seed, the OUTUNIFORM=NORMAL_UNIFDATA option names the output data set for the result of simulation in uniforms, and the PLOTS= option requests the matrix of data scatter plots and marginal distributions (DATATYPE=ORIGINAL) and theoretical cumulative distribution function contour and surface plots (DISTRIBUTION=CDF). Theoretical distribution graphs work only for the bivariate case.

```sas
/* simulate the data from bivariate normal copula */
proc copula ;
  var Y1-Y2;
  define cop normal (corr=inparm);
  simulate cop /
      ndraws = 500
      seed = 1234
      outuniform = normal_unifdata
      plots = (datatype = original
               distribution = cdf);
run;
```
The graphical output is shown in Output 10.2.2 and in Output 10.2.3.

**Output 10.2.2** Simulated Data, Uniform Marginals

Output 10.2.2 shows bivariate scatter plots of the simulated data. Also note that due to the high correlation parameter (0.8), the scatter plots are most dense around the 45 degree line, which indicates high dependence between the two variables.
Output 10.2.3 shows the theoretical CDF contour plot. If the correlation parameter were set to 0, then knowing copula properties you would expect perfectly parallel straight lines with the slope of $-45$ degrees. On the other hand, if the parameter were set to 1, you would expect perpendicular lines with corners lying on the diagonal.
Example 10.2: Simulating Default Times

The next DATA step transforms the variables from zero-one uniformly distributed to nonnegative exponentially distributed with parameter 0.5. Three indicator variables are added to the data set as well. SURVIVE1 and SURVIVE2 are equal to 1 if a respective company has remained in business for more than three years. SURVIVE is equal to 1 if both companies survived the same period together.

```sas
/* default time has exponential marginal distribution with parameter 0.5 */
data default;
  set normal_unifdata;
  array arr(2) Y1-Y2;
  array time(2) time1-time2;
  array surv(2) survive1-survive2;
  lambda = 0.5;
  do i=1 to 2;
    time[i] = -log(1-arr[i])/lambda;
    surv[i] = 0;
    if (time[i] >3) then surv[i]=1;
  end;
  survive = 0;
  if (time1 >3) && (time2 >3) then survive = 1;
run;
```

The first analysis step is to look at correlations between survival times of two companies. This step is performed with the following CORR procedure:

```sas
proc corr data = default plot=matrix kendall;
  var time1 time2;
run;
```

The output of this code is given in Output 10.2.4 and in Output 10.2.5.
Output 10.2.4 shows some descriptive statistics and two measures of correlation: Pearson and Kendall. Both of these measures indicate high and statistically significant dependence between life spans of two companies.

**Output 10.2.4** Default Time Descriptive Statistics and Correlations

```

</tbody>
</table>
```

Output 10.2.5 shows marginal distributions and scatter plots of simulated data. Distributions are noticeably close to exponential and scatter plots show a high degree of dependence.
The second and the last step is to empirically estimate the default probabilities of two companies. This is done in the following FREQ procedure:

```plaintext
proc freq data=default;
  table survive survive1-survive2;
run;
```
The result is shown in **Output 10.2.6**.

### Output 10.2.6  Probabilities of Default

<td>390</td>
<td>78.00</td>
</tr>
<tr>
<td>1</td>
<td>110</td>
<td>22.00</td>
<td>500</td>
<td>100.00</td>
</tr>
</tbody>
</table>

**Output 10.2.6** shows that the empirical default probabilities are 75% and 78%. Assuming that these companies are independent gives the probability estimate of both companies defaulting during the period of three years as: 0.75*0.78=0.59 (59%). Comparing this naive estimate with the much higher actual 83% joint default probability illustrates that neglecting the correlation between the two companies significantly underestimates the probability of default.

Overview: COUNTREG Procedure

The COUNTREG (count regression) procedure analyzes regression models in which the dependent variable takes nonnegative integer or count values. The dependent variable is usually an event count, which refers to the number of times an event occurs. For example, an event count might represent the number of ship accidents per year for a given fleet. In count regression, the conditional mean $E(y_i | x_i)$ of the dependent variable $y_i$ is assumed to be a function of a vector of covariates $x_i$.

The Poisson (log-linear) regression model is the most basic model that explicitly takes into account the nonnegative integer-valued aspect of the outcome. With this model, the probability of an event count is determined by a Poisson distribution, where the conditional mean of the distribution is a function of a vector of covariates. However, the basic Poisson regression model is limited because it forces the conditional mean of the outcome to equal the conditional variance. This assumption is often violated in real-life data. Negative binomial regression is an extension of Poisson regression in which the conditional variance can exceed the conditional mean. Also, a common characteristic of count data is that the number of zeros in the sample exceeds the number of zeros that are predicted by either the Poisson or negative binomial model. Zero-inflated Poisson (ZIP) and zero-inflated negative binomial (ZINB) models explicitly model the production of zero counts to account for excess zeros and also enable the conditional variance of the outcome to differ from the conditional mean.

In zero-inflated models, additional zeros occur with probability $\psi_i$, which is determined by a separate model, $\psi_i = F(z_i' \beta)$, where $F$ is the normal or logistic distribution function that results in a probit or logistic model and $z_i$ is a set of covariates.

PROC COUNTREG supports the following models for count data:

- Poisson regression
- Conway-Maxwell-Poisson regression
- negative binomial regression with quadratic (NEGBIN2) and linear (NEGBIN1) variance functions (Cameron and Trivedi 1986)
• zero-inflated Poisson (ZIP) model (Lambert 1992)
• zero-inflated Conway-Maxwell-Poisson (ZICMP) model
• zero-inflated negative binomial (ZINB) model
• fixed-effects and random-effects Poisson models for panel data
• fixed-effects and random-effects negative binomial models for panel data

The count data models have been used extensively in economics, political science, and sociology. For example, Hausman, Hall, and Griliches (1984) examine the effects of research and development expenditures on the number of patents obtained by U.S. companies. Cameron and Trivedi (1986) study factors that affect the number of doctor visits that a group made during a two-week period. Greene (1994) studies the number of derogatory reports to a credit reporting agency for a group of credit card applicants. As a final example, Long (1997) analyzes the number of publications by Ph.D. candidates in science in the final three years of their doctoral studies.

The COUNTREG procedure uses maximum likelihood estimation. When a model that contains a dependent count variable is estimated using linear ordinary least squares (OLS) regression, the count nature of the dependent variable is ignored. This can lead to negative predicted counts and to parameter estimates that have undesirable properties in terms of statistical efficiency, consistency, and unbiasedness unless the mean of the counts is high, in which case the Gaussian approximation and linear regression might be satisfactory.

---

**Getting Started: COUNTREG Procedure**

The COUNTREG procedure is similar in use to other SAS regression model procedures. For example, the following statements are used to estimate a Poisson regression model:

```sas
proc countreg data=one ;
   model y = x / dist=poisson ;
run;
```

The response variable `y` is numeric and has nonnegative integer values. To allow for variance greater than the mean, specify the DIST=NEGBIN option to fit the negative binomial model instead of the Poisson.

The following example illustrates the use of PROC COUNTREG. The data are taken from Long (1997) and can be found in the SAS/ETS Sample Library. This study examines how factors such as gender (`fem`), marital status (`mar`), number of young children (`kid5`), prestige of the graduate program (`phd`), and number of articles published by the mentor (`ment`) of a doctoral candidate in science affect the number of articles (`art`) published by the scientist.

The first 10 observations are shown in Figure 11.1.

</tbody>
</table>

The following SAS statements estimate the Poisson regression model:

```
proc countreg data=long97data;
  model art = fem mar kid5 phd ment / dist=poisson;
run;
```

The “Model Fit Summary” table, shown in Figure 11.2, lists several details about the model. By default, the COUNTREG procedure uses the Newton-Raphson optimization technique. The maximum log-likelihood value is shown, in addition to two information measures, Akaike’s information criterion (AIC) and Schwarz’s Bayesian information criterion (SBC), which can be used to compare competing Poisson models. Smaller values of these criteria indicate better models.

Figure 11.2 Estimation Summary Table for a Poisson Regression

</tbody>
</table>
The parameter estimates of the model and their standard errors are shown in Figure 11.3. All covariates are significant predictors of the number of articles, except for the prestige of the program (phd), which has a \( p \)-value of 0.6271.

**Figure 11.3** Parameter Estimates of Poisson Regression

| Parameter | DF | Estimate  | Standard Error  | t Value | Pr > |t| |
|-----------|----|-----------|-----------------|---------|------|----|
| Intercept | 1  | 0.304617  | 0.102982        | 2.96    | 0.0031 |
| fem       | 1  | -0.224594 | 0.054614        | -4.11   | <.0001 |
| mar       | 1  | 0.155243  | 0.061375        | 2.53    | 0.0114 |
| kid5      | 1  | -0.184883 | 0.040127        | -4.61   | <.0001 |
| phd       | 1  | 0.012823  | 0.026397        | 0.49    | 0.6271 |
| ment      | 1  | 0.025543  | 0.002006        | 12.73   | <.0001 |

The following statements fit the negative binomial model. Although the Poisson model requires that the conditional mean equal the conditional variance, the negative binomial model allows for overdispersion; that is, the conditional variance can exceed the conditional mean.

```sas
proc countreg data=long97data;
   model art = fem mar kid5 phd ment / dist=negbin(p=2) method=qn;
run;
```

The fit summary is shown in Figure 11.4, and parameter estimates are listed in Figure 11.5.

Figure 11.5  Parameter Estimates of Negative Binomial Regression

| Parameter | DF | Estimate | Standard Error | t Value | Pr > |t|  |
|-----------|----|----------|----------------|---------|-------|----|
| Intercept | 1  | 0.256144 | 0.138560       | 1.85    | 0.0645|
| fem       | 1  | -0.216418| 0.072672       | -2.98   | 0.0029|
| mar       | 1  | 0.150489 | 0.082106       | 1.83    | 0.0668|
| kid5      | 1  | -0.176415| 0.053060       | -3.32   | 0.0009|
| phd       | 1  | 0.015271 | 0.036040       | 0.42    | 0.6718|
| ment      | 1  | 0.029082 | 0.003470       | 8.38    | <.0001|
| _Alpha    | 1  | 0.441620 | 0.052967       | 8.34    | <.0001|

The parameter estimate for _Alpha of 0.4416 is an estimate of the dispersion parameter in the negative binomial distribution. A t test for the hypothesis $H_0: \alpha = 0$ is provided. It is highly significant, indicating overdispersion ($p < 0.0001$).

The null hypothesis $H_0: \alpha = 0$ can be also tested against the alternative $\alpha > 0$ by using the likelihood ratio test, as described by Cameron and Trivedi (1998, pp. 45, 77–78). The likelihood ratio test statistic is equal to $-2(\hat{L}_P - \hat{L}_{NB}) = -2(-1651 + 1561) = 180$, where $\hat{L}_P$ and $\hat{L}_{NB}$ are the log likelihoods for the Poisson and negative binomial models, respectively. The likelihood ratio test is highly significant, providing strong evidence of overdispersion.

Syntax: COUNTREG Procedure

The following statements are available in the COUNTREG procedure:

```
PROC COUNTREG <options> ;
   BOUNDS bound1 < , bound2 . . .> ;
   BY variables ;
   CLASS variables ;
   DISPMODEL dependent variable ~ < dispersion-related regressors > ;
   FREQ variable ;
   INIT initvalue1 < , initvalue2 . . . > ;
   MODEL dependent = < regressors >/ options > ;
   NLOPTIONS < options > ;
   OUTPUT < OUT=SAS-data-set> < output-options > ;
   RESTRICT restriction1 < , restriction2 . . .> ;
   SCORE DATA=SAS-data-set < OUT=SAS-data-set > < output-options > ;
   SHOW options ;
   STORE <OUT=> item-store-name ;
   WEIGHT variable </options> ;
   ZEROMODEL dependent variable ~ < zero-inflated regressors > </options> ;
```
You can specify only one MODEL statement. The CLASS statement must precede the MODEL statement. If you include the ZEROMODEL statement, it must appear after the MODEL statement. If you specify more than one FREQ or WEIGHT statement, the variable that is specified in the first instance is used.

### Functional Summary

PROC COUNTREG Statement

PROC COUNTREG <options> ;

You can specify the following options in the PROC COUNTREG statement.

Data Set Options

DATA=SAS-data-set
specifies the input SAS data set. If the DATA= option is not specified, PROC COUNTREG uses the most recently created SAS data set.

GROUPID=variable
specifies an identification variable when a panel data model is estimated. The identification variable is used as a cross-sectional ID variable.

Item Store Control Options (Experimental)

RESTORE=item-store-name
specifies the source item store for processing. An item-store-name consists of a one- or two-level name, as with SAS data sets. As with data sets, an item store is associated by default with the Work library, and any item stores that are created in this library are deleted when the SAS session concludes.

Output Data Set Options

OUTEST=SAS-data-set
writes the parameter estimates to the specified output data set.

COVOUT
writes the covariance matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.
Chapter 11: The COUNTREG Procedure

Printing Options

**CORRB**
prints the correlation matrix of the parameter estimates. This option can also be specified in the MODEL statement.

**COVB**
prints the covariance matrix of the parameter estimates. This option can also be specified in the MODEL statement.

**NOPRINT**
suppresses all printed output.

Estimation Control Options

**COVEST=value**
specifies the type of covariance matrix of the parameter estimates. The quasi-maximum-likelihood estimates are computed using COVEST=QML. By default, COVEST=HESSIAN. The supported covariance types are as follows:

- **HESSIAN** specifies the covariance from the Hessian matrix.
- **OP** specifies the covariance from the outer product matrix.
- **QML** specifies the covariance from the outer product and Hessian matrices.

Plot Control Options

**PLOTS<global-plot-options> < = specific-plot-options>**
requests that the COUNTREG procedure produce statistical graphics via the Output Delivery System, provided that ODS GRAPHICS has been enabled. For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” (SAS/STAT User’s Guide). The **global-plot-options** apply to all relevant plots that are generated by the COUNTREG procedure.

You can specify the following **global-plot-options**:

**COUNTS(value1 <value2...>)**
supplies the plots PREDPROB and PREDPROFILE with particular values of the response variable. Each value should be a nonnegative integer. Nonintegers are rounded to the nearest integer. The value can also be a list of the form X TO Y BY Z. For example, COUNTS(0 1 2 TO 10 BY 2 15) specifies plotting for counts 0, 1, 2, 4, 6, 8, 10, and 15.

**ONLY**
suppresses the default plots. Only the plots that are specifically requested are produced.

**UNPACKPANEL**
**UNPACK**
displays each graph separately. (By default, some graphs can appear together in a single panel.)

You can specify the following **specific-plot-options**:
requests that all plots appropriate for the particular analysis be produced.

**DISPERSION**

produces the overdispersion diagnostic plot.

**NONE**

suppresses all plots.

**PREDPROB**

produces the overall predictive probabilities of the specified count levels. You must also specify COUNTS in global-plot-options.

**PREDPROFILE**

produces the predictive probability profiles of specified count levels against model regressors. The regressor on the X axis is varied, whereas all other regressors are fixed at the mean of the observed data set.

**PROFILELIKE**

produces the profile likelihood functions of the model parameters. The model parameter on the X axis is varied, whereas all other parameters are fixed at their estimated maximum likelihood estimates.

**ZEROPROFILE | ZPPRO**

produces the probability profiles of zero-inflation process selection and zero count prediction against model regressors. The regressor on the X axis is varied, whereas all other regressors are fixed at the mean of the observed data set.

**Optimization Process Control Options**

PROC COUNTREG uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. All the NLO options are available in the NLOPTIONS statement. For more information, see the “NLOPTIONS Statement” on page 576. In addition, you can specify the following option in the PROC COUNTREG statement:

**METHOD=value**

specifies the iterative minimization method to use. By default, METHOD=NRA.
BOUNDS Statement

BOUNDS bound1 <, bound2 . . . > ;

The BOUNDS statement imposes simple boundary constraints on the parameter estimates. BOUNDS statement constraints refer to the parameters that are estimated by the COUNTREG procedure. You can specify any number of BOUNDS statements as follows.

Each bound is composed of parameter names, constants, and inequality operators as follows:

item operator item < operator item operator item . . . >

Each item is a constant, a parameter name, or a list of parameter names. Each operator is <, >, <=, or >=.

You can use both the BOUNDS statement and the RESTRICT statement to impose boundary constraints; however, the BOUNDS statement provides a simpler syntax for specifying these kinds of constraints. See also the section “RESTRICT Statement” on page 578.

The following BOUNDS statement constrains the estimates of the parameter for z to be negative, the parameters for x1 through x10 to be between zero and one, and the parameter for x1 in the zero-inflation model to be less than one:

bounds z < 0,
0 < x1-x10 < 1,
Inf_x1 < 1;

BY Statement

BY variables ;

A BY statement can be used with PROC COUNTREG to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the input data set should be sorted in the order of the BY variables.

CLASS Statement

CLASS variable < options > . . . < variable < options > > < /global-options > ;

The CLASS statement names the classification variables that are used to group (classify) data in the analysis. Classification variables can be either character or numeric.

Class levels are determined from the formatted values of the CLASS variables. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in the SAS Language Reference: Dictionary for details. The CLASS statement must precede the MODEL statement.

Most options can be specified either as individual variable options or as global-options. You can specify options for each variable by enclosing the options in parentheses after the variable name. You can also specify global-options for the CLASS statement by placing them after a slash (/). Global-options are applied to all the variables that are specified in the CLASS statement. If you specify more than one CLASS statement, the
**global-options** specified in any one CLASS statement apply to all CLASS statements. However, individual CLASS variable **options** override the **global-options**. You can specify the following values for either an **option** or a **global-option**:

**MISSING**

treats missing values (., _, .A, ., .Z for numeric variables and blanks for character variables) as valid values for the CLASS variable.

**ORDER=DATA | FORMATTED | FREQ | INTERNAL**
specifies the sort order for the levels of classification variables. This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option can be useful when you use the CONTRAST statement. By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent. When ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values.

The following table shows how PROC COUNTREG interprets values of the ORDER= option.

<table>
<thead>
<tr>
<th>Value of ORDER=</th>
<th>Levels Sorted By</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA</td>
<td>Order of appearance in the input data set</td>
</tr>
<tr>
<td>FORMATTED</td>
<td>External formatted values, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) values</td>
</tr>
<tr>
<td>FREQ</td>
<td>Descending frequency count; levels with more observations come earlier in the order</td>
</tr>
<tr>
<td>INTERNAL</td>
<td>Unformatted value</td>
</tr>
</tbody>
</table>

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

**PARAM=keyword**
specifies the parameterization method for the classification variable or variables. You can specify any of the **keywords** shown in the following table; by default, PARAM=GLM.

Design matrix columns are created from CLASS variables according to the corresponding coding schemes:

<table>
<thead>
<tr>
<th>Value of PARAM=</th>
<th>Coding</th>
</tr>
</thead>
<tbody>
<tr>
<td>EFFECT</td>
<td>Effect coding</td>
</tr>
<tr>
<td>GLM</td>
<td>Less-than-full-rank reference cell coding (this <strong>keyword</strong> can be used only in a global option)</td>
</tr>
<tr>
<td>REF</td>
<td>Reference cell coding</td>
</tr>
</tbody>
</table>

All parameterizations are full rank, except for the GLM parameterization. The **REF=** option in the CLASS statement determines the reference level for effect and reference coding and for their orthogonal parameterizations. It also indirectly determines the reference level for a singular GLM parameterization through the order of levels.
**Chapter 11: The COUNTREG Procedure**

**REF=’level’ | keyword**

specifies the reference level for PARAM=EFFECT, PARAM=REFERENCE, and their orthogonalizations. When PARAM=GLM, the REF= option specifies a level of the classification variable to be put at the end of the list of levels. This level thus corresponds to the reference level in the usual interpretation of the linear estimates with a singular parameterization.

For an individual variable REF= option (but not for a global REF= option), you can specify the level of the variable to use as the reference level. Specify the formatted value of the variable if a format is assigned. For a global or individual variable REF= option, you can use one of the following keywords. By default, REF=LAST.

- **FIRST** designates the first-ordered level as reference.
- **LAST** designates the last-ordered level as reference.

---

**DISPMODEL Statement**

```
DISPMODEL dependent-variable ~ <dispersion-related regressors> ;
```

The DISPMODEL statement names the variables that are used to model dispersion. This statement is ignored unless you specify DIST=CMPOISSON in the MODEL statement. The dependent-variable in the DISPMODEL statement must be the same as the dependent-variable in the MODEL statement.

The dependent-variables that appear in the DISPMODEL statement are directly used to model dispersion. Each of these $q$ variables has a parameter to be estimated in the regression. For example, let $g_i'$ be the $i$th observation’s $1 \times (q + 1)$ vector of values of the $q$ dispersion explanatory variables ($g_0$ is set to 1 for the intercept term). Then the dispersion is a function of $g_i' \delta$, where $\delta$ is the $(q + 1) \times 1$ vector of parameters to be estimated, the dispersion model intercept is $\delta_0$, and the coefficients for the $q$ dispersion covariates are $\delta_1, \ldots, \delta_q$. If you specify DISP=CMPOISSON in the MODEL statement but do not include a DISPMODEL statement, then only the intercept term $\delta_0$ is estimated. The “Parameter Estimates” table in the displayed output shows the estimates for the dispersion intercept and dispersion explanatory variables; they are labeled with the prefix “Disp_”. For example, the dispersion intercept is labeled “Disp_Intercept”. If you specify Age (a variable in your data set) as a dispersion explanatory variable, then the “Parameter Estimates” table labels the corresponding parameter estimate “Disp_Age”. The following statements fit a Conway-Maxwell-Poisson model by using the covariates SEX, ILLNESS, and INCOME and by using AGE as a dispersion covariate:

```plaintext
proc countreg data=docvisit;
  model doctorvisits=sex illness income / dist=cmpoisson;
  dispmodel doctorvisits ~ age;
run;
```

---

**FREQ Statement**

```
FREQ variable ;
```

The FREQ statement specifies a variable whose values represent the frequency of occurrence of each observation. PROC COUNTREG treats each observation as if it appears $n$ times, where $n$ is the value of the
FREQ variable for the observation. If the frequency value is not an integer, it is truncated to an integer; if it is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not specified, each observation is assigned a frequency of 1. If you specify more than one FREQ statement, then the first statement is used.

**INIT Statement**

```
INIT initvalue1 <, initvalue2 . . . > ;
```

The INIT statement sets initial values for parameters in the optimization. Each `initvalue` is written as a parameter or parameter list, followed by an optional equal sign (=), followed by a number:

```
parameter <= number
```

For continuous regressors, the names of the parameters are the same as the corresponding variables. For a regressor that is a CLASS variable, the parameter name combines the corresponding CLASS variable name with the variable level. For interaction and nested regressors, the parameter names combine the names of each regressor. The names of the parameters can be seen in the OUTEST= data set. By default, initial values are determined by OLS regression. Initial values can be displayed with the ITPRINT option in the PROC statement.

**MODEL Statement**

```
MODEL dependent-variable = <regressors> </ options> ;
```

The MODEL statement specifies the `dependent-variable` and independent covariates (`regressors`) for the regression model. If you specify no `regressors`, PROC COUNTREG fits a model that contains only an intercept. The dependent count variable should take on only nonnegative integer values in the input data set. PROC COUNTREG rounds any positive noninteger count values to the nearest integer. PROC COUNTREG ignores any observations that have a negative count.

Only one MODEL statement can be specified. You can specify following `options` in the MODEL statement after a slash (/).

**DIST=value**

specifies a type of model to be analyzed. If you specify this option in both the MODEL statement and the PROC COUNTREG statement, then only the value in the MODEL statement is used. The following model types are supported:

- **POISSON P** specifies a Poisson regression model.
- **CMPOISSON C | CMP** specifies a Conway-Maxwell-Poisson regression model.
- **NEGBIN(P=1)** specifies a negative binomial regression model with a linear variance function.
- **NEGBIN(P=2) | NEGBIN** specifies a negative binomial regression model with a quadratic variance function.
- **ZIPOISSON ZIP** specifies a zero-inflated Poisson regression. The ZEROMODEL statement must be specified when this model type is specified.
ZICMPOISSON | ZICMP specifies a zero-inflated Conway-Maxwell-Poisson regression. The ZEROMODEL statement must be specified when this model type is specified.

ZINEGBIN | ZINB specifies a zero-inflated negative binomial regression. The ZEROMODEL statement must be specified when this model type is specified.

ERRORCOMP=value
specifies a type of conditional panel model to be analyzed. The following model types are supported:

  FIXED specifies a fixed-effect error component regression model.
  RANDOM specifies a random-effect error component regression model.

NOINT
suppresses the intercept parameter.

OFFSET=variable
specifies a variable in the input data set to be used as an offset variable. The offset variable appears as a covariate in the model with its parameter restricted to 1. The offset variable cannot be the response variable, the zero-inflation offset variable (if any), or one of the explanatory variables. The “Model Fit Summary” table gives the name of the data set variable used as the offset variable; it is labeled as “Offset.”

PARAMETER=MU | LAMBDA
specifies the parameterization for the Conway-Maxwell-Poisson model. The following parameterizations are supported:

  LAMBDA estimates the original Conway-Maxwell-Poisson model (Shmueli et al. (2005))
  MU reparameterizes \( \lambda \) as documented by Guikema and Coffelt (2008), where \( \mu = \lambda^{1/v} \) and the integral part of \( \mu \) represents the mode, which can be considered a measure of central tendency (mean).

By default, PARAMETER=MU.

SELECT=INFO< (options)>
SELECTVAR=INFO< (options)>

SELECT=PEN< (options)>
SELECTVAR=PEN< (options)>

specifies variable selection.

SELECT=INFO requests that the variable selection method be based on an information criterion. For more information, see the section “Variable Selection Using an Information Criterion” on page 601. You can specify the following options:
DIRECTION=FORWARD | BACKWARD
specifies the search algorithm to use in the variable selection method. By default, DIRECTION=FORWARD.

CRITER=AIC | SBC
specifies the information criteria to use in the variable selection. By default, CRITER=SBC.

MAXSTEPS=value
specifies the maximum number of steps to allow in the search algorithm. The default is infinite; that is, the algorithm does not stop until the stopping criterion is satisfied.

LSTOP=value
specifies the stopping criterion. The value represents the percentage of decrease or increase in the AIC or SBC that is required for the algorithm to proceed; it must be a positive number less than 1. By default, LSTOP=0.

RETAINT(variable1 <variable2...>)
specifies that the variables named within parentheses be retained during the variable selection process.

SELECT=PEN requests the penalized likelihood variable selection method. For more information, see the section “Variable Selection Using Penalized Likelihood” on page 602. You can specify the following options:

LLASTEPS=value
specifies the maximum number of iterations in the algorithm of local linear approximations. By default, LLASTEPS=5.

GCVLENGTH=value
specifies the number of different values to use for the generalized cross validation (GCV) tuning parameter. The value corresponds to \( \lambda \) in the computations that are described in the section “Variable Selection Using Penalized Likelihood” on page 602. By default, GCVLENGTH=20.

GCV
specifies the generalized cross-validation (GCV) approach. For more information, see the section “The GCV Approach” on page 603.

GCV1
specifies the GCV1 approach. For more information, see the section “The GCV1 Approach” on page 604.

When SELECT=PEN, GCV1 is the default.

Printing Options
CORRB
prints the correlation matrix of the parameter estimates. The CORRB option can also be specified in the PROC COUNTREG statement.
**Chapter 11: The COUNTREG Procedure**

**COVB**
prints the covariance matrix of the parameter estimates. The COVB can also be specified in the PROC COUNTREG statement.

**ITPRINT**
prints the objective function and parameter estimates at each iteration. The objective function is the negative log-likelihood function. The ITPRINT option can also be specified in the PROC COUNTREG statement.

**PRINTALL**
requests all printing options. The PRINTALL option can also be specified in the PROC COUNTREG statement.

---

**NLOPTIONS Statement**

```plaintext
NLOPTIONS <options> ;
```

The NLOPTIONS statement provides the options to control the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. For a list of all the options of the NLOPTIONS statement, see Chapter 6, “Nonlinear Optimization Methods.”

---

**OUTPUT Statement**

```plaintext
OUTPUT <OUT=SAS-data-set> <output-options> ;
```

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimates of $x_i^\prime \beta$, the expected value of the response variable, and the probability of the response variable taking on the current value or other values that you specify. In a zero-inflated model, you can additionally request that the output data set contain the estimates of $z_i^\prime \gamma$ and the probability that the response is zero as a result of the zero-generating process. For the Conway-Maxwell-Poisson model, the estimates of $g_i^\prime \delta$, $\lambda$, $v$, $\mu$, mode, variance, and dispersion are also available. Except for the probability of the current value, these statistics can be computed for all observations in which the regressors are not missing, even if the response is missing. By adding observations that have missing response values to the input data set, you can compute these statistics for new observations or for settings of the regressors that are not present in the data without affecting the model fit.

You can specify only one OUTPUT statement. You can specify the following `output-options`:

- **OUT=SAS-data-set**
  names the output data set.

- **XBETA=name**
  names the variable that contains estimates of $x_i^\prime \beta$.

- **PRED=name**
  **MEAN=name**
  assigns a name to the variable that contains the predicted value of the response variable.
**OUTPUT Statement**  ♦  577

**PROB**=\textit{name}

names the variable that contains the probability of the response variable taking the current value, \( \Pr(Y = y_i) \).

**PROBCOUNT\((\textit{value1 <value2...})\)**

outputs the probability that the response variable will take particular values. Each value should be a nonnegative integer. Nonintegers are rounded to the nearest integer. The \textit{value} can also be a list of the form X TO Y BY Z. For example, PROBCOUNT(0 1 2 TO 10 BY 2 15) requests predicted probabilities for counts 0, 1, 2, 4, 5, 6, 8, 10, and 15. This option is not available for the fixed-effects and random-effects panel models.

**ZGAMMA**=\textit{name}

names the variable that contains estimates of \( z_i' \).

**PROBZERO**=\textit{name}

names the variable that contains the value of \( \varphi_i \), the probability of the response variable taking on the value of zero as a result of the zero-generating process. It is written to the output file only if the model is zero-inflated. This is not the overall probability of a zero response; that is provided by the PROBCOUNT(0) option.

**GDELTA**=\textit{name}

assigns a name to the variable that contains estimates of \( g_0' \delta \) for the Conway-Maxwell-Poisson distribution.

**LAMBDA**=\textit{name}

assigns a name to the variable that contains the estimate of \( \lambda \) for the Conway-Maxwell-Poisson distribution.

**NU**=\textit{name}

assigns a name to the variable that contains the estimate of \( \nu \) for the Conway-Maxwell-Poisson distribution.

**MU**=\textit{name}

assigns a name to the variable that contains the estimate of \( \mu \) for the Conway-Maxwell-Poisson distribution.

**MODE**=\textit{name}

assigns a name to the variable that contains the integral part of \( \mu \) (mode) for the Conway-Maxwell-Poisson distribution.

**VARIANCE**=\textit{name}

assigns a name to the variable that contains the estimate of variance for the Conway-Maxwell-Poisson distribution.

**DISPERSION**=\textit{name}

assigns a name to the variable that contains the value of dispersion for the Conway-Maxwell-Poisson distribution.
**RESTRICT Statement**

```
RESTRICT restriction1 <, restriction2 . . . ;
```

The RESTRICT statement imposes linear restrictions on the parameter estimates. You can specify any number of RESTRICT statements.

Each `restriction` is written as an expression, followed by an equality operator (`=`) or an inequality operator (`<`, `>`, `<=`, `>=`), followed by a second expression:

```
expression operator expression
```

The `operator` can be `=`, `<`, `>`, `<=`, or `>=`.

Restriction expressions can be composed of parameter names, constants, and the operators times (`*`), plus (`+`), and minus (`-`). The restriction expressions must be a linear function of the parameters. For continuous regressors, the names of the parameters are the same as the corresponding variables. For a regressor that is a CLASS variable, the parameter name combines the corresponding CLASS variable name with the variable level. For interaction and nested regressors, the parameter names combine the names of each regressor. The names of the parameters can be seen in the OUTEST= data set.

Lagrange multipliers are reported in the “Parameter Estimates” table for all the active linear constraints. They are identified with the names `Restrict1`, `Restrict2`, and so on. The probabilities of these Lagrange multipliers are computed using a beta distribution (LaMotte 1994). Nonactive (nonbinding) restrictions have no effect on the estimation results and are not noted in the output.

The following RESTRICT statement constrains the negative binomial dispersion parameter $\alpha$ to 1, which restricts the conditional variance to be $\mu + \mu^2$:

```
restrict _Alpha = 1;
```

**SCORE Statement (Experimental)**

```
SCORE DATA=SAS-data-set < OUT=SAS-data-set > < output-options > ;
```

The SCORE statement enables you to compute predicted values and other statistics for a SAS data set. As with the OUTPUT statement, the new data set that is created contains all the variables in the input data set and, optionally, the estimates of $x_i^T \hat{\beta}$, the expected value of the response variable, and the probability that the response variable will take the current value or other values that you specify. In a zero-inflated model, you can additionally request that the output data set contain the estimates of $z_i^T \gamma$ and the probability that the response is zero as a result of the zero-generating process. For the Conway-Maxwell-Poisson model, the estimates of $g_i^T \delta$, $\lambda$, $\nu$, $\mu$, mode, variance, and dispersion are also available. Except for the probability of the current value, these statistics can be computed for all observations in which the regressors are not missing, even if the response is missing.

The following statements fit a Poisson model by using the DocVisit data set. Additional observations in the additionalPatients data set are used to compute expected values by using the SCORE statement. The data in the additionalPatients data set are not used during the fitting stage and are used only for scoring.
SCORE Statement (Experimental)  ♦  579

```
proc countreg data=docvisit;
   model doctorvisits=sex illness income / dist=poisson;
   score data=additionalPatients out=outScores mean=meanPoisson;
run;
```

You could also fit the same model in two separate steps. In the first step, you would fit the model and use the STORE statement to preserve it in the DocVisitPoisson item store, as shown in the following statements:

```
proc countreg data=docvisit;
   model doctorvisits=sex illness income / dist=poisson;
   store docvisitPoisson;
run;
```

In the second step, you would retrieve the content of the DocVisitPoisson item store and use it to calculate expected values by using the SCORE statement for the DocVisitScore data set as follows:

```
proc countreg restore=docvisitPoisson;
   score data=additionalPatients out=outScores mean=meanPoisson probability=prob;
run;
```

By retrieving the model from the item store and using it in a postprocessing step, you can separate the fitting and scoring stages and use data for scoring that might not be available at the time when the model was fitted.

You can specify only one SCORE statement. You can specify the following output-options:

- **OUT=** SAS-data-set
  names the output data set.

- **XBETA=** name
  names the variable that contains estimates of $x_i'\beta$.

- **PRED=** name

- **MEAN=** name
  assigns a name to the variable that contains the predicted value of the response variable.

- **PROB=** name
  names the variable that contains the probability that the response variable will take the current value, $Pr(Y = y_i)$.

- **PROBCOUNT( value1 <value2...>)**
  outputs the probability that the response variable will take particular values. Each value should be a nonnegative integer. Nonintegers are rounded to the nearest integer. The value can also be a list of the form X TO Y BY Z. For example, PROBCOUNT(0 1 2 TO 10 BY 2 15) requests predicted probabilities for counts 0, 1, 2, 4, 5, 6, 8, 10, and 15. This option is not available for the fixed-effects and random-effects panel models.

- **ZGAMMA=** name
  names the variable that contains estimates of $z_i'\gamma$. 
PROBZERO=name
names the variable that contains the value of $\phi_i$, the probability of the response variable taking on the value of zero as a result of the zero-generating process. It is written to the output file only if the model is zero-inflated. This is not the overall probability of a zero response; that is provided by the PROBCOUNT(0) option.

GDELTA=name
assigns a name to the variable that contains estimates of $g'\delta$ for the Conway-Maxwell-Poisson distribution.

LAMBDA=name
assigns a name to the variable that contains the estimate of $\lambda$ for the Conway-Maxwell-Poisson distribution.

NU=name
assigns a name to the variable that contains the estimate of $\nu$ for the Conway-Maxwell-Poisson distribution.

MU=name
assigns a name to the variable that contains the estimate of $\mu$ for the Conway-Maxwell-Poisson distribution.

MODE=name
assigns a name to the variable that contains the integral part of $\mu$ (mode) for the Conway-Maxwell-Poisson distribution.

VARIANCE=name
assigns a name to the variable that contains the estimate of variance for the Conway-Maxwell-Poisson distribution.

DISPERSION=name
assigns a name to the variable that contains the value of dispersion for the Conway-Maxwell-Poisson distribution.

SHOW Statement (Experimental)

SHOW options ;

The SHOW statement displays the contents of the item store. You can use the SHOW statement to verify the contents of the item store before proceeding with the analysis.

Table 11.2 summarizes the options available in the SHOW statement.

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>

</tbody>
</table>

You can specify the following *options* after the SHOW statement:

**ALL | _ALL_**
    displays all applicable contents.

**CLASSLEVELS | CLASS**
    displays the “Class Level Information” table. This table is produced by the COUNTREG procedure by default if the model contains effects that depend on classification variables.

**CORRELATION | CORR | CORRB**
    produces the correlation matrix of the parameter estimates.

**COVARIANCE | COV | COVB**
    produces the covariance matrix of the parameter estimates.

**EFFECTS**
    displays information about the effects in the model.

**FITSTATS | FIT | FITSUMMARY**
    displays the fit statistics from the item store.

**PARAMETERS**

**PARMS**
    displays the parameter estimates table from the item store.

**PROGRAM**

**PROG**
    displays the SAS program that generates the item store, provided that this was stored at store generation time. The program does not include comments, titles, or some other global statements.

---

**STORE Statement (Experimental)**

```sas
STORE <OUT=>item-store-name ;
```

The STORE statement saves the contents of the analysis to an item store in a binary format that cannot be modified. You can restore the stored information by specifying the RESTORE= option in the PROC COUNTREG statement and use it in postprocessing analysis.
WEIGHT Statement

```
WEIGHT variable < / option> ;
```

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters. The log likelihood for each observation is multiplied by the corresponding weight variable value.

If the weight of an observation is nonpositive, that observation is not used in the estimation.

You can specify the following **option** after a slash (/):

**NONNORMALIZE**

- does not normalize the weights. By default, the weights are normalized so that they add up to the actual sample size. Weights \( w_i \) are normalized by multiplying them by \( \frac{n}{\sum_{i=1}^{n} w_i} \), where \( n \) is the sample size. If the weights are required to be used “as is,” then specify the NONNORMALIZE option.

ZEROMODEL Statement

```
ZEROMODEL dependent variable ~ < zero-inflated regressors > < / options > ;
```

The ZEROMODEL statement is required if you specify either ZIP or ZINB in the DIST= option in the MODEL statement. If ZIP or ZINB is specified, then the ZEROMODEL statement must follow immediately after the MODEL statement. The dependent variable in the ZEROMODEL statement must be the same as the dependent variable in the MODEL statement.

The zero-inflated (ZI) regressors appear in the equation that determines the probability \( (\varphi_i) \) of a zero count. Each of these \( q \) variables has a parameter to be estimated in the regression. For example, let \( z_i' \) be the \( i \)th observation’s \( 1 \times (q + 1) \) vector of values of the \( q \) ZI explanatory variables \( (w_0 \text{ is set to 1 for the intercept term}) \). Then \( \varphi_i \) is a function of \( z_i' y \), where \( y \) is the \( (q + 1) \times 1 \) vector of parameters to be estimated. (The ZI intercept is \( y_0 \); the coefficients for the \( q \) ZI covariates are \( y_1, \ldots, y_q \).) If this option is omitted, then only the intercept term \( y_0 \) is estimated. The “Parameter Estimates” table in the displayed output gives the estimates for the ZI intercept and ZI explanatory variables; they are labeled with the prefix “Inf_”. For example, the ZI intercept is labeled “Inf_intercept”. If you specify **Age** (a variable in your data set) as a ZI explanatory variable, then the “Parameter Estimates” table labels the corresponding parameter estimate “Inf_Age”.

You can specify the following options after a slash (/):

**LINK=**

- specifies the distribution function to use to compute probability of zeros. The following distribution functions are supported:
  
  - **LOGISTIC** specifies the logistic distribution.
  - **NORMAL** specifies the standard normal distribution.

If this option is omitted, then the default ZI link function is logistic.
OFFSET=variable
specifies a variable in the input data set to be used as a zero-inflated (ZI) offset variable. The ZI offset variable is included as a term, with its coefficient restricted to 1, in the equation that determines the probability (\( \phi_i \)) of a zero count. The ZI offset variable cannot be the response variable, the offset variable (if any), or one of the explanatory variables. The name of the data set variable that is used as the ZI offset variable is displayed in the “Model Fit Summary” output, where it is labeled as “Inf_offset”.

SELECT=INFO< (option) >
SELECTVAR=INFO< (option) >
specifies variable selection.

SELECT= INFO requests that the variable selection method be based on an information criterion. For more information, see the section “Variable Selection Using an Information Criterion” on page 601. You can specify the following options:

DIRECTION=FORWARD | BACKWARD
specifies the search algorithm to use in the variable selection method. By default, DIRECTION=FORWARD.

CRITER=AIC | SBC
specifies the information criterion to use in the variable selection. By default, CRITER=SBC.

MAXSTEPS=value
specifies the maximum number of steps to allow in the search algorithm. The default is infinite; that is, the algorithm does not stop until the stopping criterion is satisfied.

LSTOP=value
specifies the stopping criterion. The value represents the percentage of decrease or increase in the AIC or SBC that is required for the algorithm to proceed; it must be a positive number less than 1. By default, LSTOP=0.

RETAIN(variable1 <variable2...>)
requests that the variables named within the parentheses be retained during the variable selection process.

Details: COUNTRKG Procedure

Specification of Regressors

Each term in a model, called a regressor, is a variable or combination of variables. Regressors are specified in a special notation that uses variable names and operators. There are two kinds of variables: classification (CLASS) variables and continuous variables. There are two primary operators: crossing and nesting. A third operator, the bar operator, is used to simplify effect specification.

In the SAS System, classification (CLASS) variables are declared in the CLASS statement. (They can also be called categorical, qualitative, discrete, or nominal variables.) Classification variables can be either numeric
or character. The values of a classification variable are called levels. For example, the classification variable Sex has the levels “male” and “female.”

In a model, an independent variable that is not declared in the CLASS statement is assumed to be continuous. Continuous variables, which must be numeric, are used for covariates. For example, the heights and weights of subjects are continuous variables. A response variable is a discrete count variable and must also be numeric.

Types of Regressors

Seven different types of regressors are used in the COUNTREG procedure. In the following list, assume that A, B, C, D, and E are CLASS variables and that X1 and X2 are continuous variables:

- Regressors are specified by writing continuous variables by themselves: $X1 \times X2$.
- Polynomial regressors are specified by joining (crossing) two or more continuous variables with asterisks: $X1 \times X1 \times X1 \times X2$.
- Dummy regressors are specified by writing CLASS variables by themselves: A B C.
- Dummy interactions are specified by joining classification variables with asterisks: A*B B*C A*B*C.
- Nested regressors are specified by following a dummy variable or dummy interaction with a classification variable or list of classification variables enclosed in parentheses. The dummy variable or dummy interaction is nested within the regressor that is listed in parentheses: B(A) C(B*A) D*E(C*B*A). In this example, B(A) is read “B nested within A.”
- Continuous-by-class regressors are written by joining continuous variables and classification variables with asterisks: $X1*A$.
- Continuous-nesting-class regressors consist of continuous variables followed by a classification variable interaction enclosed in parentheses: $X1(A) \times X1*X2(A*B)$.

One example of the general form of an effect that involves several variables is

$$X1*X2*A*B*C(D*E)$$

This example contains an interaction between continuous terms and classification terms that are nested within more than one classification variable. The continuous list comes first, followed by the dummy list, followed by the nesting list in parentheses. Note that asterisks can appear within the nested list but not immediately before the left parenthesis.

The MODEL statement and several other statements use these effects. Some examples of MODEL statements that use various kinds of effects are shown in the following table, where a, b, and c represent classification variables. The variables x and z are continuous.

The Bar Operator

You can shorten the specification of a large factorial model by using the bar operator. For example, two ways of writing the model for a full three-way factorial model follow:

\[
\text{model } Y = A \mid B \mid C;
\]

\[
\text{model } Y = A \times B \times C;
\]

When the bar (\(\mid\)) is used, the right and left sides become effects, and the cross of them becomes an effect. Multiple bars are permitted. The expressions are expanded from left to right, using rules 2–4 given in Searle (1971, p. 390).

- Multiple bars are evaluated from left to right. For instance, \(A\mid B\mid C\) is evaluated as follows:

\[
A \mid B \mid C \rightarrow \{A \mid B\} \mid C
\]

\[
\rightarrow \{A \mid B\} \mid C
\]

\[
\rightarrow A \mid B \mid A \mid B \mid C \mid A \mid B \mid C
\]

- Crossed and nested groups of variables are combined. For example, \(A(B) \mid C(D)\) generates \(A\times C(B \times D)\), among other terms.

- Duplicate variables are removed. For example, \(A(C) \mid B(C)\) generates \(A\times B(C \times C)\), among other terms, and the extra \(C\) is removed.

- Effects are discarded if a variable occurs on both the crossed and nested parts of an effect. For instance, \(A(B) \mid B(D E)\) generates \(A\times B(B \times D E)\), but this effect is discarded immediately.

You can also specify the maximum number of variables involved in any effect that results from bar evaluation by specifying that maximum number, preceded by an @ sign, at the end of the bar effect. For example, the specification \(A \mid B \mid C \@2\) would result in only those effects that contain two or fewer variables: in this case, \(A \times B \times C\) \(A\times C\) and \(B\times C\).

More examples of using the \(\mid\) and @ operators follow:
A | C(B) is equivalent to A C(B) A*C(B)
A(B) | C(B) is equivalent to A(B) C(B) A*C(B)
A | B(D) is equivalent to A(B) B(D E)
A | B(A) | C is equivalent to A B(A) C A*C B*C(A)
A | B(A) | C@2 is equivalent to A B(A) C A*C
A | B | C | D@2 is equivalent to A B A*B C A*C B*C D A*D B*D C*D
A*B(C*D) is equivalent to A*B(C D)

Missing Values

Any observation in the input data set that has a missing value for one or more of the regressors is ignored by PROC COUNTREG and not used in the model fit. PROC COUNTREG rounds any positive noninteger count values to the nearest integer. PROC COUNTREG ignores any observations that have a negative count, a zero or negative weight, or a frequency less than 1.

If there are observations in the input data set that have missing response values but with nonmissing regressors, PROC COUNTREG can compute several statistics and store them in an output data set by using the OUTPUT statement. For example, you can request that the output data set contain the estimates of $\hat{x}_i^\beta$, the expected value of the response variable, and the probability that the response variable will take values that you specify. In a zero-inflated model, you can additionally request that the output data set contain the estimates of $z_i^\gamma$, and the probability that the response is zero as a result of the zero-generating process. The presence of such observations (with missing response values) does not affect the model fit.

Poisson Regression

The most widely used model for count data analysis is Poisson regression. This assumes that $y_i$, given the vector of covariates $x_i$, is independently Poisson-distributed with

$$P(Y_i = y_i | x_i) = \frac{e^{-\mu_i} \mu_i^{y_i}}{y_i!}, \quad y_i = 0, 1, 2, \ldots$$

and the mean parameter (that is, the mean number of events per period) is given by

$$\mu_i = \exp(x_i^\beta)$$

where $\beta$ is a $(k + 1) \times 1$ parameter vector. (The intercept is $\beta_0$; the coefficients for the $k$ regressors are $\beta_1, \ldots, \beta_k$.) Taking the exponential of $x_i^\beta$ ensures that the mean parameter $\mu_i$ is nonnegative. It can be shown that the conditional mean is given by

$$E(y_i | x_i) = \mu_i = \exp(x_i^\beta)$$

The name log-linear model is also used for the Poisson regression model because the logarithm of the conditional mean is linear in the parameters:

$$\ln[E(y_i | x_i)] = \ln(\mu_i) = x_i^\beta$$
Note that the conditional variance of the count random variable is equal to the conditional mean in the Poisson regression model:

\[ V(y_i | x_i) = E(y_i | x_i) = \mu_i \]

The equality of the conditional mean and variance of \( y_i \) is known as equidispersion.

The marginal effect of a regressor is given by

\[ \frac{\partial E(y_i | x_i)}{\partial x_{ji}} = \exp(x_i^\prime \beta_j) = E(y_i | x_i) \beta_j \]

Thus, a one-unit change in the \( j \)th regressor leads to a proportional change in the conditional mean \( E(y_i | x_i) \) of \( \beta_j \).

The standard estimator for the Poisson model is the maximum likelihood estimator (MLE). Because the observations are independent, the log-likelihood function is written as

\[ L = \sum_{i=1}^{N} w_i (-\mu_i + y_i \ln \mu_i - \ln y_i!) = \sum_{i=1}^{N} w_i (-e^{x_i^\prime \beta} + y_i x_i^\prime \beta - \ln y_i!) \]

where \( w_i \) is defined as follows:

1 if neither the WEIGHT nor FREQ statement is used.

\( W_i \)

where \( W_i \) are the nonnormalized values of the variable that are specified in the WEIGHT statement in which the NONORMALIZE option is specified.

\( \sum_{i=1}^{n} w_i \)

where \( W_i \) are the nonnormalized values of the variable that is specified in the WEIGHT statement.

\( F_i \)

where \( F_i \) are the values of the variable that is specified in the FREQ statement.

\( W_i F_i \)

if both the WEIGHT statement, without the NONORMALIZE option, and the FREQ statement are specified.

\( \sum_{i=1}^{n} F_i W_i \)

if both the FREQ and WEIGHT statements are specified.

The gradient and the Hessian are, respectively,

\[ \frac{\partial L}{\partial \beta} = \sum_{i=1}^{N} w_i (y_i - \mu_i)x_i = \sum_{i=1}^{N} w_i (y_i - e^{x_i^\prime \beta})x_i \]

\[ \frac{\partial^2 L}{\partial \beta \partial \beta'} = -\sum_{i=1}^{N} w_i \mu_i x_i x_i' = -\sum_{i=1}^{N} w_i e^{x_i^\prime \beta} x_i x_i' \]

The Poisson model has been criticized for its restrictive property that the conditional variance must equal the conditional mean. Real-life data are often characterized by overdispersion (that is, the variance exceeds the mean). Allowing for overdispersion can improve model predictions because the Poisson restriction of equal mean and variance results in the underprediction of zeros when overdispersion exists. The most commonly used model that accounts for overdispersion is the negative binomial model. Conway-Maxwell-Poisson regression enables you to model both overdispersion and underdispersion.
Conway-Maxwell-Poisson Regression

The Conway-Maxwell-Poisson (CMP) distribution is a generalization of the Poisson distribution that enables you to model both underdispersed and overdispersed data. It was originally proposed by Conway and Maxwell (1962), but its implementation to model under- and overdispersed count data is attributed to Shmueli et al. (2005).

Recall that $y_i$, given the vector of covariates $x_i$, is independently Poisson-distributed as

$$P(Y_i = y_i | x_i) = \frac{e^{-\lambda_i} \lambda_i^{y_i}}{y_i!} \quad y_i = 0, 1, 2, \ldots$$

The Conway-Maxwell-Poisson distribution is defined as

$$P(Y_i = y_i | x_i, z_i) = \frac{1}{Z(\lambda_i, v_i)} \frac{\lambda_i^{y_i}}{(y_i!)^{v_i}} \quad y_i = 0, 1, 2, \ldots$$

where the normalization factor is

$$Z(\lambda_i, v_i) = \sum_{n=0}^{\infty} \frac{\lambda_i^n}{(n!)^{v_i}}$$

and

$$\lambda_i = \exp(x_i' \beta)$$
$$v_i = -\exp(g_i' \delta)$$

The $\beta$ vector is a $(k + 1) \times 1$ parameter vector. (The intercept is $\beta_0$, and the coefficients for the $k$ regressors are $\beta_1, \ldots, \beta_k$). The $\delta$ vector is an $(m + 1) \times 1$ parameter vector. (The intercept is represented by $\delta_0$, and the coefficients for the $m$ regressors are $\delta_1, \ldots, \delta_k$). The covariates are represented by $x_i$ and $g_i$ vectors.

One of the restrictive properties of the Poisson model is that the conditional mean and variance must be equal:

$$E(y_i | x_i) = V(y_i | x_i) = \lambda_i = \exp(x_i' \beta)$$

The CMP distribution overcomes this restriction by defining an additional parameter, $v$, which governs the rate of decay of successive ratios of probabilities such that

$$P(Y_i = y_i - 1) / P(Y_i = y_i) = \frac{(y_i)^{v_i}}{\lambda_i}$$

The introduction of the additional parameter, $v$, allows for flexibility in modeling the tail behavior of the distribution. If $v = 1$, the ratio is equal to the rate of decay of the Poisson distribution. If $v < 1$, the rate of decay decreases, enabling you to model processes that have longer tails than the Poisson distribution (overdispersed data). If $v > 1$, the rate of decay increases in a nonlinear fashion, thus shortening the tail of the distribution (underdispersed data).
There are several special cases of the Conway-Maxwell-Poisson distribution. If κ < 1 and v → ∞, the Conway-Maxwell-Poisson results in the Bernoulli distribution. In this case, the data can take only the values 0 and 1, which represents an extreme underdispersion. If v = 1, the Poisson distribution is recovered with its equidispersion property. When v = 0 and κ < 1, the normalization factor is convergent and forms a geometric series,

$$Z(\lambda, 0) = \frac{1}{1-\lambda}$$

and the probability density function becomes

$$P(Y = y_i; \lambda_i, v_i = 0) = (1 - \lambda_i)\lambda_i^{y_i}$$

The geometric distribution represents a case of severe overdispersion.

**Mean, Variance, and Dispersion for the Conway-Maxwell-Poisson Model**

The mean and the variance of the Conway-Maxwell-Poisson distribution are defined as

$$E[Y] = \frac{\partial \ln Z}{\partial \ln \lambda}$$

$$V[Y] = \frac{\partial^2 \ln Z}{\partial^2 \ln \lambda}$$

The Conway-Maxwell-Poisson distribution does not have closed-form expressions for its moments in terms of its parameters κ and v. However, the moments can be approximated. Shmueli et al. (2005) use asymptotic expressions for Z to derive E(Y) and V(Y) as

$$E[Y] \approx \lambda^{1/\nu} + \frac{1}{2\nu} - \frac{1}{2}$$

$$V[Y] \approx \frac{1}{\nu} \lambda^{1/\nu}$$

In the Conway-Maxwell-Poisson model, the summation of infinite series is evaluated using a logarithmic expansion. The mean and variance are calculated as follows for the Shmueli et al. (2005) model:

$$E(Y) = \frac{1}{Z(\lambda, v)} \sum_{j=0}^{\infty} \frac{j \lambda^j}{(j!)^\nu}$$

$$V(Y) = \frac{1}{Z(\lambda, v)} \sum_{j=0}^{\infty} \frac{j^2 \lambda^j}{(j!)^\nu} - E(Y)^2$$

The dispersion is defined as

$$D(Y) = \frac{V(Y)}{E(Y)}$$
Likelihood Function for the Conway-Maxwell-Poisson Model

The likelihood for a set of \( n \) independently and identically distributed variables \( y_1, y_2, \ldots, y_n \) is written as

\[
L(y_1, y_2, \ldots, y_n | \lambda, v) = \frac{\prod_{i=1}^{n} \lambda^{y_i}}{(\prod_{i=1}^{n} y_i!)^v} Z(\lambda, v)^{-n}
\]

\[
= \frac{\lambda^{\sum_{i=1}^{n} y_i}}{\exp(-v \sum_{i=1}^{n} \ln(y_i !))} Z(\lambda, v)^{-n}
\]

where \( S_1 \) and \( S_2 \) are sufficient statistics for \( y_1, y_2, \ldots, y_n \). You can see from the preceding equation that the Conway-Maxwell-Poisson distribution is a member of the exponential family. The log-likelihood function can be written as

\[
\mathcal{L} = -n \ln(Z(\lambda, v)) + \sum_{i=1}^{n} (y_i \ln(\lambda) - v \ln(y_i !))
\]

The gradients can be written as

\[
\mathcal{L}_\beta = \left( \sum_{k=1}^{N} y_k - n \frac{\lambda Z(\lambda, v) \lambda}{Z(\lambda, v)} \right) x
\]

\[
\mathcal{L}_\delta = \left( \sum_{k=1}^{N} \ln(y_k !) - n \frac{Z(\lambda, v) v}{Z(\lambda, v)} \right) vz
\]

Conway-Maxwell-Poisson Regression: Guikema and Coffelt (2008) Reparameterization

Guikema and Coffelt (2008) propose a reparameterization of the Shmueli et al. (2005) Conway-Maxwell-Poisson model to provide a measure of central tendency that can be interpreted in the context of the generalized linear model. By substituting \( \lambda = \mu^v \), the Guikema and Coffelt (2008) formulation is written as

\[
P(Y = y_i; \mu, v) = \frac{1}{S(\mu, v)} \left( \frac{\mu^{y_i}}{y_i !} \right)^v
\]

where the new normalization factor is defined as

\[
S(\mu, v) = \sum_{j=0}^{\infty} \left( \frac{\mu^j}{j !} \right)^v
\]

In terms of their new formulations, the mean and variance of \( Y \) are given as

\[
E[Y] = \frac{1}{v} \frac{\partial \ln S}{\partial \ln \mu}
\]

\[
V[Y] = \frac{1}{v^2} \frac{\partial^2 \ln S}{\partial^2 \ln \mu}
\]
They can be approximated as
\[
E[Y] \approx \mu + \frac{1}{2}v - \frac{1}{2}
\]
\[
V[Y] \approx \frac{\mu}{v}
\]

In the COUNTREG procedure, the mean and variance are calculated according to the following formulas for the Guikema and Coffelt (2008) model:

\[
E(Y) = \frac{1}{Z(\lambda, \mu)} \sum_{j=0}^{\infty} \frac{j \mu^v}{(j!)^v}
\]
\[
V(Y) = \frac{1}{Z(\lambda, \mu)} \sum_{j=0}^{\infty} \frac{j^2 \mu^v}{(j!)^v} - E(Y)^2
\]

In terms of the new parameter \( \mu \), the log-likelihood function is specified as

\[
\mathcal{L} = \ln(S(\mu, v)) + v \sum_{i=1}^{N} (y_i \ln(\mu) - \ln(y_i!))
\]

and the gradients are calculated as

\[
\mathcal{L}_\beta = \left( v \sum_{i=1}^{N} y_i - \frac{\mu S(\mu, v) \mu}{S(\mu, v)} \right) x
\]
\[
\mathcal{L}_\delta = \left( \sum_{i=1}^{N} (y_i \ln(\mu) - \ln(y_i!)) - \frac{S(\mu, v) \nu}{S(\mu, v)} \right) y g
\]

The default in the COUNTREG procedure is the Guikema and Coffelt (2008) specification. The Shmueli et al. (2005) model can be estimated by specifying the PARAMETER=LAMBDA option. If you specify DISP=CMPOISSON in the MODEL statement and you omit the DISPMODEL statement, the model is estimated according to the Lord, Guikema, and Geedipally (2008) specification, where \( v \) represents a single parameter that does not depend on any covariates. The Lord, Guikema, and Geedipally (2008) specification makes the model comparable to the negative binomial model because it has only one parameter.

The dispersion is defined as

\[
D(Y) = \frac{V(Y)}{E(Y)}
\]

Using the Guikema and Coffelt (2008) specification results in the integral part of \( \mu \) representing the mode, which is a reasonable approximation for the mean. The dispersion can be written as

\[
D(Y) = \frac{V(Y)}{E(Y)} \approx \frac{\mu}{\mu + \frac{1}{2}v - \frac{1}{2}} \approx \frac{1}{v}
\]
When $\nu < 1$, the variance can be shown to be greater than the mean and the dispersion greater than 1. This is a result of overdispersed data. When $\nu = 1$, and the mean and variance are equal, the dispersion is equal to 1 (Poisson model). When $\nu > 1$, the variance is smaller than the mean and the dispersion is less than 1. This is a result of underdispersed data.

All Conway-Maxwell-Poisson models in the COUNTREG procedure are parameterized in terms of dispersion, where

$$-\ln(\nu) = \delta_0 + \sum_{n=1}^{q} \delta_n g_n$$

Negative values of $\ln(\nu)$ indicate that the data are approximately underdispersed, and values of $\ln(\nu)$ that are greater than 0 indicate that the data are approximately overdispersed.

**Negative Binomial Regression**

The Poisson regression model can be generalized by introducing an unobserved heterogeneity term for observation $i$. Thus, the individuals are assumed to differ randomly in a manner that is not fully accounted for by the observed covariates. This is formulated as

$$E(y_i|x_i, \tau_i) = \mu_i \tau_i = e^{x_i' \beta + \epsilon_i}$$

where the unobserved heterogeneity term $\tau_i = e^{\epsilon_i}$ is independent of the vector of regressors $x_i$. Then the distribution of $y_i$ conditional on $x_i$ and $\tau_i$ is Poisson with conditional mean and conditional variance $\mu_i \tau_i$:

$$f(y_i|x_i, \tau_i) = \frac{\exp(-\mu_i \tau_i)(\mu_i \tau_i)^{y_i}}{y_i!}$$

Let $g(\tau_i)$ be the probability density function of $\tau_i$. Then, the distribution $f(y_i|x_i)$ (no longer conditional on $\tau_i$) is obtained by integrating $f(y_i|x_i, \tau_i)$ with respect to $\tau_i$:

$$f(y_i|x_i) = \int_0^{\infty} f(y_i|x_i, \tau_i) g(\tau_i) d\tau_i$$

An analytical solution to this integral exists when $\tau_i$ is assumed to follow a gamma distribution. This solution is the negative binomial distribution. When the model contains a constant term, it is necessary to assume that $E(e^{\epsilon_i}) = E(\tau_i) = 1$ in order to identify the mean of the distribution. Thus, it is assumed that $\tau_i$ follows a gamma($\theta, \theta$) distribution with $E(\tau_i) = 1$ and $V(\tau_i) = 1/\theta$,

$$g(\tau_i) = \frac{\theta^\theta}{\Gamma(\theta)} \tau_i^{\theta-1} \exp(-\theta \tau_i)$$
where $\Gamma(x) = \int_0^{\infty} z^{x-1} \exp(-z) dz$ is the gamma function and $\theta$ is a positive parameter. Then, the density of $y_i$ given $x_i$ is derived as

$$f(y_i|x_i) = \int_0^{\infty} f(y_i|x_i, \tau_i) g(\tau_i) \, d\tau_i$$

$$= \frac{\theta^\theta \mu_i^{y_i}}{y_i! \Gamma(\theta)} \int_0^{\infty} e^{-(\mu_i + \theta) \tau_i} \tau_i^{\theta+y_i-1} \, d\tau_i$$

$$= \frac{\theta^\theta \mu_i^{y_i} \Gamma(y_i + \theta)}{y_i! \Gamma(\theta)(\theta + \mu_i)^{\theta+y_i}}$$

$$= \frac{\Gamma(y_i + \theta)}{y_i! \Gamma(\theta)} \left( \frac{\theta}{\theta + \mu_i} \right)^\theta \left( \frac{\mu_i}{\theta + \mu_i} \right)^{y_i}$$

Making the substitution $\alpha = \frac{1}{\theta} (\alpha > 0)$, the negative binomial distribution can then be rewritten as

$$f(y_i|x_i) = \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left( \frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \left( \frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i}, \quad y_i = 0, 1, 2, \ldots$$

Thus, the negative binomial distribution is derived as a gamma mixture of Poisson random variables. It has conditional mean

$$E(y_i|x_i) = \mu_i = e^{x_i'\beta}$$

and conditional variance

$$V(y_i|x_i) = \mu_i [1 + \frac{1}{\theta} \mu_i] = \mu_i [1 + \alpha \mu_i] > E(y_i|x_i)$$

The conditional variance of the negative binomial distribution exceeds the conditional mean. Overdispersion results from neglected unobserved heterogeneity. The negative binomial model with variance function $V(y_i|x_i) = \mu_i + \alpha \mu_i^2$, which is quadratic in the mean, is referred to as the NEGBIN2 model (Cameron and Trivedi 1986). To estimate this model, specify DIST=NEGBIN(p=2) in the MODEL statement. The Poisson distribution is a special case of the negative binomial distribution where $\alpha = 0$. A test of the Poisson distribution can be carried out by testing the hypothesis that $\alpha = \frac{1}{\theta} = 0$. A Wald test of this hypothesis is provided (it is the reported $t$ statistic for the estimated $\alpha$ in the negative binomial model).

The log-likelihood function of the negative binomial regression model (NEGBIN2) is given by

$$\mathcal{L} = \sum_{i=1}^{N} w_i \left\{ \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1}) - \ln(y_i!) \right\}$$

$$- (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(x_i'\beta)) + y_i \ln(\alpha) + y_i x_i'\beta \right\}$$

$$\frac{\Gamma(y + a)}{\Gamma(a)} = \prod_{j=0}^{y-1} (j + a)$$

if $y$ is an integer. See “Poisson Regression” on page 586 for the definition of $w_i$. 
The gradient is

\[
\frac{\partial \mathcal{L}}{\partial \beta} = \sum_{i=1}^{N} w_i \frac{y_i - \mu_i}{1 + \alpha \mu_i} x_i
\]

and

\[
\frac{\partial \mathcal{L}}{\partial \alpha} = \sum_{i=1}^{N} w_i \left\{ -\alpha^{-2} \sum_{j=0}^{y_i-1} \frac{1}{(j + \alpha^{-1})} + \alpha^{-2} \ln(1 + \alpha \mu_i) + \frac{y_i - \mu_i}{\alpha(1 + \alpha \mu_i)} \right\}
\]

Cameron and Trivedi (1986) consider a general class of negative binomial models with mean \( \mu_i \) and variance function \( \mu_i + \alpha \mu_i^p \). The NEGBIN2 model, with \( p = 2 \), is the standard formulation of the negative binomial model. Models with other values of \( p, -\infty < p < \infty \), have the same density \( f(y_i|x_i) \) except that \( \alpha^{-1} \) is replaced everywhere by \( \alpha^{-1} \mu^{2-p} \). The negative binomial model NEGBIN1, which sets \( p = 1 \), has variance function \( V(y_i|x_i) = \mu_i + \alpha \mu_i \), which is linear in the mean. To estimate this model, specify DIST=NEGBIN(p=1) in the MODEL statement.

The log-likelihood function of the NEGBIN1 regression model is given by

\[
\mathcal{L} = \sum_{i=1}^{N} w_i \left\{ \sum_{j=0}^{y_i-1} \ln \left( j + \alpha^{-1} \exp(x_i' \beta) \right) - \ln(y_i!) - (y_i + \alpha^{-1} \exp(x_i' \beta)) \ln(1 + \alpha) + y_i \ln(\alpha) \right\}
\]

See the section “Poisson Regression” on page 586 for the definition of \( w_i \).

The gradient is

\[
\frac{\partial \mathcal{L}}{\partial \beta} = \sum_{i=1}^{N} w_i \left\{ \left( \sum_{j=0}^{y_i-1} \frac{\mu_i}{(j + \alpha + \mu_i)} \right) x_i - \alpha^{-1} \ln(1 + \alpha) \mu_i x_i \right\}
\]

and

\[
\frac{\partial \mathcal{L}}{\partial \alpha} = \sum_{i=1}^{N} w_i \left\{ -\left( \sum_{j=0}^{y_i-1} \frac{\alpha^{-1} \mu_i}{(j + \alpha + \mu_i)} \right) - \alpha^{-2} \mu_i \ln(1 + \alpha) - \frac{(y_i + \alpha^{-1} \mu_i)}{1 + \alpha} + \frac{y_i}{\alpha} \right\}
\]

**Zero-Inflated Count Regression Overview**

The main motivation for zero-inflated count models is that real-life data frequently display overdispersion and excess zeros. Zero-inflated count models provide a way of modeling the excess zeros in addition to allowing for overdispersion. In particular, for each observation, there are two possible data generation processes. The result of a Bernoulli trial is used to determine which of the two processes is used. For observation \( i \), Process 1 is chosen with probability \( \varphi_i \) and Process 2 with probability \( 1 - \varphi_i \). Process 1 generates only zero counts. Process 2 generates counts from either a Poisson or a negative binomial model. In general,

\[
y_i \sim \begin{cases} 0 & \text{with probability } \varphi_i \\ g(y_i) & \text{with probability } 1 - \varphi_i \end{cases}
\]
Therefore, the probability of \( \{Y_i = y_i\} \) can be described as

\[
P(Y_i = 0|x_i) = \varphi_i + (1 - \varphi_i)g(0)
\]

\[
P(Y_i|x_i) = (1 - \varphi_i)g(y_i), \quad y_i > 0
\]

where \( g(y_i) \) follows either the Poisson or the negative binomial distribution. You can specify the probability \( \varphi \) by using the PROBZERO= option in the OUTPUT statement.

When the probability \( \varphi_i \) depends on the characteristics of observation \( i \), \( \varphi_i \) is written as a function of \( z'_i\gamma \), where \( z'_i \) is the \((q + 1)\) vector of zero-inflation covariates and \( \gamma \) is the \((q + 1) \times 1\) vector of zero-inflation coefficients to be estimated. (The zero-inflation intercept is \( \gamma_0 \); the coefficients for the \( q \) zero-inflation covariates are \( \gamma_1, \ldots, \gamma_q \).) The function \( F \) that relates the product \( z'_i\gamma \) (which is a scalar) to the probability \( \varphi_i \) is called the zero-inflation link function,

\[
\varphi_i = F_i = F(z'_i\gamma)
\]

In the COUNTREG procedure, the zero-inflation covariates are indicated in the ZEROMODEL statement. Furthermore, the zero-inflation link function \( F \) can be specified as either the logistic function,

\[
F(z'_i\gamma) = \Lambda(z'_i\gamma) = \frac{\exp(z'_i\gamma)}{1 + \exp(z'_i\gamma)}
\]

or the standard normal cumulative distribution function (also called the probit function),

\[
F(z'_i\gamma) = \Phi(z'_i\gamma) = \int_0^{z'_i\gamma} \frac{1}{\sqrt{2\pi}} \exp(-u^2/2)du
\]

The zero-inflation link function is indicated in the LINK option in ZEROMODEL statement. The default ZI link function is the logistic function.

### Zero-Inflated Poisson Regression

In the zero-inflated Poisson (ZIP) regression model, the data generation process that is referred to earlier as Process 2 is

\[
g(y_i) = \frac{\exp(-\mu_i)\mu_i^{y_i}}{y_i!}
\]

where \( \mu_i = e^{x'_i\beta} \). Thus the ZIP model is defined as

\[
P(Y_i = 0|x_i, z_i) = F_i + (1 - F_i)\exp(-\mu_i)
\]

\[
P(Y_i|x_i, z_i) = (1 - F_i)\frac{\exp(-\mu_i)\mu_i^{y_i}}{y_i!}, \quad y_i > 0
\]

The conditional expectation and conditional variance of \( y_i \) are given by

\[
E(y_i|x_i, z_i) = \mu_i(1 - F_i)
\]
Note that the ZIP model (as well as the ZINB model) exhibits overdispersion because \( V(y_i | x_i, z_i) > E(y_i | x_i, z_i) \).

In general, the log-likelihood function of the ZIP model is

\[
\mathcal{L} = \sum_{i=1}^{N} w_i \ln [ P(y_i | x_i, z_i) ]
\]

After a specific link function (either logistic or standard normal) for the probability \( \varphi_i \) is chosen, it is possible to write the exact expressions for the log-likelihood function and the gradient.

**ZIP Model with Logistic Link Function**

First, consider the ZIP model in which the probability \( \varphi_i \) is expressed using a logistic link function—namely,

\[
\varphi_i = \frac{\exp(z_i' \gamma)}{1 + \exp(z_i' \gamma)}
\]

The log-likelihood function is

\[
\mathcal{L} = \sum_{\{i: y_i = 0\}} w_i \ln \left[ \exp(z_i' \gamma) + \exp(-\exp(x_i' \beta)) \right] + \sum_{\{i: y_i > 0\}} w_i \left[ y_i x_i' \beta - \exp(x_i' \beta) - \sum_{k=2}^{y_i} \ln(k) \right] - \sum_{i=1}^{N} w_i \ln \left[ 1 + \exp(z_i' \gamma) \right]
\]

See the section “Poisson Regression” on page 586 for the definition of \( w_i \).

The gradient for this model is given by

\[
\frac{\partial \mathcal{L}}{\partial \gamma} = \sum_{\{i: y_i = 0\}} w_i \left[ \frac{\exp(z_i' \gamma)}{\exp(z_i' \gamma) + \exp(-\exp(x_i' \beta))} \right] z_i - \sum_{i=1}^{N} w_i \left[ \frac{\exp(z_i' \gamma)}{1 + \exp(z_i' \gamma)} \right] z_i
\]

\[
\frac{\partial \mathcal{L}}{\partial \beta} = \sum_{\{i: y_i = 0\}} w_i \left[ \frac{-\exp(x_i' \beta) \exp(-\exp(x_i' \beta))}{\exp(z_i' \gamma) + \exp(-\exp(x_i' \beta))} \right] x_i + \sum_{\{i: y_i > 0\}} w_i \left[ y_i - \exp(x_i' \beta) \right] x_i
\]

**ZIP Model with Standard Normal Link Function**

Next, consider the ZIP model in which the probability \( \varphi_i \) is expressed using a standard normal link function: \( \varphi_i = \Phi(z_i' \gamma) \). The log-likelihood function is

\[
\mathcal{L} = \sum_{\{i: y_i = 0\}} w_i \ln \left\{ \Phi(z_i' \gamma) + \left[ 1 - \Phi(z_i' \gamma) \right] \exp(-\exp(x_i' \beta)) \right\}
\]

\[
+ \sum_{\{i: y_i > 0\}} w_i \left\{ \ln \left[ \left( 1 - \Phi(z_i' \gamma) \right) \right] - \exp(x_i' \beta) + y_i x_i' \beta - \sum_{k=2}^{y_i} \ln(k) \right\}
\]
see the section “Poisson Regression” on page 586 for the definition of $w_i$.

The gradient for this model is given by

$$\frac{\partial L}{\partial \gamma} = \sum_{i: y_i = 0} w_i \frac{\psi(x'_i, \gamma) \left[ 1 - \exp(-\exp(x'_i \beta)) \right]}{\Phi(x'_i, \gamma) + \left[ 1 - \Phi(x'_i, \gamma) \right] \exp(-\exp(x'_i \beta))} z_i$$

$$- \sum_{i: y_i > 0} w_i \frac{\psi(x'_i, \gamma)}{1 - \Phi(x'_i, \gamma)} z_i$$

$$\frac{\partial L}{\partial \beta} = \sum_{i: y_i = 0} w_i \frac{\psi(x'_i, \gamma) \exp(x'_i \beta) \exp(-\exp(x'_i \beta))}{\Phi(x'_i, \gamma) + \left[ 1 - \Phi(x'_i, \gamma) \right] \exp(-\exp(x'_i \beta))} x_i$$

$$+ \sum_{i: y_i > 0} w_i \left[ y_i - \exp(x'_i \beta) \right] x_i$$

### Zero-Inflated Conway-Maxwell-Poisson Regression

In the Conway-Maxwell-Poisson regression model, the data generation process is defined as

$$P(Y_i = y_i | x_i, z_i) = \frac{1}{Z(\lambda_i, v_i)} \frac{\lambda_i^{y_i}}{(y_i!)^{v_i}}, \quad y_i = 0, 1, 2, \ldots$$

where the normalization factor is

$$Z(\lambda_i, v_i) = \sum_{n=0}^{\infty} \frac{\lambda_i^n}{(n!)^{v_i}}$$

and

$$\lambda_i = \exp(x'_i \beta)$$

$$v_i = -\exp(g'_i \delta)$$

The zero-inflated Conway-Maxwell-Poisson model can be written as

$$P(y_i = 0 | x_i, z_i) = F_i + (1 - F_i) \frac{1}{Z(\lambda_i, v_i)}$$

$$P(y_i | x_i, z_i) = (1 - F_i) \frac{1}{Z(\lambda_i, v_i)} \frac{\lambda_i^{y_i}}{(y_i!)^{v_i}}, \quad y_i > 0$$

The conditional expectation and conditional variance of $y_i$ are given by

$$E(y_i | x_i, z_i) = (1 - F_i) \frac{1}{Z(\lambda, v)} \sum_{j=0}^{\infty} \frac{j \lambda^j}{(j!)^v}$$
\[ V(y_i|x_i, z_i) = (1 - F_i) \frac{1}{Z(\lambda, v)} \sum_{j=0}^{\infty} \frac{j^2\lambda^j}{(j!)^2} - E(y_i|x_i, z_i)^2 \]

General form of the log-likelihood function for the Conway-Maxwell-Poisson zero-inflated model is

\[ \mathcal{L} = \sum_{i=1}^{N} w_i \ln [P(y_i|x_i, z_i)] \]

**Zero-Inflated Conway-Maxwell-Poisson Model with Logistic Link Function**

In this model the probability \( \varphi_i \) is expressed with a logistic link function as

\[ \varphi_i = \Lambda(z'_i \gamma) = \frac{\exp(z'_i \gamma)}{1 + \exp(z'_i \gamma)} \]

The log-likelihood function is

\[ \mathcal{L} = \sum_{\{i : y_i > 0\}} w_i \ln \left\{ \Lambda(z'_i \gamma) + \left[ 1 - \Lambda(z'_i \gamma) \right] \frac{1}{Z(\lambda_i, v_i)} \right\} \\
+ \sum_{\{i : y_i = 0\}} w_i \left\{ \ln \left[ \left( 1 - \Lambda(z'_i \gamma) \right) \right] - \ln(Z(\lambda, v)) + (y_i \ln(\lambda) - v \ln(y_i!)) \right\} \]

**Zero-Inflated Conway-Maxwell-Poisson Model with Normal Link Function**

For this model, the probability \( \varphi_i \) is specified with the standard normal distribution function (probit function):

\[ \varphi_i = \Phi(z'_i \gamma). \]

The log-likelihood function is written as

\[ \mathcal{L} = \sum_{\{i : y_i > 0\}} w_i \ln \left\{ \Phi(z'_i \gamma) + \left[ 1 - \Phi(z'_i \gamma) \right] \frac{1}{Z(\lambda_i, v_i)} \right\} \\
+ \sum_{\{i : y_i = 0\}} w_i \left\{ \ln \left[ \left( 1 - \Phi(z'_i \gamma) \right) \right] - \ln(Z(\lambda, v)) + (y_i \ln(\lambda) - v \ln(y_i!)) \right\} \]

**Zero-Inflated Negative Binomial Regression**

The zero-inflated negative binomial (ZINB) model in PROC COUNTREG is based on the negative binomial model with quadratic variance function \( \rho = 2 \). The ZINB model is obtained by specifying a negative binomial distribution for the data generation process referred to earlier as Process 2:

\[ g(y_i) = \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left( \frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \left( \frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i} \]
Thus the ZINB model is defined to be

\[
P(y_i = 0|x_i, z_i) = F_i + (1 - F_i)(1 + \alpha \mu_i)^{-\alpha - 1}
\]

\[
P(y_i|x_i, z_i) = (1 - F_i) \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left( \frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \times \left( \frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i}, \quad y_i > 0
\]

In this case, the conditional expectation and conditional variance of \(y_i\) are

\[
E(y_i|x_i, z_i) = \mu_i (1 - F_i)
\]

\[
V(y_i|x_i, z_i) = E(y_i|x_i, z_i) \left[ 1 + \mu_i (F_i + \alpha) \right]
\]

Like the ZIP model, the ZINB model exhibits overdispersion because the conditional variance exceeds the conditional mean.

**ZINB Model with Logistic Link Function**

In this model, the probability \(\varphi_i\) is given by the logistic function—namely,

\[
\varphi_i = \frac{\exp(z_i'y)}{1 + \exp(z_i'y)}
\]

The log-likelihood function is

\[
\mathcal{L} = \sum_{\{i: y_i = 0\}} w_i \ln \left[ \exp(z_i'y) + (1 + \alpha \exp(x_i'\beta))^{-\alpha - 1} \right] + \sum_{\{i: y_i > 0\}} w_i \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1}) + \sum_{\{i: y_i > 0\}} w_i \left\{ -\ln(y_i!) - (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(x_i'\beta)) + y_i \ln(\alpha) + y_i x_i' \beta \right\}
\]

\[- \sum_{i=1}^{N} w_i \ln \left[ 1 + \exp(z_i'y) \right]
\]

See the section “Poisson Regression” on page 586 for the definition of \(w_i\).

The gradient for this model is given by

\[
\frac{\partial \mathcal{L}}{\partial \gamma} = \sum_{\{i: y_i = 0\}} w_i \left[ \frac{\exp(z_i'y)}{\exp(z_i'y) + (1 + \alpha \exp(x_i'\beta))^{-\alpha - 1}} \right] z_i
\]

\[- \sum_{i=1}^{N} w_i \left[ \frac{\exp(z_i'y)}{1 + \exp(z_i'y)} \right] z_i
\]
\[
\frac{\partial \mathcal{L}}{\partial \beta} = \sum_{\{i: y_i = 0\}} w_i \left[ -\exp(x_i' \beta)(1 + \alpha \exp(x_i' \beta))^{-\alpha - 1} \right] x_i + \sum_{\{i: y_i > 0\}} w_i \left[ \frac{y_i - \exp(x_i' \beta)}{1 + \alpha \exp(x_i' \beta)} \right] x_i
\]

\[
\frac{\partial \mathcal{L}}{\partial \alpha} = \sum_{\{i: y_i = 0\}} w_i \frac{\alpha^{-2} \left[ (1 + \alpha \exp(x_i' \beta)) \ln(1 + \alpha \exp(x_i' \beta)) - \alpha \exp(x_i' \beta) \right]}{\exp(x_i' \gamma)(1 + \alpha \exp(x_i' \beta))^{(1+\alpha)/\alpha} + (1 + \alpha \exp(x_i' \beta))} + \sum_{\{i: y_i > 0\}} w_i \left\{ -\alpha^{-2} \sum_{j=0}^{y_i-1} \frac{1}{(j + \alpha^{-1})} + \alpha^{-2} \ln(1 + \alpha \exp(x_i' \beta)) + \frac{y_i - \exp(x_i' \beta)}{\alpha(1 + \alpha \exp(x_i' \beta))} \right\}
\]

**ZINB Model with Standard Normal Link Function**

For this model, the probability \( \varphi_i \) is specified using the standard normal distribution function (probit function): \( \varphi_i = \Phi(x_i' \gamma) \). The log-likelihood function is

\[
\mathcal{L} = \sum_{\{i: y_i = 0\}} w_i \ln \left\{ \Phi(x_i' \gamma) + [1 - \Phi(x_i' \gamma)] (1 + \alpha \exp(x_i' \beta))^{-\alpha - 1} \right\} + \sum_{\{i: y_i > 0\}} w_i \ln [1 - \Phi(x_i' \gamma)] + \sum_{\{i: y_i > 0\}} w_i \left\{ \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1}) \right\} - \sum_{\{i: y_i > 0\}} w_i \ln(y_i!) - \sum_{\{i: y_i > 0\}} w_i (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(x_i' \beta)) + \sum_{\{i: y_i > 0\}} w_i y_i \ln(\alpha) + \sum_{\{i: y_i > 0\}} w_i y_i x_i' \beta
\]

See the section “Poisson Regression” on page 586 for the definition of \( w_i \).

The gradient for this model is given by

\[
\frac{\partial \mathcal{L}}{\partial \gamma} = \sum_{\{i: y_i = 0\}} w_i \left[ \varphi(x_i' \gamma) \frac{1 - (1 + \alpha \exp(x_i' \beta))^{-\alpha - 1}}{\Phi(x_i' \gamma) + [1 - \Phi(x_i' \gamma)] (1 + \alpha \exp(x_i' \beta))^{-\alpha - 1}} \right] z_i
\]
Variable Selection

Variable Selection Using an Information Criterion

This type of variable selection uses either Akaike's information criterion (AIC) or the Schwartz Bayesian criterion (SBC) and either a forward selection method or a backward elimination method.

Forward selection starts from a small subset of variables. In each step, the variable that gives the largest decrease in the value of the information criterion specified in the CRITER= option (AIC or SBC) is added. The process stops when the next candidate to be added does not reduce the value of the information criterion by more than the amount specified in the LSTOP= option in the MODEL statement.

Backward elimination starts from a larger subset of variables. In each step, one variable is dropped based on the information criterion chosen.

You can force a variable to be retained in the variable selection process by adding a RETAIN list to the SELECT=INFO (or SELECTVAR=) option in your model. For example, suppose you add a RETAIN list to the SELECT=INFO option in your model as follows:

\[
\text{MODEL Art = Mar Kid5 PhD / dist=negbin(p=2) SELECT=INFO(lstop=0.001 RETAIN(Phd));}
\]

Then this causes the variable selection process to consider only those models that contain PhD as a regressor. As a result, you are guaranteed that PhD will appear as one of the regressor variables in whatever model the
variable selection process produces. The model that results is the “best” (relative to your selection criterion) of all the possible models that contain Phd.

When a ZEROMODEL statement is used in conjunction with a MODEL statement, then all the variables that appear in the ZEROMODEL statement are retained by default unless the ZEROMODEL statement itself contains a SELECT=INFO option.

For example, suppose you have the following:

```plaintext
MODEL Art = Mar Kid5 Phd / dist=negbin(p=2) SELECT=INFO(lstop=0.001 RETAIN(Phd));
ZEROMODEL Art ~ Fem Ment / link=normal;
```

Then Phd is retained in the MODEL statement and all the variables in the ZEROMODEL statement (Fem and Ment) are retained as well. You can add an empty SELECT=INFO clause to the ZEROMODEL statement to indicate that all the variables in that statement are eligible for elimination (that is, need not be retained) during variable selection. For example:

```plaintext
MODEL Art = Mar Kid5 Phd / dist=negbin(p=2) SELECT=INFO(lstop=0.001 RETAIN(Phd));
ZEROMODEL Art ~ Fem Ment / link=normal SELECT=INFO();
```

In this example, only Phd from the MODEL statement is guaranteed to be retained. All the other variables in the MODEL statement and all the variables in the ZEROMODEL statement are eligible for elimination.

Similarly, if your ZEROMODEL statement contains a SELECT=INFO option but your MODEL statement does not, then all the variables in the MODEL statement are retained, whereas only those variables listed in the RETAIN() list of the SELECT=INFO option for your ZEROMODEL statement are retained. For example:

```plaintext
MODEL Art = Mar Kid5 Phd / dist=negbin(p=2) ;
ZEROMODEL Art ~ Fem Ment / link=normal SELECT=INFO(RETAIN(Ment));
```

Here, all the variables in the MODEL statement (Mar Kid5 Phd) are retained, but only the Ment variable in the ZEROMODEL statement is retained.

### Variable Selection Using Penalized Likelihood

Variable selection in the linear regression context can be achieved by adding some form of penalty on the regression coefficients. One particular such form is \( L_1 \) norm penalty, which leads to LASSO:

\[
\min_\beta \| Y - X\beta \|^2 + \lambda \sum_{j=1}^{p} |\beta_j|
\]

This penalty method is becoming more popular in linear regression, because of the computational development in the recent years. However, how to generalize the penalty method for variable selection to the more general statistical models is not trivial. Some work has been done for the generalized linear models, in the sense that the likelihood depends on the data through a linear combination of the parameters and the data:

\[
l (\beta|x) = l \left( x^T \beta \right)
\]
In the more general form, the likelihood as a function of the parameters can be denoted by \( l(\theta) = \sum_i l_i(\theta) \), where \( \theta \) is a vector that can include any parameters and \( l(\cdot) \) is the likelihood for each observation. For example, in the Poisson model, \( \theta = (\beta_0, \beta_1, \ldots, \beta_p) \), and in the negative binomial model \( \theta = (\beta_0, \beta_1, \ldots, \beta_p, \alpha) \).

The following discussion introduces the penalty method, using the Poisson model as an example, but it applies similarly to the negative binomial model. The penalized likelihood function takes the form

\[
Q(\beta) = \sum_i l_i(\beta) - n \sum_{j=1}^p p_{\lambda_j}(|\beta_j|)
\]

The \( L_1 \) norm penalty function that is used in the calculation is specified as

\[
p_{\lambda}(|\beta|) = \lambda
\]

The main challenge for this penalized likelihood method is on the computation side. The penalty function is nondifferentiable at zero, posing a computational problem for the optimization. To get around this nondifferentiability problem, Fan and Li (2001) suggested a local quadratic approximation for the penalty function. However, it was later found that the numerical performance is not satisfactory in a few respects. Zou and Li (2008) proposed local linear approximation (LLA) to solve the problem (see page 603) numerically.

The algorithm replaces the penalty function with a linear approximation around a fixed point \( \hat{\beta}_{(0)} \):

\[
p_{\lambda}(|\beta_j|) \approx p_{\lambda}(|\beta_{(0)}^j|) + p'_{\lambda}(|\beta_{(0)}^j|) (|\beta_j| - |\beta_{(0)}^j|)
\]

Then the problem can be solved iteratively. Start from \( \beta_{(0)} = \hat{\beta}_M \), which denotes the usual MLE estimate. For iteration \( k \),

\[
\beta_{(k+1)} = \arg \max_\beta \left\{ \sum_i l_i(\beta) - n \sum_{j=1}^p p'_{\lambda_j}(|\beta_{(k)}^j|) |\beta_j| \right\}
\]

The algorithm stops when \( \|\beta_{(k+1)} - \beta_{(k)}\| \) is small. To save computing time, you can also choose a maximum number of iterations. This number can be specified by the LLASTEPS= option.

The objective function is nondifferentiable. The optimization problem can be solved using an optimization methods with constraints, by a variable transformation

\[
\beta_j = \beta_j^+ - \beta_j^- , \beta_j^+ \geq 0, \beta_j^- \geq 0
\]

For each fixed tuning parameter \( \lambda \), you can solve the preceding optimization problem to obtain an estimate for \( \beta \). Because of the property of the \( L_1 \) norm penalty, some of the coefficients in \( \beta \) can be exactly zero. The remaining question is to choose the best tuning parameter \( \lambda \). You can use either of the approaches that are described in the following subsections.

The GCV Approach

In the GCV approach, the generalized cross validation criteria (GCV) is computed for each value of \( \lambda \) on a predetermined grid \( \{\lambda_1, \ldots, \lambda_L\} \); the value of \( \lambda \) that achieves the minimum of the GCV is the optimal tuning parameter. The maximum value \( \lambda_L \) can be determined by lemma 1 in Park and Hastie (2007) as follows.
Suppose $\beta_0$ is free of penalty in the objective function. Let $\hat{\beta}_0$ be the MLE of $\beta_0$ by forcing the rest of the parameters to be zero. Then the maximum value of $\lambda$ is

$$
\lambda_L = \arg \max_{\lambda} \left\{ \max_{\lambda} \left| \frac{\partial l}{\partial \beta_j}(\hat{\beta}_0) \right| : n P'_\lambda(|\beta_j|), j = 1, \ldots, p \right\}
$$

$$
= \arg \max_{\lambda} \left\{ \left| \frac{1}{n} \frac{\partial l}{\partial \beta_j}(\hat{\beta}_0) \right|, j = 1, \ldots, p \right\}
$$

You can compute the GCV by using the LASSO framework. In the last step of Newton-Raphson approximation, you have

$$
\frac{1}{2} \min_{\beta} \left\{ \left( \nabla^2 I(\beta(k)) \right)^{1/2} (\beta - \beta(k)) + (\nabla^2 I(\beta(k)))^{-1/2} \nabla I(\beta(k)) \right\}^2 + n \sum_{j=1}^{p} p'_\lambda(|\beta_j^{(k)}|)|\beta_j|
$$

The solution $\hat{\beta}$ satisfies

$$
\hat{\beta} - \beta(k) = -\left( \nabla^2 I(\beta(k)) - 2W^- \right)^{-1} \left( \nabla I(\beta(k)) - 2b \right)
$$

where

$$
W^- = n \text{diag}(W_1^-, \ldots, W_p^-)
$$

$$
W_j^- = \begin{cases} 
    p'_\lambda(|\beta_j^{(k)}|) / |\beta_j|, & \text{if } \beta_j \neq 0 \\
    0, & \text{if } \beta_j = 0 
\end{cases}
$$

$$
b = n \text{diag}(p'_\lambda(|\beta_1^{(k)}|)\text{sgn}(\beta_1), \ldots, p'_\lambda(|\beta_p^{(k)}|)\text{sgn}(\beta_p))
$$

Note that the intercept term has no penalty on its absolute value, and therefore the $W_j^-$ term that corresponds to the intercept is 0. More generally, you can make any parameter (such as the $\alpha$ in the negative binomial model) in the likelihood function free of penalty, and you treat them the same as the intercept.

The effective number of parameters is

$$
e(\lambda) = \text{tr} \left\{ \left( \nabla^2 I(\beta(k)) \right)^{1/2} \left( \nabla^2 I(\beta(k)) - 2W^- \right)^{-1} \left( \nabla^2 I(\beta(k)) \right)^{1/2} \right\}
$$

$$
= \text{tr} \left\{ \left( \nabla^2 I(\beta(k)) - 2W^- \right)^{-1} \nabla^2 I(\beta(k)) \right\}
$$

and the generalized cross validation error is

$$
\text{GCV}(\lambda) = \frac{l(\hat{\beta})}{n[1 - e(\lambda)/n]^2}
$$

The GCV1 Approach

Another form of GCV uses the number of nonzero coefficients as the degrees of freedom:

$$
e_1(\lambda) = \sum_{j=0}^{p} 1[\beta_j \neq 0]
$$

$$
\text{GCV}_1(\lambda) = \frac{l(\hat{\beta})}{n[1 - e_1(\lambda)/n]^2}
$$
The standard errors follow the sandwich formula:

$$\text{cov}(\hat{\beta}) = \left\{ \nabla^2 l(\hat{\beta}^{(k)}) - 2W^{-1} \right\}^{-1} \text{cov} \left( \nabla l(\hat{\beta}^{(k)}) - 2b \right) \left\{ \nabla^2 l(\hat{\beta}^{(k)}) - 2W^{-1} \right\}^{-1}$$

$$= \left\{ \nabla^2 l(\hat{\beta}^{(k)}) - 2W^{-1} \right\}^{-1} \text{cov} \left( \nabla l(\hat{\beta}^{(k)}) \right) \left\{ \nabla^2 l(\hat{\beta}^{(k)}) - 2W^{-1} \right\}^{-1}$$

It is common practice to report only the standard errors of the nonzero parameters.

**Panel Data Analysis**

**Panel Data Poisson Regression with Fixed Effects**

The count regression model for panel data can be derived from the Poisson regression model. Consider the multiplicative one-way panel data model,

$$y_{it} \sim \text{Poisson}(\mu_{it})$$

where

$$\mu_{it} = \alpha_i \lambda_{it} = \alpha_i \exp(x'_{it} \beta), \quad i = 1, \ldots, N, \; t = 1, \ldots, T$$

Here, \( \alpha_i \) are the individual effects.

In the fixed-effects model, the \( \alpha_i \) are unknown parameters. The fixed-effects model can be estimated by eliminating \( \alpha_i \) by conditioning on \( \sum_t y_{it} \).

In the random-effects model, the \( \alpha_i \) are independent and identically distributed (iid) random variables, in contrast to the fixed effects model. The random-effects model can then be estimated by assuming a distribution for \( \alpha_i \).

In the Poisson fixed-effects model, conditional on \( \lambda_{it} \) and parameter \( \alpha_i \), \( y_{it} \) is iid Poisson-distributed with parameter \( \mu_{it} = \alpha_i \lambda_{it} = \alpha_i \exp(x'_{it} \beta) \), and \( x_{it} \) does not include an intercept. Then, the conditional joint density for the outcomes within the \( i \)th panel is

$$P[y_{i1}, \ldots, y_{iT_i} | \sum_{t=1}^{T_i} y_{it}] = P[y_{i1}, \ldots, y_{iT_i}, \sum_{t=1}^{T_i} y_{it}] / P[\sum_{t=1}^{T_i} y_{it}]$$

$$= P[y_{i1}, \ldots, y_{iT_i}] / P[\sum_{t=1}^T y_{it}]$$

Because \( y_{it} \) is iid Poisson(\( \mu_{it} \)), \( P[y_{i1}, \ldots, y_{iT_i}] \) is the product of \( T_i \) Poisson densities. Also, (\( \sum_{t=1}^{T_i} y_{it} \)) is
Poisson($\sum_{t=1}^{T_i} \mu_{it}$). Then,

$$P[y_{i1}, \ldots, y_{iT_i} | \sum_{t=1}^{T_i} y_{it}] = \frac{\sum_{t=1}^{T_i} (\exp(-\mu_{it}) \mu_{it}^{y_{it}} / y_{it}!)}{\exp(-\sum_{t=1}^{T_i} \mu_{it}) \left( \prod_{t=1}^{T_i} \mu_{it}^{y_{it}} / y_{it}! \right)}$$

$$= \frac{\exp(-\sum_{t=1}^{T_i} \mu_{it}) \prod_{t=1}^{T_i} \left( \frac{\mu_{it}}{\sum_{s=1}^{T_i} \mu_{is}} \right)^{y_{it}}}{\prod_{t=1}^{T_i} \left( \frac{\mu_{it}}{\sum_{s=1}^{T_i} \mu_{is}} \right)^{y_{it}}}$$

Thus, the conditional log-likelihood function of the fixed-effects Poisson model is given by

$$\mathcal{L} = \sum_{i=1}^{N} \left[ \ln \left( \frac{\prod_{t=1}^{T_i} y_{it}}{T_i} \right) - \sum_{t=1}^{T_i} \ln(y_{it}!) + \sum_{t=1}^{T_i} y_{it} \ln \left( \frac{\lambda_{it}}{\sum_{s=1}^{T_i} \lambda_{is}} \right) \right]$$

The gradient is

$$\frac{\partial \mathcal{L}}{\partial \beta} = \sum_{i=1}^{N} \sum_{t=1}^{T_i} y_{it} x_{it} - \sum_{i=1}^{N} \sum_{t=1}^{T_i} \left[ \frac{\exp(x_{is}' \beta) x_{is}}{\sum_{k=1}^{T_i} \exp(x_{ik}' \beta)} \right]$$

$$= \sum_{i=1}^{N} \sum_{t=1}^{T_i} y_{it} (x_{it} - \bar{x}_i)$$

where

$$\bar{x}_i = \sum_{s=1}^{T_i} \left( \frac{\exp(x_{is}' \beta)}{\sum_{k=1}^{T_i} \exp(x_{ik}' \beta)} \right) x_{is}$$

**Panel Data Poisson Regression with Random Effects**

In the Poisson random-effects model, conditional on $\lambda_{it}$ and parameter $\alpha_i$, $y_{it}$ is iid Poisson-distributed with parameter $\mu_{it} = \alpha_i \lambda_{it} = \alpha_i \exp(x_{is}' \beta)$, and the individual effects, $\alpha_i$, are assumed to be iid random variables. The joint density for observations in all time periods for the $i$th individual, $P[y_{i1}, \ldots, y_{iT_i} | \lambda_{i1}, \ldots, \lambda_{iT_i}]$, can be obtained after the density $g(\alpha)$ of $\alpha_i$ is specified.

Let

$$\alpha_i \sim \text{iid gamma}(\theta, \theta)$$
so that \( E(\alpha_i) = 1 \) and \( V(\alpha_i) = 1/\theta \):

\[
g(\alpha_i) = \frac{\theta^\theta}{\Gamma(\theta)} \alpha_i^{\theta-1} \exp(-\theta \alpha_i)
\]

Let \( \lambda_i = (\lambda_{i1}, \ldots, \lambda_{iT_i}) \). Because \( y_{it} \) is conditional on \( \lambda_{it} \) and parameter \( \alpha_i \) is iid Poisson(\( \mu_{it} = \alpha_i \lambda_{it} \)), the conditional joint probability for observations in all time periods for the \( i \)th individual, \( P[y_{i1}, \ldots, y_{iT_i} | \lambda_i, \alpha_i] \), is the product of \( T_i \) Poisson densities:

\[
P[y_{i1}, \ldots, y_{iT_i} | \lambda_i, \alpha_i] = \prod_{t=1}^{T_i} P[y_{it} | \lambda_i, \alpha_i]
= \prod_{t=1}^{T_i} \left[ \frac{\exp(-\mu_{it}) \mu_{it}^{y_{it}}}{y_{it}!} \right]
= \left[ \prod_{t=1}^{T_i} e^{-\alpha_i \lambda_{it}} (\alpha_i \lambda_{it})^{y_{it}} / y_{it}! \right]
= \left[ \prod_{t=1}^{T_i} \lambda_{it}^{y_{it} / y_{it}} \right] \exp(\alpha_i \sum_t \lambda_{it} - \sum_t y_{it})
\]

Then, the joint density for the \( i \)th panel conditional on just the \( \lambda \) can be obtained by integrating out \( \alpha_i \):

\[
P[y_{i1}, \ldots, y_{iT_i} | \lambda_i] = \int_0^\infty P[y_{i1}, \ldots, y_{iT} | \lambda_i, \alpha_i] g(\alpha_i) d\alpha_i
= \frac{\theta^\theta}{\Gamma(\theta)} \left[ \prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it} / y_{it}}}{y_{it}!} \right] \int_0^\infty \exp(-\alpha_i \sum_t \lambda_{it}) \alpha_i^{\theta-1} \exp(-\theta \alpha_i) d\alpha_i
= \frac{\theta^\theta}{\Gamma(\theta)} \left[ \prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it} / y_{it}}}{y_{it}!} \right] \int_0^\infty \exp \left[ -\alpha_i \left( \theta + \sum_t \lambda_{it} \right) \right] \alpha_i^{\theta + \sum_t y_{it} - 1} d\alpha_i
= \left[ \prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it} / y_{it}}}{y_{it}!} \right] \frac{\Gamma(\theta + \sum_t y_{it})}{\Gamma(\theta)} \times \left( \frac{\theta}{\theta + \sum_t \lambda_{it}} \right)^\theta \left( \theta + \sum_t \lambda_{it} \right)^{-\sum_t y_{it}}
= \left[ \prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it} / y_{it}}}{y_{it}!} \right] \frac{\Gamma(\alpha^{-1} + \sum_t y_{it})}{\Gamma(\alpha^{-1})} \times \left( \frac{\alpha^{-1}}{\alpha^{-1} + \sum_t \lambda_{it}} \right)^{\alpha^{-1}} \left( \alpha^{-1} + \sum_t \lambda_{it} \right)^{-\sum_t y_{it}}
\]

where \( \alpha(= 1/\theta) \) is the overdispersion parameter. This is the density of the Poisson random-effects model with gamma-distributed random effects. For this distribution, \( E(y_{it}) = \lambda_{it} \) and \( V(y_{it}) = \lambda_{it} + \alpha \lambda_{it}^2 \); that is, there is overdispersion.
Then the log-likelihood function is written as

\[
\mathcal{L} = \sum_{i=1}^{N} \left\{ \sum_{t=1}^{T_i} \ln \left( \frac{\lambda_{it}^{y_{it}}} {y_{it}!} \right) + \alpha^{-1} \ln (\alpha^{-1}) - \alpha^{-1} \ln (\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it}) \right\} \\
+ \sum_{i=1}^{N} \left\{ - \left( \sum_{t=1}^{T_i} y_{it} \right) \ln \left( \alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it} \right) \\
+ \ln \left[ \Gamma \left( \alpha^{-1} + \sum_{t=1}^{T_i} y_{it} \right) \right] - \ln(\Gamma(\alpha^{-1})) \right\}
\]

The gradient is

\[
\frac{\partial \mathcal{L}}{\partial \beta} = \sum_{i=1}^{N} \left\{ \sum_{t=1}^{T_i} y_{it} x_{it} - \frac{\alpha^{-1} \sum_{t=1}^{T_i} \lambda_{it} x_{it}} {\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it}} \right\} \\
- \sum_{i=1}^{N} \left\{ \left( \sum_{t=1}^{T_i} y_{it} \right) \frac{\sum_{t=1}^{T_i} \lambda_{it} x_{it}} {\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it}} \right\}
\]

\[
\frac{\partial \mathcal{L}}{\partial \alpha} = \sum_{i=1}^{N} \left\{ -\alpha^{-2} \left[ 1 + \ln(\alpha^{-1}) \right] - \frac{\alpha^{-1} + \sum_{t=1}^{T_i} y_{it}} {\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it}} - \ln \left( \alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it} \right) \right\}
\]

\[
+ \sum_{i=1}^{N} \left\{ -\alpha^{-2} \left[ \frac{\Gamma'(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it})} {\Gamma(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it})} - \frac{\Gamma'(\alpha^{-1})} {\Gamma(\alpha^{-1})} \right] \right\}
\]

where \( \lambda_{it} = \exp(x_{it}'\beta) \), \( \Gamma'(\cdot) = d \Gamma(\cdot)/d\cdot \) and \( \Gamma'(\cdot)/\Gamma(\cdot) \) is the digamma function.

**Panel Data Negative Binomial Regression with Fixed Effects**

This section shows the derivation of a negative binomial model with fixed effects. Keep the assumptions of the Poisson-distributed dependent variable

\[
y_{it} \sim \text{Poisson} (\mu_{it})
\]

But now let the Poisson parameter be random with gamma distribution and parameters \((\lambda_{it}, \delta)\),

\[
\mu_{it} \sim \Gamma (\lambda_{it}, \delta)
\]
where one of the parameters is the exponentially affine function of independent variables \( \lambda_{it} = \exp (x_{it} \beta) \). Use integration by parts to obtain the distribution of \( y_{it} \),

\[
P[y_{it}] = \int_0^\infty e^{-\mu_{it}} \frac{\mu_{it}^{y_{it}}}{y_{it}!} f(\mu_{it}) d\mu_{it}
\]

\[
= \frac{\Gamma (\lambda_{it} + y_{it})}{\Gamma (\lambda_{it}) \Gamma (y_{it} + 1)} \left( \frac{\delta}{1 + \delta} \right)^{\lambda_{it}} \left( 1 + \delta \right)^{y_{it}}
\]

which is a negative binomial distribution with parameters \((\lambda_{it}, \delta)\). Conditional joint distribution is given as

\[
P[y_{i1}, \ldots, y_{iT}] \prod_{t=1}^T y_{it} = \left( \prod_{t=1}^T \frac{\Gamma (\lambda_{it} + y_{it})}{\Gamma (\lambda_{it}) \Gamma (y_{it} + 1)} \right) \times \left( \frac{\Gamma (\sum_{t=1}^T \lambda_{it})}{\Gamma (\sum_{t=1}^T \lambda_{it} + \sum_{t=1}^T y_{it})} \right)
\]

Hence, the conditional fixed-effects negative binomial log-likelihood is

\[
L = \sum_{i=1}^N \left[ \log \Gamma \left( \sum_{t=1}^{T_i} \lambda_{it} \right) + \log \Gamma \left( \sum_{t=1}^{T_i} y_{it} + 1 \right) - \log \Gamma \left( \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it} \right) \right]
\]

\[+ \sum_{i=1}^N \sum_{t=1}^{T_i} \left[ \log (\lambda_{it} + y_{it}) - \log (\lambda_{it}) - \log (y_{it} + 1) \right]
\]

The gradient is

\[
\frac{\partial L}{\partial \beta} = \sum_{i=1}^N \left[ \left( \frac{\Gamma' \left( \sum_{t=1}^{T_i} \lambda_{it} \right)}{\Gamma \left( \sum_{t=1}^{T_i} \lambda_{it} \right)} - \frac{\Gamma' \left( \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it} \right)}{\Gamma \left( \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it} \right)} \right) \sum_{t=1}^{T_i} \lambda_{it} x_{it} \right]
\]

\[+ \sum_{i=1}^N \frac{\Gamma' \left( \sum_{t=1}^{T_i} y_{it} + 1 \right)}{\Gamma \left( \sum_{t=1}^{T_i} y_{it} + 1 \right)}
\]

\[+ \sum_{i=1}^N \sum_{t=1}^{T_i} \left[ \frac{\Gamma' (\lambda_{it} + y_{it})}{\Gamma (\lambda_{it} + y_{it})} - \frac{\Gamma' (\lambda_{it})}{\Gamma (\lambda_{it})} \right] \lambda_{it} x_{it} - \frac{\Gamma' (y_{it} + 1)}{\Gamma (y_{it} + 1)}
\]

**Panel Data Negative Binomial Regression with Random Effects**

This section describes the derivation of negative binomial model with random effects. Suppose

\( y_{it} \sim \text{Poisson} (\mu_{it}) \)

with the Poisson parameter distributed as gamma,

\( \mu_{it} \sim \Gamma (\nu \lambda_{it}, \delta) \)
where its parameters are also random:
\[ v_{it} \lambda_{it} = \exp(\mathbf{x}'_{it} \beta + \eta_{it}) \]
Assume that the distribution of a function of \( v_{i} \) is beta with parameters \((a, b)\):
\[ \frac{v_{i}}{1 + v_{i}} \sim Beta(a, b) \]
Explicitly, the beta density with \([0, 1]\) domain is
\[ f(z) = (B(a, b))^{-1} z^{a-1} (1-z)^{b-1} \]
where \( B(a, b) \) is the beta function. Then, conditional joint distribution of dependent variables is
\[
P[y_{i1}, \ldots, y_{iT_i} | x_{i1}, \ldots, x_{iT_i}, v_i] = \prod_{t=1}^{T_i} \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)} \left( \frac{1}{1 + v_{i}} \right)^{\lambda_{it}} \left( \frac{v_{i}}{1 + v_{i}} \right)^{y_{it}}
\]
Integrating out the variable \( v_{i} \) yields the following conditional distribution function:
\[
P[y_{i1}, \ldots, y_{iT_i} | x_{i1}, \ldots, x_{iT_i}] = \int_0^\infty \left[ \prod_{t=1}^{T_i} \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)} z^\lambda_{it} (1-z)^{y_{it}} \right] f(z_i) dz_i \]
\[
= \frac{\Gamma(a + b) \Gamma\left(a + \sum_{t=1}^{T_i} \lambda_{it}\right) \Gamma\left(b + \sum_{t=1}^{T_i} y_{it}\right)}{\Gamma(a) \Gamma(b) \Gamma\left(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it}\right)} \times \prod_{t=1}^{T_i} \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)}
\]
Consequently, the conditional log-likelihood function for a negative binomial model with random effects is
\[
\mathcal{L} = \sum_{i=1}^{N} \left[ \log \Gamma(a + b) + \log \Gamma\left(a + \sum_{t=1}^{T_i} \lambda_{it}\right) + \log \Gamma\left(b + \sum_{t=1}^{T_i} y_{it}\right) \right] - \sum_{i=1}^{N} \left[ \log \Gamma(a) + \log \Gamma(b) + \log \Gamma\left(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it}\right) \right] + \sum_{i=1}^{N} \sum_{t=1}^{T_i} \left[ \log(\lambda_{it} + y_{it}) - \log(\lambda_{it}) - \log(y_{it} + 1) \right]
\]
The gradient is
\[
\frac{\partial \mathcal{L}}{\partial \beta} = \sum_{i=1}^{N} \left[ \frac{\Gamma'(a + \sum_{t=1}^{T_i} \lambda_{it})}{\Gamma(a + \sum_{t=1}^{T_i} \lambda_{it})} \sum_{t=1}^{T_i} \lambda_{it} x_{it} + \frac{\Gamma'(b + \sum_{t=1}^{T_i} y_{it})}{\Gamma(b + \sum_{t=1}^{T_i} y_{it})} \right] - \sum_{i=1}^{N} \left[ \frac{\Gamma'(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})}{\Gamma(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})} \sum_{t=1}^{T_i} \lambda_{it} x_{it} \right] + \sum_{i=1}^{N} \sum_{t=1}^{T_i} \left[ \left( \frac{\Gamma'(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it} + y_{it})} - \frac{\Gamma'(\lambda_{it})}{\Gamma(\lambda_{it})} \right) \lambda_{it} x_{it} - \frac{\Gamma'(y_{it} + 1)}{\Gamma(y_{it} + 1)} \right]
\]
The time and memory that PROC COUNTREG requires are proportional to the number of parameters in the model and the number of observations in the data set being analyzed. Less time and memory are required for smaller models and fewer observations. Also affecting these resources are the method that is chosen to calculate the variance-covariance matrix and the optimization method. All optimization methods available through the METHOD= option have similar memory use requirements.

The processing time might differ for each method, depending on the number of iterations and functional calls needed. The data set is read into memory to save processing time. If not enough memory is available to hold the data, the COUNTREG procedure stores the data in a utility file on disk and rereads the data as needed from this file. When this occurs, the execution time of the procedure increases substantially. The gradient and the variance-covariance matrix must be held in memory. If the model has \(p\) parameters including the intercept, then at least 8 \(\times (p + p \times (p + 1)/2)\) bytes are needed. If the quasi-maximum likelihood method is used to estimate the variance-covariance matrix (COVEST=QML), an additional 8 \(\times p \times (p + 1)/2\) bytes of memory are needed.

Time is also a function of the number of iterations needed to converge to a solution for the model parameters. The number of iterations that are needed cannot be known in advance. The MAXITER= option can be used to limit the number of iterations that PROC COUNTREG does. The convergence criteria can be altered by nonlinear optimization options available in the PROC COUNTREG statement. For a list of all the nonlinear optimization options, see Chapter 6, “Nonlinear Optimization Methods.”

**Nonlinear Optimization Options**

PROC COUNTREG uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. In the PROC COUNTREG statement, you can specify nonlinear optimization options that are then
passed to the NLO subsystem. For a list of all the nonlinear optimization options, see Chapter 6, “Nonlinear Optimization Methods.”

**Covariance Matrix Types**

The COUNTREG procedure enables you to specify the estimation method for the covariance matrix. The COVEST=HESSIAN option estimates the covariance matrix based on the inverse of the Hessian matrix, COVEST=OP uses the outer product of gradients, and COVEST=QML produces the covariance matrix based on both the Hessian and outer product matrices. The default is COVEST=HESSIAN.

Although all three methods produce asymptotically equivalent results, they differ in computational intensity and produce results that might differ in finite samples. The COVEST=OP option provides the covariance matrix that is typically the easiest to compute. In some cases, the OP approximation is considered more efficient than the Hessian or QML approximation because it contains fewer random elements. The QML approximation is computationally the most complex because both the outer product of gradients and the Hessian matrix are required. In most cases, OP or Hessian approximation is preferred to QML. The need to use QML approximation arises in some cases when the model is misspecified and the information matrix equality does not hold.

**Displayed Output**

PROC COUNTREG produces the following displayed output.

**Class Level Information**

If you specify the CLASS statement, the COUNTREG procedure displays a table that contains the following information:

- class variable name
- number of levels of the class variable
- list of values of the class variable

**Iteration History for Parameter Estimates**

If you specify the ITPRINT or PRINTALL option in the PROC COUNTREG statement, PROC COUNTREG displays a table that contains the following information for each iteration. Some information is specific to the model-fitting procedure that you choose (for example, Newton-Raphson, trust region, quasi-Newton).

- iteration number
- number of restarts since the fitting began
- number of function calls
- number of active constraints at the current solution
• value of the objective function (−1 times the log-likelihood value) at the current solution
• change in the objective function from previous iteration
• value of the maximum absolute gradient element
• step size (for Newton-Raphson and quasi-Newton methods)
• slope of the current search direction (for Newton-Raphson and quasi-Newton methods)
• lambda (for trust region method)
• radius value at current iteration (for trust region method)

Model Fit Summary

The “Model Fit Summary” table contains the following information:

• dependent (count) variable name
• number of observations used
• number of missing values in data set, if any
• data set name
• type of model that was fit
• parameterization for the Conway-Maxwell-Poisson model
• offset variable name, if any
• zero-inflated link function, if any
• zero-inflated offset variable name, if any
• log-likelihood value at solution
• maximum absolute gradient at solution
• number of iterations
• AIC value at solution (a smaller value indicates better fit)
• SBC value at solution (a smaller value indicates better fit)

Under the “Model Fit Summary” is a statement about whether the algorithm successfully converged.
Parameter Estimates

The “Parameter Estimates” table gives the estimates of the model parameters. In zero-inflated (ZI) models, estimates are also given for the ZI intercept and ZI regressor parameters labeled with the prefix “Inf_”. For example, the ZI intercept is labeled “Inf_intercept”. If you specify “Age” as a ZI regressor, then the “Parameter Estimates” table labels the corresponding parameter estimate “Inf_Age”. If you do not list any ZI regressors, then only the ZI intercept term is estimated.

If the DISPMODEL statement is specified for the Conway-Maxwell-Poisson model, the estimates are given for the dispersion intercept, and parameters are labeled with the prefix “Dsp_”. For example, the dispersion model intercept is labeled “Dsp_Intercept”. If you specify “Education” as a dispersion model regressor, then the “Parameter Estimates” table labels the corresponding parameter estimate “Dsp_Education”. If you do not list any dispersion regressors, then only the dispersion intercept is estimated.

“_Alpha” is the negative binomial dispersion parameter. The t statistic given for “_Alpha” is a test of overdispersion.

Last Evaluation of the Gradient

If you specify the model option ITPRINT, the COUNTREG procedure displays the last evaluation of the gradient vector.

Covariance of Parameter Estimates

If you specify the COVB option in the MODEL statement or in the PROC COUNTREG statement, the COUNTREG procedure displays the estimated covariance matrix, defined as the inverse of the information matrix at the final iteration.

Correlation of Parameter Estimates

If you specify the CORRB option in the MODEL statement or in the PROC COUNTREG statement, PROC COUNTREG displays the estimated correlation matrix. It is based on the Hessian matrix that is used in the final iteration.

OUTPUT OUT= Data Set

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimates of \( x_i \beta \), the expected value of the response variable, and the probability that the response variable will take the current value or other values that you specify. In a zero-inflated model, you can also request that the output data set contain the estimates of \( z_i \gamma \), and the probability that the response is zero as a result of the zero-generating process. In a Conway-Maxwell-Poisson model, you can also request that the output data set contains estimates of \( g_i \delta, \lambda, \nu, \mu \), mode, variance and dispersion.
Except for the probability of the current value, these statistics can be computed for all observations in which
the regressors are not missing, even if the response is missing. By adding observations that have missing
response values to the input data set, you can compute these statistics for new observations or for settings of
the regressors that are not present in the data without affecting the model fit.

**OUTEST= Data Set**

The OUTEST= data set is has two rows: the first row (with _TYPE_ = ‘PARAM’) contains each of the parameter
estimates in the model, and the second row (with _TYPE_ = ‘STD’) contains the standard errors for the
parameter estimates in the model.

If you specify the COVOUT option in the PROC COUNTREG statement, the OUTEST= data set also
contains the covariance matrix for the parameter estimates. The covariance matrix appears in the observations
for which _TYPE_ = ‘COV’, and the _NAME_ variable labels the rows with the parameter names.

The names of the parameters are used as variable names. These are the same names that are used in the INIT,
BOUNDS, and RESTRICT statements.

**ODS Table Names**

PROC COUNTREG assigns a name to each table that it creates. You can use these names to denote the table
when using the Output Delivery System (ODS) to select tables and create output data sets. These names are
listed in Table 11.3.

ODS Graphics

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS Graphics to create graphics by using the COUNTREG procedure.

To request these graphs, you must specify the ODS GRAPHICS statement. There is no default plot for the COUNTREG procedure. If, in addition to the ODS GRAPHICS statement, you specify the ALL option in the PROC COUNTREG statement, then all applicable plots are created.

ODS Graph Names

PROC COUNTREG assigns a name to each graph that it creates using ODS. You can use these names to refer to the graphs when using ODS. The names are listed in Table 11.4.

Examples: COUNTREG Procedure

Example 11.1: Basic Models

Data Description and Objective

The data set DocVisit contains information for approximately 5,000 Australian individuals about the number and possible determinants of doctor visits that were made during a two-week interval. This data set contains a subset of variables that are taken from the Racd3 data set used by Cameron and Trivedi (1998). The DocVisit data set can be found in the SAS/ETS Sample Library.

The variable Doctorco represents doctor visits. Additional variables in the data set that you want to evaluate as determinants of doctor visits include Sex (coded 0=male, 1=female), Age (age in years divided by 100), Illness (number of illnesses during the two-week interval, with five or more coded as five), Income (annual income in Australian dollars divided by 1,000), and Hscore (a score on a general health questionnaire, in which a high score indicates bad health). Summary statistics for these variables are computed in the following statements and presented in Output 11.1.1.

```plaintext
proc means data=docvisit;
   var doctorco sex age illness income hscore;
run;
```

Poisson Model

The following statements fit a Poisson model to the data by using the covariates Sex, Illness, Income, and Hscore:

```plaintext
proc countreg data=docvisit plots(only counts(0 to 4 by 1))=(predprob predpro);
   model doctorco=sex illness income hscore / dist=poisson printall;
run;
```
Output 11.1.2 Mean Predicted Count Probabilities

Output 11.1.2 shows the predicted probabilities of count levels 0 to 4 from the Poisson model. Most of the observed counts are in the range 0 to 4 and account for more than 99% of the entire data set. One factor that would be interesting to explore is how the model-predicted probabilities of those count levels react to different regressor values. Output 11.1.3 shows the predictive profiles of the count levels in question against the first three regressors in the model. In each panel, the regressor in question is varied while all other regressors are fixed at their observed mean and the model parameters are fixed at their MLE.
Example 11.1: Basic Models

Output 11.1.3 Profile Function of Predictive Probabilities

In this example, the DIST= option in the MODEL statement specifies the Poisson distribution. In addition, the PRINTALL option displays the correlation and covariance matrices for the parameters, log-likelihood values, and convergence information in addition to the parameter estimates. The parameter estimates for this model are shown in Output 11.1.4.

Output 11.1.4 Parameter Estimates of Poisson Model

| Parameter  | DF  | Estimate  | Standard Error | t Value | Pr > |t| |
|------------|-----|-----------|----------------|---------|------|---|
| Intercept  | 1   | -1.855552 | 0.074545       | -24.89  | <.0001 |
| sex        | 1   | 0.235583  | 0.054362       | 4.33    | <.0001 |
| illness    | 1   | 0.270326  | 0.017080       | 15.83   | <.0001 |
| income     | 1   | -0.242095 | 0.077829       | -3.11   | 0.0019 |
| hscore     | 1   | 0.096313  | 0.009089       | 10.60   | <.0001 |
Using the CLASS Statement

If some regressors are categorical in nature (meaning that these variables can take only a few discrete qualitative values), specify them in the CLASS statement. In this example, Sex is categorical because it takes only two values. A CLASS variable can be numeric or character.

Consider the following extension:

```sas
proc countreg data=docvisit;
  class sex;
  model doctorco=sex illness income hscore / dist=poisson;
run;
```

The partial output is given in Output 11.1.5.

**Output 11.1.5** Parameter Estimates of Poisson Model with CLASS statement

| Parameter | DF | Estimate  | Standard Error | t Value | Pr > |t| |
|-----------|----|-----------|----------------|---------|------|---|
| Intercept | 1  | -1.61969  | 0.063985       | -25.32  | <.0001 |
| sex 0     | 1  | -0.235583 | 0.054362       | -4.33   | <.0001 |
| sex 1     | 0  |           |                |         |      |   |
| illness   | 1  | 0.270326  | 0.017080       | 15.83   | <.0001 |
| income    | 1  | -0.242095 | 0.077829       | -3.11   | 0.0019 |
| hscore    | 1  | 0.096313  | 0.009089       | 10.60   | <.0001 |

If the CLASS statement is present, the COUNTREG procedure creates as many indicator or dummy variables as there are categories in a CLASS variable and uses them as independent variables. In order to avoid collinearity with the intercept, the last-created dummy variable is assigned a zero coefficient by default. This means that only the dummy variable that is associated with the first level of Sex (male=0) is used as a regressor. Consequently, the estimated coefficient for this dummy variable is the negative of the one for the original Sex variable in Output 11.1.4, because the reference level has switched from male to female.

Now consider a more practical task. The previous example implicitly assumes that each additional illness during the two-week interval has the same effect. In other words, this variable is thought of as a continuous variable. But this variable has only six values, and it is quite possible that the number of illnesses has a nonlinear effect on doctor visits. In order to check this conjecture, the following statements specify the Illness variable in the CLASS statement so that it is represented in the model by a set of six dummy variables that can account for any type of nonlinearity:

```sas
proc countreg data=docvisit;
  class sex illness;
  model doctorco=sex illness income hscore / dist=poisson;
run;
```

The parameter estimates are displayed in Output 11.1.6.
Output 11.1.6 Parameter Estimates of Poisson Model with CLASS statement

The COUNTREG Procedure

Parameter Estimates

| Parameter | DF | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----|----------|----------------|---------|-------|---|
| Intercept | 1  | -0.385930 | 0.088062 | -4.38 | <.0001 |
| sex 0     | 1  | -0.219118 | 0.054190 | -4.04 | <.0001 |
| sex 1     | 0  | 0         | . | . | . | . |
| illness 0 | 1  | -1.934983 | 0.121267 | -15.96 | <.0001 |
| illness 1 | 1  | -0.698307 | 0.089732 | -7.78 | <.0001 |
| illness 2 | 1  | -0.471100 | 0.090742 | -5.19 | <.0001 |
| illness 3 | 1  | -0.488481 | 0.099127 | -4.93 | <.0001 |
| illness 4 | 1  | -0.272372 | 0.107593 | -2.53 | 0.0114 |
| illness 5 | 0  | 0         | . | . | . | . |
| income    | 1  | -0.253583 | 0.077441 | -3.27 | 0.0011 |
| hscore    | 1  | 0.094590  | 0.009025 | 10.48 | <.0001 |

The Estimate column shows the difference between each ILLNESS parameter and ILLNESS=5. Note that these estimates for different Illness categories do not increase linearly but instead show a relatively large jump from zero illnesses to one illness, followed by relatively smaller increases.

Zero-Inflated Poisson (ZIP) Model

Suppose you suspect that the population of individuals can be viewed as two distinct groups: a low-risk group, consisting of individuals who never go to the doctor, and a high-risk group, consisting of individuals who do go to the doctor. You might suspect that the data have this structure both because the sample variance of Doctorco (0.64) exceeds its sample mean (0.30), which suggests overdispersion, and because a large fraction of the Doctorco observations (80%) have the value zero. Estimating a zero-inflated model is one way to deal with overdispersion that results from excess zeros.

Suppose also that you suspect that the covariate Age has an impact on whether an individual belongs to the low-risk group. For example, younger individuals might have illnesses of much lower severity when they do get sick and be less likely to visit a doctor, all other factors being equal. The following statements estimate a zero-inflated Poisson regression, with Age as a covariate in the zero-generation process:

```r
proc countreg data=docvisit plots(only)=(dispersion zeroprofile);  
  model doctorco=sex illness income hscore / dist=zip;  
  zeromodel doctorco ~ age;  
run;
```
You might be interested in exploring how the zero process selection probability reacts to different regressor values. Output 11.1.7 displays this information in much the same fashion as Output 11.1.3. Because Sex, Illness, Income, and Hscore do not appear in the ZEROMODEL statement, the zero-inflation selection probability does not change for different values of those regressors. However, the plot shows that Age positively affects the zero process selection probability in a linear fashion.

In this case, the ZEROMODEL statement that follows the MODEL statement specifies that both an intercept and the variable Age be used to estimate the likelihood of zero doctor visits. Output 11.1.8 shows the resulting parameter estimates.
The estimates of the zero-inflated intercept (Inf_Intercept) and the zero-inflated regression coefficient for Age (Inf_age) are approximately 0.99 and –2.09, respectively. Because the zero-inflation model uses a logistic link by default, you can estimate the probabilities for individuals of ages 20, 50, and 70 as follows:

\[
\begin{align*}
20\text{ years: } & \quad \frac{e^{(0.99-2.09\cdot 20)}}{1+e^{(0.99-2.09\cdot 20)}} = 0.64 \\
50\text{ years: } & \quad \frac{e^{(0.99-2.09\cdot 50)}}{1+e^{(0.99-2.09\cdot 50)}} = 0.49 \\
70\text{ years: } & \quad \frac{e^{(0.99-2.09\cdot 70)}}{1+e^{(0.99-2.09\cdot 70)}} = 0.38
\end{align*}
\]

That is, the estimated probability of belonging to the low-risk group is about 0.64 for a 20-year-old individual, 0.49 for a 50-year-old individual, and only 0.38 for a 70-year-old individual. This supports the suspicion that older individuals are more likely to have a positive number of doctor visits.

Alternative models to account for the overdispersion are the negative binomial and the zero-inflated negative binomial models, which can be fit using the DIST=NEGBIN and DIST=ZINB options, respectively.
Output 11.1.9 plots the conditional variance against the conditional mean and can be used as a diagnostic tool to check the level of overdispersion in a model.

Example 11.2: ZIP and ZINB Models for Data That Exhibit Extra Zeros

In the study by Long (1997) of the number of published articles by scientists (see the section “Getting Started: COUNTREG Procedure” on page 561), the observed proportion of scientists who publish no articles is 0.3005. The following statements use PROC FREQ to compute the proportion of scientists who publish each observed number of articles. Output 11.2.1 shows the results.

```plaintext
proc freq data=long97data;
   table art / out=obs;
run;
```

PROC COUNTREG is then used to fit Poisson and negative binomial models to the data. For each model, the PROBCOUNT option computes the probability that the number of published articles is \( m \), for \( m = 0 \) to \( 10 \). The following statements compute the estimates for Poisson and negative binomial models. The MEAN procedure is then used to compute the average probability of a zero response.

```plaintext
proc countreg data=long97data;
   model art=fem mar kid5 phd ment / dist=poisson;
   output out=predpoi probcount(0 to 10);
run;

proc means mean data=predpoi;
   var p_0;
run;
```

The output from the Poisson model for the COUNTREG and MEAN procedures is shown in Output 11.2.2.

```

```
proc means mean data=prednb;
  var p_0;
run;
```
Output 11.2.3 Profile Likelihood Functions
Output 11.2.3 show the profile likelihood functions of the negative binomial model for the Long (1997) data set, in which each model parameter is varied while holding all others fixed at the MLE. This can serve as a diagnostic tool for model performance, because a large number of flat profile likelihood functions indicates poor optimization results and the resulting MLE should be used with caution.

Output 11.2.4 shows the results of the preceding statements.

For each model, the predicted proportion of zero articles can be calculated as the average predicted probability of zero articles across all scientists. Under the Poisson model, the predicted proportion of zero articles is 0.2092, which considerably underestimates the observed proportion. The negative binomial more closely estimates the proportion of zeros (0.3036). Also, the test of the dispersion parameter, _Alpha, in the negative binomial model indicates significant overdispersion ($p < 0.0001$). As a result, the negative binomial model is preferred to the Poisson model.
Another way to account for the large number of zeros in this data set is to fit a zero-inflated Poisson (ZIP) or a zero-inflated negative binomial (ZINB) model. In the following statements, DIST=ZIP requests the ZIP model. In the ZEROMODEL statement, you can specify the predictors, \( z \), for the process that generates the additional zeros. The ZEROMODEL statement also specifies the model for the probability \( \varphi \). By default, a logistic model is used for \( \varphi \). You can change the default by using the LINK= option. In this particular ZIP model, all variables that are used to model the article counts are also used to model \( \varphi \).

```plaintext
proc countreg data=long97data;
   model art = fem mar kid5 phd ment / dist=zip;
   zeromodel art ~ fem mar kid5 phd ment;
   output out=predzip probcount(0 to 10);
run;

proc means data=predzip mean;
   var p_0;
run;
```

The parameters of the ZIP model are displayed in Output 11.2.5. The first set of parameters gives the estimates of \( \beta \) in the model for the Poisson process mean. Parameters that have the prefix “Inf_” are the estimates of \( \varphi \) in the logistic model for \( \varphi \).

**Output 11.2.5 ZIP Model Estimation**

The proportion of zeros that are predicted by the ZIP model is 0.2986, which is much closer to the observed proportion than the Poisson model. But Output 11.2.7 shows that both models deviate from the observed proportions at one, two, and three articles.

The ZINB model is specified by the DIST=ZINB option. All variables are again used to model both the number of articles and . The METHOD=QN option specifies that the quasi-Newton method be used to fit the model rather than the default Newton-Raphson method. These options are implemented in the following statements:

```plaintext
proc countreg data=long97data;
    model art=fem mar kid5 phd ment / dist=zinb method=qn;
    zeromodel art ~ fem mar kid5 phd ment;
    output out=predzinb probcount(0 to 10);
run;
```

```plaintext
proc means data=predzinb mean;
    var p_0;
run;
```

The estimated parameters of the ZINB model are shown in Output 11.2.6. The test for overdispersion again indicates a preference for the negative binomial version of the zero-inflated model (p < 0.0001). The ZINB model also does a good job of estimating the proportion of zeros (0.3119), and it follows the observed proportions well, though possibly not as well as the negative binomial model.

The following statements compute the average predicted count probability across all scientists for each count 0, 1, ..., 10. The averages for each model, along with the observed proportions, are then arranged for plotting by PROC SGPLOT.
Example 11.2: ZIP and ZINB Models for Data That Exhibit Extra Zeros

For each of the four fitted models, Output 11.2.7 shows the average predicted count probability for each article count across all scientists. The Poisson model clearly underestimates the proportion of zero articles published, whereas the other three models are quite accurate at zero. All the models do well at the larger numbers of articles.
Example 11.3: Variable Selection

This example demonstrates two algorithms of automatic variable selection in the COUNTREG procedure. Automatic variable selection is most effective when the number of possible candidates for explaining the variation of some variable is large. For clarity of exposition, this example uses only a small number of variables. The data set Article published by Long (1997) contains six variables. (This data set is also used in “Example 11.2: ZIP and ZINB Models for Data That Exhibit Extra Zeros” on page 624.) The dependent variable Art records the number of articles that were published by a doctoral student in the last three years of his or her program. Explanatory variables include sex of the student (Fem), marital status (Mar), number of children (Kid5), prestige of the program (Phd), and publishing activity of the academic adviser (Ment). All these variables intuitively suggest their affect on the students’ primary academic output.

First, for comparison purposes, estimate the simple Poisson model. The choice of model is specified by DIST= option in the MODEL statement, as follows:

```plaintext
proc countreg data = long97data;
  model art = fem mar kid5 phd ment / dist = poisson;
run;
```
Example 11.3: Variable Selection

The output of these statements is shown in Figure 11.3.1.

**Output 11.3.1** Poisson Model for the Number of Published Articles

```

Parameter Estimates

| Parameter | DF | Estimate | Error | t Value | Pr > |t| |
|-----------|----|----------|-------|---------|------|---|
| Intercept | 1  | 0.304617 | 0.102982 | 2.96 | 0.0031 |
| fem | 1  | -0.224594 | 0.054614 | -4.11 | <.0001 |
| mar | 1  | 0.155243 | 0.061375 | 2.53 | 0.0114 |
| kid5 | 1  | -0.184883 | 0.040127 | -4.61 | <.0001 |
| phd | 1  | 0.012823 | 0.026397 | 0.49 | 0.6271 |
| ment | 1  | 0.025543 | 0.002006 | 12.73 | <.0001 |

Note that the Newton-Raphson optimization algorithm took five steps to converge. All parameters, except for one, are significant at a 1% or 5% level, whereas Phd is not significant even at the 10% level.

In this case, it might be easy to identify the variables that have limited explanatory power. However, if the number of variables were large, the manual selection could be time-consuming and inaccurate. For a large number of variables, you would be better off in applying one of the automatic algorithms of variable selection. The following statements use the penalized likelihood method, which is indicated by SELECT=PEN option in the MODEL statement:

```
proc countreg data = long97data method = qn;
   model art = fem mar kid5 phd ment / dist = poisson
       select = PEN;
run;
```

The output of these statements is shown in Output 11.3.2.
Output 11.3.2 Poisson Model for the Number of Published Articles with Penalized Likelihood Method

Parameter Estimates

| Parameter | DF | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----|----------|----------------|---------|------|---|
| Intercept | 1  | 0.345174 | 0.060125       | 5.74    | <.0001 |
| fem       | 1  | -0.225303| 0.054615       | -4.13   | <.0001 |
| mar       | 1  | 0.152175 | 0.061067       | 2.49    | 0.0127 |
| kid5      | 1  | -0.184993| 0.040139       | -4.61   | <.0001 |
| ment      | 1  | 0.025761 | 0.001950       | 13.21   | <.0001 |

The "Parameter Estimates" table shows that the variable Phd was dropped from the model.

The next statements use the information criterion by specifying the SELECT=INFO option. The direction of the search is chosen to be forward, and the information criterion is AIC. In order to achieve the same selection of variables as for the penalized likelihood method, 0.001 is specified for the percentage of decrease in the information criterion necessary for the algorithm to stop.

```sas
proc countreg data = long97data;
    model art = fem mar kid5 phd ment / dist = poisson
                 select = INFO
                    ( direction = forward
                      criter = AIC
                      lstop = 0.001 );
run;
```

The output of these statements is shown in Figure 11.3.3.
Output 11.3.3 Poisson Model for the Number of Published Articles with Search Method Using Information Criterion

Overview: DATASOURCE Procedure

The DATASOURCE procedure extracts time series and event data from many different kinds of data files distributed by various data vendors and stores them in a SAS data set. Once stored in a SAS data set, the time series and event variables can be processed by other SAS procedures.

The DATASOURCE procedure has statements and options to extract only a subset of time series data from an input data file. It gives you control over the frequency of data to be extracted, time series variables to be selected, cross sections to be included, and time range of data to be output.

The DATASOURCE procedure can create auxiliary data sets containing descriptive information on the time series variables and cross sections. More specifically, the OUTCONT= option names a data set containing information on time series variables, the OUTBY= option names a data set that reports information on cross-sectional variables, and the OUTALL= option names a data set that combines both time series variables and cross-sectional information.

In addition to the auxiliary data sets, two types of primary output data sets are the OUT= and OUTEVENT= data sets. The OUTEVENT= data set contains event variables but excludes periodic time series data. The OUT= data set contains periodic time series data and any event variables referenced in the KEEP statement.

The output variables in the output and auxiliary data sets can be assigned various attributes by the DATASOURCE procedure. These attributes are labels, formats, new names, and lengths. While the first three attributes in this list are used to enhance the output, the length attribute is used to control the memory and disk-space usage of the DATASOURCE procedure.

Data files currently supported by the DATASOURCE procedure include the following:

- U.S. Bureau of Economic Analysis data files:
  - National Income and Product Accounts
  - National Income and Product Accounts PC format
  - S-pages

- U.S. Bureau of Labor Statistics data files:

Getting Started: DATASOURCE Procedure

Structure of a SAS Data Set Containing Time Series Data

SAS procedures require time series data to be in a specific form recognizable by the SAS System. This form is a two-dimensional array, called a SAS data set, whose columns correspond to series variables and whose rows correspond to measurements of these variables at certain time periods.

The time periods at which observations are recorded can be included in the data set as a time ID variable. The DATASOURCE procedure does include a time ID variable by the name of DATE.

For example, the following data set in Table 12.1, extracted from a DRIBASIC data file, gives the foreign exchange rates for Japan, Switzerland, and the United Kingdom, respectively.

Table 12.1 The Form of SAS Data Sets Required by Most SAS/ETS Procedures

</tbody>
</table>

Reading Data Files

The DATASOURCE procedure is designed to read data from many different files and to place them in a SAS data set. For example, if you have a DRI Basic Economics data file you want to read, use the following statements:

```sas
proc datasource filetype=dribasic infile=citifile out=dataset;
run;
```
Here, the FILETYPE= option indicates that you want to read DRI’s Basic Economics data file, the INFILE= option specifies the fileref CITIFILE of the external file you want to read, and the OUT= option names the SAS data set to contain the time series data.

Subsetting Input Data Files

When only a subset of a data file is needed, it is inefficient to extract all the data and then subset it in a subsequent DATA step. Instead, you can use the DATASOURCE procedure options and statements to extract only needed information from the data file.

The DATASOURCE procedure offers the following subsetting capabilities:

- the INTERVAL= option controls the frequency of data output
- the KEEP or DROP statement selects a subset of time series variables
- the RANGE statement restricts the time range of data
- the WHERE statement selects a subset of cross sections

Controlling the Frequency of Data – The INTERVAL= Option

The OUT= data set contains only data with the same frequency. If the data file you want to read contains time series data with several frequencies, you can indicate the frequency of data you want to extract with the INTERVAL= option. For example, the following statements extract all monthly time series from the DRIBASIC file CITIFILE:

```plaintext
proc datasource filetype=dribasic infile=citifile
   interval=month out=dataset;
run;
```

When the INTERVAL= option is not given, the default frequency defined for the FILETYPE= type file is used. For example, the statements in the previous section extract yearly series since INTERVAL=YEAR is the default frequency for DRI’s Basic Economic Data files.

To extract data for several frequencies, you need to execute the DATASOURCE procedure once for each frequency.

Selecting Time Series Variables – The KEEP and DROP Statements

If you want to include specific series in the OUT= data set, list them in a KEEP statement. If, on the other hand, you want to exclude some variables from the OUT= data set, list them in a DROP statement. For example, the following statements extract monthly foreign exchange rates for Japan (EXRJAN), Switzerland (EXRSW), and the United Kingdom (EXRUK) from a DRIBASIC file CITIFILE:
Chapter 12: The DATASOURCE Procedure

proc datasource filetype=dribasic infile=citifile
   interval=month out=dataset;
   keep  exrjan  exrsr  exrku;
run;

The KEEP statement also allows input names to be quoted strings. If the name of a series in the input file contains blanks or special characters that are not valid SAS name syntax, put the series name in quotes to select it. Another way to allow the use of special characters in your SAS variable names is to use the SAS options statement to designate VALIDVARNAME=ANY. This option will allow PROC DATASOURCE to include special characters in your SAS variable names. The following is an example of extracting series from a FAME database by using the DATASOURCE procedure.

proc datasource filetype=fame dbname='fame_nys /disk1/prc/prc'
   interval=weekday out=outds outcont=attrs;
   range '1jan90'd to '1feb90'd;
   keep cci.close
      '{ibm.high,ibm.low,ibm.close}'
      'mave(ibm.close,30)'
      'crosslist({gm,f,c},{volume})'
      'cci.close+ibm.close';
   rename 'mave(ibm.close,30)' = ibm30day
     'cci.close+ibm.close' = cci_ibm;
run;

The resulting output data set OUTDS contains the following series: DATE, CCI_CLOS, IBM_HIGH, IBM_LOW, IBM_CLOS, IBM30DAY, GM_VOLUME, F_VOLUME, C_VOLUME, CCI_IBM.

Obviously, to be able to use KEEP and DROP statements, you need to know the name of time series variables available in the data file. The OUTCONT= option gives you this information. More specifically, the OUTCONT= option creates a data set containing descriptive information on the same frequency time series. This descriptive information includes series names, a flag indicating if the series is selected for output, series variable types, lengths, position of series in the OUT= data set, labels, format names, format lengths, format decimals, and a set of FILETYPE= specific descriptor variables.

For example, the following statements list some of the monthly series available in the CITIFILE and are shown in Figure 12.1.

```sas
/*--- Selecting Time Series Variables -- The KEEP and DROP Statements ---*/
filename citifile "%sysget(DATASRC_DATA)citiaf.dat" RECFM=F LRECL=80;
proc datasource filetype=dribasic infile=citifile
   interval=month outcont=vars;
   drop e: ;
run;

title1 'Some Time Series Variables Available in CITIFILE';
proc print data=vars;
run;
```

Controlling the Time Range of Data – The RANGE Statement

The RANGE statement is used to control the time range of observations included in the output data set. Figure 12.2 shows an example extracting the foreign exchange rates from September 1985 to February 1987, you can use the following statements:

```sas
/*--- Controlling the Time Range of Data – The RANGE Statement ---*/
filename citifile "%sysget(DATASRC_DATA)citiaf.dat" RECFM=F LRECL=80;
proc datasource filetype=dribasic infile=citifile
   interval=month out=dataset;
      keep  exrjan exrsw exruk;
      range from 1985:9 to 1987:2;
run;

title1 'Printout of the OUT= Data Set';
proc print data=dataset;
run;
```

Reading in Data Files Containing Cross Sections

Some data files group time series data with respect to cross-section identifiers; for example, International Financial Statistics files, distributed by IMF, group data with respect to countries (COUNTRY). Within each country, data are further grouped by Control Source Code (CSC), Partner Country Code (PARTNER), and Version Code (VERSION).
If a data file contains cross-section identifiers, the DATASOURCE procedure adds them to the output data set as BY variables. For example, the data set in Table 12.2 contains three cross sections:

- Cross-section one is identified by (COUNTRY='112' CSC='F' PARTNER=' ' VERSION='Z').
- Cross-section two is identified by (COUNTRY='146' CSC='F' PARTNER=' ' VERSION='Z').
- Cross-section three is identified by (COUNTRY='158' CSC='F' PARTNER=' ' VERSION='Z').

Note that the data sets in Table 12.1 and Table 12.2 use two different ways of representing time series data for three different countries: the United Kingdom (COUNTRY='112'), Switzerland (COUNTRY='146'), and Japan (COUNTRY='158'). The first representation (Table 12.1) incorporates each country’s name into the series names, while the second representation (Table 12.2) represents countries as different cross sections by using the BY variable named COUNTRY. See “Time Series and SAS Data Sets” in Chapter 3, “Working with Time Series Data.”

Obtaining Descriptive Information on Cross Sections

If you want to know the unique set of values BY variables assume for each cross section in the data file, use the OUTBY= option. For example, the following statements list some of the cross sections available for an IFS file, and are shown in Figure 12.3.
Chapter 12: The DATASOURCE Procedure

```plaintext
filename ifsfile "%sysget(DATASRC_DATA)imfifs1.dat" RECFM=F LRECL=88;
proc datasource
    filetype=imfifsp infile=ifsfile
    outselect=on ebcdic
    interval=month
    outby=xsection;
run;

title1 'Some Cross Sections Available in IFSFILE';
proc print data=xsection;
run;
```

**Figure 12.3** Listing of the OUTBY= Data Set

</tbody>
</table>

The OUTBY= data set reports the total number of series, NSERIES, defined in each cross section, NSELECT of which represent the selected variables. If you want to see the descriptive information on each of these NSELECT variables for each cross section, specify the OUTALL= option. For example, the following statements print descriptive information on all monthly series defined for all cross sections (COUNTRY='111', COUNTRY='112', COUNTRY='146', COUNTRY='158', and COUNTRY='186') which are shown in Figure 12.4.

```plaintext
filename datafile "%sysget(DATASRC_DATA)imfifs1.dat" RECFM=F LRECL=88;

proc datasource filetype=imfifsp
    outselect=on ebcdic
    interval=month
    outall=ifsall;
run;

title4 'Cross Sections Available in OUTALL=IFSALL Data Set';
proc print
    data=ifsall;
run;
```

| 14 | 0 | JAN1957 | SEP1986 | 357 | 357 | TURKEY | S | F | U | 5 |
| 15 | 0 | JAN1957 | SEP1986 | 357 | 357 | TURKEY | S | A | U | 3 |
The OUTCONT= data set contains one observation for each time series variable with the descriptive information summarized over BY groups. When the data file contains no cross sections, the OUTCONT= and OUTALL= data sets are equivalent, except that the OUTALL= data set also reports time ranges of available data. The OUTBY= data set in this case contains a single observation reporting the number of series and time ranges for the whole data file.

### Subsetting a Data File Containing Cross Sections

Data files containing cross sections can be subsetted by controlling which cross sections to include in the output data set. Selecting a subset of cross sections is accomplished using the WHERE statement. The WHERE statement gives a condition that the BY variables must satisfy for a cross section to be selected. For example, the following statements extract the monthly market rate conversion factors for the United Kingdom (COUNTRY='112') and Switzerland (COUNTRY='146') for the period from September 1985 to February 1986.

```plaintext
filename datafile "%sysget(DATASRC_DATA)imfifs1.dat" RECFM=F LRECL=88;

title3 'Time Series Defined in Selected Cross Sections';
proc datasource filetype=imfifsp
   outselect=on ebcdic
   interval=month
   out=ifs;
   where country in ('146', '112') and partner=' ';
   keep F___AA F___AC;
   range from '01sep85'd to '01feb86'd;
run;

title4 'OUTALL=IFS Data Set';
proc print
   data=ifs;
run;
```

### Renaming Time Series Variables

Sometimes the time series variable names as given by data vendors are not descriptive enough, or you may prefer a different naming convention. In such cases, you can use the RENAME statement to assign more meaningful names to time series variables. You can also use LABEL statements to associate descriptive labels with your series variables.

For example, the series names for market rate conversion factor (F___AA) and market rate conversion factor (F___AC) used by IMF can be given more descriptive names and labels by the following statements and are shown in Figure 12.5 and Figure 12.6.
filename ifsfile "%sysget(DATASRC_DATA)imfifs1.dat" RECFM=F LRECL=88;

proc datasource filetype=imfifsp infile=ifsfile
  interval=month
  out=market outcont=mrktvars;
  where country in ('112','146','158') and partner=' ';
  keep f___aa f___ac;
  range from '01jun85'd to '01feb86'd;
  rename f___aa=alphmkt f___ac=charmkt;
  label f___aa='F___AA: Market Rate Conversion Factor Used in Alpha Test'
       f___ac='F___AC: Market Rate Conversion Used in Charlie Test';
run;

title1 'Printout of OUTCONT= Showing New NAMES and LABELs';
proc print data=mrktvars;
  var name label length;
run;

title1 'Contents of OUT= Showing New NAMES and LABELs';
proc contents data=market;
run;

The RENAME statement allows input names to be quoted strings. If the name of a series in the input file contains blanks or special characters that are not in valid SAS name syntax, use the SAS option VALIDVARNAME=ANY or put the series name in quotes to rename it. See the FAME example using rename in the “Selecting Time Series Variables – The KEEP and DROP Statements” on page 645 section.

**Figure 12.5** Renaming and Labeling Variables

<table>
<thead>
<tr>
<th>Obs</th>
<th>NAME</th>
<th>LABEL</th>
<th>LENGTH</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>alphmkt</td>
<td>F___AA: Market Rate Conversion Factor Used in Alpha Test</td>
<td>5</td>
</tr>
<tr>
<td>2</td>
<td>charmkt</td>
<td>F___AC: Market Rate Conversion Used in Charlie Test</td>
<td>5</td>
</tr>
</tbody>
</table>

**Figure 12.6** Renaming and Labeling Variables

<table>
<thead>
<tr>
<th>#</th>
<th>Variable</th>
<th>Type</th>

</tr>
<tr>
<td>7</td>
<td>charmkt</td>
<td>Num</td>
<td>5</td>
<td></td>
<td>F___AC: Market Rate Conversion Used in Charlie Test</td>
</tr>
</tbody>
</table>
Notice that even though you changed the names of F___AA and F___AC to alphmkt and charmkt, respectively, you still use their old names in the KEEP and LABEL statements because renaming takes place at the output stage.

### Changing the Lengths of Numeric Variables

The length attribute indicates the number of bytes the SAS System uses for storing the values of variables in output data sets. Therefore, the shorter the variable lengths, the more efficient the disk-space usage. However, there is a trade-off. The lengths of numeric variables are closely tied to their precision, and reducing their lengths arbitrarily can cause precision loss.

The DATASOURCE procedure uses default lengths for series variables appropriate to each file type. For example, the default lengths for numeric variables are 5 for IMFIFSP type files. In some cases, however, you may want to assign different lengths. Assigning lengths less than the defaults reduces memory and disk-space usage at the expense of precision. Specifying lengths longer than the defaults increases the precision but causes the DATASOURCE procedure to use more memory and disk space. The following statements define a default length of 4 for all numeric variables in the IFSFILE and then assign a length of 6 to the exchange rate index. Output is shown in Figure 12.7 and Figure 12.8.

```sas
filename ifsfile "%sysget(DATASRC_DATA)imfifs1.dat" RECFM=F LRECL=88;
proc datasource filetype=imfifsp infile=ifsfile
   interval=month
   out=market outcont=mrktvars;
where country in ('112','146','158') and partner=' ';
keep f___aa f___ac;
range from '01jun85'd to '01feb86'd;
rename f___aa=alphmkt f___ac=charmkt;
label f___aa='F___AA: Market Rate Conversion Factor Used in Alpha Test'
   f___ac='F___AC: Market Rate Conversion Used in Charlie Test';
length _numeric_ 4;
length f___aa 6;
run;
```

```sas
title1 'Printout of OUTCONT= Showing New NAMES and LABELs';
proc print data=mrktvars ;
   var name label length;
run;
```

```sas
title1 'Contents of OUT= Showing New NAMES and LABELs';
proc contents data=market;
run;
```

![Figure 12.7](image_url) Changing the Lengths of Numeric Variables

<table>
<thead>
<tr>

<td>6</td>
</tr>
<tr>
<td>2</td>
<td>charmkt</td>
<td>F___AC: Market Rate Conversion Used in Charlie Test</td>
<td>4</td>
</tr>
</tbody>
</table>
The default lengths of the character variables are set to the minimum number of characters that can hold the longest possible value.

## Syntax: DATASOURCE Procedure

The DATASOURCE procedure uses the following statements:

```sas
PROC DATASOURCE options ;
   KEEP variable-list ;
   DROP variable-list ;
   KEEPEVENT event-list ;
   DROPEVENT event-list ;
   WHERE where-expression ;
   RANGE FROM from TO to ;
   ATTRIBUTE variable-list attribute-list . . . ;
   FORMAT variable-list format . . . ;
   LABEL variable="label" . . . ;
   LENGTH variable-list length . . . ;
   RENAME old-name=new-name . . . ;
```

The PROC DATASOURCE statement is required. All the rest of the statements are optional.

The DATASOURCE procedure uses two kinds of statements, subsetting statements and attribute statements. Subsetting statements provide selection of time series data over selected time periods and cross sections from the input data file. Attribute statements control the attributes of the variables in the output SAS data set.

The subsetting statements are the KEEP, DROP, KEEPEVENT, and DROPEVENT statements (which select output variables); the RANGE statement (which selects time ranges); and the WHERE statement (which selects cross sections). The attribute statements are the ATTRIBUTE, FORMAT, LABEL, LENGTH, and RENAME statements.

The statements and options used by PROC DATASOURCE are summarized in Table 12.3.

PROC DATASOURCE Statement

PROC DATASOURCE options ;

The following options can be used in the PROC DATASOURCE statement:

ALIGN= option
controls the alignment of SAS dates used to identify output observations. The ALIGN= option allows the following values: BEGINNING | BEG | B, MIDDLE | MID | M, and ENDING | END | E. BEGINNING is the default.
ASCII  
specifies the incoming data is ASCII. This option is used when the native character set of your host machine is EBCDIC.

DBNAME= ’database name’  
specifies the FAME database to access. Only use this option with the filetype=FAME option. The character string you specify in the DBNAME= option is passed through to FAME. Specify the value of this option as you would in accessing the database from within FAME software.

EBCDIC  
specifies the incoming data is ebcdic. This option is needed when the native character set of your host machine is ASCII.

FAMEPRINT  
prints the FAME command file generated by PROC DATASOURCE and the log file produced by the FAME component of the interface system. Only use this option with the filetype=FAME option.

FILETYPE= entry  
DBTYPE= dbtype  
specifies the kind of input data file to process. See “Data Elements Reference: DATASOURCE Procedure” on page 671 for a list of supported file types. The FILETYPE= option is required.

INDEX  
creates a set of single indexes from BY variables for the OUT= data set. Under some circumstances, creating indexes for a SAS data set may increase the efficiency in locating observations when BY or WHERE statements are used in subsequent steps. Refer to SAS Language Reference: Concepts for more information on SAS indexes. The INDEX option is ignored when no OUT= data set is created or when the data file does not contain any BY variables. The INDEX= data set option can be used to override the index variable definitions.

INFILE= fileref  
INFILE= (fileref1 fileref2 . . . filerefn)  
specifies the fileref assigned to the input data file. The default value is DATAFILE. The fileref used in the INFILE= option (or if no INFILE= option is specified, the fileref DATAFILE) must be associated with the physical data file in a FILENAME statement. (On some operating systems, the fileref assignment can be made with the system’s control language, and a FILENAME statement may not be needed. Refer to SAS Statements: Reference for more details on the FILENAME statement.

Physical data files can reside on DVD, CD-ROM, or other media.

For some file types, the data are distributed over several files. In this case, the INFILE= option is required, and it lists in parentheses the filerefs for each of the files making up the database. The order in which these FILEREFS are listed is important and must conform to the specifics of each file type as explained in “Data Elements Reference: DATASOURCE Procedure” on page 671.

LRECL= lrecl  
LRECL= (lrecl1 lrecl2 . . . lreclin)  

The logical record length in bytes of the infile. Only use this if you need to override the default LRECL of the file. For some file types, the data are distributed over several files. In this case, the LRECL= option lists in parentheses the LRECLs for each of the files making up the database. The order in which these LRECLs are listed is important and must conform to the specifics of each file type as explained in “Data Elements Reference: DATASOURCE Procedure” on page 671.
**RECFM= recfm**

**RECFM= (recfm1 recfm2 . . . recfmn)**

The record format of the infile. Only use this if you need to override the default record format of the file. For some file types, the data are distributed over several files. In this case, the RECFM= option lists in parentheses the RECFMs for each of the files making up the database. The order in which these RECFMs are listed is important and must conform to the specifics of each file type as explained in “Data Elements Reference: DATASOURCE Procedure” on page 671. The possible values of RECFM are

- F or FIXED for fixed length records
- N or BIN for binary records
- D or VAR for varying length records
- U or DEF for host default record format
- DOM_V or DOMAIN_VAR or BIN_V or BIN_VAR for UNIX binary record format

**INTERVAL= interval**

**FREQUENCY= interval**

**TYPE= interval**

specifies the periodicity of series selected for output to the OUT= data set. The OUT= data set created by PROC DATASOURCE can contain only time series with the same periodicity. Some data files contain time series with different periodicities; for example, a file can contain both monthly series and quarterly series. Use the INTERVAL= option to indicate which periodicity you want. If you want to extract series with different periodicities, use different PROC DATASOURCE invocations with the desired INTERVAL= options.

Common values for INTERVAL= are YEAR, QUARTER, MONTH, WEEK, and DAY. The values allowed, as well as the default value of the INTERVAL= option, depend on the file type. See “Data Elements Reference: DATASOURCE Procedure” on page 671 for the INTERVAL= values appropriate to the data file type you are reading.

**OUT= SAS-data-set**

names the output data set for the time series extracted from the data file. If none of the output data set options are specified, including the OUT= data set itself, an OUT= data set is created and named according to the DATA convention. However, when you create any of the other output data sets, such as OUTCONT=, OUTBY=, OUTALL=, or OUTEVENT=, you must explicitly specify the OUT= data set; otherwise, it will not be created. See “OUT= Data Set” on page 666 for further details.

**OUTALL= SAS-data-set**

writes information on the contents of the input data file to an output data set. The OUTALL= data set includes descriptive information, time ranges, and observation counts for all the time series within each BY group. By default, no OUTALL= data set is created.

The OUTALL= data set contains the Cartesian product of the information output by the OUTCONT= and OUTBY= options. In data files for which there are no cross sections, the OUTALL= and OUTCONT= data sets are almost equivalent, except that OUTALL= data set also reports time ranges and observation counts of series. See “OUTALL= Data Set” on page 669 for further details.
**OUTBY= SAS-data-set**
writes information on the BY variables to an output data set. The OUTBY= data set contains the list of cross sections in the database delimited by the unique set of values that the BY variables assume. Unless the OUTSELECT=OFF option is present, only the selected BY groups are written to the OUTBY= data set. If you omit the OUTBY= option, no OUTBY= data set is created. See “OUTBY= Data Set” on page 668 for further details.

**OUTCONT= SAS-data-set**
writes information on the contents of the input data file to an output data set. By default, the OUTCONT= data set includes descriptive information on all of the unique series of the selected periodicity in the data file. When the OUTSELECT=OFF option is omitted, the OUTCONT= data set includes observations only for the series selected for output to the OUT= data set. By default, no OUTCONT= data set is created. See “OUTCONT= Data Set” on page 667 for further details.

**OUTEVENT= SAS-data-set**
names the output data set to output event-oriented time series data. This option can only be used when CRSP stock files are being processed. For all other file types, it will be ignored. See “OUTEVENT= Data Set” on page 670 for further details.

**OUTSELECT= ON | OFF**
determines whether to output all observations (OUTSELECT=OFF) or only those corresponding to the selected time series and selected BY groups (OUTSELECT=ON) to OUTCONT=, OUTBY=, and OUTALL= data sets. The default is OUTSELECT=ON. The OUTSELECT= option is only relevant when any one of the auxiliary data sets is specified. The option writes observations to OUTCONT=, OUTBY=, and OUTALL= data sets for only the selected time series and selected BY groups if it is set ON. The OUTSELECT= option is only relevant when any one of the OUTCONT=, OUTBY=, and OUTALL= options is specified. The default is OUTSELECT=ON.

---

**KEEP Statement**

**KEEP variable-list ;**
The KEEP statement specifies which variables in the data file are to be included in the OUT= data set. Only the time series and event variables can be specified in a KEEP statement. All the BY variables and the time ID variable DATE are always included in the OUT= data set; they cannot be referenced in a KEEP statement. If they are referenced, a warning message is given and the reference is ignored.

The variable list can contain variable names or name range specifications. See “Variable Lists” on page 665 for details.

There is a default KEEP list for each file type. Usually, descriptor type variables, like footnotes, are not included in the default KEEP list. If you give a KEEP statement, the default list becomes undefined.

Only one KEEP or one DROP statement can be used. KEEP and DROP are mutually exclusive.

You can also use the KEEP= data set option to control which variables to include in the OUT= data set. However, the KEEP statement differs from the KEEP= data set option in several respects:

- The KEEP statement selection is applied before variables are read from the data file, while the KEEP= data set option selection is applied after variables are read and as they are written to the OUT= data set. Therefore, using the KEEP statement instead of the KEEP= data set option is much more efficient.
• If the KEEP statement causes no series variables to be selected, then no observations are output to the OUT= data set.

• The KEEP statement variable specifications are applied to each cross section independently. This behavior may produce variables different from those produced by the KEEP= data set option when order-range variable list specifications are used.

**DROP Statement**

```plaintext
DROP variable-list ;
```

The DROP statement specifies that some variables be excluded from the OUT= data set. Only the time series and event variables can be specified in a DROP statement. None of the BY variables or the time ID variable DATE can be excluded from the OUT= data set. If they are referenced in a DROP statement, a warning message is given and the reference is ignored. Use the WHERE statement for selection based on BY variables, and use the RANGE statement for date selections.

The variable list can contain variable names or name range specifications. See “Variable Lists” on page 665 for details.

Only one DROP or one KEEP statement can be used. KEEP and DROP are mutually exclusive.

There is a default DROP or KEEP list for each file type. Usually, descriptor type variables, like footnotes, are not included in the default KEEP list. If you specify a DROP statement, the default list becomes undefined.

You can also use the DROP= data set option to control which variables to exclude from the OUT= data set. However, the DROP statement differs from the DROP= data set option in several aspects:

• The DROP statement selection is applied before variables are read from the data file, while the DROP= data set option selection is applied after variables are read and as they are written to the OUT= data set. Therefore, using the DROP statement instead of the DROP= data set option is much more efficient.

• If the DROP statement causes all series variables to be excluded, then no observations are output to the OUT= data set.

• The DROP statement variable specifications are applied to each cross section independently. This behavior may produce variables different from those produced by the DROP= data set option when order-range variable list specifications are used.

**KEEPEVENT Statement**

```plaintext
KEEPEVENT variable-list ;
```

The KEEPEVENT statement specifies which event variables in the data file are to be included in the OUTEVENT= data set. As a result, the KEEPEVENT statement is valid only for data files containing event-oriented time series data. All the BY variables, the time ID variable DATE, and the event-grouping variable EVENT are always included in the OUTEVENT= data set. These variables cannot be referenced in
the KEEPEVENT statement. If any of these variables are referenced, a warning message is given and the reference is ignored.

The variable list can contain variable names or name range specifications. See “Variable Lists” on page 665 for details.

Only one KEEPEVENT or one DROPEVENT statement can be used. KEEPEVENT and DROPEVENT are mutually exclusive.

You can also use the KEEP= data set option to control which event variables to include in the OUTEVENT= data set. However, the KEEPEVENT statement differs from the KEEP= data set option in several respects:

- The KEEPEVENT statement selection is applied before variables are read from the data file, while the KEEP= data set option selection is applied after variables are read and as they are written to the OUTEVENT= data set. Therefore, using the KEEPEVENT statement instead of the KEEP= data set option is much more efficient.
- If the KEEPEVENT statement causes no event variables to be selected, then no observations are output to the OUTEVENT= data set.

**DROPEVENT Statement**

```plaintext
DROPEVENT variable-list ;
```

The DROPEVENT statement specifies that some event variables be excluded from the OUTEVENT= data set. As a result, the DROPEVENT statement is valid only for data files containing event-oriented time series data. All the BY variables, the time ID variable DATE, and the event-grouping variable EVENT are always included in the OUTEVENT= data set. These variables cannot be referenced in the DROPEVENT statement. If any of these variables are referenced, a warning message is given and the reference is ignored.

The variable list can contain variable names or name range specifications. See “Variable Lists” on page 665 for details.

Only one DROPEVENT or one KEEPEVENT statement can be used. DROPEVENT and KEEPEVENT are mutually exclusive.

You can also use the DROP= data set option to control which event variables to exclude from the OUTEVENT= data set. However, the DROPEVENT statement differs from the DROP= data set option in several respects:

- The DROPEVENT statement selection is applied before variables are read from the data file, while the DROP= data set option selection is applied after variables are read and as they are written to the OUTEVENT= data set. Therefore, using the DROPEVENT statement instead of the DROP= data set option is much more efficient.
- If the DROPEVENT statement causes all series variables to be excluded, then no observations are output to the OUTEVENT= data set.
WHERE Statement

WHERE where-expression ;

The WHERE statement specifies conditions that BY variables must satisfy in order for a cross section to be included in the OUT= and OUTEVENT= data sets. By default, all BY groups are selected.

The where-expression must refer only to BY variables defined for the file type you are reading. The “Data Elements Reference: DATASOURCE Procedure” on page 671 lists the names of the BY variables for each file type.

For example, DOTS (Direction of Trade Statistics) files, distributed by the International Monetary Fund, have four BY variables: COUNTRY, CSC, PARTNER, and VERSION. Both COUNTRY and PARTNER are three-digit country codes. To select the direction of trade statistics of the United States (COUNTRY='111') with Turkey (COUNTRY='186'), Japan (COUNTRY='158'), and the oil exporting countries group (COUNTRY='985'), you should specify

where country='111' and partner in ('186','158','985');

You can use any SAS language operators and special WHERE expression operators in the WHERE statement condition. Refer to SAS Language Reference: Concepts for a more detailed discussion of WHERE expressions.

If you want to see the names of the BY variables and the values they assume for each cross section, you can first run PROC DATASOURCE with only the OUTBY= option. The information contained in the OUTBY= data set will aid you in selecting the appropriate BY groups for subsequent PROC DATASOURCE steps.

RANGE Statement

RANGE FROM from TO to ;

The RANGE statement selects the time range of observations written to the OUT= and OUTEVENT= data sets. The from and to values can be SAS date, time, or datetime constants, or they can be specified as year or year : period, where year is a two-digit or four-digit year, and period (when specified) is a period within the year corresponding to the INTERVAL= option. (For example, if INTERVAL=QTR, then period refers to quarters.) When period is omitted, the beginning of the year is assumed for the from value, and the end of the year is assumed for the to value.

If a two-digit year is specified, PROC DATASOURCE uses the current value of the YEARCUTOFF option to determine the century of your data. Warnings are issued in the SAS log whenever DATASOURCE needs to determine the century from a two-digit year specification.

The default YEARCUTOFF value is 1926. To use a different YEARCUTOFF value, specify

options yearcutoff=yyyy;

where YYYY is the YEARCUTOFF value you want to use. See SAS System Options: Reference for a more detailed discussion of the YEARCUTOFF option.
Both the FROM and TO specifications are optional, and both the FROM and TO keywords are optional. If the FROM limit is omitted, the output observations start with the minimum date for which data are available for any selected series. Similarly, if the TO limit is omitted, the output observations end with the maximum date for which data are available.

The following are some examples of RANGE statements:

```
  range from 1980 to 1990;
  range 1980 - 1990;
  range from 1980;
  range 1980;
  range to 1990;
  range to 1990:2;
  range from '31aug89'd to '28feb1990'd;
```

The RANGE statement applies to each BY group independently. If all the selected series contain no data in the specified range for a given BY group, then there will be no observations for that BY group in the OUT= and OUTEVENT= data sets.

If you want to know the time ranges for which periodic time series data are available, you can first run PROC DATASOURCE with the OUTBY= or OUTALL= option. The OUTBY= data set reports the union of the time ranges over all the series within each BY group, while the OUTALL= data set gives time ranges for each series separately in each BY group.

---

**ATTRIBUTE Statement**

```
ATTRIBUTE variable-list attribute-list . . . ;
```

The ATTRIBUTE statement assigns formats, labels, and lengths to variables in the output data sets.

The `variable-list` can contain variable names and variable name range specifications. See “Variable Lists” on page 665 for details. The attributes specified in the following attribute list apply to all variables in the variable list.

An `attribute-list` consists of one or more of the following options:

- `FORMAT= format` associates a format with variables in `variable-list`. The `format` can be either a standard SAS format or a format defined with the FORMAT procedure. The default formats for variables depend on the file type.

- `LABEL= "label"` assigns a label to the variables in the variable list. The default labels for variables depend on the file type. Labels can be up to 256 bytes in length.

- `LENGTH= length` specifies the number of bytes used to store the values of variables in the variable list. The default lengths for numeric variables depend on the file type. Usually default lengths are set to 5 bytes.

The length specification also controls the amount of memory that PROC DATASOURCE uses to hold variable values while processing the input data file. Thus, specifying a `LENGTH= value` smaller than the default will reduce both the disk space taken up by the output data sets and the amount of memory used by the PROC DATASOURCE step, at the cost of precision of output data values.
FORMAT Statement

FORMAT variable-list format . . . ;

The FORMAT statement assigns formats to variables in output data sets. The variable-list can contain variable names and variable name range specifications. See “Variable Lists” on page 665 for details. The format specified applies to all variables in the variable list.

A single FORMAT statement can assign the same format to several variables or different formats to different variables. The FORMAT statement can use standard SAS formats or formats defined using the FORMAT procedure.

Any later format specification for a variable, using either the FORMAT statement or the FORMAT= option in the ATTRIBUTE statement, always overrides the previous one.

LABEL Statement

LABEL variable = "label" . . . ;

The LABEL statement assigns SAS variable labels to variables in the output data sets. You can give labels for any number of variables in a single LABEL statement. The default labels for variables depend on the file type. Extra-long labels ( > 256 bytes ) reside in the OUTCONT data set as the DESCRIPT variable.

Any later label specification for a variable, using either the LABEL statement or the LABEL= option in the ATTRIBUTE statement, always overrides the previous one.

LENGTH Statement

LENGTH variable-list length . . . ;

The LENGTH statement, like the LENGTH= option in the ATTRIBUTE statement, specifies the number of bytes used to store values of variables in output data sets. The default lengths for numeric variables depend on the file type. Usually default lengths are set to 5 bytes.

The default lengths of character variables are defined as the minimum number of characters that can hold the longest possible value.

For some file types, the LENGTH statement also controls the amount of memory used to store values of numeric variables while processing the input data file. Thus, specifying LENGTH values smaller than the default will reduce both the disk space taken up by the output data sets and the amount of memory used by the PROC DATASOURCE step, at the cost of precision of output data values.

Any later length specification for a variable, using either the LENGTH statement or the LENGTH= option in the ATTRIBUTE statement, always overrides the previous one.

RENAME Statement

RENAME old-name = new-name . . . ;
The RENAME statement is used to change the names of variables in the output data sets. Any number of variables can be renamed in a single RENAME statement. The most recent RENAME specification overrides any previous ones for a given variable. The *new-name* is limited to 32 characters. Renaming of variables is done at the output stage. Therefore, you need to use the old variable names in all other PROC DATASOURCE statements. For example, the series variable names DATA1-DATA350 used with annual COMPUSTAT files are not very descriptive, so you may choose to rename them to reflect the financial aspect they represent. You may rename “DATA51” as “INVESTMNT” with the RENAME statement

```
rename data51=investtax;
```

since it contains investment tax credit data. However, in all other DATASOURCE statements, you must use the old name, DATA51.

---

**Details: DATASOURCE Procedure**

**Variable Lists**

Variable lists used in PROC DATASOURCE statements can consist of any combination of variable names and name range specifications. Items in variable lists can have the following forms:

- a name, such as PZU.
- an alphabetic range *name1-name2*. For example, A-DZZZZZZZ specifies all variables with names starting with A, B, C, or D.
- a prefix range *prefix:*. For example, IP: selects all variables with names starting with the letters IP.
- an order range *name1-name2*. For example, GLR72–GLRD72 specifies all variables in the input data file between GLR72 and GRLD72 inclusive.
- a numeric order range *name1-NUMERIC-name2*. For example, GLR72-NUMERIC-GLRD72 specifies all numeric variables between GLR72 and GRLD72 inclusive.
- a character order range *name1-CHARACTER-name2*. For example, GLR72-CHARACTER-GLRD72 specifies all character variables between GLR72 and GRLD72 inclusive.
- one of the keywords _NUMERIC_, _CHARACTER_, or _ALL_. The keyword _NUMERIC_ specifies all numeric variables, _CHARACTER_ specifies all character variables, and _ALL_ specifies all variables.

To determine the order of series in a data file, run PROC DATASOURCE with the OUTCONT= option, and print the output data set. Note that order and alphabetic range specifications are inclusive, meaning that the beginning and ending names of the range are also included in the variable list.

For order ranges, the names used to define the range must actually name variables in the input data file. For alphabetic ranges, however, the names used to define the range need not be present in the data file. Note that variable specifications are applied to each cross section independently. This may cause the order-range variable list specification to behave differently than its DATA step and data set option counterparts.
This is because PROC DATASOURCE knows which variables are defined for which cross sections, while the DATA step applies order range specification to the whole collection of time series variables.

If the ending variable name in an order range specification is not in the current cross section, all variables starting from the beginning variable to the last variable defined in that cross section get selected. If the first variable is not in the current cross section, then order range specification has no effect for that cross section.

The variable names used in variable list specifications can refer either to series names appearing in the input data file or to the SAS names assigned to series data fields internally if the series names are not recorded to the INFILE= file. When the latter is the case, internally defined variable names are listed in “Data Elements Reference: DATASOURCE Procedure” on page 671 later in this chapter.

The following are examples of the use of variable lists:

```plaintext
keep ip: pw112-pw117 pzu;
drop data1-data99 data151-data350;
length data1-numeric-aftnt350 ucode 4;
```

The first statement keeps all the variables starting with IP:, all the variables between PW112 and PW117 including PW112 and PW117 themselves, and a single variable PZU. The second statement drops all the variables that fall alphabetically between DATA1 and DATA99, and between DATA151 and DATA350. Finally, the third statement assigns a length of 4 bytes to all the numeric variables defined between DATA1 and AFTNT350, and UCODE. Variable lists can not exceed 200 characters in length.

**OUT= Data Set**

The OUT= data set can contain the following variables:

- the BY variables, which identify cross-sectional dimensions when the input data file contains time series replicated for different values of the BY variables. Use the BY variables in a WHERE statement to process the OUT= data set by cross sections. The order in which BY variables are defined in the OUT= data set corresponds to the order in which the data file is sorted.

- DATE, a SAS date-, time-, or datetime-valued variable that reports the time period of each observation. The values of the DATE variable may span different time ranges for different BY groups. The format of the DATE variable depends on the INTERVAL= option.

- the periodic time series variables, which are included in the OUT= data set only if they have data in at least one selected BY group and they are not discarded by a KEEP or DROP statement

- the event variables, which are included in the OUT= data set if they are not discarded by a KEEP or DROP statement. By default, these variables are not output to OUT= data set.

The values of BY variables remain constant in each cross section. Observations within each BY group correspond to the sampling of the series variables at the time periods indicated by the DATE variable.

You can create a set of single indexes for the OUT= data set by using the INDEX option, provided there are BY variables. Under some circumstances, this may increase the efficiency of subsequent PROC and DATA steps that use BY and WHERE statements. However, there is a cost associated with creation and maintenance
of indexes. The SAS Language Reference: Concepts lists the conditions under which the benefits of indexes outweigh the cost.

With data files containing cross sections, there can be various degrees of overlap among the series variables. One extreme is when all the series variables contain data for all the cross sections. In this case, the output data set is very compact. In the other extreme case, however, the set of time series variables are unique for each cross section, making the output data set very sparse, as depicted in Table 12.4.

<table>
<thead>
<tr>
<th>Table 12.4</th>
<th>The OUT= Data Set Containing Unique Series for Each BY Group</th>
</tr>
</thead>
<tbody>
<tr>
<td>BY Variables</td>
<td>Series in first BY group</td>
</tr>
<tr>
<td>BY group 1</td>
<td>F1 F2 F3 \ldots FN</td>
</tr>
<tr>
<td>BY group 2</td>
<td>DATA is here</td>
</tr>
<tr>
<td>\vdots</td>
<td>DATA is here</td>
</tr>
<tr>
<td>BY group N</td>
<td>DATA is here</td>
</tr>
</tbody>
</table>

The data in Table 12.4 can be represented more compactly if cross-sectional information is incorporated into series variable names.

**OUTCONT= Data Set**

The OUTCONT= data set contains descriptive information for the time series variables. This descriptive information includes various attributes of the time series variables. The OUTCONT= data set contains the following variables:

- **NAME**, a character variable that contains the series name
- **KEPT**, a numeric variable that indicates whether the series was selected for output by the DROP or KEEP statements. KEPT is usually the same as SELECTED, but can differ if a WHERE statement is used.
- **SELECTED**, a numeric variable that indicates whether the series is selected for output to the OUT= data set. The series is included in the OUT= data set (SELECTED=1) if it is kept (KEPT=1) and it has data for at least one selected BY group.
Chapter 12: The DATASOURCE Procedure

- TYPE, a numeric variable that indicates the type of the time series variable. TYPE=1 for numeric series; TYPE=2 for character series.

- LENGTH, a numeric variable that gives the number of bytes allocated for the series variable in the OUT= data set.

- VARNUM, a numeric variable that gives the variable number of the series in the OUT= data set. If the series variable is not selected for output (SELECTED=0), then VARNUM has a missing value. Likewise, if no OUT= option is given, VARNUM has all missing values.

- LABEL, a character variable that contains the label of the series variable. LABEL contains only the first 256 characters of the labels. If they are longer than 256 characters, then the variable, DESCRIPT, is defined to hold the whole length of series labels. Note that if a data file assigns different labels to the same series variable within different cross sections, only the first occurrence of labels will be transferred to the LABEL column.

- the variables FORMAT, FORMATL, and FORMATD, which give the format name, length, and number of format decimals, respectively.

- the GENERIC variables, whose values may vary from one series to another, but whose values remain constant across BY groups for the same series.

By default, the OUTCONT= data set contains observations for only the selected series where SELECTED=1. If the OUTSELECT=OFF option is specified, the OUTCONT= data set contains one observation for each unique series of the specified periodicity contained in the input data file.

If you do not know what series are in the data file, you can run PROC DATASOURCE with the OUTCONT= option and OUTSELECT=OFF. The information contained in the OUTCONT= data set can then help you to determine which time series data you want to extract.

OUTBY= Data Set

The OUTBY= data set contains information on the cross sections contained in the input data file. These cross sections are represented as BY groups in the OUT= data set. The OUTBY= data set contains the following variables:

- the BY variables, whose values identify the different cross sections in the data file. The BY variables depend on the file type.

- BYSELECT, a numeric variable that reports the outcome of the WHERE statement condition for the BY variable values for this observation. The value of BYSELECT is 1 for BY groups selected by the WHERE statement for output to the OUT= data set and is 0 for BY groups that are excluded by the WHERE statement. BYSELECT is added to the data set only if a WHERE statement is given. When there is no WHERE statement, then all the BY groups are selected.

- ST_DATE, a numeric variable that gives the starting date for the BY group. The starting date is the earliest of the starting dates of all the series that have data for the current BY group.

- END_DATE, a numeric variable that gives the ending date for the BY group. The ending date is the latest of the ending dates of all the series that have data for the BY group.
• NTIME, a numeric variable that gives the number of time periods between ST_DATE and END_DATE, inclusive. Usually, this is the same as NOBS, but they differ when time periods are not equally spaced and when the OUT= data set is not specified. NTIME is a maximum limit on NOBS.

• NOBS, a numeric variable that gives the number of time series observations in the OUT= data set between ST_DATE and END_DATE inclusive. When a given BY group is discarded by a WHERE statement, the NOBS variable corresponding to this BY group becomes 0, since the OUT= data set does not contain any observations for this BY group. Note that BYSELECT=0 for every discarded BY group.

• NINRANGE, a numeric variable that gives the number of observations in the range (from, to) defined by the RANGE statement. This variable is only added to the OUTBY= data set when the RANGE statement is specified.

• NSERIES, a numeric variable that gives the total number of unique time series variables having data for the BY group

• NSELECT, a numeric variable that gives the total number of selected time series variables having data for the BY group

• the generic variables, whose values remain constant for all the series in the current BY group

In this list, you can only control the attributes of the BY and GENERIC variables.

The variables NOBS, NTIME, and NINRANGE give observation counts, while the variables NSERIES and NSELECT give series counts.

By default, observations for only the selected BY groups (where BYSELECT=1) are output to the OUTBY= data set, and the date and time range variables are computed over only the selected time series variables. If the OUTSELECT=OFF option is specified, the OUTBY= data set contains an observation for each BY group, and the date and time range variables are computed over all the time series variables.

For file types that have no BY variables, the OUTBY= data set contains one observation giving ST_DATE, END_DATE, NTIME, NOBS, NINRANGE, NSERIES, and NSELECT for all the series in the file.

If you do not know the BY variable names or their possible values, you can do an initial run of PROC DATASOURCE with the OUTBY= option. The information contained in the OUTBY= data set can help you design your WHERE expression and RANGE statement for the subsequent executions of PROC DATASOURCE to obtain different subsets of the same data file.

---

**OUTALL= Data Set**

The OUTALL= data set combines and expands the information provided by the OUTCONT= and OUTBY= data sets. That is, the OUTALL= data set not only reports the OUTCONT= information separately for each BY group, but also reports the OUTBY= information separately for each series. Each observation in the OUTBY= data set gets expanded to NSERIES or NSELECT observations in the OUTALL= data set, depending on whether the OUTSELECT=OFF option is specified.

By default, only the selected BY groups and series are included in the OUTALL= data set. If the OUTSELECT=OFF option is specified, then all the series within all the BY groups are reported.
The OUTALL= data set contains all the variables defined in the OUTBY= and OUTCONT= data sets and also contains the GENERIC variables (whose values can vary from one series to another and from one BY group to another). Another additional variable is BLKNUM, which gives the data block number in the data file containing the series variable.

The OUTALL= data set is useful when BY groups do not contain the same time series variables or when the time ranges for series change across BY groups.

You should be careful in using the OUTALL= option, since the OUTALL= data set can get very large for many file types. Some file types have the same series and time ranges for each BY group; the OUTALL= option should not be used with these file types. For example, you should not specify the OUTALL= option with COMPUSTAT files, since all the BY groups contain the same series variables.

The OUTALL= and OUTCONT= data sets are equivalent when there are no BY variables, except that the OUTALL= data set contains extra information about the time ranges and observation counts of the series variables.

**OUTEVENT= Data Set**

The OUTEVENT= data set is used to output event-oriented time series data. Events occurring at discrete points in time are recorded along with the date they occurred. Only CRSP stock files contain event-oriented time series data. For all other types of files, the OUTEVENT= option is ignored.

The OUTEVENT= data set contains the following variables:

- the BY variables, which identify cross-sectional dimensions when the input data file contains time series replicated for different values of the BY variables. Use the BY variables in a WHERE statement to process the OUTEVENT= data set by cross sections. The order in which BY variables are defined in the OUTEVENT= data set corresponds to the order in which the data file is sorted.

- DATE, a SAS date-, time- or datetime-valued variable that reports the discrete time periods at which events occurred. The format of the DATE variable depends on the INTERVAL= option, and should accurately report the date based on the SAS YEARCUTOFF option. The default value for YEARCUTOFF is 1920. The dates used can span up to 250 years.

- EVENT, a character variable that contains the event group name. The EVENT variable is another cross-sectional variable.

- the event variables, which are included in the OUTEVENT= data set only if they have data in at least one selected BY group, and are not discarded by a KEEP EVENT or DROP EVENT statement.

Note that each event group contains a nonoverlapping set of event variables; therefore, the OUTEVENT= data set is very sparse. You should exercise care when selecting event variables to be included in the OUTEVENT= data set.

Also note that even though the OUTEVENT= data set cannot contain any periodic time series variables, the OUT= data set can contain event variables if they are explicitly specified in a KEEP statement. In summary, you can specify event variables in a KEEP statement, but you cannot specify periodic time series variables in a KEEP EVENT statement.
While variable selection for OUT= and OUTEVENT= data sets are controlled by a different set of statements (KEEP versus KEEPEVENT or DROP versus DROPEVENT), cross-section and range selections are controlled by the same statements, so in summary, the WHERE and the RANGE statements are effective for both output data sets.

**Data Elements Reference: DATASOURCE Procedure**

PROC DATASOURCE can process only certain kinds of data files. For certain time series databases, the DATASOURCE procedure has built-in information on the layout of files composing the database. PROC DATASOURCE knows how to read only these kinds of data files. To access these databases, you must indicate the data file type in the FILETYPE= option. For more detailed information, see the corresponding document for each filetype. (See “References”.) The currently supported file types are summarized in Table 12.5.

Global Insight DRI Data Files

The DRIBASIC (formerly CITIBASE) database contains economic and financial indicators of the U.S. and international economies gathered from various government and private sources by DRI/McGraw-Hill, Inc. There are over 8000 yearly, quarterly, monthly, weekly, and daily time series.

Global Insight, formerly DRI/McGraw-Hill, distributes Basic Economic data files on various media. Old DRIDDS data files can be read by DATASOURCE using the DRIDDS filetype.

The following DRI file types are supported.

FILETYPE=DRIBASIC–Global Insight DRI Basic Economic Data Files

Table 12.13 FILETYPE=DRIBASIC–Global Insight DRI Basic Economic Data Files

<table>
<thead>
<tr>
<th>Metadata Field Types</th>
<th>Metadata Fields</th>

<td></td>
</tr>
<tr>
<td>Missing Codes</td>
<td>MISSING=( '1.000000E9'='NA'-'ND'= )</td>
<td></td>
</tr>
</tbody>
</table>

Note that when you specify the INTERVAL=WEEK option, all the weekly series will be aggregated, and the DATE variable in the OUT= data set will be set to the date of Sundays. The date of first observation for each series is the Sunday marking the beginning of the week that contains the starting date of that variable.

COMPUSTAT Data Files

COMPUSTAT data files, distributed by Standard & Poor’s Compustat Services, Inc., consist of a collection of financial, statistical, and market information covering several thousand industrial and nonindustrial companies. Data are available in both an IBM 360/370 format and a “Universal Character” format, both of which further subdivide into annual and quarterly formats.

The BY variables are used to select individual companies or a group of companies. Individual companies can be selected by their unique six-digit CUSIP issuer code (CNUM). A number of specific groups of companies can be extracted by the following key fields:

- **FILE** specifies the file identification code used to group companies by files.
- **ZLIST** specifies the exchange listing code that can be used to group companies by exchange.
- **DNUM** is used to extract companies in a specific SIC industry group.

Series names are internally constructed from the data array names documented in the COMPUSTAT manual. Each column of data array is treated as a SAS variable. The names of these variables are generated by concatenating the corresponding column numbers to the array name.

Missing values use four codes. Missing code ‘.C’ represents a combined figure where the data item has been combined into another data item, ‘.I’ reports an insignificant figure, ‘.S’ represents a semi-annual figure in the second and fourth quarters, ‘.A’ represents an annual figure in the fourth quarter, and ‘.’ indicates that the data item is not available. The missing codes ‘.C’ and ‘.I’ are not used for Aggregate or Prices, Dividends, and Earnings (PDE) files. The missing codes ‘.S’ and ‘.A’ are used only on the Industrial Quarterly File and not on the Aggregate Quarterly, Business Information, or PDE files.

CRSP Stock Files

The Center for Research in Security Prices provides comprehensive security price data through two primary stock files, the NYSE/AMEX file and the NASDAQ file. These files contain master and return components, available separately or combined. CRSP stock files are further differentiated by the frequency at which prices and returns are reported, daily or monthly. Both daily and monthly files contain annual data fields.

CRSP data files are distributed in CRSPAccess format. See Chapter 38, “The SASECRSP Interface Engine,” for more about accessing your CRSPAccess database. You can convert your CRSPAccess data to binary format (SFA format) by using the CRSP-supplied utility (STK_DUMP_BIN). Use the DATASOURCE procedure for SFA format access and use SASECRSP Interface for CRSPAccess.
CRSP stock data (in SFA format) are provided in two files, a main data file containing security information and a calendar/indices file containing a list of trading dates and market information associated with those trading dates.

The file types for CRSP stock files are constructed by concatenating CRSP with a D or M to indicate the frequency of data, followed by B, C, or I to indicate file formats. B is for host binary, C is for character, and I is for IBM binary formats. The last character in the file type indicates if you are reading the Calendar/Indices file (I), or if you are extracting the security (S) or annual data (A). For example, the file type for the daily NYSE/AMEX combined data in IBM binary format is CRSPDIS. Its calendar/indices file can be read by CRSPDII, and its annual data can be extracted by CRSPDIA.

Starting in 1995, binary data used split records (RICFAC=2), so the 1995 filetypes (CR95*) should be used for 1995 and 1996 binary data. If you use utility routines supplied by CRSP to convert a character format file to a binary format file on a given host, then you need to use host binary file types (RIDFAC=1) to read those files in. Note that you cannot do the conversion on one host and transfer and read the file on another host.

If you are using the CRSPAccess Database, you will need to use the utility routine (stk_dump_bin) supplied by CRSP to generate the UNIX binary format of the data. You can access the UNIX (or SUN) binary data by using PROC DATASOURCE with the CRSPDUS for daily or CRSPMUS for monthly stock data.

For the four-digit year data, use the Y2K-compliant filetypes for that data type.

For CRSP file types, the INFILE= option must be of the form

```
INFILE=( calfile security1 < security2 ... > )
```

where `calfile` is the fileref assigned to the calendar/indices file, and `security1 < security2 ... >` are the filerefs given to the security files, in the order in which they should be read.

### FAME Information Services Databases

The DATASOURCE procedure provides access to FAME Information Services databases for UNIX-based systems only. See “The SASEFAME Interface Engine” in Chapter 41, “The SASEFAME Interface Engine,” for information about a more flexible FAME database access.

The DATASOURCE interface to FAME requires a component supplied by FAME Information Services, Inc. Once this FAME component is installed on your system, you can use the DATASOURCE procedure to extract data from your FAME databases by giving the following specifications.

Specify FILETYPE=FAME in the PROC DATASOURCE statement and give the FAME database name to access with a DBNAME=’fame-database ’ option. The character string you specify in the DBNAME= option is passed through to FAME; specify the value of this option as you would in accessing the database from within FAME software.

Specify the output SAS data set to be created, the frequency of the series to be extracted, and other usual DATASOURCE procedure options as appropriate.

Specify the time range to extract with a RANGE statement. The RANGE statement is required when extracting series from FAME databases.

Name the FAME series to be extracted with a KEEP statement. The items in the KEEP statement are passed through to FAME software; therefore, you can use any valid FAME expression to specify the series to be extracted. Enclose in quotes any FAME series name or expression that is not a valid SAS name.
Name the SAS variable names you want to use for the extracted series in a RENAME statement. Give the FAME series name or expression (in quotes if needed) followed by an equal sign and the SAS name. The RENAME statement is not required; however, if the FAME series name is not a valid SAS variable name, the DATASOURCE procedure will construct a SAS name by translating and truncating the FAME series name. This process might not produce the desired name for the variable in the output SAS data set, so a rename statement could be used to produce a more appropriate variable name. The VALIDVARNAME=ANY option in your SAS options statement can be used to allow special characters in the SAS variable name.

For an alternative solution to PROC DATASOURCE’s access to FAME, see “The SASEFAME Interface Engine” in Chapter 41, “The SASEFAME Interface Engine.”

BY Variables None

Series Variables Variable names are constructed from the FAME series codes. Note that series names are limited to 32 bytes.

Haver Analytics Data Files

Haver Analytics offers a broad range of economic, financial, and industrial data for the United States and other countries. See “The SASEHAVR Interface Engine” in Chapter 42, “The SASEHAVR Interface Engine,” for information about accessing your HAVER DLX database. SASEHAVR is supported on most Windows environments. Use the DATASOURCE procedure for serial access of your data. The format of Haver Analytics data files is similar to the CITIBASE/DRIBASIC formats.

IMF Data Files

The International Monetary Fund’s Economic Information System (EIS) offers subscriptions for their International Financial Statistics (IFS), Direction of Trade Statistics (DOTS), Balance of Payment Statistics (BOPS), and Government Finance Statistics (GFS) databases. The first three contain annual, quarterly, and monthly data, while the GFS file has only annual data.

PROC DATASOURCE supports only the packed format IMF data.

FILETYPE=IMFIFSP–International Financial Statistics, Packed Format

The IFS data files contain over 23,000 time series including interest and exchange rates, national income and product accounts, price and production indexes, money and banking, export commodity prices, and balance of payments for nearly 200 countries and regional aggregates.

Examples: DATASOURCE Procedure

Example 12.1: BEA National Income and Product Accounts

In this example, exports and imports of goods and services are extracted to demonstrate how to work with a National Income and Product Accounts (NIPA) file.

From the “Statistical Tables” published by the United States Department of Commerce, Bureau of Economic Analysis, the relation of foreign transactions in the Balance of Payments Accounts (BPA) are given in the fifth table (TABNUM=’05’) of the “Foreign Transactions” section (PARTNO=’4’). Moreover, the first line in the table gives BPAs, while the eighth gives exports of goods and services. The series names __00100 and __00800, are constructed by two underscores followed by three digits as the line numbers, and then two digits as the column numbers.

The following statements put this information together to extract quarterly BPAs and exports from a BEANIPA type file:

```sas
/*-- assign fileref to the external file to be processed ---------*/
filename ascifile "%sysget(DATASRC_DATA)beanipa.data" recfm=v lrecl=108;

title1 'Relation of Foreign Transactions to Balance of Payment Accounts';
title2 'Range from 1984 to 1989';
title3 'Annual';
proc datasource filetype=beanipa infile=ascifile
  interval=year
  outselect=off
  outkey=byfor4;
  range from 1984 to 1989;
  keep __00100 __00800;
  label __00100='Balance of Payment Accounts';
  label __00800='Exports of Goods and Services';
  rename __00100=BPAs __00800=exports;
run;

proc print data=byfor4;
run;
```
Example 12.1: BEA National Income and Product Accounts

/* assign fileref to the external file to be processed */

filename ascifile "%sysget(DATASRC_DATA)beanipa.data" recfm=v lrecl=108;

title1 'Relation of Foreign Transactions to Balance of Payment Accounts';
title2 'Range from 1984 to 1989';
title3 'Annual';
proc datasource filetype=beanipa infile=ascifile
   interval=year
   outselect=off
   outkey=byfor4
   out=foreign4;

   range from 1984 to 1989;
   keep __00100 __00800;

   label __00100='Balance of Payment Accounts';
   label __00800='Exports of Goods and Services';

   rename __00100=BPAs __00800=exports;

run;

proc contents data=foreign4;
run;
proc print data=foreign4;
run;

The results are shown in Output 12.1.1, Output 12.1.2, and Output 12.1.3.

This example illustrates the following features:

- You need to know the series variables names used by a particular vendor in order to construct the KEEP statement.
- You need to know the BY-variable names and their values for the required cross sections.
- You can use RENAME and LABEL statements to associate more meaningful names and labels with your selected series variables.
Example 12.2: BLS Consumer Price Index Surveys

This example compares changes of the prices in medical care services with respect to different regions for all urban consumers (SURVEY='CU') since May 1975. The source of the data is the Consumer Price Index Surveys distributed by the U.S. Department of Labor, Bureau of Labor Statistics.

An initial run of PROC DATASOURCE gives the descriptive information on different regions available (the OUTBY= data set), as well as the series variable name corresponding to medical care services (the OUTCONT= data set).

```latex
options yearcutoff = 1900;

filename datafile "%sysget(DATASRC_DATA)blscpi1.data" recfm=v lrecl=152;
proc datasource filetype=blscpi
  interval=mon
  outselect=off
  outby=cpikey(where=( upcase(areaname) in ('NORTHEAST','NORTH CENTRAL','SOUTH','WEST')) )
  outcont=cpicont(where= ( index( upcase(label), 'MEDICAL CARE' )) )
  where survey='CU';
run;

title1 'OUTBY= Data Set, By AREANAME Selection';
proc print
data=cpikey;
run;

title1 'OUTCONT= Data Set, By LABEL Selection';
proc print
data=cpicont;
run;
```

The OUTBY= data set in Output 12.2.1 lists all cross sections available for the four geographical regions: Northeast (AREA='0100'), North Central (AREA='0200'), Southern (AREA='0300'), and Western (AREA='0400'). The OUTCONT= data set in Output 12.2.2 gives the variable names for medical care related series.

The OUTALL= data set in Output 12.2.3 indicates that data values are stored with one decimal place (see the NDEC variable). Therefore, they need to be rescaled, as follows:

```plaintext
data medical;  
  set medical;  
  medcare = medcare * 0.1;  
run;```

This example illustrates the following features:

- Descriptive information needed to write KEEP and WHERE statements can be obtained with an initial run of the DATASOURCE procedure.
- The OUTCONT= and OUTALL= data sets contain information on how data values are stored, such as the precision, the units, and so on.
- The OUTCONT= and OUTALL= data sets report the new series names assigned by the RENAME statement, not the old names (see the NAME variable in Output 12.2.3).
Example 12.3: BLS State and Area Employment, Hours, and Earnings Surveys

This example illustrates how to extract specific series from a State and Area Employment, Hours, and Earnings Survey. The series to be extracted is total employment in real estate and construction industries with respect to states from March 1989 to March 1990.

The State and Area, Employment, Hours and Earnings survey designates the totals for statewide figures by AREA='0000'.

The data type code for total employment is reported to be 1. Therefore, the series name for this variable is SA1, since series names are constructed by adding an SA prefix to the data type codes given by BLS.

Output 12.3.1 and Output 12.3.2 show statewide figures for total employment (SA1) in many industries from March 1989 through March 1990.

```plaintext
filename ascifile `%sysget(DATASRC_DATA)blseesa.dat' RECFM=F LRECL=152;
proc datasource filetype=blseesa
  infile=ascifile
  outall=totkey
  out=totemp;
  keep sa1;
  range from 1989:3 to 1990:3;
  rename sa1=totemp;
run;

title1 'Information on Total Employment, OUTALL= Data Set';
proc print data=totkey;
run;

title1 'Total Employment, OUT= Data Set';
proc print data=totemp;
run;
```

Note the following for this example:

- When the INFILE= option is omitted, the fileref assigned to the BLSEESA file is the default value DATAFILE.
- The FROM and TO values in the RANGE statement correspond to monthly data points since the INTERVAL= option defaults to MONTH for the BLSEESA filetype.

Example 12.4: DRI/McGraw-Hill Format CITIBASE Files

Output 12.4.1 and Output 12.4.2 illustrate how to extract weekly series from a sample CITIBASE file. They also demonstrate how the OUTSELECT= option affects the contents of the auxiliary data sets.

The weekly series contained in the sample data file CITIDEMO are listed by the following statements:
options yearcutoff=1920;
filename datafile "%sysget(DATASRC_DATA)citidem.dat" RECFM=D LRECL=80;
proc datasource filetype=citibase interval=week
   outall=citiall outby=citikey;
run;
title1 'Summary Information on Weekly Data for CITIDEMO File';
proc print data=citikey;
run;
title1 'Weekly Series Available in CITIDEMO File';
proc print data=citicall( drop=label );
run;

Output 12.4.1 Listing of the OUTBY= CITIKEY Data Set

Note the following from Output 12.4.2:

• The OUTALL= data set reports the time ranges of variables.
• There are six observations in the OUTALL= data set, the same number as reported by NSERIES and NSELECT variables in the OUTBY= data set.
Example 12.4: DRI/McGraw-Hill Format CITIBASE Files

- The VARNUM variable contains all MISSING values, since no OUT= data set is created.

Output 12.4.3 and Output 12.4.4 demonstrate how the OUTSELECT= option affects the contents of the OUTBY= and OUTALL= data sets when a KEEP statement is present. First, set the OUTSELECT= option to OFF.

```plaintext
filename citidemo "%sysget(DATASRC_DATA)citidem.dat" RECFM=D LRECL=80;
proc datasource filetype=citibase infile=citidemo interval=week
   outall=alloff outby=keyoff outselect=off;
   keep WSP:;
run;

title1 'Summary Information on Weekly Data for CITIDEMO File';
proc print data=keyoff;
run;

title1 'Weekly Series Available in CITIDEMO File';
proc print data=alloff( keep=name kept selected st_date end_date ntime nobs );
run;
```

Setting the OUTSELECT= option ON gives results shown in Output 12.4.5 and Output 12.4.6.

```plaintext
filename citidemo "%sysget(DATASRC_DATA)citidem.dat" RECFM=D LRECL=80;
proc datasource filetype=citibase infile=citidemo interval=week
   outall=allon outby=keyon outselect=on;
   keep WSP:;
run;
```
Chapter 12: The DATASOURCE Procedure

```plaintext
title1 'Summary Information on Weekly Data for CITIDEMO File';
proc print data=keyon;
run;

title1 'Weekly Series Available in CITIDEMO File';
proc print data=allon( keep=name kept selected st_date
end_date ntime nobs );
run;

Output 12.4.5 Listing of the OUTBY= Data Set with OUTSELECT=ON

<table>

</tr>
</tbody>
</table>
```

Comparison of Output 12.4.4 and Output 12.4.6 reveals the following:

- The OUTALL= data set contains six (NSERIES) observations when OUTSELECT=OFF, and four (NSELECT) observations when OUTSELECT=ON.
- The observations in OUTALL=ALLON are those for which SELECTED=1 in OUTALL=ALLOFF.
- The time ranges in the OUTBY= data set are computed over all the variables (selected or not) for OUTSELECT=OFF, but only computed over the selected variables for OUTSELECT=ON. This corresponds to computing time ranges over all the series reported in the OUTALL= data set.
- The variable NTIME is the number of time periods between ST_DATE and END_DATE, while NOBS is the number of observations the OUT= data set is to contain. Thus, NTIME is different depending on whether the OUTSELECT= option is set to ON or OFF, while NOBS stays the same.

The KEEP statement in the last two examples illustrates the use of an additional variable, KEPT, in the OUTALL= data sets of Output 12.4.4 and Output 12.4.6. KEPT, which reports the outcome of the KEEP statement, is only added to the OUTALL= data set when there is KEEP statement.

Adding the RANGE statement to the last example generates the data sets in Output 12.4.7 and Output 12.4.8:
Example 12.4: DRI/McGraw-Hill Format CITIBASE Files

filename citidemo "%sysget(DATASRC_DATA)citidem.dat" RECFM=D LRECL=80;
proc datasource filetype=citibase infile=citidemo interval=week
  outby=keyrange out=citiout outselect=on;
  keep WSP:;
  range from '01dec1990'd;
run;
title1 'Summary Information on Weekly Data for CITIDEMO File';
proc print data=keyrange;
run;
title1 'Weekly Data in CITIDEMO File';
proc print data=citiout;
run;

Output 12.4.7 Listing of the OUTBY=KEYRANGE Data Set for FILETYPE=CITIBASE

<table>
<thead>
<tr>
<th>Obs</th>
<th>ST_DATE</th>
<th>END_DATE</th>
<th>NTIME</th>
<th>NOBS</th>
<th>NINRANGE</th>
<th>NSERIES</th>
<th>NSELECT</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>

<td>9.70000</td>
<td>9.59000</td>
<td>9.81000</td>
<td>8.62000</td>
</tr>
<tr>
<td>12</td>
<td>Sun, 10 Feb 1991</td>
<td>9.38000</td>
<td>9.29000</td>
<td>9.48000</td>
<td>8.14000</td>
</tr>
</tbody>
</table>

The OUTBY= data set in this last example contains an additional variable NINRANGE. This variable is added since there is a RANGE statement. Its value, 15, is the number of observations in the OUT= data set. In this case, NOBS gives the number of observations the OUT= data set would contain if there were not a RANGE statement.
Example 12.5: DRI Data Delivery Service Database

This example demonstrates the DRIDDS filetype for the daily Federal Reserve Series fxrates.dds. Use VALIDVARNAME=ANY in your SAS options statement to allow special characters such as @, $, and % to be in the series name. Note the use of long variable names in the OUT= data set in Output 12.5.2 and long labels in the OUTCONT= data set in Output 12.5.1.

The following statements extract daily series starting in January 1,1997:

```sas
options validvarname=any;
filename datafile "%sysget(DATASRC_DATA)drifxrat.dat" RECFM=F LRECL=80;
proc format;
   value distekfm 0 = 'Unspecified'
                 2 = 'Linear'
                 4 = 'Triag'
                 6 = 'Polynomial'
                 8 = 'Even'
                10 = 'Step'
                12 = 'Stocklast'
                14 = 'LinearUnadjusted'
                16 = 'PolyUnadjusted'
                18 = 'StockWithNAS'
                99 = 'None'
                255 = 'None';
   value convtkfm 0 = 'Unspecified'
                 1 = 'Average'
                 3 = 'AverageX'
                 5 = 'Sum'
                 7 = 'SumAnn'
                11 = 'StockBegin'
                13 = 'AvgNP'
                15 = 'MaxNP'
                17 = 'MinNP'
                19 = 'StockEndNP'
                21 = 'StockBeginNP'
                23 = 'Max'
                25 = 'Min'
                27 = 'AvgXNP'
                29 = 'SumNP'
                31 = 'SumAnnNP'
                99 = 'None'
                255 = 'None';

/*----------------------------------------* 
* process daily series                  * 
*----------------------------------------*/
title3 'Reading DAILY Federal Reserve Series with fxrates.dds';
proc datasource filetype=dridds

Example 12.6: PC Format CITIBASE Database

This example uses a PC format CITIBASE database (FILETYPE=CITIDISK) to extract annual population estimates for females and males with respect to various age groups.

Population estimate series for all ages of females including those in the armed forces overseas are given by PANF, while PANM gives the population estimate for all ages of males including those in armed forces overseas. More population estimate time series are described in Output 12.6.1 and are output in Output 12.6.2.

The following statements extract the required population estimates series:

```plaintext
filename keyfile "%sysget(DATASRC_DATA)basekey.dat" RECFM=V LRECL=22;
filename indfile "%sysget(DATASRC_DATA)baseind.dat" RECFM=F LRECL=84;
filename dbfile "%sysget(DATASRC_DATA)basedb.dat" RECFM=F LRECL=4;

proc datasource filetype=citidisk infile=( keyfile indfile dbfile )
   out=popest outall=popinfo;
run;

proc print data=popinfo;
run;
proc print data=popest;
run;
```

Output 12.6.1 Listing of the OUTALL=POPINFO Data Set for FILETYPE=CITIDISK

This example demonstrates the following:

- The INFILE= options lists the filerefs of the key, index, and database files, in that order.
- The INTERVAL= option is omitted since the default interval for CITIDISK type files is YEAR.

Example 12.7: Quarterly COMPUSTAT Data Files

This example shows how to extract data from a 48-quarter Compustat Database File. For COMPUSTAT data files, the series variable names are constructed by concatenating the name of the data array DATA and the column number containing the required information. For example, for quarterly files the common stock data is in column 56. Therefore, the variable name for this series is DATA56. Similarly, the series variable names for quarterly footnotes are constructed by adding the column number to the array name, QFTNT. For example, the variable name for common stock footnotes is QFTNT14 since the 14th column of the QFTNT array contains this information.

The following example extracts common stock series (DATA56) and its footnote (QFTNT14) for companies whose stocks are traded over-the-counter and not in the S&P 500 Index (ZLIST=06) and whose data reside in the over-the-counter file (FILE=06).
filename compstat "%sysget(DATASRC_DATA)csqibm.dat" recfm=s370v lrecl=4820 blksize=14476;
proc datasource filetype=cs48qibm infile=compstat
   out=stocks outby=company;
   keep data56 qftnt14;
   rename data56=comstock qftnt14=ftcomstk;
   label data56='Common Stock'
      qftnt14='Footnote for Common Stock';
   range from 1990:4;
run;

/* add company name to the out= data set */
data stocks;
   merge stocks company( keep=dnum cnum cic coname );
   by dnum cnum cic;
run;

title1 'Common Stocks for Last Quarter of 1990';
proc print data=stocks ;
run;

Output 12.7.1 contains a listing of the STOCKS data set.
### Output 12.7.1 Listing of the OUT=STOCKS Data Set

#### Common Stocks for Last Quarter of 1990

Note that quarterly Compustat data are also available in Universal Character format. If you have this type of file instead of IBM 360/370 General format, use the FILETYPE=CS48QUC option instead.

Example 12.8: Annual COMPUSTAT Data Files, V9.2 New Filetype CSAUC3

Annual COMPUSTAT data in Universal Character format is read for PRICES since the year 2002, so that the desired output show the PRICE (HIGH), PRICE (LOW), and PRICE (CLOSE) for each company.

```plaintext
filename datafile "%sysget(DATASRC_DATA)csaucy3.dat" RECFM=F LRECL=13612;
/*--------------------------------------------------------------*
* create OUT=csauy3 data set with ASCII 2003 Industrial Data *
* compare it with the OUT=csauc data set created by DATA STEP *
*--------------------------------------------------------------*/
proc datasource filetype=csaucy3 ascii
    infile=datafile
    interval=year
    outselect=on
    outkey=y3key
    out=csauy3;
    keep data197-data199 label;
    range from 2002;
run;
proc sort
    data=csauy3 out=csauy3;
    by dnum cnum cic file zlist smbl xrel stk;
run;
title1 'Price, High, Low and Close for Range from 2002';
proc contents data=csauy3;
run;
proc print data=csauy3;
run;
```

Output 12.8.1 shows information on the contents of the CSAUY3 data set while Output 12.8.2 shows a listing of the CSAUY3 data set.

</tbody>
</table>

Note that annual COMPUSTAT data are available in either IBM 360/370 General format or Universal Character format. The first example expects an IBM 360/370 General format file since the FILETYPE= is set to CSAIBM, while the second example uses a Universal Character format file (FILETYPE=CSAUC).
Example 12.9: CRSP Daily NYSE/AMEX Combined Stocks

This sample code reads all the data on a three-volume daily NYSE/AMEX combined character data set. Assume that the following filerefs are assigned to the calendar/indices file and security files that this database comprises:

<table>
<thead>
<tr>
<th>Fileref</th>
<th>VOLSER</th>
<th>File Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>calfile</td>
<td>DXAA1</td>
<td>calendar/indices file on volume 1</td>
</tr>
<tr>
<td>secfile1</td>
<td>DXAA1</td>
<td>security file on volume 1</td>
</tr>
<tr>
<td>secfile2</td>
<td>DXAA2</td>
<td>security file on volume 2</td>
</tr>
<tr>
<td>secfile3</td>
<td>DXAA3</td>
<td>security file on volume 3</td>
</tr>
</tbody>
</table>

The data set CALDATA is created by the following statements to contain the calendar/indices file:

```plaintext
proc datasource filetype=crspdci infile=calfile out=caldata;
run;
```

Here the FILETYPE=CRSPDCI indicates that you are reading a character format (indicated by a C in the 6th position) daily (indicated by a D in the 5th position) calendar/indices file (indicated by an I in the 7th position).

The annual data in security files can be obtained by the following statements:

```plaintext
proc datasource filetype=crspdca
  infile=( secfile1 secfile2 secfile3 )
  out=annual;
run;
```

Similarly, the data sets to contain the daily security data (the OUT= data set) and the event data (the OUTEVENT= data set) are obtained by the following statements:

```plaintext
proc datasource filetype=crspdcs
  infile=( calfile secfile1 secfile2 secfile3 )
  out=periodic index outevent=events;
run;
```

Note that the FILETYPE= has an S in the 7th position, since you are reading the security files. Also, the INFILE= option first expects the fileref of the calendar/indices file since the dating variable (CALDT) is contained in that file. Following the fileref of calendar/indices file, you give the list of security files in the order in which you want to read them. When data span more than one physical volume, the filerefs of the security files residing on each volume must be given following the fileref of the calendar/indices file. The DATASOURCE procedure reads each of these files in the order in which they are specified. Therefore, you can request that all three volumes be mounted to the same drive, if you choose to do so.

This sample code illustrates the following points:

- The INDEX option in the second PROC DATASOURCE run creates an index file for the OUT=PERIODIC data set. This index file provides random access to the OUT= data set and may increase the efficiency of the subsequent PROC and DATA steps that use BY and WHERE statements. The index variables are CUSIP, CRSP permanent number (PERMNO), NASDAQ company number
Example 12.9: CRSP Daily NYSE/AMEX Combined Stocks

(COMPNO), NASDAQ issue number (ISSUNO), header exchange code (HEXCD), and header SIC code (HSICCD). Each one of these variables forms a different key which is a single index. If you want to form keys from a combination of variables (composite indexes) or use some other variables as indexes, you should use the INDEX=data set option for the OUT=data set.

- The OUTEVENT=EVENTS data set is sparse. In fact, for each EVENT type, a unique set of event variables are defined. For example, for EVENT='SHARES', only the variables SHROUT and SHRFLG are defined, and they have missing values for all other EVENT types. Pictorially, this structure is similar to the data set shown in Figure 12.4. Because of this sparse representation, you should create the OUTEVENT=data set only when you need a subset of securities and events.

By default, the OUT=data set contains only the periodic data. However, you may also want to include the event-oriented data in the OUT=data set. This is accomplished by listing the event variables together with periodic variables in a KEEP statement. For example, if you want to extract the historical CUSIP (NCUSIP), number of shares outstanding (SHROUT), and dividend cash amount (DIVAMT) together with all the periodic series, use the following statements.

```plaintext
proc datasource filetype=crspdcs
  infile=( calfile secfile1 secfile2 secfile3 )
  out=both outevent=events;
  where cusip='09523220';
  keep bidlo askhi prc vol ret sxret bxret ncusip shrout divamt;
run;
```

The KEEP statement has no effect on the event variables output to the OUTEVENT=data set. If you want to extract only a subset of event variables, you need to use the KEEPEVENT statement. For example, the following sample code outputs only NCUSIP and SHROUT to the OUTEVENT=data set for CUSIP='09523220':

```plaintext
proc datasource filetype=crspdxc
  infile=( calfile secfile )
  outevent=subevts;
  where cusip='09523220';
  keepevent ncusip shrout;
run;
```

Output 12.9.1, Output 12.9.2, Output 12.9.3, and Output 12.9.4 show how to read the CRSP Daily NYSE/AMEX Combined ASCII Character Files.

```plaintext
filename dxci "%sysget(DATASRC_DATA)dxccal95.dat" RECFM=F LRECL=130;
filename dxc "%sysget(DATASRC_DATA)dxcsub95.dat" RECFM=F LRECL=400;
/*---- create output data sets from character format DX files ----*/
/*-- create securities output data sets using DATASOURCE --------*/
/*-- statements -----*/
proc datasource filetype=crspdcs ascii
  infile=( dxci dxc )
  interval=day
  outcont=dxcccont
  outkey=dxckey
  outall=dxcall
  out=dxc
```
```plaintext
outevent=dxcevent
outselect=off;
    range from '15aug95'd to '28aug95'd ;
    where cusip in ('12709510','35614220');
run;

title1 'Date Range 15aug95-28aug95 ';

title3 'DX Security File Outputs';
title4 'OUTKEY= Data Set';
proc print data=dxckey;
run;

title4 'OUTCONT= Data Set';
proc print data=dxccont;
run;

title4 "Listing of OUT= Data Set for cusip in ('12709510','35614220')";
proc print data=dxc;
run;

title4 "Listing of OUTEVENT= Data Set for cusip in ('12709510','35614220')";
proc print data=dxcevent;
run;

Output 12.9.1  Listing of the OUTBY= Data Set with OUTSELECT=OFF

Overview: ENTROPY Procedure

The ENTROPY procedure implements a parametric method of linear estimation based on generalized maximum entropy. The ENTROPY procedure is suitable when there are outliers in the data and robustness is required, when the model is ill-posed or under-determined for the observed data, or for regressions that involve small data sets.

The main features of the ENTROPY procedure are as follows:

- estimation of simultaneous systems of linear regression models
- estimation of Markov models
- estimation of seemingly unrelated regression (SUR) models
- estimation of unordered multinomial discrete Choice models
- solution of pure inverse problems
- allowance of bounds and restrictions on parameters
- performance of tests on parameters
- allowance of data and moment constrained generalized cross entropy

It is often the case that the statistical/economic model of interest is ill-posed or under-determined for the observed data. For the general linear model, this can imply that high degrees of collinearity exist among explanatory variables or that there are more parameters to estimate than observations available to estimate them. These conditions lead to high variances or non-estimability for traditional generalized least squares (GLS) estimates.

Under these situations it might be in the researcher’s or practitioner’s best interest to consider a nontraditional technique for model fitting. The principle of maximum entropy is the foundation for an estimation methodology that is characterized by its robustness to ill-conditioned designs and its ability to fit over-parameterized models. See Mittelhammer, Judge, and Miller (2000) and Golan, Judge, and Miller (1996) for a discussion of Shannon’s maximum entropy measure and the related Kullback-Leibler information.

Generalized maximum entropy (GME) is a means of selecting among probability distributions to choose the distribution that maximizes uncertainty or uniformity remaining in the distribution, subject to information already known about the distribution. Information takes the form of data or moment constraints in the estimation procedure. PROC ENTROPY creates a GME distribution for each parameter in the linear model, based upon support points supplied by the user. The mean of each distribution is used as the estimate of the
parameter. Estimates tend to be biased, as they are a type of shrinkage estimate, but typically portray smaller variances than ordinary least squares (OLS) counterparts, making them more desirable from a mean squared error viewpoint (see Figure 13.1).

**Figure 13.1** Distribution of Maximum Entropy Estimates versus OLS

Maximum entropy techniques are most widely used in the econometric and time series fields. Some important uses of maximum entropy include the following:

- size distribution of firms
- stationary Markov Process
- social accounting matrix (SAM)
- consumer brand preference
- exchange rate regimes
- wage-dependent firm relocation
- oil market dynamics
Getting Started: ENTROPY Procedure

This section introduces the ENTROPY procedure and shows how to use PROC ENTROPY for several kinds of statistical analyses.

Simple Regression Analysis

The ENTROPY procedure is similar in syntax to the other regression procedures in SAS. To demonstrate the similarity, suppose the endogenous/dependent variable is $y$, and $x_1$ and $x_2$ are two exogenous/independent variables of interest. To estimate the parameters in this single equation model using PROC ENTROPY, use the following SAS statements:

```sas
proc entropy;
  model y = x1 x2;
run;
```

Test Scores Data Set

Consider the following test score data compiled by Coleman et al. (1966):

```sas
title "Test Scores compiled by Coleman et al. (1966)";
data coleman;
  input test_score 6.2 teach_sal 6.2 prcnt_prof 8.2 socio_stat 9.2 teach_score 8.2 mom_ed 7.2;
  label test_score="Average sixth grade test scores in observed district";
  label teach_sal="Average teacher salaries per student (1000s of dollars)"
  label prcnt_prof="Percent of students' fathers with professional employment"
  label socio_stat="Composite measure of socio-economic status in the district"
  label teach_score="Average verbal score for teachers"
  label mom_ed="Average level of education (years) of the students' mothers"
  datalines;
  37.01  3.83  28.87  7.20  26.60  6.19
  ...
```

This data set contains outliers, and the condition number of the matrix of regressors, $X$, is large, which indicates collinearity among the regressors. Since the maximum entropy estimates are both robust with respect to the outliers and also less sensitive to a high condition number of the $X$ matrix, maximum entropy estimation is a good choice for this problem.

To fit a simple linear model to this data by using PROC ENTROPY, use the following statements:

```sas
proc entropy data=coleman;
  model test_score = teach_sal prcnt_prof socio_stat teach_score mom_ed;
run;
```
This requests the estimation of a linear model for TEST\_SCORE with the following form:

\[
\text{test\_score} = \text{intercept} + a \times \text{teach\_sal} + b \times \text{prcnt\_prof} + c \times \text{socio\_stat} \\
+ d \times \text{teach\_score} + e \times \text{mom\_ed} + \epsilon;
\]

This estimation produces the “Model Summary” table in Figure 13.2, which shows the equation variables used in the estimation.

**Figure 13.2** Model Summary Table

The item labeled “Objective Function Value” is the value of the entropy estimation criterion for this estimation problem. This measure is analogous to the log-likelihood value in a maximum likelihood estimation. The “Parameter Information Index” and the “Error Information Index” are normalized entropy values that measure the proximity of the solution to the prior or target distributions.

The next table displayed is the ANOVA table, shown in **Figure 13.4**. This is in the same form as the ANOVA table for the MODEL procedure, since this is also a multivariate procedure.

| socio_stat     | 1  | 0.55576            | 0.09296        | 5.98    | <.0001|
| teach_score    | 1  | 1.11017            | 0.43377        | 2.56    | 0.0227|
| mom_ed         | 1  | -1.81092           | 2.02739        | -0.89   | 0.3868|

This data set contains two outliers, observations 3 and 18. These can be seen in a plot of the residuals shown in Figure 13.7.
The presence of outliers suggests that a robust estimator such as $M$-estimator in the ROBUSTREG procedure should be used. The following statements use the ROBUSTREG procedure to estimate the model.

```sas
proc robustreg data=coleman;
   model test_score = teach_sal prcnt_prof socio_stat
teach_score mom_ed;
run;
```

The results of the estimation are shown in Figure 13.8.

</tr>
</tbody>
</table>

Note that TEACH_SAL(VAR1) and MOM_ED(VAR5) change greatly when the robust estimation is used. Unfortunately, these two coefficients are negative, which implies that the test scores increase with decreasing teacher salaries and decreasing levels of the mother’s education. Since ROBUSTREG is robust to outliers, they are not causing the counterintuitive parameter estimates.

The condition number of the regressor matrix $X$ also plays an important role in parameter estimation. The condition number of the matrix can be obtained by specifying the COLLIN option in the PROC ENTROPY statement.

```plaintext
proc entropy data=coleman collin;
   model test_score = teach_sal prcnt_prof socio_stat teach_score mom_ed;
run;
```

The output produced by the COLLIN option is shown in Figure 13.9.

</tbody>
</table>

The condition number of the $X$ matrix is reported to be 84.85. This means that the condition number of $X'X$ is $84.85^2 = 7199.5$, which is very large.

Ridge regression can be used to offset some of the problems associated with ill-conditioned $X$ matrices. Using the formula for the ridge value as

$$\lambda_R = \frac{kS^2}{\hat{\beta}'\hat{\beta}} \approx 0.9$$

where $\hat{\beta}$ and $S^2$ are the least squares estimators of $\beta$ and $\sigma^2$ and $k = 6$. A ridge regression of the test score model was performed by using the data set with the outliers removed. The following PROC REG code performs the ridge regression:

```plaintext
data coleman;
  set coleman;
  if _n_ = 3 or _n_ = 18 then delete;
run;

proc reg data=coleman ridge=0.9 outest=t noprint;
  model test_score = teach_sal prcnt_prof socio_stat teach_score mom_ed;
run;

proc print data=t;
run;
```

The results of the estimation are shown in Figure 13.10.
Note that the ridge regression estimates are much closer to the estimates produced by the ENTROPY procedure that uses the original data set. Ridge regressions are not robust to outliers as maximum entropy estimates are. This might explain why the estimates still differ for TEACH_SAL.

### Using Prior Information

You can use prior information about the parameters or the residuals to improve the efficiency of the estimates. Some authors prefer the terms *pre-sample* or *pre-data* over the term *prior* when used with maximum entropy to avoid confusion with Bayesian methods. The maximum entropy method described here does not use Bayes’ rule when including prior information in the estimation.

To perform regression, the ENTROPY procedure uses a generalization of maximum entropy called *generalized maximum entropy*. In maximum entropy estimation, the unknowns are probabilities. Generalized maximum entropy expands the set of problems that can be solved by introducing the concept of *support points*. Generalized maximum entropy still estimates probabilities, but these are the probabilities of a support point. Support points are used to map the $(0, 1)$ domain of the maximum entropy to the any finite range of values.

Prior information, such as expected ranges for the parameters or the residuals, is added by specifying support points for the parameters or the residuals. Support points are points in one dimension that specify the expected domain of the parameter or the residual. The wider the domain specified, the less efficient your parameter estimates are (the more variance they have). Specifying more support points in the same width interval also improves the efficiency of the parameter estimates at the cost of more computation. Golan, Judge, and Miller (1996) show that the gains in efficiency fall off for adding more than five support points. You can specify between 2 to 256 support points in the ENTROPY procedure.

If you have only a small amount of data, the estimates are very sensitive to your selection of support points and weights. For larger data sets, incorrect priors are discounted if they are not supported by the data.

Consider the data set generated by the following SAS statements:
```sas
data prior;
  do by = 1 to 100;
    do t = 1 to 10;
      y = 2*t + 5 * rannor(4);
    end;
  end;
run;
```
Chapter 13: The ENTROPY Procedure (Experimental)

The PRIOR data set contains 100 samples of 10 observations each from the population

\[ y = 2t + \epsilon \]
\[ \epsilon \sim N(0, 5) \]

You can estimate these samples using PROC ENTROPY as

```sas
proc entropy data=prior outest=parm1 noprint;
  model y = t ;
  by by;
run;
```

The 100 estimates are summarized by using the following SAS statements:

```sas
proc univariate data=parm1;
  var t;
run;
```

The summary statistics from PROC UNIVARIATE are shown in Output 13.11. The true value of the coefficient \( T \) is 2.0, demonstrating that maximum entropy estimates tend to be biased.

**Figure 13.11** No Prior Information Monte Carlo Summary

<table>

</tr>
</tbody>
</table>

Now assume that you have prior information about the slope and the intercept for this model. You are reasonably confident that the slope is 2 and you are less confident that intercept is zero. To specify prior information about the parameters, use the PRIORS statement.

There are two parts to the prior information specified in the PRIORS statement. The first part is the support points for a parameter. The support points specify the domain of the parameter. For example, the following statement sets the support points \(-1000\) and \(1000\) for the parameter associated with variable \( T \):

```sas
priors t -1000 1000;
```
This means that the coefficient lies in the interval \([-1000, 1000]\). If the estimated value of the coefficient is actually outside of this interval, the estimation will not converge. In the previous PRIORS statement, no weights were specified for the support points, so uniform weights are assumed. This implies that the coefficient has a uniform probability of being in the interval \([-1000, 1000]\).

The second part of the prior information is the weights on the support points. For example, the following statements sets the support points 10, 15, 20, and 25 with weights 1, 5, 5, and 1 respectively for the coefficient of T:

```sas
priors t 10(1) 15(5) 20(5) 25(1);
```

This creates the prior distribution on the coefficient shown in Figure 13.12. The weights are automatically normalized so that they sum to one.

**Figure 13.12** Prior Distribution of Parameter T

For the PRIOR data set created previously, the expected value of the coefficient of T is 2. The following SAS statements reestimate the parameters with a prior weight specified for each one.
proc entropy data=prior outest=parm2 noprint;
  priors t 0(1) 2(3) 4(1)
         intercept -100(.5) -10(1.5) 0(2) 10(1.5) 100(0.5);
  model y = t;
  by by;
run;

The priors on the coefficient of T express a confident view of the value of the coefficient. The priors on INTERCEPT express a more diffuse view on the value of the intercept. The following PROC UNIVARIATE statement computes summary statistics from the estimations:

proc univariate data=parm2;
  var t;
run;

The summary statistics for the distribution of the estimates of T are shown in Figure 13.13.

The prior information improves the estimation of the coefficient of T dramatically. The downside of specifying priors comes when they are incorrect. For example, say the priors for this model were specified as

    priors t -2(1) 0(3) 2(1);

to indicate a prior centered on zero instead of two.

The resulting summary statistics shown in *Figure 13.14* indicate how the estimation is biased away from the solution.
The more data available for estimation, the less sensitive the parameters are to the priors. If the number of observations in each sample is 50 instead of 10, then the summary statistics shown in Figure 13.15 are produced. The prior information is not supported by the data, so it is discounted.

**Pure Inverse Problems**

A special case of systems of equations estimation is the pure inverse problem. A pure problem is one that contains an exact relationship between the dependent variable and the independent variables and does not have an error component. A pure inverse problem can be written as

\[ y = X\beta \]

where \( y \) is a \( n \)-dimensional vector of observations, \( X \) is a \( n \times k \) matrix of regressors, and \( \beta \) is a \( k \)-dimensional vector of unknowns. Notice that there is no error term.

A classic example is a dice problem (Jaynes 1963). Given a six-sided die that can take on the values \( x = 1, 2, 3, 4, 5, 6 \) and the average outcome of the die \( y = A \), compute the probabilities \( \beta = (p_1, p_2, \cdots, p_6)' \) of
rolling each number. This infers six values from two pieces of information. The data points are the expected value of \( y \), and the sum of the probabilities is one. Given \( E(y) = 4.0 \), this problem is solved by using the following SAS code:

```sas
data one;
    array x[6] ( 1 2 3 4 5 6 );
    y=4.0;
run;

proc entropy data=one pure;
    priors x1 0 1 x2 0 1 x3 0 1 x4 0 1 x5 0 1 x6 0 1;
    model y = x1-x6/ noint;
    restrict x1 + x2 + x3 + x4 + x5 + x6 = 1;
run;
```

The probabilities are given in Figure 13.16.

**Figure 13.16** Jaynes’ Dice Pure Inverse Problem

<table>
<thead>

</tr>
<tr>
<td>Restrict0</td>
<td>2.388082</td>
<td></td>
<td>( x1 + x2 + x3 + x4 + x5 + x6 = 1 )</td>
</tr>
</tbody>
</table>

Note how the probabilities are skewed to the higher values because of the high average roll provided in the input data.

**First-Order Markov Process Estimation**

A more useful inverse problem is the first-order markov process. Companies have a share of the marketplace where they do business. Generally, customers for a specific market space can move from company to company. The movement of customers can be visualized graphically as a flow diagram, as in Figure 13.17. The arrows represent movements of customers from one company to another.
You can model the probability that a customer moves from one company to another using a first-order Markov model. Mathematically the model is:

\[ y_t = P y_{t-1} \]

where \( y_t \) is a vector of \( k \) market shares at time \( t \) and \( P \) is a \( k \times k \) matrix of unknown transition probabilities. The value \( p_{ij} \) represents the probability that a customer who is currently using company \( j \) at time \( t - 1 \) moves to company \( i \) at time \( t \). The diagonal elements then represent the probability that a customer stays with the current company. The columns in \( P \) sum to one.

Given market share information over time, you can estimate the transition probabilities \( P \). In order to estimate \( P \) using traditional methods, you need at least \( k \) observations. If you have fewer than \( k \) transitions, you can use the ENTROPY procedure to estimate the probabilities.

Suppose you are studying the market share for four companies. If you want to estimate the transition probabilities for these four companies, you need a time series with four observations of the shares. Assume the current transition probability matrix is as follows:

\[
\begin{bmatrix}
0.7 & 0.4 & 0.0 & 0.1 \\
0.1 & 0.5 & 0.4 & 0.0 \\
0.0 & 0.1 & 0.6 & 0.0 \\
0.2 & 0.0 & 0.0 & 0.9
\end{bmatrix}
\]

The following SAS DATA step statements generate a series of market shares from this probability matrix. A transition is represented as the current period shares, \( y \), and the previous period shares, \( x \).
data m;
   /* Known Transition matrix */
   array p[4,4] (0.7 .4 .0 .1
               0.1 .5 .4 .0
               0.0 .1 .6 .0
               0.2 .0 .0 .9 ) ;
   /* Initial Market shares */
   array y[4] y1-y4 ( .4 .3 .2 .1 );
   array x[4] x1-x4;
   drop p1-p16 i;
   do i = 1 to 3;
      x[1] = y[1]; x[2] = y[2];
      y[1] = p[1,1] * x1 + p[1,2] * x2 + p[1,3] * x3 + p[1,4] * x4;
   output;
   end;
run;

The following SAS statements estimate the transition matrix by using only the first transition.

```
proc entropy markov pure data=m(obs=1);
  model y1-y4 = x1-x4;
run;
```

The MARKOV option implies NOINT for each model, that the sum of the parameters in each column is one, and chooses support points of 0 and 1. This model can be expressed equivalently as

```
proc entropy pure data=m(obs=1) ;
  priors y1.x1 0 1 y1.x2 0 1 y1.x3 0 1 y1.x4 0 1;
  priors y2.x1 0 1 y2.x2 0 1 y2.x3 0 1 y2.x4 0 1;
  priors y3.x1 0 1 y3.x2 0 1 y3.x3 0 1 y3.x4 0 1;
  priors y4.x1 0 1 y4.x2 0 1 y4.x3 0 1 y4.x4 0 1;

  model y1 = x1-x4 / noint;
  model y2 = x1-x4 / noint;
  model y3 = x1-x4 / noint;
  model y4 = x1-x4 / noint;

  restrict y1.x1 + y2.x1 + y3.x1 + y4.x1 = 1;
  restrict y1.x2 + y2.x2 + y3.x2 + y4.x2 = 1;
  restrict y1.x3 + y2.x3 + y3.x3 + y4.x3 = 1;
  restrict y1.x4 + y2.x4 + y3.x4 + y4.x4 = 1;
run;
```

The transition matrix is given in Figure 13.18.

<td>0.2856</td>
</tr>
<tr>
<td>y4.x4</td>
<td>0.223364</td>
<td>0.2337</td>
</tr>
</tbody>
</table>

Note that $P$ varies greatly from the true solution.

If two transitions are used instead (OBS=2), the resulting transition matrix is shown in Figure 13.19.

```低温
proc entropy markov pure data=m(obs=2);
    model y1-y4 = x1-x4;
run;
```
This transition matrix is much closer to the actual transition matrix.

If, in addition to the transitions, you had other information about the transition matrix, such as your own company’s transition values, that information can be added as restrictions to the parameter estimates. For noisy data, the PURE option should be dropped. Note that this example has six zero probabilities in the transition matrix; the accurate estimation of transition matrices with fewer zero probabilities generally requires more transition observations.

### Analyzing Multinomial Response Data

Multinomial discrete choice models suffer the same problems with collinearity of the regressors and small sample sizes as linear models. Unordered multinomial discrete choice models can be estimated using a variant of GME for discrete models called GME-D.

Consider the model shown in Golan, Judge, and Perloff (1996). In this model, there are five occupational categories, and the categories are considered a function of four individual characteristics. The sample contains 337 individuals.

```sas
data kpdata;
  input job x1 x2 x3 x4;
  datalines;
  0 1 3 11 1
  ... more lines ...
```
The dependent variable in this data, job, takes on values 0 through 4. Support points are used only for the error terms; so error supports are specified on the MODEL statement.

```plaintext
proc entropy data=kpdata gmed tech=nra;
    model job = x1 x2 x3 x4 / noint
       esupports=( -.1 -0.0666 -0.0333 0 0.0333 0.0666 .1 );
run;
```

**Figure 13.20** Estimate of Jobs Model by Using GME-D

| Variable | Estimate | Approx Std Err | t Value | Pr > |t| |
|----------|----------|----------------|---------|------|---|
| x1_1     | 1.802572 | 1.3610         | 1.32    | 0.1863 |
| x2_1     | -0.00251 | 0.0154         | -0.16   | 0.8705 |
| x3_1     | -0.17282 | 0.0885         | -1.95   | 0.0517 |
| x4_1     | 1.054659 | 0.6986         | 1.51    | 0.1321 |
| x1_2     | 0.089156 | 1.2764         | 0.07    | 0.9444 |
| x2_2     | 0.019947 | 0.0146         | 1.37    | 0.1718 |
| x3_2     | 0.010716 | 0.0830         | 0.13    | 0.8974 |
| x4_2     | 0.288629 | 0.5775         | 0.50    | 0.6176 |
| x1_3     | -4.62047 | 1.6476         | -2.80   | 0.0053 |
| x2_3     | 0.026175 | 0.0166         | 1.58    | 0.1157 |
| x3_3     | 0.245198 | 0.0986         | 2.49    | 0.0134 |
| x4_3     | 1.285466 | 0.8367         | 1.54    | 0.1254 |
| x1_4     | -9.72734 | 1.5813         | -6.15   | <.0001 |
| x2_4     | 0.027382 | 0.0156         | 1.75    | 0.0805 |
| x3_4     | 0.660836 | 0.0947         | 6.98    | <.0001 |
| x4_4     | 1.47479  | 0.6970         | 2.12    | 0.0351 |

Note there are five estimates of the parameters produced for each regressor, one for each choice. The first choice is restricted to zero for normalization purposes. PROC ENTROPY drops the zeroed regressors. PROC ENTROPY also generates tables of marginal effects for each regressor. The following statements generate the marginal effects table for the previous analysis at the means of the variables.

```plaintext
proc entropy data=kpdata gmed tech=nra;
    model job = x1 x2 x3 x4 / noint
       esupports=( -.1 -0.0666 -0.0333 0 0.0333 0.0666 .1 )
       marginals;
run;
```
The marginals are derivatives of the probabilities with respect to each variable and so summarize how a small change in each variable affects the overall probability.

PROC ENTROPY also enables the user to specify where the derivative is evaluated, as shown below:

```plaintext
proc entropy data=kpdata gmed tech=nra;
   model job = x1 x2 x3 x4 / noint
       esupports=( -.1 -0.0666 -0.0333 0 0.0333 0.0666 .1 )
       marginals=( x2=.4 x3=10 x4=0);
run;
```

PROC ENTROPY Statement

PROC ENTROPY options;

The following options can be specified in the PROC ENTROPY statement.

General Options

COLLIN
requests that the collinearity diagnostics of the \( X'X \) matrix be printed.

COVBEST=CROSS | GME | GMEM
specifies the method for producing the covariance matrix of parameters for output and for standard error calculations. GMEM and GME are aliases and are the default.

GME | GCE
requests generalized maximum entropy or generalized cross entropy. This is the default estimation method.

GMEM | GCEM
requests moment maximum entropy or the moment cross entropy.

GMED
requests a variant of GME suitable for multinomial discrete choice models.

MARKOV
specifies that the model is a first-order Markov model.

PURE
specifies a regression without an error term.

SUR | ITSUR
specifies seemingly unrelated regression or iterated seemingly unrelated regression.

VARDEF=N | WGT | DF | WDF
specifies the denominator to be used in computing variances and covariances. VARDEF=N specifies that the number of nonmissing observations be used. VARDEF=WGT specifies that the sum of the weights be used. VARDEF=DF specifies that the number of nonmissing observations minus the model degrees of freedom (number of parameters) be used. VARDEF=WDF specifies that the sum of the weights minus the model degrees of freedom be used. The default is VARDEF=DF.

Data Set Options

DATA=SAS-data-set
specifies the input data set. Values for the variables in the model are read from this data set.

PDATA=SAS-data-set
names the SAS data set that contains the data about priors and supports.
OUT=SAS-data-set
names the SAS data set to contain the residuals from each estimation.

OUTCOV
COVOUT
writes the covariance matrix of the estimates to the OUTEST= data set in addition to the parameter estimates. The OUTCOV option is applicable only if the OUTEST= option is also specified.

OUTEST=SAS-data-set
names the SAS data set to contain the parameter estimates and optionally the covariance of the estimates.

OUTL=SAS-data-set
names the SAS data set to contain the estimated Lagrange multipliers for the models.

OUTP=SAS-data-set
names the SAS data set to contain the support points and estimated probabilities.

OUTS=SAS-data-set
names the SAS data set to contain the estimated covariance matrix of the equation errors. This is the covariance of the residuals computed from the parameter estimates.

OUTSUSED=SAS-data-set
names the SAS data set to contain the S matrix used in the objective function definition. The OUTSUSED= data set is the same as the OUTS= data set for the methods that iterate the S matrix.

SDATA=SAS-data-set
specifies a data set that provides the covariance matrix of the equation errors. The matrix read from the SDATA= data set is used for the equation error covariance matrix (S matrix) in the estimation. The SDATA= matrix is used to provide only the initial estimate of S for the methods that iterate the S matrix.

Printing Options

ITPRINT
prints the parameter estimates, objective function value, and convergence criteria at each iteration.

NOPRINT
suppresses the normal printed output but does not suppress error listings. Using any other print option turns the NOPRINT option off.

PLOTS=global-plot-options | plot-request
controls the plots that the ENTROPY procedure produces. (For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” (SAS/STAT User’s Guide.) The global-plot-options apply to all relevant plots generated by the ENTROPY procedure.

The global-plot-options supported by the ENTROPY procedure are as follows:

ONLY suppresses the default plots. Only the plots specifically requested are produced.
UNPACKPANEL displays each graph separately. (By default, some graphs can appear together in a single panel.)
The specific plot-request values supported by the ENTROPY procedure are as follows:

- **ALL**: requests that all plots appropriate for the particular analysis be produced. ALL is equivalent to specifying FITPLOT, COOKSD, QQ, RESIDUALHISTOGRAM, and STUDENTRESIDUAL.
- **FITPLOT**: plots the predicted and actual values.
- **COOKSD**: produces the Cook’s D plot.
- **QQ**: produces a Q-Q plot of residuals.
- **RESIDUALHISTOGRAM**: plots the histogram of residuals.
- **STUDENTRESIDUAL**: plots the studentized residuals.
- **NONE**: suppresses all plots.

The default behavior is to plot all plots appropriate for the particular analysis (ALL) in a panel.

**Options to Control the Minimization Process**

The following options can be helpful if a convergence problem occurs for a given model and set of data. The ENTROPY procedure uses the nonlinear optimization subsystem (NLO) to perform the model optimizations. In addition to the options listed below, all options supported in the NLO subsystem can be specified on the ENTROPY procedure statement. See Chapter 6, “Nonlinear Optimization Methods,” for more details.

- **CONVERGE=** value
- **GCONV=** value
  - specifies the convergence criteria for $S$-iterated methods. The convergence measure computed during model estimation must be less than value before convergence is assumed. The default value is CONVERGE=0.001.
- **DUAL | PRIMAL**
  - specifies whether the optimization problem is solved using the dual or primal form. The dual form is the default.
- **MAXITER=** n
  - specifies the maximum number of iterations allowed. The default is MAXITER=100.
- **MAXSUBITER=** n
  - specifies the maximum number of subiterations allowed for an iteration. The MAXSUBITER option limits the number of step halvings. The default is MAXSUBITER=30.
- **METHOD=TR | NEWRAP | NRR | QN | CONGR | NSIMP | DBLDOG | LEVMAR**
- **TECHNIQUE=TR | NEWRAP | NRR | QN | CONGR | NSIMP | DBLDOG | LEVMAR**
- **TECH=TR | NEWRAP | NRR | QN | CONGR | NSIMP | DBLDOG | LEVMAR**
  - specifies the iterative minimization method to use. METHOD=TR specifies the trust region method, METHOD=NEWRAP specifies the Newton-Raphson method, METHOD=NRR specifies the Newton-Raphson ridge method, and METHOD=QN specifies the quasi-Newton method. See Chapter 6, “Nonlinear Optimization Methods,” for more details about optimization methods. The default is METHOD=QN for the dual form and METHOD=NEWRAP for the primal form.
BOUND Statement

BOUND bound1 <, bound2 ... >;

The BOUNDS statement imposes simple boundary constraints on the parameter estimates. BOUNDS statement constraints refer to the parameters estimated by the ENTROPY procedure. You can specify any number of BOUNDS statements.

Each boundary constraint is composed of variables, constants, and inequality operators in the following form:

```
item operator item <,operator item <,operator item ...> >
```

Each item is a constant, the name of a regressor variable, or a list of regressor names. Each operator is <, >, <=, or >=.

You can use either the BOUNDS statement or the RESTRICT statement to impose boundary constraints; the BOUNDS statement provides a simpler syntax for specifying inequality constraints. See section “RESTRICT Statement” on page 761 for more information about the computational details of estimation with inequality restrictions.

Lagrange multipliers are reported for all the active boundary constraints. In the printed output and in the OUTEST= data set, the Lagrange multiplier estimates are identified with the names BOUND1, BOUND2, and so forth. The probability of the Lagrange multipliers are computed using a beta distribution (LaMotte 1994). Nonactive or nonbinding bounds have no effect on the estimation results and are not noted in the output. To give the constraints more descriptive names, use the RESTRICT statement instead of the BOUNDS statement.

The following BOUNDS statement constrains the estimates of the coefficients of WAGE and TARGET and the 10 coefficients of x1 through x10 to be between zero and one. This example illustrates the use of parameter lists to specify boundary constraints.

```
bounds 0 < wage target x1-x10 < 1;
```

The following is an example of the use of the BOUNDS statement to impose boundary constraints on the variables X1, X2, and X3:

```
proc entropy data=zero;
    bounds .1 <= x1 <= 100,
         0 <= x2 <= 25.6,
         0 <= x3 <= 5;

    model y = x1 x2 x3;
    run;
```

The parameter estimates from this run are shown in Figure 13.23.

BY Statement

BY variables;

A BY statement is used to obtain separate estimates for observations in groups defined by the BY variables. To save parameter estimates for each BY group, use the OUTEST= option.

ID Statement

ID variables;

The ID statement specifies variables to identify observations in error messages or other listings and in the OUT= data set. The ID variables are normally SAS date or datetime variables. If more than one ID variable is used, the first variable is used to identify the observations and the remaining variables are added to the OUT= data set.

MODEL Statement

MODEL dependent = regressors < / options >;

The MODEL statement specifies the dependent variable and independent regressor variables for the regression model. If no independent variables are specified in the MODEL statement, only the mean (intercept) is estimated. To model a system of equations, specify more than one MODEL statement.

The following options can be used in the MODEL statement after a slash (/).

ESUPPORTS=( support (prior) . . . )

specifies the support points and prior weights on the residuals for the specified equation. The default is the following five support values:

-10 * value, -value, 0, value, 10 * value
where \( \text{value} \) is computed as

\[
\text{value} = (\max(y) - \bar{y}) \times \text{multiplier}
\]

for GME, where \( y \) is the dependent variable, and

\[
\text{value} = (\max(y) - \bar{y}) \times \text{multiplier} \times nobs \times \max(X) \times 0.1
\]

for generalized maximum entropy—moments (GME-M), where \( X \) is the information matrix, and \( nobs \) is the number of observations. The \( \text{multiplier} \) depends on the \text{MULTIPLIER=} option. The \text{MULTIPLIER=} option defaults to 2 for unrestricted models and to 4 for restricted models. The prior probabilities default to the following:

\[
0.0005, 0.333, 0.333, 0.333, 0.0005
\]

The support points and prior weights are selected so that hypothesis tests can be performed without adding significant bias to the estimation. These prior probability values are ad hoc.

**NOINT**

suppresses the intercept parameter.

**MARGINALS** = \( (\text{variable} = \text{value}, \ldots, \text{variable} = \text{value}) \)

requests that the marginal effects of each variable be calculated for GME-D. Specifying the \text{MARGINALS} option with an optional list of values calculates the marginals at that vector of values. For example, if \( x_1 - x_4 \) are explanatory variables, then including

\[
\text{MARGINALS} = (x_1 = 2, x_2 = 4, x_3 = -1, x_4 = 5)
\]

calculates the marginal effects at that vector. A skipped variable implies that its mean value is to be used.

**CENSORED** \( (\text{UB} | \text{LB}) = (\text{variable} | \text{value}), \text{ESUPPORTS} = (\text{support} (\text{prior}) \ldots) \)

specifies that the dependent variable be observed with censoring and specifies the censoring thresholds and the supports of the censored observations.

**CATEGORY** = \( \text{variable} \)

specifies the variable that keeps track of the categories the dependent variable is in when there is range censoring. When the actual value is observed, this variable should be set to \text{MISSING}.

**RANGE** \( (\text{ID} = (\text{QS} | \text{INT}) L = (\text{NUMBER}) R = (\text{NUMBER}), \text{ESUPPORTS} = (\text{support} < (\text{prior}) \ldots) \) \)

specifies that the dependent variable be range bound. The \text{RANGE} option defines the range and the key \( (\text{RANGE}) \) that is used to identify the observation as being range bound. The \text{RANGE} = \text{value} should be some value in the \text{CATEGORY} = \text{variable}. The \text{L} and \text{R} define, respectively, the left endpoint of the range and the right endpoint of the range. \text{ESUPPORTS} sets the error supports on the variable.

**PRIORS Statement**

**PRIORS** \( \text{variable} < \text{support points} < (\text{priors}) > > \text{variable} < \text{support points} < (\text{priors}) > > \ldots \)

The \text{PRIORS} statement specifies the support points and prior weights for the coefficients on the variables.
Support points for coefficients default to five points, determined as follows:

\[-2 \times \text{value}, -\text{value}, 0, \text{value}, 2 \times \text{value}\]

where \text{value} is computed as

\[\text{value} = (|\text{mean}| + 3 \times \text{stderr}) \times \text{multiplier}\]

where the \text{mean} and the \text{stderr} are obtained from OLS and the \text{multiplier} depends on the \text{MULTIPLIER=} option. The \text{MULTIPLIER=} option defaults to 2 for unrestricted models and to 4 for restricted models. The prior probabilities for each support point default to the uniform distribution.

The number of support points must be at least two. If priors are specified, they must be positive and there must be the same number of priors as there are support points. Priors and support points can also be specified through the \text{PDATA=} data set.

---

**RESTRICT Statement**

\[\text{RESTRICT restrictions1 < , restrictions2 . . . >};\]

The RESTRICT statement is used to impose linear restrictions on the parameter estimates. You can specify any number of RESTRICT statements.

Each \text{restriction} is written as an optional name, followed by an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

\[<"\text{name}" > \text{expression operator expression}\]

The optional “\text{name}” is a string used to identify the restriction in the printed output and in the OUTEST= data set. The \text{operator} can be =, <, >, <=, or >=. The operator and second expression are optional, as in the TEST statement, where they default to = 0.

Restriction expressions can be composed of variable names, multiplication (*), and addition (+) operators, and constants. Variable names in restriction expressions must be among the variables whose coefficients are estimated by the model. The restriction expressions must be a linear function of the variables.

The following is an example of the use of the RESTRICT statement:

\[
\begin{align*}
\text{proc entropy data=one;}
\text{restrict y1.x1*2 <= x2 + y2.x1;}
\text{model y1 = x1 x2;}
\text{model y2 = x1 x3;}
\text{run;}
\end{align*}
\]

This example illustrates the use of compound names, \text{y1.x1}, to specify coefficients of specific equations.

---

**TEST Statement**

\[\text{TEST < "name"} > \text{test1 < , test2 . . . > < ,/ options >};\]

The TEST statement performs tests of linear hypotheses on the model parameters.
The TEST statement applies only to parameters estimated in the model. You can specify any number of TEST statements.

Each test is written as an expression optionally followed by an equal sign (=) and a second expression:

\[ \text{expression} \leq \text{expression} \]

Test expressions can be composed of variable names, multiplication (*), addition (+), and subtraction (−) operators, and constants. Variables named in test expressions must be among the variables estimated by the model.

If you specify only one expression in a TEST statement, that expression is tested against zero. For example, the following two TEST statements are equivalent:

\[
\begin{align*}
\text{test } a + b; \\
\text{test } a + b = 0;
\end{align*}
\]

When you specify multiple tests on the same TEST statement, a joint test is performed. For example, the following TEST statement tests the joint hypothesis that both of the coefficients on a and b are equal to zero:

\[ \text{test } a, b; \]

To perform separate tests rather than a joint test, use separate TEST statements. For example, the following TEST statements test the two separate hypotheses that a is equal to zero and that b is equal to zero:

\[
\begin{align*}
\text{test } a; \\
\text{test } b;
\end{align*}
\]

You can use the following options in the TEST statement:

- **WALD**
  - specifies that a Wald test be computed. WALD is the default.

- **LM**
- **RAO**
- **LAGRANGE**
  - specifies that a Lagrange multiplier test be computed.

- **LR**
- **LIKE**
  - specifies that a pseudo-likelihood ratio test be computed.

- **ALL**
  - requests all three types of tests.

- **OUT=**
  - specifies the name of an output SAS data set that contains the test results. The format of the OUT= data set produced by the TEST statement is similar to that of the OUTEST= data set.
**WEIGHT Statement**

```
WEIGHT variable ;
```

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters.

If the weight of an observation is nonpositive, that observation is not used for the estimation. Variable must be a numeric variable in the input data set. The regressors and the dependent variables are multiplied by the square root of the weight variable to form the weighted X matrix and the weighted dependent variable. The same weight is used for all MODEL statements.

**Details: ENTROPY Procedure**

Shannon’s measure of entropy for a distribution is given by

\[
\begin{align*}
\text{maximize} & \quad \sum_{i=1}^{n} p_i \ln(p_i) \\
\text{subject to} & \quad \sum_{i=1}^{n} p_i = 1
\end{align*}
\]

where \( p_i \) is the probability associated with the \( i \)th support point. Properties that characterize the entropy measure are set forth by Kapur and Kesavan (1992).

The objective is to maximize the entropy of the distribution with respect to the probabilities \( p_i \) and subject to constraints that reflect any other known information about the distribution (Jaynes 1957). This measure, in the absence of additional information, reaches a maximum when the probabilities are uniform. A distribution other than the uniform distribution arises from information already known.

**Generalized Maximum Entropy**

Reparameterization of the errors in a regression equation is the process of specifying a support for the errors, observation by observation. If a two-point support is used, the error for the \( i \)th observation is reparameterized by setting \( e_i = w_{i1} v_{i1} + w_{i2} v_{i2} \), where \( v_{i1} \) and \( v_{i2} \) are the upper and lower bounds for the \( i \)th error \( e_i \), and \( w_{i1} \) and \( w_{i2} \) represent the weight associated with the point \( v_{i1} \) and \( v_{i2} \). The error distribution is usually chosen to be symmetric, centered around zero, and the same across observations so that \( v_{i1} = -v_{i2} = R \), where \( R \) is the support value chosen for the problem (Golan, Judge, and Miller 1996).

The generalized maximum entropy (GME) formulation was proposed for the ill-posed or underdetermined case where there is insufficient data to estimate the model with traditional methods. \( \beta \) is reparameterized by defining a support for \( \beta \) (and a set of weights in the cross entropy case), which defines a prior distribution for \( \beta \).

In the simplest case, each \( \beta_k \) is reparameterized as \( \beta_k = p_{k1} z_{k1} + p_{k2} z_{k2} \), where \( p_{k1} \) and \( p_{k2} \) represent the probabilities ranging from \([0,1]\) for each \( \beta \), and \( z_{k1} \) and \( z_{k2} \) represent the lower and upper bounds placed
on $\beta_k$. The support points, $z_{k1}$ and $z_{k2}$, are usually distributed symmetrically around the most likely value for $\beta_k$ based on some prior knowledge.

With these reparameterizations, the GME estimation problem is

$$\begin{align*}
\text{maximize} & \quad H(p, w) = -p' \ln(p) - w' \ln(w) \\
\text{subject to} & \quad y = X Z p + V w \\
& \quad 1_K = (I_K \otimes 1_L') p \\
& \quad 1_T = (I_T \otimes 1_T') w
\end{align*}$$

where $y$ denotes the column vector of length $T$ of the dependent variable; $X$ denotes the $(T \times K)$ matrix of observations of the independent variables; $p$ denotes the $LK$ column vector of weights associated with the points in $Z$; $w$ denotes the $LT$ column vector of weights associated with the points in $V$; $1_K$, $1_L$, and $1_T$ are $K$, $L$, and $T$-dimensional column vectors, respectively, of ones; and $I_K$ and $I_T$ are $(K \times K)$ and $(T \times T)$ dimensional identity matrices.

These equations can be rewritten using set notation as follows:

$$\begin{align*}
\text{maximize} & \quad H(p, w) = -\sum_{l=1}^L \sum_{k=1}^K p_{kl} \ln(p_{kl}) - \sum_{l=1}^L \sum_{t=1}^T w_{tl} \ln(w_{tl}) \\
\text{subject to} & \quad y_t = \sum_{l=1}^L \left[ \sum_{k=1}^K (X_{kl} Z_{kl} p_{kl}) + V_{tl} w_{tl} \right] \\
& \quad \sum_{l=1}^L p_{kl} = 1 \quad \text{and} \quad \sum_{l=1}^L w_{tl} = 1
\end{align*}$$

The subscript $l$ denotes the support point ($l=1, 2, ..., L$), $k$ denotes the parameter ($k=1, 2, ..., K$), and $t$ denotes the observation ($t=1, 2, ..., T$).

The GME objective is strictly concave; therefore, a unique solution exists. The optimal estimated probabilities, $p$ and $w$, and the prior supports, $Z$ and $V$, can be used to form the point estimates of the unknown parameters, $\beta$, and the unknown errors, $e$.

---

**Generalized Cross Entropy**

Kullback and Leibler (1951) cross entropy measures the “discrepancy” between one distribution and another. Cross entropy is called a measure of discrepancy rather than distance because it does not satisfy some of the properties one would expect of a distance measure. (See Kapur and Kesavan (1992) for a discussion of cross entropy as a measure of discrepancy.) Mathematically, cross entropy is written as

$$\begin{align*}
\text{minimize} & \quad \sum_{i=1}^n p_i \ln\left(\frac{p_i}{q_i}\right) \\
\text{subject to} & \quad \sum_{i=1}^n p_i = 1,
\end{align*}$$
where \( q_i \) is the probability associated with the \( i \)th point in the distribution from which the discrepancy is measured. The \( q_i \) (in conjunction with the support) are often referred to as the prior distribution. The measure is nonnegative and is equal to zero when \( p_i \) equals \( q_i \). The properties of the cross entropy measure are examined by Kapur and Kesavan (1992).

The principle of minimum cross entropy (Kullback 1959; Good 1963) states that one should choose probabilities that are as close as possible to the prior probabilities. That is, out of all probability distributions that satisfy a given set of constraints which reflect known information about the distribution, choose the distribution that is closest (as measured by \( p(\ln(p) - \ln(q)) \)) to the prior distribution. When the prior distribution is uniform, maximum entropy and minimum cross entropy produce the same results (Kapur and Kesavan 1992), where the higher values for entropy correspond exactly with the lower values for cross entropy.

If the prior distributions are nonuniform, the problem can be stated as a generalized cross entropy (GCE) formulation. The cross entropy terminology specifies weights, \( q_i \) and \( u_i \), for the points \( Z \) and \( V \), respectively. Given informative prior distributions on \( Z \) and \( V \), the GCE problem is

\[
\begin{align*}
\text{minimize} & \quad I(p,q,w,u) = p' \ln(p/q) + w' \ln(w/u) \\
\text{subject to} & \quad y = X Z p + V w \\
& \quad 1_K = (I_K \otimes 1'_L) p \\
& \quad 1_T = (I_T \otimes 1'_L) w
\end{align*}
\]

where \( y \) denotes the \( T \) column vector of observations of the dependent variables; \( X \) denotes the \((T \times K)\) matrix of observations of the independent variables; \( q \) and \( p \) denote \( LK \) column vectors of prior and posterior weights, respectively, associated with the points in \( Z \); \( u \) and \( w \) denote the \( LT \) column vectors of prior and posterior weights, respectively, associated with the points in \( V \); \( 1_K, 1_L, \) and \( 1_T \) are \( K-, L-, \) and \( T\)-dimensional column vectors, respectively, of ones; and \( I_K \) and \( I_T \) are \((K \times K)\) and \((T \times T)\) dimensional identity matrices.

The optimization problem can be rewritten using set notation as follows

\[
\begin{align*}
\text{minimize} & \quad I(p,q,w,u) = \sum_{l=1}^{L} \sum_{k=1}^{K} p_{kl} \ln(p_{kl}/q_{kl}) + \sum_{l=1}^{L} \sum_{t=1}^{T} w_{tl} \ln(w_{tl}/u_{tl}) \\
\text{subject to} & \quad y_t = \sum_{l=1}^{L} \left[ \sum_{k=1}^{K} (X_{kt} Z_{kl} p_{kl}) + V_{tl} w_{tl} \right] \\
& \quad \sum_{l=1}^{L} p_{kl} = 1 \quad \text{and} \quad \sum_{l=1}^{L} w_{tl} = 1
\end{align*}
\]

The subscript \( l \) denotes the support point \((l=1, 2, ..., L)\), \( k \) denotes the parameter \((k=1, 2, ..., K)\), and \( t \) denotes the observation \((t=1, 2, ..., T)\).

The objective function is strictly convex; therefore, there is a unique global minimum for the problem (Golan, Judge, and Miller 1996). The optimal estimated weights, \( p \) and \( w \), and the prior supports, \( Z \) and \( V \), can be used to form the point estimates of the unknown parameters, \( \beta \), and the unknown errors, \( \epsilon \), by using
Computational Details

This constrained estimation problem can be solved either directly (primal) or by using the dual form. Either way, it is prudent to factor out one probability for each parameter and each observation as the sum of the other probabilities. This factoring reduces the computational complexity significantly. If the primal formalization is used and two support points are used for the parameters and the errors, the resulting GME problem is $O(n_{\text{parms}}^3 n_{\text{obs}}^3)$. For the dual form, the problem is $O((n_{\text{obs}}^3)^3)$. Therefore for large data sets, GME-M should be used instead of GME.

Moment Generalized Maximum Entropy

The default estimation technique is moment generalized maximum entropy (GME-M). This is simply GME with the data constraints modified by multiplying both sides by $X'$. GME-M then becomes

\[
\begin{align*}
\text{maximize} \quad & H(p, w) = -p' \ln(p) - w' \ln(w) \\
\text{subject to} \quad & X'y = X'X Z p + X'V w \\
& 1_K = (I_K \otimes 1_L^T) p \\
& 1_T = (I_T \otimes 1_L^T) w
\end{align*}
\]
There is also the cross entropy version of GME-M, which has the same form as GCE but with the moment constraints.

**GME versus GME-M**

GME-M is more computationally attractive than GME for large data sets because the computational complexity of the estimation problem depends primarily on the number of parameters and not on the number of observations. GME-M is based on the first moment of the data, whereas GME is based on the data itself. If the distribution of the residuals is well defined by its first moment, then GME-M is a good choice. So if the residuals are normally distributed or exponentially distributed, then GME-M should be used. On the other hand if the distribution is Cauchy, lognormal, or some other distribution where the first moment does not describe the distribution, then use GME. See Example 13.1 for an illustration of this point.

**Maximum Entropy-Based Seemingly Unrelated Regression**

In a multivariate regression model, the errors in different equations might be correlated. In this case, the efficiency of the estimation can be improved by taking these cross-equation correlations into account. Seemingly unrelated regression (SUR), also called joint generalized least squares (JGLS) or Zellner estimation, is a generalization of OLS for multi-equation systems.

Like SUR in the least squares setting, the generalized maximum entropy SUR (GME-SUR) method assumes that all the regressors are independent variables and uses the correlations among the errors in different equations to improve the regression estimates. The GME-SUR method requires an initial entropy regression to compute residuals. The entropy residuals are used to estimate the cross-equation covariance matrix. In the iterative GME-SUR (ITGME-SUR) case, the preceding process is repeated by using the residuals from the GME-SUR estimation to estimate a new cross-equation covariance matrix. ITGME-SUR method alternates between estimating the system coefficients and estimating the cross-equation covariance matrix until the estimated coefficients and covariance matrix converge.

The estimation problem becomes the generalized maximum entropy system adapted for multi-equations as follows:

\[
\begin{align*}
\text{maximize} & \quad H(p, w) = -p' \ln(p) - w' \ln(w) \\
\text{subject to} & \quad y = X Z p + V w \\
& \quad 1_{KM} = (I_{KM} \otimes 1_L') p \\
& \quad 1_{MT} = (I_{MT} \otimes 1_L') w \\
\end{align*}
\]

where

\[
\beta = Z p
\]
Chapter 13: The ENTROPY Procedure (Experimental)

\[ Z = \begin{bmatrix}
  z_{11} & \cdots & z_{1L_1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & \ddots & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & z_{11}^K & \cdots & z_{1L_1}^K & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & \ddots & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & 0 & z_{11}^L & \cdots & z_{11}^L & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \ddots & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & z_{1M}^K & \cdots & z_{1M}^K \\
  0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \ddots & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \ddots & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & z_{1M}^L & \cdots & z_{1M}^L \\
\end{bmatrix} \]

\[ p = [ p_{11}^1 \cdot p_{1L_1}^1 \cdot p_{11}^K \cdot p_{1L_1}^K \cdot p_{1M}^1 \cdot p_{1LM}^1 \cdot p_{1M}^K \cdot p_{1LM}^K ]' \]

\[ e = V w \]

\[ V = \begin{bmatrix}
  v_{11}^1 & \cdots & v_{11}^L & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & \ddots & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & v_{1T}^1 & \cdots & v_{1T}^L & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & \ddots & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & 0 & v_{1M_1}^1 & \cdots & v_{1M_1}^L & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \ddots & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & v_{1MT}^1 & \cdots & v_{1MT}^L \\
\end{bmatrix} \]

\[ w = [ w_{11}^1 \cdot w_{11}^L \cdot w_{1T}^1 \cdot w_{1T}^L \cdot w_{1M_1}^1 \cdot w_{1M_1}^L \cdot w_{1MT}^1 \cdot w_{1MT}^L ]' \]

\( y \) denotes the \( MT \) column vector of observations of the dependent variables; \( X \) denotes the \((MT \times KM)\) matrix of observations for the independent variables; \( p \) denotes the \( LKM \) column vector of weights associated with the points in \( Z \); \( w \) denotes the \( LMT \) column vector of weights associated with the points in \( V \); \( 1_L, 1_K, \) and \( 1_M \) are \( L-, K-, \) and \( M- \) dimensional column vectors, respectively, of ones; and \( I_{KM} \) and \( I_{MT} \) are \((KM \times KM)\) and \((MT \times MT)\) dimensional identity matrices. The subscript \( l \) denotes the support point \((l = 1, 2, \ldots, L)\), \( k \) denotes the parameter \((k = 1, 2, \ldots, K)\), \( m \) denotes the equation \((m = 1, 2, \ldots, M)\), and \( t \) denotes the observation \((t = 1, 2, \ldots, T)\).

Using this notation, the maximum entropy problem that is analogous to the OLS problem used as the initial step of the traditional SUR approach is

\[
\text{maximize} \quad H(p, w) = -p' \ln(p) - w' \ln(w) \\
\text{subject to} \quad (y - X Z p) = \sqrt{\sum} V w \\
1_{KM} = (I_{KM} \otimes 1_L^T) p \\
1_{MT} = (I_{MT} \otimes 1_L^T) w
\]
The results are GME-SUR estimates with independent errors, the analog of OLS. The covariance matrix $\hat{\Sigma}$ is computed based on the residual of the equations, $Vw = e$. An $L'L$ factorization of the $\hat{\Sigma}$ is used to compute the square root of the matrix.

After solving this problem, these entropy-based estimates are analogous to the Aitken two-step estimator. For iterative GME-SUR, the covariance matrix of the errors is recomputed, and a new $\hat{\Sigma}$ is computed and factored. As in traditional ITSUR, this process repeats until the covariance matrix and the parameter estimates converge.

The estimation of the parameters for the normed-moment version of SUR (GME-SUR-NM) uses an identical process. The constraints for GME-SUR-NM is defined as:

$$X'y = X'(S^{-1} \otimes I)XZp + X'(S^{-1} \otimes I)Vw$$

The estimation of the parameters for GME-SUR-NM uses an identical process as outlined previously for GME-SUR.

### Generalized Maximum Entropy for Multinomial Discrete Choice Models

Multinomial discrete choice models take the form of an experiment that consists of $n$ trials. On each trial, one of $k$ alternatives is observed. If $y_{ij}$ is the random variable that takes on the value 1 when alternative $j$ is selected for the $i$th trial and 0 otherwise, then the probability that $y_{ij}$ is 1, conditional on a vector of regressors $X_i$ and unknown parameter vector $\beta_j$, is

$$\Pr(y_{ij} = 1|X_i, \beta_j) = G(X_i' \beta_j)$$

where $G()$ is a link function. For noisy data the model becomes:

$$y_{ij} = G(X_i' \beta_j) + \epsilon_{ij} = p_{ij} + \epsilon_{ij}$$

The standard maximum likelihood approach for multinomial logit is equivalent to the maximum entropy solution for discrete choice models. The generalized maximum entropy approach avoids an assumption of the form of the link function $G()$.

The generalized maximum entropy for discrete choice models (GME-D) is written in primal form as

$$\text{maximize} \quad H(p, w) = -p' \ln(p) - w' \ln(w)$$

subject to

$$(I_j \otimes X'y) = (I_j \otimes X')p + (I_j \otimes X')Vw$$

$$\sum_j p_{ij} = 1 \text{ for } i = 1 \text{ to } N$$

$$\sum_m w_{ijm} = 1 \text{ for } i = 1 \text{ to } N \text{ and } j = 1 \text{ to } k$$

Golan, Judge, and Miller (1996) have shown that the dual unconstrained formulation of the GME-D can be viewed as a general class of logit models. Additionally, as the sample size increases, the solution of the dual problem approaches the maximum likelihood solution. Because of these characteristics, only the dual approach is available for the GME-D estimation method.

The parameters $\beta_j$ are the Lagrange multipliers of the constraints. The covariance matrix of the parameter estimates is computed as the inverse of the Hessian of the dual form of the objective function.
Censored or Truncated Dependent Variables

In practice, you might find that variables are not always measured throughout their natural ranges. A given variable might be recorded continuously in a range, but, outside of that range, only the endpoint is denoted. In other words, say that the data generating process is:

\[ y_i = x_i \epsilon + \epsilon. \]

However, you observe the following:

\[ y_i^* = \begin{cases} 
ub : & y_i \geq \ub \\
\epsilon : & lb < y_i < \ub \\
lb : & y_i \leq lb 
\end{cases} \]

The primal problem is simply a slight modification of the primal formulation for GME-GCE. You specify different supports for the errors in the truncated or censored region, perhaps reflecting some nonsample information. Then the data constraints are modified. The constraints that arise in the censored areas are changed to inequality constraints (Golan, Judge, and Perloff 1997). Let the variable \( X^u \) denote the observations of the explanatory variable where censoring occurs from the top, \( X^l \) from the bottom, and \( X^a \) in the middle region (no censoring). Let, \( V^u \) be the supports for the observations at the upper bound, \( V^l \) lower bound, and \( V^a \) in the middle.

You have:

\[
\begin{bmatrix}
y^u \geq \ub \\
y^a \\
y^l \leq lb 
\end{bmatrix} = \begin{bmatrix}
X^u \\
X^a \\
X^l 
\end{bmatrix} Zp + \begin{bmatrix}
V^u w^u \\
V^a w^a \\
V^l w^l 
\end{bmatrix}
\]

The primal problem then becomes

\[
\text{maximize } H(p, w) = -p' \ln(p) - w' \ln(w) \\
\text{subject to } y^a = X^a V^a p + V^a w^a \\
y^u \geq X^u V^u p + V^u w^u \\
y^l \leq X^l V^l p + V^l w^l \\
1_K = (I_K \otimes 1_L^t) p \\
1_T = (I_T \otimes 1_L^t) w
\]

PROC ENTROPY requires that the number of supports be identical for all three regions.

Alternatively, you can think of cases where the dependent variable is observed continuously for most of its range. However, the variable’s range is reported for some observations. Such data is often found in highly disaggregated state level employment measures.

\[ y_i^* = \begin{cases} 
\text{missing} : & l_1 \leq y \leq r_1 \\
\vdots \\
\text{missing} : & l_k \leq y \leq r_k \\
x_i \epsilon : & \text{otherwise} 
\end{cases} \]

Just as in the censored case, each range yields two inequality constraints for each observation in that range.
Information Measures

PROC ENTROPY returns several measures of fit. First, the value of the objective function is returned. Next, the signal entropy is provided followed by the noise entropy. The sum of the noise and signal entropies should equal the value of the objective function. The next two metrics that follow are the normed entropies of both the signal and the noise.

Normalized entropy (NE) measures the relative informational content of both the signal and noise components through $p$ and $w$, respectively (Golan, Judge, and Miller 1996). Let $S$ denote the normalized entropy of the signal, $X\beta$, defined as:

$$S(\hat{p}) = \frac{-\hat{p}' \ln(\hat{p})}{-q' \ln(q)}$$

where $S(\hat{p}) \in [0, 1]$. In the case of GME, where uniform priors are assumed, $S$ can be written as:

$$S(\hat{p}) = \frac{-\hat{p}' \ln(\hat{p})}{\sum_i \ln(M_i)}$$

where $M_i$ is the number of support points for parameter $i$. A value of 0 for $S$ implies that there is no uncertainty regarding the parameters; hence, it is a degenerate situation. However, a value of 1 implies that the posterior distributions equal the priors, which indicates total uncertainty if the priors are uniform.

Because NE is relative, it can be used for comparing various situations. Consider adding a data point to the model. If $S_{T+1} = S_T$, then there is no additional information contained within that data constraint. However, if $S_{T+1} < S_T$, then the data point gives a more informed set of parameter estimates.

NE can be used for determining the importance of particular variables with regard to the reduction of the uncertainty they bring to the model. Each of the $k$ parameters that is estimated has an associated NE defined as

$$S(\hat{p}_k) = \frac{-\hat{p}'_k \ln(\hat{p}_k)}{-\ln(q_k)}$$

or, in the GME case,

$$S(\hat{p}_k) = \frac{-\hat{p}'_k \ln(\hat{p}_k)}{\ln(M)}$$

where $\hat{p}_k$ is the vector of supports for parameter $\beta_k$ and $M$ is the corresponding number of support points. Since a value of 1 implies no relative information for that particular sample, Golan, Judge, and Miller (1996) suggest an exclusion criteria of $S(\hat{p}_k) > 0.99$ as an acceptable means of selecting noninformative variables. See Golan, Judge, and Miller (1996) for some simulation results.

The final set of measures of fit are the parameter information index and error information index. These measures can be best summarized as $1 -$ the appropriate normed entropy.
Parameter Covariance For GCE

For the cross-entropy problem, the estimate of the asymptotic variance of the signal parameter is given by:

\[
\hat{\text{Var}}(\hat{\theta}) = \frac{\hat{\sigma}^2(\hat{\theta})}{\hat{\psi}^2(\hat{\theta})} (X'X)^{-1}
\]

where

\[
\hat{\sigma}^2(\hat{\theta}) = \frac{1}{N} \sum_{i=1}^{N} \gamma_i^2
\]

and \(\gamma_i\) is the Lagrange multiplier associated with the \(i\)th row of the \(Vw\) constraint matrix. Also,

\[
\hat{\psi}^2(\hat{\theta}) = \left( \frac{1}{N} \sum_{i=1}^{N} \left( \sum_{j=1}^{J} v_{ij}^2 w_{ij} - \left( \sum_{j=1}^{J} v_{ij} w_{ij} \right)^2 \right)^{-1} \right)^2
\]

Parameter Covariance For GCE-M

Golan, Judge, and Miller (1996) give the finite approximation to the asymptotic variance matrix of the moment formulation as:

\[
\hat{\text{Var}}(\hat{\theta}) = \Sigma z X'X C^{-1} D C^{-1} X'X \Sigma z
\]

where

\[
C = X'X \Sigma z X'X + \Sigma v
\]

and

\[
D = X' \Sigma e X
\]

Recall that in the moment formulation, \(V\) is the support of \(X'e\), which implies that \(\Sigma v\) is a \(K\)-dimensional variance matrix. \(\Sigma z\) and \(\Sigma v\) are both diagonal matrices with the form

\[
\Sigma z = \begin{bmatrix}
\sum_{l=1}^{L} z_{1l}^2 p_{1l} - (\sum_{l=1}^{L} z_{1l} p_{1l})^2 & 0 & 0 \\
0 & \ddots & 0 \\
0 & 0 & \sum_{l=1}^{L} z_{Kl}^2 p_{Kl} - (\sum_{l=1}^{L} z_{Kl} p_{Kl})^2
\end{bmatrix}
\]

and

\[
\Sigma v = \begin{bmatrix}
\sum_{j=1}^{J} v_{1j}^2 w_{1j} - (\sum_{j=1}^{J} v_{1j} w_{1j})^2 & 0 & 0 \\
0 & \ddots & 0 \\
0 & 0 & \sum_{j=1}^{J} v_{Kj}^2 w_{Kj} - (\sum_{j=1}^{J} v_{Kj} w_{Kj})^2
\end{bmatrix}
\]
Statistical Tests

Since the GME estimates have been shown to be asymptotically normally distributed, the classical Wald, Lagrange multiplier, and likelihood ratio statistics can be used for testing linear restrictions on the parameters.

Wald Tests

Let \( H_0 : L\beta = m \), where \( L \) is a set of linearly independent combinations of the elements of \( \beta \). Then under the null hypothesis, the Wald test statistic,

\[
T_W = (L\beta - m)' \left( L(\text{Var}(\hat{\beta}))L' \right)^{-1} (L\beta - m)
\]

has a central \( \chi^2 \) limiting distribution with degrees of freedom equal to the rank of \( L \).

Pseudo-Likelihood Ratio Tests

Using the conditionally maximized entropy function as a pseudo-likelihood, \( F \), Mittelhammer and Cardell (2000) state that:

\[
\frac{2\hat{\psi}(\hat{\beta})}{\sigma^2(\hat{\beta})} \left( F(\hat{\beta}) - F(\tilde{\beta}) \right)
\]

has the limiting distribution of the Wald statistic when testing the same hypothesis. Note that \( F(\hat{\beta}) \) and \( F(\tilde{\beta}) \) are the maximum values of the entropy objective function over the full and restricted parameter spaces, respectively.

Lagrange Multiplier Tests

Again using the GME function as a pseudo-likelihood, Mittelhammer and Cardell (2000) define the Lagrange multiplier statistic as:

\[
\frac{1}{\sigma^2(\tilde{\beta})} G(\tilde{\beta})'(X'X)^{-1} G(\tilde{\beta})
\]

where \( G \) is the gradient of \( F \), which is being evaluated at the optimum point for the restricted parameters. This test statistic shares the same limiting distribution as the Wald and pseudo-likelihood ratio tests.

Missing Values

If an observation in the input data set contains a missing value for any of the regressors or dependent values, that observation is dropped from the analysis.
Input Data Sets

**DATA= Data Set**

The DATA= data set specified in the PROC ENTROPY statement is the data set that contains the data to be analyzed.

**PDATA= Data Set**

The PDATA= data set specified in the PROC ENTROPY statement specifies the support points and prior probabilities to be used in the estimation. The PDATA= can be used in lieu of a PRIORS statement, but is intended for use in conjunction with the OUTP= option. Once priors are entered through a PRIORS statement, they can be reused in subsequent estimations by specifying the PDATA= option.

The variables in the data set are as follows:

- **BY variables (if any)**
- **__TYPE__,** a character variable of length 8 that identifies the estimation method: GME or GMEM. This is an optional column.
- **variable,** a character variable of length 32 that indicates the name of the regressor. The regressor name and the equation name identify a unique coefficient. This is required.
- **__OBS__,** a numeric variable that is either missing when the probabilities are for coefficients or the observation number when the probabilities are for the residual terms. The __OBS__ and the equation name identify which residual the probability is associated with. This is an optional column.
- **equation,** a character variable of length 32 indicating the name of the dependent variable. This is a required column.
- **NSupport,** a numeric variable that indicates the number of support points for each basis. This variable is required.
- **support,** a numeric variable that is the support value the probability is associated with. This is a required column.
- **prior,** a numeric variable that is the prior probability associated with the probability. This is a required column.
- **Prb,** a numeric variable that is the estimated probability. This is optional.

**SDATA= Data Set**

The SDATA= data set specifies a data set that provides the covariance matrix of the equation errors. The matrix read from the SDATA= data set is used for the equation covariance matrix (S matrix) in the estimation. (The SDATA= S matrix is used to provide only the initial estimate of S for the methods that iterate the S matrix.)
Output Data Sets

OUT= Data Set

The OUT= data set specified in the PROC ENTROPY statement contains residuals of the dependent variables computed from the parameter estimates. The ID and BY variables are also added to this data set.

OUTEST= Data Set

The OUTEST= data set contains parameter estimates and, if requested via the COVOUT option, estimates of the covariance of the parameter estimates.

The variables in the data set are as follows:

- BY variables
- _NAME_, a character variable of length 32, blank for observations that contain parameter estimates or a parameter name for observations that contain covariances
- _TYPE_, a character variable of length 8 that identifies the estimation method: GME or GMEM
- the parameters estimated

If the COVOUT option is specified, an additional observation is written for each row of the estimate of the covariance matrix of parameter estimates, with the _NAME_ values containing the parameter names for the rows.

OUTP= Data Set

The OUTP= data set specified in the PROC ENTROPY statement contains the probabilities estimated for each support point, as well as the support points and prior probabilities used in the estimation.

The variables in the data set are as follows:

- BY variables (if any)
- _TYPE_, a character variable of length 8 that identifies the estimation method: GME or GMEM.
- variable, a character variable of length 32 that indicates the name of the regressor. The regressor name and the equation name identify a unique coefficient.
- _OBS_, a numeric variable that is either missing when the probabilities are for coefficients or the observation number when the probabilities are for the residual terms. The _OBS_ and the equation name identify which residual the probability is associated with.
- equation, a character variable of length 32 that indicates the name of the dependent variable
- NSupport, a numeric variable that indicates the number of support points for each basis
- support, a numeric variable that is the support value the probability is associated with
- prior, a numeric variable that is the prior probability associated with the probability
- Prb, a numeric variable that is the estimated probability
OUTL= Data Set

The OUTL= data set specified in the PROC ENTROPY statement contains the Lagrange multiplier values for the underlying maximum entropy problem.

The variables in the data set are as follows:

- BY variables
- equation, a character variable of length 32 that indicates the name of the dependent variable
- variable, a character variable of length 32 that indicates the name of the regressor. The regressor name and the equation name identify a unique coefficient.
- _OBS_, a numeric variable that is either missing when the probabilities are for coefficients or the observation number when the probabilities are for the residual terms. The _OBS_ and the equation name identify which residual the Lagrange multiplier is associated with
- LagrangeMult, a numeric variable that contains the Lagrange multipliers

ODS Table Names

PROC ENTROPY assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

ODS Graphics

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the ENTROPY procedure.

**ODS Graph Names**

PROC ENTROPY assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 13.3.

To request these graphs, you must specify the ODS GRAPHICS statement.

**Examples: ENTROPY Procedure**

**Example 13.1: Nonnormal Error Estimation**

This example illustrates the difference between GME-M and GME. One of the basic assumptions of OLS estimation is that the errors in the estimation are normally distributed. If this assumption is violated, the estimated parameters are biased. For GME-M, the story is similar. If the first moment of the distribution of the errors and a scale factor cannot be used to describe the distribution, then the parameter estimates from GME-MN are more biased. GME is much less sensitive to the underlying distribution of the errors than GME-M.

To illustrate this, data for the following model is simulated with three different error distributions:

$$y = a * x_1 + b * x_2 + \epsilon.$$  

For the first simulation, $\epsilon$ is distributed normally, then a chi-squared distribution with six degrees of freedom is assumed for the second simulation, and finally $\epsilon$ is assumed to have a Cauchy distribution in the third simulation.

In each of the three simulations, 100 samples of 10 observations each were simulated. The data for the model with the Cauchy error distribution is generated using the following DATA step code:
Chapter 13: The ENTROPY Procedure (Experimental)

data one;
call streaminit(156789);
do by = 1 to 100;
do x2 = 1 to 10;
x1 = 10 * ranuni( 512);
y = x1 + 2*x2 + rand('cauchy');
output;
end;
end;
run;

The statements for the other distributions are identical except for the argument to the RAND() function.

The parameters to the model were estimated by using maximum entropy with the following programming statements:

```
proc entropy data=one gme outest=parm1;
    model y = x1 x2;
    by by;
run;
```

The estimation by using moment-constrained maximum entropy was performed by changing the GME option to GMEM. For comparison, the same model was estimated by using OLS with the following PROC REG statements:

```
proc reg data=one outest=parm3;
    model y = x1 x2;
    by by;
run;
```

The 100 estimations of the coefficient on variable x1 are then summarized for each of the three error distributions by using PROC UNIVARIATE, as follows:

```
proc univariate data=parm1;
    var x1;
run;
```

The following table summarizes the results from the estimations. The true value for the coefficient on x1 is 1.0.

</table>

For normally distributed or nearly normally distributed data, moment-constrained maximum entropy is a good choice. For distributions not well described by a normal distribution, data-constrained maximum entropy is a good choice.
Factorial experiments are useful for studying the effects of various factors on a response. For the practitioner constrained to the use of OLS regression, there must be replication to estimate all of the possible main and interaction effects in a factorial experiment. Using OLS regression to analyze unreplicated experimental data results in zero degrees of freedom for error in the ANOVA table, since there are as many parameters as observations. This situation leaves the experimenter unable to compute confidence intervals or perform hypothesis testing on the parameter estimates.

Several options are available when replication is impossible. The higher-order interactions can be assumed to have negligible effects, and their degrees of freedom can be pooled to create the error degrees of freedom used to perform inference on the lower-order estimates. Or, if a preliminary experiment is being run, a normal probability plot of all effects can provide insight as to which effects are significant, and therefore focused, in a later, more complete experiment.

The following example illustrates the probability plot methodology and the alternative by using PROC ENTROPY. Consider a $2^4$ factorial model with no replication. The data are taken from Myers and Montgomery (1995).

```plaintext
data rate;
  do a=-1,1; do b=-1,1; do c=-1,1; do d=-1,1;
    input y @@;
    ab=a*b; ac=a*c; ad=a*d; bc=b*c; bd=b*d; cd=c*d;
    abc=a*b*c; abd=a*b*d; acd=a*c*d; bcd=b*c*d;
    abcd=a*b*c*d;
    output;
  end; end; end; end;
datalines;
45 71 48 65 68 60 80 65 43 100 45 104 75 86 70 96
;run;
```

Analyze the data by using PROC REG, then output the resulting estimates.

```plaintext
proc reg data=rate outest=regout;
  model y=a b c d ab ac ad bc bd cd abc abd acd bcd abcd;
run;
```

```plaintext
proc transpose data=regout out=ploteff name=effect prefix=est;
  var a b c d ab ac ad bc bd cd abc abd acd bcd abcd;
run;
```

Now the normal scores for the estimates can be computed with the rank procedure as follows:

```plaintext
proc rank data=ploteff normal=blom out=qqplot;
  var est1;
  ranks normalq;
run;
```
To create the probability plot, simply plot the estimates versus their normal scores by using PROC SGPLOT as follows:

```sas
title "Unreplicated Factorial Experiments";
proc sgplot data=qqplot;
   scatter x=est1 y=normalq / markerchar=effect
       markercharattrs=(size=10pt);
   xaxis label="Estimate";
   yaxis label="Normal Quantile";
run;
```

**Output 13.2.1** Normal Probability Plot of Effects

The plot shown in Output 13.2.1 displays evidence that the $a$, $b$, $d$, $ad$, and $bd$ estimates do not fit into the purely random normal model, which suggests that they may have some significant effect on the response variable. To verify this, fit a reduced model that contains only these effects.

```sas
proc reg data=rate;
   model y=a b d ad bd;
run;
```

The estimates for the reduced model are shown in Output 13.2.2.
### Output 13.2.2 Reduced Model OLS Estimates

| Variable | DF | Parameter Estimate | Standard Error | t Value | Pr > |t| |
|----------|----|--------------------|----------------|---------|------|-------|
| Intercept | 1  | 70.06250           | 1.10432        | 63.44   | <.0001 |
| a        | 1  | 7.31250            | 1.10432        | 6.62    | <.0001 |
| b        | 1  | 4.93750            | 1.10432        | 4.47    | 0.0012 |
| d        | 1  | 10.81250           | 1.10432        | 9.79    | <.0001 |
| ad       | 1  | 8.31250            | 1.10432        | 7.53    | <.0001 |
| bd       | 1  | -9.06250           | 1.10432        | -8.21   | <.0001 |

These results support the probability plot methodology.

PROC ENTROPY can directly estimate the full model without having to rely upon the probability plot for insight into which effects can be significant. To illustrate this, PROC ENTROPY is run by using default parameter and error supports in the following statements:

```plaintext
proc entropy data=rate;
   model y=a b c d ab ac ad bc bd cd abc abd acd bcd abcd;
run;
```

The resulting GME estimates are shown in Output 13.2.3. Note that the parameter estimates associated with the a, b, d, ad, and bd effects are all significant.
Output 13.2.3  Full Model Entropy Results

Unreplicated Factorial Experiments

The ENTROPY Procedure

GME Variable Estimates

| Variable | Approx Estimate | Std Err | t Value | Pr > |t| |
|----------|----------------|---------|---------|------|---|
| a        | 5.688414       | 0.7911  | 7.19    | <.0001 |
| b        | 2.988032       | 0.5464  | 5.47    | <.0001 |
| c        | 0.234331       | 0.1379  | 1.70    | 0.1086 |

| ad       | 6.833076       | 0.8627  | 7.92    | <.0001 |
| bc       | 0.113908       | 0.0941  | 1.21    | 0.2435 |
| bd       | -7.68105       | 0.9053  | -8.48   | <.0001 |
| cd       | 0.00002        | 0.000364| 0.05    | 0.9569 |
| abc      | -0.14876       | 0.1087  | -1.37   | 0.1900 |
| abd      | -0.0399        | 0.0516  | -0.77   | 0.4509 |
| acd      | 0.466938       | 0.1961  | 2.38    | 0.0300 |
| bcd      | 0.059581       | 0.0654  | 0.91    | 0.3756 |
| abcd     | 0.024785       | 0.0387  | 0.64    | 0.5312 |
| Intercept| 69.87294       | 1.1403  | 61.28   | <.0001 |

Example 13.3: Censored Data Models in PROC ENTROPY

Data available to an analyst might sometimes be censored, where only part of the actual series is observed. Consider the case in which only observations greater than some lower bound are recorded, as defined by the following process:

\[ y = \max (X\beta + \epsilon, lb) \]

Running ordinary least squares estimation on data generated by the preceding process is not optimal because the estimates are likely to be biased and inefficient. One alternative to estimating models with censored data is the tobit estimator. This model is supported in the QLIM procedure in SAS/ETS and in the LIFEREG procedure in SAS/STAT. PROC ENTROPY provides another alternative which can make it very easy to estimate such a model correctly.
The following DATA step generates censored data in which any negative values of the dependent variable, $y$, are set to a lower bound of 0.

```sas
data cens;
  do t = 1 to 100;
    x1 = 5 * ranuni(456);
    x2 = 10 * ranuni(456);
    y = 4.5*x1 + 2*x2 + 15 * rannor(456);
    if( y<0 ) then y = 0;
    output;
  end;
run;
```

To illustrate the effect of the censored option in PROC ENTROPY, the model is initially estimated without accounting for censoring in the following statements:

```sas
proc entropy data = cens gme primal;
  priors intercept -32 32
                x1   -15 15
                x2   -15 15;
  model y = x1 x2 /
            esupports = (-25 1 25);
run;
```

Output 13.3.1 GME Estimates

| Variable | Estimate (Approx) | Std Err (Approx) | t Value (Approx) | Pr > |t| |
|----------|-------------------|------------------|------------------|------|---|
| x1       | 2.377609          | 0.000503         | 4725.98          | < .0001 |
| x2       | 2.353014          | 0.000255         | 9244.87          | < .0001 |
| intercept| 5.478121          | 0.00188          | 2906.41          | < .0001 |

The previous model is reestimated by using the CENSORED option in the following statements:

```sas
proc entropy data = cens gme primal;
  priors intercept -32 32
                x1   -15 15
                x2   -15 15;
  model y = x1 x2 /
            esupports = (-25 1 25)
            censored(lb=0, esupports=(-15 1 15));
run;
```
Output 13.3.2  Entropy Estimates

| Variable | Estimate  | Std Err | t Value | Pr > |t| |
|----------|-----------|---------|---------|------|---|
| x1       | 4.429697  | 0.00690 | 641.85  | <.0001 |
| x2       | 1.46858   | 0.00349 | 420.61  | <.0001 |
| intercept | 8.261412  | 0.0259  | 319.51  | <.0001 |

The second set of entropy estimates are much closer to the true parameter estimates of 4.5 and 2. Since another alternative available for fitting a model of censored data is a tobit model, PROC QLIM is used in the following statements to fit a tobit model to the data:

```plaintext
proc qlim data=cens;
    model y = x1 x2;
    endogenous y ~ censored(lb=0);
run;
```

Output 13.3.3  QLIM Estimates

| Parameter | DF | Estimate  | Std Error | t Value | Pr > |t| |
|-----------|----|-----------|-----------|---------|------|---|
| Intercept | 1  | 2.979455  | 3.824252  | 0.78    | 0.4359 |
| x1        | 1  | 4.882284  | 1.019913  | 4.79    | <.0001 |
| x2        | 1  | 1.374006  | 0.513000  | 2.68    | 0.0074 |
| _Sigma    | 1  | 13.723213 | 1.032911  | 13.29   | <.0001 |

For this data and code, PROC ENTROPY produces estimates that are closer to the true parameter values than those computed by PROC QLIM.

Example 13.4: Use of the PDATA= Option

It is sometimes useful to specify priors and supports by using the PDATA= option. This example illustrates how to create a PDATA= data set which contains the priors and support points for use in a subsequent PROC ENTROPY step. In order to have a model to estimate in PROC ENTROPY, you must first have data to analyze. The following DATA step generates the data used in this analysis:
title "Using a PDATA= data set";
data a;
  array x[4];
  do t = 1 to 100;
    ys = -5;
    do k = 1 to 4;
      x[k] = rannor( 55372 ) ;
      ys = ys + x[k] * k;
    end;
    ys = ys + rannor( 55372 );
  output;
  end;
run;

Next you fit this data with some arbitrary parameter support points and priors by using the following PROC ENTROPY statements:

```
proc entropy data = a gme primal;
priors x1 -10(2) 30(1)
x2  -20(3) 30(2)
x3  -15(4) 30(4)
x4  -25(3) 30(2)
    intercept  -13(4) 30(2) ;
  model ys = x1 x2 x3 x4 / esupports=(-25 0 25);
run;
```

These statements produce the output shown in Output 13.4.1.

**Output 13.4.1** Output From PROC ENTROPY

| Variable | Estimate  | Std Err | t Value | Pr > |t| |
|----------|-----------|---------|---------|------|---|
| x1       | 1.195688  | 0.1078  | 11.09   | <.0001 |
| x2       | 1.844903  | 0.1018  | 18.12   | <.0001 |
| x3       | 3.268396  | 0.1136  | 28.77   | <.0001 |
| x4       | 3.908194  | 0.0934  | 41.83   | <.0001 |
| intercept| -4.94319  | 0.1005  | -49.21  | <.0001 |

You can estimate the same model by first creating a PDATA= data set, which includes the same information as the PRIORS statement in the preceding PROC ENTROPY step.
A data set that defines the supports and priors for the model parameters is shown in the following statements:

```latex
\begin{verbatim}
data test;
  length Variable $ 12 Equation $ 12;
  input Variable $ Equation $ Nsupport Support Prior ;
  datalines;
    Intercept . 2 -13 0.66667
    Intercept . 2 30 0.33333
    x1 . 2 -10 0.66667
    x1 . 2 30 0.33333
    x2 . 2 -20 0.60000
    x2 . 2 30 0.40000
    x3 . 2 -15 0.50000
    x3 . 2 30 0.50000
    x4 . 2 -25 0.60000
    x4 . 2 30 0.40000
  ;
\end{verbatim}
```

The following statements reestimate the model by using these support points.

```latex
\begin{verbatim}
proc entropy data=a gme primal pdata=test;
  model ys = x1 x2 x3 x4 / esupports=(-25 0 25);
run;
\end{verbatim}
```

These statements produce the output shown in Output 13.4.2.

**Output 13.4.2** Output From PROC ENTROPY with PDATA= option

```
Using a PDATA= data set
The ENTROPY Procedure
GME Variable Estimates

| Variable | Estimate | Approx Std Err | t Value | Approx Pr > |t| |
|----------|----------|----------------|---------|-------------|---|
| x1       | 1.195686 | 0.1078         | 11.09   | <.0001      |
| x2       | 1.844902 | 0.1018         | 18.12   | <.0001      |
| x3       | 3.268395 | 0.1136         | 28.77   | <.0001      |
| x4       | 3.908194 | 0.0934         | 41.83   | <.0001      |
| Intercept| -4.94319 | 0.1005         | -49.21  | <.0001      |
```

These results are identical to the ones produced by the previous PROC ENTROPY step.

**Example 13.5: Illustration of ODS Graphics**

This example illustrates how to use ODS graphics in the ENTROPY procedure. This example is a continuation of the example in the section “Simple Regression Analysis” on page 732. Graphical displays are requested by specifying the ODS GRAPHICS statement. For information about the graphics available in the ENTROPY procedure, see the section “ODS Graphics” on page 776.
The following statements show how to generate ODS graphics plots with the ENTROPY procedure. The plots are displayed in Output 13.5.1.

```plaintext
proc entropy data=coleman;
   model test_score = teach_sal prcnt_prof socio_stat 
                    teach_score mom_ed;
run;
```

  Example 14.5: Illustration of ODS Graphics ......................... 821
Overview: ESM Procedure

The ESM procedure generates forecasts by using exponential smoothing models with optimized smoothing weights for many time series or transactional data.

- For typical time series, you can use the following smoothing models:
  - simple
  - double
  - linear
  - damped trend
  - seasonal
  - Winters method (additive and multiplicative)
- Additionally, transformed versions of these models are provided:
  - log
  - square root
  - logistic
  - Box-Cox

Graphics are available with the ESM procedure. For more information, see the section “ODS Graphics” on page 813.

The exponential smoothing models supported in PROC ESM differ from those supported in PROC FORECAST since all parameters associated with the forecasting model are optimized by PROC ESM based on the data.

The ESM procedure writes the time series extrapolated by the forecasts, the series summary statistics, the forecasts and confidence limits, the parameter estimates, and the fit statistics to output data sets. The ESM procedure optionally produces printed output for these results by using the Output Delivery System (ODS).

The ESM procedure can forecast both time series data, whose observations are equally spaced by a specific time interval (for example, monthly, weekly), or transactional data, whose observations are not spaced with respect to any particular time interval. Internet, inventory, sales, and similar data are typical examples of transactional data. For transactional data, the data are accumulated based on a specified time interval to form a time series prior to modeling and forecasting.

Getting Started: ESM Procedure

The ESM procedure is simple to use and does not require in-depth knowledge of forecasting methods. It can provide results in output data sets or in other output formats by using the Output Delivery System (ODS). The following examples are more fully illustrated in “Example 14.2: Forecasting of Transactional Data” on page 817.
Given an input data set that contains numerous time series variables recorded at a specific frequency, the ESM procedure can forecast the series as follows:

```plaintext
proc esm data=<input-data-set> out=<output-data-set>
    id <time-ID-variable> interval=<frequency>
    forecast <time-series-variables>
run;
```

For example, suppose that the input data set SALES contains sales data recorded monthly, the variable that represents time is DATE, and the forecasts are to be recorded in the output data set NEXTYEAR. The ESM procedure could be used as follows:

```plaintext
proc esm data=sales out=nextyear
    id date interval=month
    forecast _numeric_
run;
```

The preceding statements generate forecasts for every numeric variable in the input data set SALES for the next twelve months and store these forecasts in the output data set NEXTYEAR. Other output data sets can be specified to store the parameter estimates, forecasts, statistics of fit, and summary data.

By default, PROC ESM generates no printed output. If you want to print the forecasts by using the Output Delivery System (ODS), then you need to add the PRINT=FORECASTS option to the PROC ESM statement, as shown in the following example:

```plaintext
proc esm data=sales out=nextyear print=forecasts
    id date interval=month
    forecast _numeric_
run;
```

Other PRINT= options can be specified to print the parameter estimates, statistics of fit, and summary data.

The ESM procedure can forecast both time series data, whose observations are equally spaced by a specific time interval (for example, monthly, weekly), or transactional data, whose observations are not spaced with respect to any particular time interval.

Given an input data set that contains transactional variables not recorded at any specific frequency, the ESM procedure accumulates the data to a specific time interval and forecasts the accumulated series as follows:

```plaintext
proc esm data=<input-data-set> out=<output-data-set>
    id <time-ID-variable> interval=<frequency>
    accumulate=<accumulation>
    forecast <time-series-variables> / model=<esm>
run;
```

For example, suppose that the input data set WEBSITES contains three variables (BOATS, CARS, PLANES) that are Internet data recorded on no particular time interval, and the variable that represents time is TIME, which records the time of the Web hit. The forecasts for the total daily values are to be recorded in the output data set NEXTWEEK. The ESM procedure could be used as follows:
The preceding statements accumulate the data into a daily time series, generate forecasts for the **BOATS**, **CARS**, and **PLANES** variables in the input data set (**WEBSITES**) for the next seven days, and store the forecasts in the output data set (**NEXTWEEK**). Because the **MODEL=** option is not specified in the **FORECAST** statement, a simple exponential smoothing model is fit to each series.

### Syntax: ESM Procedure

The following statements are used with the ESM procedure:

```
PROC ESM options ;
  BY variables ;
  ID variable INTERVAL= interval options ;
  FORECAST variable-list / options ;
```

### Functional Summary

The statements and options that control the ESM procedure are summarized in the following table.

<table>
<thead>
<tr>
<th>Description</th>

BACK=n
specifies the number of observations before the end of the data where the multistep forecasts are to begin. The default is BACK=0.

DATA=SAS-data-set
names the SAS data set that contains the input data for the procedure to forecast. If the DATA= option is not specified, the most recently created SAS data set is used.

LEAD=n
specifies the number of periods ahead to forecast (forecast lead or horizon). The default is LEAD=12.

The LEAD= value is relative to the BACK= option specification and to the last observation in the input data set or the accumulated series, and not to the last nonmissing observation of a particular series. Thus, if a series has missing values at the end, the actual number of forecasts computed for that series is greater than the LEAD= value.

MAXERROR=number
limits the number of warning and error messages produced during the execution of the procedure to the specified value. The default is MAXERRORS=50. This option is particularly useful in BY-group processing where it can be used to suppress the recurring messages.

NOOUTALL
specifies that only forecasts are written to the OUT= and OUTFOR= data sets. The NOOUTALL option includes only the final forecast observations in the output data sets; it does not include the one-step forecasts for the data before the forecast period.

The OUT= and OUTFOR= data set will only contain the forecast results starting at the next period following the last observation and ending with the forecast horizon specified by the LEAD= option.

OUT=SAS-data-set
names the output data set to contain the forecasts of the variables specified in the subsequent FORECAST statements. If an ID variable is specified, it is also included in the OUT= data set. The values are accumulated based on the ACCUMULATE= option, and forecasts are appended to these values based on the FORECAST statement USE= option. The OUT= data set is particularly useful in extending the independent variables. The OUT= data set can be used as the input data set in a subsequent PROC step to forecast a dependent series by using a regression modeling procedure. If the OUT= option is not specified, a default output data set is created by using the DATAn convention. If you do not want the OUT= data set created, use OUT=_NULL_.

OUTEST=SAS-data-set
names the output data set to contain the model parameter estimates and the associated test statistics and probability values. The OUTEST= data set is useful for evaluating the significance of the model parameters and understanding the model dynamics.

OUTFOR=SAS-data-set
names the output data set to contain the forecast time series components (actual, predicted, lower confidence limit, upper confidence limit, prediction error, prediction standard error). The OUTFOR= data set is useful for displaying the forecasts in tabular or graphical form.
**OUTPROCINFO**=`SAS-data-set`

names the output data set to contain information in the SAS log, specifically the number of notes, errors, and warnings and the number of series processed, forecasts requested, and forecasts failed.

**OUTSTAT**=`SAS-data-set`

names the output data set to contain the statistics of fit (or goodness-of-fit statistics). The OUTSTAT= data set is useful for evaluating how well the model fits the series.

**OUTSUM**=`SAS-data-set`

names the output data set to contain the summary statistics and the forecast summation. The summary statistics are based on the accumulated time series when the ACCUMULATE= or SETMISSING= options are specified. The forecast summations are based on the LEAD=, STARTSUM=, and USE= options. The OUTSUM= data set is useful when forecasting large numbers of series and a summary of the results are needed.

**PLOT**=`option` | `( options )`

specifies the graphical output desired. By default, the ESM procedure produces no graphical output. The following plotting options are available:

- **ACF** plots prediction error autocorrelation function graphics.
- **ALL** is the same as specifying all of the PLOT= options.
- **BASIC** equivalent to specifying PLOT=(CORR ERRORS MODELFORECASTS).
- **CORR** plots the prediction error series graphics panel containing the ACF, IACF, PACF, and white noise probability plots.
- **ERRORS** plots prediction error time series graphics.
- **FORECASTS** plots forecast graphics.
- **FORECASTSONLY** plots the forecast in the forecast horizon only.
- **IACF** plots prediction error inverse autocorrelation function graphics.
- **LEVELS** plots smoothed level component graphics.
- **MODELFORECASTS** plots the one-step ahead model forecast and its confidence bands in the historical period; the forecast and its confidence bands over the forecast horizon.
- **MODELS** plots model graphics.
- **PACF** plots prediction error partial autocorrelation function graphics.
- **PERIODOGRAM** plots prediction error periodogram.
- **SEASONS** plots smoothed seasonal component graphics.
- **SPECTRUM** plots periodogram and smoothed periodogram of the prediction error series in a single graph.
- **TRENDS** plots smoothed trend (slope) component graphics.
- **WN** plots white noise graphics.

For example, PLOT=FORECASTS plots the forecasts for each series. The PLOT= option produces printed output for these results by using the Output Delivery System (ODS).
Chapter 14: The ESM Procedure

**PRINT**=option | ( options )
specifies the printed output desired. By default, the ESM procedure produces no printed output. The following printing options are available:

- **ESTIMATES**    prints the results of parameter estimation.
- **FORECASTS**    prints the forecasts.
- **PERFORMANCE**  prints the performance statistics for each forecast.
- **PERFORMANCESUMMARY**  prints the performance summary for each BY group.
- **PERFORMANCEOVERALL**  prints the performance summary for all of the BY groups.
- **STATISTICS**    prints the statistics of fit.
- **STATES**       prints the backcast, initial, and final states.
- **SUMMARY**      prints the summary statistics for the accumulated time series.
- **ALL**          Same as PRINT=(ESTIMATES FORECASTS STATISTICS SUMMARY).

For example, PRINT=FORECASTS prints the forecasts, PRINT=(ESTIMATES FORECASTS) prints the parameter estimates and the forecasts, and PRINT=ALL prints all of the output.

**PRINTDETAILS**
specifies that output requested with the PRINT= option be printed in greater detail.

**SEASONALITY**=number
specifies the length of the seasonal cycle. For example, SEASONALITY=3 means that every group of three observations forms a seasonal cycle. The SEASONALITY= option is applicable only for seasonal forecasting models. By default, the length of the seasonal cycle is one (no seasonality) or the length implied by the INTERVAL= option specified in the ID statement. For example, INTERVAL=MONTH implies that the length of the seasonal cycle is twelve.

**SORTNAMES**
specifies that the variables specified in the FORECAST statements are processed in sorted order.

**STARTSUM**=n
specifies the starting forecast lead (or horizon) for which to begin summation of the forecasts specified by the LEAD= option. The STARTSUM= value must be less than the LEAD= value. The default is STARTSUM=1; that is, the sum from the one-step ahead forecast (which is the first forecast in the forecast horizon) to the multistep forecast specified by the LEAD= option.

The prediction standard errors of the summation of forecasts take into account the correlation between the multistep forecasts. The section “Forecast Summation” on page 807 describes the STARTSUM= option in more detail.

---

**BY Statement**

```plaintext
BY variables ;
```

A BY statement can be used with PROC ESM to obtain separate dummy variable definitions for groups of observations defined by the BY variables.
When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the option NOTSORTED or DESCENDING in the BY statement for the ESM procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see SAS Language Reference: Concepts. For more information about the DATASETS procedure, see the discussion in the Base SAS Procedures Guide.

**FORECAST Statement**

```plaintext
FORECAST variable-list / options ;
```

The FORECAST statement lists the numeric variables in the DATA= data set whose accumulated values represent time series to be modeled and forecast. The options specify which forecast model is to be used.

A data set variable can be specified in only one FORECAST statement. Any number of FORECAST statements can be used. The following options can be used with the FORECAST statement.

- **ACCUMULATE=** option
  specifies how the data set observations are accumulated within each time period for the variables listed in the FORECAST statement. If the ACCUMULATE= option is not specified in the FORECAST statement, accumulation is determined by the ACCUMULATE= option of the ID statement. Use the ACCUMULATE= option with multiple FORECAST statements when you want different accumulation specifications for different variables. See the ID statement ACCUMULATE= option for more details.

- **ALPHA=** number
  specifies the significance level to use in computing the confidence limits of the forecast. The ALPHA= value must be between 0 and 1. The default is ALPHA=0.05, which produces 95% confidence intervals.

- **MEDIAN**
  specifies that the median forecast values are to be estimated. Forecasts can be based on the mean or median. By default, the mean value is provided. If no transformation is applied to the time series by using the TRANSFORM= option, the mean and median forecast values are identical.

- **MODEL=** model-name
  specifies the forecasting model to be used to forecast the time series. The default is MODEL=SIMPLE, which performs simple exponential smoothing. The following forecasting models are provided:

  - NONE no forecast
  - SIMPLE simple (single) exponential smoothing. This is the default.
Chapter 14: The ESM Procedure

DOUBLE double (Brown) exponential smoothing
LINEAR linear (Holt) exponential smoothing
DAMPTREND damped trend exponential smoothing
ADDSEASONAL|SEASONAL additive seasonal exponential smoothing
MULTSEASONAL multiplicative seasonal exponential smoothing
WINTERS Winters multiplicative method
ADDWINTERS Winters additive method

When the option MODEL=NONE is specified, the time series is appended with missing values in the OUT= data set. This option is useful when the results stored in the OUT= data set are used in a subsequent analysis where forecasts of the independent variables are needed to forecast the dependent variable.

NBACKCAST=n
specifies the number of observations used to initialize the backcast states. The default is the entire series.

REPLACEBACK
specifies that actual values excluded by the BACK= option are replaced with one-step-ahead forecasts in the OUT= data set.

REPLACEMISSING
specifies that embedded missing values are replaced with one-step-ahead forecasts in the OUT= data set.

SETMISSING=option | number
specifies how missing values (either input or accumulated) are assigned in the accumulated time series for variables listed in the FORECAST statement. If the SETMISSING= option is not specified in the FORECAST statement, missing values are set based on the SETMISSING= option of the ID statement. See the ID statement SETMISSING= option for more details.

TRANSFORM=option
specifies the time series transformation to be applied to the input or accumulated time series. The following transformations are provided:

NONE no transformation. This is the default.
LOG logarithmic transformation
SQRT square-root transformation
LOGISTIC logistic transformation
BOXCOX(n) Box-Cox transformation with parameter number where number is between –5 and 5

When the TRANSFORM= option is specified, the time series must be strictly positive. After the time series is transformed, the model parameters are estimated by using the transformed series. The forecasts of the transformed series are then computed, and finally the transformed series forecasts are inverse transformed. The inverse transform produces either mean or median forecasts depending on whether the MEDIAN option is specified. The sections “Transformations” on page 806 and “Inverse Transformations” on page 807 describe this in more detail.
**USE=option**
specifies which forecast values are appended to the actual values in the OUT= and OUTSUM= data sets. The following USE= options are provided:

- **PREDICT** The predicted values are appended to the actual values. This option is the default.
- **LOWER** The lower confidence limit values are appended to the actual values.
- **UPPER** The upper confidence limit values are appended to the actual values.

Thus, the USE= option enables the OUT= and OUTSUM= data sets to be used for worst-case, best-case, average-case, and median-case decisions.

**ZEROMISS=option**
specifies how beginning or ending zero values (either input or accumulated) are interpreted in the accumulated time series for variables listed in the FORECAST statement. If the ZEROMISS= option is not specified in the FORECAST statement, beginning or ending zero values are set to missing values based on the ZEROMISS= option of the ID statement. See the ID statement ZEROMISS= option for more details.

---

**ID Statement**

```sas
ID variable INTERVAL= interval < options > ;
```

The ID statement names a numeric variable that identifies observations in the input and output data sets. The ID variable’s values are assumed to be SAS date or datetime values. In addition, the ID statement specifies the (desired) frequency associated with the time series. The ID statement options also specify how the observations are accumulated and how the time ID values are aligned to form the time series to be forecast. The information specified affects all variables specified in subsequent FORECAST statements. If the ID statement is specified, the INTERVAL= option must be specified. If an ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID. The following options can be used with the ID statement.

**ACCUMULATE=option**
specifies how the data set observations are accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option. The ID variable contains the time ID values. Each time ID variable value corresponds to a specific time period. The accumulated values form the time series, which is used in subsequent model fitting and forecasting.

The ACCUMULATE= option is particularly useful when there are gaps in the input data or when there are multiple input observations that coincide with a particular time period (for example, transactional data). The EXPAND procedure offers additional frequency conversions and transformations that can also be useful in creating a time series.

The following options determine how the observations are accumulated within each time period based on the ID variable and the frequency specified by the INTERVAL= option:

- **NONE** No accumulation occurs; the ID variable values must be equally spaced with respect to the frequency. This is the default option.
- **TOTAL** Observations are accumulated based on the total sum of their values.
Chapter 14: The ESM Procedure

AVERAGE | AVG Observations are accumulated based on the average of their values.
MINIMUM | MIN Observations are accumulated based on the minimum of their values.
MEDIAN | MED Observations are accumulated based on the median of their values.
MAXIMUM | MAX Observations are accumulated based on the maximum of their values.
N Observations are accumulated based on the number of nonmissing observations.
NMISS Observations are accumulated based on the number of missing observations.
NOBS Observations are accumulated based on the number of observations.
FIRST Observations are accumulated based on the first of their values.
LAST Observations are accumulated based on the last of their values.
STDDEV | STD Observations are accumulated based on the standard deviation of their values.
CSS Observations are accumulated based on the corrected sum of squares of their values.
USS Observations are accumulated based on the uncorrected sum of squares of their values.

If the ACCUMULATE= option is specified, the SETMISSING= option is useful for specifying how accumulated missing values are treated. If missing values should be interpreted as zero, then SETMISSING=0 should be used. The section “Accumulation” on page 804 describes accumulation in greater detail.

ALIGN=option controls the alignment of SAS dates used to identify output observations. The ALIGN= option accepts the following values: BEGINNING | BEG | B, MIDDLE | MID | M, and ENDING | END | E. BEGINNING is the default.

END=date | datetime specifies a SAS date or datetime literal value that represents the end of the data. If the last time ID variable value is less than the END= value, the series is extended with missing values. If the last time ID variable value is greater than the END= value, the series is truncated. For example, END='1jan2008'D specifies that data for time periods after the first of January 2008 not be used. The option END="&sysdate"D uses the automatic macro variable SYSDATE to extend or truncate the series to the current date. This option and the START= option can be used to ensure that data associated with each BY group contains the same number of observations.

FORMAT=format specifies the SAS format for the time ID values. If the FORMAT= option is not specified, the default format is implied from the INTERVAL= option.

INTERVAL=interval specifies the frequency of the input time series or for the time series to be accumulated from the input data. For example, if the input data set consists of quarterly observations, then INTERVAL=QTR should be used. If the SEASONALITY= option is not specified, the length of the seasonal cycle
is implied by the INTERVAL= option. For example, INTERVAL=QTR implies a seasonal cycle of length 4. If the ACCUMULATE= option is also specified, the INTERVAL= option determines the time periods for the accumulation of observations.

The basic intervals are YEAR, SEMIYEAR, QTR, MONTH, SEMIMONTH, TENDAY, WEEK, WEEKDAY, DAY, HOUR, MINUTE, SECOND. See Chapter 4, “Date Intervals, Formats, and Functions,” for more information about the intervals that can be specified.

NOTSORTED specifies that the time ID values are not in sorted order. The ESM procedure sorts the data with respect to the time ID prior to analysis.

SETMISSING=option | number specifies how missing values (either input or accumulated) are assigned in the accumulated time series. If a number is specified, missing values are set to that number. If a missing value on the input data set indicates an unknown value, the SETMISSING= option should not be used. If a missing value indicates no value, SETMISSING=0 should be used. You typically use SETMISSING=0 for transactional data, because no recorded data usually implies no activity. The following options can also be used to determine how missing values are assigned:

- MISSING: Missing values are set to missing. This is the default option.
- AVERAGE | AVG: Missing values are set to the accumulated average value.
- MINIMUM | MIN: Missing values are set to the accumulated minimum value.
- MEDIAN | MED: Missing values are set to the accumulated median value.
- MAXIMUM | MAX: Missing values are set to the accumulated maximum value.
- FIRST: Missing values are set to the accumulated first nonmissing value.
- LAST: Missing values are set to the accumulated last nonmissing value.
- PREVIOUS | PREV: Missing values are set to the previous accumulated nonmissing value.
- NEXT: Missing values are set to the next accumulated nonmissing value. Missing values at the end of the accumulated series remain missing.

If SETMISSING=MISSING is specified, the missing observations are replaced with predicted values computed from the exponential smoothing model.

START= date | datetime specifies a SAS date or datetime literal value that represents the beginning of the data. If the first time ID variable value is greater than the START= value, the series is prefixed with missing values. If the first time ID variable value is less than the START= value, the series is truncated. This option and the END= option can be used to ensure that data associated with each BY group contains the same number of observations.

ZEROMISS=option specifies how beginning and/or ending zero values (either input or accumulated) are interpreted in the accumulated time series. The following values can be specified for the ZEROMISS= option:
NONE Beginning and/or ending zeros are unchanged. This is the default.
LEFT Beginning zeros are set to missing.
RIGHT Ending zeros are set to missing.
BOTH Both beginning and ending zeros are set to missing.

If the accumulated series is all missing and/or zero the series is not changed.

---

**Details: ESM Procedure**

The ESM procedure can be used to forecast time series data as well as transactional data. If the data is transactional, then the procedure must first accumulate the data into a time series before it can be forecast. The procedure uses the following sequential steps to produce forecasts, with the options that control the step listed to the right:

<table>
<thead>
<tr>
<th>Step</th>
<th>Operation</th>
<th>Option</th>
<th>Statement</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
</tbody>
</table>

Each of the steps shown in Table 14.2 is described in the following sections.

---

**Accumulation**

If the ACCUMULATE= option is specified in the ID statement, data set observations are accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option, and the ID variable contains the time ID values. Each time ID value corresponds to a specific time period. Accumulation is particularly useful when the input data set contains transactional data, whose observations are not spaced with respect to any particular time interval. The accumulated values form the time series that is used in subsequent analyses by the ESM procedure.

For example, suppose a data set contains the following observations:

<table>
<thead>
<tr>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>19MAR1999</td>
<td>10</td>
</tr>
<tr>
<td>19MAR1999</td>
<td>30</td>
</tr>
<tr>
<td>11MAY1999</td>
<td>50</td>
</tr>
<tr>
<td>12MAY1999</td>
<td>20</td>
</tr>
<tr>
<td>23MAY1999</td>
<td>20</td>
</tr>
</tbody>
</table>
If the INTERVAL=MONTH option is specified on the ID statement, all of the preceding observations fall within three time periods: March 1999, April 1999, and May 1999. The observations are accumulated within each time period as follows.

If the ACCUMULATE=NONE option is specified, an error is generated because the ID variable values are not equally spaced with respect to the specified frequency (MONTH).

If the ACCUMULATE=TOTAL option is specified, the resulting time series is:

```
 01MAR1999  40
 01APR1999   .
 01MAY1999  90
```

If the ACCUMULATE=AVERAGE option is specified, the resulting time series is:

```
 01MAR1999  20
 01APR1999   .
 01MAY1999  30
```

If the ACCUMULATE=MINIMUM option is specified, the resulting time series is:

```
 01MAR1999  10
 01APR1999   .
 01MAY1999  20
```

If the ACCUMULATE=MEDIAN option is specified, the resulting time series is:

```
 01MAR1999  20
 01APR1999   .
 01MAY1999  20
```

If the ACCUMULATE=MAXIMUM option is specified, the resulting time series is:

```
 01MAR1999  30
 01APR1999   .
 01MAY1999  50
```

If the ACCUMULATE=FIRST option is specified, the resulting time series is:

```
 01MAR1999  10
 01APR1999   .
 01MAY1999  50
```

If the ACCUMULATE=LAST option is specified, the resulting time series is:

```
 01MAR1999  30
 01APR1999   .
 01MAY1999  20
```
If the ACCUMULATE=STDDEV option is specified, the resulting time series is:

<table>
<thead>
<tr>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>O1MAR1999</td>
<td>14.14</td>
</tr>
<tr>
<td>O1APR1999</td>
<td>.</td>
</tr>
<tr>
<td>O1MAY1999</td>
<td>17.32</td>
</tr>
</tbody>
</table>

As can be seen from the preceding examples, even though the data set observations contained no missing values, the accumulated time series can have missing values.

### Missing Value Interpretation

Sometimes missing values should be interpreted as truly unknown values and retained as missing values in the data set. The forecasting models used by the ESM procedure can effectively handle missing values (see the section “Missing Value Modeling Issues” on page 806). However, sometimes missing values are known, such as when missing values are created from accumulation and represent no observed values for the variable. In this case, the value for the period should be interpreted as zero (no values), and the SETMISSING=0 option should be used to cause PROC ESM to recode missing values as zero. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and missing-value-recoded time series is used in subsequent analyses in PROC ESM.

### Transformations

If the TRANSFORM= option is specified in the FORECAST statement, the time series is transformed prior to model parameter estimation and forecasting. Only strictly positive series can be transformed. An error is generated when the TRANSFORM= option is used with a nonpositive series. (See Chapter 52, “Forecasting Process Details,” for more details about forecasting transformed time series.)

### Parameter Estimation

All the parameters (smoothing weights) associated with the exponential smoothing model used to forecast the time series (as specified by the MODEL= option) are optimized based on the data, with the default parameter restrictions imposed. If the TRANSFORM= option is specified, the transformed time series data are used to estimate the model parameters.

The techniques used in the ESM procedure are identical to those used for exponential smoothing models in the Time Series Forecasting System of SAS/ETS software. See Chapter 44, “Overview of the Time Series Forecasting System,” for more information.

### Missing Value Modeling Issues

The treatment of missing values varies with the forecasting model. Missing values after the start of the series are replaced with one-step-ahead predicted values, and the predicted values are used in the smoothing equations.
The treatment of missing values can also be specified with the SETMISSING= option, which changes the missing values prior to modeling.

**NOTE:** Even if all of the observed data are nonmissing, the ACCUMULATE= option can create missing values in the accumulated series (when the data contain no observations for some of the time periods specified by the INTERVAL= option).

### Forecasting

Once the model parameters are estimated, one-step-ahead forecasts are generated for the full range of the accumulated and optionally transformed time series data, and multistep forecasts are generated from the end of the time series to the future time period specified by the LEAD= option. If there are missing values at the end of the time series, the forecast horizon will be greater than that specified by the LEAD= option.

### Inverse Transformations

If the TRANSFORM= option is specified in the FORECAST statement, the forecasts of the transformed time series are inverse transformed. By default, forecasts of the mean (expected value) are generated. If the MEDIAN option is specified, median forecasts are generated. (See Chapter 52, “Forecasting Process Details,” for more details about forecasting transformed time series.)

### Statistics of Fit

The statistics of fit are computed by comparing the time series data (after accumulation and missing value recoding, if specified) with the generated forecasts. If the TRANSFORM= option is specified, the statistics of fit are based on the inverse transformed forecasts. (See Chapter 52, “Forecasting Process Details,” for more details about statistics of fit for forecasting models.)

### Forecast Summation

The multistep forecasts generated by the preceding steps can optionally be summed from the STARTSUM= value to the LEAD= value. For example, if the options STARTSUM=4 and LEAD=6 are specified on the PROC ESM statement, the four-step through six-step ahead forecasts are summed.

The forecasts are simply summed; however, the prediction error variance of this sum is computed by taking into account the correlation between the individual predictions. (These variance-related computations are performed only when no transformation is specified; that is, when TRANSFORM=NONE.) The upper and lower confidence limits for the sum of the predictions is then computed based on the prediction error variance of the sum.

The forecast summation is particularly useful when it is desirable to model in one frequency but the forecast of interest is another frequency. For example, if a time series has a monthly frequency (INTERVAL=MONTH) and you want a forecast for the third and fourth future months, a forecast summation for the third and fourth month can be obtained by specifying STARTSUM=3 and LEAD=4.
Data Set Output

The ESM procedure can create the OUT=, OUTEST=, OUTFOR=, OUTSTAT=, and OUTSUM= data sets. These data sets contain the variables listed in the BY statement and statistics related to the variables listing in the FORECAST statement. In general, if a forecasting step related to an output data set fails, the values of this step are not recorded or are set to missing in the related output data set and appropriate error and/or warning messages are recorded in the log.

OUT= Data Set

The OUT= data set contains the variables specified in the BY, ID, and FORECAST statements. If the ID statement is specified, the ID variable values are aligned and extended based on the ALIGN= and INTERVAL= options. The values of the variables specified in the FORECAST statements are accumulated based on the ACCUMULATE= option, and missing values are interpreted based on the SETMISSING= option. If the REPLACEMISSING option is specified, embedded missing values are replaced by the one-step-ahead predicted values.

These FORECAST variables are then extrapolated based on the forecasts from the fitted models, or extended with missing values when the MODEL=NONE option is specified. If USE=LOWER is specified, the variable is extrapolated with the lower confidence limits; if USE=UPPER, the variable is extrapolated using the upper confidence limits; otherwise, the variable values are extrapolated with the predicted values. If the TRANSFORM= option is specified, the predicted values contain either mean or median forecasts depending on whether or not the MEDIAN option is specified.

If any of the forecasting steps fail for a particular variable, the variable is extended by missing values.

OUTEST= Data Set

The OUTEST= data set contains the variables specified in the BY statement as well as the variables listed below. For variables listed in FORECAST statements where the option MODEL=NONE is specified, no observations are recorded in the OUTEST= data set. For variables listed in FORECAST statements where the option MODEL=NONE is not specified, the following variables in the OUTEST= data set contain observations related to the parameter estimation step:

_NAME_ variable name
_MODEL_ forecasting model
_TRANSFORM_ transformation
_PARM_ parameter name
_EST_ parameter estimate
_STDERR_ standard errors
_TVALUE_ t values
_PVALUE_ probability values

If the parameter estimation step fails for a particular variable, no observations are output to the OUTEST= data set for that variable.
OUTFOR= Data Set

The OUTFOR= data set contains the variables specified in the BY statement as well as the variables listed below. For variables listed in FORECAST statements where the option MODEL=NONE is specified, no observations are recorded in the OUTFOR= data set for these variables. For variables listed in FORECAST statements where the option MODEL=NONE is not specified, the following variables in the OUTFOR= data set contain observations related to the forecasting step:

- _NAME_ variable name
- _TIMEID_ time ID values
- ACTUAL actual values
- PREDICT predicted values
- STD prediction standard errors
- LOWER lower confidence limits
- UPPER upper confidence limits
- ERROR prediction errors

If the forecasting step fails for a particular variable, no observations are recorded in the OUTFOR= data set for that variable. If the TRANSFORM= option is specified, the values in the preceding variables are the inverse transform forecasts. If the MEDIAN option is specified, the median forecasts are stored; otherwise, the mean forecasts are stored.

OUTPROCINFO= Data Set

The OUTPROCINFO= data set contains information about the run of the ESM procedure. The following variables are present:

- _SOURCE_ set to the name of the procedure, in this case ESM
- _NAME_ name of an item being reported; can be the number of errors, notes, or warnings, number of forecasts requested, and so on
- _LABEL_ descriptive label for the item in _NAME_
- _STAGE_ set to the current stage of the procedure, for ESM this is set to ALL
- _VALUE_ value of the item specified in _NAME_

OUTSTAT= Data Set

The OUTSTAT= data set contains the variables specified in the BY statement as well as the variables listed below. For variables listed in FORECAST statements where the option MODEL=NONE is specified, no observations are recorded for these variables in the OUTSTAT= data set. For variables listed in FORECAST statements where the option MODEL=NONE is not specified, the following variables in the OUTSTAT= data set contain observations related to the statistics of fit:

- _NAME_ variable name
Chapter 14: The ESM Procedure

_REGION_ the region in which the statistics are calculated. Statistics calculated in the fit region are indicated by FIT. Statistics calculated in the forecast region, which happens only if the BACK= option is greater than zero, are indicated by FORECAST.

DFE degrees of freedom error
N number of observations
NOBS number of observations used
NMISSA number of missing actuals
NMISSP number of missing predicted values
NPARMS number of parameters
TSS total sum of squares
SST corrected total sum of squares
SSE sum of square error
MSE mean square error
UMSE unbiased mean square error
RMSE root mean square error
URMSE unbiased root mean square error
MAPE mean absolute percent error
MAE mean absolute error
MASE mean absolute scaled error
RSQUARE R square
ADJRSQ adjusted R square
AADJRSQ Amemiya’s adjusted R square
RWRQS random walk R square
AIC Akaike information criterion
AICC finite sample corrected AIC
SBC Schwarz Bayesian information criterion
APC Amemiya’s prediction criterion
MAXERR maximum error
MINERR minimum error
MINPE minimum percent error
MAXPE maximum percent error
ME mean error
MPE mean percent error
MDAPE median absolute percent error
GMAPE geometric mean absolute percent error
MINPPE  minimum predictive percent error  
MAXPPE  maximum predictive percent error  
MSPE    mean predictive percent error  
MAPPE   symmetric mean absolute predictive percent error  
GMAPPE  geometric mean absolute predictive percent error  
MINSPE  minimum symmetric percent error  
MAXSPE  maximum symmetric percent error  
MSPE    mean symmetric percent error  
SMAPE   symmetric mean absolute percent error  
MDASPE  median absolute symmetric percent error  
GMASPE  geometric mean absolute symmetric percent error  
MINRE   minimum relative error  
MAXRE   maximum relative error  
MRE     mean relative error  
MRAE    mean relative absolute error  
MDRAE   median relative absolute error  
GMRAE   geometric mean relative absolute error  
MINAPES minimum absolute error percent of standard deviation  
MAXAPES maximum absolute error percent of standard deviation  
MAPES   mean absolute error percent of standard deviation  
MDAPES  median absolute error percent of standard deviation  
GMAPES  geometric mean absolute error percent of standard deviation  

If the statistics of fit cannot be computed for a particular variable, no observations are recorded in the OUTSTAT= data set for that variable. If the TRANSFORM= option is specified, the values in the preceding variables are computed based on the inverse transform forecasts. If the MEDIAN option is specified, the median forecasts are the basis; otherwise, the mean forecasts are the basis.

OUTSUM= Data Set

The OUTSUM= data set contains the variables specified in the BY statement as well as the variables listed below. The OUTSUM= data set records the summary statistics for each variable specified in a FORECAST statement. For variables listed in FORECAST statements where the option MODEL=NONE is specified, the values related to forecasts are set to missing for those variables in the OUTSUM= data set. For variables listed in FORECAST statements where the option MODEL=NONE is not specified, the forecast values are set based on the USE= option.

The following variables related to summary statistics are based on the ACCUMULATE= and SETMISSING= options:
Chapter 14: The ESM Procedure

_NAME_ variable name
_STATUS_ forecasting status. Nonzero values imply that no forecast was generated for the series.
NOBS number of observations
N number of nonmissing observations
NMISS number of missing observations
MIN minimum value
MAX maximum value
MEAN mean value
STDDEV standard deviation

The following variables related to forecast summation are based on the LEAD= and STARTSUM= options:
PREDICT forecast summation predicted values
STD forecast summation prediction standard errors
LOWER forecast summation lower confidence limits
UPPER forecast summation upper confidence limits

Variance-related computations are computed only when no transformation is specified (TRANSFORM=NONE).
The following variables related to multistep forecast are based on the LEAD= and USE= options:

_LEADn_ multistep forecast (n ranges from one to the value of the LEAD= option). If USE=LOWER, this variable contains the lower confidence limits; if USE=UPPER, this variable contains the upper confidence limits; otherwise, this variable contains the predicted values.

If the forecast step fails for a particular variable, the variables that are related to forecasting are set to missing for that variable. The OUTSUM= data set contains both a summary of the (accumulated) time series and optionally its forecasts for all series.

Printed Output

The ESM procedure optionally produces printed output by using the Output Delivery System (ODS). By default, the procedure produces no printed output. All output is controlled by the PRINT= and PRINTDE- TAILS options in the PROC ESM statement. In general, if a forecasting step that is related to printed output fails, the values of this step are not printed and appropriate error or warning messages are recorded in the log. The printed output is similar to the output data sets.
The printed output produced by the PRINT= option values is described as follows:

SUMMARY prints the summary statistics and forecast summaries similar to the OUT- SUM= data set.
ESTIMATES prints the parameter estimates similar to the OUTEST= data set.
FORECASTS prints the forecasts similar to the OUTFOR= data set.
PERFORMANCE prints the performance statistics.
PERFORMANCESUMMARY prints the performance summary for each BY group.
PERFORMANCEOVERALL prints the performance summary for all BY groups.
STATES prints the backcast, initial, and final smoothed states.
STATISTICS prints the statistics of fit similar to the OUTSTAT= data set.

The PRINTDETAILS option is the opposite of the NOOUTALL option. Specifically, if PRINT=FORECASTS and the PRINTDETAILS options are specified in the PROC ESM statement, the one-step-ahead forecasts through the range of the data are printed in addition to the information related to a specific forecasting model, such as the smoothing states. If the PRINTDETAILS option is not specified, only the multistep forecasts are printed.

**ODS Table Names**

Table 14.3 relates the PRINT= options to ODS tables:

The ODS table “ForecastSummary” is related to all time series within a BY group. The other tables are related to a single series within a BY group.

**ODS Graphics**

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the ESM procedure. To request these graphs you must specify the PLOT= option in the PROC ESM statement.

**ODS Graph Names**

PROC ESM assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 14.4.

Example 14.1: Forecasting of Time Series Data

This example uses retail sales data to illustrate how the ESM procedure can be used to forecast time series data.

The following DATA step creates a data set from data recorded monthly at numerous points of sale. The data set, SALES, contains a variable DATE that represents time and a variable for each sales item. Each value of the DATE variable is recorded in ascending order, and the values of each of the other variables represent a single time series:

```sas
data sales;
    format date date9.;
    input date : date9. shoes socks laces dresses coats shirts ties belts hats blouses;
    datalines;
    01JAN1994 3557 3718 6368.80 575 987 10.8200 15.0000 102.600 12410 15013
    ...
```

The following ESM procedure statements forecast each of the monthly time series:

```sas
proc esm data=sales out=nextyear;
    id date interval=month;
    forecast _numeric_;
run;
```

The preceding statements generate forecasts for every numeric variable in the input data set SALES for the next twelve months and store these forecasts in the output data set NEXTYEAR.

The following statements plot the forecasts:

```sas
title1 "Shoe Department Sales";
proc sgplot data=nextyear;
    series x=date y=shoes / markers
        markerattrs=(symbol=circlefilled color=red)
        lineattrs=(color=red);
    series x=date y=socks / markers
        markerattrs=(symbol=asterisk color=blue)
        lineattrs=(color=blue);
    series x=date y=laces / markers
        markerattrs=(symbol=circle color=styg)
        lineattrs=(color=styg);
    reline '01JAN1999'd / axis=x;
    xaxis values=('01JAN1994'd to '01DEC2000'd by year);
    yaxis values=(2000 to 10000 by 1000) minor label='Websites';
run;
```

The plots are shown in Output 14.1.1. The historical data is shown to the left of the reference line and the forecasts for the next twelve monthly periods is shown to the right.
The default simple exponential smoothing model is used because the MODEL= option is omitted on the FORECAST statement. Note that for simple exponential smoothing the forecasts are constant.

The following ESM procedure statements are identical to the preceding statements except that the PRINT=FORECASTS option is specified:

```
proc esm data=sales out=nextyear print=forecasts;
  id date interval=month;
  forecast _numeric_;  
run;
```

In addition to forecasting each of the monthly time series, the preceding statements print the forecasts by using the Output Delivery System (ODS); the forecasts are partially shown in Output 14.1.2. This output shows the predictions, prediction standard errors, and the upper and lower confidence limits for the next twelve monthly periods.
Example 14.2: Forecasting of Transactional Data

This example illustrates how the ESM procedure can be used to forecast transactional data. The following DATA step creates a data set from data recorded at several Internet Web sites. The data set WEBSITES contains a variable TIME that represents time and the variables ENGINE, BOATS, CARS, and PLANES that represent Internet Web site data. Each value of the TIME variable is recorded in ascending order, and the values of each of the other variables represent a transactional data series.

The following ESM procedure statements forecast each of the transactional data series:

```latex
proc esm data=websites out=nextweek lead=7;
  id time interval=dtday accumulate=total;
  forecast boats cars planes;
run;
```

The preceding statements accumulate the data into a daily time series, generate forecasts for the BOATS, CARS, and PLANES variables in the input data set WEBSITES for the next week, and the forecasts are stored in the OUT= data set NEXTWEEK.
The following statements plot the forecasts related to the Internet data:

```sas
proc sgplot data=nextweek;
    series x=time y=boats / markers
        markerattrs=(symbol=circlefilled color=red)
        lineattrs=(color=red);
    series x=time y=cars / markers
        markerattrs=(symbol=asterisk color=blue)
        lineattrs=(color=blue);
    series x=time y=planes / markers
        markerattrs=(symbol=circle color=styg)
        lineattrs=(color=styg);
    refline '11APR2000:00:00:00'dt / axis=x;
    xaxis values=('13MAR2000:00:00:00'dt to '18APR2000:00:00:00'dt by dtweek);
    yaxis label='Websites' minor;
run;
```

The plots are shown in Output 14.2.1. The historical data is shown to the left of the reference line and the forecasts for the next seven days are shown to the right.

**Output 14.2.1** Internet Data Forecast Plots
Example 14.3: Specifying the Forecasting Model

This example illustrates how the ESM procedure can be used to specify different models for different series. Internet data from the previous example are used for this illustration.

This example, forecasts the BOATS variable by using the seasonal exponential smoothing model (SEASONAL), the CARS variable by using the Winters (multiplicative) model (MULTWINTERS), and the PLANES variable by using the Log Winters (additive) model. The following ESM procedure statements forecast each of the transactional data series based on these requirements:

```plaintext
proc esm data=websites out=nextweek lead=7;
    id time interval=dtday accumulate=total;
    forecast boats / model=seasonal;
    forecast cars / model=multwinters;
    forecast planes / model=addwinters transform=log;
run;
```

Example 14.4: Extending the Independent Variables for Multivariate Forecasts

In the previous example, the ESM procedure was used to forecast several transactional series variables by using univariate models. This example illustrates how the ESM procedure can be used to extend the independent variables that are associated with a multiple regression forecasting problem.

This example accumulates and forecasts the BOATS, CARS, and PLANES variables that were illustrated in the previous example. In addition, this example accumulates the ENGINES variable to form a time series that is then extended with missing values within the forecast horizon with the specification of MODEL=NONE.

```plaintext
proc esm data=websites out=nextweek lead=7;
    id time interval=dtday accumulate=total;
    forecast engines / model=none;
    forecast boats / model=seasonal;
    forecast cars / model=multwinters;
    forecast planes / model=addwinters transform=log;
run;
```

The following AUTOREG procedure statements are used to forecast the ENGINES variable by regressing on the independent variables (BOATS, CARS, and PLANES).

```plaintext
proc autoreg data= nextweek;
    model engines = boats cars planes / noprint;
    output out=enginehits p=predicted;
run;
```
The NEXTWEEK data set created by PROC ESM is used as an input data set to PROC AUTOREG. The output data set from PROC AUTOREG contains the forecast of the variable ENGINES based on the regression model with the variables BOATS, CARS, and PLANES as regressors. See Chapter 8, “The AUTOREG Procedure,” for details about autoregression models.

The following statements plot the forecasts related to the ENGINES variable:

```plaintext
title1 "Website Data";
proc sgplot data=enginehits;
    series x=time y=boats / markers
        markerattrs=(symbol=circlefilled color=red) lineattrs=(color=red);
    series x=time y=cars / markers
        markerattrs=(symbol=asterisk color=blue) lineattrs=(color=blue);
    series x=time y=planes / markers
        markerattrs=(symbol=circle color=styg) lineattrs=(color=styg);
    scatter x=time y=predicted / markerattrs=(symbol=plus color=black);
    reline '11APR2000:00:00:00'dt / axis=x;
    xaxis values=('13MAR2000:00:00:00'dt to '18APR2000:00:00:00'dt by dtweek);
    yaxis label='Websites' minor;
run;
```

The plots are shown in Output 14.4.1. The historical data is shown to the left of the reference line and the forecasts for the next seven daily periods are shown to the right.
Example 14.5: Illustration of ODS Graphics

This example illustrates the use of ODS graphics in the ESM procedure and uses the SASHELP.AIR data set to forecast the time series of international airline travel.

The graphical displays are requested by specifying the PLOT= option in the PROC ESM statement. In this case, all plots are requested. Output 14.5.1 through Output 14.5.5 show a selection of the plots created.

For information about the graphics available in the ESM procedure, see the section “ODS Graphics” on page 813.
proc esm data=sashelp.air out=_null_
    lead=20
    back=20
    print=all
    plot=all;

Overview: EXPAND Procedure

The EXPAND procedure converts time series from one sampling interval or frequency to another and interpolates missing values in time series. A wide array of data transformations is also supported. Using PROC EXPAND, you can collapse time series data from higher frequency intervals to lower frequency intervals, or expand data from lower frequency intervals to higher frequency intervals. For example, quarterly values can be aggregated to produce an annual series, or quarterly estimates can be interpolated from an annual series.

Time series frequency conversion is useful when you need to combine series with different sampling intervals into a single data set. For example, if you need as input to a monthly model a series that is only available quarterly, you might use PROC EXPAND to interpolate the needed monthly values.

You can also interpolate missing values in time series, either without changing series frequency or in conjunction with expanding or collapsing the series.

You can convert between any combination of input and output frequencies that can be specified by SAS time interval names. (See Chapter 4, “Date Intervals, Formats, and Functions,” for a complete description of SAS interval names.) When the FROM= and TO= options are used to specify from and to intervals, PROC EXPAND automatically accounts for calendar effects such as the differing number of days in each month and leap years.

The EXPAND procedure also handles conversions of frequencies that cannot be defined by standard interval names. Using the FACTOR= option, you can interpolate any number of output observations for each group of a specified number of input observations. For example, if you specify the option FACTOR=(13:2), 13 equally spaced output observations are interpolated from each pair of input observations.

You can also convert aperiodic series, observed at arbitrary points in time, into periodic estimates. For example, a series of randomly timed quality control spot-check results might be interpolated to form estimates of monthly average defect rates.

The EXPAND procedure can also change the observation characteristics of time series. Time series observations can measure beginning-of-period values, end-of-period values, midpoint values, or period averages or totals. PROC EXPAND can convert between these cases. You can construct estimates of interval averages from end-of-period values of a variable, estimate beginning-of-period or midpoint values from interval averages, or compute averages from interval totals, and so forth.

By default, the EXPAND procedure fits cubic spline curves to the nonmissing values of variables to form continuous-time approximations of the input series. Output series are then generated from the spline approximations. Several alternate conversion methods are described in the section “Conversion Methods” on page 846. You can also interpolate estimates of the rate of change of time series by differentiating the interpolating spline curve.

Various transformations can be applied to the input series prior to interpolation and to the interpolated output series. For example, the interpolation process can be modified by transforming the input series, interpolating the transformed series, and applying the inverse of the input transformation to the output series. PROC EXPAND can also be used to apply transformations to time series without interpolation or frequency conversion.

The results of the EXPAND procedure are stored in a SAS data set. No printed output is produced.
Converting to Higher Frequency Series

To create higher frequency estimates, specify the input and output intervals with the FROM= and TO= options, and list the variables to be converted in a CONVERT statement. For example, suppose variables X, Y, and Z in the data set ANNUAL are annual time series, and you want monthly estimates. You can interpolate monthly estimates by using the following statements:

```plaintext
proc expand data=annual out=monthly from=year to=month;
   convert x y z;
run;
```

Note that interpolating values of a time series does not add any real information to the data as the interpolation process is not the same process that generated the other (nonmissing) values in the series. While time series interpolation can sometimes be useful, great care is needed in analyzing time series containing interpolated values.

Aggregating to Lower Frequency Series

PROC EXPAND provides two ways to convert from a higher frequency to a lower frequency. When a curve fitting method is used, converting to a lower frequency is no different than converting to a higher frequency—you just specify the desired output frequency with the TO= option. This provides for interpolation of missing values and allows conversion from non-nested intervals, such as converting from weekly to monthly values.

Alternatively, you can specify simple aggregation or selection without interpolation of missing values. This might be useful, for example, if you want to add up monthly values to produce annual totals, but want the annual output data set to contain values only for complete years.

To perform simple aggregation, use the METHOD=AGGREGATE option in the CONVERT statement. For example, the following statements aggregate monthly values to yearly values:

```plaintext
proc expand data=monthly out=annual
   from=month to=year;
   convert x y z / method=aggregate;
   convert a b c / method=aggregate observed=total;
   id date;
run;
```

This example assumes that the variables X, Y, and Z represent point-in-time values observed at the beginning of each month, and that the desired results are point-in-time values observed at the beginning of each year. (The default value of the OBSERVED= option is OBSERVED=(BEGINNING,BEGINNING).) The variables A, B, and C are assumed to represent monthly totals, and that the desired results are annual totals; therefor the option OBSERVED=TOTAL is specified. See the section “Specifying Observation Characteristics” on page 832 for more information on the OBSERVED= option.
Note that the AGGREGATE method can be used only if the input intervals are nested within the output intervals, as when converting from daily to monthly or from monthly to yearly frequency.

**Combining Time Series with Different Frequencies**

One important use of PROC EXPAND is to combine time series measured at different sampling frequencies. For example, suppose you have data on monthly money stocks (M1), quarterly gross domestic product (GDP), and weekly interest rates (INTEREST), and you want to perform an analysis of a model that uses all these variables. To perform the analysis, you first need to convert the series to a common frequency and then combine the variables into one data set.

The following statements illustrate this process for the three data sets QUARTER, MONTHLY, and WEEKLY. The data sets QUARTER and WEEKLY are converted to monthly frequency using two PROC EXPAND steps, and the three data sets are then merged using a DATA step MERGE statement to produce the data set COMBINED. The quarterly GDP data are interpolated as the total GDP over each month (OBSERVED=TOTAL) while the weekly INTEREST data are converted to average rates over each month (OBSERVED=AVERAGE).

```plaintext
proc expand data=quarter out=temp1
   from=qtr to=month;
   id date;
   convert gdp / observed=total;
run;
proc expand data=weekly out=temp2
   from=week to=month;
   id date;
   convert interest / observed=average;
run;
data combined;
   merge monthly temp1 temp2;
   by date;
run;
```

See Chapter 3, “Working with Time Series Data,” for further discussion of time series periodicity, time series dating, and time series interpolation. See the section “Specifying Observation Characteristics” on page 832 for more information on the OBSERVED= option.

**Interpolating Missing Values**

To interpolate missing values in time series without converting the observation frequency, leave off the TO= option on the PROC EXPAND statement. For example, the following statements interpolate any missing values in the time series in the data set ANNUAL.

```plaintext
proc expand data=annual out=new from=year;
   id date;
   convert x y z;
   convert a b c / observed=total;
run;
```
This example assumes that the variables X, Y, and Z represent point-in-time values observed at the beginning of each year. (The default value of the OBSERVED= option is OBSERVED=BEGINNING.) The variables A, B, and C are assumed to represent annual totals.

To interpolate missing values in variables observed at specific points in time, omit both the FROM= and TO= options and use the ID statement to supply time values for the observations. The observations do not need to be periodic or form regular time series, but the data set must be sorted by the ID variable. For example, the following statements interpolate any missing values in the numeric variables in the data set A.

```sas
proc expand data=a out=b;
    id date;
run;
```

If the observations are equally spaced in time, and all the series are observed as beginning-of-period values, only the input and output data sets need to be specified. For example, the following statements interpolate any missing values in the numeric variables in the data set A using a cubic spline function, assuming that the observations are at equally spaced points in time.

```sas
proc expand data=a out=b;
run;
```

Refer to the section “Missing Values” on page 854 for further information.

---

**Requesting Different Interpolation Methods**

By default, a cubic spline curve is fit to the input series, and the output is computed from this interpolating curve. Other interpolation methods can be specified with the METHOD= option on the CONVERT statement. The section “Conversion Methods” on page 846 explains the available methods.

For example, the following statements convert annual series to monthly series using linear interpolation instead of cubic spline interpolation.

```sas
proc expand data=annual out=monthly from=year to=month;
    id date;
    convert x y z / method=join;
run;
```

---

**Using the ID Statement**

An ID statement is normally used with PROC EXAND to specify a SAS date or datetime variable to identify the time of each input observation. An ID variable allows PROC EXPAND to do the following:

- identify the observations in the output data set
- determine the time span between observations and detect gaps in the input series caused by omitted observations
• account for calendar effects such as the number of days in each month and leap years

If you do not specify an ID variable with SAS date or datetime values, PROC EXPAND makes default assumptions that may not be what you want. See the section “ID Statement” on page 840 for details.

Specifying Observation Characteristics

It is important to distinguish between variables that are measured at points in time and variables that represent totals or averages over an interval. Point-in-time values are often called stocks or levels. Variables that represent totals or averages over an interval are often called flows or rates.

For example, the annual series U.S. Gross Domestic Product represents the total value of production over the year and also the yearly average rate of production in dollars per year. However, a monthly variable inventory may represent the cost of a stock of goods as of the end of the month.

When the data represent periodic totals or averages, the process of interpolation to a higher frequency is sometimes called distribution, and the total values of the larger intervals are said to be distributed to the smaller intervals. The process of interpolating periodic total or average values to lower frequency estimates is sometimes called aggregation.

By default, PROC EXPAND assumes that all time series represent beginning-of-period point-in-time values. If a series does not measure beginning of period point-in-time values, interpolation of the data values using this assumption is not appropriate, and you should specify the correct observation characteristics of the series. The observation characteristics of the series are specified with the OBSERVED= option on the CONVERT statement.

For example, suppose that the data set ANNUAL contains variables A, B, and C that measure yearly totals, while the variables X, Y, and Z measure first-of-year values. The following statements estimate the contribution of each month to the annual totals in A, B, and C, and interpolate first-of-month estimates of X, Y, and Z.

```
proc expand data=annual out=monthly
  from=year to=month;
  id date;
  convert x y z;
  convert a b c / observed=total;
run;
```

The EXPAND procedure supports five different observation characteristics. The OBSERVED= options for these five observation characteristics are:

- BEGINNING: beginning-of-period values
- MIDDLE: period midpoint values
- END: end-of-period values
- TOTAL: period totals
- AVERAGE: period averages
The interpolation of each series is adjusted appropriately for its observation characteristics. When OBSERVED=TOTAL or AVERAGE is specified, the interpolating curve is fit to the data values so that the area under the curve within each input interval equals the value of the series. For OBSERVED=MIDDLE or END, the curve is fit through the data points, with the time position of each data value placed at the specified offset from the start of the interval.

See the section “OBSERVED= Option” on page 844 for details.

Converting Observation Characteristics

The EXPAND procedure can be used to interpolate values for output series with different observation characteristics than the input series. To change observation characteristics, specify two values in the OBSERVED= option. The first value specifies the observation characteristics of the input series; the second value specifies the observation characteristics of the output series.

For example, the following statements convert the period total variable A in the data set ANNUAL to yearly midpoint estimates. This example does not change the series frequency, and the other variables in the data set are copied to the output data set unchanged.

```
proc expand data=annual out=new from=year;
  id date;
  convert a / observed=(total,middle);
run;
```

Creating New Variables

You can use the CONVERT statement to name a new variable to contain the results of the conversion. Using this feature, you can create several different versions of a series in a single PROC EXPAND step. Specify the new name after the input variable name and an equal sign:

```
convert variable=newname ...;
```

For example, suppose you are converting quarterly data to monthly and you want both first-of-month and midmonth estimates for a beginning-of-period variable X. The following statements perform this task:
Chapter 15: The EXPAND Procedure

Transforming Series

The interpolation methods used by PROC EXPAND assume that there are no restrictions on the range of values that series can have. This assumption can sometimes cause problems if the series must be within a certain range.

For example, suppose you are converting monthly sales figures to weekly estimates. Sales estimates should never be less than zero, but since the spline curve ignores this restriction some interpolated values may be negative. One way to deal with this problem is to transform the input series before fitting the interpolating spline and then reverse transform the output series.

You can apply various transformations to the input series using the TRANSFORMIN= option on the CONVERT statement. (The TRANSFORMIN= option can be abbreviated as TRANSFORM= or TIN=.) You can apply transformations to the output series using the TRANSFORMOUT= option. (The TRANSFORMOUT= option can be abbreviated as TOUT=.)

For example, you might use a logarithmic transformation of the input sales series and exponentiate the interpolated output series. The following statements fit a spline curve to the log of SALES and then exponentiate the output series.

```
proc expand data=a out=b from=month to=week;
  id date;
  convert sales / observed=total
    transformin=(log)
    transformout=(exp);
run;
```

Note that the transformations specified by the TRANSFORMIN= option are applied before the data are interpolated; the cubic spline curve or other interpolation method is fitted to transformed input data. The transformations specified by the TRANSFORMOUT= option are applied to interpolated values computed from the curves fit to the transformed input data.

As another example, suppose you are interpolating missing values in a series of market share estimates. Market shares must be between 0% and 100%, but applying a spline interpolation to the raw series can produce estimates outside of this range.

The following statements use the logistic transformation to transform proportions in the range 0 to 1 to values in the range $-\infty$ to $+\infty$. The TIN= option first divides the market shares by 100 to rescale percent values to proportions and then applies the LOGIT function. The TOUT= option applies the inverse logistic function ILOGIT to the interpolated values to convert back to proportions and then multiplies by 100 to rescale back to percentages.

```
proc expand data=a out=b from=month to=week;
  id date;
  convert sales / observed=total
    transformin=(log)
    transformout=(exp);
run;
```
proc expand data=a out=b;
  id date;
  convert mshare / tin=( / 100 logit )
          tout=( ilogit * 100 );
run;

When more than one transformation is specified in the TRANSFORMIN= or TRANSFORMOUT= option, the transformations are applied in the order in which they are listed. Thus in the above example the complete input transformation is \text{logit}(mshare/100) \text{ (and not logit}(mshare)/100) because the division operation is listed first in the TIN= option.

You can also use the TRANSFORM= (or TRANSFORMOUT=) option as a convenient way to do calculations normally performed with the SAS DATA step. For example, the following statements add the lead of X to the data set A. The METHOD=NONE option is used to suppress interpolation.

proc expand data=a method=none;
  id date;
  convert x=xlead / transform=(lead);
run;

Any number of operations can be listed in the TRANSFORMIN= and TRANSFORMOUT= options. See Table 15.2 for a list of the operations supported.

Syntax: EXPAND Procedure

The EXPAND procedure uses the following statements:

\text{PROC EXPAND} \ text{options ;}
  \text{BY} \ text{variables ;}
  \text{CONVERT} \ text{variables / options ;}
  \text{ID} \ text{variable ;}

Functional Summary

The statements and options controlling the EXPAND procedure are summarized in the following table.

**PROC EXPAND Statement**

```plaintext
PROC EXPAND options;
```

The following options can be used with the PROC EXPAND statement:

**Data Set Options**

- **DATA= SAS-data-set**
  names the input data set. If the DATA= option is omitted, the most recently created SAS data set is used.

- **OUT= SAS-data-set**
  names the output data set containing the resulting time series. If OUT= is not specified, the data set is named using the DATAn convention. See the section “OUT= Data Set” on page 862 for details.

- **OUTEST= SAS-data-set**
  names an output data set containing the coefficients of the spline curves fit to the input series. If the OUTEST= option is not specified, the spline coefficients are not output. See the section “OUTEST= Data Set” on page 863 for details.
Options That Define Input and Output Frequencies

**ALIGN= option**
controls the alignment of SAS dates used to identify output observations. The ALIGN= option allows the following values: BEGINNING | BEG | B, MIDDLE | MID | M, and ENDING | END | E. BEGINNING is the default.

**FACTOR= n**

**FACTOR=( n : m )**
specifies the number of output observations to be created from the input observations. FACTOR=specifies that output observations are to be produced for each input observation. FACTOR=( n : m ) specifies that output observations are to be produced for each group of m input observations. FACTOR=n is the same as FACTOR=(n : 1).

In the FACTOR=() option, a comma can be used instead of a colon or the delimiter can be omitted. Thus FACTOR=( n , m ) or FACTOR=( n m ) is the same as FACTOR=( n : m ).

The FACTOR= option cannot be used if the TO= option is used. The default value is FACTOR=(1:1). For more information, see the section “Frequency Conversion” on page 841.

**FROM= interval**
specifies the time interval between observations in the input data set. Examples of FROM= values are YEAR, QTR, MONTH, DAY, and HOUR. See Chapter 4, “Date Intervals, Formats, and Functions,” for a complete description and examples of interval specifications.

**TO= interval**
specifies the time interval between observations in the output data set. By default, the TO= interval is generated from the combination of the FROM= and the FACTOR= values or is set to be the same as the FROM= value if FACTOR= is not specified. See Chapter 4, “Date Intervals, Formats, and Functions,” for a description of interval specifications.

Options to Control the Interpolation

**EXTRAPOLATE**
specifies that missing values at the beginning or end of input series be replaced with values produced by a linear extrapolation of the interpolating curve fit to the input series. See the section “Extrapolation” on page 843 later in this chapter for details.

By default, PROC EXPAND avoids extrapolating values beyond the first or last input value for a series and only interpolates values within the range of the nonmissing input values. Note that the extrapolated values are often not very accurate and for the SPLINE method the EXTRAPOLATE option results may be very unreasonable. The EXTRAPOLATE option is rarely used.

**METHOD= option**

**METHOD=SPLINE( constraint < , constraint > )**
specifies the method used to convert the data series. The methods supported are SPLINE, JOIN, STEP, AGGREGATE, and NONE. The METHOD= option specified on the PROC EXPAND statement can be overridden for particular series by the METHOD= option on the CONVERT statement. The default is METHOD=SPLINE. The constraint specifications for METHOD=SPLINE can have the values NOTAKNOT (the default), NATURAL, SLOPE=value, and/or CURVATURE=value. See the section “Conversion Methods” on page 846 for more information about these methods.
OBSERVED= value
OBSERVED=( from-value , to-value )

indicates the observation characteristics of the input time series and of the output series. Specifying the OBSERVED= option on the PROC EXPAND statement sets the default OBSERVED= value for subsequent CONVERT statements. See the sections “CONVERT Statement” on page 839 and “OBSERVED= Option” on page 844 later in this chapter for details. The default is OBSERVED=BEGINNING.

Options to Control Graphical Output

PLOTS= option | ( options )

specifies the graphical output desired. If the PLOTS= option is used, the specified graphical output is produced for each output variable that is specified by a CONVERT statement. By default, the EXPAND procedure produces no graphical output. The following PLOTS= options are available:

INPUT plots the input series.
TRANSFORMIN plots the transformed input series. The TRANSFORMIN= option must also be specified in the CONVERT statement.
CROSSINPUT plots both the input series and the transformed input series on one plot with two Y axes. The input and transformed series are shown on separate scales. The TRANSFORMIN= option must also be specified in the CONVERT statement.
JOINTINPUT plots both the input series and the transformed input series on one plot with one Y axis. The input and transformed series are shown on the same scale. The TRANSFORMIN= option must also be specified in the CONVERT statement.
CONVERTED plots the converted series after input transformations and interpolation, but before any TRANSFORMOUT= transformations are applied. The METHOD= option must also be specified in the PROC EXPAND or CONVERT statements.
TRANSFORMOUT plots the transformed output series. The TRANSFORMOUT= option must also be specified in the CONVERT statement.
CROSSOUTPUT plots both the converted series and the transformed output series on one plot with two Y axes. The converted and transformed output series are shown on separate scales. The TRANSFORMOUT= option must also be specified in the CONVERT statement.
JOINTOUTPUT plots both the converted series and the transformed output series on one plot with one Y axis. The converted and transformed output series are shown on the same scale. The TRANSFORMOUT= option must also be specified in the CONVERT statement.
OUTPUT plots the series stored in the OUT= data set. The OUTPUT option does not require any options to be specified in the CONVERT statement.
ALL produces all plots except the joint and cross plots. PLOTS=ALL is the same as PLOTS=(INPUT TRANFORMIN CONVERTED TRANSFORMOUT).

The PLOTS= option produces results associated with each CONVERT statement output variable and the options listed in the PLOTS= specification. See the section “PLOTS= Option Details” on page 864 for more information.
BY Statement

`BY variables ;`

A BY statement can be used with PROC EXPAND to obtain separate analyses on observations in groups defined by the BY variables. The input data set must be sorted by the BY variables and be sorted by the ID variable within each BY group.

Use a BY statement when you want to interpolate or convert time series within levels of a cross-sectional variable. For example, suppose you have a data set STATE containing annual estimates of average disposable personal income per capita (DPI) by state and you want quarterly estimates by state. These statements convert the DPI series within each state:

```plaintext
proc sort data=state;
   by state date;
run;

proc expand data=state out=stateqtr from=year to=qtr;
   convert dpi;
   by state;
   id date;
run;
```

CONVERT Statement

`CONVERT variable = newname ...< / options > ;`

The CONVERT statement lists the variables to be processed. Only numeric variables can be processed.

For each of the variables listed, a new variable name can be specified after an equal sign to name the variable in the output data set that contains the converted values. If a name for the output series is not given, the variable in the output data set has the same name as the input variable. Variable lists may be used only when no name is given for the output series.

For example, variable lists can be specified as follows:

```plaintext
convert y1-y25 / observed=(beginning,end);
convert x--a / observed=average;
convert x-numeric-a / observed=average;
```

Any number of CONVERT statements can be used. If no CONVERT statement is used, all the numeric variables in the input data set except those appearing in the BY and ID statements are processed.

The following options can be used with the CONVERT statement.
Chapter 15: The EXPAND Procedure

METHOD= option

METHOD=SPLINE( constraint < , constraint > )
specifies the method used to convert the data series. (The method specified by the METHOD= option is applied to the input data series after applying any transformations specified by the TRANSFORMIN= option.) The methods supported are SPLINE, JOIN, STEP, AGGREGATE, and NONE. The METHOD= option specified on the PROC EXPAND statement can be overridden for particular series by the METHOD= option on the CONVERT statement. The default is METHOD=SPLINE. The constraint specifications for METHOD=SPLINE can have the values NOTAKNOT (the default), NATURAL, SLOPE=value, and/or CURVATURE=value. See the section “Conversion Methods” on page 846 section for more information about these methods.

OBSERVED= value

OBSERVED=( from-value , to-value )
indicates the observation characteristics of the input time series and of the output series. The values supported are TOTAL, AVERAGE, BEGINNING, MIDDLE, and END. In addition, DERIVATIVE can be specified as the to-value when the SPLINE method is used.

When only one value is specified, that value specifies both the from-value and the to-value. (That is, OBSERVED=value is equivalent to OBSERVED=(value, value).) If the OBSERVED= option is omitted from both the PROC EXPAND and the CONVERT statements, the default is OBSERVED=(BEGINNING, BEGINNING). See the section “OBSERVED= Option” on page 844 for details.

TRANSFORMIN=( operation . . . )
specifies a list of transformations to be applied to the input series before the interpolating function is fit. The operations are applied in the order listed. See the section “Transformation Operations” on page 848 later in this chapter for the operations that can be specified. The TRANSFORMIN= option can be abbreviated as TRANSIN=, TIN=, or TRANSFORM=.

TRANSFORMOUT=( operation . . . )
specifies a list of transformations to be applied to the output series. The operations are applied in the order listed. See the section “Transformation Operations” on page 848 later in this chapter for the operations that can be specified. The TRANSFORMOUT= option can be abbreviated as TRANSOUT=, or TOUT=.

ID Statement

ID variable ;
The ID statement names a numeric variable that identifies observations in the input and output data sets. The ID variable’s values are assumed to be SAS date or datetime values.

The input data must form time series. This means that the observations in the input data set must be sorted by the ID variable (within the BY variables, if any). Moreover, there should be no duplicate observations, and no two observations should have ID values within the same time interval as defined by the FROM= option.

If the ID statement is omitted, SAS date or datetime values are generated to label the input observations. These ID values are generated by assuming that the input data set starts at a SAS date value of 0, that is, 1 January 1960. This default starting date is then incremented for each observation by the FROM= interval.
(using the same logic as DATA step INTNX function). If the FROM= option is not specified, the ID values are generated as the observation count minus 1. When the ID statement is not used, an ID variable is added to the output data set named either DATE or DATETIME, depending on the value specified in the TO= option. If neither the TO= option nor the FROM= option is given, the ID variable in the output data set is named TIME.

**Details: EXPAND Procedure**

**Frequency Conversion**

Frequency conversion is controlled by the FROM=, TO=, and FACTOR= options. The possible combinations of these options are explained in the following:

**None Used**

If FROM=, TO=, and FACTOR= are not specified, no frequency conversion is done. The data are processed to interpolate any missing values and perform any specified transformations. Each input observation produces one output observation.

**FACTOR=(n:m)**

FACTOR=(n:m) specifies that n output observations are produced for each group of m input observations. The fraction \( \frac{m}{n} \) is reduced first: thus FACTOR=(10:6) is equivalent to FACTOR=(5:3). Note that if \( \frac{m}{n} = 1 \), the result is the same as the case given previously under “None Used”.

**FROM=interval**

The FROM= option used alone establishes the frequency and interval widths of the input observations. Missing values are interpolated, and any specified transformations are performed, but no frequency conversion is done.

**TO=interval**

When the TO= option is used without the FROM= option, output observations with the TO= frequency are generated over the range of input ID values. The first output observation is for the TO= interval containing the ID value of the first input observation; the last output observation is for the TO= interval containing the ID value of the last input observation. The input observations are not assumed to form regular time series and may represent aperiodic points in time. An ID variable is required to give the date or datetime of the input observations.

**FROM=interval TO=interval**

When both the FROM= and TO= options are used, the input observations have the frequency given by the FROM= interval, and the output observations have the frequency given by the TO= interval.

**FROM=interval FACTOR=(n:m)**

When both the FROM= and FACTOR= options are used, a TO= interval is inferred from the combination of the FROM= interval and the FACTOR=(n:m) values specified. For example, FROM=YEAR FACTOR=4 is the same as FROM=YEAR TO=QTR. Also, FROM=YEAR FACTOR=(3:2) is the same as FROM=YEAR used with TO=MONTH.8. Once the implied TO= interval is determined, this combination operates the same as if FROM= and TO= had been specified. If no valid TO= interval can be constructed from the combination of the FROM= and FACTOR= options, an error is produced.
**TO=interval FACTOR=(n:m)**

The combination of the TO= option and the FACTOR= option is not allowed and produces an error.

**ALIGN= option**

Controls the alignment of SAS dates used to identify output observations. The ALIGN= option allows the following values: BEGINNING | BEG | B, MIDDLE | MID | M, and ENDING | END | E. BEGINNING is the default.

**Converting to a Lower Frequency**

When converting to a lower frequency, the results are either exact or approximate, depending on whether or not the input interval nests within the output interval and depending on the need to interpolate missing values within the series. If the TO= interval is nested within the FROM= interval (as when converting from monthly to yearly), and if there are no missing input values or partial periods, the results are exact.

When values are missing or the FROM= interval is not nested within the TO= interval (as when aggregating from weekly to monthly), the results depend on an interpolation. The METHOD=AGGREGATE option always produces exact results, never an interpolation. However, this method can only be used if the FROM= interval is nested within the TO= interval.

**Identifying Observations**

The variable specified in the ID statement is used to identify the observations. Usually, SAS date or datetime values are used for this variable. PROC EXPAND uses the ID variable to do the following:

- identify the time interval of the input values
- validate the input data set observations
- compute the ID values for the observations in the output data set

**Identifying the Input Time Intervals**

When the FROM= option is specified, observations are understood to refer to the whole time interval and not to a single time point. The ID values are interpreted as identifying the FROM= time interval containing the value. In addition, the widths of these input intervals are used by the OBSERVED= values TOTAL, AVERAGE, MIDDLE, and END.

For example, if FROM=MONTH is specified, then each observation is for the whole calendar month containing the ID value for the observation, and the width of the time interval covered by the observation is the number of days in that month. Therefore, if FROM=MONTH, the ID value ’31MAR92’D is equivalent to the ID value ’1MAR92’D–both of these ID values identify the same interval, March of 1992.

**Widths of Input Time Intervals**

When the FROM= option is not specified, the ID variable values are usually interpreted as referring to points in time. However, if an OBSERVED= option value is specified that assumes the observations refer to whole intervals and also requires interval widths (TOTAL or AVERAGE), then, in the absence of the FROM=
specification, interval widths are assumed to be the time span between ID values. For the last observation, the interval width is assumed to be the same as for the next to last observation. (If neither the FROM= option nor the ID statement are specified, interval widths are assumed to be 1.0.) A note is printed in the SAS log warning that this assumption is made.

Validating the Input Data Set Observations

The ID variable is used to verify that successive observations read from the input data set correspond to sequential FROM= intervals. When the FROM= option is not used, PROC EXPAND verifies that the ID values are nonmissing and in ascending order. An error message is produced and the observation is ignored when an invalid ID value is found in the input data set.

ID values for Observations in the Output Data Set

The time unit used for the ID variable in the output data set is controlled by the interval value specified by the TO= option. If you specify a date interval for the TO= value, the ID variable values in the output data set are SAS date values. If you specify a datetime interval for the TO= value, the ID variable values in the output data set are SAS datetime values.

The date or datetime values for the ID variable for output observations is the first date or datetime of the TO= interval, unless the ALIGN= option is used to specify a different alignment. (For example, if TO=WEEK is specified, then the output dates are Sundays. If TO=WEEK.2 is specified, then the output date are Mondays.) See Chapter 4, “Date Intervals, Formats, and Functions,” for more information on interval specifications.

Range of Output Observations

If no frequency conversion is done, the range of output observations is the same as in the input data set.

When frequency conversion is done, the observations in the output data set range from the earliest start of any result series to the latest end of any result series. Observations at the beginning or end of the input range for which all result values are missing are not written to the OUT= data set.

When the EXTRAPOLATE option is not used, the range of the nonmissing output results for each series is as follows. The first result value is for the TO= interval that contains the ID value of the start of the FROM= interval containing the ID value of the first nonmissing input observation for the series. The last result value is for the TO= interval that contains the end of the FROM= interval containing the ID value of the last nonmissing input observation for the series.

When the EXTRAPOLATE option is used, result values for all series are computed for the full time range covered by the input data set.

Extrapolation

The spline functions fit by the EXPAND procedure are very good at approximating continuous curves within the time range of the input data but poor at extrapolating beyond the range of the data. The accuracy of the results produced by PROC EXPAND may be somewhat less at the ends of the output series than at time periods for which there are several input values at both earlier and later times. The curves fit by PROC EXPAND should not be used for forecasting.
Chapter 15: The EXPAND Procedure

PROC EXPAND normally avoids extrapolation of values beyond the time range of the nonmissing input data for a series, unless the EXTRAPOLATE option is used. However, if the start or end of the input series does not correspond to the start or end of an output interval, some output values may depend in part on an extrapolation.

For example, if FROM=YEAR, TO=WEEK, and OBSERVED=BEGINNING are specified, then the first observation output for a series is for the week of 1 January of the first nonmissing input year. If 1 January of that year is not a Sunday, the beginning of this week falls before the date of the first input value, and therefore a beginning-of-period output value for this week is extrapolated.

This extrapolation is made only to the extent needed to complete the terminal output intervals that overlap the endpoints of the input series and is limited to no more than the width of one FROM= interval or one TO= interval, whichever is less. This restriction of the extrapolation to complete terminal output intervals is applied to each series separately, and it takes into account the OBSERVED= option for the input and output series.

When the EXTRAPOLATE option is used, the normal restriction on extrapolation is overridden. Output values are computed for the full time range covered by the input data set.

For the SPLINE method, extrapolation is performed by a linear projection of the trend of the cubic spline curve fit to the input data, not by extrapolation of the first and last cubic segments.

The EXTRAPLOTE option should be used with caution.

OBSERVED= Option

The values of the CONVERT statement OBSERVED= option are as follows:

- BEGINNING indicates that the data are beginning-of-period values. OBSERVED=BEGINNING is the default.
- MIDDLE indicates that the data are period midpoint values.
- ENDING indicates that the data represent end-of-period values.
- TOTAL indicates that the data values represent period totals for the time interval corresponding to the observation.
- AVERAGE indicates that the data values represent period averages.
- DERIVATIVE requests that the output series be the derivatives of the cubic spline curve fit to the input data by the SPLINE method.

If only one value is specified in the OBSERVED= option, that value applies to both the input and the output series. For example, OBSERVED=TOTAL is the same as OBSERVED=(TOTAL,TOTAL), which indicates that the input values represent totals over the time intervals corresponding to the input observations, and the converted output values also represent period totals. The value DERIVATIVE can be used only as the second OBSERVED= option value, and it can be used only when METHOD=SPLINE is specified or is the default method.

Since the TOTAL, AVERAGE, MIDDLE, and END cases require that the width of each input interval be known, both the FROM= option and an ID statement are normally required if one of these observation characteristics is specified for any series. However, if the FROM= option is not specified, each input interval
is assumed to extend from the ID value for the observation to the ID value of the next observation, and the width of the interval for the last observation is assumed to be the same as the width for the next to last observation.

**Scale of OBSERVED= AVERAGE Values**

The average values are assumed to be expressed in the time units defined by the FROM= or TO= option. That is, the product of the average value for an interval and the width of the interval is assumed to equal the total value for the interval. For purposes of interpolation, OBSERVED=AVERAGE values are first converted to OBSERVED=TOTAL values using this assumption, and then the interpolated totals are converted back to averages by dividing by the widths of the output intervals.

For example, suppose the options FROM=MONTH, TO=HOUR, and OBSERVED=AVERAGE are specified. Since FROM=MONTH is specified, each input value is assumed to represent an average rate per day such that the product of the value and the number of days in the month is equal to the total for the month. The input values are assumed to represent a per-day rate because FROM=MONTH implies SAS date ID values that measure time in days, and therefore the widths of MONTH intervals are measured in days. If FROM=DTMONTH is used instead, the values are assumed to represent a per-second rate, because the widths of DTMONTH intervals are measured in seconds.

Since TO=HOUR is specified, the output values are scaled as an average rate per second such that the product of each output value and the number of seconds in an hour (3600) is equal to the interpolated hourly total. A per-second rate is used because TO=HOUR implies SAS datetime ID values that measure time in seconds, and therefore the widths of HOUR intervals are measured in seconds.

Note that the scale assumed for OBSERVED=AVERAGE data is important only when converting between AVERAGE and another OBSERVED= option, or when converting between SAS date and SAS datetime ID values. When both the input and the output series are AVERAGE values, and the units for the ID values are not changed, the scale assumed does not matter.

For example, suppose you are converting gross domestic product (GDP) from quarterly to monthly. The GDP values are quarterly averages measured at annual rates. If you want the interpolated monthly values to also be measured at annual rates, then the option OBSERVED=AVERAGE works fine. Since there is no change of scale involved in this problem, it makes no difference that PROC EXPAND assumes daily rates instead of annual rates.

However, suppose you want to convert GDP from quarterly to monthly and also convert from annual rates to monthly rates, so that the result is total gross domestic product for the month. Using the option OBSERVED=(AVERAGE, TOTAL) would fail, because PROC EXPAND assumes the average is scaled to daily, not annual, rates.

One solution is to rescale to quarterly totals and treat the data as totals. You could use the options TRANSFORMIN=( / 4 ) OBSERVED=TOTAL. Alternatively, you could treat the data as averages but first convert to daily rates. In this case you would use the options TRANSFORMIN=( / 365.25 ) OBSERVED=AVERAGE.

**Results of the OBSERVED= DERIVATIVE Option**

If the first value of the OBSERVED= option is BEGINNING, TOTAL, or AVERAGE, the result is the derivative of the spline curve evaluated at first-of-period ID values for the output observation. For OBSERVED=(MIDDLE, DERIVATIVE), the derivative of the function is evaluated at output interval midpoints. For OBSERVED=(END, DERIVATIVE), the derivative is evaluated at end-of-period ID values.
Conversion Methods

The SPLINE Method

The SPLINE method fits a cubic spline curve to the input values. A cubic spline is a segmented function consisting of third-degree (cubic) polynomial functions joined together so that the whole curve and its first and second derivatives are continuous.

For point-in-time input data, the spline curve is constrained to pass through the given data points. For interval total or average data, the definite integrals of the spline over the input intervals are constrained to equal the given interval totals.

For boundary constraints, the *not-a-knot* condition is used by default. This means that the first two spline pieces are constrained to be part of the same cubic curve, as are the last two pieces. Thus the spline used by PROC EXPAND by default is not the same as the commonly used natural spline, which uses zero second-derivative endpoint constraints. While de Boor (1978) recommends the *not-a-knot* constraint for cubic spline interpolation, using this constraint can sometimes produce anomalous results at the ends of the interpolated series. PROC EXPAND provides options to specify other endpoint constraints for spline curves.

To specify endpoint constraints, use the following form of the METHOD= option.

```
METHOD=SPLINE( constraint < , constraint > )
```

The first constraint specification applies to the lower endpoint, and the second constraint specification applies to the upper endpoint. If only one constraint is specified, it applies to both the lower and upper endpoints.

The *constraint* specifications can have the following values:

- **NOTAKNOT**
  specifies the not-a-knot constraint. This is the default.

- **NATURAL**
  specifies the *natural* spline constraint. The second derivative of the spline curve is constrained to be zero at the endpoint.

- **SLOPE=value**
  specifies the first derivative of the spline curve at the endpoint. The value specified can be any positive or negative number, but extreme values may produce unreasonable results.

- **CURVATURE=value**
  specifies the second derivative of the spline curve at the endpoint. The value specified can be any positive or negative number, but extreme values may produce unreasonable results. Specifying CURVATURE=0 is equivalent to specifying the NATURAL option.

For example, to specify natural spline interpolation, use the following option in the CONVERT or PROC EXPAND statement:

```
method=spline(natural)
```

For OBSERVED=BEGINNING, MIDDLE, and END series, the spline knots are placed at the beginning, middle, and end of each input interval, respectively. For total or averaged series, the spline knots are set at the start of the first interval, at the end of the last interval, and at the interval midpoints, except that there are no knots for the first two and last two midpoints.
Once the cubic spline curve is fit to the data, the spline is extended by adding linear segments at the beginning and end. These linear segments are used for extrapolating values beyond the range of the input data.

For point-in-time output series, the spline function is evaluated at the appropriate points. For interval total or average output series, the spline function is integrated over the output intervals.

**The JOIN Method**

The JOIN method fits a continuous curve to the data by connecting successive straight line segments. For point-in-time data, the JOIN method connects successive nonmissing input values with straight lines. For interval total or average data, interval midpoints are used as the break points, and ordinates are chosen so that the integrals of the piecewise linear curve agree with the input totals.

For point-in-time output series, the JOIN function is evaluated at the appropriate points. For interval total or average output series, the JOIN function is integrated over the output intervals.

**The STEP Method**

The STEP method fits a discontinuous piecewise constant curve. For point-in-time input data, the resulting step function is equal to the most recent input value. For interval total or average data, the step function is equal to the average value for the interval.

For point-in-time output series, the step function is evaluated at the appropriate points. For interval total or average output series, the step function is integrated over the output intervals.

**The AGGREGATE Method**

The AGGREGATE method performs simple aggregation of time series without interpolation of missing values.

If the input data are totals or averages, the results are the sums or averages, respectively, of the input values for observations corresponding to the output observations. That is, if either TOTAL or AVERAGE is specified for the OBSERVED= option, the METHOD=AGGREGATE result is the sum or mean of the input values corresponding to the output observation. For example, suppose METHOD=AGGREGATE, FROM=MONTH, and TO=YEAR are specified. For OBSERVED=TOTAL series, the result for each output year is the sum of the input values over the months of that year. If any input value is missing, the corresponding sum or mean is also a missing value.

If the input data are point-in-time values, the result value of each output observation equals the input value for a selected input observation determined by the OBSERVED= attribute. For example, suppose METHOD=AGGREGATE, FROM=MONTH, and TO=YEAR are specified. For OBSERVED-BEGINNING series, January observations are selected as the annual values. For OBSERVED-MIDDLE series, July observations are selected as the annual values. For OBSERVED-END series, December observations are selected as the annual values. If the selected value is missing, the output annual value is missing.

The AGGREGATE method can be used only when the FROM= intervals are nested within the TO= intervals. For example, you can use METHOD=AGGREGATE when FROM=MONTH and TO=QTR because months are nested within quarters. You cannot use METHOD=AGGREGATE when FROM=WEEK and TO=QTR because weeks are not nested within quarters.
In addition, the AGGREGATE method cannot convert between point-in-time data and interval total or average data. Conversions between TOTAL and AVERAGE data are allowed, but conversions between BEGINNING, MIDDLE, and END are not.

Missing input values produce missing result values for METHOD=AGGREGATE. However, gaps in the sequence of input observations are not allowed. For example, if FROM=MONTH, you may have a missing value for a variable in an observation for a given February. But if an observation for January is followed by an observation for March, there is a gap in the data, and METHOD=AGGREGATE cannot be used.

When the AGGREGATE method is used, there is no interpolating curve, and therefore the EXTRAPOLATE option is not allowed.

Alternate methods for aggregating or accumulating time series data are supported by the TIMESERIES procedure. See Chapter 32, “The TIMESERIES Procedure,” for more information.

**METHOD=NONE**

The option METHOD=NONE specifies that no interpolation be performed. This option is normally used in conjunction with the TRANSFORMIN= or TRANSFORMOUT= option.

When METHOD=NONE is specified, there is no difference between the TRANSFORMIN= and TRANSFORMOUT= options; if both are specified, the TRANSFORMIN= operations are performed first, followed by the TRANSFORMOUT= operations. TRANSFORM= can be used as an abbreviation for TRANSFORMIN=.

**Transformation Operations**

The operations that can be used in the TRANSFORMIN= and TRANSFORMOUT= options are shown in Table 15.2. Operations are applied to each value of the series. Each value of the series is replaced by the result of the operation.

In Table 15.2, \( x_t \) or \( x \) represents the value of the series at a particular time period \( t \) before the transformation is applied, \( y_t \) represents the value of the result series, and \( N \) represents the total number of observations.

The notation \( n_{\text{optional}} \) indicates that the argument \( n_{\text{optional}} \) is an optional integer; the default is 1. The notation \( \text{window} \) is used as the argument for the moving statistics operators, and it indicates that you can specify either a number of periods \( n \) (where \( n \) is an integer) or a list of \( n \) weights in parentheses. The internal maximum value of the number of periods \( n \) is clipped at the number of observations in the series. The notation \( \text{sequence} \) is used as the argument for the sequence operators, and it indicates that you must specify a sequence of numbers. The notation \( s \) indicates the length of seasonality, and it is a required argument.

</table>
Moving Time Window Operators

Some operators compute statistics for a set of values within a moving time window; these are called *moving time window operators*. There are centered and backward versions of these operators.

The centered moving time window operators are `CMOVAVE`, `CMOVCSS`, `CMOVGMEAN`, `CMOVMAX`, `CMOVMED`, `CMOVMIN`, `CMOVPROD`, `CMOVRANGE`, `CMOVRANK`, `CMOVSTD`, `CMOVSUM`, `CMOVTVVALUE`, `CMOVSUM`, and `CMOVVAR`. These operators compute statistics of the \( n \) values \( x_i \) for observations \( t - (n + n \mod 2)/2 + 1 \leq i \leq t + (n - n \mod 2)/2 \).

The backward moving time window operators are `MOVAVE`, `MOVCSS`, `MOVGMEAN`, `MOVMAX`, `MOVMED`, `MOVMIN`, `MOVPRED`, `MOVRANGE`, `MOVRANK`, `MOVSTD`, `MOVSUM`, `MOVTVALUE`, `MOUVSS`, and `MOVVAR`. These operators compute statistics of the \( n \) values \( x_t, x_{t-1}, \ldots, x_{t-n+1} \).

All the moving time window operators accept an argument \( n \) specifying the number of periods to include in the time window. For example, the following statement computes a five-period backward moving average of \( X \).

```plaintext
convert x=y / transformout=( movave 5 );
```

In this example, the resulting transformation is

\[
y_t = (x_t + x_{t-1} + x_{t-2} + x_{t-3} + x_{t-4})/5
\]

The following statement computes a five-period centered moving average of \( X \).

```plaintext
convert x=y / transformout=( cmovave 5 );
```

In this example, the resulting transformation is

\[
y_t = (x_{t-2} + x_{t-1} + x_t + x_{t+1} + x_{t+2})/5
\]

If the window with a centered moving time window operator is not an odd number, one more lead value than lag value is included in the time window. For example, the result of the `CMOVAVE` 4 operator is

\[
y_t = (x_{t-1} + x_t + x_{t+1} + x_{t+2})/4
\]

You can compute a forward moving time window operation by combining a backward moving time window operator with the `REVERSE` operator. For example, the following statement computes a five-period forward moving average of \( X \).

```plaintext
convert x=y / transformout=( reverse movave 5 reverse );
```
In this example, the resulting transformation is
\[ y_t = (x_t + x_{t+1} + x_{t+2} + x_{t+3} + x_{t+4})/5 \]

Some of the moving time window operators enable you to specify a list of weight values to compute weighted statistics. These are CMOVAVE, CMOVCSS, CMOVGMEAN, CMOVPROD, CMOVSTD, CMOVTVVALUE, CMOVUSS, CMOVVAR, MOVAVE, MOVCSS, MOVGMEAN, MOVPROD, MOVSTD, MOVTVVALUE, MOVUSS, and MOVVAR.

To specify a weighted moving time window operator, enter the weight values in parentheses after the operator name. The window width \( n \) is equal to the number of weights that you specify; do not specify \( n \).

For example, the following statement computes a weighted five-period centered moving average of \( X \).

```plaintext
convert x=y / transformout=( cmovave( .1 .2 .4 .2 .1 ) );
```

In this example, the resulting transformation is
\[ y_t = .1x_{t-2} + .2x_{t-1} + .4x_t + .2x_{t+1} + .1x_{t+2} \]

The weight values must be greater than zero. If the weights do not sum to 1, the weights specified are divided by their sum to produce the weights used to compute the statistic.

A complete time window is not available at the beginning of the series. For the centered operators a complete window is also not available at the end of the series. The computation of the moving time window operators is adjusted for these boundary conditions as follows.

For backward moving window operators, the width of the time window is shortened at the beginning of the series. For example, the results of the MOVSUM 3 operator are

\[
\begin{align*}
y_1 & = x_1 \\
y_2 & = x_1 + x_2 \\
y_3 & = x_1 + x_2 + x_3 \\
y_4 & = x_2 + x_3 + x_4 \\
y_5 & = x_3 + x_4 + x_5 \\
\end{align*}
\]

For centered moving window operators, the width of the time window is shortened at the beginning and the end of the series due to unavailable observations. For example, the results of the CMOVSUM 5 operator are

\[
\begin{align*}
y_1 & = x_1 + x_2 + x_3 \\
y_2 & = x_1 + x_2 + x_3 + x_4 \\
y_3 & = x_1 + x_2 + x_3 + x_4 + x_5 \\
y_4 & = x_2 + x_3 + x_4 + x_5 + x_6 \\
\end{align*}
\]

\[
\begin{align*}
y_{N-2} & = x_{N-4} + x_{N-3} + x_{N-2} + x_{N-1} + x_N \\
y_{N-1} & = x_{N-3} + x_{N-2} + x_{N-1} + x_N \\
y_N & = x_{N-2} + x_{N-1} + x_N \\
\end{align*}
\]
For weighted moving time window operators, the weights for the unavailable or unused observations are ignored and the remaining weights renormalized to sum to 1.

**Cumulative Statistics Operators**

Some operators compute cumulative statistics for a set of current and previous values of the series. The cumulative statistics operators are CUAVE, CUCSS, CUMAX, CUMED, CUMIN, CURANGE, CUSTD, CUSUM, CUUSS, and CUVAR.

By default, the cumulative statistics operators compute the statistics from all previous values of the series, so that $y_t$ is based on the set of values $x_t, x_{t-1}, \ldots, x_1$. For example, the following statement computes $y_t$ as the cumulative sum of nonmissing $x_i$ values for $i \leq t$.

```plaintext
convert x=y / transformout=( cusum );
```

You can specify a lag increment argument $n$ for the cumulative statistics operators. In this case, the statistic is computed from the current and every $n^{th}$ previous value. When $n$ is specified these operators compute statistics of the values $x_t, x_{t-n}, x_{t-2n}, \ldots, x_{t-in}$ for $t - in > 0$.

For example, the following statement computes $y_t$ as the cumulative sum of nonmissing $x_i$ values for odd $i$ when $t$ is odd and for even $i$ when $t$ is even.

```plaintext
convert x=y / transformout=( cusum 2 );
```

The results of this example are

\[
\begin{align*}
y_1 & = x_1 \\
y_2 & = x_2 \\
y_3 & = x_1 + x_3 \\
y_4 & = x_2 + x_4 \\
y_5 & = x_1 + x_3 + x_5 \\
y_6 & = x_2 + x_4 + x_6 \\
\end{align*}
\]

... 

**Missing Values**

You can truncate the length of the result series by using the TRIM, TRIMLEFT, and TRIMRIGHT operators to set values to missing at the beginning or end of the series.

You can use these functions to trim the results of moving time window operators so that the result series contains only values computed from a full width time window. For example, the following statements compute a centered five-period moving average of $X$, and they set to missing values at the ends of the series that are averages of fewer than five values.

```plaintext
convert x=y / transformout=( cmovave 5 trim 2 );
```
Normally, the moving time window and cumulative statistics operators ignore missing values and compute their results for the nonmissing values. When preceded by the NOMISS operator, these functions produce a missing result if any value within the time window is missing.

The NOMISS operator does not perform any calculations, but serves to modify the operation of the moving time window operator that follows it. The NOMISS operator has no effect unless it is followed by a moving time window operator.

For example, the following statement computes a five-period moving average of the variable X but produces a missing value when any of the five values are missing.

```
convert x=y / transformout=( nomiss movave 5 );
```

The following statement computes the cumulative sum of the variable X but produces a missing value for all periods after the first missing X value.

```
convert x=y / transformout=( nomiss cusum );
```

Similar to the NOMISS operator, the MISSONLY operator does not perform any calculations (unless followed by the MEAN option), but it serves to modify the operation of the moving time window operator that follows it. When preceded by the MISSONLY operator, these moving time window operators replace any missing values with the moving statistic and leave nonmissing values unchanged.

For example, the following statement replaces any missing values of the variable X with an exponentially weighted moving average of the past values of X and leaves nonmissing values unchanged. The missing values are interpolated using the specified exponentially weighted moving average. (This is also called simple exponential smoothing.)

```
convert x=y / transformout=( missonly ewma 0.3 );
```

The following statement replaces any missing values of the variable X with the overall mean of X.

```
convert x=y / transformout=( missonly mean );
```

You can use the SETMISS operator to replace missing values with a specified number. For example, the following statement replaces any missing values of the variable X with the number 8.77.

```
convert x=y / transformout=( setmiss 8.77 );
```

### Classical Decomposition Operators

If $x_t$ is a seasonal time series with $s$ observations per season, classical decomposition methods “break down” the time series into four components: trend, cycle, seasonal, and irregular components. The trend and cycle components are often combined to form the trend-cycle component. There are two basic forms of classical decomposition: multiplicative and additive, which are shown below.

$$
x_t = TC_tS_tI_t
$$

$$
x_t = TC_t + S_t + I_t
$$

where
Chapter 15: The EXPAND Procedure

$TC_t$ is the trend-cycle component

$S_t$ is the seasonal component or seasonal factors that are periodic with period $s$ and with mean one (multiplicative) or zero (additive)

$I_t$ is the irregular or random component that is assumed to have mean one (multiplicative) or zero (additive)

For multiplicative decomposition, all of the $x_t$ values should be positive.

The CD_TC operator computes the trend-cycle component for both the multiplicative and additive models. When $s$ is odd, this operator computes an $s$-period centered moving average as follows:

$$TC_t = \sum_{k=-\lfloor s/2 \rfloor}^{\lfloor s/2 \rfloor} x_{t+k}/s$$

For example, in the case where $s=5$, the CD_TC $s$ operator

```plaintext
convert x=tc / transformout=( cd_tc 5 );
```

is equivalent to the following CMOVAVE operator:

```plaintext
convert x=tc / transformout=( cmovave 5 trim 2 );
```

When $s$ is even, the CD_TC $s$ operator computes the average of two adjacent $s$-period centered moving averages as follows:

$$TC_t = \sum_{k=-\lfloor s/2 \rfloor}^{\lfloor s/2 \rfloor-1} (x_{t+k} + x_{t+1+k})/2s$$

For example, in the case where $s=12$, the CD_TC $s$ operator

```plaintext
convert x=tc / transformout=( cd_tc 12 );
```

is equivalent to the following CMOVAVE operator:

```plaintext
convert x=tc / transformout=(cmovave 12 movave 2 trim 6);
```

The CD_S and CDA_S operators compute the seasonal components for the multiplicative and additive models, respectively. First, the trend-cycle component is computed as shown previously. Second, the seasonal-irregular component is computed by $SI_t = x_t/TC_t$ for the multiplicative model and by $SI_t = x_t - TC_t$ for the additive model. The seasonal component is obtained by averaging the seasonal-irregular component for each season.

$$S_{k+js} = \sum_{t=k \mod s}^{S_I_t} n/s$$
where \(0 \leq j \leq n/s\) and \(1 \leq k \leq s\). The seasonal components are normalized to sum to one (multiplicative) or zero (additive).

The CD_I and CDA_I operators compute the irregular component for the multiplicative and additive models respectively. First, the seasonal component is computed as shown previously. Next, the irregular component is determined from the seasonal-irregular and seasonal components as appropriate.

\[
I_t = SI_t / S_t \\
I_t = SI_t - S_t
\]

The CD_SA and CDA_SA operators compute the seasonally adjusted time series for the multiplicative and additive models, respectively. After decomposition, the original time series can be seasonally adjusted as appropriate.

\[
\tilde{x}_t = x_t / S_t = TC_t I_t \\
\tilde{x}_t = x_t - S_t = TC_t + I_t
\]

The following statements compute all the multiplicative classical decomposition components for the variable \(X\) for \(s=12\).

```plaintext
convert x=tc / transformout=(cd_tc 12);
convert x=s / transformout=(cd_s 12);
convert x=i / transformout=(cd_i 12);
convert x=sa / transformout=(cd_sa 12);
```

The following statements compute all the additive classical decomposition components for the variable \(X\) for \(s=4\).

```plaintext
convert x=tc / transformout=(cd_tc 4);
convert x=s / transformout=(cda_s 4);
convert x=i / transformout=(cda_i 4);
convert x=sa / transformout=(cda_sa 4);
```

**Fractional Operators**

For fractional operators, the parameter, \(d\), represents the order of fractional differencing. Fractional summation is the inverse operation of fractional differencing.

**Examples of Usage**

Suppose that \(X\) is a fractionally integrated time series variable of order \(d=0.25\). Fractionally differencing \(X\) forms a time series variable \(Y\) which is not integrated.

```plaintext
convert x=y / transformout=(fdif 0.25);
```
Suppose that $Z$ is a non-integrated time series variable. Fractionally summing $Z$ forms a time series $W$ which is fractionally integrated of order $d = 0.25$.

```plaintext
convert z=w / transformout=(fsum 0.25);
```

**Moving Rank Operators**

For the rank operators, the ranks are computed based on the current value with respect to the cumulative, centered, or moving window values. If the current value is missing, the transformed current value is set to missing. If the NOMISS option was previously specified and if any missing values are present in the moving window, the transformed current value is set to missing. Otherwise, redundant values from the moving window are removed and the rank of the current value is computed among the unique values of the moving window.

**Examples of Usage**

The trades of a particular security are recorded for each weekday in a variable named PRICE. Given the historical daily trades, the ranking of the price of this security for each trading day, considering its entire past history, can be computed as follows:

```plaintext
convert price=history / transformout=( curank );
```

The ranking of the price of this security for each trading day considering the previous week’s history can be computed as follows:

```plaintext
convert price=lastweek / transformout=( movrank 5 );
```

The ranking of the price of this security for each trading day considering the previous two week’s history can be computed as follows:

```plaintext
convert price=twoweek / transformout=( movrank 10 );
```

**Moving Product and Geometric Mean Operators**

For the product and geometric mean operators, the current transformed value is computed based on the (weighted) product of the cumulative, centered, or moving window values. If missing values are present in the moving window and the NOMISS operator is previously specified, the current transformed value is set to missing. Otherwise, the current transformed value is set to the product of the nonmissing values within the moving window. If a geometric mean operator is specified for a window of size $n$, the $n$th root of the product is taken. In cases where weights are specified explicitly, both the product and geometric mean operators normalize these exponents so that they sum to one.
Examples of Usage
The interest rates for a savings account are recorded for each month in the data set variable RATES. The cumulative interest rate for each month considering the entire account past history can be computed as follows:

\[
\text{convert rates=history / transformout=\{ + 1 cuprod - 1\};}
\]

The interest rate for each quarter considering the previous quarter’s history can be computed as follows:

\[
\text{convert rates=lastqtr / transformout=\{ + 1 movprod 3 - 1\};}
\]

The average interest rate for the previous quarter’s history can be computed as follows:

\[
\text{convert rates=lastqtr / transformout=\{ + 1 movprod (1 1 1) - 1\};}
\]

Sequence Operators
For the sequence operators, the sequence values are used to compute the transformed values from the original values in a sequential fashion. You can add to or subtract from the original series or you can multiply or divide by the sequence values. The first sequence value is applied to the first observation of the series, the second sequence value is applied to the second observation of the series, and so on until the end of the sequence is reached. At this point, the first sequence value is applied to the next observation of the series and the second sequence value on the next observation and so on.

Let \( v_1, \ldots, v_m \) be the sequence values and let \( x_t, t = 1, \ldots, N \), be the original time series. The transformed series, \( y_t \), is computed as follows:

\[
\begin{align*}
y_1 &= x_1 \text{ op } v_1 \\
y_2 &= x_2 \text{ op } v_2 \\
\vdots \\
y_m &= x_m \text{ op } v_m \\
y_{m+1} &= x_{m+1} \text{ op } v_1 \\
y_{m+2} &= x_{m+2} \text{ op } v_2 \\
\vdots \\
y_{2m} &= x_{2m} \text{ op } v_m \\
y_{2m+1} &= x_{2m+1} \text{ op } v_1 \\
y_{2m+2} &= x_{2m+2} \text{ op } v_2 \\
\vdots
\end{align*}
\]

where \( \text{op = +, -, *, or /} \).
Examples of Usage

The multiplicative seasonal indices are 0.9, 1.2, 0.8, and 1.1 for the four quarters. Let SEASADJ be a quarterly time series variable that has been seasonally adjusted in a multiplicative fashion. To restore the seasonality to SEASADJ use the following transformation:

```
convert seasadj=seasonal / 
    transformout=(seqmult (0.9 1.2 0.8 1.1));
```

The additive seasonal indices are 4.4, -1.1, -2.1, and -1.2 for the four quarters. Let SEASADJ be a quarterly time series variable that has been seasonally adjusted in additive fashion. To restore the seasonality to SEASADJ use the following transformation:

```
convert seasadj=seasonal / 
    transformout=(seqadd (4.4 -1.1 -2.1 -1.2));
```

Set Operators

For the set operators, the first parameter, \( n_1 \), represents the value to be replaced and the second parameter, \( n_2 \), represents the replacement value. The replacement can be localized to the beginning, middle, or end of the series.

Examples of Usage

Suppose that a store opened recently and that the sales history is stored in a database that does not recognize missing values. Even though demand may have existed prior to the stores opening, this database assigns the value of zero. Modeling the sales history may be problematic because the sales history is mostly zero. To compensate for this deficiency, the leading zero values should be set to missing with the remaining zero values unchanged (representing no demand).

```
convert sales=demand / transformout=(setleft (0 .));
```

Likewise, suppose a store is closed recently. The demand might still be present; hence, a recorded value of zero does not accurately reflect actual demand.

```
convert sales=demand / transformout=(setright (0 .));
```

Scale Operator

For the scale operator, the first parameter, \( n_1 \), represents the value associated with the minimum value \( (x_{\text{min}}) \) and the second parameter, \( n_2 \), represents the value associated with the maximum value \( (x_{\text{max}}) \) of the original series \( (x_t) \). The scale operator rescales the original data to be between the parameters \( n_1 \) and \( n_2 \) as follows:

\[
y_t = \left( \frac{n_2 - n_1}{x_{\text{max}} - x_{\text{min}}} \right) (x_t - x_{\text{min}}) + n_1
\]
Examples of Usage
Suppose that two new product sales histories are stored in variables X and Y and you wish to determine their adoption rates. In order to compare their adoption histories the variables must be scaled for comparison.

```
convert x=w / transformout=(scale 0 1);
convert y=z / transformout=(scale 0 1);
```

Adjust Operator

For the moving summation and product window operators, the window widths at the beginning and end of the series are smaller than those in the middle of the series. Likewise, if there are embedded missing values, the window width is smaller than specified. When preceded by the ADJUST operator, the moving summation (MOVSUM CMOVSUM) and moving product operators (MOVPROD CMOVPROD) are adjusted by the window width.

For example, suppose the variable X has 10 values and the moving summation operator of width 3 is applied to X to create the variable Y with window width adjustment and the variable Z without adjustment.

```
convert x=y / transformout=(adjust movsum 3);
convert x=z / transformout=(movsum 3);
```

The above transformations result in the following relationship between Y and Z: \( y_1 = 3z_1, y_2 = \frac{3}{2}z_2, \)
\( y_t = z_t \) for \( t > 2 \) because the first two window widths are smaller than 3.

For example, suppose the variable X has 10 values and the moving multiplicative operator of width 3 is applied to X to create the variable Y with window width adjustment and the variable Z without adjustment.

```
convert x=y / transformout=(adjust movprod 3);
convert x=z / transformout=(movprod 3);
```

The above transformation result in the following: \( y_1 = z_1^3, y_2 = \frac{3^2}{2}z_2^2, y_t = z_t \) for \( t > 2 \) because the first two window widths are smaller than 3.

Moving T-Value Operators

The moving t-value operators (CUTVALUE, MOVTVVALUE, CMOVTVVALUE) compute the t-value of the cumulative series or moving window. They can be viewed as combinations of the moving average (CUAVE, MOVAVE, CMOVAVE) and the moving standard deviation (CUSTD, MOVSTD, CMOVSTD), respectively.

Percent Operators

The percentage operators compute the percent summation and the percent difference of the current value and the lag(n). The percent summation operator (PCTSUM) computes \( y_t = 100x_t / \text{cusum}(x_{t-n}) \). If any of the values of the preceding equation are missing or the cumulative summation is zero, the result is set to missing. The percent difference operator (PCTDIF) computes \( y_t = 100(x_t - x_{t-n}) / x_{t-n} \). If any of the values of the preceding equation are missing or the lag value is zero, the result is set to missing.

For example, suppose variable X contains the series. The percent summation of lag 4 is applied to X to create the variable Y. The percent difference of lag 4 is applied to X to create the variable Z.
convert x=y / transformout=(pctsum 4);
convert x=z / transformout=(pctdif 4);

**Ratio Operators**

The ratio operator computes the ratio of the current value and the lag(n) value. The ratio operator (RATIO) computes \( y_t = \frac{x_t}{x_{t-n}} \). If any of the values of the preceding equation are missing or the lag value is zero, the result is set to missing.

For example, suppose variable X contains the series. The ratio of the current value and the lag 4 value of X assigned to the variable Y. The percent ratio of the current value and lag 4 value of X is assigned to the variable Z.

convert x=y / transformout=(ratio 4);
convert x=z / transformout=(ratio 4 * 100);

---

**OUT= Data Set**

The OUT= output data set contains the following variables:

- the BY variables, if any
- an ID variable that identifies the time period for each output observation
- the result variables
- if no frequency conversion is performed (so that there is one output observation corresponding to each input observation), all the other variables in the input data set are copied to the output data set

The ID variable in the output data set is named as follows:

- If an ID statement is used, the new ID variable has the same name as the variable used in the ID statement.
- If no ID statement is used, but the FROM= option is used, then the name of the ID variable is either DATE or DATETIME, depending on whether the TO= option indicates SAS date or SAS datetime values.
- If neither an ID statement nor the TO= option is used, the ID variable is named TIME.
**OUTEST= Data Set**

The OUTEST= data set contains the coefficients of the spline curves fit to the input series. The OUTEST= data set is of interest if you want to verify the interpolating curve PROC EXPAND uses, or if you want to use this function in another context, (for example, in a SAS/IML program).

The OUTEST= data set contains the following variables:

- the BY variables, if any
- VARNAME, a character variable containing the name of the input variable to which the coefficients apply
- METHOD, a character variable containing the value of the METHOD= option used to fit the series
- OBSERVED, a character variable containing the first letter of the OBSERVED= option name for the input series
- the ID variable that contains the lower breakpoint (or “knot”) of the spline segment to which the coefficients apply. The ID variable has the same name as the variable used in the ID statement. If an ID statement is not used, but the FROM= option is used, then the name of the ID variable is DATE or DATETIME, depending on whether the FROM= option indicates SAS date or SAS datetime values. If neither an ID statement nor the FROM= option is used, the ID variable is named TIME.
- CONSTANT, the constant coefficient for the spline segment
- LINEAR, the linear coefficient for the spline segment
- QUAD, the quadratic coefficient for the spline segment
- CUBIC, the cubic coefficient for the spline segment

For each BY group, the OUTEST= data set contains observations for each polynomial segment of the spline curve fit to each input series. To obtain the observations defining the spline curve used for a series, select the observations where the value of VARNAME equals the name of the series.

The observations for a series in the OUTEST= data set encode the spline function fit to the series as follows. Let \( a_i, b_i, c_i, \) and \( d_i \) be the values of the variables CUBIC, QUAD, LINEAR, and CONSTANT, respectively, for the \( i \) th observation for the series. Let \( x_i \) be the value of the ID variable for the \( i \) th observation for the series. Let \( n \) be the number of observations in the OUTEST= data set for the series. The value of the spline function evaluated at a point \( x \) is

\[
f(x) = a_i(x - x_i)^3 + b_i(x - x_i)^2 + c_i(x - x_i) + d_i
\]

where the segment number \( i \) is selected as follows:

\[
i = \begin{cases} 
i & x_i \leq x < x_{i+1}, 1 \leq i < n \\
i & x < x_1 \\
n & x \geq x_n
\end{cases}
\]
In other words, if \( x \) is between the first and last ID values \( (x_1 \leq x < x_n) \), use the observation from the OUTEST= data set with the largest ID value less than or equal to \( x \). If \( x \) is less than the first ID value \( x_1 \), then \( i = 1 \). If \( x \) is greater than or equal to the last ID value \( (x \geq x_n) \), then \( i = n \).

For METHOD=JOIN, the curve is a linear spline, and the values of CUBIC and QUAD are 0. For METHOD=STEP, the curve is a constant spline, and the values of CUBIC, QUAD, and LINEAR are 0. For METHOD=AGGREGATE, no coefficients are output.

### ODS Graphics

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the EXPAND procedure. To request these graphs, you must specify the PLOTS= option in the PROC EXPAND statement.

### ODS Graph Names

PROC EXPAND assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 15.3.

**PLOTS= Option Details**

Some plots are produced for a series only if the relevant options are also specified. For example, if PLOTS=TRANSFORMIN is specified, then the TRANSFORMIN plot is not produced for a variable unless the TRANSFORMIN= option is specified in a CONVERT statement for that variable. The
PLOTS=TRANSFORMIN option plots the series after the input transformation (TRANSFORMIN= option) is applied.

The PLOTS=CONVERTED option plots the series after the input transformation (TRANSFORMIN= option) is applied and after frequency conversion (METHOD= option). If there is no frequency conversion for an output variable, the converted series plot is not produced.

The PLOTS=TRANSFORMOUT option plots the series after the output transformation (TRANSFORMOUT= option) is applied. If the TRANFORMOUT= option is not specified in the CONVERT statement for an output variable, the output transformation plot is not produced.

The PLOTS=OUTPUT option plots the series after it has undergone input transformation (TRANSFORMIN= option), frequency conversion (METHOD= option), and output transformation (TRANSFORMOUT= option) if these CONVERT statement options were specified.

**Cross and Joint Plots**

The PLOTS= option values CROSSINPUT and CROSSOUTPUT produce graphs that overlay plots of two series by using two Y axes and with each of the two plots shown at a separate scale. These plots are called cross plots.

The PLOTS= option values JOINTINPUT and JOINTOUTPUT produce graphs that overlay plots of two series by using a single Y axis and with both of the plots shown on the same scale. These plots are called joint plots. The joint graphics options (PLOTS=JOINTINPUT or PLOTS=JOINTOUTPUT) plot the (input or converted) series and the transformed series on the same scale; therefore if the transformation changes, the range of the series these plots might be hard to visualize.

The PLOTS=CROSSINPUT option plots both the input series and the series after the input transformation (TRANSFORMIN= option) is applied. The left vertical axis refers to the input series, while the right vertical axis refers to the series after the transformation. If the TRANFORMIN= option is not specified in the CONVERT statement for an output variable, then the cross input plot is not produced for that variable.

The PLOTS=JOINTINPUT option jointly plots both the input series and the series after the input transformation (TRANSFORMIN= option) is applied. If the TRANSFORMIN= option is not specified in the CONVERT statement for an output variable, then the joint input plot is not produced for that variable.

The PLOTS=CROSSOUTPUT option plots both the converted series and the converted series after the output transformation (TRANSFORMOUT= option) is applied. The left vertical axis refers to the input series, while the right vertical axis refers to the series after the transformation. If the TRANSFORMOUT= option is not specified in the CONVERT statement for an output variable, then the cross output plot is not produced for that variable.

The PLOTS=JOINTOUTPUT option jointly plots both the converted series and the converted series after the output transformation (TRANSFORMOUT= option) is applied. If the TRANSFORMOUT= option is not specified in the CONVERT statement for an output variable, then the joint output plot is not produced for that variable.

**Requesting All Plots**

The PLOTS=ALL option is a convenient way to specify all the plots except the OUTPUT plots and the joint and cross plots. The option PLOTS=(ALL OUTPUT JOINTINPUT JOINTOUTPUT CROSSINPUT CROSSOUTPUT) requests that all possible plots be produced.
Chapter 15: The EXPAND Procedure

Examples: EXPAND Procedure

Example 15.1: Combining Monthly and Quarterly Data

This example combines monthly and quarterly data sets by interpolating monthly values for the quarterly series. The series are extracted from two small sample data sets stored in the SASHELP library. These data sets were contributed by Citicorp Data Base services and contain selected U.S. macro economic series.

The quarterly series gross domestic product (GDP) and implicit price deflator (GD) are extracted from SASHELP.CITIQTR. The monthly series industrial production index (IP) and unemployment rate (LHUR) are extracted from SASHELP.CITIMON. Only observations for the years 1990 and 1991 are selected. PROC EXPAND is then used to interpolate monthly estimates for the quarterly series, and the interpolated series are merged with the monthly data.

The following statements extract and print the quarterly data, shown in Output 15.1.1.

```latex
\begin{verbatim}
data qtrly;
  set sashelp.citiqtr;
  where date >= '1jan1990'd &
      date < '1jan1992'd ;
  keep date gdp gd;
run;

title "Quarterly Data";
proc print data=qtrly;
run;
\end{verbatim}

Output 15.1.1  Quarterly Data Set

</table>

The following statements interpolate monthly estimates for the quarterly series and merge the interpolated series with the monthly data. The resulting combined data set is then printed, as shown in **Output 15.1.3**.

```
proc expand data=qtrly out=temp from=qtr to=month;
    convert gdp gd / observed=average;
    id date;
run;

data combined;
    merge monthly temp;
    by date;
run;

title "Combined Data Set";
proc print data=combined;
run;
```
Example 15.2: Illustration of ODS Graphics

This example illustrates the use of ODS graphics with PROC EXPAND.

The graphical displays are requested by specifying the PLOTS= option in the PROC EXPAND statement. For information about the graphics available in the EXPAND procedure, see the section “ODS Graphics” on page 864.

The following statements utilize the SASHELP.WORKERS data set to convert the time series of electrical workers from monthly to quarterly frequency and display ODS graphics plots. The PLOTS=ALL option is specified to request the plots of the input series, the transformed input series, the converted series, and the transformed output series. Figure 15.2.1 through Figure 15.2.4 show these plots.

Example 15.2: Illustration of ODS Graphics

```sas
proc expand data=sashelp.workers out=out
    from=month to=qtr
    plots=all;
    id date;
    convert electric=eout / method=spline
        transformin=(movmed 4)
        transformout=(movave 3);
run;
```

Output 15.2.1 Input Series Plot
Chapter 15: The EXPAND Procedure

Output 15.2.2 Transformed Input Series Plot—Four-Period Moving Median

Transformed Input Series

- Y-axis: electrical workers, thousands
- X-axis: DATE

Graph shows a series of electrical workers data points from January 1977 to July 1982, with a four-period moving median applied. The data shows fluctuations over time, with peaks and troughs indicated by the plotted points.
Example 15.2: Illustration of ODS Graphics

Output 15.2.3 Converted Plot of Transformed Input Series

[Graph showing the converted series with transformed electrical workers, thousands on the y-axis and dates from January 1977 to July 1982 on the x-axis.]
Example 15.3: Interpolating Irregular Observations

This example shows the interpolation of a series of values measured at irregular points in time. The data are hypothetical. Assume that a series of randomly timed quality control inspections are made and defect rates for a process are measured. The problem is to produce two reports: estimates of monthly average defect rates for the months within the period covered by the samples, and a plot of the interpolated defect rate curve over time.

The following statements read and print the input data, as shown in Output 15.3.1.

```plaintext
data samples;
  input date : date9. defects @@;
  label defects = "Defects per 1000 Units";
  format date date9.;
datalines;
... more lines ...
```
Example 15.3: Interpolating Irregular Observations

To compute the monthly estimates, use PROC EXPAND with the TO=MONTH option and specify OBSERVED=(BEGINNING,AVERAGE). The following statements interpolate the monthly estimates.

```plaintext
proc expand data=samples
  out=monthly
to=month
plots=(input output);
  id date;
  convert defects / observed=(beginning,average);
run;
```

The following PROC PRINT step prints the results, as shown in Output 15.3.2.

```plaintext
proc print data=monthly;
run;
```
Output 15.3.2 Monthly Average Estimates

<table>
<thead>
<tr>

<tr>
<td>2</td>
<td>FEB1992</td>
<td>82.000</td>
</tr>
<tr>
<td>3</td>
<td>MAR1992</td>
<td>66.909</td>
</tr>
<tr>
<td>4</td>
<td>APR1992</td>
<td>70.205</td>
</tr>
<tr>
<td>5</td>
<td>MAY1992</td>
<td>82.762</td>
</tr>
<tr>
<td>6</td>
<td>JUN1992</td>
<td>99.701</td>
</tr>
<tr>
<td>7</td>
<td>JUL1992</td>
<td>101.564</td>
</tr>
<tr>
<td>8</td>
<td>AUG1992</td>
<td>105.491</td>
</tr>
<tr>
<td>9</td>
<td>SEP1992</td>
<td>79.206</td>
</tr>
</tbody>
</table>

The plots produced by PROC EXPAND are shown in Output 15.3.3.

Output 15.3.3 Interpolated Defects Rate Curve
Example 15.4: Using Transformations

This example shows the use of PROC EXPAND to perform various transformations of time series. The following statements read in monthly values for a variable X.

```sas
data test;
  input year qtr x;
  date = yyq( year, qtr );
  format date yyqc.;
datalines;
1989 3 5238
1989 4 5289
1990 1 5375
1990 2 5443
1990 3 5514
1990 4 5527
1991 1 5557
1991 2 5615
;```

The following statements use PROC EXPAND to compute lags and leads and a 3-period moving average of the X series.

```sas
proc expand data=test out=out method=none;
   id date;
   convert x = x_lag2 / transformout=(lag 2);
   convert x = x_lag1 / transformout=(lag 1);
   convert x;
   convert x = x_lead1 / transformout=(lead 1);
   convert x = x_lead2 / transformout=(lead 2);
   convert x = x_movave / transformout=(movave 3);
run;

title "Transformed Series";
proc print data=out;
run;
```

Because there are no missing values to interpolate and no frequency conversion, the METHOD=NONE option is used to prevent PROC EXPAND from performing unnecessary computations. Because no frequency conversion is done, all variables in the input data set are copied to the output data set. The CONVERT X; statement is included to control the position of X in the output data set. This statement can be omitted, in which case X is copied to the output data set following the new variables computed by PROC EXPAND.

The results are shown in Output 15.4.1.

**Output 15.4.1** Output Data Set with Transformed Variables

Overview: FORECAST Procedure

The FORECAST procedure is obsolete and has been superseded by newer SAS/ETS procedures. These newer procedures provide more powerful and flexible versions of the forecasting methods that PROC FORECAST uses, and they also provide additional forecasting methods that are not available in PROC FORECAST.

The FORECAST procedure is still available for use. However, before choosing to use PROC FORECAST, consider the following alternatives:

- For forecasting by using exponential smoothing methods or Winters method, consider using the ESM procedure. The models that can be selected by the PROC FORECAST options METHOD=EXPO, METHOD=WINTERS, and METHOD=ADDWINTERS are provided by PROC ESM, which also provides additional forecasting methods that PROC FORECAST does not support. Unlike PROC FORECAST, the ESM procedure optimizes the smoothing weights for the forecasting model based on the data. Also unlike PROC FORECAST, the ESM procedure can automatically select the form of exponential smoothing model that is most appropriate for your data. For information about forecasting with PROC ESM, see Chapter 14, “The ESM Procedure.”

- For forecasting by using time trend models with autoregressive errors, consider using the AUTOREG procedure. The models that can be selected by the PROC FORECAST options METHOD=STEPAR and TREND= can be fit and forecast using PROC AUTOREG, which also allows the inclusion of additional predictor variables in the forecasting model. For information about PROC AUTOREG, see Chapter 8, “The AUTOREG Procedure.”

- For forecasting by using more general and sophisticated time series models, consider using the UCM procedure, which fits and forecasts unobserved components models that are not available in PROC FORECAST. Using UCM models, you can fit and forecast much more complex data patterns than you can by using the simple methods that PROC FORECAST provides. Unlike PROC FORECAST, the UCM procedure can also model and forecast the effect of independent predictor variables. For information about PROC UCM, see Chapter 34, “The UCM Procedure.”

- For forecasting by using ARIMA models and the Box-Jenkins methodology, consider using the ARIMA procedure. PROC ARIMA identifies, fits, and forecasts general autoregressive integrated moving average models, optionally incorporating transfer function models for the effects of independent predictor variables. (As a special case, you can use seasonal ARMA models for forecasting seasonal series for which the Winters and additive Winters methods might be used.) PROC ARIMA also provides features for automatically identifying the specific ARIMA model that is most appropriate for the data. ARIMA and ARIMAX models are not available in PROC FORECAST. For information about PROC ARIMA, see Chapter 7, “The ARIMA Procedure.”

- For forecasting multivariate time series, where two or more related variables need to be forecast jointly, consider using the VARMAX procedure or the SSM procedure. PROC VARMAX fits and forecasts vector autoregressive moving average models, optionally incorporating multivariate transfer function models for the effects of independent predictor variables. For information about PROC VARMAX, see Chapter 35, “The VARMAX Procedure.” PROC SSM fits and forecasts general linear state space models. The general state space model encompasses most of the other forecasting models that are mentioned in this section, and it enables generalizations that can model time series data patterns of
almost any type and complexity. For information about PROC SSM, see Chapter 27, “The SSM Procedure.”

- For forecasting both the future expectation and future volatility or risk, consider using the AUTOREG procedure or the VARMAX procedure. PROC AUTOREG can fit and forecast many types of GARCH models of time-varying volatility, while also fitting and forecasting future expected values of the dependent variable. PROC VARMAX supports multivariate GARCH models. For information about PROC AUTOREG, see Chapter 8, “The AUTOREG Procedure.” For information about PROC VARMAX, see Chapter 35, “The VARMAX Procedure.”

If you decide to use PROC FORECAST instead of these newer alternatives, this chapter explains the features of the FORECAST procedure.

The FORECAST procedure provides a quick and automatic way to generate forecasts for many time series in one step. The procedure can forecast hundreds of series at a time, with the series organized into separate variables or across BY groups. PROC FORECAST uses extrapolative forecasting methods where the forecasts for a series are functions only of time and past values of the series, not of other variables.

You can use the following forecasting methods. For each of these methods, you can specify linear, quadratic, or no trend.

- The stepwise autoregressive method is used by default. This method combines time trend regression with an autoregressive model and uses a stepwise method to select the lags to use for the autoregressive process.

- The exponential smoothing method produces a time trend forecast. However, in fitting the trend, the parameters are allowed to change gradually over time, and earlier observations are given exponentially declining weights. Single, double, and triple exponential smoothing are supported, depending on whether no trend, linear trend, or quadratic trend, respectively, is specified. Holt two-parameter linear exponential smoothing is supported as a special case of the Holt-Winters method without seasons.

- The Winters method (also called Holt-Winters) combines a time trend with multiplicative seasonal factors to account for regular seasonal fluctuations in a series. Like the exponential smoothing method, the Winters method allows the parameters to change gradually over time, with earlier observations given exponentially declining weights. You can also specify the additive version of the Winters method, which uses additive instead of multiplicative seasonal factors. When seasonal factors are omitted, the Winters method reduces to the Holt two-parameter version of double exponential smoothing.

The FORECAST procedure writes the forecasts and confidence limits to an output data set. It can also write parameter estimates and fit statistics to an output data set. The FORECAST procedure does not produce printed output.

PROC FORECAST is an extrapolation procedure useful for producing practical results efficiently. However, in the interest of speed, PROC FORECAST uses some shortcuts that cause some statistical results (such as confidence limits) to be only approximate. For many time series, the FORECAST procedure, with appropriately chosen methods and weights, can yield satisfactory results. Other SAS/ETS procedures can produce better forecasts.
Getting Started: FORECAST Procedure

To use PROC FORECAST, specify the input and output data sets and the number of periods to forecast in the PROC FORECAST statement, and then list the variables to forecast in a VAR statement.

For example, suppose you have monthly data on the sales of some product in a data set named PAST, as shown in Figure 16.1, and you want to forecast sales for the next 10 months.

**Figure 16.1 Example Data Set PAST**

The following statements forecast 10 observations for the variable SALES by using the default STEPAR method and write the results to the output data set PRED:

```
proc forecast data=past lead=10 out=pred;
  var sales;
run;
```

The following statements use the PRINT procedure to print the data set PRED:

```
proc print data=pred;
run;
```

The PROC PRINT listing of the forecast data set PRED is shown in Figure 16.2.

**Giving Dates to Forecast Values**

Normally, your input data set has an ID variable that gives dates to the observations, and you want the forecast observations to have dates also. Usually, the ID variable has SAS date values. (See Chapter 3, “Working with Time Series Data,” for information about using SAS date and datetime values.) The ID statement specifies the identifying variable.

If the ID variable contains SAS date or datetime values, the INTERVAL= option should be used on the PROC FORECAST statement to specify the time interval between observations. (See Chapter 4, “Date Intervals, Formats, and Functions,” for more information about time intervals.) The FORECAST procedure uses the INTERVAL= option to generate correct dates for forecast observations.

The data set PAST, shown in Figure 16.1, has monthly observations and contains an ID variable DATE with SAS date values identifying each observation. The following statements produce the same forecast as the preceding example and also include the ID variable DATE in the output data set. Monthly SAS date values are extrapolated for the forecast observations.

```sas
proc forecast data=past interval=month lead=10 out=pred;
  var sales;
  id date;
run;
```

**Computing Confidence Limits**

Depending on the output options specified, multiple observations are written to the OUT= data set for each time period. The different parts of the results are contained in the VAR statement variables in observations identified by the character variable _TYPE_ and by the ID variable.

For example, the following statements use the OUTLIMIT option to write forecasts and 95% confidence limits for the variable SALES to the output data set PRED. This data set is printed with the PRINT procedure.
The output data set PRED is shown in Figure 16.3.

</table>
Form of the OUT= Data Set

The OUT= data set PRED, shown in Figure 16.3, contains three observations for each of the 10 forecast periods. Each of these three observations has the same value of the ID variable DATE, the SAS date value for the month and year of the forecast.

The three observations for each forecast period have different values of the variable _TYPE_. For the _TYPE_=FORECAST observation, the value of the variable SALES is the forecast value for the period indicated by the DATE value. For the _TYPE_=L95 observation, the value of the variable SALES is the lower limit of the 95% confidence interval for the forecast. For the _TYPE_=U95 observation, the value of the variable SALES is the upper limit of the 95% confidence interval.

You can control the types of observations written to the OUT= data set with the PROC FORECAST statement options OUTLIMIT, OUTRESID, OUTACTUAL, OUT1STEP, OUTSTD, OUTFULL, and OUTALL. For example, the OUTFULL option outputs the confidence limit values, the one-step-ahead predictions, and the actual data, in addition to the forecast values. See the sections “Syntax: FORECAST Procedure” on page 895 and “OUTEST= Data Set” on page 913 for more information.

Plotting Forecasts

The forecasts, confidence limits, and actual values can be plotted on the same graph with the SGPLOT procedure. Use the appropriate output control options in the PROC FORECAST statement to include in the OUT= data set the series you want to plot. Use the _TYPE_ variable in the SGPLOT procedure GROUP option to separate the observations for the different plots.

The OUTFULL option is used in the following statements. The resulting output data set contains the actual and predicted values, as well as the upper and lower 95% confidence limits.

```sas
proc forecast data=past interval=month lead=10
    out=pred outfull;
    id date;
    var sales;
run;

proc sgplot data=pred;
    series x=date y=sales / group=_type_ lineattrs=(pattern=1);
    xaxis values=('1jan90'd to '1jan93'd by qtr);
    reline '15jul91'd / axis=x;
run;
```

The _TYPE_ variable is used in the SGPLOT procedure’s PLOT statement to make separate plots over time for each type of value. A reference line marks the start of the forecast period. (See SAS/GRAPH: Reference for more information about using PROC SGPLOT.) The WHERE statement restricts the range of the actual data shown in the plot. In this example, the variable SALES has monthly data from July 1989 through July 1991, but only the data for 1990 and 1991 are shown in Figure 16.4.
Plotting Residuals

You can plot the residuals from the forecasting model by using PROC SGPLOT and a WHERE statement.

1. Use the OUTRESID option or the OUTALL option in the PROC FORECAST statement to include the residuals in the output data set.

2. Use a WHERE statement to specify the observation type of ’RESIDUAL’ in the PROC GPLOT code.

The following statements add the OUTRESID option to the preceding example and plot the residuals:

```plaintext
proc forecast data=past interval=month lead=10
   out=pred outfull outresid;
   id date;
   var sales;
run;
```
You can write the parameters of the forecasting models used, as well as statistics that measure how well the forecasting models fit the data, to an output SAS data set by using the OUTEST= option. The options OUTFITSTATS, OUTESTTHEIL, and OUTESTALL control what goodness-of-fit statistics are added to the OUTEST= data set.

For example, the following statements add the OUTEST= and OUTFITSTATS options to the previous example to create the output statistics data set EST for the results of the default stepwise autoregressive forecasting method:

```sas
proc sgplot data=pred;
    where _type_='RESIDUAL';
    needle x=date y=sales / markers;
    xaxis values=('1jan89'd to '1oct91'd by qtr);
run;
```

The plot of residuals is shown in Figure 16.5.
proc forecast data=past interval=month lead=10  
out=pred outfull outresid  
outest=est outfitstats;  
   id date;  
   var sales;  
run;

proc print data=est;  
run;

The PRINT procedure prints the OUTEST= data set, as shown in Figure 16.6.

</tbody>
</table>
In the OUTEST= data set, the DATE variable contains the ID value of the last observation in the data set used to fit the forecasting model. The variable SALES contains the statistic indicated by the value of the _TYPE_ variable. The _TYPE_=N, NRESID, and DF observations contain, respectively, the number of observations read from the data set, the number of nonmissing residuals used to compute the goodness-of-fit statistics, and the number of nonmissing observations minus the number of parameters used in the forecasting model.

The observation that has _TYPE_=SIGMA contains the estimate of the standard deviation of the one-step prediction error computed from the residuals. The _TYPE_=CONSTANT and _TYPE_=LINEAR observations contain the coefficients of the time trend regression. The _TYPE_=AR1, AR2, ..., AR8 observations contain the estimated autoregressive parameters. A missing autoregressive parameter indicates that the autoregressive term at that lag was not retained in the model by the stepwise model selection method. (See the section “STEPAR Method” on page 903 for more information.)

The other observations in the OUTEST= data set contain various goodness-of-fit statistics that measure how well the forecasting model used fits the given data. See the section “OUTEST= Data Set” on page 913 for details.

**Controlling the Forecasting Method**

The METHOD= option controls which forecasting method is used. The TREND= option controls the degree of the time trend model used. For example, the following statements produce forecasts of SALES as in the preceding example but use the double exponential smoothing method instead of the default STEPAR method:

```sas
proc forecast data=past interval=month lead=10
   method=expo trend=2
   out=pred outfull outresid
   outest=est outfitstats;
   var sales;
   id date;
run;

proc print data=est;
run;
```

The PRINT procedure prints the OUTEST= data set for the EXPO method, as shown in Figure 16.7.

See the section “Syntax: FORECAST Procedure” on page 895 for other options that control the forecasting method. See the section “Introduction to Forecasting Methods” on page 890 and the section “Forecasting Methods” on page 903 for an explanation of the different forecasting methods.

Introduction to Forecasting Methods

This section briefly introduces the forecasting methods used by the FORECAST procedure. See textbooks on forecasting and see the section “Forecasting Methods” on page 903 for more detailed discussions of forecasting methods.

The FORECAST procedure combines three basic models to fit time series:

- time trend models for long-term, deterministic change
- autoregressive models for short-term fluctuations
- seasonal models for regular seasonal fluctuations
Two approaches to time series modeling and forecasting are *time trend models* and *time series methods*.

**Time Trend Models**

Time trend models assume that there is some permanent deterministic pattern across time. These models are best suited to data that are not dominated by random fluctuations.

Examining a graphical plot of the time series you want to forecast is often very useful in choosing an appropriate model. The simplest case of a time trend model is one in which you assume the series is a constant plus purely random fluctuations that are independent from one time period to the next. Figure 16.8 shows how such a time series might look.

**Figure 16.8** Time Series without Trend

The $x_t$ values are generated according to the equation

$$x_t = b_0 + \epsilon_t$$

where $\epsilon_t$ is an independent, zero-mean, random error and $b_0$ is the true series mean.

Suppose that the series exhibits growth over time, as shown in Figure 16.9.
A linear model is appropriate for this data. For the linear model, assume the $x_t$ values are generated according to the equation

$$x_t = b_0 + b_1 t + \epsilon_t$$

The linear model has two parameters. The predicted values for the future are the points on the estimated line.

The extension of the polynomial model to three parameters is the quadratic (which forms a parabola). This allows for a constantly changing slope, where the $x_t$ values are generated according to the equation

$$x_t = b_0 + b_1 t + b_2 t^2 + \epsilon_t$$

PROC FORECAST can fit three types of time trend models: constant, linear, and quadratic. For other kinds of trend models, other SAS procedures can be used.
Exponential smoothing fits a time trend model by using a smoothing scheme in which the weights decline geometrically as you go backward in time. The forecasts from exponential smoothing are a time trend, but the trend is based mostly on the recent observations instead of on all the observations equally. How well exponential smoothing works as a forecasting method depends on choosing a good smoothing weight for the series.

To specify the exponential smoothing method, use the METHOD=EXPO option. Single exponential smoothing produces forecasts with a constant trend (that is, no trend). Double exponential smoothing produces forecasts with a linear trend, and triple exponential smoothing produces a quadratic trend. Use the TREND= option with the METHOD=EXPO option to select single, double, or triple exponential smoothing.

The time trend model can be modified to account for regular seasonal fluctuations of the series about the trend. To capture seasonality, the trend model includes a seasonal parameter for each season. Seasonal models can be additive or multiplicative.

\[
x_t = b_0 + b_1 t + s(t) + \epsilon_t \quad \text{(additive)}
\]

\[
x_t = (b_0 + b_1 t)s(t) + \epsilon_t \quad \text{(multiplicative)}
\]

where \(s(t)\) is the seasonal parameter for the season that corresponds to time \(t\).

The Winters method is similar to exponential smoothing, but it includes seasonal factors. The Winters method can use either additive or multiplicative seasonal factors. Like exponential smoothing, good results with the Winters method depend on choosing good smoothing weights for the series to be forecast.

To specify the multiplicative or additive versions of the Winters method, use the METHOD=WINTERS or METHOD=ADDWINTERS options, respectively. To specify seasonal factors to include in the model, use the SEASONS= option.

Many observed time series do not behave like constant, linear, or quadratic time trends. However, you can partially compensate for the inadequacies of the trend models by fitting time series models to the departures from the time trend, as described in the following sections.

Time Series Methods

Time series models assume the future value of a variable to be a linear function of past values. If the model is a function of past values for a finite number of periods, it is an autoregressive model and is written as follows:

\[
x_t = a_0 + a_1 x_{t-1} + a_2 x_{t-2} + \ldots + a_p x_{t-p} + \epsilon_t
\]

The coefficients \(a_i\) are autoregressive parameters. One of the simplest cases of this model is the random walk, where the series dances around in purely random jumps. This is illustrated in Figure 16.10.
Chapter 16: The FORECAST Procedure

Figure 16.10 Random Walk Series

The \( x_t \) values are generated by the equation

\[
x_t = x_{t-1} + \epsilon_t
\]

In this type of model, the best forecast of a future value is the present value. However, with other autoregressive models, the best forecast is a weighted sum of recent values. Pure autoregressive forecasts always damp down to a constant (assuming the process is stationary).

Autoregressive time series models can also be used to predict seasonal fluctuations.

Combining Time Trend with Autoregressive Models

Trend models are suitable for capturing long-term behavior, whereas autoregressive models are more appropriate for capturing short-term fluctuations. One approach to forecasting is to combine a deterministic time trend model with an autoregressive model.

The stepwise autoregressive method (STEPAR method) combines a time trend regression with an autoregressive model for departures from trend. The combined time trend and autoregressive model is written as
follows:

\[ x_t = b_0 + b_1 t + b_2 t^2 + u_t \]

\[ u_t = a_1 u_{t-1} + a_2 u_{t-2} + \ldots + a_p u_{t-p} + \epsilon_t \]

The autoregressive parameters included in the model for each series are selected by a stepwise regression procedure, so that autoregressive parameters are included only at those lags at which they are statistically significant.

The stepwise autoregressive method is fully automatic. Unlike the exponential smoothing and Winters methods, it does not depend on choosing smoothing weights. However, the STEPAR method assumes that the long-term trend is stable; that is, the time trend regression is fit to the whole series with equal weights for the observations.

The stepwise autoregressive model is used when you specify the METHOD=STEPAR option or do not specify any METHOD= option. To select a constant, linear, or quadratic trend for the time-trend part of the model, use the TREND= option.

---

**Syntax: FORECAST Procedure**

The following statements are used with PROC FORECAST:

```sas
PROC FORECAST options ;
   BY variables ;
   ID variables ;
   VAR variables ;
```

---

**Functional Summary**

Table 16.1 summarizes the statements and options that control the FORECAST procedure.

### Initializing Smoothed Values

- **specify number of beginning values to use in calculating starting values**
  - `PROC FORECAST NSTART=`
- **specify number of beginning values to use in calculating initial seasonal parameters**
  - `PROC FORECAST NSSTART=`
- **specify starting values for constant term**
  - `PROC FORECAST ASTART=`
- **specify starting values for linear trend**
  - `PROC FORECAST BSTART=`
- **specify starting values for the quadratic trend**
  - `PROC FORECAST CSTART=`

---

### PROC FORECAST Statement

**PROC FORECAST** *options* ;

The following options can be specified in the PROC FORECAST statement:

**ALIGN=** *option*
- controls the alignment of SAS dates used to identify output observations. The `ALIGN=` option allows the following values: BEGINNING | BEG | B, MIDDLE | MID | M, and ENDING | END | E. BEGINNING is the default.

**ALPHA=** *value*
- specifies the significance level to use in computing the confidence limits of the forecast. The value of the `ALPHA=` option must be between 0.01 and 0.99. You should use only two digits for the `ALPHA=` option because PROC FORECAST rounds the value to the nearest percent (ALPHA=0.101 is the same as ALPHA=0.10). The default is ALPHA=0.05, which produces 95% confidence limits.

**AR=** *n*

**NLAGS=** *n*
- specifies the maximum order of the autoregressive model. The `AR=` option is valid only for METHOD=STEPAR. The default value of *n* depends on the INTERVAL= option and on the number of observations in the DATA= data set. See the section “STEPAR Method” on page 903 for details.

**ASTART=** *value*

**ASTART=** *(value . . .)*
- specifies starting values for the constant term for the exponential smoothing, Winters, and additive Winters methods. This option is ignored if METHOD=STEPAR. The values specified are associated with the variables in the VAR statement in the order in which the variables are listed. See the section “Starting Values for EXPO, WINTERS, and ADDWINTERS Methods” on page 910 for details.
**BSTART=value**

**BSTART=(value ...)**
specifies starting values for the linear trend for the exponential smoothing, Winters, and additive Winters methods. The values specified are associated with the variables in the VAR statement in the order in which the variables are listed. This option is ignored if METHOD=STEPAR or TREND=1. See the section “Starting Values for EXPO, WINTERS, and ADDWINTERS Methods” on page 910 for details.

**CSTART=value**

**CSTART=(value ...)**
specifies starting values for the quadratic trend for the exponential smoothing, Winters, and additive Winters methods. The values specified are associated with the variables in the VAR statement in the order in which the variables are listed. This option is ignored if METHOD=STEPAR or TREND=1 or 2. See the section “Starting Values for EXPO, WINTERS, and ADDWINTERS Methods” on page 910 for details.

**DATA=SAS-data-set**
names the SAS data set that contains the input time series for the procedure to forecast. If the DATA= option is not specified, the most recently created SAS data set is used.

**INTERVAL=interval**
specifies the frequency of the input time series. For example, if the input data set consists of quarterly observations, then INTERVAL=QTR should be used. See Chapter 4, “Date Intervals, Formats, and Functions,” for more details about the intervals available.

**INTPER=n**
when the INTERVAL= option is not used, specifies an increment (other than 1) to use in generating the values of the ID variable for the forecast observations in the output data set.

**LEAD=n**
specifies the number of periods ahead to forecast. The default is LEAD=12.

The LEAD= value is relative to the last observation in the input data set and not to the end of a particular series. Thus, if a series has missing values at the end, the actual number of forecasts computed for that series will be greater than the LEAD= value.

**MAXERRORS=n**
limits the number of warning and error messages produced during the execution of the procedure to the specified value. The default is MAXERRORS=50.

This option is particularly useful in BY-group processing where it can be used to suppress the recurring messages.

**METHOD=method-name**
specifies the method to use to model the series and generate the forecasts.

METHOD=STEPAR specifies the stepwise autoregressive method.

METHOD=EXPO specifies the exponential smoothing method.

METHOD=WINTERS specifies the Holt-Winters exponentially smoothed trend-seasonal method.

METHOD=ADDWINTERS specifies the additive seasonal factors variant of the Winters method.
For more information, see the section “Forecasting Methods” on page 903. The default is METHOD=STEPAR.

**NSTART=n**

**NSTART=MAX**

specifies the number of beginning values of the series to use in calculating starting values for the trend parameters in the exponential smoothing, Winters, and additive Winters methods. This option is ignored if METHOD=STEPAR.

For METHOD=EXPO, \( n \) beginning values of the series are used in forming the exponentially smoothed values \( S_1, S_2, \) and \( S_3 \), where \( n \) is the value of the NSTART= option. The parameters are initialized by fitting a time trend regression to the first \( n \) nonmissing values of the series.

For METHOD=WINTERS or METHOD=ADDWINTERS, \( n \) beginning complete seasonal cycles are used to compute starting values for the trend parameters. For example, for monthly data the seasonal cycle is one year, and NSTART=2 specifies that the first 24 observations at the beginning of each series are used for the time trend regression used to calculate starting values.

When NSTART=MAX is specified, all the observations are used. The default for METHOD=EXPO is NSTART=8; the default for METHOD=WINTERS or METHOD=ADDWINTERS is NSTART=2. See the section “Starting Values for EXPO, WINTERS, and ADDWINTERS Methods” on page 910 for details.

**NSSTART=n**

**NSSTART=MAX**

specifies the number of beginning values of the series to use in calculating starting values for seasonal parameters for METHOD=WINTERS or METHOD=ADDWINTERS. The seasonal parameters are initialized by averaging over the first \( n \) values of the series for each season, where \( n \) is the value of the NSSTART= option. When NSSTART=MAX is specified, all the observations are used.

If NSTART= is specified, but NSSTART= is not, NSSTART= defaults to the value specified for NSTART=. If neither NSTART= nor NSSTART= is specified, then the default is NSSTART=2. This option is ignored if METHOD=STEPAR or METHOD=EXPO. See the section “Starting Values for EXPO, WINTERS, and ADDWINTERS Methods” on page 910 for details.

**OUT=SAS-data-set**

names the output data set to contain the forecasts. If the OUT= option is not specified, the data set is named by using the DATA\( n \) convention. See the section “OUTEST= Data Set” on page 913 for details.

**OUTACTUAL**

writes the actual values to the OUT= data set.

**OUTALL**

provides all the output control options (OUTLIMIT, OUT1STEP, OUTACTUAL, OUTRESID, and OUTSTD).

**OUTEST=SAS-data-set**

names an output data set to contain the parameter estimates and goodness-of-fit statistics. When the OUTEST= option is not specified, the parameters and goodness-of-fit statistics are not stored. See the section “OUTEST= Data Set” on page 913 for details.
OUTESTALL
writes additional statistics to the OUTEST= data set. This option is the same as specifying both OUTESTTHEIL and OUTFITSTATS.

OUTESTTHEIL
writes Theil forecast accuracy statistics to the OUTEST= data set.

OUTFITSTATS
writes various R-square-type forecast accuracy statistics to the OUTEST= data set.

OUTFULL
provides OUTACTUAL, OUT1STEP, and OUTLIMIT output control options in addition to the forecast values.

OUTLIMIT
writes the forecast confidence limits to the OUT= data set.

OUTRESID
writes the residuals (when available) to the OUT= data set.

OUTSTD
writes the standard errors of the forecasts to the OUT= data set.

OUT1STEP
writes the one-step-ahead predicted values to the OUT= data set.

SEASONS=\text{interval}\n\text{SEASONS=} (\text{interval1} [\text{interval2} [\text{interval3} ]])\n\text{SEASONS=}(\text{n1} [\text{n2} [\text{n3} ]])
specifies the seasonality for seasonal models. The interval can be QTR, MONTH, DAY, or HOUR, or multiples of these (for example, QTR2, MONTH2, MONTH3, MONTH4, MONTH6, HOUR2, HOUR3, HOUR4, HOUR6, HOUR8, and HOUR12).
Alternatively, seasonality can be specified by giving the length of the seasonal cycles. For example, SEASONS=3 means that every group of three observations forms a seasonal cycle. The SEASONS= option is valid only for METHOD=WINTERS or METHOD=ADDWINTERS. See the section “Specifying Seasonality” on page 910 for details.

SINGULAR=value
gives the criterion for judging singularity. The default depends on the precision of the computer that you run SAS programs on.

SINTPER=m
\text{SINTPER=} (\text{m1} [\text{m2} [\text{m3} ]])\nspecifies the number of periods to combine in forming a season. For example, SEASONS=3 SINTPER=2 specifies that each group of two observations forms a season and that the seasonal cycle repeats every six observations. The SINTPER= option is valid only when the SEASONS= option is used. See the section “Specifying Seasonality” on page 910 for details.
**BY Statement**

```plaintext
BY variables;
```

A BY statement can be used with PROC FORECAST to obtain separate analyses on observations in groups defined by the BY variables.

**ID Statement**

```plaintext
ID variables;
```

The first variable listed in the ID statement identifies observations in the input and output data sets. Usually, the first ID variable is a SAS date or datetime variable. Its values are interpreted and extrapolated according
to the values of the INTERVAL= option. See the section “Data Periodicity and Time Intervals” on page 902 for details.

If more than one ID variable is specified in the ID statement, only the first is used to identify the observations; the rest are just copied to the OUT= data set and will have missing values for forecast observations.

**VAR Statement**

```
VAR variables;
```

The VAR statement specifies the variables in the input data set that you want to forecast. If no VAR statement is specified, the procedure forecasts all numeric variables except the ID and BY variables.

### Details: FORECAST Procedure

#### Missing Values

The treatment of missing values varies by method. For METHOD=STEPAR, missing values are tolerated in the series; the autocorrelations are estimated from the available data and tapered, if necessary. For the EXPO, WINTERS, and ADDWINTERS methods, missing values after the start of the series are replaced with one-step-ahead predicted values, and the predicted values are applied to the smoothing equations. For the WINTERS method, negative or zero values are treated as missing.

#### Data Periodicity and Time Intervals

The INTERVAL= option is used to establish the frequency of the time series. For example, INTERVAL=MONTH specifies that each observation in the input data set represents one month. If INTERVAL=MONTH2, each observation represents two months. Thus, there is a two-month time interval between each pair of successive observations, and the data frequency is bimonthly.

See Chapter 4, “Date Intervals, Formats, and Functions,” for details about the interval values supported.

The INTERVAL= option is used together with the ID statement to fully describe the observations that make up the time series. The first variable specified in the ID statement is used to identify the observations. Usually, SAS date or datetime values are used for this variable. PROC FORECAST uses the ID variable in the following ways:

- to validate the data periodicity. When the INTERVAL= option is specified, the ID variable is used to check the data and verify that successive observations have valid ID values that correspond to successive time intervals. When the INTERVAL= option is not used, PROC FORECAST verifies that the ID values are nonmissing and in ascending order. A warning message is printed when an invalid ID value is found in the input data set.
• to check for gaps in the input observations. For example, if INTERVAL=MONTH and an input observation for January 1970 is followed by an observation for April 1970, there is a gap in the input data, with two observations omitted. When a gap in the input data is found, a warning message is printed, and PROC FORECAST processes missing values for each omitted input observation.

• to label the forecast observations in the output data set. The values of the ID variable for the forecast observations after the end of the input data set are extrapolated according to the frequency specifications of the INTERVAL= option. If the INTERVAL= option is not specified, the ID variable is extrapolated by incrementing the ID variable value for the last observation in the input data set by the INTPER= value, if specified, or by one.

The ALIGN= option controls the alignment of SAS dates. See Chapter 4, “Date Intervals, Formats, and Functions,” for more information.

Forecasting Methods

This section explains the forecasting methods used by PROC FORECAST.

STEPAR Method

In the STEPAR method, PROC FORECAST first fits a time trend model to the series and takes the difference between each value and the estimated trend. (This process is called detrending.) Then, the remaining variation is fit by using an autoregressive model.

The STEPAR method fits the autoregressive process to the residuals of the trend model by using a backwards-stepping method to select parameters. Because the trend and autoregressive parameters are fit in sequence rather than simultaneously, the parameter estimates are not optimal in a statistical sense. However, the estimates are usually close to optimal, and the method is computationally inexpensive.

The STEPAR Algorithm

The STEPAR method consists of the following computational steps:

1. Fit the trend model as specified by the TREND= option by using ordinary least-squares regression. This step detrends the data. The default trend model for the STEPAR method is TREND=2, a linear trend model.

2. Take the residuals from step 1 and compute the autocovariances to the number of lags specified by the NLAGS= option.

3. Regress the current values against the lags, using the autocovariances from step 2 in a Yule-Walker framework. Do not bring in any autoregressive parameter that is not significant at the level specified by the SLENTRY= option. (The default is SLENTRY=0.20.) Do not bring in any autoregressive parameter that results in a nonpositive-definite Toeplitz matrix.

4. Find the autoregressive parameter that is least significant. If the significance level is greater than the SLSTAY= value, remove the parameter from the model. (The default is SLSTAY=0.05.) Continue this process until only significant autoregressive parameters remain. If the OUTEST= option is specified, write the estimates to the OUTEST= data set.
5. Generate the forecasts by using the estimated model and output to the OUT= data set. Form the confidence limits by combining the trend variances with the autoregressive variances.

Missing values are tolerated in the series; the autocorrelations are estimated from the available data and tapered if necessary.

This method requires at least three passes through the data: two passes to fit the model and a third pass to initialize the autoregressive process and write to the output data set.

**Default Value of the NLAGS= Option**

If the NLAGS= option is not specified, the default value of the NLAGS= option is chosen based on the data frequency specified by the INTERVAL= option and on the number of observations in the input data set, if this can be determined in advance. (PROC FORECAST cannot determine the number of input observations before reading the data when a BY statement or a WHERE statement is used or if the data are from a tape format SAS data set or external database. The NLAGS= value must be fixed before the data are processed.)

If the INTERVAL= option is specified, the default NLAGS= value includes lags for up to three years plus one, subject to the maximum of 13 lags or one-third of the number of observations in your data set, whichever is less. If the number of observations in the input data set cannot be determined, the maximum NLAGS= default value is 13. If the INTERVAL= option is not specified, the default is NLAGS=13 or one-third the number of input observations, whichever is less.

If the Toeplitz matrix formed by the autocovariance matrix at a given step is not positive definite, the maximal number of autoregressive lags is reduced.

For example, for INTERVAL=QTR, the default is NLAGS=13 (that is, \( 4 \times 3 + 1 \)) provided that there are at least 39 observations. The NLAGS= option default is always at least 3.

**EXPO Method**

Exponential smoothing is used when the METHOD=EXPO option is specified. The term exponential smoothing is derived from the computational scheme developed by Brown and others (Brown and Meyer 1961; Brown 1962). Estimates are computed with updating formulas that are developed across time series in a manner similar to smoothing.

The EXPO method fits a trend model such that the most recent data are weighted more heavily than data in the early part of the series. The weight of an observation is a geometric (exponential) function of the number of periods that the observation extends into the past relative to the current period. The weight function is

\[
    w_t = \omega (1 - \omega)^{t-t}
\]

where \( \tau \) is the observation number of the past observation, \( t \) is the current observation number, and \( \omega \) is the weighting constant specified with the WEIGHT= option.

You specify the model with the TREND= option as follows:

- TREND=1 specifies single exponential smoothing (a constant model)
- TREND=2 specifies double exponential smoothing (a linear trend model)
- TREND=3 specifies triple exponential smoothing (a quadratic trend model)
**Updating Equations**

The single exponential smoothing operation is expressed by the formula

$$S_t = \omega x_t + (1 - \omega)S_{t-1}$$

where $S_t$ is the smoothed value at the current period, $t$ is the time index of the current period, and $x_t$ is the current actual value of the series. The smoothed value $S_t$ is the forecast of $x_{t+1}$ and is calculated as the smoothing constant $\omega$ times the value of the series, $x_t$, in the current period plus $(1 - \omega)$ times the previous smoothed value $S_{t-1}$, which is the forecast of $x_t$ computed at time $t - 1$.

Double and triple exponential smoothing are derived by applying exponential smoothing to the smoothed series, obtaining smoothed values as follows:

$$S_t^{[2]} = \omega S_t + (1 - \omega)S_{t-1}^{[2]}$$

$$S_t^{[3]} = \omega S_t^{[2]} + (1 - \omega)S_{t-1}^{[3]}$$

Missing values after the start of the series are replaced with one-step-ahead predicted values, and the predicted value is then applied to the smoothing equations.

The polynomial time trend parameters CONSTANT, LINEAR, and QUAD in the OUTEST= data set are computed from $S_T$, $S_T^{[2]}$, and $S_T^{[3]}$, the final smoothed values at observation $T$, the last observation used to fit the model. In the OUTEST= data set, the values of $S_T$, $S_T^{[2]}$, and $S_T^{[3]}$ are identified by _TYPE_=S1, _TYPE_=S2, and _TYPE_=S3, respectively.

**Smoothing Weights**

*Exponential smoothing forecasts* are forecasts for an integrated moving-average process; however, the weighting parameter is specified by the user rather than estimated from the data. Experience has shown that good values for the WEIGHT= option are between 0.05 and 0.3. As a general rule, smaller smoothing weights are appropriate for series with a slowly changing trend, while larger weights are appropriate for volatile series with a rapidly changing trend. If unspecified, the weight defaults to $(1 - 0.8^{1/trend})$, where *trend* is the value of the TREND= option. This produces defaults of WEIGHT=0.2 for TREND=1, WEIGHT=0.10557 for TREND=2, and WEIGHT=0.07168 for TREND=3.

The ESM procedure can be used to forecast time series by using exponential smoothing with smoothing weights that are optimized automatically. See Chapter 14, “The ESM Procedure.”

The Time Series Forecasting System provides for exponential smoothing models and enables you to either specify or optimize the smoothing weights. See Chapter 45, “Getting Started with Time Series Forecasting,” for details.

**Confidence Limits**

The confidence limits for exponential smoothing forecasts are calculated as they would be for an exponentially weighted time trend regression, using the simplifying assumption of an infinite number of observations. The variance estimate is computed by using the mean square of the unweighted one-step-ahead forecast residuals.

More detailed descriptions of the forecast computations can be found in Montgomery and Johnson (1976); Brown (1962).
**WINTERS Method**

The WINTERS method uses updating equations similar to exponential smoothing to fit parameters for the model

\[ x_t = (a + bt)s(t) + \epsilon_t \]

where \( a \) and \( b \) are the trend parameters and the function \( s(t) \) selects the seasonal parameter for the season that corresponds to time \( t \).

The WINTERS method assumes that the series values are positive. If negative or zero values are found in the series, a warning is printed and the values are treated as missing.

The preceding standard WINTERS model uses a linear trend. However, PROC FORECAST can also fit a version of the WINTERS method that uses a quadratic trend. When TREND=3 is specified for METHOD=WINTERS, PROC FORECAST fits the following model:

\[ x_t = (a + bt + ct^2)s(t) + \epsilon_t \]

The quadratic trend version of the Winters method is often unstable, and its use is not recommended.

When TREND=1 is specified, the following constant trend version is fit:

\[ x_t = as(t) + \epsilon_t \]

The default for the WINTERS method is TREND=2, which produces the standard linear trend model.

**Seasonal Factors**

The notation \( s(t) \) represents the selection of the seasonal factor used for different time periods. For example, if INTERVAL=DAY and SEASONS=MONTH, there are 12 seasonal factors, one for each month in the year, and the time index \( t \) is measured in days. For any observation, \( t \) is determined by the ID variable and \( s(t) \) selects the seasonal factor for the month that \( t \) falls in. For example, if \( t \) is 9 February 1993 then \( s(t) \) is the seasonal parameter for February.

When there are multiple seasons specified, \( s(t) \) is the product of the parameters for the seasons. For example, if SEASONS=(MONTH DAY), then \( s(t) \) is the product of the seasonal parameter for the month that corresponds to period \( t \) and the seasonal parameter for the day of the week that corresponds to period \( t \). When the SEASONS= option is not specified, the seasonal factors \( s(t) \) are not included in the model. See the section “Specifying Seasonality” on page 910 for more information about specifying multiple seasonal factors.

**Updating Equations**

This section shows the updating equations for the Winters method. In the following formula, \( x_t \) is the actual value of the series at time \( t \); \( a_t \) is the smoothed value of the series at time \( t \); \( b_t \) is the smoothed trend at time \( t \); \( c_t \) is the smoothed quadratic trend at time \( t \); \( s_{t-1}(t) \) selects the old value of the seasonal factor that corresponds to time \( t \) before the seasonal factors are updated.

The estimates of the constant, linear, and quadratic trend parameters are updated by using the following equations:

For TREND=3,

\[
\begin{align*}
a_t &= \omega_1 \frac{x_t}{s_{t-1}(t)} + (1 - \omega_1)(a_{t-1} + b_{t-1} + c_{t-1}) \\
\end{align*}
\]
\[ b_t = \omega_2 (a_t - a_{t-1} + c_{t-1}) + (1 - \omega_2)(b_{t-1} + 2c_{t-1}) \]
\[ c_t = \omega_2 \frac{1}{2} (b_t - b_{t-1}) + (1 - \omega_2)c_{t-1} \]

For TREND=2,
\[ a_t = \omega_1 \frac{x_t}{s_{t-1}(t)} + (1 - \omega_1)(a_{t-1} + b_{t-1}) \]
\[ b_t = \omega_2 (a_t - a_{t-1}) + (1 - \omega_2)b_{t-1} \]

For TREND=1,
\[ a_t = \omega_1 \frac{x_t}{s_{t-1}(t)} + (1 - \omega_1)a_{t-1} \]

In this updating system, the trend polynomial is always centered at the current period so that the intercept parameter of the trend polynomial for predicted values at times after \( t \) is always the updated intercept parameter \( a_t \). The predicted value for \( \tau \) periods ahead is
\[ x_{t+\tau} = (a_t + b_t \tau)s_t(t + \tau) \]

The seasonal parameters are updated when the season changes in the data, using the mean of the ratios of the actual to the predicted values for the season. For example, if SEASONS=MONTH and INTERVAL=DAY, then when the observation for the first of February is encountered, the seasonal parameter for January is updated by using the formula
\[ s_t(t - 1) = \omega_3 \frac{1}{31} \sum_{i=t-31}^{t-1} \frac{x_i}{a_i} + (1 - \omega_3)s_{t-1}(t - 1) \]

where \( t \) is February 1 of the current year, \( s_t(t - 1) \) is the seasonal parameter for January updated with the data available at time \( t \), and \( s_{t-1}(t - 1) \) is the seasonal parameter for January of the previous year.

When multiple seasons are used, \( s_t(t) \) is a product of seasonal factors. For example, if SEASONS=(MONTH DAY) then \( s_t(t) \) is the product of the seasonal factors for the month and for the day of the week:
\[ s_t(t) = s^m_t(t)s^d_t(t). \]

The factor \( s^m_t(t) \) is updated at the start of each month by using a modification of the preceding formula that adjusts for the presence of the other seasonal by dividing the summands \( \frac{x_i}{a_i} \) by the that corresponds to day of the week effect \( s^d_t(i) \).

Similarly, the factor \( s^d_t(t) \) is updated by using the following formula:
\[ s^d_t(t) = \omega_3 \frac{x_t}{a_t s^m_t(t)} + (1 - \omega_3)s^d_{t-1}(t) \]

where \( s^d_{t-1}(t) \) is the seasonal factor for the same day of the previous week.

Missing values after the start of the series are replaced with one-step-ahead predicted values, and the predicted value is substituted for \( x_i \) and applied to the updating equations.
Normalization
The parameters are normalized so that the seasonal factors for each cycle have a mean of 1.0. This normalization is performed after each complete cycle and at the end of the data. Thus, if INTERVAL=MONTH and SEASONS=MONTH are specified and a series begins with a July value, then the seasonal factors for the series are normalized at each observation for July and at the last observation in the data set. The normalization is performed by dividing each of the seasonal parameters, and multiplying each of the trend parameters, by the mean of the unnormalized seasonal parameters.

Smoothing Weights
The weight for updating the seasonal factors, $\omega_3$, is given by the third value specified in the WEIGHT= option. If the WEIGHT= option is not used, then $\omega_3$ defaults to 0.25; if the WEIGHT= option is used but does not specify a third value, then $\omega_3$ defaults to $\omega_2$. The weight for updating the linear and quadratic trend parameters, $\omega_2$, is given by the second value specified in the WEIGHT= option; if the WEIGHT= option does not specify a second value, then $\omega_2$ defaults to $\omega_1$. The updating weight for the constant parameter, $\omega_1$, is given by the first value specified in the WEIGHT= option. As a general rule, smaller smoothing weights are appropriate for series with a slowly changing trend, while larger weights are appropriate for volatile series with a rapidly changing trend.

If the WEIGHT= option is not used, then $\omega_1$ defaults to $(1 - 0.81^{trend})$, where trend is the value of the TREND= option. This produces defaults of WEIGHT=0.2 for TREND=1, WEIGHT=0.10557 for TREND=2, and WEIGHT=0.07168 for TREND=3.

The ESM procedure and the Time Series Forecasting System provide for generating forecast models that use Winters Method and enable you to specify or optimize the weights. (See Chapter 14, “The ESM Procedure,” and Chapter 45, “Getting Started with Time Series Forecasting,” for details.)

Confidence Limits
A method for calculating exact forecast confidence limits for the WINTERS method is not available. Therefore, the approach taken in PROC FORECAST is to assume that the true seasonal factors have small variability about a set of fixed seasonal factors and that the remaining variation of the series is small relative to the mean level of the series. The equations are written

$$s_t(t) = I(t)(1 + \delta_t)$$
$$x_t = \mu I(t)(1 + \gamma_t)$$
$$a_t = \xi (1 + \alpha_t)$$

where $\mu$ is the mean level and $I(t)$ are the fixed seasonal factors. Assuming that $\alpha_t$ and $\delta_t$ are small, the forecast equations can be linearized and only first-order terms in $\delta_t$ and $\alpha_t$ kept. In terms of forecasts for $\gamma_t$, this linearized system is equivalent to a seasonal ARIMA model. Confidence limits for $\gamma_t$ are based on this ARIMA model and converted into confidence limits for $x_t$ using $s_t(t)$ as estimates of $I(t)$.

The exponential smoothing confidence limits are based on an approximation to a weighted regression model, whereas the preceding Winters confidence limits are based on an approximation to an ARIMA model. You can use METHOD=WINTERS without the SEASONS= option to do exponential smoothing and get confidence limits for the EXPO forecasts based on the ARIMA model approximation. These are generally more pessimistic than the weighted regression confidence limits produced by METHOD=EXPO.
**ADDWINTERS Method**

The ADDWINTERS method is like the WINTERS method except that the seasonal parameters are added to the trend instead of multiplied with the trend. The default TREND=2 model is as follows:

\[ x_t = a + bt + s(t) + \epsilon_t \]

The WINTERS method for updating equation and confidence limits calculations described in the preceding section are modified accordingly for the additive version.

**Holt Two-Parameter Exponential Smoothing**

If the seasonal factors are omitted (that is, if the SEASONS= option is not specified), the WINTERS (and ADDWINTERS) method reduces to the Holt two-parameter version of exponential smoothing. Thus, the WINTERS method is often referred to as the Holt-Winters method.

Double exponential smoothing is a special case of the Holt two-parameter smoother. The double exponential smoothing results can be duplicated with METHOD=WINTERS by omitting the SEASONS= option and appropriately setting the WEIGHT= option. Letting \( \alpha = \omega(2 - \omega) \) and \( \beta = \omega/(2 - \omega) \), the following statements produce the same forecasts:

```plaintext
proc forecast method=expo trend=2 weight=\( \alpha \) ...;
proc forecast method=winters trend=2 weight=(\( \alpha \), \( \beta \)) ...;
```

Although the forecasts are the same, the confidence limits are computed differently.

**Choice of Weights for EXPO, WINTERS, and ADDWINTERS Methods**

For the EXPO, WINTERS, and ADDWINTERS methods, properly chosen smoothing weights are of critical importance in generating reasonable results. There are several factors to consider in choosing the weights.

The noisier the data, the lower should be the weight given to the most recent observation. Another factor to consider is how quickly the mean of the time series is changing. If the mean of the series is changing rapidly, relatively more weight should be given to the most recent observation. The more stable the series over time, the lower should be the weight given to the most recent observation.

Note that the smoothing weights should be set separately for each series; weights that produce good results for one series might be poor for another series. Since PROC FORECAST does not have a feature to use different weights for different series, when forecasting multiple series with the EXPO, WINTERS, or ADDWINTERS method it might be desirable to use different PROC FORECAST steps with different WEIGHT= options.

For the Winters method, many combinations of weight values might produce unstable *noninvertible* models, even though all three weights are between 0 and 1. When the model is noninvertible, the forecasts depend strongly on values in the distant past, and predictions are determined largely by the starting values. Unstable models usually produce poor forecasts. The Winters model can be unstable even if the weights are optimally chosen to minimize the in-sample MSE. See Archibald (1990) for a detailed discussion of the unstable region of the parameter space of the Winters model.

Optimal weights and forecasts for exponential smoothing models can be computed by using the ESM and ARIMA procedures and by the Time Series Forecasting System.
Starting Values for EXPO, WINTERS, and ADDWINTERS Methods

The exponential smoothing method requires starting values for the smoothed values $S_0$, $S_0^{[2]}$, and $S_0^{[3]}$. The Winters and additive Winters methods require starting values for the trend coefficients and seasonal factors.

By default, starting values for the trend parameters are computed by a time trend regression over the first few observations for the series. Alternatively, you can specify the starting value for the trend parameters with the ASTART=, BSTART=, and CSTART= options.

The number of observations used in the time trend regression for starting values depends on the NSTART= option. For METHOD=EXPO, NSTART= beginning values of the series are used, and the coefficients of the time trend regression are then used to form the initial smoothed values $S_0$, $S_0^{[2]}$, and $S_0^{[3]}$.

For METHOD=WINTERS or METHOD=ADDWINTERS, $n$ complete seasonal cycles are used to compute starting values for the trend parameter, where $n$ is the value of the NSTART= option. For example, for monthly data the seasonal cycle is one year, so NSTART=2 specifies that the first 24 observations at the beginning of each series are used for the time trend regression used to calculate starting values.

The starting values for the seasonal factors for the WINTERS and ADDWINTERS methods are computed from seasonal averages over the first few complete seasonal cycles at the beginning of the series. The number of seasonal cycles averaged to compute starting seasonal factors is controlled by the NSSTART= option. For example, for monthly data with SEASONS=12 or SEASONS=MONTH, the first $n$ January values are averaged to get the starting value for the January seasonal parameter, where $n$ is the value of the NSSTART= option.

The $s_0(i)$ seasonal parameters are set to the ratio (for WINTERS) or difference (for ADDWINTERS) of the mean for the season to the overall mean for the observations used to compute seasonal starting values.

For example, if METHOD=WINTERS, INTERVAL=DAY, SEASON=(MONTH DAY), and NSTART=2 (the default), the initial seasonal parameter for January is the ratio of the mean value over days in the first two Januaries after the start of the series (that is, after the first nonmissing value) to the mean value for all days read for initialization of the seasonal factors. Likewise, the initial factor for Sundays is the ratio of the mean value for Sundays to the mean of all days read.

For the ASTART=, BSTART=, and CSTART= options, the values specified are associated with the variables in the VAR statement in the order in which the variables are listed (the first value with the first variable, the second value with the second variable, and so on). If there are fewer values than variables, default starting values are used for the later variables. If there are more values than variables, the extra values are ignored.

Specifying Seasonality

Seasonality of a time series is a regular fluctuation about a trend. This is called seasonality because the time of year is the most common source of periodic variation. For example, sales of home heating oil are regularly greater in winter than during other times of the year.

Seasonality can be caused by many things other than weather. In the United States, sales of nondurable goods are greater in December than in other months because of the Christmas shopping season. The term seasonality is also used for cyclical fluctuation at periods other than a year. Often, certain days of the week cause regular fluctuation in daily time series, such as increased spending on leisure activities during weekends.
Three kinds of seasonality are supported in PROC FORECAST: time-of-year, day-of-week, and time-of-day. The seasonal part of the model is specified by using the SEASONS= option. The values for the SEASONS= option are listed in Table 16.2.

<table>
<thead>
<tr>
<th>SEASONS= Value</th>
<th>Cycle Length</th>
<th>Type of Seasonality</th>
</tr>
</thead>
<tbody>
<tr>
<td>QTR</td>
<td>yearly</td>
<td>time of year</td>
</tr>
<tr>
<td>MONTH</td>
<td>yearly</td>
<td>time of year</td>
</tr>
<tr>
<td>DAY</td>
<td>weekly</td>
<td>day of week</td>
</tr>
<tr>
<td>HOUR</td>
<td>daily</td>
<td>time of day</td>
</tr>
</tbody>
</table>

The three kinds of seasonality can be combined. For example, SEASONS=(MONTH DAY HOUR) specifies that 24 hour-of-day seasons are nested within 7 day-of-week seasons, which in turn are nested within 12 month-of-year seasons. The different kinds of intervals can be listed in the SEASONS= option in any order. Thus, SEASONS=(HOUR DAY MONTH) is the same as SEASONS=(MONTH DAY HOUR). Note that the Winters method smoothing equations might be less stable when multiple seasonal factors are used.

Multiple period seasons can also be used. For example, SEASONS=QTR2 specifies two semiannual time-of-year seasons. The grouping of observations into multiple period seasons starts with the first interval in the seasonal cycle. Thus, MONTH2 seasons are January–February, March–April, and so on. (There is no provision for shifting seasonal intervals; thus, there is no way to specify seasons December–January, February–March, April–May, and so on.)

For multiple period seasons, the number of intervals combined to form the seasons must evenly divide and be less than the basic cycle length. For example, with SEASONS=MONTHn, the basic cycle length is 12, so MONTH2, MONTH3, MONTH4, and MONTH6 are valid SEASONS= values (because 2, 3, 4, and 6 evenly divide 12 and are less than 12), but MONTH5 and MONTH12 are not valid SEASONS= values.

The frequency of the seasons must not be greater than the frequency of the input data. For example, you cannot specify SEASONS=MONTH if INTERVAL=QTR or SEASONS=MONTH if INTERVAL=MONTH2. You also cannot specify two seasons of the same basic cycle. For example, SEASONS=(MONTH QTR) or SEASONS=(MONTH2 MONTH4) is not allowed.

Alternatively, the seasonality can be specified by giving the number of seasons in the SEASONS= option. SEASONS=n specifies that there are n seasons, with observations 1, n + 1, 2n + 1, and so on in the first season, observations 2, n + 2, 2n + 2, and so on in the second season, and so forth.

The options SEASONS=n and SINTPER=m cause PROC FORECAST to group the input observations into n seasons, with m observations to a season, which repeat every nm observations. The options SEASONS=( n1 n2 ) and SINTPER=( m1 m2 ) produce n1 seasons with m1 observations to a season nested within n2 seasons with n1m1m2 observations to a season.

If the SINTPER=m option is used with the SEASONS= option, the SEASONS= interval is multiplied by the SINTPER= value. For example, specifying both SEASONS=(QTR HOUR) and SINTPER=(2 3) is the same as specifying SEASONS=(QTR2 HOUR3) and also the same as specifying SEASONS=(HOUR3 QTR2).
Data Requirements

You should have ample data for the series that you forecast by using PROC FORECAST. However, the results might be poor unless you have a good deal more than the minimum amount of data the procedure allows. The minimum number of observations required for the different methods is as follows:

- If METHOD=STEPAR is used, the minimum number of nonmissing observations required for each series forecast is the TREND= option value plus the value of the NLAGS= option. For example, using NLAGS=13 and TREND=2, at least 15 nonmissing observations are needed.
- If METHOD=EXPO is used, the minimum is the TREND= option value.
- If METHOD=WINTERS or ADDWINTERS is used, the minimum number of observations is either the number of observations in a complete seasonal cycle or the TREND= option value, whichever is greater. (However, there should be data for several complete seasonal cycles, or the seasonal factor estimates might be poor.) For example, for the seasonal specifications SEASONS=MONTH, SEASONS=(QTR DAY), or SEASONS=(MONTH DAY HOUR), the longest cycle length is one year, so at least one year of data is required. At least two years of data is recommended.

OUT= Data Set

The FORECAST procedure writes the forecast to the output data set named by the OUT= option. The OUT= data set contains the following variables:

- the BY variables
- _TYPE_, a character variable that identifies the type of observation
- _LEAD_, a numeric variable that indicates the number of steps ahead in the forecast. The value of _LEAD_ is 0 for the one-step-ahead forecasts before the start of the forecast period.
- the ID statement variables
- the VAR statement variables, which contain the result values as indicated by the _TYPE_ variable value for the observation

The FORECAST procedure processes each of the input variables listed in the VAR statement and writes several observations for each forecast period to the OUT= data set. The observations are identified by the value of the _TYPE_ variable. The options OUTACTUAL, OUTALL, OUTLIMIT, OUTRESID, OUT1STEP, OUTFULL, and OUTSTD control which types of observations are included in the OUT= data set.

The values of the variable _TYPE_ are as follows:

ACTUAL The VAR statement variables contain actual values from the input data set. The OUTACTUAL option writes the actual values. By default, only the observations for the forecast period are output.
FORECAST
The VAR statement variables contain forecast values. The OUT1STEP option writes the one-step-ahead predicted values for the observations used to fit the model.

RESIDUAL
The VAR statement variables contain residuals. The residuals are computed by subtracting the forecast value from the actual value (residual = actual – forecast). The OUTRESID option writes observations for the residuals.

Lnn
The VAR statement variables contain lower nn % confidence limits for the forecast values for the future observations specified by the LEAD= option. The value of nn depends on the ALPHA= option; with the default ALPHA=0.05, the _TYPE_ value is L95 for the lower confidence limit observations. The OUTLIMIT option writes observations for the upper and lower confidence limits.

Unn
The VAR statement variables contain upper nn % confidence limits for the forecast values for the future observations specified by the LEAD= option. The value of nn depends on the ALPHA= option; with the default ALPHA=0.05, the _TYPE_ value is U95 for the upper confidence limit observations. The OUTLIMIT option writes observations for the upper and lower confidence limits.

STD
The VAR statement variables contain standard errors of the forecast values. The OUTSTD option writes observations for the standard errors of the forecast.

If no output control options are specified, PROC FORECAST outputs only the forecast values for the forecast periods.

The _TYPE_ variable can be used to subset the OUT= data set. For example, the following data step splits the OUT= data set into two data sets, one that contains the forecast series and the other that contains the residual series. For example

```sql
proc forecast out=out outresid ...;
   ... 
run;

data fore resid;
   set out;
   if _TYPE_='FORECAST' then output fore;
   if _TYPE_='RESIDUAL' then output resid;
run;
```

See Chapter 3, “Working with Time Series Data,” for more information about processing time series data sets in this format.

---

**OUTEST= Data Set**

The FORECAST procedure writes the parameter estimates and goodness-of-fit statistics to an output data set when the OUTEST= option is specified. The OUTEST= data set contains the following variables:

- the BY variables
- the first ID variable, which contains the value of the ID variable for the last observation in the input data set used to fit the model
• _TYPE_, a character variable that identifies the type of each observation

• the VAR statement variables, which contain statistics and parameter estimates for the input series. The values contained in the VAR statement variables depend on the _TYPE_ variable value for the observation.

The observations contained in the OUTEST= data set are identified by the _TYPE_ variable. The OUTEST= data set might contain observations with the following _TYPE_ values:

AR1–ARn The observation contains estimates of the autoregressive parameters for the series. Two-digit lag numbers are used if the value of the NLAGS= option is 10 or more; in that case these _TYPE_ values are AR01–ARn. These observations are output for the STEPAR method only.

CONSTANT The observation contains the estimate of the constant or intercept parameter for the time trend model for the series. For the exponential smoothing and the Winters’ methods, the trend model is centered (that is, \( t = 0 \)) at the last observation used for the fit.

LINEAR The observation contains the estimate of the linear or slope parameter for the time trend model for the series. This observation is output only if you specify TREND=2 or TREND=3.

N The observation contains the number of nonmissing observations used to fit the model for the series.

QUAD The observation contains the estimate of the quadratic parameter for the time trend model for the series. This observation is output only if you specify TREND=3.

SIGMA The observation contains the estimate of the standard deviation of the error term for the series.

S1–S3 The observations contain exponentially smoothed values at the last observation. _TYPE_=S1 is the final smoothed value of the single exponential smooth. _TYPE_=S2 is the final smoothed value of the double exponential smooth. _TYPE_=S3 is the final smoothed value of the triple exponential smooth. These observations are output for METHOD=EXPO only.

S_name The observation contains estimates of the seasonal parameters. For example, if SEASONS=MONTH, the OUTEST= data set contains observations with _TYPE_=S_JAN, _TYPE_=S_FEB, _TYPE_=S_MAR, and so forth.

For multiple-period seasons, the names of the first and last interval of the season are concatenated to form the season name. Thus, for SEASONS=MONTH4, the OUTEST= data set contains observations with _TYPE_=S_JANAPR, _TYPE_=S_MAYAUG, and _TYPE_=S_SEPDEC.

When the SEASONS= option specifies numbers, the seasonal factors are labeled _TYPE_=S_i_j. For example, SEASONS=(2 3) produces observations with _TYPE_ values of S_1_1, S_1_2, S_2_1, S_2_2, and S_2_3. The observation with _TYPE_=S_i_j contains the seasonal parameters for the jth season of the ith seasonal cycle. These observations are output only for METHOD=WINTERS or METHOD=ADDWINTERS.

WEIGHT The observation contains the smoothing weight used for exponential smoothing. This is the value of the WEIGHT= option. This observation is output for METHOD=EXPO only.
WEIGHT1 | WEIGHT2 | WEIGHT3  The observations contain the weights used for smoothing the WINTERS or ADDWINTERS method parameters (specified by the WEIGHT= option). _TYPE_=WEIGHT1 is the weight used to smooth the CONSTANT parameter. _TYPE_=WEIGHT2 is the weight used to smooth the LINEAR and QUAD parameters. _TYPE_=WEIGHT3 is the weight used to smooth the seasonal parameters. These observations are output only for the WINTERS and ADDWINTERS methods.

NRESID  The observation contains the number of nonmissing residuals, \( n \), used to compute the goodness-of-fit statistics. The residuals are obtained by subtracting the one-step-ahead predicted values from the observed values.

SST  The observation contains the total sum of squares for the series, corrected for the mean. 
\[
SST = \sum_{t=1}^{n} (y_t - \bar{y})^2,
\]
where \( \bar{y} \) is the series mean.

SSE  The observation contains the sum of the squared residuals, uncorrected for the mean. 
\[
SSE = \sum_{t=1}^{n} (y_t - \hat{y}_t)^2,
\]
where \( \hat{y}_t \) is the one-step predicted value for the series.

MSE  The observation contains the mean squared error, calculated from one-step-ahead forecasts. 
\[
MSE = \frac{1}{n-k} SSE,
\]
where \( k \) is the number of parameters in the model.

RMSE  The observation contains the root mean squared error. 
\[
RMSE = \sqrt{MSE}.
\]

MAPE  The observation contains the mean absolute percent error. 
\[
MAPE = \frac{100}{n} \sum_{t=1}^{n} \frac{\left| y_t - \hat{y}_t \right|}{y_t}.
\]

MPE  The observation contains the mean percent error. 
\[
MPE = \frac{100}{n} \sum_{t=1}^{n} \frac{y_t - \hat{y}_t}{y_t}.
\]

MAE  The observation contains the mean absolute error. 
\[
MAE = \frac{1}{n} \sum_{t=1}^{n} \left| y_t - \hat{y}_t \right|.
\]

ME  The observation contains the mean error. 
\[
ME = \frac{1}{n} \sum_{t=1}^{n} (y_t - \hat{y}_t).
\]

MAXE  The observation contains the maximum error (the largest residual).

MINE  The observation contains the minimum error (the smallest residual).

MAXPE  The observation contains the maximum percent error.

MINPE  The observation contains the minimum percent error.

RSQUARE  The observation contains the R square statistic, 
\[
R^2 = 1 - \frac{SSE}{SST}.
\]
If the model fits the series badly, the model error sum of squares \( SSE \) might be larger than \( SST \) and the R square statistic will be negative.

ADJRSQ  The observation contains the adjusted R square statistic. 
\[
ADJRSQ = 1 - \left( \frac{n-1}{n-k} \right)(1 - R^2).
\]

ARSQ  The observation contains Amemiya’s adjusted R square statistic. 
\[
ARSQ = 1 - \left( \frac{n+k}{n-k} \right)(1 - R^2).
\]

RW_RSQ  The observation contains the random walk R square statistic (Harvey’s \( R^2_W \) statistic that uses the random walk model for comparison). 
\[
RW_RSQ = 1 - \left( \frac{n-1}{n} \right) SSE / RWSSE,
\]
where \( RWSSE = \sum_{t=2}^{n} (y_t - y_{t-1} - \mu)^2 \) and \( \mu = \frac{1}{n-1} \sum_{t=2}^{n} (y_t - y_{t-1}) \).

AIC  The observation contains Akaike’s information criterion. 
\[
AIC = n \ln(SSE/n) + 2k.
\]
Chapter 16: The FORECAST Procedure

SBC The observation contains Schwarz’s Bayesian criterion.
\[ SBC = n \ln(SSE/n) + k \ln(n). \]

APC The observation contains Amemiya’s prediction criterion.
\[ APC = \frac{1}{n} SST \left( \frac{n+k}{n-k} \right)(1-R^2) = \left( \frac{n+k}{n-k} \right) \frac{1}{n} SSE. \]

CORR The observation contains the correlation coefficient between the actual values and the one-step-ahead predicted values.

THEILU The observation contains Theil’s U statistic that uses original units. See Maddala (1977, pp. 344–345), and Pindyck and Rubinfeld (1981, pp. 364–365) for more information about Theil statistics.

RTHEILU The observation contains Theil’s U statistic calculated using relative changes.

THEILUM The observation contains the bias proportion of Theil’s U statistic.

THEILUS The observation contains the variance proportion of Theil’s U statistic.

THEILUC The observation contains the covariance proportion of Theil’s U statistic.

THEILUR The observation contains the regression proportion of Theil’s U statistic.

THEILUD The observation contains the disturbance proportion of Theil’s U statistic.

RTHEILUM The observation contains the bias proportion of Theil’s U statistic, calculated by using relative changes.

RTHEILUS The observation contains the variance proportion of Theil’s U statistic, calculated by using relative changes.

RTHEILUC The observation contains the covariance proportion of Theil’s U statistic, calculated by using relative changes.

RTHEILUR The observation contains the regression proportion of Theil’s U statistic, calculated by using relative changes.

RTHEILUD The observation contains the disturbance proportion of Theil’s U statistic, calculated by using relative changes.

Examples: FORECAST Procedure

Example 16.1: Forecasting Auto Sales

This example uses the Winters method to forecast the monthly U. S. sales of passenger cars series (VEHICLES) from the data set SASHELP.USECON. These data are taken from Business Statistics, published by the U. S. Bureau of Economic Analysis.

The following statements plot the series. The plot is shown in Output 16.1.1.

```
title1 "Sales of Passenger Cars";
symbol1 i=spline v=dot;
```
Example 16.1: Forecasting Auto Sales

Output 16.1.1  Monthly Passenger Car Sales

The following statements produce the forecast:

```
proc forecast data=sashelp.usecon interval=month
   method=winters seasons=month lead=12
   out=out outfull outresid outest=est;
   id date;
   var vehicles;
   where date >= '1jan80'd;
run;
```
The INTERVAL=MONTH option indicates that the data are monthly, and the ID DATE statement gives the
dating variable. The METHOD=WINTERS specifies the Winters smoothing method. The LEAD=12 option
forecasts 12 months ahead. The OUT=OUT option specifies the output data set, while the OUTFULL and
OUTRESID options include in the OUT= data set the predicted and residual values for the historical period
and the confidence limits for the forecast period. The OUTEST= option stores various statistics in an output
data set. The WHERE statement is used to include only data from 1980 on.

The following statements print the OUT= data set (first 20 observations):

```sql
title2 'The OUT= Data Set';
proc print data=out (obs=20) noobs;
run;
```

The listing of the output data set produced by PROC PRINT is shown in part in Output 16.1.2.

**Output 16.1.2** The OUT= Data Set Produced by PROC FORECAST (First 20 Observations)

Overview: LOAN Procedure

The LOAN procedure analyzes and compares fixed rate, adjustable rate, buydown, and balloon payment loans. The LOAN procedure computes the loan parameters and outputs the loan summary information for each loan.

Multiple loan specifications can be processed and compared in terms of economic criteria such as after-tax or before-tax present worth of cost and true interest rate, breakeven of periodic payment and of interest paid, and outstanding balance at different periods in time. PROC LOAN selects the best alternative in terms of the specified economic criterion for each loan comparison period.

The LOAN procedure allows various payment and compounding intervals (including continuous compounding) and uniform or lump sum prepayments for a loan. Down payments, discount points, and other initialization costs can be included in the loan analysis and comparison.

The LOAN procedure does not support an input data set. All loans analyzed are specified with statements in the PROC LOAN step. The SAS DATA step provides a function MORT that can be used for data-driven analysis of many fixed-rate mortgage or installment loans. However, the MORT function supports only simple fixed rate loans.

Getting Started: LOAN Procedure

PROC LOAN supports four types of loans. You specify each type of loan with the corresponding statement: FIXED, BALLOON, ARM, and BUYDOWN.

- FIXED—Fixed rate loans have a constant interest rate and periodic payment throughout the life of the loan.

- BALLOON—Balloon payment loans are fixed rate loans with lump sum payments in certain payment periods in addition to the constant periodic payment.

- ARM—Adjustable rate loans are those in which the interest rate and periodic payment vary over the life of the loan. The future interest rates of an adjustable rate loan are not known with certainty, but they will vary within specified limits according to terms stated in the loan agreement. In practice, the rate adjustment terms vary. PROC LOAN offers a flexible set of options to capture a wide variety of rate adjustment terms.

- BUYDOWN—Buydown rate loans are similar to adjustable rate loans, but the interest rate adjustments are predetermined at the initialization of the loan, usually by paying interest points at the time of loan initialization.
Analyzing Fixed Rate Loans

The most common loan analysis is the calculation of the periodic payment when the loan amount, life, and interest rate are known. The following PROC LOAN statements analyze a 15-year (180 monthly payments) fixed rate loan for $100,000 with an annual nominal interest rate of 7.5%:

```sas
proc loan;
   fixed amount=100000 rate=7.5 life=180;
run;
```

Another parameter the PROC LOAN statement can compute is the maximum amount you can borrow given the periodic payment you can afford and the rates available in the market. The following SAS statements analyze a loan for 180 monthly payments of $900, with a nominal annual rate of 7.5%, and compute the maximum amount that can be borrowed:

```sas
proc loan;
   fixed payment=900 rate=7.5 life=180;
run;
```

Assume that you want to borrow $100,000 and can pay $900 a month. You know that the lender charges a 7.5% nominal interest rate compounded monthly. To determine how long it will take you to pay off your debt, use the following statements:

```sas
proc loan;
   fixed amount=100000 payment=900 rate=7.5;
run;
```

Sometimes, a loan is expressed in terms of the amount borrowed and the amount and number of periodic payments. In this case, you want to calculate the annual nominal rate charged on the loan to compare it to other alternatives. The following statements analyze a loan of $100,000 paid in 180 monthly payments of $800:

```sas
proc loan;
   fixed amount=100000 payment=800 life=180;
run;
```

There are four basic parameters that define a loan: life (number of periodic payments), principal amount, interest rate, and the periodic payment amount. PROC LOAN calculates the missing parameter among these four. Loan analysis output includes a loan summary table and an amortization schedule.

You can use the START= and LABEL= options to enhance your output. The START= option specifies the date of loan initialization and dates all the output accordingly. The LABEL= specification is used to label all output that corresponds to a particular loan; it is especially useful when multiple loans are analyzed. For example, the preceding statements for the first fixed rate loan are revised to include the START= and LABEL= options as follows:
proc loan start=1998:12;
    fixed amount=100000 rate=7.5 life=180
    label='BANK1, Fixed Rate';
run;

Loan Summary Table

The loan summary table is produced by default and contains loan analysis information. It shows the principal amount, the costs at the time of loan initialization (down payment, discount points, and other loan initialization costs), the total payment and interest, the initial nominal and effective interest rates, payment and compounding intervals, the length of the loan in the time units specified, the start and end dates (if specified), a list of nominal and effective interest rates, and periodic payments throughout the life of the loan.

Figure 17.1 shows the loan summary table for the fixed rate loan labeled “BANK1, Fixed Rate.”

| Downpayment 0.00 | Principal Amount 100000.00 |
| Initialization 0.00 | Points 0.00 |
| Total Interest 66862.61 | Nominal Rate 7.5000% |
| Total Payment 166862.61 | Effective Rate 7.7633% |
| Pay Interval MONTHLY | Compounding MONTHLY |
| No. of Payments 180 | No. of Compoundings 180 |
| Start Date DEC1998 | End Date DEC2013 |
| Rates and Payments for BANK1, Fixed Rate |
| Date DEC1998 | Nominal Rate 7.5000% | Effective Rate 7.7633% | Payment 927.01 |

The loan is initialized in December 1998 and paid off in December 2013. The monthly payment is calculated to be $927.01, and the effective interest rate is 7.7633%. Over the 15 years, $66,862.61 is paid for interest charges on the loan.

Analyzing Balloon Payment Loans

You specify balloon payment loans like fixed rate loans, with the additional specification of the balloon payments. Assume you have an alternative to finance the $100,000 investment with a 15-year balloon payment loan. The annual nominal rate is 7.5%, as in the fixed rate loan. The terms of the loan require two balloon payments of $2000 and $1000 at the 15th and 48th payment periods, respectively. These balloon payments keep the periodic payment lower than that of the fixed rate loan. The balloon payment loan is defined by the following BALLOON statement:
List of Balloon Payments

In addition to the information for the fixed rate loan, the “Loan Summary Table” for the balloon payment loan includes a list of balloon payments in the list of rates and payments. For example, the balloon payment loan described previously includes two balloon payments, as shown in Figure 17.2.

Figure 17.2  List of Rates and Payments for a Balloon Payment Loan

<table>
<thead>
<tr>
<th>Date</th>
<th>Nominal Rate</th>
<th>Effective Rate</th>
<th>Payment</th>
</tr>
</thead>
<tbody>
<tr>
<td>DEC1998</td>
<td>7.5000%</td>
<td>7.7633%</td>
<td>903.25</td>
</tr>
</tbody>
</table>

The periodic payment for the balloon payment loan is $23.76 less than that of the fixed rate loan.

Analyzing Adjustable Rate Loans

In addition to specifying the basic loan parameters, you need to specify the terms of the rate adjustments for an adjustable rate loan. There are many ways of stating the rate adjustment terms, and PROC LOAN facilitates all of them. For details, see the section “Rate Adjustment Terms Options” on page 951.

Assume that you have an alternative to finance the $100,000 investment with a 15-year adjustable rate loan with an initial annual nominal interest rate of 5.5%. The rate adjustment terms specify a 0.5% annual cap, a 2.5% life cap, and a rate adjustment every 12 months. Annual cap refers to the maximum increase in interest rate per adjustment period, and life cap refers to the maximum increase over the life of the loan. The following ARM statement specifies this adjustable rate loan by assuming the interest rate adjustments will always increase by the maximum allowed by the terms of the loan. These assumptions are specified by the WORSTCASE and CAPS= options, as shown in the following statements:
proc loan start=1998:12;
    arm amount=100000 rate=5.5 life=180 worstcase
caps=(0.5, 2.5)
    label='BANK3, Adjustable Rate';
run;

List of Rates and Payments for Adjustable Rate Loans

The list of rates and payments in the loan summary table for the adjustable rate loans reflects the changes in the interest rates and payments and the dates these changes become effective. For the adjustable rate loan described previously, Figure 17.3 shows the list of rates and payments that indicate five annual rate adjustments in addition to the initial rate and payment.

Figure 17.3  List of Rates and Payments for an Adjustable Rate Loan

<table>
<thead>
<tr>
<th>Date</th>
<th>Nominal Rate</th>
<th>Effective Rate</th>
<th>Payment</th>
</tr>
</thead>
<tbody>
<tr>
<td>DEC1998</td>
<td>5.5000%</td>
<td>5.6408%</td>
<td>817.08</td>
</tr>
<tr>
<td>JAN2000</td>
<td>6.0000%</td>
<td>6.1678%</td>
<td>842.33</td>
</tr>
<tr>
<td>JAN2001</td>
<td>6.5000%</td>
<td>6.6972%</td>
<td>866.44</td>
</tr>
<tr>
<td>JAN2002</td>
<td>7.0000%</td>
<td>7.2290%</td>
<td>889.32</td>
</tr>
<tr>
<td>JAN2003</td>
<td>7.5000%</td>
<td>7.7633%</td>
<td>910.88</td>
</tr>
<tr>
<td>JAN2004</td>
<td>8.0000%</td>
<td>8.3000%</td>
<td>931.03</td>
</tr>
</tbody>
</table>

Notice that the periodic payment of the adjustable rate loan as of January 2004 ($931.03) exceeds that of the fixed rate loan ($927.01).

Analyzing Buydown Rate Loans

A 15-year buydown rate loan is another alternative to finance the $100,000 investment. The nominal annual interest rate is 6.5% initially and will increase to 8% and 9% as of the 24th and 48th payment periods, respectively. The nominal annual interest rate is lower than that of the fixed rate alternative, at the cost of a 1% discount point ($1000) paid at the initialization of the loan. The following BUYDOWN statement represents this loan alternative:

proc loan start=1998:12;
    buydown amount=100000 rate=6.5 life=180
    buydownrates=(24=8 48=9) pointpct=1
    label='BANK4, Buydown';
run;

List of Rates and Payments for Buydown Rate Loans

Figure 17.4 shows the list of rates and payments in the loan summary table. It reflects the two rate adjustments and the corresponding monthly payments as well as the initial values for these parameters. As of December
2000, the periodic payment of the buydown loan exceeds the periodic payment for any of the other alternatives.

**Figure 17.4** List of Rates and Payments for a Buydown Rate Loan

<table>

<td>8.3000%</td>
<td>946.50</td>
</tr>
<tr>
<td>DEC2002</td>
<td>9.0000%</td>
<td>9.3807%</td>
<td>992.01</td>
</tr>
</tbody>
</table>

**Loan Repayment Schedule**

In addition to the loan summary, you can print a loan repayment (amortization) schedule for each loan. For each payment period, this schedule contains the year and period within the year (or date, if the START= option is specified), the principal balance at the beginning of the period, the total payment, interest payment, principal repayment for the period, and the principal balance at the end of the period.

To print the first year of the amortization schedule for the fixed rate loan shown in Figure 17.5, use the following statements:

```plaintext
proc loan start=1998:12;
   fixed amount=100000 rate=7.5 life=180
   schedule=1
   label='BANK1, Fixed Rate';
run;
```
The principal balance at the end of one year is $96,248.67. The total payment for the year is $11,124.12, of which $3,751.33 went toward principal repayment.

You can also print the amortization schedule with annual summary information or for a specified number of years. The SCHEDULE=YEARLY option produces an annual summary loan amortization schedule, which is useful for loans with a long life. For example, to print the annual summary loan repayment schedule for the buydown loan shown in Figure 17.6, use the following statements:

```r
proc loan start=1998:12;
   buydown amount=100000 rate=6.5 life=180
       buydownrates=(24=8 48=9) pointpct=1
       schedule=yearly
       label='BANK4, Buydown';
run;
```
Loan Comparison

The LOAN procedure can compare alternative loans on the basis of different economic criteria and help select the most desirable loan. You can compare alternative loans through different points in time. The economic criteria offered by PROC LOAN are:

- outstanding principal balance—that is, the unpaid balance of the loan

- present worth of cost—that is, before-tax or after-tax net value of the loan cash flow through the comparison period. The cash flow includes all payments, discount points, initialization costs, down payment, and the outstanding principal balance at the comparison period.

- true interest rate—that is, before-tax or after-tax effective annual interest rate charged on the loan. The cash flow includes all payments, discount points, initialization costs, and the outstanding principal balance at the specified comparison period.

- periodic payment

- the total interest paid on the loan

The figures for present worth of cost, true interest rate, and interest paid are reported on the cash flow through the comparison period. The reported outstanding principal balance and the periodic payment are the values as of the comparison period.
The COMPARE statement specifies the type of comparison and the periods of comparison. For each period specified in the COMPARE statement, a loan comparison report is printed that also indicates the best alternative. Different criteria can lead to selection of different alternatives. Also, the period of comparison might change the desirable alternative. See the section “Loan Comparison Details” on page 957 for further information.

**Comparison of 15-Year versus 30-Year Loan Alternatives**

An issue that arises in the purchase of a house is the length of the loan life. Residential home loans are often for 15 or 30 years. Ordinarily, 15-year loans have a lower interest rate but higher periodic payments than 30-year loans. A comparison of both loans might identify the better loan for your means and needs. The following SAS statements compare two such loans:

```sas
proc loan start=1998:12 amount=120000;
   fixed rate=7.5 life=360 label='30 year loan';
   fixed rate=6.5 life=180 label='15 year loan';
   compare;
run;
```

**Default Loan Comparison Report**

The default loan comparison report in Figure 17.7 shows the ending outstanding balance, periodic payment, interest paid, and before-tax true rate at the end of 30 years. In the case of the default loan comparison, the selection of the best alternative is based on minimization of the true rate.

**Figure 17.7 Default Loan Comparison Report**

<table>
<thead>
<tr>
<th>Loan Label</th>
<th>Ending Outstanding</th>
<th>Interest Paid</th>
<th>True Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>30 year loan</td>
<td>0.00</td>
<td>835.48</td>
<td>182058.02</td>
</tr>
<tr>
<td>15 year loan</td>
<td>0.00</td>
<td>1044.95</td>
<td>68159.02</td>
</tr>
</tbody>
</table>

**NOTE:** "15 year loan" is the best alternative based on true rate analysis through DEC2028.

Based on true rate, the best alternative is the 15-year loan. However, if the objective were to minimize the periodic payment, the 30-year loan would be the more desirable.

**Comparison of Fixed Rate and Adjustable Rate Loans**

Suppose you want to compare a fixed rate loan to an adjustable rate alternative. The nominal interest rate on the adjustable rate loan is initially 1.5% lower than the fixed rate loan. The future rates of the adjustable rate loan are calculated using the worst case scenario.
The interest paid on a loan might be deductible for tax purposes, depending on the purpose of the loan and applicable laws. In the following example, the TAXRATE=28 (income tax rate) option in the COMPARE statement bases the calculations of true interest rate on the after-tax cash flow. Assume, also, that you are uncertain as to how long you will keep this property. The AT=(60 120) option, as shown in the following example, produces two loan comparison reports through the end of the 5th and the 10th years, respectively:

```plaintext
proc loan start=1998:12 amount=120000 life=360;
  fixed rate=7.5 label='BANK1, Fixed Rate';
  arm rate=6.0 worstcase caps=(0.5 2.5) label='BANK3, Adjustable Rate';
  compare taxrate=28 at=(60 120);
run;
```

### After-Tax Loan Comparison Reports
The two loan comparison reports in Figure 17.8 and Figure 17.9 show the ending outstanding balance, periodic payment, interest paid, and after-tax true rate at the end of five years and ten years, respectively.

#### Figure 17.8 Loan Comparison Report as of December 2003

<table>
<thead>
<tr>
<th>Loan Label</th>
<th>Ending Outstanding</th>
<th>Interest Paid</th>
<th>True Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>BANK1, Fixed Rate</td>
<td>113540.74</td>
<td>43884.34</td>
<td>5.54</td>
</tr>
<tr>
<td>BANK3, Adjustable Rate</td>
<td>112958.49</td>
<td>40701.93</td>
<td>5.11</td>
</tr>
</tbody>
</table>

NOTE: "BANK3, Adjustable Rate" is the best alternative based on true rate analysis through DEC2003.

#### Figure 17.9 Loan Comparison Report as of December 2008

<table>
<thead>
<tr>
<th>Loan Label</th>
<th>Ending Outstanding</th>
<th>Interest Paid</th>
<th>True Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>BANK1, Fixed Rate</td>
<td>104153.49</td>
<td>84840.69</td>
<td>5.54</td>
</tr>
<tr>
<td>BANK3, Adjustable Rate</td>
<td>104810.98</td>
<td>87128.62</td>
<td>5.60</td>
</tr>
</tbody>
</table>

NOTE: "BANK1, Fixed Rate" is the best alternative based on true rate analysis through DEC2008.
The loan comparison report through December 2003 picks the adjustable rate loan as the best alternative, whereas the report through December 2008 shows the fixed rate loan as the better alternative. This implies that if you intend to keep the loan for 10 years or longer, the best alternative is the fixed rate alternative. Otherwise, the adjustable rate loan is the better alternative in spite of the worst-case scenario. Further analysis shows that the actual breakeven of true interest rate occurs at August 2008. That is, the desirable alternative switches from the adjustable rate loan to the fixed rate loan in August 2008.

Note that, under the assumption of worst-case scenario for the rate adjustments, the periodic payment for the adjustable rate loan already exceeds that of the fixed rate loan on December 2003 (as of the rate adjustment on January 2003 to be exact). If the objective were to minimize the periodic payment, the fixed rate loan would have been more desirable as of December 2003. However, all of the other criteria at that point still favor the adjustable rate loan.

Syntax: LOAN Procedure

The following statements are used with PROC LOAN:

```plaintext
PROC LOAN options ;
FIXED options ;
BALLOON options ;
ARM options ;
BUYDOWN options ;
COMPARE options ;
```

Functional Summary

Table 17.1 summarizes the statements and options that control the LOAN procedure. Many of the loan specification options can be used on all of the statements except the COMPARE statement. For these options, the statement column is left blank. Options specific to a type of loan indicate the statement name.

**Required Specifications**

- specify the loan amount
- specify life of loan as number of payments
- specify the periodic payment
- specify the initial annual nominal interest rate

**Loan Specifications Options**

- specify loan amount as percentage of price
- specify time interval between compoundings
- specify down payment at loan initialization
- specify down payment as percentage of price
- specify amount paid for loan initialization
- specify initialization costs as a percent
- specify time interval between payments
- specify label for the loan
- specify amount paid for discount points
- specify discount points as a percent
- specify uniform or lump sum prepayments
- specify the purchase price
- specify number of decimal places for rounding
- specify the date of loan initialization

**Balloon Payment Loan Specification Option**

- specify the list of balloon payments

**Rate Adjustment Terms Options**

- specify frequency of rate adjustments
- specify periodic and life cap on rate adjustment
- specify maximum rate adjustment
- specify maximum annual nominal interest rate
- specify minimum annual nominal interest rate

**Rate Adjustment Case Options**

- specify best-case (optimistic) scenario
- specify predicted interest rates
- specify constant rate
- specify worst case (pessimistic) scenario

**Buydown Rate Loan Specification Option**

- specify list of nominal interest rates

PROC LOAN Statement

PROC LOAN options;

The OUTSUM= option can be used in the PROC LOAN statement. In addition, the following loan specification options can be specified in the PROC LOAN statement to be used as defaults for all loans unless otherwise specified for a given loan:

- AMOUNT=
- AMOUNTPCT=
- COMPOUND=
- DOWNPAYMENT=
- DOWNPAYPCT=
- INITIAL=
- INITIALPCT=
- INTERVAL=
- LABEL=
- LIFE=
- NOSUMMARYPRINT=
- POINTPCT=
- PREPAYMENTS=
- PRICE=
- RATE=
- NOSUMMARYPRINT=
- POINTS=
- SCHEDULE=
- ROUND=
- START=

Output Option

OUTSUM= SAS-data-set

creates an output data set that contains loan summary information for all loans other than those for which a different OUTSUM= output data set is specified.

FIXED Statement

FIXED options;

The FIXED statement specifies a fixed rate and periodic payment loan. It can be specified using the options that are common to all loan statements. The FIXED statement options are listed in this section.

You must specify three of the following options in each loan statement: AMOUNT=, LIFE=, RATE=, and PAYMENT=. The LOAN procedure calculates the fourth parameter based on the values you give the other three. If you specify all four of the options, the PAYMENT= specification is ignored, and the periodic payment is recalculated for consistency.
As an alternative to specifying the AMOUNT= option, you can specify the PRICE= option along with one of the following options to facilitate the calculation of the loan amount: AMOUNTPCT=, DOWNPAYMENT=, or DOWNPAYPCT=.

### Required Specifications

**AMOUNT=** *amount*

A= *amount*

specifies the loan amount (the outstanding principal balance at the initialization of the loan).

**LIFE=** *n*

L= *n*

gives the life of the loan in number of payments. (The payment frequency is specified by the INTERVAL= option.) For example, if the life of the loan is 10 years with monthly payments, use LIFE=120 and INTERVAL=MONTH (default) to indicate a 10-year loan in which 120 monthly payments are made.

**PAYMENT=** *amount*

P= *amount*

specifies the periodic payment. For ARM and BUYDOWN loans where the periodic payment might change, the PAYMENT= option specifies the initial amount of the periodic payment.

**RATE=** *rate*

R= *rate*

specifies the initial annual (nominal) interest rate in percent notation. The rate specified must be in the range 0% to 120%. For example, use RATE=12.75 for a 12.75% loan. For ARM and BUYDOWN loans, where the rate might change over the life of the loan, the RATE= option specifies the initial annual interest rate.

### Specification Options

**AMOUNTPCT=** *value*

APCT= *value*

specifies the loan amount as a percentage of the purchase price (PRICE= option). The AMOUNTPCT= specification is used to calculate the loan amount if the AMOUNT= option is not specified. The value specified must be in the range 1% to 100%.

If both the AMOUNTPCT= and DOWNPAYPCT= options are specified and the sum of their values is not equal to 100, the value of the downpayment percentage is set equal to 100 minus the value of the amount percentage.

**COMPOUND=** *time-unit*

specifies the time interval between compoundings. The default is the time unit given by the INTERVAL= option. If the INTERVAL= option is not used, then the default is COMPOUND=MONTH. The following time units are valid COMPOUND= values: CONTINUOUS, DAY, SEMIMONTH, MONTH, QUARTER, SEMIYEAR, and YEAR. The compounding interval is used to calculate the simple interest rate per payment period from the nominal annual interest rate or vice versa.
**DOWNPAYMENT=** *amount*

*DP=amount*
specifies the down payment at the initialization of the loan. The down payment is included in the calculation of the present worth of cost but not in the calculation of the true interest rate. The after-tax analysis assumes that the down payment is not tax-deductible. (Specify after-tax analysis with the TAXRATE= option in the COMPARE statement.)

**DOWNPAYPCT=** *value*

*DPCT=value*
specifies the down payment as a percentage of the purchase price (PRICE= option). The DOWNPAYPCT= specification is used to calculate the down payment amount if you do not specify the DOWNPAYMENT= option. The value you specify must be in the range 0% to 99%.

If you specified both the AMOUNTPCT= and DOWNPAYPCT= options and the sum of their values is not equal to 100, the value of the downpayment percentage is set equal to 100 minus the value of the amount percentage.

**INITIAL=** *amount*

*INIT=amount*
specifies the amount paid for loan initialization other than the discount points and down payment. This amount is included in the calculation of the present worth of cost and the true interest rate. The after-tax analysis assumes that the initial amount is not tax-deductible. (After-tax analysis is specified by the TAXRATE= option in the COMPARE statement.)

**INITIALPCT=** *value*

*INITPCT=value*
specifies the initialization costs as a percentage of the loan amount (AMOUNT= option). The INITIALPCT= specification is used to calculate the amount paid for loan initialization if you do not specify the INITIAL= option. The value you specify must be in the range of 0% to 100%.

**INTERVAL=** *time-unit*
gives the time interval between periodic payments. The default is INTERVAL=MONTH. The following time units are valid INTERVAL values: SEMIMONTH, MONTH, QUARTER, SEMIYEAR, and YEAR.

**LABEL=’loan-label’**
specifies a label for the loan. If you specify the LABEL= option, all output related to the loan is labeled accordingly. If you do not specify the LABEL= option, the loan is labeled by sequence number.

**POINTS=** *amount*

*PNT=amount*
specifies the amount paid for discount points at the initialization of the loan. This amount is included in the calculation of the present worth of cost and true interest rate. The amount paid for discount points is assumed to be tax-deductible in after-tax analysis (that is, if the TAXRATE= option is specified in the COMPARE statement).

**POINTPCT=** *value*
PNTPCT=value

specifies the discount points as a percentage of the loan amount (AMOUNT= option). The POINTPCT=
specification is used to calculate the amount paid for discount points if you do not specify the POINTS=
option. The value you specify must be in the range of 0% to 100%.

PREPAYMENTS=amount

PREPAYMENTS=( date1=prepayment1 date2=prepayment2 ... )

PREPAYMENTS=( period1=prepayment1 period2=prepayment2 ... )

PREP=

specifies either a uniform prepayment $p$ throughout the life of the loan or lump sum prepayments.
A uniform prepayment $p$ is assumed to be paid with each periodic payment. Specify lump sum
prepayments by pairs of periods (or dates) and respective prepayment amounts.

You can specify the prepayment periods as dates if you specify the START= option. Prepayment
periods or dates and the respective prepayment amounts must be in time sequence. The prepayments
are treated as principal payments, and the outstanding principal balance is adjusted accordingly. In the
adjustable rate and buydown rate loans, if there is a rate adjustment after prepayments, the adjusted
periodic payment is calculated based on the outstanding principal balance. The prepayments do not
result in periodic payment amount adjustments in fixed rate and balloon payment loans.

PRICE=amount

PRC=amount

specifies the purchase price, which is the loan amount plus the down payment. If you specify the
PRICE= option along with the loan amount (AMOUNT= option) or the down payment (DOWNPAY-
MENT= option), the value of the other one is calculated.

If you specify the PRICE= option with the AMOUNTPCT= or DOWNPAYPCT= options, the loan
amount and the downpayment are calculated.

ROUND=n

ROUND=None

specifies the number of decimal places to which the monetary amounts are rounded for the loan. Valid
values for $n$ are integers from 0 to 6. If you specify ROUND=None, the values are not rounded off
internally, but the printed output is rounded off to two decimal places. The default is ROUND=2.

START=SAS-date-literal

START=yyyy:period

S=

gives the date of loan initialization. The first payment is assumed to be one payment interval after
the start date. For example, you can specify the START= option as START='1APR2010'D or as
START=2010:3, where 3 is the third payment interval within the year 2010. If INTERVAL=QUARTER,
3 refers to the third quarter. If you specify the START= option, all output for the particular loan is
dated accordingly.
Chapter 17: The LOAN Procedure

Output Options

NOSUMMARYPRINT

NOSUMPR

suppresses the printing of the loan summary report. The NOSUMMARYPRINT option is usually used when an OUTSUM= data set is created to store loan summary information.

NOPRINT

NOP

suppresses all printed output for the loan.

OUT=SAS-data-set

writes the loan amortization schedule to an output data set.

OUTSUM=SAS-data-set

writes the loan summary for the individual loan to an output data set.

SCHEDULE

SCHEDULE=nyears

SCHEDULE=YEARLY

SCHED

prints the amortization schedule for the loan. SCHEDULE=nyears specifies the number of years the printed amortization table covers. If you omit the number of years or specify a period longer than the loan life, the schedule is printed for the full term of the loan. SCHEDULE=YEARLY prints yearly summary information in the amortization schedule rather than the full amortization schedule. SCHEDULE=YEARLY is useful for long-term loans.

BALLOON Statement

BALLOON options ;

The BALLOON statement specifies a fixed rate loan with scheduled balloon payments in addition to the periodic payment. The following option is used in the BALLOON statement, in addition to the required options listed under the FIXED statement:

BALLOONPAYMENT=( date1=payment1 date2=payment2 ... )

BALLOONPAYMENT=( period1=payment1 period2=payment2 ... )

BPAY=( date1=payment1 date2=payment2 ... )

BPAY=( period1=payment1 period2=payment2 ... )

specifies pairs of periods and amounts of balloon (lump sum) payments in excess of the periodic payment during the life of the loan. You can also specify the balloon periods as dates if you specify the START= option. The dates are specified as SAS date literals. For example, BALLOONPAYMENT= ( ‘1MAR2011’ D=1000 ) specifies a payment of 1000 in March of 2011.

If you do not specify this option, the calculations are identical to a loan specified in a FIXED statement. Balloon periods (or dates) and the respective balloon payments must be in time sequence.
**ARM Statement**

**ARM options ;**

The ARM statement specifies an adjustable rate loan where the future interest rates are not known with certainty but will vary within specified limits according to the terms stated in the loan agreement. In practice, the adjustment terms vary. Adjustments in the interest rate can be captured using the ARM statement options.

In addition to the required specifications and options listed under the FIXED statement, you can use the following options with the ARM statement.

**Rate Adjustment Terms Options**

**ADJUSTFREQ=n**

specifies the number of periods, in terms of the INTERVAL= specification, between rate adjustments. 

**INTERVAL=MONTH ADJUSTFREQ=6** indicates that the nominal interest rate can be adjusted every six months until the life cap or maximum rate (whichever is specified) is reached. The default is **ADJUSTFREQ=12**. The periodic payment is adjusted every adjustment period even if there is no rate change; therefore, if prepayments are made (as specified with the PREPAYMENTS= option), the periodic payment might change even if the nominal rate does not.

**CAPS=( periodic-cap, life-cap )**

specifies the maximum interest rate adjustment, in percent notation, allowed by the loan agreement. The **periodic cap** specifies the maximum adjustment allowed at each adjustment period. The **life cap** specifies the maximum total adjustment over the life of the loan. For example, a loan specified with **CAPS=(0.5, 2)** indicates that the nominal interest rate can change by 0.5% each adjustment period, and the annual nominal interest rate throughout the life of the loan will be within a 2% range of the initial annual nominal rate.

**MAXADJUST=rate**

**MAXAD=rate**

specifies the maximum rate adjustment, in percent notation, allowed at each adjustment period. Use the MAXADJUST= option with the MAXRATE= and MINRATE= options. The initial nominal rate plus the maximum adjustment should not exceed the specified MAXRATE= value. The initial nominal rate minus the maximum adjustment should not be less than the specified MINRATE= value.

**MAXRATE=rate**

**MAXR=rate**

specifies the maximum annual nominal rate, in percent notation, that might be charged on the loan. The maximum annual nominal rate should be greater than or equal to the initial annual nominal rate specified with the RATE= option.

**MINRATE=rate**

**MINR=rate**

specifies the minimum annual nominal rate, in percent notation, that might be charged on the loan. The minimum annual nominal rate should be less than or equal to the initial annual nominal rate specified with the RATE= option.
Chapter 17: The LOAN Procedure

Rate Adjustment Case Options

PROC LOAN supports four rate adjustment scenarios for analysis of adjustable rate loans: pessimistic (WORSTCASE), optimistic (BESTCASE), no-change (FIXEDCASE), and estimated (ESTIMATEDCASE). The estimated case enables you to analyze the adjustable rate loan with your predictions of future interest rates. The default is worst-case analysis. If more than one case is specified, worst-case analysis is performed. You can specify options for adjustable rate loans as follows:

**BESTCASE**

B

specifies a best-case analysis. The best-case analysis assumes that the interest rate charged on the loan will reach its minimum allowed limits at each adjustment period and over the life of the loan. If you use the BESTCASE option, you must specify either the CAPS= option or the MINRATE= and MAXADJUST= options.

**ESTIMATEDCASE=(date1=rate1 date2=rate2 ...)**

**ESTIMATEDCASE=(period1=rate1 period2=rate2 ...)**

**ESTC=**

specifies an estimated case analysis that indicates the rate adjustments will follow the rates you predict. This option specifies pairs of periods and estimated nominal interest rates.

The ESTIMATEDCASE= option can specify adjustments that cannot fit into the BESTCASE, WORSTCASE, or FIXEDCASE specifications, or “what-if” type analysis. If you specify the START= option, you can also specify the estimation periods as dates, in the form of SAS date literals. Estimated rates and the respective periods must be in time sequence.

If the estimated period falls between two adjustment periods (determined by ADJUSTFREQ= option), the rate is adjusted in the next adjustment period. The nominal interest rate charged on the loan is constant between two adjustment periods.

If any of the MAXRATE=, MINRATE=, CAPS=, and MAXADJUST= options are specified to indicate the rate adjustment terms of the loan agreement, these specifications are used to bound the rate adjustments. By using the ESTIMATEDCASE= option, you are predicting what the annual nominal rates in the market will be at different points in time, not necessarily the interest rate on your particular loan. For example, if the initial nominal rate (RATE= option) is 6.0, ADJUSTFREQ=6, MAXADJUST=0.5, and the ESTIMATEDCASE=(6=6.5, 12=7.5), the actual nominal rates charged on the loan would be 6.0% initially, 6.5% for the sixth through the eleventh periods, and 7.5% for the twelfth period onward.

**FIXEDCASE**

**FIXCASE**

specifies a fixed case analysis that assumes the rate will stay constant. The FIXEDCASE option calculates the ARM loan values similar to a fixed rate loan, but the payments are updated every adjustment period even if the rate does not change, leading to minor differences between the two methods. One such difference is in the way prepayments are handled. In a fixed rate loan, the rate and the payments are never adjusted; therefore, the payment stays the same over the life of the loan even when prepayments are made (instead, the life of the loan is shortened). In an ARM loan with the FIXEDCASE option, on the other hand, if prepayments are made, the payment is adjusted in the following adjustment period, leaving the life of the loan constant.
BUYDOWN Statement

BUYDOWN options;

The BUYDOWN statement specifies a buydown rate loan. The buydown rate loans are similar to ARM loans, but the interest rate adjustments are predetermined at the initialization of the loan, usually by paying interest points at the time of loan initialization.

You must use all the required specifications and options listed under the FIXED statement with the BUYDOWN statement. The following option is specific to the BUYDOWN statement and is required:

BUYDOWNRATES=(date1=rate1 date2=rate2 ... )

BUYDOWNRATES=(period1=rate1 period2=rate2 ... )

BDR=

specifies pairs of periods and the predetermined nominal interest rates that will be charged on the loan starting at the corresponding time periods.

You can also specify the buydown periods as dates in the form of SAS date literals if you also specify the date of the initial payment by using a date value in the START= option. Buydown periods (or dates) and the respective buydown rates must be in time sequence.

COMPARE Statement

COMPARE options;

The COMPARE statement compares multiple loans, or it can be used with a single loan. You can use only one COMPARE statement. COMPARE statement options specify the periods and desired types of analysis for loan comparison. The default analysis reports the outstanding principal balance, breakeven of payment, breakeven of interest paid, and before-tax true interest rate. The default comparison period corresponds to the first LIFE= option specification. If the LIFE= option is not specified for any loan, the loan comparison period defaults to the first calculated life.

You can use the following options with the COMPARE statement. For more detailed information on loan comparison, see the section “Loan Comparison Details” on page 957.
Chapter 17: The LOAN Procedure

Analysis Options

**ALL**
is equivalent to specifying the BREAKINTEREST, BREAKPAYMENT, PWOFCOST, and TRUEINTEREST options. The loan comparison report includes all the criteria. You need to specify the MARR= option for present worth of cost calculation.

**AT=( date1 date2 ... )**

**AT=( period1 period2 ... )**
specifies the periods for loan comparison reports. If you specify the START= option in the PROC LOAN statement, you can specify the AT= option as a list of dates expressed as SAS date literals instead of periods. The comparison periods do not need to be in time sequence. If you do not specify the AT= option, the comparison period defaults to the first LIFE= option specification. If you do not specify the LIFE= option for any of the loans, the loan comparison period defaults to the first calculated life.

**BREAKINTEREST**

**BI**
specifies breakeven analysis of the interest paid. The loan comparison report includes the interest paid for each loan through the specified comparison period (AT= option).

**BREAKPAYMENT**

**BP**
specifies breakeven analysis of payment. The periodic payment for each loan is reported for every comparison period specified in the AT=option.

**MARR=rate**
specifies the MARR (minimum attractive rate of return) in percent notation. The MARR reflects the cost of capital or the opportunity cost of money. The MARR= option is used in calculating the present worth of cost.

**PWOFCOST**

**PWC**
calculates the present worth of cost (net present value of costs) for each loan based on the cash flow through the specified comparison periods. The calculations account for down payment, initialization costs, and discount points, as well as the payments and outstanding principal balance at the comparison period. If you specify the TAXRATE= option, the present worth of cost is based on after-tax cash flow. Otherwise, before-tax present worth of cost is calculated. You need to specify the MARR= option for present worth of cost calculations.

**TAXRATE=rate**

**TAX=rate**
specifies income tax rate in percent notation for the after-tax calculations of the true interest rate and present worth of cost for those assets that qualify for tax deduction. If you specify this option, the amount specified in the POINTS= option and the interest paid on the loan are assumed to be tax-deductible. Otherwise, it is assumed that the asset does not qualify for tax deductions, and the cash flow is not adjusted for tax savings.
TRUEINTEREST
 TI calculates the true interest rate (effective interest rate based on the cash flow of all payments, initialization costs, discount points, and the outstanding principal balance at the comparison period) for all the specified loans through each comparison period. If you specify the TAXRATE= option, the true interest rate is based on after-tax cash flow. Otherwise, the before-tax true interest rate is calculated.

Output Options

NOCOMPRINT
 NOCP suppresses the printing of the loan comparison report. The NOCOMPRINT option is usually used when an OUTCOMP= data set is created to store loan comparison information.

OUTCOMP=SAS-data-set
 writes the loan comparison report to an output data set.

Details: LOAN Procedure

Computational Details

These terms are used in the formulas that follow:

\[ p \] periodic payment
\[ a \] principal amount
\[ r_a \] nominal annual rate
\[ f \] compounding frequency (per year)
\[ f' \] payment frequency (per year)
\[ r \] periodic rate
\[ r_e \] effective interest rate
\[ n \] total number of payments

The periodic rate, or the simple interest applied during a payment period, is given by

\[ r = \left( 1 + \frac{r_a}{f} \right)^{f/f'} - 1 \]

Note that the interest calculation is performed at each payment period rather than at the compound period. This is done by adjusting the nominal rate. See Muxsian (1984) for details.

Note that when \( f = f' \) (that is, when the payment and compounding frequency coincide), the preceding expression reduces to the familiar form:

\[ r = \frac{r_a}{f} \]
The periodic rate for continuous compounding can be obtained from this general expression by taking the limit as the compounding frequency $f$ goes to infinity. The resulting expression is

$$ r = \exp \left( \frac{ra}{f} \right) - 1 $$

The effective interest rate, or annualized percentage rate (APR), is that rate which, if compounded once per year, is equivalent to the nominal annual rate compounded $f$ times per year. Thus,

$$(1 + r_e) = (1 + r)^f = \left(1 + \frac{ra}{f}\right)^f$$

or

$$r_e = \left(1 + \frac{ra}{f}\right)^f - 1$$

For continuous compounding, the effective interest rate is given by

$$r_e = \exp (ra) - 1$$

See Muksian (1984) for details.

The payment is calculated as

$$p = \frac{ar}{1 - \frac{1}{(1+r)^n}}$$

The amount is calculated as

$$a = \frac{p}{r} \left(1 - \frac{1}{(1+r)^n}\right)$$

Both the payment and amount are rounded to the nearest hundredth (cent) unless the ROUND= specification is different than the default, 2.

The total number of payments $n$ is calculated as

$$n = \frac{-\ln \left(1 - \frac{ar}{p}\right)}{\ln(1 + r)}$$

The total number of payments is rounded up to the nearest integer.

The nominal annual rate is calculated using the bisection method, with $a$ as the objective and $r$ starting in the interval between $8 \times 10^{-6}$ and 0.1 with an initial midpoint 0.01 and successive midpoints bisecting.
In order to compare the costs of different alternatives, the input cash flow for the alternatives must be represented in equivalent values. The equivalent value of a cash flow accounts for the time-value of money. That is, it is preferable to pay the same amount of money later than to pay it now, since the money can earn interest while you keep it. The MARR (minimum attractive rate of return) reflects the cost of capital or the opportunity cost of money—that is, the interest that would have been earned on the savings that is foregone by making the investment. The MARR is used to discount the cash flow of alternatives into equivalent values at a fixed point in time. The MARR can vary for each investor and for each investment. Therefore, the MARR= option must be specified in the COMPARE statement if present worth of cost (PWOFCOST option) comparison is specified.

Present worth of cost reflects the equivalent amount at loan initialization of the loan cash flow discounted at MARR, not accounting for inflation. Present worth of cost accounts for the down payment, initialization costs, discount points, periodic payments, and the principal balance at the end of the report period. Therefore, it reflects the present worth of cost of the asset, not the loan. It is meaningful to use minimization of present worth of cost as a selection criterion only if the assets (down payment plus loan amount) are of the same value.

Another economic selection criterion is the rate of return (internal rate of return) of the alternatives. If interest is being earned by an alternative, the objective is to maximize the rate of return. If interest is being paid, as in loan alternatives, the best alternative is the one that minimizes the rate of return. The true interest rate reflects the effective annual rate charged on the loan based on the cash flow, including the initialization cost and the discount points.

The effects of taxes on different alternatives must be accounted for when these vary among different alternatives. Since interest costs on certain loans are tax-deductible, the comparisons for those loans are made based on the after-tax cash flows. The cost of the loan is reduced by the tax benefits it offers through the loan life if the TAXRATE= option is specified. The present worth of cost and true interest rate are calculated based on the after-tax cash flow of the loan. The down payment on the loan and initialization costs are assumed to be not tax-deductible in after-tax analysis. Discount points and the interest paid in each periodic payment are assumed to be tax-deductible if the TAXRATE= option is specified. If the TAXRATE= option is not specified, the present worth of cost and the true interest rate are based on before-tax cash flow, assuming that the interest paid on the specified loan does not qualify for tax benefits.

The other two selection criteria are breakeven analysis of periodic payment and interest paid. If the objective is to minimize the periodic payment, the best alternative is the one with the minimum periodic payment. If the objective is to minimize the interest paid on the principal, then the best alternative is the one with the least interest paid.

Another criterion might be the minimization of the outstanding balance of the loan at a particular point in time. For example, if you plan to sell a house before the end of the loan life (which is often the case), you might want to select the loan with the minimum principal balance at the time of the sale, since this balance must be paid at that time. The outstanding balance of the alternative loans is calculated for each loan comparison period by default.

If you specified the START= option in the PROC LOAN statement, the present worth of cost reflects the equivalent amount for each loan at that point in time. Any loan that has a START= specification different from the one in the PROC LOAN statement is not processed in the loan comparison.
The loan comparison report for each comparison period contains for each loan the loan label, outstanding balance, and any of the following measures if requested in the COMPARE statement: periodic payment (BREAKPAYMENT option), total interest paid to date (BREAKINTEREST option), present worth of cost (PWOFCOST option), and true interest rate (TRUEINTEREST option). The best loan is selected on the basis of present worth of cost or true interest rate. If both PWOFCOST and TRUEINTEREST options are specified, present worth of cost is the basis for the selection of the best loan.

You can use the OUTCOMP= option in the COMPARE statement to write the loan comparison report to a data set. The NOCOMPRINT option suppresses the printing of a loan comparison report.

**OUT= Data Set**

The OUT= option writes the loan amortization schedule to an output data set. The OUT= data set contains one observation for each payment period (or one observation for each year if you specified the SCHEDULE=YEARLY option). If you specified the START= option, the DATE variable denotes the date of the payment. Otherwise, YEAR and period variable (SEMIMONTH, MONTH, QUARTER, or SEMIYEAR) denote the payment year and period within the year.

The OUT= data set contains the following variables:

- DATE, date of the payment. DATE is included in the OUT= data set only when you specify the START= option.
- YEAR, year of the payment period. YEAR is included in the OUT= data set only when you do not specify the START= option.
- PERIOD, period within the year of the payment period. The name of the period variable matches the INTERVAL= specification (SEMIMONTH, MONTH, QUARTER, or SEMIYEAR.) The PERIOD variable is included in the OUT= data set only when you do not specify the START= option.
- BEGPRIN, beginning principal balance
- PAYMENT, payment
- INTEREST, interest payment
- PRIN, principal repayment
- ENDPRIN, ending principal balance

**OUTCOMP= Data Set**

The OUTCOMP= option in the COMPARE statement writes the loan comparison analysis results to an output data set. If you specified the START= option, the DATE variable identifies the date of the loan comparison. Otherwise, the PERIOD variable identifies the comparison period.

The OUTCOMP= data set contains one observation for each loan and for each loan comparison period. The OUTCOMP= data set contains the following variables.
• DATE, date of loan comparison report. The DATE variable is included in the OUTCOMP= data set only when you specify the START= option.

• PERIOD, period of the loan comparison for the observation. The PERIOD variable is included in the OUTCOMP= data set only when you do not specify the START= option.

• LABEL, label string for the loan

• TYPE, type of the loan

• PAYMENT, periodic payment at the time of report. The PAYMENT is included in the OUTCOMP= data set if you specified the BREAKPAYMENT or ALL option or if you used default criteria.

• INTPAY, interest paid through the time of report. The INTPAY variable is included in the OUTCOMP= data set if you specified the BREAKINTEREST or ALL option or if you used default criteria.

• TRUERATE, true interest rate charged on the loan. The TRUERATE variable is included in the OUTCOMP= data set if you specified the TRUERATE or ALL option or if you used default criteria.

• PWOFCOST, present worth of cost. The PWOFCOST variable is included in the OUTCOMP= data set only if you specified the PWOFCOST or ALL option.

• BALANCE, outstanding principal balance at the time of report

OUTSUM= Data Set

The OUTSUM= option writes the loan summary to an output data set. If you specified this option in the PROC LOAN statement, the loan summary information for all loans is written to the specified data set, except for those loans for which you specified a different OUTSUM= data set in the ARM, BALLOON, BUYDOWN, or FIXED statement.

The OUTSUM= data set contains one observation for each loan and contains the following variables:

• TYPE, type of loan

• LABEL, loan label

• PAYMENT, periodic payment

• AMOUNT, loan principal

• DOWNPAY, down payment. DOWNPAY is included in the OUTSUM= data set only when you specify a down payment.

• INITIAL, loan initialization costs. INITIAL is included in the OUTSUM= data set only when you specify initialization costs.

• POINTS, discount points. POINTS is included in the OUTSUM= data set only when you specify discount points.

• TOTAL, total payment
• INTEREST, total interest paid
• RATE, nominal annual interest rate
• EFFRATE, effective interest rate
• INTERVAL, payment interval
• COMPOUND, compounding interval
• LIFE, loan life (that is, the number of payment intervals)
• NCOMPND, number of compounding intervals
• COMPUTE, computed loan parameter: life, amount, payment, or rate

If you specified the START= option either in the PROC LOAN statement or for the individual loan, the OUTSUM= data set also contains the following variables:

• BEGIN, start date
• END, loan termination date

Printed Output

The output from PROC LOAN consists of the loan summary table, loan amortization schedule, and loan comparison report.

Loan Summary Table

The loan summary table shows the total payment and interest, the initial nominal annual and effective interest rates, payment and compounding intervals, the length of the loan in the time units specified, the start and end dates if specified, a list of nominal and effective interest rates, and periodic payments throughout the life of the loan.

A list of balloon payments for balloon payment loans and a list of prepayments if specified are printed with their respective periods or dates.

The loan summary table is printed for each loan by default. The NOSUMMARYPRINT option specified in the PROC LOAN statement suppresses the printing of the loan summary table for all loans. The NOSUMMARYPRINT option can be specified in individual loan statements to selectively suppress the printing of the loan summary table.
**Loan Repayment Schedule**

The amortization schedule contains for each payment period: the year and period within the year (or date, if you specified the START= option); principal balance at the beginning of the period; total payment, interest payment and principal payment for the period; and the principal balance at the end of the period. If you specified the SCHEDULE=YEARLY option, the amortization contains a summary for each year instead of for each payment period.

The amortization schedule is not printed by default. The SCHEDULE option in the PROC LOAN statement requests the printing of amortization tables for all loans. You can specify the SCHEDULE option in individual loan statements to selectively request the printing of the amortization schedule.

**Loan Comparison Report**

The loan comparison report is processed for each report period and contains the results of economic analysis of the loans. The quantities reported can include the outstanding principal balance, after-tax or before-tax present worth of cost and true interest rate, periodic payment, and the interest paid through the report period for each loan. The best alternative is identified if the asset value (down payment plus loan amount) is the same for each alternative.

The loan comparison report is printed by default. The NOCOMPRINT option specified in the COMPARE statement suppresses the printing of the loan comparison report.

**ODS Table Names**

PROC LOAN assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 17.2.

Example 17.1: Discount Points for Lower Interest Rates

This example illustrates the comparison of two $100,000 loans. The major difference between the two loans is that the nominal interest rate in the second loan is lower than the first with the added expense of paying discount points at the time of initialization.

Both alternatives are 30-year loans. The first loan is labeled “8.25% - no discount points” and the second one is labeled “8% - 1 discount point.”

Assume that the interest paid qualifies for a tax deduction and you are in the 33% tax bracket. Also, your minimum attractive rate of return (MARR) for an alternative investment is 4% (adjusted for tax rate).

You use the following statements to find the break-even point in the life of the loan for your preference between the loans:

```sas
proc loan start=1992:1 nosummaryprint amount=100000 life=360;
   fixed rate=8.25 label='8.25% - no discount points';
   fixed rate=8 points=1000 label='8% - 1 discount point';
   compare at=(48 54 60) all taxrate=33 marr=4;
run;
```

Output 17.1.1 shows the loan comparison reports as of January 1996 (48th period), July 1996 (54th period), and January 1997 (60th period).
### Example 17.1: Discount Points for Lower Interest Rates

Loan Comparison Report
Analysis through JAN1997

<table>
<thead>
<tr>
<th>Loan Label</th>
<th>True Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>8.25% - no discount points</td>
<td>5.67</td>
</tr>
<tr>
<td>8% - 1 discount point</td>
<td>5.66</td>
</tr>
</tbody>
</table>

NOTE: "8% - 1 discount point" is the best alternative based on present worth of cost analysis through JAN1997.

Notice that the breakeven point for present worth of cost and true rate both happen on July 1996. This indicates that if you intend to keep the loan for 4.5 years or more, it is better to pay the discount points for the lower rate. If your objective is to minimize the interest paid or the periodic payment, the “8% - 1 discount point” loan is the preferred choice.

Example 17.2: Refinancing a Loan

Assume that you obtained a fixed rate 15-year loan in June 1995 for $78,500 with a nominal annual rate of 9%. By early 1998, the market offers a 6.5% interest rate, and you are considering whether to refinance your loan.

Use the following statements to find out the status of the loan on February 1998. Output 17.2.1 shows the results:

```sas
proc loan start=1995:6;
   fixed life=180 rate=9 amount=78500 noprint
   label='Original Loan';
   compare at=('10FEB1998'd);
run;
```
Example 17.2: Refinancing a Loan

Output 17.2.1 Loan Comparison Report for Original Loan

<table>
<thead>
<tr>
<th>Loan Label</th>
<th>Ending Outstanding</th>
<th>Payment</th>
<th>Interest Paid</th>
<th>True Rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>Original Loan</td>
<td>71028.75</td>
<td>796.20</td>
<td>18007.15</td>
<td>9.38</td>
</tr>
</tbody>
</table>

The monthly payment on the original loan is $796.20. The ending outstanding principal balance as of February is $71,028.75. At this point, you might want to refinance your loan with another 15-year loan. The alternate loan has a 6.5% nominal annual rate. The initialization costs are $1,419.00. Use the following statements to compare your alternatives:

```plaintext
proc loan start=1998:2 amount=71028.75;
  fixed rate=9 payment=796.20
  label='Keep the original loan' noprint;
  fixed life=180 rate=6.5 init=1419
  label='Refinance at 6.5%' noprint;
  compare at=(15 16) taxrate=33 marr=4 all;
run;
```

The comparison reports of May 1999 and June 1999 in Output 17.2.2 illustrate the break even between the two alternatives. If you intend to keep the loan through June 1999 or longer, your initialization costs for the refinancing are justified. The periodic payment of the refinanced loan is $618.74.
### Output 17.2.2 Loan Comparison Report for Refinancing Decision

#### The LOAN Procedure

Example 17.3: Prepayments on a Loan

This example compares a 30-year loan with and without prepayments. Assume the $240,000 30-year loan has an 8.25% nominal annual rate. Use the following statements to see the effect of making uniform prepayments of $500 with periodic payment:

```
proc loan start=1992:12 rate=8.25 amount=240000 life=360;
  fixed label='No prepayments';
  fixed label='With Prepayments' prepay=500;
  compare at=(120) taxrate=33 marr=4 all;
run;
```

NOTE: "With Prepayments" is the best alternative based on present worth of cost analysis through DEC2002.

Output 17.3.1 through Output 17.3.3 illustrate the Loan Summary Reports and the Loan Comparison report. Notice that with prepayments you pay off the loan in slightly more than 15 years. Also, the total payments and total interest are considerably lower with the prepayments. If you can afford the prepayments of $500 each month, another alternative you should consider is using a 15-year loan, which is generally offered at a lower nominal interest rate.
Example 17.4: Output Data Sets

This example shows the analysis and comparison of five alternative loans. Initialization cost, discount points, and both lump sum and periodic payments are included in the specification of these loans. Although no printed output is produced, the loan summary and loan comparison information is stored in the OUTSUM= and OUTCOMP= data sets.

```plaintext
proc loan start=1998:12 noprint outsum=loans

Example 17.5: Piggyback Loans

The piggyback loan is becoming a widely available alternative. Borrowers like to avoid the PMI (private mortgage insurance) required with loans where the borrower has a down payment of less than 20% of the price. The piggyback allows a secondary home equity loan to be packaged with a primary loan with less than 20% down payment. The secondary loan usually has a shorter life and higher interest rate. The interest paid on both loans are tax-deductible whereas PMI does not qualify for a tax deduction.

The following example compares a conventional fixed rate loan with 20% down as opposed to a piggyback loan: one primary fixed rate with 10% down payment and a secondary, home equity loan for 10% of the original price. All loans have monthly payments.

The conventional loan alternative is a 30-year loan with a fixed annual rate of 7.5%. The primary loan in the piggyback loan setup is also a 30-year loan with a fixed annual rate of 7.75%. The secondary loan is a 15-year loan with a fixed annual interest rate of 8.25%.

The comparison output for the two loans comprising the piggyback loan is aggregated using the TIMESERIES procedure with a minimum of specified options:

- The INTERVAL= option requests that the data be aggregated into periods of length 5 years beginning on the 25th month, resulting in appropriately identified periods.
- The ACC=TOTAL option specifies that the output should reflect accumulated totals as opposed to, say, averages.
- The NOTSORTED option indicates that the input data set has not been sorted by the ID variable.

See Chapter 32, “The TIMESERIES Procedure,” for more information about this procedure.

Use the following statements to analyze the conventional loan, as well as the piggyback alternative, and compare them on the basis of their present worth of cost, outstanding balance, and interest payment amounts at the end of 5, 10, and 15 years into the loan life.

```
title1 'LOAN: Piggyback loan example';
title2 'LOAN: Conventional loan';
proc loan start=2002:1 noprint;
   fixed price=200000 dp=40000 rate=7.5 life=360
       label='20 percent down: Conventional Fixed Rate' ;
   compare at=(60 120 180) pwofcost taxrate=30 marr=12
       breakpay breakint outcomp=comploans;
run;
title2 'LOAN: Piggyback: Primary Loan';
proc loan start=2002:1 noprint;
   fixed amount=160000 dp=20000 rate=7.75 life=360
```
Chapter 17: The LOAN Procedure

label='Piggyback: Primary loan' out=loan1;

   compare at=(60 120 180 ) pwofcost taxrate=30 marr=12
   breakpay breakint outcomp=cloan1;

run;

title2 'LOAN: Piggyback: Secondary (Home Equity) Loan';

proc loan start=2002:1 noprint;

   fixed amount=20000 rate=8.25 life=180
   label='Piggyback: Secondary (Home Equity) Loan' out=loan2;

   compare at=(60 120 180 ) pwofcost taxrate=30 marr=12
   breakpay breakint outcomp=cloan2;

run;

data cloan12;
   set cloan1 cloan2;
run;

proc timeseries data=cloan12 out= totcomp ;
   id date interval=year5.25 acc=total notsorted;
   var payment interest pwofcost balance ;
run;

/*-- LOAN: Piggyback loan --*/
title;
proc print data=totcomp;
   format date monyy7.;
run;

data comploans;
   set comploans;
   drop type label;
run;

/*** LOAN: Conventional Loan --*/
title;
proc print data=comploans;
run;

The loan comparisons in Output 17.5.1 and Output 17.5.2 illustrate the after-tax comparison of the loans. The after-tax present value of cost for the piggyback loan is lower than the 20% down conventional fixed rate loan.

Overview: MDC Procedure

The MDC (multinomial discrete choice) procedure analyzes models in which the choice set consists of multiple alternatives. This procedure supports conditional logit, mixed logit, heteroscedastic extreme value, nested logit, and multinomial probit models. The MDC procedure uses the maximum likelihood (ML) or simulated maximum likelihood method for model estimation. The term *multinomial logit* is often used in the econometrics literature to refer to the *conditional logit* model of McFadden (1974). Here, the term *conditional logit* refers to McFadden’s conditional logit model, and the term *multinomial logit* refers to a model that differs slightly. Early applications of the multinomial logit model in the econometrics literature are provided by Schmidt and Strauss (1975); Theil (1969). The main difference between McFadden’s conditional logit model and the multinomial logit model is that the multinomial logit model makes the choice probabilities depend on the characteristics of the individuals only, whereas the conditional logit model considers the effects of choice attributes on choice probabilities as well.

Unordered multiple choices are observed in many settings in different areas of application. For example, choices of housing location, occupation, political party affiliation, type of automobile, and mode of transportation are all unordered multiple choices. Economics and psychology models often explain observed choices by using the *random utility* function. The utility of a specific choice can be interpreted as the relative pleasure or happiness that the decision maker derives from that choice with respect to other alternatives in a finite choice set. It is assumed that the individual chooses the alternative for which the associated utility is highest. However, the utilities are not known to the analyst with certainty and are therefore treated by the analyst as random variables. When the utility function contains a random component, the individual choice behavior becomes a probabilistic process.

The random utility function of individual $i$ for choice $j$ can be decomposed into deterministic and stochastic components

$$U_{ij} = V_{ij} + \epsilon_{ij}$$

where $V_{ij}$ is a deterministic utility function, assumed to be linear in the explanatory variables, and $\epsilon_{ij}$ is an unobserved random variable that captures the factors that affect utility that are not included in $V_{ij}$. Different assumptions on the distribution of the errors, $\epsilon_{ij}$, give rise to different classes of models.

The features of discrete choice models available in the MDC procedure are summarized in Table 18.1.
IEV stands for type I extreme-value (or Gumbel) distribution with the probability density function and the cumulative distribution function of the random error given by 
\[ f(\epsilon_{ij}) = \exp(-\epsilon_{ij}) \exp(-\exp(-\epsilon_{ij})) \]
and 
\[ F(\epsilon_{ij}) = \exp(-\exp(-\epsilon_{ij})). \]
HEV stands for heteroscedastic extreme-value distribution with the probability density function and the cumulative distribution function of the random error given by 
\[ f(\epsilon_{ij}) = \frac{1}{\theta_j} \exp\left(\frac{\xi_{ij}}{\theta_j}\right) \exp\left[-\exp\left(-\frac{\xi_{ij}}{\theta_j}\right)\right] \]
and 
\[ F(\epsilon_{ij}) = \exp\left[-\exp\left(-\frac{\xi_{ij}}{\theta_j}\right)\right], \]
where \( \theta_j \) is a scale parameter for the random component of the \( j \)th alternative. GEV stands for generalized extreme-value distribution. MVN represents multivariate normal distribution; and \( \xi_{ij} \) is an error component. See the “Mixed Logit Model” on page 1013 section for more information about \( \xi_{ij} \).

### Getting Started: MDC Procedure

#### Conditional Logit: Estimation and Prediction

The MDC procedure is similar in use to the other regression model procedures in the SAS System. However, the MDC procedure requires identification and choice variables. For example, consider a random utility function

\[ U_{ij} = x_{1,ij}\beta_1 + x_{2,ij}\beta_2 + \epsilon_{ij} \quad j = 1, \ldots, 3 \]

where the cumulative distribution function of the stochastic component is a Type I extreme value, \( F(\epsilon_{ij}) = \exp(-\exp(-\epsilon_{ij})) \). You can estimate this conditional logit model with the following statements:

```sas
proc mdc;
  model decision = x1 x2 / type=clogit
  choice=(mode 1 2 3);
  id pid;
run;
```
Note that the MDC procedure, unlike other regression procedures, does not include the intercept term automatically. The dependent variable decision takes the value 1 when a specific alternative is chosen; otherwise, it takes the value 0. Each individual is allowed to choose one and only one of the possible alternatives. In other words, the variable decision takes the value 1 one time only for each individual. If each individual has three elements (1, 2, and 3) in the choice set, the NCHOICE=3 option can be specified instead of CHOICE=(mode 1 2 3).

Consider the following trinomial data from Daganzo (1979). The original data (origdata) contain travel time (ttime1–ttime3) and choice (choice) variables. The variables ttime1–ttime3 are the travel times for three different modes of transportation, and choice indicates which one of the three modes is chosen. The choice variable must have integer values.

```plaintext
data origdata;
  input ttime1 ttime2 ttime3 choice @@;
datalines;
   16.481  16.196  23.890  2
   15.123  11.373  14.182  2
   19.469  8.822   20.819  2
   18.847  15.649  21.280  2
   12.578  10.671  18.335  2
   11.513  20.582  27.838  1
   10.651  15.537  17.418  1
   8.359   15.675  21.050  1
... more lines ...
```

A new data set (newdata) is created because PROC MDC requires that each individual decision maker has one case for each alternative in his choice set. Note that the ID statement is required for all MDC models. In the following example, there are two public transportation modes, 1 and 2, and one private transportation mode, 3, and all individuals share the same choice set.

The first nine observations of the raw data set are shown in Figure 18.1.

![Figure 18.1 Initial Choice Data](image-url)
The following statements transform the data according to MDC procedure requirements:

```sas
data newdata(keep=pid decision mode ttime);
  set origdata;
  array tvec{3} ttime1 - ttime3;
  retain pid 0;
  pid + 1;
  do i = 1 to 3;
    mode = i;
    ttime = tvec{i};
    decision = ( choice = i );
    output;
  end;
run;
```

The first nine observations of the transformed data set are shown in Figure 18.2.

![Figure 18.2 Transformed Modal Choice Data](image_url)

The decision variable, decision, must have one nonzero value for each decision maker that corresponds to the actual choice. When the RANK option is specified, the decision variable must contain rank data. For more details, see the section “MODEL Statement” on page 998. The following SAS statements estimate the conditional logit model by using maximum likelihood:

```sas
proc mdc data=newdata;
  model decision = ttime / type=clogit
                 nchoice=3
                 optmethod=qn
                 covest=hess;
  id pid;
run;
```

The MDC procedure enables different individuals to have different choice sets. When all individuals have the same choice set, the NCHOICE= option can be used instead of the CHOICE= option. However, the NCHOICE= option is not allowed when a nested logit model is estimated. When the NCHOICE=number option is specified, the choices are generated as 1, . . . , number. For more flexible alternatives (for example, 1, 3, 6, 8), you need to use the CHOICE= option. The choice variable must have integer values.

The OPTMETHOD=QN option specifies the quasi-Newton optimization technique. The covariance matrix of the parameter estimates is obtained from the Hessian matrix because COVEST=HESS is specified. You
can also specify COVEST=OP or COVEST=QML. See the section “MODEL Statement” on page 998 for more details.

The MDC procedure produces a summary of model estimation displayed in Figure 18.3. Since there are multiple observations for each individual, the “Number of Cases” (150)—that is, the total number of choices faced by all individuals—is larger than the number of individuals, “Number of Observations” (50).

The MDC procedure computes nine goodness-of-fit measures for the discrete choice model. Seven of them are pseudo-R-square measures based on the null hypothesis that all coefficients except for an intercept term are zero (Figure 18.5). McFadden’s likelihood ratio index (LRI) is the smallest in value. For more details, see the section “Model Fit and Goodness-of-Fit Statistics” on page 1021.

**Nested Logit Modeling**

A more general model can be specified using the nested logit model.

Consider, for example, the following random utility function:

\[ U_{ij} = x_{ij} \beta + \epsilon_i \quad j = 1, \ldots, 3 \]
Suppose the set of all alternatives indexed by \( j \) is partitioned into \( K \) nests, \( B_1, \ldots, B_K \). The nested logit model is obtained by assuming that the error term in the utility function has the GEV cumulative distribution function

\[
\exp \left( - \sum_{k=1}^{K} \left( \sum_{j \in B_k} \exp\left\{ -\epsilon_{ij} / \lambda_k \right\} \right)^{\lambda_k} \right)
\]

where \( \lambda_k \) is a measure of a degree of independence among the alternatives in nest \( k \). When \( \lambda_k = 1 \) for all \( k \), the model reduces to the standard logit model.

Since the public transportation modes, 1 and 2, tend to be correlated, these two choices can be grouped together. The decision tree displayed in Figure 18.8 is constructed.

**Figure 18.8** Decision Tree for Model Choice

The two-level decision tree is specified in the NEST statement. The NCHOICE= option is not allowed for nested logit estimation. Instead, the CHOICE= option needs to be specified, as in the following statements:

```plaintext
/*-- nested logit estimation --*/
proc mdc data=newdata;
  model decision = ttime /
    type=nlogit
    choice=(mode 1 2 3)
    covest=hess;
  id pid;
  utility u(1,) = ttime;
  nest level(1) = (1 2 @ 1, 3 @ 2),
    level(2) = (1 2 @ 1);
run;
```

In Figure 18.9, estimates of the inclusive value parameters, INC_L2G1C1 and INC_L2G1C2, are indicative of a nested model structure. See the section “Nested Logit” on page 1017 and the section “Decision Tree and Nested Logit” on page 1019 for more details about inclusive values.
Figure 18.9 Two-Level Nested Logit Estimates

The nested logit model is estimated with the restriction INC_L2G1C1 = INC_L2G1C2 by specifying the SAMESCALE option, as in the following statements:

```plaintext
/*-- nlogit with same scale option --*/
proc mdc data=newdata;
  model decision = ttime /
    type=nlogit
    choice=(mode 1 2 3)
    same scale
    cov est=hess;
  id pid;
  utility u(1,) = ttime;
  nest level(1) = (1 2 @ 1, 3 @ 2),
    level(2) = (1 2 @ 1);
run;
```

The estimation result is displayed in Figure 18.10.

Figure 18.10 Nested Logit Estimates with One Dissimilarity Parameter

The nested logit model is equivalent to the conditional logit model if INC_L2G1C1 = INC_L2G1C2 = 1. You can verify this relationship by estimating a constrained nested logit model as shown in the following statements. (See the section “RESTRICT Statement” on page 1007 for details about imposing linear restrictions on parameter estimates.)
/**-- constrained nested logit estimation --*/

```sas
proc mdc data=newdata;
   model decision = ttime /
       type=nlogit
       choice=(mode 1 2 3)
       covest=hess;
   id pid;
   utility u(1,) = ttime;
   nest level(1) = (1 2 @ 1, 3 @ 2),
                   level(2) = (1 2 @ 1);
   restrict INC_L2G1C1 = 1, INC_L2G1C2 =1;
run;
```

The parameter estimates and the active linear constraints for the constrained nested logit model are displayed in Figure 18.11.

**Figure 18.11** Constrained Nested Logit Estimates

Chapter 18: The MDC Procedure

Multivariate Normal Utility Function

Consider the random utility function

\[ U_{ij} = \text{ttime}_{ij}\beta + \epsilon_{ij}, \quad j = 1, 2, 3 \]

where

\[
\begin{bmatrix}
\epsilon_{i1} \\
\epsilon_{i2} \\
\epsilon_{i3}
\end{bmatrix} \sim N\left(0, \begin{bmatrix}
1 & \rho_{21} & 0 \\
\rho_{21} & 1 & 0 \\
0 & 0 & 1
\end{bmatrix}\right)
\]

The correlation coefficient (\(\rho_{21}\)) between \(U_{i1}\) and \(U_{i2}\) represents commonly neglected attributes of public transportation modes, 1 and 2. The following SAS statements estimate this trinomial probit model:

```sas
/*-- homoscedastic mprobit --*/
proc mdc data=newdata;
  model decision = ttime /
    type=mprobit
    nchoice=3
    unitvariance=(1 2 3)
    covest=hess;
  id pid;
run;
```

The UNITVARIANCE=(1 2 3) option specifies that the random component of utility for each of the choices has unit variance. If the UNITVARIANCE= option is specified, it needs to include at least two choices. The results of this constrained multinomial probit model estimation are displayed in Figure 18.12 and Figure 18.13. The test for \(\text{ttime} = 0\) is rejected at the 1% significance level.

HEV and Multinomial Probit: Heteroscedastic Utility Function

When the stochastic components of utility are heteroscedastic and independent, you can model the data by using an HEV or a multinomial probit model. The HEV model assumes that the utility of alternative $j$ for each individual $i$ has heteroscedastic random components,

$$U_{ij} = V_{ij} + \epsilon_{ij}$$

where the cumulative distribution function of the Gumbel distributed $\epsilon_{ij}$ is

$$F(\epsilon_{ij}) = \exp(-\exp(-\epsilon_{ij}/\theta_j))$$

Note that the variance of $\epsilon_{ij}$ is $\frac{1}{6}\pi^2\theta_j^2$. Therefore, the error variance is proportional to the square of the scale parameter $\theta_j$. For model identification, at least one of the scale parameters must be normalized to 1. The following SAS statements estimate an HEV model under a unit scale restriction for mode “1” ($\theta_1 = 1$):

```sas
/*-- hev with gauss-laguerre method --*/
proc mdc data=newdata;
   model decision = ttime /
      type=hev
      nchoice=3
      hev=(unitscale=1, integrate=laguerre)
      covest=hess;
      id pid;
run;
```
The results of computation are presented in Figure 18.14 and Figure 18.15.

<tr>
<td>Parameter Estimates</td>
</tr>
<tr>
<td>Parameter</td>
</tr>
<tr>
<td>ttime</td>
</tr>
<tr>
<td>SCALE2</td>
</tr>
<tr>
<td>SCALE3</td>
</tr>
</tbody>
</table>

The parameters SCALE2 and SCALE3 in the output correspond to the estimates of the scale parameters $\theta_2$ and $\theta_3$, respectively.

Note that the estimate of the HEV model is not always stable because computation of the log-likelihood function requires numerical integration. Bhat (1995) proposed the Gauss-Laguerre method. In general, the log-likelihood function value of HEV should be larger than that of conditional logit because HEV models include the conditional logit as a special case. However, in this example the reverse is true (–33.414 for the HEV model, which is less than –33.321 for the conditional logit model). (See Figure 18.14 and Figure 18.3.) This indicates that the Gauss-Laguerre approximation to the true probability is too coarse. You can see how well the Gauss-Laguerre method works by specifying a unit scale restriction for all modes, as in the following statements, since the HEV model with the unit variance for all modes reduces to the conditional logit model:

```plaintext
/*-- hev with gauss-laguerre and unit scale --*/
proc mdc data=newdata;
   model decision = ttime / type=hev
```
Figure 18.16 shows that the $t_{time}$ coefficient is not close to that of the conditional logit model.

**Figure 18.16** HEV Estimates with All Unit Scale Parameters

| Parameter | DF | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----|----------|----------------|---------|-------|
| $t_{time}$ | 1   | -0.2926  | 0.0438         | -6.68   | <.0001|

There is another option of specifying the integration method. The INTEGRATE=HARDY option uses the adaptive Romberg-type integration method. The adaptive integration produces much more accurate probability and log-likelihood function values, but often it is not practical to use this method of analyzing the HEV model because it requires excessive CPU time. The following SAS statements produce the HEV estimates by using the adaptive Romberg-type integration method:

```sas
/*-- hev with adaptive integration --*/
proc mdc data=newdata;
   model decision = ttime /
       type=hev
       nchoice=3
       hev=(unitscale=1, integrate=hardy)
       covest=hess;
   id pid;
run;
```
The results are displayed in Figure 18.17 and Figure 18.18.

</tbody>
</table>

With the INTEGRATE=HARDY option, the log-likelihood function value of the HEV model, $-33.026$, is greater than that of the conditional logit model, $-33.321$. (See Figure 18.17 and Figure 18.3.)

When you impose unit scale restrictions on all choices, as in the following statements, the HEV model gives the same estimates as the conditional logit model. (See Figure 18.19 and Figure 18.6.)

```plaintext
/*-- hev with adaptive integration and unit scale --*/
proc mdc data=newdata;
   model decision = ttime /
       type=hev
       nchoice=3
       hev=(unitscale=1 2 3, integrate=hardy)
       covest=hess;
   id pid;
run;
```
For comparison, the following statements estimate a heteroscedastic multinomial probit model by imposing a zero restriction on the correlation parameter, $\rho_{31} = 0$. The MDC procedure requires normalization of at least two of the error variances in the multinomial probit model. Also, for identification, the correlation parameters associated with a unit normalized variance are restricted to be zero. When the UNITVARIANCE= option is specified, the zero restriction on correlation coefficients applies to the last choice of the list. In the following statements, the variances of the first and second choices are normalized. The UNITVARIANCE=(1 2) option imposes additional restrictions that $\rho_{32} = \rho_{21} = 0$. The default for the UNITVARIANCE= option is the last two choices (which would have been equivalent to UNITVARIANCE=(2 3) for this example). The result is presented in Figure 18.20.

The utility function can be defined as

$$U_{ij} = V_{ij} + \epsilon_{ij}$$

where

$$\epsilon_i \sim N \left( 0, \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \sigma_i^2 \end{bmatrix} \right)$$

/*--- mprobit estimation ---*/
proc mdc data=newdata;
   model decision = ttime /
      type=mprobit
      nchoice=3
      unitvariance=(1 2)
      covest=hess;
   id pid;
   restrict RHO_31 = 0;
run;
### Parameter Heterogeneity: Mixed Logit

One way of modeling unobserved heterogeneity across individuals in their sensitivity to observed exogenous variables is to use the mixed logit model with a random parameters or random coefficients specification. The probability of choosing alternative $j$ is written as

$$P_i(j) = \frac{\exp(x_{ij}'\beta)}{\sum_{k=1}^{J} \exp(x_{ik}'\beta)}$$

where $\beta$ is a vector of coefficients that varies across individuals and $x_{ij}$ is a vector of exogenous attributes.

For example, you can specify the distribution of the parameter $\beta$ to be the normal distribution.

The mixed logit model uses a Monte Carlo simulation method to estimate the probabilities of choice. There are two simulation methods available. If the RANDNUM=PSEUDO option is specified in the MODEL statement, pseudo-random numbers are generated; if the RANDNUM=HALTON option is specified, Halton quasi-random sequences are used. The default value is RANDNUM=HALTON.
You can estimate the model with normally distributed random coefficients of `ttime` with the following SAS statements:

```sas
/*-- mixed logit estimation --*/
proc mdc data=newdata type=mixedlogit;
  model decision = ttime /
    nchoice=3
    mixed=(normalparm=ttime);
  id pid;
run;
```

Let $\beta^m$ and $\beta^s$ be mean and scale parameters, respectively, for the random coefficient, $\beta$. The relevant utility function is

$$U_{ij} = ttime_{ij} \beta + \epsilon_{ij}$$

where $\beta = \beta^m + \beta^s \eta$ ($\beta^m$ and $\beta^s$ are fixed mean and scale parameters, respectively). The stochastic component, $\eta$, is assumed to be standard normal since the NORMALPARM= option is given. Alternatively, the UNIFORMPARM= or LOGNORMALPARM= option can be specified. The LOGNORMALPARM= option is useful when nonnegative parameters are being estimated. The NORMALPARM=, UNIFORMPARM=, and LOGNORMALPARM= variables must be included in the right-hand side of the MODEL statement. See the section “Mixed Logit Model” on page 1013 for more details. To estimate a mixed logit model by using the transportation mode choice data, the MDC procedure requires the MIXED= option for random components. Results of the mixed logit estimation are displayed in Figure 18.21.

**Figure 18.21** Mixed Logit Model Parameter Estimates

| Parameter | DF | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----|----------|----------------|---------|------|---|
| `ttime_M` | 1  | -0.5342  | 0.2184         | -2.45   | 0.0144 |   |
| `ttime_S` | 1  | 0.2843   | 0.1911         | 1.49    | 0.1368 |   |

Note that the parameter `ttime_M` corresponds to the constant mean parameter $\beta^m$ and the parameter `ttime_S` corresponds to the constant scale parameter $\beta^s$ of the random coefficient $\beta$. 
Syntax: MDC Procedure

The MDC procedure is controlled by the following statements:

```plaintext
PROC MDC options ;
   MDCDATA options ;
   BOUNDS bound1 < , bound2 . . . > ;
   BY variables ;
   CLASS options ;
   ID variable ;
   MODEL dependent variables = regressors / options ;
   NEST LEVEL(value) = ((values)@(value), . . . , (values)@(value)) ;
   NLOPTIONS options ;
   OUTPUT options ;
   RESTRICT restriction1 < , restriction2 . . . > ;
   TEST options ;
   UTILITY U() = variables, . . . , U() = variables ;
```

Functional Summary

Table 18.2 summarizes the statements and options used with the MDC procedure.

Chapter 18: The MDC Procedure

**Description Statement Option**

Requests the Lagrange multiplier test

Requests the likelihood ratio test

**PROC MDC Statement**

PROC MDC options;

The following options can be used in the PROC MDC statement.

**DATA=SAS-data-set**

specifies the input SAS data set. If the DATA= option is not specified, PROC MDC uses the most recently created SAS data set.

**OUTEST=SAS-data-set**

names the SAS data set that the parameter estimates are written to. See “OUTEST= Data Set” later in this chapter for information about the contents of this data set.

**COVOUT**

writes the covariance matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

In addition, any of the following MODEL statement options can be specified in the PROC MDC statement, which is equivalent to specifying the option for the MODEL statement: ALL, CONVERGE=, CORRB, COVB, COVEST=, HALTONSTART=, ITPRINT, MAXITER=, NOPRINT, NSIMUL=, OPTMETHOD=, RANDINIT, RANK, RESTART=, SAMESCALE, SEED=, SPSCALE, TYPE=, and UNITVARIANCE=.

**MDCDATA Statement**

MDCDATA options < / OUT=SAS-data-set> ;

The MDCDATA statement prepares data for use by PROC MDC when the choice-specific information is stored in multiple variables (for example, see Figure 18.1 in the section “Conditional Logit: Estimation and Prediction” on page 977).

**VARLIST**(name1 = (var1 var2 . . . ) name2 = (var1 var2 . . . ) . . .)

creates name variables from a multiple-variable list of choice alternatives in parentheses. The choice-specific dummy variables are created for the first set of multiple variables. At least one set of multiple variables must be specified. The order of (var1 var2 ...) in the VARLIST option determines the numbering of the alternative; that is, var1 corresponds to alternative 1, var2 corresponds to alternative 2, and so on.

**SELECT=(variable)**

specifies a variable that contains choices for each individual. The SELECT= variable needs to be a character-type variable, with values that match variable names in the first VARLIST option: name1=(var1 var2 ...).
**BOUNDS Statement**

The BOUNDS statement imposes simple boundary constraints on the parameter estimates. BOUNDS statement constraints refer to the parameters estimated by the MDC procedure. You can specify any number of BOUNDS statements.

Each bound is composed of parameters, constants, and inequality operators:

```plaintext
item operator item < operator item < operator item . . . > ;
```

Each item is a constant, parameter, or list of parameters. Parameters associated with a regressor variable are referred to by the name of the corresponding regressor variable. Each operator is <, >, <=, or >=.

You can use both the BOUNDS statement and the RESTRICT statement to impose boundary constraints; however, the BOUNDS statement provides a simpler syntax for specifying these kinds of constraints. See also the section “RESTRICT Statement” on page 1007.

Lagrange multipliers are reported for all the active boundary constraints. In the displayed output, the Lagrange multiplier estimates are identified with the names Restrict1, Restrict2, and so on. The probability of the Lagrange multipliers is computed using a beta distribution (LaMotte 1994). Nonactive (nonbinding) bounds have no effect on the estimation results and are not noted in the output.

The following BOUNDS statement constrains the estimates of the coefficient of ttime to be negative and the coefficients of x1 through x10 to be between zero and one. This example illustrates the use of parameter lists to specify boundary constraints.

```plaintext
bounds ttime < 0,
     0 < x1-x10 < 1;
```

**BY Statement**

A BY statement can be used with PROC MDC to obtain separate analyses on observations in groups defined by the BY variables.
**CLASS Statement**

```r
CLASS variables ;
```

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric.

**ID Statement**

```r
ID variable ;
```

The ID statement must be used with PROC MDC to specify the identification variable that controls multiple choice-specific cases. The MDC procedure requires only one ID statement even with multiple MODEL statements.

**MODEL Statement**

```r
MODEL dependent = regressors < / options > ;
```

The MODEL statement specifies the dependent variable and independent regressor variables for the regression model. When the nested logit model is estimated, regressors in the UTILITY statement are used for estimation. The following options can be used in the MODEL statement after a slash (/).

- **CHOICE=( variables )**
- **CHOICE=( variable numbers )**
  specifies the variables that contain possible choices for each individual. Choice variables must have integer values. Multiple choice variables are allowed only for nested logit models and must be specified in order from the highest level to the lowest level. For example, CHOICE=(upmode, mode) indicates that the nested logit model has two levels. The choices at the upper level are described by the upmode variable, and the choices at the lower level are described by the mode variable. If all possible alternatives are written with the variable name, the MDC procedure checks all values of the choice variable. CHOICE=(X 1 2 3) implies that the value of X should be 1, 2, or 3. On the other hand, the CHOICE=(X) considers all distinctive nonmissing values of X as elements of the choice set.

- **CONVERGE=number**
  specifies the convergence criterion. The CONVERGE= option is the same as the ABSGCONV= option in the NLOPTIONS statement. The ABSGCONV= option in the NLOPTIONS statement overrides the CONVERGE= option. The default value is 1E–5.

- **HALTONSTART=number**
  specifies the starting point of the Halton sequence. The specified number must be a positive integer. The default is HALTONSTART=11.

- **HEV=( option-list )**
  specifies options that are used to estimate the HEV model. The HEV model with a unit scale for the alternative 1 is estimated using the following SAS statement:
model y = x1 x2 x3 / hev=(unitscale=1);

The following options can be used in the HEV= option. These options are listed within parentheses and separated by commas.

**INTORDER=number**
  specifies the number of summation terms for Gaussian quadrature integration. The default is INTORDER=40. The maximum order is limited to 45. This option applies only to the INTEGRATION=LAGUERRE method.

**UNITSCALE=number-list**
  specifies restrictions on scale parameters of stochastic utility components.

**INTEGRATE=LAGUERRE | HARDY**
  specifies the integration method. The INTEGRATE=HARDY option specifies an adaptive integration method, while the INTEGRATE=LAGUERRE option specifies the Gauss-Laguerre approximation method. The default is INTEGRATE=LAGUERRE.

**MIXED=( option-list )**
  specifies options that are used for mixed logit estimation. The mixed logit model with normally distributed random parameters is specified as follows:

  \[ \text{model } y = x_1 x_2 x_3 / \text{mixed=(normalparm=x1)}; \]

The following options can be used in the MIXED= option. The options are listed within parentheses and separated by commas.

**LOGNORMALPARM=variables**
  specifies the variables whose random coefficients are lognormally distributed. LOGNORMALPARM= variables must be included on the right-hand side of the MODEL statement.

**NORMALEC=variables**
  specifies the error component variables whose coefficients have a normal distribution \( N(0, \sigma^2) \).

**NORMALPARM=variables**
  specifies the variables whose random coefficients are normally distributed. NORMALPARM= variables must be included on the right-hand side of the MODEL statement.

**UNIFORMEC=variables**
  specifies the error component variables whose coefficients have a uniform distribution \( U(-\sqrt{3}\sigma, \sqrt{3}\sigma) \).

**UNIFORMPARM=variables**
  specifies the variables whose random coefficients are uniformly distributed. UNIFORMPARM= variables must be included on the right-hand side of the MODEL statement.

**NCHOICE=number**
  specifies the number of choices for multinomial choice models when all individuals have the same choice set. When individuals have different number of choices, the NCHOICE= option is not allowed, and the CHOICE= option should be used. The NCHOICE= and CHOICE= options must not be used simultaneously, and the NCHOICE= option cannot be used for nested logit models.
**NSIMUL=number**
specifies the number of simulations when the mixed logit or multinomial probit model is estimated. The default is NSIMUL=100. In general, you need a smaller number of simulations with RANDNUM=HALTON than with RANDNUM=PSEUDO.

**RANDNUM=value**
specifies the type of the random number generator used for simulation. RANDNUM=HALTON is the default. The following option values are allowed:

- PSEUDO specifies pseudo-random number generation.
- HALTON specifies Halton sequence generation.

**RANDINIT**

**RANDINIT=number**
specifies that initial parameter values be perturbed by uniform pseudo-random numbers for numerical optimization of the objective function. The default is $U(-1, 1)$. When the RANDINIT=r option is specified, $U(-r, r)$ pseudo-random numbers are generated. The value $r$ should be positive. With a RANDINIT or RANDINIT= option, there are pure random searches for a given number of trials (1,000 for conditional or nested logit, and 500 for other models) to get a maximum (or minimum) value of the objective function. For example, when there is a parameter estimate with an initial value of 1, the RANDINIT option adds a generated random number $u$ to the initial value and computes an objective function value by using $1 + u$. This option is helpful in finding the initial value automatically if there is no guidance in setting the initial estimate.

**RANK**
specifies that the dependent variable contain ranks. The numbers must be positive integers starting from 1. When the dependent variable has value 1, the corresponding alternative is chosen. This option is provided only as a convenience to the user; the extra information contained in the ranks is not currently used for estimation purposes.

**RESTART=( option-list )**
specifies options that are used for reiteration of the optimization problem. When the ADDRANDOM option is specified, the initial value of reiteration is computed using random grid searches around the initial solution, as follows:

```sas
model y = x1 x2 / type=clogit
   restart=(addvalue=(.01 .01));
```

The preceding SAS statement reestimates a conditional logit model by adding ADDVALUE= values. If the ADDVALUE= option contains missing values, the RESTART= option uses the corresponding estimate from the initial stage. If no ADDVALUE= value is specified for an estimate, a default value equal to (|estimate| * 1e-3) is added to the corresponding estimate from the initial stage. If both the ADDVALUE= and ADDRANDOM(=) options are specified, ADDVALUE= is ignored.

The following options can be used in the RESTART= option. The options are listed within parentheses.

**ADDMAXIT=number**
specifies the maximum number of iterations for the second stage of the estimation. The default is ADDMAXIT=100.
MODEL Statement

ADDRANDOM | ADDRANDOM=value
specifies random added values to the estimates from the initial stage. With the ADDRANDOM option, $U(-1, 1)$ random numbers are created and added to the estimates obtained in the initial stage. When the ADDRANDOM=r option is specified, $U(-r, r)$ random numbers are generated. The restart initial value is determined based on the given number of random searches (1,000 for conditional or nested logit, and 500 for other models).

ADDVALUE=(value-list)
specifies values added to the estimates from the initial stage. A missing value in the list is considered as a zero value for the corresponding estimate. When the ADDVALUE= option is not specified, default values equal to (|estimate| * 1e-3) are added.

SAMESCALE
specifies that the parameters of the inclusive values be the same within a group at each level when the nested logit is estimated.

SEED=number
specifies an initial seed for pseudo-random number generation. The SEED= value must be less than $2^{31} - 1$. If the SEED= value is negative or zero, the time of day from the computer’s clock is used to obtain the initial seed. The default is SEED=0.

SPSCALE
specifies that the parameters of the inclusive values be the same for any choice with only one nested choice within a group, for each level in a nested logit model. This option is useful in analyzing stated preference data.

TYPE=value
specifies the type of model to be analyzed. The following model types are supported:

CONDITIONLOGIT | CLOGIT | CL
specifies a conditional logit model.

HEV
specifies a heteroscedastic extreme-value model.

MIXEDLOGIT | MXL
specifies a mixed logit model.

MULTINOMPROBIT | MPROBIT | MP
specifies a multinomial probit model.

NESTEDLOGIT | NLOGIT | NL
specifies a nested logit model.

UNITVARIANCE=(number-list)
