specifies normalization restrictions on error variances of multinomial probit for the choices whose numbers are given in the list. If the UNITVARIANCE= option is specified, it must include at least two choices. Also, for identification, additional zero restrictions are placed on the correlation coefficients for the last choice in the list.

COVEST=value
specifies the type of covariance matrix. The following types are supported:

OP
specifies the covariance from the outer product matrix.

HESSIAN
specifies the covariance from the Hessian matrix.
QML specifies the covariance from the outer product and Hessian matrices.

When COVEST=OP is specified, the outer product matrix is used to compute the covariance matrix of the parameter estimates. The COVEST=HESSIAN option produces the covariance matrix by using the inverse Hessian matrix. The quasi-maximum likelihood estimates are computed with COVEST=QML. The default is COVEST=HESSIAN when the Newton-Raphson method is used. COVEST=OP is the default when the OPTMETHOD=QN option is specified.

Printing Options

- **ALL**
  requests all printing options.

- **COVB**
  displays the estimated covariances of the parameter estimates.

- **CORRB**
  displays the estimated correlation matrix of the parameter estimates.

- **ITPRINT**
  displays the initial parameter estimates, convergence criteria, and constraints of the optimization. At each iteration, the objective function value, the maximum absolute gradient element, the step size, and the slope of search direction are printed. The objective function is the full negative log-likelihood function for the maximum likelihood method. When the ITPRINT option is specified and the NLOPTIONS statement is specified, all printing options in the NLOPTIONS statement are ignored.

- **NOPRINT**
  suppresses all displayed output.

Estimation Control Options

You can also specify detailed optimization options in the NLOPTIONS statement. The OPTMETHOD= option overrides the TECHNIQUE= option in the NLOPTIONS statement. The NLOPTIONS statement is ignored if the OPTMETHOD= option is specified.

- **INITIAL=( initial-values )**
- **START=( initial-values )**
  specifies initial values for some or all of the parameter estimates. The values specified are assigned to model parameters in the same order in which the parameter estimates are displayed in the MDC procedure output.

  When you use the INITIAL= option, the initial values in the INITIAL= option must satisfy the restrictions specified for the parameter estimates. If they do not, the initial values you specify are adjusted to satisfy the restrictions.

- **MAXITER=number**
  sets the maximum number of iterations allowed. The MAXITER= option overrides the MAXITER= option in the NLOPTIONS statement. The default is MAXITER=100.
**OPTMETHOD=value**
specifies the optimization technique when the estimation method uses nonlinear optimization. The following techniques are supported:

- **QN** specifies the quasi-Newton method.
- **NR** specifies the Newton-Raphson method.
- **TR** specifies the trust region method.

The OPTMETHOD=NR option is the same as the TECHNIQUE=NEWRAP option in the NLOPTONS statement. For the conditional and nested logit models, the default is OPTMETHOD=NR. For other models, the default is OPTMETHOD=QN.

**NEST Statement**

```
NEST LEVEL (level-number) = (choices@choice, . . .);
```

The NEST statement is used when one choice variable contains all possible alternatives and the TYPE=NLOGIT option is specified. The decision tree is constructed based on the NEST statement. When the choice set is specified using multiple CHOICE= variables in the MODEL statement, the NEST statement is ignored.

Consider the following eight choices that are nested in a three-level tree structure.

<table>
<thead>
<tr>
<th>Level 1</th>
<th>Level 2</th>
<th>Level 3</th>
<th>Top</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>3</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>4</td>
<td>2</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>5</td>
<td>2</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>6</td>
<td>2</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>7</td>
<td>3</td>
<td>2</td>
<td>1</td>
</tr>
<tr>
<td>8</td>
<td>3</td>
<td>2</td>
<td>1</td>
</tr>
</tbody>
</table>

You can use the following NEST statement to specify the tree structure displayed in Figure 18.22:

```
nest level(1) = (1 2 3 @ 1, 4 5 6 @ 2, 7 8 @ 3),
level(2) = (1 2 @ 1, 3 @ 2),
level(3) = (1 2 @ 1);
```
Note that the decision tree is constructed based on the sequence of first-level choice set specification. Therefore, specifying another order at Level 1 builds a different tree. The following NEST statement builds the tree displayed in Figure 18.23:

```plaintext
nest level(1) = (4 5 6 @ 2, 1 2 3 @ 1, 7 8 @ 3),
level(2) = (1 2 @ 1, 3 @ 2),
level(3) = (1 2 @ 1);
```

However, the NEST statement with a different sequence of choice specification at higher levels builds the same tree as displayed in Figure 18.22 if the sequence at the first level is the same:
nest \text{level}(1) = (1\ 2\ 3\ @\ 1,\ 4\ 5\ 6\ @\ 2,\ 7\ 8\ @\ 3), \\
\text{level}(2) = (3\ @\ 2,\ 1\ 2\ @\ 1), \\
\text{level}(3) = (1\ 2\ @\ 1);

The following specifications are equivalent:

\begin{align*}
\text{nest level}(2) &= (3\ @\ 2,\ 1\ 2\ @\ 1) \\
\text{nest level}(2) &= (3\ @\ 2,\ 1\ @\ 1,\ 2\ @\ 1) \\
\text{nest level}(2) &= (1\ @\ 1,\ 2\ @\ 1,\ 3\ @\ 2)
\end{align*}

Since the MDC procedure contains multiple cases for each individual, it is important to keep the data sequence in the proper order. Consider the four-choice multinomial model with one explanatory variable \text{cost}:

\begin{center}
\begin{tabular}{c|c|c|c}
\hline
\text{pid} & \text{choice} & \text{y} & \text{cost} \\
\hline
1 & 1 & 1 & 10 \\
1 & 2 & 0 & 25 \\
1 & 3 & 0 & 20 \\
1 & 4 & 0 & 30 \\
2 & 1 & 0 & 15 \\
2 & 2 & 0 & 22 \\
2 & 3 & 1 & 16 \\
2 & 4 & 0 & 25 \\
\hline
\end{tabular}
\end{center}

The order of data needs to correspond to the value of choice. Therefore, the following data set is equivalent to the preceding data:

\begin{center}
\begin{tabular}{c|c|c|c}
\hline
\text{pid} & \text{choice} & \text{y} & \text{cost} \\
\hline
1 & 2 & 0 & 25 \\
1 & 3 & 0 & 20 \\
1 & 1 & 1 & 10 \\
1 & 4 & 0 & 30 \\
2 & 3 & 1 & 16 \\
2 & 4 & 0 & 25 \\
2 & 1 & 0 & 15 \\
2 & 2 & 0 & 22 \\
\hline
\end{tabular}
\end{center}

The two-level nested model is estimated with a NEST statement, as follows:

\begin{verbatim}
proc mdc data=one type=nlogit;
  model y = cost / choice=(choice);
  id pid;
  utility(1,) = cost;
  nest level(1) = (1\ 2\ 3\ @\ 1,\ 4\ @\ 2),
    level(2) = (1\ 2\ @\ 1);
run;
\end{verbatim}

The tree is constructed as in Figure 18.24.
Another model is estimated if you specify the decision tree as in Figure 18.25. The different nested tree structure is specified in the following SAS statements:

```sas
proc mdc data=one type=nlogit;
   model y = cost / choice=(choice);
   id pid;
   utility u(1,) = cost;
   nest level(1) = (1 @ 1, 2 3 4 @ 2),
      level(2) = (1 2 @ 1);
run;
```

**Figure 18.25** An Alternate Two-Level Tree

**NLOPTIONS Statement**

```sas
NLOPTIONS options;
```

PROC MDC uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. The NLOPTIONS statement specifies nonlinear optimization options. The NLOPTIONS statement must follow the MODEL statement. For a list of all the options of the NLOPTIONS statement, see Chapter 6, “Nonlinear Optimization Methods.”
OUTPUT Statement

OUTPUT options;

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimated linear predictors (XBETA) and predicted probabilities (P). The input data set must be sorted by the choice variables within each ID.

OUT=SAS-data-set
specifies the name of the output data set.

PRED=variable name
P=variable name
requests the predicted probabilities by naming the variable that contains the predicted probabilities in the output data set.

XBETA=variable name
names the variable that contains the linear predictor ($x\beta$) values. However, the XBETA= option is not supported in the nested logit model.

RESTRICT Statement

RESTRICT restriction1 < , restriction2 . . . >;

The RESTRICT statement imposes linear restrictions on the parameter estimates. You can specify any number of RESTRICT statements.

Each restriction is written as an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

expression operator expression;

The operator can be =, <, >, <=, or >=.

Restriction expressions can be composed of parameters; multiplication (*), summation (+), and subtraction (−) operators; and constants. Parameters named in restriction expressions must be among the parameters estimated by the model. Parameters associated with a regressor variable are referred to by the name of the corresponding regressor variable. The restriction expressions must be a linear function of the parameters.

Lagrange multipliers are reported for all the active linear constraints. In the displayed output, the Lagrange multiplier estimates are identified with the names Restrict1, Restrict2, and so on. The probability of the Lagrange multipliers is computed using a beta distribution (LaMotte 1994).

The following are examples of using the RESTRICT statement:

```sas
proc mdc data=one;
model y = x1-x10 /
    type=clogit
    choice=(mode 1 2 3);
    id pid;
    restrict x1*2 <= x2 + x3, ;
run;
```
Chapter 18: The MDC Procedure

```plaintext
proc mdc data=newdata;
model decision = ttime / type=mprobit
   nchoice=3
   unitvariance=(1 2)
   covest=hess;
   id pid;
   restrict RHO_31 = 0, STD_3<=1;
run;
```

**TEST Statement**

```plaintext
<'label'> TEST <'string'>: equation <,equation...> </ options> ;
```

The TEST statement performs Wald, Lagrange multiplier, and likelihood ratio tests of linear hypotheses about the regression parameters in the preceding MODEL statement. Each equation specifies a linear hypothesis to be tested. All hypotheses in one TEST statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. The keyword INTERCEPT refers to the coefficient of the intercept.

The following options can be specified after the slash (/):

- **ALL**
  - requests Wald, Lagrange multiplier, and likelihood ratio tests.

- **WALD**
  - requests the Wald test.

- **LM**
  - requests the Lagrange multiplier test.

- **LR**
  - requests the likelihood ratio test.

The following statements illustrate the use of the TEST statement:

```plaintext
proc mdc;
   model decision = x1 x2 / type=clogit
      choice=(mode 1 2 3);
   id pid;
   test x1 = 0, 0.5 * x1 + 2 * x2 = 0;
run;
```

The test investigates the joint hypothesis that

\[ \beta_1 = 0 \]

and

\[ 0.5\beta_1 + 2\beta_2 = 0 \]
Only linear equality restrictions and tests are permitted in PROC MDC. Tests expressions can be composed only of algebraic operations that use the addition symbol (+), subtraction symbol (–), and multiplication symbol (*).

The TEST statement accepts labels that are reproduced in the printed output. The TEST statement can be labeled in two ways. A TEST statement can be preceded by a label followed by a colon. Alternatively, the keyword TEST can be followed by a quoted string followed by a colon. If both are present, PROC MDC uses the label that precedes the first colon. If no label is present, PROC MDC automatically labels the tests.

### UTILITY Statement

**UTILITY U (level < , choices >)= variables ;**

The UTILITY statement specifies a utility function that can be used in estimating a nested logit model. The U()= option can have two arguments. The first argument contains level information, and the second argument is related to choice information. The second argument can be omitted for the first level when all the choices at the first level share the same variables and the same parameters. However, for any level above the first, the second argument must be provided. The UTILITY statement specifies a utility function while the NEST statement constructs the decision tree.

Consider a two-level nested logit model that has one explanatory variable at level 1. This model can be specified as follows:

```plaintext
proc mdc data=one type=nlogit;
   model y = cost / choice=(choice);
   id pid;
   utility u(1, 2 3 4) = cost;
   nest level(1) = (1 @ 1, 2 3 4 @ 2),
                   level(2) = (1 2 @ 1);
run;
```

You also can specify the following statement because all the variables at the first level share the same explanatory variable, cost:

```plaintext
utility u(1,) = cost;
```

The variable, cost, must be listed in the MODEL statement. When the additional explanatory variable, dummy, is included at level 2, another U()= option needs to be specified. Note that the U()= option must specify choices within any level above the first. Thus, it is specified as U(2, 1 2) in the following statements:

```plaintext
proc mdc data=one type=nlogit;
   model y = cost dummy / choice=(choice);
   id pid;
   utility u(1,) = cost,
                 u(2,1 2) = dummy;
   nest level(1) = (1 @ 1, 2 3 4 @ 2),
                   level(2) = (1 2 @ 1);
run;
```
Details: MDC Procedure

Multinomial Discrete Choice Modeling

When the dependent variable takes multiple discrete values, you can use multinomial discrete choice modeling to analyze the data. This section considers models for unordered multinomial data.

Let the random utility function be defined by

\[ U_{ij} = V_{ij} + \epsilon_{ij} \]

where the subscript \( i \) is an index for the individual, the subscript \( j \) is an index for the alternative, \( V_{ij} \) is a nonstochastic utility function, and \( \epsilon_{ij} \) is a random component (error) that captures unobserved characteristics of alternatives or individuals or both. In multinomial discrete choice models, the utility function is assumed to be linear, so that \( V_{ij} = x_{ij}' \beta \).

In the conditional logit model, each \( \epsilon_{ij} \) for all \( j \in C_i \) is distributed independently and identically (iid) with the Type I extreme-value distribution, \( \exp(-\exp(-\epsilon_{ij})) \), also known as the Gumbel distribution.

The iid assumption on the random components of the utilities of the different alternatives can be relaxed to overcome the well-known and restrictive independence from irrelevant alternatives (IIA) property of the conditional logit model. This allows for more flexible substitution patterns among alternatives than the one imposed by the conditional logit model. See the section “Independence from Irrelevant Alternatives (IIA)” on page 1012.

The nested logit model is derived by allowing the random components to be identical but nonindependent. Instead of independent Type I extreme-value errors, the errors are assumed to have a generalized extreme-value distribution. This model generalizes the conditional logit model to allow for particular patterns of correlation in unobserved utility (McFadden 1978).

Another generalization of the conditional logit model, the heteroscedastic extreme-value (HEV) model, is obtained by allowing independent but nonidentical errors distributed with a Type I extreme-value distribution (Bhat 1995). It permits different variances on the random components of utility across the alternatives.

Mixed logit models are also generalizations of the conditional logit model that can represent very general patterns of substitution among alternatives. See the “Mixed Logit Model” on page 1013 section for details.

The multinomial probit (MNP) model is derived when the errors, \( (\epsilon_{ij_1}, \epsilon_{ij_2}, \ldots, \epsilon_{ij_J}) \), have a multivariate normal (MVN) distribution. Thus, this model accommodates a very general error structure.

The multinomial probit model requires burdensome computation compared to a family of multinomial choice models derived from the Gumbel distributed utility function, since it involves multi-dimensional integration (with dimension \( J - 1 \)) in the estimation process. In addition, the multinomial probit model requires more parameters than other multinomial choice models. As a result, conditional and nested logit models are used more frequently, even though they are derived from a utility function whose random component is more restrictively defined than the multinomial probit model.

The event of a choice being made, \( \{y_i = j\} \), can be expressed using a random utility function

\[ U_{ij} \geq \max_{k \in C_i, k \neq j} U_{ik} \]
where \( C_i \) is the choice set of individual \( i \). Individual \( i \) chooses alternative \( j \) if and only if it provides a level of utility that is greater than or equal to that of any other alternative in his choice set. Then, the probability that individual \( i \) chooses alternative \( j \) (from among the \( n_i \) choices in his choice set \( C_i \)) is

\[
P_i(j) = P_{ij} = P[x_{ij}' \beta + \epsilon_{ij} \geq \max_{k \in C_i} (x_{ik}' \beta + \epsilon_{ik})]
\]

**Multinomial Logit and Conditional Logit**

When explanatory variables contain only individual characteristics, the multinomial logit model is defined as

\[
P(y_i = j) = P_{ij} = \frac{\exp(x_{ij}' \beta_j)}{\sum_{k=0}^{J} \exp(x_{ik}' \beta_k)} \text{ for } j = 0, \ldots, J
\]

where \( y_i \) is a random variable that indicates the choice made, \( x_i \) is a vector of characteristics specific to the \( i \)th individual, and \( \beta_j \) is a vector of coefficients specific to the \( j \)th alternative. Thus, this model involves choice-specific coefficients and only individual specific regressors. For model identification, it is often assumed that \( \beta_0 = 0 \). The multinomial logit model reduces to the binary logit model if \( J = 1 \).

The ratio of the choice probabilities for alternatives \( j \) and \( l \) (the odds ratio of alternatives \( j \) and \( l \)) is

\[
\frac{P_{ij}}{P_{il}} = \frac{\exp(x_{ij}' \beta_j)/\sum_{k=0}^{J} \exp(x_{ik}' \beta_k)}{\exp(x_{il}' \beta_l)/\sum_{k=0}^{J} \exp(x_{ik}' \beta_k)} = \exp[x_{ij}'(\beta_j - \beta_l)]
\]

Note that the odds ratio of alternatives \( j \) and \( l \) does not depend on any alternatives other than \( j \) and \( l \). For more information, see the section “Independence from Irrelevant Alternatives (IIA)” on page 1012.

The log-likelihood function of the multinomial logit model is

\[
\mathcal{L} = \sum_{i=1}^{N} \sum_{j=0}^{J} d_{ij} \ln P(y_i = j)
\]

where

\[
d_{ij} = \begin{cases} 1 & \text{if individual } i \text{ chooses alternative } j \\ 0 & \text{otherwise} \end{cases}
\]

This type of multinomial choice modeling has a couple of weaknesses: it has too many parameters (the number of individual characteristics times \( J \)), and it is difficult to interpret. The multinomial logit model can be used to predict the choice probabilities, among a given set of \( J + 1 \) alternatives, of an individual with known vector of characteristics \( x_i \).

The parameters of the multinomial logit model can be estimated with the TYPE=CLOGIT option in the MODEL statement; however, this requires modification of the conditional logit model to allow individual specific effects.

The conditional logit model, sometimes called the multinomial logit model, is similarly defined when choice-specific data are available. Using properties of Type I extreme-value (Gumbel) distribution, the probability that individual \( i \) chooses alternative \( j \) from among the choices in his choice set \( C_i \) is

\[
P(y_i = j) = P_{ij} = P[x_{ij}' \beta + \epsilon_{ij} \geq \max_{k \in C_i, k \neq j} (x_{ik}' \beta + \epsilon_{ik})] = \frac{\exp(x_{ij}' \beta)}{\sum_{k \in C_i} \exp(x_{ik}' \beta)}
\]
where $x_{ij}$ is a vector of attributes specific to the $j$th alternative as perceived by the $i$th individual. It is assumed that there are $n_i$ choices in each individual’s choice set, $C_i$.

The log-likelihood function of the conditional logit model is

$$L = \sum_{i=1}^{N} \sum_{j \in C_i} d_{ij} \ln P(y_i = j)$$

The conditional logit model can be used to predict the probability that an individual will choose a previously unavailable alternative, given knowledge of $\beta$ and the vector $x_{ij}$ of choice-specific characteristics.

**Independence from Irrelevant Alternatives (IIA)**

The problematic aspect of the conditional logit (and the multinomial logit) model lies in the property of independence from irrelevant alternatives (IIA). The IIA property can be derived from the probability ratio of any two choices. For the conditional logit model,

$$\frac{P_{ij}}{P_{il}} = \frac{\exp(x_{ij}'\beta)}{\sum_{k \in C_i} \exp(x_{ik}'\beta)} / \frac{\exp(x_{il}'\beta)}{\sum_{k \in C_i} \exp(x_{ik}'\beta)} = \exp[(x_{ij} - x_{il})'\beta]$$

It is evident that the ratio of the probabilities for alternatives $j$ and $l$ does not depend on any alternatives other than $j$ and $l$. This was also shown to be the case for the multinomial logit model. Thus, for the conditional and multinomial logit models, the ratio of probabilities of any two alternatives is necessarily the same regardless of what other alternatives are in the choice set or what the characteristics of the other alternatives are. This is referred to as the IIA property.

The IIA property is useful from the point of view of estimation and forecasting. For example, it allows the prediction of demand for currently unavailable alternatives. If the IIA property is appropriate for the choice situation being considered, then estimation can be based on the set of currently available alternatives, and then the estimated model can be used to calculate the probability that an individual would choose a new alternative not considered in the estimation procedure. However, the IIA property is restrictive from the point of view of choice behavior. Models that display the IIA property predict that a change in the attributes of one alternative changes the probabilities of the other alternatives proportionately such that the ratios of probabilities remain constant. Thus, cross elasticities due to a change in the attributes of an alternative $j$ are equal for all alternatives $k \neq j$. This particular substitution pattern might be too restrictive in some choice settings.

The IIA property of the conditional logit model follows from the assumption that the random components of utility are identically and independently distributed. The other models in PROC MDC (namely, nested logit, HEV, mixed logit, and multinomial probit) relax the IIA property in different ways.

For an example of Hausman’s specification test of IIA assumption, see “Example 18.6: Hausman’s Specification Test” on page 1046.

**Heteroscedastic Extreme-Value Model**

The heteroscedastic extreme-value (HEV) model (Bhat 1995) allows the random components of the utility function to be nonidentical. Specifically, the HEV model assumes independent but nonidentical error terms distributed with the Type I extreme-value distribution. The HEV model allows the variances of the random
components of utility to differ across alternatives. Bhat (1995) argues that the HEV model does not have the IIA property. The HEV model contains the conditional logit model as a special case. The probability that an individual \( i \) will choose alternative \( j \) from the set \( C_i \) of available alternatives is

\[
P_i(j) = \int_{-\infty}^{\infty} \prod_{k \in C_i, k \neq j} \Gamma \left[ \frac{x_{ij}' \beta - x_{ik}' \beta + \theta_j w}{\theta_k} \right] \gamma(w) dw
\]

where the choice set \( C_i \) has \( n_i \) elements and

\[
\Gamma(x) = \exp(-\exp(-x)) \quad \gamma(x) = \exp(-x) \Gamma(x)
\]

are the cumulative distribution function and probability density function of the Type I extreme-value distribution. The variance of the error term for the \( j \)th alternative is \( \frac{1}{6} \pi^2 \theta_j^2 \). If the scale parameters, \( \theta_j \), of the random components of utility of all alternatives are equal, then this choice probability is the same as that of the conditional logit model. The log-likelihood function of the HEV model can be written as

\[
\mathcal{L} = \sum_{i=1}^{N} \sum_{j \in C_i} d_{ij} \ln[P_i(j)]
\]

where

\[
d_{ij} = \begin{cases} 
1 & \text{if individual } i \text{ chooses alternative } j \\
0 & \text{otherwise}
\end{cases}
\]

Since the log-likelihood function contains an improper integral function, it is computationally difficult to get a stable estimate. With the transformation \( u = \exp(-w) \), the probability can be written

\[
P_i(j) = \int_{0}^{\infty} \prod_{k \in C_i, k \neq j} \Gamma \left[ \frac{x_{ij}' \beta - x_{ik}' \beta - \theta_j \ln(u)}{\theta_k} \right] \exp(-u) du
\]

\[
= \int_{0}^{\infty} G_{ij}(u) \exp(-u) du
\]

Using the Gauss-Laguerre weight function, \( W(x) = \exp(-u) \), the integration of the log-likelihood function can be replaced with a summation as follows:

\[
\int_{0}^{\infty} G_{ij}(u) \exp(-u) du = \sum_{k=1}^{K} w_k G_{ij}(x_k)
\]

Weights \( (w_k) \) and abscissas \( (x_k) \) are tabulated by Abramowitz and Stegun (1970).

**Mixed Logit Model**

In mixed logit models, an individual’s utility from any alternative can be decomposed into a deterministic component, \( x_{ij}' \beta \), which is a linear combination of observed variables, and a stochastic component, \( \xi_{ij} + \epsilon_{ij} \).

\[
U_{ij} = x_{ij}' \beta + \xi_{ij} + \epsilon_{ij}
\]
where \( x_{ij} \) is a vector of observed variables that relate to individual \( i \) and alternative \( j \), \( \beta \) is a vector of parameters, \( \xi_{ij} \) is an error component that can be correlated among alternatives and heteroscedastic for each individual, and \( \varepsilon_{ij} \) is a random term with zero mean that is independently and identically distributed over alternatives and individuals. The conditional logit model is derived if you assume \( \varepsilon_{ij} \) has an iid Gumbel distribution and \( V(\xi_{ij}) = 0 \).

The mixed logit model assumes a general distribution for \( \xi_{ij} \) and an iid Gumbel distribution for \( \varepsilon_{ij} \). Denote the density function of the error component \( \xi_{ij} \) as \( f(\xi_{ij}|\nu) \), where \( \nu \) is a parameter vector of the distribution of \( \xi_{ij} \). The choice probability of alternative \( j \) for individual \( i \) is written as

\[
P_i(j) = \int Q_i(j|\xi_{ij}) f(\xi_{ij}|\nu) d\xi_{ij}
\]

where the conditional choice probability for a given value of \( \xi_{ij} \) is the logit

\[
Q_i(j|\xi_{ij}) = \frac{\exp(x_{ij}'\beta + \xi_{ij})}{\sum_{k \in C_i} \exp(x_{ik}'\beta + \xi_{ik})}
\]

Since \( \xi_{ij} \) is not given, the unconditional choice probability, \( P_i(j) \), is the integral of the conditional choice probability, \( Q_i(j|\xi_{ij}) \), over the distribution of \( \xi_{ij} \). This model is called “mixed logit” since the choice probability is a mixture of logits with \( f(\xi_{ij}|\nu) \) as the mixing distribution.

In general, the mixed logit model does not have an exact likelihood function because the probability \( P_i(j) \) does not always have a closed form solution. Therefore, a simulation method is used for computing the approximate probability,

\[
\tilde{P}_i(j) = 1/S \sum_{s=1}^{S} \tilde{Q}_i(j|\xi_{ij}^s)
\]

where \( S \) is the number of simulation replications and \( \tilde{P}_i(j) \) is a simulated probability. The simulated log-likelihood function is computed as

\[
\tilde{\mathcal{L}} = \sum_{i=1}^{N} \sum_{j=1}^{n_i} d_{ij} \ln(\tilde{P}_i(j))
\]

where

\[
d_{ij} = \begin{cases} 
1 & \text{if individual } i \text{ chooses alternative } j \\
0 & \text{otherwise}
\end{cases}
\]

For simulation purposes, assume that the error component has a specific structure,

\[
\xi_{ij} = z_{ij}'\mu + w_{ij}'\beta^*
\]

where \( z_{ij} \) is a vector of observed data and \( \mu \) is a random vector with zero mean and density function \( \psi(\mu|\nu) \). The observed data vector \( (z_{ij}) \) of the error component can contain some or all elements of \( x_{ij} \). The component \( z_{ij}'\mu \) induces heteroscedasticity and correlation across unobserved utility components of the alternatives. This allows flexible substitution patterns among the alternatives. The \( k \)th element of vector \( \mu \) is distributed as

\[
\mu_k \sim (0, \sigma_k^2)
\]
Therefore, $\mu_k$ can be specified as

$$
\mu_k = \alpha_k \epsilon_{\mu}
$$

where

$$
\epsilon_{\mu} \sim N(0, 1)
$$

or

$$
\epsilon_{\mu} \sim U(-\sqrt{3}, \sqrt{3})
$$

In addition, $\beta^*$ is a vector of random parameters (random coefficients). Random coefficients allow heterogeneity across individuals in their sensitivity to observed exogenous variables. The observed data vector, $w_{ij}$, is a subset of $x_{ij}$. The following three types of distributions for the random coefficients are supported, where the $m$th element of $\beta^*$ is denoted as $\beta^*_m$:

- Normally distributed coefficient with the mean $b_m$ and spread $s_m$ being estimated.

$$
\beta^*_m = b_m + s_m \epsilon_{\beta} \quad \text{and} \quad \epsilon_{\beta} \sim N(0, 1)
$$

- Uniformly distributed coefficient with the mean $b_m$ and spread $s_m$ being estimated. A uniform distribution with mean $b$ and spread $s$ is $U(b-s, b+s)$.

$$
\beta^*_m = b_m + s_m \epsilon_{\beta} \quad \text{and} \quad \epsilon_{\beta} \sim U(-1, 1)
$$

- Lognormally distributed coefficient. The coefficient is calculated as

$$
\beta^*_m = \exp(b_m + s_m \epsilon_{\beta}) \quad \text{and} \quad \epsilon_{\beta} \sim N(0, 1)
$$

where $b_m$ and $s_m$ are parameters that are estimated.

The estimate of spread for normally, uniformly, and lognormally distributed coefficients can be negative. The absolute value of the estimated spread can be interpreted as an estimate of standard deviation for normally distributed coefficients.

A detailed description of mixed logit models can be found, for example, in Brownstone and Train (1999).

---

**Multinomial Probit**

The multinomial probit model allows the random components of the utility of the different alternatives to be nonindependent and nonidentical. Thus, it does not have the IIA property. The increase in the flexibility of the error structure comes at the expense of introducing several additional parameters in the covariance matrix of the errors.

Consider the random utility function

$$
U_{ij} = x'_{ij} \beta + \epsilon_{ij}
$$

where the joint distribution of \((\epsilon_{i1}, \epsilon_{i2}, \cdots, \epsilon_{iJ})\) is multivariate normal:

\[
\begin{bmatrix}
\epsilon_{i1} \\
\epsilon_{i2} \\
\vdots \\
\epsilon_{iJ}
\end{bmatrix} 
\sim N(0, \Sigma)
\]

\[
\Sigma = \begin{bmatrix}
\sigma_{jk}
\end{bmatrix}_{j,k=1,\ldots,J}
\]

The dimension of the error covariance matrix is determined by the number of alternatives \(J\). Given \((x_{i1}, x_{i2}, \cdots, x_{iJ})\), the \(j\)th alternative is chosen if and only if \(U_{ij} \geq U_{ik}\) for all \(k \neq j\). Thus, the probability that the \(j\)th alternative is chosen is

\[
P(y_i = j) = P_{ij} = P[\epsilon_{i1} - \epsilon_{ij} < (x_{ij} - x_{i1})' \beta, \ldots, \epsilon_{iJ} - \epsilon_{ij} < (x_{ij} - x_{iJ})' \beta]
\]

where \(y_i\) is a random variable that indicates the choice made. This is a cumulative probability from a \((J-1)\)-variate normal distribution. Since evaluation of this probability involves multidimensional integration, it is practical to use a simulation method to estimate the model. Many studies have shown that the simulators proposed by the following authors (henceforth referred to as GHK) perform well: Geweke (1989); Hajivassiliou (1993); Keane (1994). For example, Hajivassiliou, McFadden, and Ruud (1996) compare 13 simulators using 11 different simulation methods and conclude that the GHK simulation method is the most reliable. To compute the probability of the multivariate normal distribution, the recursive simulation method is used. Refer to Hajivassiliou (1993) for more details about GHK simulators.

The log-likelihood function for the multinomial probit model can be written as

\[
\mathcal{L} = \sum_{i=1}^{N} \sum_{j=1}^{J} d_{ij} \ln P(y_i = j)
\]

where

\[
d_{ij} = \begin{cases} 
1 & \text{if individual } i \text{ chooses alternative } j \\
0 & \text{otherwise}
\end{cases}
\]

For identification of the multinomial probit model, two of the diagonal elements of \(\Sigma\) are normalized to 1, and it is assumed that for one of the choices whose error variance is normalized to 1 (say, \(k\)), it is also true that \(\sigma_{jk} = \sigma_{kj} = 0\) for \(j = 1, \cdots, J\) and \(j \neq k\). Thus, a model with \(J\) alternatives has at most \(J(J-1)/2 - 1\) covariance parameters after normalization.

Let \(D\) and \(R\) be defined as

\[
D = \begin{bmatrix}
\sigma_1 & 0 & \cdots & 0 \\
0 & \sigma_2 & \cdots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \cdots & \sigma_J
\end{bmatrix}
\]

\[
R = \begin{bmatrix}
1 & \rho_{12} & \cdots & \rho_{1J} \\
\rho_{21} & 1 & \cdots & \rho_{2J} \\
\vdots & \vdots & \ddots & \vdots \\
\rho_{J1} & \rho_{J2} & \cdots & 1
\end{bmatrix}
\]
where $\sigma_j^2 = \sigma_{jj}$ and $\rho_{jk} = \frac{\sigma_{jk}}{\sigma_{jj}\sigma_{kk}}$. Then, for identification, $\sigma_{J-1} = \sigma_J = 1$ and $\rho_{kJ} = \rho_{JK} = 0$, for all $k \neq J$ can be imposed, and the error covariance matrix is $\Sigma = DRD$.

In the standard MDC output, the parameter estimates STD$_j$ and RHO$_{jk}$ correspond to $\sigma_j$ and $\rho_{jk}$.

In principle, the multinomial probit model is fully identified with the preceding normalizations. However, in practice, convergence in applications of the model with more than three alternatives often requires additional restrictions on the elements of $\Sigma$.

It must also be noted that the unrestricted structure of the error covariance matrix makes it impossible to forecast demand for a new alternative without knowledge of the new ($J + 1$) by ($J + 1$) error covariance matrix.

---

**Nested Logit**

The nested logit model (McFadden 1978, 1981) allows partial relaxation of the assumption of independence of the stochastic components of utility of alternatives. In some choice situations, the IIA property holds for some pairs of alternatives but not all. In these situations, the nested logit model can be used if the set of alternatives faced by an individual can be partitioned into subsets such that the IIA property holds within subsets but not across subsets.

In the nested logit model, the joint distribution of the errors is generalized extreme value (GEV). This is a generalization of the Type I extreme-value distribution that gives rise to the conditional logit model. Note that all $\epsilon_{ij}$ within each subset are correlated with each other. Refer to McFadden (1978, 1981) for details.

Nested logit models can be described analytically following the notation of McFadden (1981). Assume that there are $L$ levels, with 1 representing the lowest and $L$ representing the highest level of the tree. The index of a node at level $h$ in the tree is a pair $(j_h, \pi_h)$, where $\pi_h = (j_{h+1}, \cdots, j_L)$ is the index of the adjacent node at level $h+1$. Thus, the primitive alternatives, at level 1 in the tree, are indexed by vectors $(j_1, \cdots, j_L)$, and the alternative nodes at level $L$ are indexed by integers $j_L$. The choice set $C_{\pi_h}$ is the set of primitive alternatives (at level 1) that belong to branches below the node $\pi_h$. The notation $C_{\pi_h}$ is also used to denote a set of indices $j_h$ such that $(j_h, \pi_h)$ is a node immediately below $\pi_h$. Note that $C_{\pi_0}$ is a set with a single element, while $C_{\pi_h}$ represents a choice set that contains all possible alternatives. As an example, consider the circled node at level 1 in Figure 18.26. Since it stems from node 11, $\pi_h = 11$, and since it is the second node stemming from 11, $j_h = 2$, its index is $\pi_{h-1} = \pi_0 = (j_h, \pi_h) = 211$. Similarly, $C_{11} = \{111, 211, 311\}$ contains all the possible choices below 11.

Although this notation is useful for writing closed-form solutions for probabilities, the MDC procedure allows a more flexible definition of indices. See the section “NEST Statement” on page 1003 for more details about how to describe decision trees within the MDC procedure.
Let $x_{i:j,\pi_h}^{(h)}$ denote the vector of observed variables for individual $i$ common to the alternatives below node $j,\pi_h$. The probability of choice at level $h$ has a closed-form solution and is written

$$P_i(j_h|\pi_h) = \frac{\exp\left[x_{i:j,\pi_h}^{(h)}\beta^{(h)} + \sum_{k \in C_i:j,\pi_h} I_{k,j,\pi_h} \theta_{k,j,\pi_h}\right]}{\sum_{j \in C_i:\pi_h} \exp\left[x_{i:j,\pi_h}^{(h)}\beta^{(h)} + \sum_{k \in C_i:j,\pi_h} I_{k,j,\pi_h} \theta_{k,j,\pi_h}\right]}, \quad h = 2, \ldots, L$$

where $I_{\pi_h}$ is the inclusive value (at level $h + 1$) of the branch below node $\pi_h$ and is defined recursively as follows:

$$I_{\pi_h} = \ln \left\{ \sum_{j \in C_i:\pi_h} \exp\left[x_{i:j,\pi_h}^{(h)}\beta^{(h)} + \sum_{k \in C_i:j,\pi_h} I_{k,j,\pi_h} \theta_{k,j,\pi_h}\right] \right\}$$

$$0 \leq \theta_{k,\pi_1} \leq \cdots \leq \theta_{k,\pi_{L-1}}$$

The inclusive value $I_{\pi_h}$ denotes the average utility that the individual can expect from the branch below $\pi_h$. The dissimilarity parameters or inclusive value parameters ($\theta_{k,j,\pi_h}$) are the coefficients of the inclusive values and have values between 0 and 1 if nested logit is the correct model specification. When they all take value 1, the nested logit model is equivalent to the conditional logit model.

At decision level 1, there is no inclusive value; that is, $I_{\pi_0} = 0$. Therefore, the conditional probability is

$$P_i(j_1|\pi_1) = \frac{\exp\left[x_{i:j,\pi_1}^{(1)}\beta^{(1)}\right]}{\sum_{j \in C_i:\pi_1} \exp\left[x_{i:j,\pi_1}^{(1)}\beta^{(1)}\right]}$$

The log-likelihood function at level $h$ can then be written

$$\mathcal{L}^{(h)} = \sum_{i=1}^{N} \sum_{\pi_h \in C_i,\pi_{h+1}} \sum_{j \in C_i,\pi_h} y_{i,j,\pi_h} \ln P(C_i,j,\pi_h|C_i,\pi_{h'})$$
where $y_{i,j}^h$ is an indicator variable that has the value of 1 for the selected choice. The full log-likelihood function of the nested logit model is obtained by adding the conditional log-likelihood functions at each level:

$$\mathcal{L} = \sum_{h=1}^{L} \mathcal{L}^{(h)}$$

Note that the log-likelihood functions are computed from conditional probabilities when $h < L$. The nested logit model is estimated using the full information maximum likelihood method.

---

### Decision Tree and Nested Logit

You can view choices as a decision tree and model the decision tree by using the nested logit model. You need to use either the NEST statement or the CHOICE= option of the MODEL statement to specify the nested tree structure. Additionally, you need to identify which explanatory variables are used at each level of the decision tree. These explanatory variables are arguments for what is called a utility function. The utility function is specified using UTILITY statements. For example, consider a two-level decision tree. The tree structure is displayed in Figure 18.27.

#### Figure 18.27 Two-Level Decision Tree

A nested logit model with two levels can be specified using the following SAS statements:

```sas
proc mdc data=one type=nlogit;
  model decision = x1 x2 x3 x4 x5 / choice=(upmode 1 2, mode 1 2 3 4 5);
  id pid;
  utility u(1, 3 4 5 @ 2) = x1 x2,
       u(1, 1 2 @ 1) = x3 x4,
       u(2, 1 2) = x5;
run;
```

The DATA=one data set should be arranged as follows:
Chapter 18: The MDC Procedure

All model variables, \(x_1\) through \(x_5\), are specified in the UTILITY statement. It is required that entries denoted as \# have values for model estimation and prediction. The values of the level 2 utility variable \(x_5\) should be the same for all the primitive (level 1) alternatives below node 1 at level 2 and, similarly, for all the primitive alternatives below node 2 at level 2. In other words, \(x_5\) should have the same value for primitive alternatives 1 and 2 and, similarly, it should have the same value for primitive alternatives 3, 4, and 5. More generally, the values of any level 2 or higher utility function variables should be constant across primitive alternatives under each node for which the utility function applies. Since PROC MDC expects this to be the case, it uses the values of \(x_5\) only for the primitive alternatives 1 and 3, ignoring the values for the primitive alternatives 2, 4, and 5. Thus, PROC MDC uses the values of the utility function variable only for the primitive alternatives that come first under each node for which the utility function applies. This behavior applies to any utility function variables that are specified above the first level. The choice variable for level 2 (\(upmode\)) should be placed before the first-level choice variable (\(mode\)) when the \(CHOICE=\) option is specified. Alternatively, the NEST statement can be used to specify the decision tree. The following SAS statements fit the same nested logit model:

```sas
proc mdc data=a type=nlogit;
  model decision = x1 x2 x3 x4 x5 / choice=(mode 1 2 3 4 5);
  id pid;
  utility u(1, 3 4 5 @ 2) = x1 x2,
      u(1, 1 2 @ 1) = x3 x4,
      u(2, 1 2) = x5;
  nest level(1) = (1 2 @ 1, 3 4 5 @ 2),
                  level(2) = (1 2 @ 1);
run;
```

The \(U(1, 3 4 5 @ 2)=\) option specifies three choices, 3, 4, and 5, at level 1 of the decision tree. They are connected to the upper branch 2. The specified variables (\(x_1\) and \(x_2\)) are used to model this utility function. The bottom level of the decision tree is level 1. All variables in the UTILITY statement must be included in the MODEL statement. When all choices at the first level share the same variables, you can omit the second argument of the \(U()=\) option for that level. However, \(U(1, ) = x1 x2\) is not equivalent to the following statements:

\[
\begin{align*}
  u(1, 3 4 5 @ 2) &= x1 x2; \\
  u(1, 1 2 @ 1) &= x1 x2;
\end{align*}
\]

The \(CHOICE=\) variables need to be specified from the top to the bottom level. To forecast demand for new products, stated preference data are widely used. Stated preference data are attractive for market researchers...
because attribute variations can be controlled. Hensher (1993) explores the advantage of combining revealed preference (market data) and stated preference data. The scale factor \( \frac{V_{rp}}{V_{sp}} \) can be estimated using the nested logit model with the decision tree structure displayed in Figure 18.28.

**Figure 18.28** Decision Tree for Revealed and Stated Preference Data

Example SAS statements are as follows:

```sas
proc mdc data=a type=nlogit;
   model decision = x1 x2 x3 /
      spscale
      choice=(mode 1 2 3 4 5 6);
   id pid;
   utility u(1,) = x1 x2 x3;
   nest level(1) = (1 2 3 @ 1, 4 @ 2, 5 @ 3, 6 @ 4),
      level(2) = (1 2 3 4 @ 1);
run;
```

The SPSCALE option specifies that parameters of inclusive values for nodes 2, 3, and 4 at level 2 be the same. When you specify the SAMESCALE option, the MDC procedure imposes the same coefficient of inclusive values for choices 1–4.

---

**Model Fit and Goodness-of-Fit Statistics**

McFadden (1974) suggests a likelihood ratio index that is analogous to the R-square in the linear regression model:

\[
R^2_M = 1 - \frac{\ln L}{\ln L_0}
\]

where \( L \) is the maximum of the log-likelihood function and \( L_0 \) is the maximum of the log-likelihood function when all coefficients, except for an intercept term, are zero. McFadden’s likelihood ratio index is bounded by 0 and 1.

Estrella (1998) proposes the following requirements for a goodness-of-fit measure to be desirable in discrete choice modeling:

- The measure must take values in \([0, 1]\), where 0 represents no fit and 1 corresponds to perfect fit.
• The measure should be directly related to the valid test statistic for the significance of all slope coefficients.
• The derivative of the measure with respect to the test statistic should comply with corresponding derivatives in a linear regression.

Estrella’s measure is written as

\[ R_{E1}^2 = 1 - \left( \frac{\ln L}{\ln L_0} \right)^{-\frac{1}{2}} \ln L_0 \]

Estrella suggests an alternative measure,

\[ R_{E2}^2 = 1 - \left[ \ln L - K \right] \ln L_0^{-\frac{1}{2}} \ln L_0 \]

where \( \ln L_0 \) is computed with null parameter values, \( N \) is the number of observations used, and \( K \) represents the number of estimated parameters.

Other goodness-of-fit measures are summarized as follows:

\[ R_{CU1}^2 = 1 - \left( \frac{L_0}{L} \right)^{\frac{1}{2}} \]

(Cragg-Uhler 1)

\[ R_{CU2}^2 = \frac{1 - (L_0/L)^{\frac{1}{2}}}{1 - L_0^{\frac{1}{2}}} \]

(Cragg-Uhler 2)

\[ R_A^2 = \frac{2 \ln L - \ln L_0}{2 \ln L - \ln L_0 + N} \]

(Aldrich-Nelson)

\[ R_{VZ}^2 = R_A^2 - \frac{2 \ln L_0 - N}{2 \ln L_0} \]

(Veall-Zimmermann)

The AIC and SBC are computed as follows:

\[ AIC = -2 \ln (L) + 2k \]
\[ SBC = -2 \ln (L) + \ln (n) k \]

where \( \ln (L) \) is the log-likelihood value for the model, \( k \) is the number of parameters estimated, and \( n \) is the number of observations (that is, the number of respondents).

**Tests on Parameters**

In general, the hypothesis to be tested can be written as

\[ H_0 : h(\theta) = 0 \]

where \( h(\theta) \) is an \( r \)-by-1 vector-valued function of the parameters \( \theta \) given by the \( r \) expressions specified in the TEST statement.

Let \( \hat{V} \) be the estimate of the covariance matrix of \( \hat{\theta} \). Let \( \hat{\theta} \) be the unconstrained estimate of \( \theta \) and \( \tilde{\theta} \) be the constrained estimate of \( \theta \) such that \( h(\tilde{\theta}) = 0 \). Let

\[ A(\theta) = \frac{\partial h(\theta)}{\partial \theta} |_{\tilde{\theta}} \]

Using this notation, the test statistics for the three kinds of tests are computed as follows:
• The Wald test statistic is defined as
\[ W = h'(\hat{\theta}) \left( A(\hat{\theta}) \tilde{V} A' (\hat{\theta}) \right)^{-1} h(\hat{\theta}) \]

The Wald test is not invariant to reparameterization of the model (Gregory and Veall 1985; Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

• The Lagrange multiplier test statistic is
\[ LM = \lambda' A(\tilde{\theta}) \tilde{V} A' (\tilde{\theta}) \lambda \]

where \( \lambda \) is the vector of Lagrange multipliers from the computation of the restricted estimate \( \tilde{\theta} \).

• The likelihood ratio test statistic is
\[ LR = 2 \left( L(\hat{\theta}) - L(\tilde{\theta}) \right) \]

where \( \tilde{\theta} \) represents the constrained estimate of \( \theta \) and \( L \) is the concentrated log-likelihood value.

For each kind of test, under the null hypothesis the test statistic is asymptotically distributed as a \( \chi^2 \) random variable with \( r \) degrees of freedom, where \( r \) is the number of expressions in the TEST statement. The \( p \)-values reported for the tests are computed from the \( \chi^2(r) \) distribution and are only asymptotically valid.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation to its small sample distribution than that of the other two tests. However, the Wald test has the lowest computational cost, since it does not require computation of the constrained estimate \( \tilde{\theta} \).

The following statements are an example of using the TEST statement to perform a likelihood ratio test:

```sas
proc mdc;
  model decision = x1 x2 / type=clogit
    choice=(mode 1 2 3);
  id pid;
  test 0.5 * x1 + 2 * x2 = 0 / lr;
run;
```

**OUTEST= Data Set**

The OUTEST= data set contains all the parameters that are estimated in a MODEL statement. The OUTEST= option can be used when the PROC MDC call contains one MODEL statement. There are additional restrictions. For the HEV and multinomial probit models, you need to specify exactly all possible elements of the choice set, since additional parameters (for example, SCALE1 or STD1) are generated automatically in the MDC procedure. Therefore, the following SAS statements are not valid when the OUTEST= option is specified:

```sas
proc mdc data=a outest=e;
  model y = x / type=hev choice=(alter);
run;
```
Chapter 18: The MDC Procedure

You need to specify all possible choices in the CHOICE= option since the OUTEST= option is specified as follows:

```sas
proc mdc data=a outest=e;
   model y = x / type=hev choice=(alter 1 2 3);
run;
```

When the NCHOICE= option is specified, no additional information about possible choices is required. Therefore, the following SAS statements are correct:

```sas
proc mdc data=a outest=e;
   model y = x / type=mprobit nchoice=3;
run;
```

The nested logit model does not produce the OUTEST= data set unless the NEST statement is specified.

Each parameter contains the estimate for the corresponding parameter in the corresponding model. In addition, the OUTEST= data set contains the following variables:

- `_DEPVAR_` the name of the dependent variable
- `_METHOD_` the estimation method
- `_MODEL_` the label of the MODEL statement if one is specified, or blank otherwise
- `_STATUS_` a character variable that indicates whether the optimization process reached convergence or failed to converge: 0 indicates that the convergence was reached, 1 indicates that the maximum number of iterations allowed was exceeded, 2 indicates a failure to improve the function value, and 3 indicates a failure to converge because the objective function or its derivatives could not be evaluated or improved, or linear constraints were dependent, or the algorithm failed to return to feasible region, or the number of iterations was greater than prespecified.
- `_NAME_` the name of the row of the covariance matrix for the parameter estimate, if the COVOUT option is specified, or blank otherwise
- `_LIKLHD_` the log-likelihood value
- `_STDERR_` standard error of the parameter estimate, if the COVOUT option is specified
- `_TYPE_` PARMS for observations that contain parameter estimates, or COV for observations that contain covariance matrix elements

The OUTEST= data set contains one observation for the MODEL statement giving the parameter estimates for that model. If the COVOUT option is specified, the OUTEST= data set includes additional observations for the MODEL statement giving the rows of the covariance matrix of parameter estimates. For covariance observations, the value of the _TYPE_ variable is COV, and the _NAME_ variable identifies the parameter associated with that row of the covariance matrix.
ODS Table Names

PROC MDC assigns a name to each table it creates. You can use these names to denote the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the Table 18.3.

Examples: MDC Procedure

Example 18.1: Binary Data Modeling

The MDC procedure supports various multinomial choice models. However, you can also use PROC MDC to estimate binary choice models such as binary logit and probit because these models are special cases of multinomial models.
Spector and Mazzeo (1980) studied the effectiveness of a new teaching method on students’ performance in an economics course. They reported grade point average (gpa), previous knowledge of the material (tuce), a dummy variable for the new teaching method (psi), and the final course grade (grade). A value of 1 is recorded for grade if a student earned the letter grade “A,” and 0 otherwise.

The binary logit can be estimated using the conditional logit model. In order to use the MDC procedure, the data are converted as follows so that each possible choice corresponds to one observation:

```sas
data smdata;
  input gpa tuce psi grade;
datalines;
  2.66 20 0 0
  2.89 22 0 0
  3.28 24 0 0
  2.92 12 0 0
... more lines ...
run;
```

The first 10 observations are displayed in Output 18.1.1. The variables related to grade=0 are omitted since these are not used for binary choice model estimation.

```sas
data smdata1;
  set smdata;
  retain id 0;
  id + 1;

  /*-- first choice --*/
  choice1 = 1;
  choice2 = 0;
  decision = (grade = 0);
  gpa_2 = 0;
  tuce_2 = 0;
  psi_2 = 0;
  output;

  /*-- second choice --*/
  choice1 = 0;
  choice2 = 1;

Consider the choice probability of the conditional logit model for binary choice:

\[
P_i(j) = \frac{\exp(x_i'j\beta)}{\sum_{k=1}^{2} \exp(x_i'k\beta)}, \quad j = 1, 2
\]

The choice probability of the binary logit model is computed based on normalization. The preceding conditional logit model can be converted as

\[
P_i(1) = \frac{1}{1 + \exp((x_i2 - x_i1)'\beta)}
\]

\[
P_i(2) = \frac{\exp((x_i2 - x_i1)'\beta)}{1 + \exp((x_i2 - x_i1)'\beta)}
\]

Therefore, you can interpret the binary choice data as the difference between the first and second choice characteristics. In the following statements, it is assumed that \(x_{i1} = 0\). The binary logit model is estimated and displayed in Output 18.1.2.

```sas
/*--- Conditional Logit ---*/
proc mdc data=smdatal;
   model decision = choice2 gpa_2 tuce_2 psi_2 /
       type=clogit
       nchoice=2
       covest=hess;
   id id;
run;
```
Consider the choice probability of the multinomial probit model:

\[ P_i(j) = P[\epsilon_{i1} - \epsilon_{ij} < (x_{ij} - x_{i1})'\beta, \ldots, \epsilon_{ij} - \epsilon_{ij} < (x_{ij} - x_{ij})'\beta] \]

The probabilities of choice of the two alternatives can be written as

\[ P_i(1) = P[\epsilon_{i2} - \epsilon_{i1} < (x_{i1} - x_{i2})'\beta] \]
\[ P_i(2) = P[\epsilon_{i1} - \epsilon_{i2} < (x_{i2} - x_{i1})'\beta] \]

where \( \begin{bmatrix} \epsilon_{i1} \\ \epsilon_{i2} \end{bmatrix} \sim N\left(0, \begin{bmatrix} \sigma^2_1 & \sigma_{12} \\ \sigma_{12} & \sigma^2_2 \end{bmatrix}\right) \). Assume that \( x_{i1} = 0 \) and \( \sigma_{12} = 0 \). The binary probit model is estimated and displayed in Output 18.1.3. You do not get the same estimates as that of the usual binary probit model. The probabilities of choice in the binary probit model are

\[ P_i(2) = P[\epsilon_i < x_i'\beta] \]
\[ P_i(1) = 1 - P[\epsilon_i < x_i'\beta] \]

where \( \epsilon_i \sim N(0, 1) \). However, the multinomial probit model has the error variance \( \text{Var}(\epsilon_{i2} - \epsilon_{i1}) = \sigma^2_1 + \sigma^2_2 \) if \( \epsilon_{i1} \) and \( \epsilon_{i2} \) are independent (\( \sigma_{12} = 0 \)). In the following statements, unit variance restrictions are imposed on choices 1 and 2 (\( \sigma^2_1 = \sigma^2_2 = 1 \)). Therefore, the usual binary probit estimates (and standard errors) can be obtained by multiplying the multinomial probit estimates (and standard errors) in Output 18.1.3 by \( 1/\sqrt{2} \).

```plaintext
/*-- Multinomial Probit --*/
proc mdc data=smdatal;
   model decision = choice2 gpa_2 tuce_2 psi_2 /
       type=mprobit
       nchoice=2
       covest=hess
       unitvariance=(1 2);
   id id;
run;
```
Example 18.2: Conditional Logit and Data Conversion

In this example, data are prepared for use by the MDCDATA statement. Sometimes, choice-specific information is stored in multiple variables. Since the MDC procedure requires multiple observations for each decision maker, you need to arrange the data so that there is an observation for each subject-alternative (individual-choice) combination. Simple binary choice data are obtained from Ben-Akiva and Lerman (1985). The following statements create the SAS data set:

```sas
data travel;
    length mode $ 8;
    input auto transit mode $;
datalines;
52.9 4.4 Transit
4.1 28.5 Transit
4.1 86.9 Auto
56.2 31.6 Transit
51.8 20.2 Transit
0.2 91.2 Auto
27.6 79.7 Auto
89.9 2.2 Transit
41.5 24.5 Transit
95.0 43.5 Transit
99.1 8.4 Transit
... more lines ...
```

The travel time is stored in two variables, auto and transit. In addition, the chosen alternatives are stored in a character variable, mode. The choice variable, mode, is converted to a numeric variable, decision, since the MDC procedure supports only numeric variables. The following statements convert the original data set, travel, and estimate the binary logit model. The first 10 observations of a relevant subset of the new data set and the parameter estimates are displayed in Output 18.2.1 and Output 18.2.2, respectively.

The following statements perform the binary logit estimation:

proc mdc data=new;
  model decision = autodum ttime /
    type=clogit
    nchoice=2;
  id id;
run;
Example 18.2: Conditional Logit and Data Conversion

Output 18.2.2 Binary Logit Estimation of Modal Choice Data

| Parameter | DF | Estimate  | Standard Error | t Value | Pr > |t| |
|-----------|----|-----------|----------------|---------|-------|-----|
| autodum   | 1  | -0.2376   | 0.7505         | -0.32   | 0.7516|
| ttime     | 1  | -0.0531   | 0.0206         | -2.57   | 0.0101|

In order to handle more general cases, you can use the MDCDATA statement. Choice-specific dummy variables are generated and multiple observations for each individual are created. The following example converts the original data set `travel` by using the MDCDATA statement and performs conditional logit analysis. Interleaved data are output into the new data set `new3`. This data set has twice as many observations as the original `travel` data set.

```
proc mdc data=travel;
  mdcdata varlist( x1 = (auto transit) )
    select=mode
    id=id
    alt=alternative
    decvar=Decision / out=new3;
  model decision = auto x1 /
    nchoice=2
    type=clogit;
  id id;
run;
```

The first nine observations of the modified data set are shown in Output 18.2.3. The result of the preceding program is listed in Output 18.2.4.

Example 18.3: Correlated Choice Modeling

Often, it is not realistic to assume that the random components of utility for all choices are independent. This example shows the solution to the problem of correlated random components by using multinomial probit and nested logit.

To analyze correlated data, trinomial choice data (1,000 observations) are created using a pseudo-random number generator by using the following statements. The random utility function is

\[ U_{ij} = V_{ij} + \epsilon_{ij}, \quad j = 1, 2, 3 \]

where

\[ \epsilon_{ij} \sim N \left( 0, \begin{bmatrix} 2 & .6 & 0 \\ .6 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \right) \]

/*--- generate simulated series ---*/
%let ndim = 3;
%let nobs = 1000;

data trichoice;
  array error{&ndim} e1-e3;
  array vtemp{&ndim} _temporary_;
  array lm{6} _temporary_ (1.4142136 0.4242641 1 0 0 1);
  retain nseed 345678;
  do id = 1 to &nobs;
    index = 0;
    /* generate independent normal variate */
    do i = 1 to &ndim;
      /* index of diagonal element */
      vtemp{i} = rannor(nseed);
    end;
    /* get multivariate normal variate */
    index = 0;
    do i = 1 to &ndim;
Example 18.3: Correlated Choice Modeling

```plaintext
error[i] = 0;
do j = 1 to i;
    error[i] = error[i] + lm{index+j}*vtemp{j};
end;
index = index + i;
end;
x1 = 1.0 + 2.0 * ranuni(nseed);
x2 = 1.2 + 2.0 * ranuni(nseed);
x3 = 1.5 + 1.2 * ranuni(nseed);
util1 = 2.0 * x1 + e1;
util2 = 2.0 * x2 + e2;
util3 = 2.0 * x3 + e3;
do i = 1 to &ndim;
    vtemp{i} = 0;
end;
if ( util1 > util2 & util1 > util3 ) then
    vtemp{1} = 1;
else if ( util2 > util1 & util2 > util3 ) then
    vtemp{2} = 1;
else if ( util3 > util1 & util3 > util2 ) then
    vtemp{3} = 1;
else continue;
/*-- first choice --*/
x = x1;
mode = 1;
decision = vtemp{1};
output;
/*-- second choice --*/
x = x2;
mode = 2;
decision = vtemp{2};
output;
/*-- third choice --*/
x = x3;
mode = 3;
decision = vtemp{3};
output;
end;
run;
```

First, the multinomial probit model is estimated (see the following statements). Results show that
the standard deviation, correlation, and slope estimates are close to the parameter values. Note that
\[
\rho_{12} = \frac{\sigma_{12}}{\sqrt{\sigma_{1}^{2}\sigma_{2}^{2}}} = \frac{0.6}{\sqrt{2}(1)} = 0.42, \sigma_{1} = \sqrt{2} = 1.41, \sigma_{2} = \sqrt{1} = 1, \text{ and the parameter value for }
\]
the variable \( x \) is 2.0. (See Output 18.3.1.)

```plaintext
/*-- Trinomial Probit --*/
proc mdc data=trichoice randnum=halton nsimul=100;
model decision = x /
    type=mprob
    choice=(mode 1 2 3)
    covest=op
    optmethod=qn;
    id id;
run;
```
Chapter 18: The MDC Procedure

Output 18.3.1 Trinomial Probit Model Estimation

| Parameter | DF | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----|----------|---------------|---------|-------|
| x         | 1  | 1.7685   | 0.1191        | 14.85   | <.0001|
| STD_1     | 1  | 1.2514   | 0.1494        | 8.38    | <.0001|
| RHO_21    | 1  | 0.3971   | 0.1087        | 3.65    | 0.0003|

Figure 18.29 shows a two-level decision tree.

Figure 18.29 Nested Tree Structure

The following statements estimate the nested model shown in Figure 18.29:

```sql
/*-- Two-Level Nested Logit --*/
proc mdc data=trichoice;
  model decision = x / type=nlogit
                     choice=(mode 1 2 3)
                     covest=op
                     optmethod=qn;
  id id;
  utility u(1,) = x;
  nest level(1) = (1 2 @ 1, 3 @ 2),
                  level(2) = (1 2 @ 1);
run;
```

The estimated result (see Output 18.3.2) shows that the data support the nested tree model since the estimates of the inclusive value parameters are significant and are less than 1.
Example 18.4: Testing for Homoscedasticity of the Utility Function

The conditional logit model imposes equal variances on random components of utility of all alternatives. This assumption can often be too restrictive and the calculated results misleading. This example shows several approaches to testing the homoscedasticity assumption.

The section “Getting Started: MDC Procedure” on page 977 analyzes an HEV model by using Daganzo’s trinomial choice data and displays the HEV parameter estimates in Figure 18.15. The inverted scale estimates for mode “2” and mode “3” suggest that the conditional logit model (which imposes equal variances on random components of utility of all alternatives) might be misleading. The HEV estimation summary from that analysis is repeated in Output 18.4.1.

Output 18.4.1 HEV Estimation Summary ($\theta_1 = 1$)

<table>
<thead>
<tr>
<th>Model Fit Summary</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dependent Variable</td>
</tr>
<tr>
<td>Number of Observations</td>
</tr>
<tr>
<td>Number of Cases</td>
</tr>
<tr>
<td>Log Likelihood</td>
</tr>
<tr>
<td>Maximum Absolute Gradient</td>
</tr>
<tr>
<td>Number of Iterations</td>
</tr>
<tr>
<td>Optimization Method</td>
</tr>
<tr>
<td>AIC</td>
</tr>
<tr>
<td>Schwarz Criterion</td>
</tr>
</tbody>
</table>

You can estimate the HEV model with unit scale restrictions on all three alternatives ($\theta_1 = \theta_2 = \theta_3 = 1$) with the following statements.
/*-- HEV Estimation --*/
proc mdc data=newdata;
  model decision = ttime / type=hev
                   nchoice=3
                   hev=(unitscale=1 2 3, integrate=laguerre)
                   covest=hess;
    id pid;
run;

Output 18.4.2 displays the estimation summary.

\textbf{Output 18.4.2} HEV Estimation Summary ($\theta_1 = \theta_2 = \theta_3 = 1$)

\begin{verbatim}
The MDC Procedure
Heteroscedastic Extreme Value Model Estimates

Model Fit Summary

Dependent Variable       decision
Number of Observations   50
Number of Cases          150
Log Likelihood           -34.12756
Maximum Absolute Gradient 6.7951E-9
Number of Iterations     5
Optimization Method      Dual Quasi-Newton
AIC                     70.25512
Schwarz Criterion       72.16714
\end{verbatim}

The test for scale equivalence (SCALE2=SCALE3=1) is performed using a likelihood ratio test statistic. The following SAS statements compute the test statistic (1.4276) and its $p$-value (0.4898) from the log-likelihood values in Output 18.4.1 and Output 18.4.2:

\begin{verbatim}
data _null_;  
  /*-- test for H0: scale2 = scale3 = 1 --*/  
  /* ln L(max) = -34.1276 */  
  /* ln L(0) = -33.4138 */  
  stat = -2 * ( - 34.1276 + 33.4138 );  
  df = 2;  
  p_value = 1 - probchi(stat, df);  
  put stat= p_value=;  
run;
\end{verbatim}

The test statistic fails to reject the null hypothesis of equal scale parameters, which implies that the random utility function is homoscedastic.

A multinomial probit model also allows heteroscedasticity of the random components of utility for different alternatives. Consider the utility function
\[ U_{ij} = V_{ij} + \epsilon_{ij} \]
Example 18.4: Testing for Homoscedasticity of the Utility Function

where

$$\epsilon_i \sim N \left( 0, \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \sigma^2 \end{bmatrix} \right)$$

This multinomial probit model is estimated by using the following statements:

```sas
/*-- Heteroscedastic Multinomial Probit --*/
proc mdc data=newdata;
   model decision = ttime /
      type=mprobit
      nchoice=3
      unitvariance=(1 2)
      covest=hess;
   id pid;
   restrict RHO_31 = 0;
run;
```

The estimation summary is displayed in Output 18.4.3.

**Output 18.4.3** Heteroscedastic Multinomial Probit Estimation Summary

<table>
<thead>
<tr>
<th>Dependent Variable</th>
<th>decision</th>
</tr>
</thead>
<tbody>
<tr>
<td>Number of Observations</td>
<td>50</td>
</tr>
<tr>
<td>Number of Cases</td>
<td>150</td>
</tr>
<tr>
<td>Log Likelihood</td>
<td>-33.88604</td>

</tr>
</tbody>
</table>

Next, the multinomial probit model with unit variances ($\sigma_1 = \sigma_2 = \sigma_3 = 1$) is estimated in the following statements:

```sas
/*-- Homoscedastic Multinomial Probit --*/
proc mdc data=newdata;
   model decision = ttime /
      type=mprobit
      nchoice=3
      unitvariance=(1 2 3)
      covest=hess;
   id pid;
   restrict RHO_21 = 0;
run;
```
The estimation summary is displayed in **Output 18.4.4**.

**Output 18.4.4** Homoscedastic Multinomial Probit Estimation Summary

<table>
<thead>
<tr>
<th>Model Fit Summary</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dependent Variable decision</td>
</tr>
<tr>
<td>Number of Observations</td>
</tr>
<tr>
<td>Number of Cases</td>
</tr>
<tr>

</tr>
<tr>
<td>Starting Point of Halton Sequence</td>
</tr>
</tbody>
</table>

The test for homoscedasticity \( (\sigma_3 = 1) \) under \( \sigma_1 = \sigma_2 = 1 \) shows that the error variance is not heteroscedastic since the test statistic (1.313) is less than \( \chi^2_{0.05,1} = 3.84 \). The marginal probability or \( p \)-value computed in the following statements from the PROBCHI function is 0.2519:

```plaintext
data _null_;  /*-- test for H0: sigma3 = 1 --*/  /* ln L(max) = -33.8860 */  /* ln L(0) = -34.5425 */  stat = -2 * ( -34.5425 + 33.8860 );  df = 1;  p_value = 1 - probchi(stat, df);  put stat= p_value=;  run;
```

**Example 18.5: Choice of Time for Work Trips: Nested Logit Analysis**

This example uses sample data of 527 automobile commuters in the San Francisco Bay Area to demonstrate the use of nested logit model.

Brownstone and Small (1989) analyzed a two-level nested logit model that is displayed in Figure 18.30. The probability of choosing \( j \) at level 2 is written as

\[
P_i(j) = \frac{\exp(\tau_j I_j)}{\sum_{j'=1}^{3} \exp(\tau_{j'} I_{j'})}
\]
where $I_{j'}$ is an inclusive value and is computed as

$$I_{j'} = \ln \left( \sum_{k' \in C_{j'}} \exp(x'_{ik} \beta) \right)$$

The probability of choosing an alternative $k$ is denoted as

$$P_i(k | j) = \frac{\exp(x'_{ik} \beta)}{\sum_{k' \in C_j} \exp(x'_{ik'} \beta)}$$

The full information maximum likelihood (FIML) method maximizes the following log-likelihood function:

$$\mathcal{L} = \sum_{i=1}^{N} \sum_{j=1}^{J} d_{ij} [\ln(P_i(k | j)) + \ln(P_i(j))]$$

where $d_{ij} = 1$ if a decision maker $i$ chooses $j$, and 0 otherwise.

**Figure 18.30** Decision Tree for Two-Level Nested Logit

Sample data of 527 automobile commuters in the San Francisco Bay Area have been analyzed by Small (1982); Brownstone and Small (1989). The regular time of arrival is recorded as between 42.5 minutes early and 17.5 minutes late, and indexed by 12 alternatives, using five-minute interval groups. Refer to Small (1982) for more details on these data. The following statements estimate the two-level nested logit model:

```plaintext
/*--- Two-level Nested Logit ---*/
proc mdc data=small maxit=200 outest=a;
   model decision = r15 r10 ttime ttime_cp sde sde_cp
                        sdl sdlx d2l /
       type=nlogit
       choice=(alt);
   id id;
   utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp
                     sdl sdlx d2l;
   nest level(1) = (1 2 3 4 5 6 7 8 @ 1, 9 @ 2, 10 11 12 @ 3),
                   level(2) = (1 2 3 @ 1);
run;
```
The following statements add the `upalt` variable, which describes the choice at the upper level of the nested tree to the data set:

```sas
data small;
  set small;
  upalt=1;
  if alt=9 then upalt=2;
  if alt>9 then upalt=3;
run;
```

The following statements show an alternative specification, which uses the `Choice=` option with two nested levels that are represented by `upalt` and `alt`:

```sas
proc mdc data=upalt maxit=200;
  model decision = r15 r10 ttime ttime_cp sde sde_cp
                   sdl sdlx d2l /
     type=nlogit
     choice=(upalt,alt);
  id id;
  utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp
                   sdl sdlx d2l;
run;
```

The estimation summary, discrete response profile, and the FIML estimates are displayed in **Output 18.5.1** through **Output 18.5.3**.

Now policy makers are particularly interested in predicting shares of each alternative to be chosen by population. One application of such predictions are market shares. Going even further, it is extremely useful to predict choice probabilities out of sample; that is, under alternative policies.

Suppose that in this particular transportation example you are interested in projecting the effect of a new program that indirectly shifts individual preferences with respect to late arrival to work. This means that you manage to decrease the coefficient for the “late dummy” D2L, which is a penalty for violating some margin of arriving on time. Suppose that you alter it from an estimated $-1.0941$ to almost twice that level, $-2.0941$. 
But first, in order to have a benchmark share, you predict probabilities to choose each particular option and output them to the new data set with the following additional statement:

```bash
/*!-- Create new data set with predicted probabilities --*/
output out=predicted1 p=probs;
```

Having these in sample predictions, you sort the data by alternative and aggregate across each of them as shown in the following statements:

```bash
/*!-- Sort the data by alternative --*/
proc sort data=predicted1;
   by alt;
run;

/*!-- Calculate average probabilities of each alternative --*/
proc means data=predicted1 nonobs mean;
   var probs;
   class alt;
run;
```

Output 18.5.4 shows the summary table that is produced by the preceding statements.

**Output 18.5.4** Average Probabilities of Choosing Each Particular Alternative

<table>
<thead>
<tr>
<th>alt</th>
<th>Mean</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0.0178197</td>
</tr>
<tr>
<td>2</td>
<td>0.0161712</td>

<td>0.0096334</td>
</tr>
<tr>
<td>12</td>
<td>0.0049677</td>
</tr>
</tbody>
</table>
Now you change the preference parameter for variable \( D2L \). In order to fix all the parameters, you use the \texttt{MAXIT=0} option to prevent optimization and the \texttt{START=} option in \texttt{MODEL} statement to specify initial parameters.

```sas
/*--- Two-level Nested Logit ---*/
proc mdc data=small maxit=0 outest=a;
   model decision = r15 r10 ttime ttime_cp sde sde_cp
                     sdl sdlx d2l /
      type=nlogit
   choice=(alt)
   start=\((1.1034, 0.3931, -0.0465, -0.0498, -0.6618, 0.0519, -2.1006, -3.5240, -2.0941, 0.6762, 1.0906, 0.7622)\);
   id id;
   utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp
                     sdl sdlx d2l;
   nest level(1) = (1 2 3 4 5 6 7 8 @ 1, 9 @ 2, 10 11 12 @ 3),
                   level(2) = (1 2 3 @ 1);
   output out=predicted2 p=probs;
run;
```

You apply the same \texttt{SORT} and \texttt{MEANS} procedures as applied earlier to obtain the following summary table in \textit{Output 18.5.5}.

Comparing the two tables shown in Output 18.5.4 and Output 18.5.5, you clearly see the effect of increased dislike of late arrival. People shifted their choices towards earlier times (alternatives 1–8) from the on-time option (alternative 9).

Brownstone and Small (1989) also estimate the two-level nested logit model with equal scale parameter constraints, $\tau_1 = \tau_2 = \tau_3$. Replication of their model estimation is shown in the following statements:

```plaintext
/*--- Nested Logit with Equal Dissimilarity Parameters ---*/
proc mdc data=small maxit=200 outest=a;
  model decision = r15 r10 ttime ttime_cp sde sde_cp
                   sdl sdlx d2l /
                   samescale
                   type=nlogit
                   choice=(alt);
  id id;
  utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp
                   sdl sdlx d2l;
  nest level(1) = (1 2 3 4 5 6 7 8 @ 1, 9 @ 2, 10 11 12 @ 3),
                  level(2) = (1 2 3 @ 1);
run;
```
The parameter estimates and standard errors are almost identical to those in Brownstone and Small (1989, p. 69). Output 18.5.6 and Output 18.5.7 display the results.

**Output 18.5.6** Nested Logit Estimation Summary with Equal Dissimilarity Parameters

```

However, the test statistic for $H_0 : \tau_1 = \tau_2 = \tau_3$ rejects the null hypothesis at the 5% significance level since $-2 \times (\ln L(0) - \ln L) = 7.15 > x^2_{0.05,2} = 5.99$. The $p$-value is computed in the following statements and is equal to 0.0280:

```
data _null_;   /*-- test for H0: tau1 = tau2 = tau3 --*/
  /*  ln L(max) = -990.8191 */
  /*  ln L(0)   = -994.3940 */
```
Example 18.6: Hausman’s Specification Test

As discussed under multinomial and conditional logits, the odds ratios in the multinomial or conditional logits are independent of the other alternatives. See the section “Multinomial Logit and Conditional Logit” on page 1011. This property of the logit models is often viewed as rather restrictive and provides substitution patterns that do not represent the actual relationship among choice alternatives.

This independence assumption, called independence of irrelevant alternatives (IIA), can be tested with Hausman’s specification test. According to Hausman and McFadden (1984), if a subset of choice alternatives is irrelevant, it can be omitted from the sample without changing the remaining parameters systematically.

Under the null hypothesis (IIA holds), omitting the irrelevant alternatives leads to consistent and efficient parameter estimates $\hat{\beta}_R$, while parameter estimates $\hat{\beta}_U$ from the unrestricted model are consistent but inefficient. Under the alternative, only the parameter estimates $\hat{\beta}_U$ obtained from the unrestricted model are consistent.

This example demonstrates the use of Hausman’s specification test to analyze the IIA assumption and decide on an appropriate model that provides less restrictive substitution patterns (nested logit or multinomial probit). A sample data set of 527 automobile commuters in the San Francisco Bay Area is used (Small 1982). The regular time of arrival is recorded as between 42.5 minutes early and 17.5 minutes late, and is indexed by 12 alternatives, using five-minute interval groups. See Small (1982) for more details about these data.

The data can be divided into three groups: commuters who arrive early (alternatives 1 – 8), commuters who arrive on time (alternative 9), and commuters who arrive late (alternatives 10 – 12). Suppose that you want to test whether the IIA assumption holds for commuters who arrived on time (alternative 9).

Hausman’s specification test is distributed as $\chi^2$ with $k$ degrees of freedom (equal to the number of independent variables) and can be written as

$$\chi^2 = (\hat{\beta}_U - \hat{\beta}_R) [\hat{V}_U - \hat{V}_R]^{-1} (\hat{\beta}_U - \hat{\beta}_R)$$

where $\hat{\beta}_R$ and $\hat{V}_R$ represent parameter estimates and the variance-covariance matrix, respectively, from the model where the ninth alternative was omitted, and $\hat{\beta}_U$ and $\hat{V}_U$ represent parameter estimates and the variance-covariance matrix, respectively, from the full model. The following macro can be used to perform the IIA test for the ninth alternative:

```plaintext
/*---------------------------------------------------------------
* name: %IIA
* note: This macro test the IIA hypothesis using the Hausman's
* specification test. Inputs into the macro are as follows:
* indata:   input data set
* varlist:  list of RHS variables
* nchoice:  number of choices for each individual
* choice:   list of choices
* nvar:     number of independent variables
*/
```
Example 18.6: Hausman’s Specification Test

* nIIA: number of choice alternatives used to test IIA
* IIA: choice alternatives used to test IIA
* id: ID variable
* decision: 0-1 LHS variable representing nchoice choices
* purpose: Hausman’s specification test
*--------------------------------------------------------------*/

%macro IIA(indata=, varlist=, nchoice=, choice=, nvar=, IIA=, nIIA=, id=, decision=);

%let n=%eval(&nchoice-&nIIA);
proc mdc data=&indata outest=cov covout ;
  model &decision = &varlist / type=clogit nchoice=&nchoice;
  id &id;
run;

data two;
  set &indata;
  if &choice in &IIA and &decision=1 then output;
run;

data two;
  set two;
  keep &id ind;
  ind=1;
run;

data merged;
  merge &indata two;
  by &id;
  if ind=1 or &choice in &IIA then delete;
run;
proc mdc data=merged outest=cov2 covout ;
  model &decision = &varlist / type=clogit nchoice=&n;
  id &id;
run;
proc IML;
  use cov var(_TYPE_ &varlist);
  read first into BetaU;
  read all into CovVarU where(_TYPE_='COV');
  close cov;
  use cov2 var(_TYPE_ &varlist);
  read first into BetaR;
  read all into CovVarR where(_TYPE_='COV');
  close cov;
tmp = BetaU-BetaR;
ChiSq=tmp*ginv(CovVarR-CovVarU)*tmp';
if ChiSq<0 then ChiSq=0;
Prob=1-Probchi(ChiSq, &nvar);
Print "Hausman Test for IIA for Variable &IIA";
Print ChiSq Prob;
run; quit;

%mend IIA;

The following statement invokes the %IIA macro to test IIA for commuters who arrive on time:

%IIA( indata=small,
    varlist=r15 r10 ttime ttime_cp sde sde_cp sdl sdlx d2l,
    nchoice=12,
    choice=alt,
    nvar=9,
    nIIA=1,
    IIA=(9),
    id=id,
    decision=decision );

The obtained $\chi^2$ of 7.9 and the $p$-value of 0.54 indicate that IIA holds for commuters who arrive on time (alternative 9). If the IIA assumption did not hold, the following model (nested logit), which reserves a subcategory for alternative 9, might be more appropriate. See Output 18.30.

```
proc mdc data=small maxit=200 outest=a;
    model decision = r15 r10 ttime ttime_cp sde sde_cp sdl sdlx d2l /
        type=nlogit
        choice=(alt);
    id id;
    utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp
                   sdl sdlx d2l;
    nest level(1) = (1 2 3 4 5 6 7 8 @ 1, 9 @ 2, 10 11 12 @ 3),
                    level(2) = (1 2 3 @ 1);
run;
```

Similarly, IIA could be tested for commuters who arrive approximately on time (alternative 8, 9, 10), as follows:

```
%IIA( indata=small,
    varlist=r15 r10 ttime ttime_cp sde sde_cp sdl sdlx d2l,
    nchoice=12,
    choice=alt,
    nvar=9,
    nIIA=3,
    IIA=(8 9 10),
    id=id,
    decision=decision );
```

Based on this test, independence of irrelevant alternatives is not rejected for this subgroup ($\chi^2 = 10.3$ and $p$-value=0.326), and it is concluded that a more complex nested logit model with commuters who arrive approximately on time in one subcategory is not needed. Since the two Hausman’s specification tests just performed did not reject IIA, it might be a good idea to test whether the nested logit model is even needed.
This is done using the likelihood ratio test in the next example.

**Example 18.7: Likelihood Ratio Test**

This example is an extension of Example 18.6; it performs another specification test, the likelihood ratio test (LR). Suppose you are interested in testing whether the nested logit model (Output 18.30) with three subgroups that represent commuters who arrive early, on time, and late is more appropriate than the standard multinomial logit. This can be done by adding the TEST statement to the model as follows:

```sas
/*--- Restricted Model with Inclusive Value Parameters
   Constrained to One ---*/
proc mdc data=small maxit=200 outest=a;
  model decision = r15 r10 ttime ttime_cp sde sde_cp
    sdl sdlx d2l /
    type=nlogit
    choice=(alt);
  id id;
  utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp
    sdl sdlx d2l;
  nest level(1) = (1 2 3 4 5 6 7 8 @ 1, 9 @ 2, 10 11 12 @ 3),
    level(2) = (1 2 3 @ 1);
  test INC_L2G1C1=1, INC_L2G1C2=1, INC_L2G1C3=1 /LR;
run;
```

**Output 18.7.1** Likelihood Ratio Test

</tbody>
</table>

Based on this test, you can conclude that the inclusive values, INC_L2G1C1, INC_L2G1C2, and INC_L2G1C3 are jointly statistically different from the value 1 at the 5% level and therefore the nested logit is a more appropriate model. The LR test can be used to test other types of restrictions in the nested logit setting as long as one model can be nested within another.

Overview: MODEL Procedure

The MODEL procedure analyzes models in which the relationships among the variables form a system of one or more nonlinear equations. Primary uses of the MODEL procedure are estimation, simulation, and forecasting of nonlinear simultaneous equation models.

PROC MODEL features include the following:

- SAS programming statements to define simultaneous systems of nonlinear equations
- tools to analyze the structure of the simultaneous equation system
- ARIMA, PDL, and other dynamic modeling capabilities
- tools to specify and estimate the error covariance structure
- tools to estimate and solve ordinary differential equations
- the following methods of parameter estimation:
Chapter 19: The MODEL Procedure

- ordinary least squares (OLS)
- two-stage least squares (2SLS)
- seemingly unrelated regression (SUR) and iterative SUR (ITSUR)
- three-stage least squares (3SLS) and iterative 3SLS (IT3SLS)
- generalized method of moments (GMM)
- simulated method of moments (SMM)
- full information maximum likelihood (FIML)
- general log-likelihood maximization

• simulation and forecasting capabilities
  • Monte Carlo simulation
  • goal-seeking solutions

A system of equations can be nonlinear in the parameters, nonlinear in the observed variables, or nonlinear in both the parameters and the variables. Nonlinear in the parameters means that the mathematical relationship between the variables and parameters is not required to have a linear form. (A linear model is a special case of a nonlinear model.) A general nonlinear system of equations can be written as

\[
\begin{align*}
q_1(y_{1,t}, y_{2,t}, \ldots, y_{g,t}, x_{1,t}, x_{2,t}, \ldots, x_{m,t}, \theta_1, \theta_2, \ldots, \theta_p) &= \epsilon_{1,t} \\
q_2(y_{1,t}, y_{2,t}, \ldots, y_{g,t}, x_{1,t}, x_{2,t}, \ldots, x_{m,t}, \theta_1, \theta_2, \ldots, \theta_p) &= \epsilon_{2,t} \\
& \vdots \\
q_g(y_{1,t}, y_{2,t}, \ldots, y_{g,t}, x_{1,t}, x_{2,t}, \ldots, x_{m,t}, \theta_1, \theta_2, \ldots, \theta_p) &= \epsilon_{g,t}
\end{align*}
\]

where \( y_{i,t} \) is an endogenous variable, \( x_{i,t} \) is an exogenous variable, \( \theta_i \) is a parameter, and \( \epsilon_i \) is the unknown error. The subscript \( t \) represents time or some index to the data.

In econometrics literature, the observed variables are either endogenous (dependent) variables or exogenous (independent) variables. This system can be written more succinctly in vector form as

\[
q(y_t, x_t, \theta) = \epsilon_t
\]

This system of equations is in general form because the error term is by itself on one side of the equality. Systems can also be written in normalized form by placing the endogenous variable on one side of the equality, with each equation defining a predicted value for a unique endogenous variable. A normalized form equation system can be written in vector notation as

\[
y_t = f(y_t, x_t, \theta) + \epsilon_t.
\]

PROC MODEL handles equations written in both forms.

Econometric models often explain the current values of the endogenous variables as functions of past values of exogenous and endogenous variables. These past values are referred to as lagged values, and the variable \( x_{t-i} \) is called lag \( i \) of the variable \( x_t \). Using lagged variables, you can create a dynamic, or time-dependent, model. In the preceding model systems, the lagged exogenous and endogenous variables are included as part of the exogenous variables.
If the data are time series, so that $t$ indexes time (see Chapter 3, “Working with Time Series Data,” for more information on time series), it is possible that $\epsilon_t$ depends on $\epsilon_{t-1}$ or, more generally, the $\epsilon_t$'s are not identically and independently distributed. If the errors of a model system are autocorrelated, the standard error of the estimates of the parameters of the model will be inflated.

Sometimes the $\epsilon_t$'s are not identically distributed because the variance of $\epsilon$ is not constant. This is known as heteroscedasticity. Heteroscedasticity in an estimated model can also inflate the standard error of the estimates of the parameters. Using a weighted estimation can sometimes eliminate this problem. Alternately, a variance model such as GARCH or EGARCH can be estimated to correct for heteroscedasticity. If the proper weighting scheme and the form of the error model is difficult to determine, generalized methods of moments (GMM) estimation can be used to determine parameter estimates with very few assumptions about the form of the error process.

Other problems can also arise when estimating systems of equations. Consider the following system of equations, which is nonlinear in its parameters and cannot be estimated with linear regression:

\[
\begin{align*}
y_{1,t} &= \theta_1 + (\theta_2 + \theta_3 \theta_4^t)^{-1} + \theta_5 y_{2,t} + \epsilon_{1,t} \\
y_{2,t} &= \theta_6 + (\theta_7 + \theta_8 \theta_9^t)^{-1} + \theta_{10} y_{1,t} + \epsilon_{2,t}
\end{align*}
\]

This system of equations represents a rudimentary predator-prey process with $y_1$ as the prey and $y_2$ as the predator (the second term in both equations is a logistics curve). The two equations must be estimated simultaneously because of the cross-dependency of $y$'s. This cross-dependency makes $\epsilon_1$ and $\epsilon_2$ violate the assumption of independence. Nonlinear ordinary least squares estimation of these equations produce biased and inconsistent parameter estimates. This is called simultaneous equation bias.

One method to remove simultaneous equation bias, in the linear case, is to replace the endogenous variables on the right-hand side of the equations with predicted values that are uncorrelated with the error terms. These predicted values can be obtained through a preliminary, or “first-stage,” instrumental variable regression. Instrumental variables, which are uncorrelated with the error term, are used as regressors to model the predicted values. The parameter estimates are obtained by a second regression by using the predicted values of the regressors. This process is called two-stage least squares.

In the nonlinear case, nonlinear ordinary least squares estimation is performed iteratively by using a linearization of the model with respect to the parameters. The instrumental solution to simultaneous equation bias in the nonlinear case is the same as the linear case, except the linearization of the model with respect to the parameters is predicted by the instrumental regression. Nonlinear two-stage least squares is one of several instrumental variables methods available in the MODEL procedure to handle simultaneous equation bias.

When you have a system of several regression equations, the random errors of the equations can be correlated. In this case, the large-sample efficiency of the estimation can be improved by using a joint generalized least squares method that takes the cross-equation correlations into account. If the equations are not simultaneous (no dependent regressors), then seemingly unrelated regression (SUR) can be used. The SUR method requires an estimate of the cross-equation error covariance matrix, $\Sigma$. The usual approach is to first fit the equations by using OLS, compute an estimate $\hat{\Sigma}$ from the OLS residuals, and then perform the SUR estimation based on $\hat{\Sigma}$. The MODEL procedure estimates $\Sigma$ by default, or you can supply your own estimate of $\Sigma$.

If the equation system is simultaneous, you can combine the 2SLS and SUR methods to take into account both simultaneous equation bias and cross-equation correlation of the errors. This is called three-stage least squares or 3SLS.

A different approach to the simultaneous equation bias problem is the full information maximum likelihood (FIML) estimation method. FIML does not require instrumental variables, but it assumes that the equation
errors have a multivariate normal distribution. 2SLS and 3SLS estimation do not assume a particular distribution for the errors.

Other nonnormal error distribution models can be estimated as well. The centered $t$ distribution with estimated degrees of freedom and nonconstant variance is an additional built-in likelihood function. If the distribution of the equation errors is not normal or $t$ but known, then the log likelihood can be specified by using the ERRORMODEL statement.

Once a nonlinear model has been estimated, it can be used to obtain forecasts. If the model is linear in the variables you want to forecast, a simple linear solve can generate the forecasts. If the system is nonlinear, an iterative procedure must be used. The preceding example system is linear in its endogenous variables. The MODEL procedure’s SOLVE statement is used to forecast nonlinear models.

One of the main purposes of creating models is to obtain an understanding of the relationship among the variables. There are usually only a few variables in a model you can control (for example, the amount of money spent on advertising). Often you want to determine how to change the variables under your control to obtain some target goal. This process is called goal seeking. PROC MODEL allows you to solve for any subset of the variables in a system of equations given values for the remaining variables.

The nonlinearity of a model creates two problems with the forecasts: the forecast errors are not normally distributed with zero mean, and no formula exists to calculate the forecast confidence intervals. PROC MODEL provides Monte Carlo techniques, which, when used with the covariance of the parameters and error covariance matrix, can produce approximate error bounds on the forecasts. The following distributions on the errors are supported for multivariate Monte Carlo simulation:

- Cauchy
- chi-squared
- empirical
- $F$
- Poisson
- $t$
- uniform

A transformation technique is used to create a covariance matrix for generating the correct innovations in a Monte Carlo simulation.

---

**Getting Started: MODEL Procedure**

This section introduces the MODEL procedure and shows how to use PROC MODEL for several kinds of nonlinear regression analysis and nonlinear systems simulation problems.
Nonlinear Regression Analysis

One of the most important uses of PROC MODEL is to estimate unknown parameters in a nonlinear model. A simple nonlinear model has the form:

\[ y = f(x, \theta) + \epsilon \]

where \( x \) is a vector of exogenous variables. To estimate unknown parameters by using PROC MODEL, do the following:

1. Use the DATA= option in a PROC MODEL statement to specify the input SAS data set that contains \( y \) and \( x \), the observed values of the variables.

2. Write the equation for the model by using SAS programming statements, including all parameters and arithmetic operators but leaving off the unobserved error component, \( \epsilon \).

3. Use a FIT statement to fit the model equation to the input data to determine the unknown parameters, \( \theta \).

An Example

The SASHELP library contains the data set CITIMON, which contains the variable LHUR, the monthly unemployment figures, and the variable IP, the monthly industrial production index. You suspect that the unemployment rates are inversely proportional to the industrial production index. Assume that these variables are related by the following nonlinear equation:

\[ lhur = \frac{1}{a \cdot ip + b} + c + \epsilon \]

In this equation \( a, b, \) and \( c \) are unknown coefficients and \( \epsilon \) is an unobserved random error.

The following statements illustrate how to use PROC MODEL to estimate values for \( a, b, \) and \( c \) from the data in SASHELP.CITIMON.

```sas
proc model data=sashelp.citimon;
   lhur = 1/(a * ip + b) + c;
   fit lhur;
run;
```

Notice that the model equation is written as a SAS assignment statement. The variable LHUR is assumed to be the dependent variable because it is named in the FIT statement and is on the left-hand side of the assignment.

PROC MODEL determines that LHUR and IP are observed variables because they are in the input data set. A, B, and C are treated as unknown parameters to be estimated from the data because they are not in the input data set. If the data set contained a variable named A, B, or C, you would need to explicitly declare the parameters with a PARMS statement.

In response to the FIT statement, PROC MODEL estimates values for A, B, and C by using nonlinear least squares and prints the results. The first part of the output is a “Model Summary” table, shown in Figure 19.1.
This table details the size of the model, including the number of programming statements that define the model, and lists the dependent variables (LHUR in this case), the unknown parameters (A, B, and C), and the model equations. In this case the equation is named for the dependent variable, LHUR.

PROC MODEL then prints a summary of the estimation problem, as shown in Figure 19.2.

The notation used in the summary of the estimation problem indicates that LHUR is a function of A, B, and C, which are to be estimated by fitting the function to the data. If the partial derivative of the equation with respect to a parameter is a simple variable or constant, the derivative is shown in parentheses after the parameter name. In this case, the derivative with respect to the intercept C is 1. The derivatives with respect to A and B are complex expressions and so are not shown.

Next, PROC MODEL prints an estimation summary as shown in Figure 19.3.
Figure 19.3 continued

Final Convergence Criteria

<table>

</tr>
<tr>
<td>Missing</td>
<td>1</td>
</tr>
</tbody>
</table>

The estimation summary provides information on the iterative process used to compute the estimates. The heading “OLS Estimation Summary” indicates that the nonlinear ordinary least squares (OLS) estimation method is used. This table indicates that all three parameters were estimated successfully by using 144 non-missing observations from the data set SASHELP.CITIMON. Calculating the estimates required 10 iterations of the GAUSS method. Various measures of how well the iterative process converged are also shown. For example, the “RPC(B)” value 0.00968 means that on the final iteration the largest relative change in any estimate was for parameter B, which changed by 0.968 percent. See the section “Convergence Criteria” on page 1139 for details.

PROC MODEL then prints the estimation results. The first part of this table is the summary of residual errors, shown in Figure 19.4.

Figure 19.4 Summary of Residual Errors Report

<table>
<thead>
<tr>
<th>Equation</th>
<th>DF Model</th>
<th>DF Error</th>
<th>SSE</th>
<th>MSE</th>
<th>R-Square</th>
<th>Adj R-Sq</th>
</tr>
</thead>
<tbody>
<tr>
<td>LHUR</td>
<td>3</td>
<td>141</td>
<td>75.1989</td>
<td>0.5333</td>
<td>0.7472</td>
<td>0.7436</td>
</tr>
</tbody>
</table>

This table lists the sum of squared errors (SSE), the mean squared error (MSE), the root mean squared error (root MSE), and the R² and adjusted R² statistics. The R² value of 0.7472 means that the estimated model explains approximately 75 percent more of the variability in LHUR than a mean model explains.

Following the summary of residual errors is the parameter estimates table, shown in Figure 19.5.
Figure 19.5  Parameter Estimates

| Parameter | Estimate | Approx Std Err | t Value | Approx Pr > |t| |
|-----------|----------|----------------|---------|-------------|-------------|
| a         | 0.009046 | 0.00343       | 2.63    | 0.0094      |             |
| b         | -0.57059 | 0.2617        | -2.18   | 0.0309      |             |
| c         | 3.337151 | 0.7297        | 4.57    | <.0001      |             |

Because the model is nonlinear, the standard error of the estimate, the \( t \) value, and its significance level are only approximate. These values are computed using asymptotic formulas that are correct for large sample sizes but only approximately correct for smaller samples. Thus, you should use caution in interpreting these statistics for nonlinear models, especially for small sample sizes. For linear models, these results are exact and are the same as standard linear regression.

The last part of the output produced by the FIT statement is shown in Figure 19.6.

Figure 19.6  System Summary Statistics

<table>
<thead>
<tr>
<th>Number of Observations</th>
<th>Statistics for System</th>
</tr>
</thead>
<tbody>
<tr>
<td>Used</td>
<td>Objective 0.5222</td>
</tr>
<tr>
<td>Missing</td>
<td>Objective*N 75.1989</td>
</tr>
</tbody>
</table>

This table lists the objective value for the estimation of the nonlinear system. Since there is only a single equation in this case, the objective value is the same as the residual MSE for LHUR except that the objective value does not include a degrees-of-freedom correction. This can be seen in the fact that “Objective*N” equals the residual SSE, 75.1989. N is 144, the number of observations used.

Convergence and Starting Values

Computing parameter estimates for nonlinear equations requires an iterative process. Starting with an initial guess for the parameter values, PROC MODEL tries different parameter values until the objective function of the estimation method is minimized. (The objective function of the estimation method is sometimes called the fitting function.) This process does not always succeed, and whether it does succeed depends greatly on the starting values used. By default, PROC MODEL uses the starting value 0.0001 for all parameters.

Consequently, in order to use PROC MODEL to achieve convergence of parameter estimates, you need to know two things: how to recognize convergence failure by interpreting diagnostic output, and how to specify reasonable starting values. The MODEL procedure includes alternate iterative techniques and grid search capabilities to aid in finding estimates. See the section “Troubleshooting Convergence Problems” on page 1141 for more details.
Nonlinear Systems Regression

If a model has more than one endogenous variable, several facts need to be considered in the choice of an estimation method. If the model has endogenous regressors, then an instrumental variables method such as 2SLS or 3SLS can be used to avoid simultaneous equation bias. Instrumental variables must be provided to use these methods. A discussion of possible choices for instrumental variables is provided in the section “Choice of Instruments” on page 1192 in this chapter.

The following is an example of the use of 2SLS and the INSTRUMENTS statement:

```sas
proc model data=test2;
  exogenous x1 x2;
  parms a1 a2 b2 2.5 c2 55 d1;
  y1 = a1 * y2 + b2 * x1 * x1 + d1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;
  fit y1 y2 / 2sls;
  instruments b2 c2 _exog_;
run;
```

The estimation method selected is added after the slash (/) on the FIT statement. The INSTRUMENTS statement follows the FIT statement and in this case selects all the exogenous variables as instruments with the _EXOG_ keyword. The parameters B2 and C2 in the instruments list request that the derivatives with respect to B2 and C2 be additional instruments.

Full information maximum likelihood (FIML) can also be used to avoid simultaneous equation bias. FIML is computationally more expensive than an instrumental variables method and assumes that the errors are normally distributed. On the other hand, FIML does not require the specification of instruments. FIML is selected with the FIML option on the FIT statement.

The preceding example is estimated with FIML by using the following statements:

```sas
proc model data=test2;
  exogenous x1 x2;
  parms a1 a2 b2 2.5 c2 55 d1;
  y1 = a1 * y2 + b2 * x1 * x1 + d1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;
  fit y1 y2 / fiml;
run;
```

General Form Models

The single equation example shown in the preceding section was written in normalized form and specified as an assignment of the regression function to the dependent variable LHUR. However, sometimes it is impossible or inconvenient to write a nonlinear model in normalized form.
To write a general form equation, give the equation a name with the prefix “EQ.”. This EQ.-prefixed variable represents the equation error. Write the equation as an assignment to this variable.

For example, suppose you have the following nonlinear model that relates the variables \( x \) and \( y \):

\[
\epsilon = a + b \ln(cy + dx)
\]

Naming this equation ‘one’, you can fit this model with the following statements:

```plaintext
proc model data=xydata;
   eq.one = a + b * log( c * y + d * x );
   fit one;
run;
```

The use of the EQ. prefix tells PROC MODEL that the variable is an error term and that it should not expect actual values for the variable ONE in the input data set.

**Supply and Demand Models**

General form specifications are often useful when you have several equations for the same dependent variable. This is common in supply and demand models, where both the supply equation and the demand equation are written as predictions for quantity as functions of price.

For example, consider the following supply and demand system:

\[
\begin{align*}
\text{(supply)} & \quad \text{quantity} = \alpha_1 + \alpha_2 \text{ price} + \epsilon_1 \\
\text{(demand)} & \quad \text{quantity} = \beta_1 + \beta_2 \text{ price} + \beta_3 \text{ income} + \epsilon_2
\end{align*}
\]

Assume the quantity of interest is the amount of energy consumed in the U.S., the price is the price of gasoline, and the income variable is the consumer debt. When the market is at equilibrium, these equations determine the market price and the equilibrium quantity. These equations are written in general form as

\[
\begin{align*}
\epsilon_1 &= \text{quantity} - (\alpha_1 + \alpha_2 \text{ price}) \\
\epsilon_2 &= \text{quantity} - (\beta_1 + \beta_2 \text{ price} + \beta_3 \text{ income})
\end{align*}
\]

Note that the endogenous variables quantity and price depend on two error terms so that OLS should not be used. The following example uses three-stage least squares estimation.

Data for this model is obtained from the SASHELP.CITIMON data set.

```plaintext
title1 'Supply-Demand Model using General-form Equations';
proc model data=sashelp.citimon;
   endogenous eegp eec;
   exogenous exvus cciutc;
   parameters a1 a2 b1 b2 b3 ;
   label eegp = 'Gasoline Retail Price'
             eec = 'Energy Consumption'
             cciutc = 'Consumer Debt';

   /* -------- Supply equation ------------- */
```
eq.supply = eec - (a1 + a2 * eegp);

/* -------- Demand equation ------------- */
eq.demand = eec - (b1 + b2 * eegp + b3 * cciutc);

/* -------- Instrumental variables -------*/
lageegp = lag(eegp); lag2eegp=lag2(eegp);

/* -------- Estimate parameters --------- */
fit supply demand / n3sls fsrsq;
    instruments _EXOG_ lageegp lag2eegp;
run;

The FIT statement specifies the two equations to estimate and the method of estimation, N3SLS. Note that ‘3SLS’ is an alias for N3SLS. The option FSRSQ is selected to get a report of the first stage R² to determine the acceptability of the selected instruments.

Since three-stage least squares is an instrumental variables method, instruments are specified with the INSTRUMENTS statement. The instruments selected are all the exogenous variables, selected with the _EXOG_ option, and two lags of the variable EEGP: LAGEEGP and LAG2EEGP.

The data set CITIMON has four observations that generate missing values because values for EEGP, EEC, or CCIUTC are missing. This is revealed in the “Observations Processed” output shown in Figure 19.7. Missing values are also generated when the equations cannot be computed for a given observation. Missing observations are not used in the estimation.

**Figure 19.7** Supply-Demand Observations Processed

<table>

</tr>
<tr>
<td>Used     139</td>
</tr>
<tr>
<td>Missing  4</td>
</tr>
<tr>
<td>Lagged   2</td>
</tr>
</tbody>
</table>

The lags used to create the instruments also reduce the number of observations used. In this case, the first two observations were used to fill the lags of EEGP.

The data set has a total of 145 observations, of which four generated missing values and two were used to fill lags, which left 139 observations for the estimation. In the estimation summary, in Figure 19.8, the total degrees of freedom for the model and error is 139.
One disadvantage of specifying equations in general form is that there are no actual values associated with the equation, so the $R^2$ statistic cannot be computed.

### Solving Simultaneous Nonlinear Equation Systems

You can use a SOLVE statement to solve the nonlinear equation system for some variables when the values of other variables are given.

Consider the supply and demand model shown in the preceding example. The following statement computes equilibrium price (EEGP) and quantity (EEC) values for given observed cost (CCIUTC) values and stores them in the output data set EQUILIB.

```
title1 'Supply-Demand Model using General-form Equations';
proc model data=sashelp.citimon(where=(eec ne .));
   endogenous eegp eec;
   exogenous exvus cciutc;
   parameters a1 a2 a3 b1 b2 ;
   label eegp = 'Gasoline Retail Price'
       eec = 'Energy Consumption'
       cciutc = 'Consumer Debt';
   /* -------- Supply equation ------------- */
   eq.supply = eec - (a1 + a2 * eegp + a3 * cciutc);
   /* -------- Demand equation ------------- */
   /* */
```

---

/* -------- Estimate parameters --------- */
instruments _EXOG_ lageegp lag2eegp;
fit supply demand / n3s1s ;
solve eegp eec / out=equilib;
run;

As a second example, suppose you want to compute points of intersection between the square root function and hyperbolas of the form $a + b/x$. That is, you want to solve the system:

(square root) $y = \sqrt{x}$

(hyperbola) $y = a + \frac{b}{x}$

The following statements read parameters for several hyperbolas in the input data set TEST and solve the nonlinear equations. The SOLVEPRINT option in the SOLVE statement prints the solution values. The ID statement is used to include the values of A and B in the output of the SOLVEPRINT option.

```r
title1 'Solving a Simultaneous System';
data test;
   input a b @@;
datalines;
   0 1 1 1 1 2;
proc model data=test;
   eq.sqrt = sqrt(x) - y;
   eq.hyperbola = a + b / x - y;
solve x y / solveprint;
id a b;
run;
```

The printed output produced by this example consists of a model summary report, a listing of the solution values for each observation, and a solution summary report. The model summary for this example is shown in Figure 19.9.

**Figure 19.9 Model Summary Report**

Iterations 4 CC 0.000000

Solution Values

x y
2.875130 1.695621
For each observation, a heading line is printed that lists the values of the ID variables for the observation and information about the iterative process used to compute the solution. The number of iterations required, and the convergence measure (labeled CC) are printed. This convergence measure indicates the maximum error by which solution values fail to satisfy the equations. When this error is small enough (as determined by the CONVERGE= option), the iterations terminate. The equation with the largest error is indicated. For example, for observation 3 the HYPERBOLA equation has an error of $4.42 \times 10^{-13}$ while the error of the SQRT equation is even smaller. Following the heading line for the observation, the solution values are printed.

The last part of the SOLVE statement output is the solution summary report shown in Figure 19.11. This report summarizes the solution method used (Newton’s method by default), the iteration history, and the observations processed.

Monte Carlo Simulation

The RANDOM= option is used to request Monte Carlo (or stochastic) simulation to generate confidence intervals for a forecast. The confidence intervals are implied by the model’s relationship to implicit random error term \( \epsilon \) and the parameters.

The Monte Carlo simulation generates a random set of additive error values, one for each observation and each equation, and computes one set of perturbations of the parameters. These new parameters, along with the additive error terms, are then used to compute a new forecast that satisfies this new simultaneous system. Then a new set of additive error values and parameter perturbations is computed, and the process is repeated the requested number of times.

Consider the following exchange rate model for the U.S. dollar with the German mark and the Japanese yen:

\[
\begin{align*}
\text{rate}_{\text{jp}} & = a_1 + b_1 \text{im}_{\text{jp}} + c_1 \text{di}_{\text{jp}}; \\
\text{rate}_{\text{wg}} & = a_2 + b_2 \text{im}_{\text{wg}} + c_1 \text{di}_{\text{wg}};
\end{align*}
\]

where \( \text{rate}_{\text{jp}} \) and \( \text{rate}_{\text{wg}} \) are the exchange rate of the Japanese yen and the German mark versus the U.S. dollar, respectively; \( \text{im}_{\text{jp}} \) and \( \text{im}_{\text{wg}} \) are the imports from Japan and Germany in 1984 dollars, respectively; and \( \text{di}_{\text{jp}} \) and \( \text{di}_{\text{wg}} \) are the differences in inflation rate of Japan and the U.S., and Germany and the U.S., respectively. The Monte Carlo capabilities of the MODEL procedure are used to generate error bounds on a forecast by using this model.

```r
proc model data=exchange;
    endo im_jp im_wg;
    exo di_jp di_wg;
    parms a1 a2 b1 b2 c1 c2;
    label rate_jp = 'Exchange Rate of Yen/$'
                   rate_wg = 'Exchange Rate of Gm/$'
                   im_jp = 'Imports to US from Japan in 1984 $'
                   im_wg = 'Imports to US from WG in 1984 $'
                   di_jp = 'Difference in Inflation Rates US-JP'
                   di_wg = 'Difference in Inflation Rates US-WG';
    rate_jp = a1 + b1*im_jp + c1*di_jp;
    rate_wg = a2 + b2*im_wg + c1*di_wg;
    /* Fit the EXCHANGE data */
    fit rate_jp rate_wg / sur outest=xch_est outcov outs=s;
    /* Solve using the WHATIF data set */
    solve rate_jp rate_wg / data=whatif estdata=xch_est sdata=s
        random=100 seed=123 out=monte forecast;
    id yr;
    range yr=1986;
run;
```
Data for the EXCHANGE data set was obtained from the Department of Commerce and the yearly “Economic Report of the President.”

First, the parameters are estimated using SUR selected by the SUR option in the FIT statement. The OUTEST= option is used to create the XCH_EST data set which contains the estimates of the parameters. The OUTCOV option adds the covariance matrix of the parameters to the XCH_EST data set. The OUTS= option is used to save the covariance of the equation error in the data set S.

Next, Monte Carlo simulation is requested by using the RANDOM= option in the SOLVE statement. The data set WHATIF is used to drive the forecasts. The ESTDATA= option reads in the XCH_EST data set which contains the parameter estimates and covariance matrix. Because the parameter covariance matrix is included, perturbations of the parameters are performed. The SDATA= option causes the Monte Carlo simulation to use the equation error covariance in the S data set to perturb the equation errors. The SEED= option selects the number 123 as a seed value for the random number generator. The output of the Monte Carlo simulation is written to the data set MONTE selected by the OUT= option.

To generate a confidence interval plot for the forecast, use PROC UNIVARIATE to generate percentile bounds and use PROC SGPLOT to plot the graph. The following SAS statements produce the graph in Figure 19.12.

```sas
proc sort data=monte;
    by yr;
run;

proc univariate data=monte noprint;
    by yr;
    var rate_jp rate_wg;
    output out=bounds mean=mean p5=p5 p95=p95;
run;

**Printing Options for FIT Tasks**

- Prints the modified Breusch-Pagan test for heteroscedasticity: FIT BREUSCH
- Prints the Chow test for structural breaks: FIT CHOW=
- Prints collinearity diagnostics: FIT COLLIN
- Prints the correlation matrices: FIT CORR
- Prints the correlation matrix of the parameters: FIT CORRB
- Prints the correlation matrix of the residuals: FIT CORRS
- Prints the covariance matrices: FIT COV
- Prints the covariance matrix of the parameters: FIT COVB
- Prints the covariance matrix of the residuals: FIT COVS
- Prints Durbin-Watson $d$ statistics: FIT DW
- Prints first-stage $R^2$ statistics: FIT FSRSQ
- Prints Godfrey’s tests for autocorrelated residuals for each equation: FIT GODFREY
- Prints Hausman’s specification test: FIT HAUSMAN
- Prints tests of normality of the model residuals: FIT NORMAL
- Prints the predictive Chow test for structural breaks: FIT PCHOW=
- Specifies all the printing options: FIT PRINTALL
- Prints White’s test for heteroscedasticity: FIT WHITE

**Options to Control FIT Iteration Output**

- Prints the inverse of the crossproducts Jacobian matrix: FIT I
- Prints a summary iteration listing: FIT ITPRINT
- Prints a detailed iteration listing: FIT ITDETAILS
- Prints the crossproduct Jacobian matrix: FIT XPX
- Specifies all the iteration printing-control options: FIT ITALL

**Options to Control the Minimization Process**

- Specifies the convergence criteria: FIT CONVERGE=
- Selects the Hessian approximation used for FIML: FIT HESSIAN=

**Statements that Declare Variables**

- Associates a name with a list of variables and constants: ARRAY
- Declares a variable to have a fixed value: CONTROL
- Declares a variable to be a dependent or endogenous variable: ENDOGENOUS
- Declares a variable to be an independent or exogenous variable: EXOGENOUS
- Specifies identifying variables: ID
- Assigns a label to a variable: LABEL
- Selects additional variables to be output: OUTVARS
- Declares a variable to be a parameter: PARAMETERS
- Forces a variable to hold its value from a previous observation: RETAIN
- Declares a model variable: VAR
- Declares an instrumental variable: INSTRUMENTS
- Omits the default intercept term in the instruments list: INSTRUMENTS NOINT

**General FIT Statement Options**

- Omits parameters from the estimation: FIT DROP=
- Associates a variable with an initial value as a parameter or a constant: FIT INITIAL=
- Bypasses OLS to get initial parameter estimates for GMM, ITGMM, or FIML: FIT NOOLS
- Bypasses 2SLS to get initial parameter estimates for GMM, ITGMM, or FIML: FIT NO2SLS
- Specifies the parameters to estimate: FIT PARMS=

## General TEST Statement Options
- Specifies that a Wald test be computed: `TEST WALD`
- Specifies that a Lagrange multiplier test be computed: `TEST LM`
- Specifies that a likelihood ratio test be computed: `TEST LR`
- Request all three types of tests: `TEST ALL`
- Specifies the name of an output SAS data set that contains the test results: `TEST OUT=`

## Miscellaneous Statements
- Specifies the range of observations to be used: `RANGE`
- Subsets the data set with BY variables: `BY`

## PROC MODEL Statement

```plaintext
PROC MODEL options;
```

The following options can be specified in the PROC MODEL statement. All of the nonassignment options (the options that do not accept a value after an equal sign) can have NO prefixed to the option name in the RESET statement to turn the option off. The default case is not explicitly indicated in the discussion that follows. Thus, for example, the option DETAILS is documented in the following, but NODETAILS is not documented since it is the default. Also, the NOSTORE option is documented because STORE is the default.

### Data Set Options

- **DATA=SAS-data-set**
  
  names the input data set. Variables in the model program are looked up in the DATA= data set and, if found, their attributes (type, length, label, format) are set to be the same as those in the input data set (if not previously defined otherwise). The values for the variables in the program are read from the input data set when the model is estimated or simulated by FIT and SOLVE statements.

- **OUTPARMS=SAS-data-set**
  
  writes the parameter estimates to a SAS data set. See the section “Output Data Sets” on page 1217 for details.

- **PARMSDATA=SAS-data-set**
  
  names the SAS data set that contains the parameter estimates. In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used. See the section “Input Data Sets” on page 1211 for details.
PROC MODEL Statement

PLOTS<(global-plot-options)>(plot-request...)>
selects plots that the MODEL procedure produces via the Output Delivery System. For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” (SAS/STAT User’s Guide). The global-plot-options apply to all relevant plots generated by the MODEL procedure. The global-plot-options and specific plot-request options supported by the MODEL procedure follow.

Global Plot Options

ONLY suppresses the default plots. Only the plots specifically requested are produced.

UNPACKPANEL displays each graph separately. (By default, some graphs can appear together in a single panel.)

Specific Plot Options

ALL requests that all plots appropriate for the particular analysis be produced.

ACF produces the autocorrelation function plot.

DEPENDENCY< (OUTLINE=ON | OFF)> produces the dependency analysis plots. Specifying the OUTLINE= option displays, or suppresses outlines around the dependency cells.

IACF produces the inverse autocorrelation function plot of residuals.

PACF produces the partial autocorrelation function plot of residuals.

FITPLOT plots the predicted and actual values.

COOKSD produces the Cook’s D plot.

QQ produces a QQ plot of residuals.

RESIDUAL | RES plots the residuals.

STUDENTRESIDUAL plots the studentized residuals.

RESIDUALHISTOGRAM | RESIDHISTOGRAM plots the histogram of residuals.

NONE suppresses all plots.

Options to Read and Write Model Files

MODEL=model-name
MODEL=(model-list)
reads the model from one or more input model files created by previous PROC MODEL executions. Model files are written by the OUTMODEL= option.

NOSTORE suppresses the default output of the model file. This option is applicable only when FIT or SOLVE statements are not used, the MODEL= option is not used, and when a model is specified.

OUTCAT=(outcat-name MODNAME=model-key < outcat-options>)
SLIST=(outcat-name MODNAME=model-key < outcat-options>)
specifies the name and model-key for writing fitted model files. The model-key is a SAS name. Files written using the OUTCAT= option are used by SAS Risk Dimensions. The OUTCAT= option only applies to FIT statements. You can specify the following outcat-options:
DIM=n specifies the dimensionality of the model.

GROUP|MODGROUP=group specifies a SAS name which is the group for the model.

INTERVAL=interval specifies the time interval between observations.

MODLABEL=label specifies a label for the model.

STARTDATE=date specifies the starting date of the model.

**OUTMODEL=model-name**
specifies the name of an output model file to which the model is to be written. Starting with SAS 9.2, model files are being stored as XML-based SAS data sets instead of being stored as members of a SAS catalog as in earlier releases. This makes MODEL files more readily extensible in the future and enables Java-based applications to read the MODEL files directly. To change this behavior, use the SAS global-CMPMODEL-options. You can choose the format in which the output model file is stored and read by using the CMPMODEL=global-CMPMODEL-options in an OPTIONS statement as follows.

**OPTIONS CMPMODEL=global-CMPMODEL-options;**

You can specify the following global-CMPMODEL-options:

- **CATALOG** specifies that model files be written and read from SAS catalogs only.
- **XML** specifies that model files be written and read from XML data sets only.
- **BOTH** specifies that model files be written to both XML and CATALOG formats. When BOTH is specified, model files are read from the data set first and read from the SAS catalog only if the data set is not found. This is the default.

**Options to List or Analyze the Structure of the Model**

These options produce reports on the structure of the model or list the programming statements that define the models. These options are automatically reset (turned off) after the reports are printed. To turn these options back on after a RUN statement has been entered, use the RESSET statement or specify the options in a FIT or SOLVE statement.

**ANALYZEDEP=(dependency-plot1 < dependency-plot2 . . . >)** plots analyses of the dependencies among equations and solve variables. Each dependency-plot is one of the following:

- **BLOCK** specifies a block dependency matrix of the entire system.
- **BLOCK(eq-list, var-list)** specifies a block dependency matrix for a subset of equations and solve variables.
- **DETAILS** specifies a dependency matrix of all equations and solve variables.
- **DETAILS(eq-list, var-list)** specifies a dependency matrix for a subset of equations and solve variables.
- **NOLISTBLOCK** suppresses the listing of dependency blocks.
You can specify which equations and solve variables are included in the dependency analysis by qualifying both the BLOCK and DETAILS dependency-plot options with a pair of lists. The first list in the pair is the `eq-list`. It specifies which equations to include in the dependency analysis. You can specify a mix of equation names and equation group labels in the `eq-list`. The MODEL procedure replaces each equation group label in the `eq-list` with the list of equations that are specified in the corresponding EQGROUP statement. The second list in the pair is the `var-list`. It specifies which solve variables to include in the dependency analysis. You can specify a mix of variable names and variable group labels in the `var-list`. The MODEL procedure replaces each variable group label in the `var-list` with the list of variables that are specified in the corresponding VARGROUP statement. By default, when you specify a BLOCK option, a listing of the equations and solve variables that form each dependency block is generated. The NOLISTBLOCK option suppresses this listing. The ANALYZEDEP= option applies only to SOLVE steps. For more information about the analyses that are performed by the ANALYZEDEP= option, see the section “Diagnostics and Debugging” on page 1276.

**BLOCK**

prints an analysis of the structure of the model given by the assignments to model variables that appear in the model program. This analysis includes a classification of model variables into endogenous (dependent) and exogenous (independent) groups based on the presence of the variable on the left side of an assignment statement. The endogenous variables are grouped into simultaneously determined blocks. The dependency structure of the simultaneous blocks and exogenous variables is also printed. The BLOCK option cannot analyze dependencies implied by general form equations.

**GRAPH**

prints the graph of the dependency structure of the model. The GRAPH option also invokes the BLOCK option and produces a graphical display of the information listed by the BLOCK option.

**LIST**

prints the model program and variable lists, including the statements added by PROC MODEL and macros.

**LISTALL**

selects the LIST, LISTDEP, LISTDER, and LISTCODE options.

**LISTCODE**

prints the derivative tables and compiled model program code. LISTCODE is a debugging feature and is not normally needed.

**LISTDEP**

prints a report that lists for each variable in the model program the variables that depend on it and that it depends on. These lists are given separately for current-period values and for lagged values of the variables.

The information displayed is the same as that used to construct the BLOCK report but differs in that the information is listed for all variables (including parameters, control variables, and program variables), not just for the model variables. Classification into endogenous and exogenous groups and analysis of simultaneous structure is not done by the LISTDEP report.
LISTDER
prints a table of derivatives for FIT and SOLVE tasks. (The LISTDER option is applicable only for
the default NEWTON method for SOLVE tasks.) The derivatives table shows each nonzero derivative
computed for the problem. The derivative listed can be a constant, a variable in the model program,
or a special derivative variable created to hold the result of the derivative expression. This option is
turned on by the LISTCODE and PRINTALL options.

XREF
prints a cross-reference of the variables in the model program that shows where each variable was
referenced or given a value. The XREF option is normally used in conjunction with the LIST option.
A more detailed description is given in the section “Diagnostics and Debugging” on page 1276.

General Printing Control Options

DETAILS
specifies the detailed printout. Parts of the printed output are expanded when the DETAILS option
is specified. The following additional graphs of the residuals are produced when graphics output is
enabled: ACF, PACF, IACF, white noise, and QQ plot versus the normal.

FLOW
prints a message for each statement in the model program as it is executed. This debugging option is
needed very rarely and produces voluminous output.

MAXERRORS=n
specifies the maximum number of execution errors that can be printed. The default is MAXER-
RORS=50.

MEMORYUSE
prints a report of the memory required for the various parts of the analysis.

NDEC=n
specifies the precision of the format that PROC MODEL uses when printing various numbers. The
default is NDEC=3, which means that PROC MODEL attempts to print values by using the D format
but ensures that at least three significant digits are shown. If the NDEC= value is greater than nine, the
BEST. format is used. The smallest value allowed is NDEC=2.

The NDEC= option affects the format of most, but not all, of the floating point numbers that PROC
MODEL can print. For some values (such as parameter estimates), a precision limit one or two digits
greater than the NDEC= value is used. This option does not apply to the precision of the variables in
the output data set.

NOPRINT
suppresses the normal printed output but does not suppress error listings. Using any other print option
turns the NOPRINT option off. The PRINT option can be used with the RESET statement to turn off
NOPRINT.

PRINTALL
turns on all the printing-control options. The options set by PRINTALL are DETAILS; the model
information options LIST, LISTDEP, LISTDER, XREF, BLOCK, and GRAPH; the FIT task printing
options FSRSQ, COVB, CORRB, COVS, CORRS, DW, and COLLIN; and the SOLVE task printing
options STATS, THEIL, SOLVEPRINT, and ITPRINT.
REPORTMISSINGS
prints tables that summarize missing values that are encountered during a SOLVE or FIT task. The missing values that are summarized in these tabular reports can be produced by missing values in the DATA= data set or by calculations in the model program that generate missing values. The number of missing values that are reported can be limited by using the MAXERRORS= option.

TRACE
prints the result of each operation in each statement in the model program as it is executed, in addition to the information printed by the FLOW option. This debugging option is needed very rarely and produces voluminous output.

FIT Task Options
The following options are used in the FIT statement (parameter estimation) and can also be used in the PROC MODEL statement: COLLIN, CONVERGE=, CORR, CORRB, CORRS, COVB, COVBEST=, COVS, DW, FI ML, FSRSQ, GMM, HESSIAN=, I, INTGPRINT, ITALL, ITDETAILS, ITGMM, ITPRINT, ITOLS, ITSUR, IT2SLS, IT3SLS, KERNEL=, LTEBOUND=, MAXITER=, MAXSUBITER=, METHOD=, MINTIMESTEP=, NESTIT, N2SLS, N3SLS, OLS, OUTPREDICT, OUTRESID, OUTACTUAL, OUTLAGS, OUTALL, OUTCOV, SINGULAR=, STARTITER=, SUR, TIME=, VARDEF, and XPX. See the section “FIT Statement” on page 1095 for a description of these options.

When used in the PROC MODEL or RESET statement, these are default options for subsequent FIT statements. For example, the statement

```
proc model n2s1s ... ;
```

makes two-stage least squares the default parameter estimation method for FIT statements that do not specify an estimation method.

SOLVE Task Options
The following options for the SOLVE statement can also be used in the PROC MODEL statement: CONVERGE=, DYNAMIC, FORECAST, INTGPRINT, ITPRINT, JACOBI, LTEBOUND=, MAXITER=, MAXSUBITER=, MINTIMESTEP=, NAHEAD=, NEWTON, OUTPREDICT, OUTRESID, OUTACTUAL, OUTLAGS, OUTERRORS, OUTALL, SEED=, SEIDEL, SIMULATE, SINGLE, SINGULAR=, SOLVEPRINT, START=, STATIC, STATS, THEIL, TIME=, and TYPE=. For more information about these options, see section “SOLVE Statement” on page 1111.

When used in the PROC MODEL or RESET statement, these options provide default values for subsequent SOLVE statements.

BOUNDS Statement

```
BOUNDS bound1 <, bound2 ... > ;
```

The BOUNDS statement imposes simple boundary constraints either on the parameters in an estimation or on the solution variables specified in a solve operation. A BOUNDS statement that applies to parameters constrains the parameters estimated in the preceding FIT statement or, in the absence of a preceding FIT
statement, in the following FIT statement. A BOUNDS statement that is applied to solution variables constrains the solution of the preceding SOLVE statement or, in the absence of a preceding SOLVE statement, of the following SOLVE statement. You can specify any number of BOUNDS statements.

Each bound is composed of either parameters or solution variables, constants, and inequality operators:

\[
\text{item operator item} < \text{operator item} < \text{operator item} \ldots > >
\]

For BOUNDS statements that apply to FIT statements, each item is a constant, the name of an estimated parameter, or a list of parameter names. For BOUNDS statements that apply to SOLVE statements, each item is a constant, the name of a solution variable, or a list of solution variables. Each operator is \(<\), \(\geq\), \(\leq\), or \(\geq\).

You can use either the BOUNDS statement or the RESTRICT statement to impose boundary constraints when estimating parameters or solving for solution variables.

The BOUNDS statement provides a simpler syntax for specifying boundary constraints than the RESTRICT statement. For more information about the computational details of estimation and solutions with inequality restrictions, see the section "RESTRICT Statement" on page 1109.

Parameter Estimates

Each active boundary constraint on estimated parameters is associated with a Lagrange multiplier. In the printed output and in the OUTEST= data set, the Lagrange multiplier estimates are identified with the names BOUND0, BOUND1, and so forth. The probabilities of the Lagrange multipliers are computed by using a beta distribution (LaMotte 1994). To give the constraints more descriptive names, use the RESTRICT statement instead of the BOUNDS statement.

The following BOUNDS statement constrains the estimates of the parameters A and B and the ten parameters P1 through P10 to be between 0 and 1. This example illustrates the use of parameter lists to specify boundary constraints.

\[
\text{bounds} \ 0 < a \ b \ p1-p10 < 1;
\]

The following statements show how to use the BOUNDS statement, and they produce the output shown in Figure 19.13:

```plaintext
title 'Holzman Function (1969), Himmelblau No. 21, N=3';
data zero;
do i = 1 to 99;
  output;
end;
run;

proc model data=zero;
  parms x1= 100 x2= 12.5 x3= 3;
  bounds .1 <= x1 <= 100,
         0 <= x2 <= 25.6,
         0 <= x3 <= 5;
  t = 2 / 3;
  u = 25 + (-50 * log(0.01 * i)) ** t;
  v = (u - x2) ** x3;
  w = exp(-v / x1);
  eq.foo = -.01 * i + w;
```

fit foo / method=marquardt;
run;

Figure 19.13 Output from Bounded Estimation

| Parameter | Estimate | Std Err | t Value | Pr > |t| |
|-----------|----------|---------|---------|------|---|
| x1        | 49.99999 | 0       | .       | .    |   |
| x2        | 25       | 0       | .       | .    |   |
| x3        | 1.5      | 0       | .       | .    |   |

Holzman Function (1969), Himmelblau No. 21, N=3

The MODEL Procedure

Nonlinear OLS Parameter Estimates

Solution Variables

Boundary constraints on solution variables can be used to specify which solution is reported when an equation has multiple solutions. The BOUNDS statement in the following example causes its associated SOLVE statement to compute only the negative value of the solution variable shown in Figure 19.14:

data d;
  date = 0;
run;

proc model data=d;
  endo x;
  bounds x < 0;
  eq.sqrt = x**2 - 4;
  solve / optimize out=o;
run;

proc print data = o; run;

BY Statement

BY variables;

A BY statement is used with the FIT statement to obtain separate estimates for observations in groups defined by the BY variables. If an output model file is written using the OUTMODEL= option, the parameter values that are stored are those from the last BY group processed. To save parameter estimates for each BY group, use the OUTEST= option in the FIT statement.

A BY statement is used with the SOLVE statement to obtain solutions for observations in groups defined by the BY variables. If the BY variables in the DATA= data set and the ESTDATA= data set are identical, then the two data sets are synchronized and the calculations are performed by using the data and parameters for each BY group. This holds for BY variables in the SDATA= data set as well. If the BY variables do not match, BY-group processing is abandoned in either the ESTDATA= data set or the SDATA= data set, whichever has the missing BY value. If the DATA= data set does not contain BY variables and the ESTDATA= data set or the SDATA= data set does, then BY-group processing is performed for the ESTDATA= data set and the SDATA= data set by reusing the data in the DATA= data set for each BY group.

If both FIT and SOLVE tasks require BY-group processing, then two separate BY statements are needed. If parameters for each BY group in the OUTEST= data set that is obtained from the FIT task are to be used for the corresponding BY group for the SOLVE task, then one of the two BY statements must appear after the SOLVE statement.

The following linear regression example illustrates the use of BY-group processing. Both the data sets A and D to be used for fitting and solving, respectively, have three groups.

/*------ data set for fit task------ */
data a ;
  do group = 1 to 3 ;
    do i = 1 to 100 ;
      x = normal(1);
      y = 2 + 3*x + rannor(1) ;
      output ;
    end ;
  end ;
r
run ;

/*------ data set for solve task------ */
data d ;
  do group = 1 to 3 ;
    x = normal(1) ;
    output ;
  end ;
r
run ;

/* ------ 2 BY statements, one of them appear after SOLVE statement ------ */
proc model data = a ;
  by group ;
  y = a0 + a1*x ;
  fit y / outest = b1 ;
  solve y / data = d estdata = b1 out = c1 ;
  by group ;
run;
proc print data = b1 ;run;
proc print data = c1 ; run;

Each of the parameter estimates obtained from the BY group processing in the FIT statement shown in Figure 19.15 is used in the corresponding BY group variables in the SOLVE statement. The output dataset is shown in Figure 19.16.

</tbody>
</table>

If only one BY statement is used and it appears before the SOLVE statement, then parameters for the last BY group in the OUTEST = data set are used for all BY groups for the SOLVE task.

```/*------ 1 BY statement that appears before SOLVE statement------ */
proc model data = a ;
    by group ;
    y = a0 + a1*x ;
    fit y / outest = b2 ;
    solve y / data = d estdata = b2 out = c2 ;
run;

proc print data = b2 ; run;
proc print data = c2 ; run;
```

The estimates of the parameters are shown in Figure 19.17, and the output data set of the SOLVE statement is shown in Figure 19.18. Hence, the estimates and the predicted values obtained in the last BY group variable of both DATA C1 and C2 are the same while the others do not match.

If only one BY statement is used and it appears after the SOLVE statement, then BY group processing does not apply to the FIT task. In this case, the OUTEST=data set does not contain the BY variable, and the single set of parameter estimates obtained from the FIT task are used for all BY groups during the SOLVE task.

/*------ 1 BY statement that appears after SOLVE statement------*/
proc model data = a ;
y = a0 + a1*x ;
fit y / outest = b3 ;
solve y / data = d estdata = b3 out = c3 ;
by group ;
run;

proc print data = b3 ; run;
proc print data = c3 ; run;
The output data B3 and C3 are listed in Figure 19.19 and Figure 19.20, respectively.

CONTROL Statement

CONTROL variable < value > . . . ;
The CONTROL statement declares control variables and specifies their values. A control variable is like a parameter except that it has a fixed value and is not estimated from the data. You can use control variables for constants in model equations that you might want to change in different solution cases. You can use control variables to vary the program logic. Unlike the retained variables, these values are fixed across iterations.

**DELETEMODEL Statement**

```
DELETEMODEL model < MODNAME=model-name > ;
```

The DELETEMODEL statement deletes a model created using the OUTMODEL= option in a previous PROC MODEL execution. The `model` argument specifies the catalog or XML-based data set containing the model to be deleted, and the `model-name` argument specifies which model is to be deleted.

**ENDOGENOUS Statement**

```
ENDOGENOUS variable < initial-values > . . . ;
```

The ENDOGENOUS statement declares model variables and identifies them as endogenous. You can declare model variables with an ENDOGENOUS statement instead of with a VAR statement to help document the model or to indicate the default solution variables. The variables declared endogenous are solved when a SOLVE statement does not indicate which variables to solve. Valid abbreviations for the ENDOGENOUS statement are ENDOG and ENDO.

The DEPENDENT statement is equivalent to the ENDOGENOUS statement and is provided for the convenience of noneconometric practitioners.

The ENDOGENOUS statement optionally provides initial values for lagged dependent variables. See the section “Lag Logic” on page 1269 for more information.

**EQGROUP Statement**

```
EQGROUP label=equation . . . ;
```

The EQGROUP statement applies a group label to the specified list of equations in the model program. Equation groups identify sets of related equations. The equation groups can be used by the ANALYZEDEP= option in a subsequent SOLVE statement to help specify and understand the role of groups of equations in a SOLVE step. If an equation appears in more than one EQGROUP statement, the label that is specified in the last EQGROUP statement is applied to that equation.

**ERRORMODEL Statement**

```
ERRORMODEL equation-name ~ distribution < CDF= CDF(options) > ;
```

The ERRORMODEL statement is the mechanism for specifying the distribution of the residuals. You must specify the dependent/endogenous variables or general form model name, a tilde (~), and then a `distribution` with its parameters. You can specify the following options:
Options to Specify the Distribution

**CAUCHY**( <location, scale> )
specifies the Cauchy distribution. This option is supported only for simulation. The arguments correspond to the arguments of the SAS CDF function that computes the cumulative distribution function (ignoring the random variable argument).

**CHISQUARED**( <df, nc> )
specifies the χ² distribution. This option is supported only for simulation. The arguments correspond to the arguments of the SAS CDF function (ignoring the random variable argument).

**GENERAL**(Likelihood <, parm1, parm2, . . . parmn > )
specifies the negative of a general log-likelihood function that you construct by using SAS programming statements. The procedure minimizes the negative log-likelihood function specified. parm1, parm2, . . . parmn are optional parameters for this distribution and are used for documentation purposes only.

**F**( <ndf, ddf> )
specifies the F distribution. This option is supported only for simulation. The arguments correspond to the arguments of the SAS CDF function (ignoring the random variable argument).

**NORMAL**(v1 v2 . . . vn )
specifies a multivariate normal (Gaussian) distribution with mean 0 and variances v1 through vn.

**POISSON**(mean )
specifies the Poisson distribution. This option is supported only for simulation. The arguments correspond to the arguments of the SAS CDF function (ignoring the random variable argument).

**T**(v1 v2 . . . vn, df )
specifies a multivariate t distribution with noncentrality 0, variance v1 through vn, and common degrees of freedom df.

**UNIFORM**( <left, right> )
specifies the uniform distribution. This option is supported only for simulation. The arguments correspond to the arguments of the SAS CDF function (ignoring the random variable argument).

Options to Specify the CDF for Simulation

**CDF=**( CDF(options) )
specifies the univariate distribution that is used for simulation so that the estimation can be done for one set of distributional assumptions and the simulation for another. The CDF can be any of the distributions from the previous section with the exception of the general likelihood. In addition, you can specify the empirical distribution of the residuals.

**EMPIRICAL=**( <TAILS=(options)> )
uses the sorted residual data to create an empirical CDF.

**TAILS=**( tail-options )
specifies how to handle the tails in computing the inverse CDF from an empirical distribution, where tail-options are:
NORMAL specifies the normal distribution to extrapolate the tails.

T( df ) specifies the t distribution to extrapolate the tails.

PERCENT= p specifies the percentage of the observations to use in constructing each tail. The default for the PERCENT= option is 10. A normal distribution or a t distribution is used to extrapolate the tails to infinity. The variance for the tail distribution is obtained from the data so that the empirical CDF is continuous.

**ESTIMATE Statement**

The ESTIMATE statement computes estimates of functions of the parameters.

The ESTIMATE statement refers to the parameters estimated by the associated FIT statement (that is, to either the preceding FIT statement or, in the absence of a preceding FIT statement, to the following FIT statement). You can use any number of ESTIMATE statements.

Let \( h(\theta) \) denote the function of parameters that needs to be estimated. Let \( \hat{\theta} \) denote the unconstrained estimate of the parameter of interest, \( \theta \). Let \( \hat{V} \) be the estimate of the covariance matrix of \( \theta \). Denote

\[
A(\theta) = \frac{\partial h(\theta)}{\partial \theta} \bigg|_{\hat{\theta}}
\]

Then the standard error of the parameter function estimate is computed by obtaining the square root of \( A(\hat{\theta})\hat{V}A(\hat{\theta}) \). This is the same as the variance needed for a Wald type test statistic with null hypothesis \( h(\theta) = 0 \).

If the expression of the function in the ESTIMATE statement includes a variable, then the value used in computing the function estimate is the last observation of the variable in the DATA= data set.

If you specify options on the ESTIMATE statement, a comma is required before the “/” character that separates the test expressions from the options, since the “/” character can also be used within test expressions to indicate division. Each item is written as an optional name followed by an expression,

\(< "name" > expression\)

where "name" is a string used to identify the estimate in the printed output and in the OUTEST= data set.

Expressions can be composed of parameter names, arithmetic operators, functions, and constants. Comparison operators (such as = or <) and logical operators (such as &) cannot be used in ESTIMATE statement expressions. Parameters named in ESTIMATE expressions must be among the parameters estimated by the associated FIT statement.

You can use the following options in the ESTIMATE statement:

**OUTEST=**

specifies the name of the data set in which the estimate of the functions of the parameters are to be written. The format for this data set is identical to the OUTEST= data set for the FIT statement.

If you specify a name in the ESTIMATE statement, that name is used as the parameter name for the estimate in the OUTEST= data set. If no name is provided and the expression is just a symbol, the symbol name is used; otherwise, the string “_Estimate #” is used, where “#” is the variable number in the OUTEST= data set.
OUTCOV
writes the covariance matrix of the functions of the parameters to the OUTEST= data set in addition to the parameter estimates.

COVB
prints the covariance matrix of the functions of the parameters.

CORRB
prints the correlation matrix of the functions of the parameters.

The following statements are an example of the use of the ESTIMATE statement in a segmented model and produce the output shown in Figure 19.21:

data a;
  input y x @@;
datalines;
  .46 1 .47 2 .57 3 .61 4 .62 5 .68 6 .69 7
  .78 8 .70 9 .74 10 .77 11 .78 12 .74 13 .80 13
  .80 15 .78 16
;
title 'Segmented Model -- Quadratic with Plateau';
proc model data=a;
  x0 = -.5 * b / c;
  if x < x0 then y = a + b*x + c*x*x;
  else y = a + b*x0 + c*x0*x0;
  fit y start=( a .45 b .5 c -.0025 );
  estimate 'Join point' x0 ,
      'plateau' a + b*x0 + c*x0*x0; run;

Figure 19.21  ESTIMATE Statement Output

| Term        | Estimate | Std Err | t Value | Pr > |t| Label          |
|-------------|----------|---------|---------|------|----------------|
| Join point  | 12.7504  | 1.2785  | 9.97    | <.0001 | x0             |
| plateau     | 0.777516 | 0.0123  | 63.10   | <.0001 | a + b*x0 + c*x0*x0**2 |
EXOGENOUS Statement

EXOGENOUS variable < initial-values > . . . ;

The EXOGENOUS statement declares model variables and identifies them as exogenous. You can declare model variables with an EXOGENOUS statement instead of with a VAR statement to help document the model or to indicate the default instrumental variables. The variables declared exogenous are used as instruments when an instrumental variables estimation method is requested (such as N2SLS or N3SLS) and an INSTRUMENTS statement is not used. Valid abbreviations for the EXOGENOUS statement are EXOG and EXO.

The INDEPENDENT statement is equivalent to the EXOGENOUS statement and is provided for the convenience of non-econometric practitioners.

The EXOGENOUS statement optionally provides initial values for lagged exogenous variables. See the section “Lag Logic” on page 1269 for more information.

FIT Statement

FIT < equations > < PARMS=( parameter < values > . . . ) > < START=( parameter values . . . ) > < DROP=( parameter . . . ) > < INITIAL=( variable = parameter | constant > . . . ) > < / options > ;

The FIT statement estimates model parameters by fitting the model equations to input data and optionally selects the equations to be fit. If the list of equations is omitted, all model equations that contain parameters are fitted.

The following options can be used in the FIT statement.

DROP= ( parameters . . . )

specifies that the named parameters not be estimated. All the parameters in the equations fit are estimated except those listed in the DROP= option. The dropped parameters retain their previous values and are not changed by the estimation.

INITIAL= ( variable = < parameter | constant > . . . )

associates a variable with an initial value as a parameter or a constant. This option applies only to ordinary differential equations. See the section “Ordinary Differential Equations” on page 1174 for more information.

PARMS= ( parameters [values] . . . )

selects a subset of the parameters for estimation. When the PARMS= option is used, only the named parameters are estimated. Any parameters not specified in the PARMS= list retain their previous values and are not changed by the estimation.

In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used.
PRL= WALD | LR | BOTH
requests confidence intervals on estimated parameters. By default, the PRL option produces 95% likelihood ratio confidence limits. The coverage of the confidence interval is controlled by the ALPHA= option in the FIT statement.

START= ( parameter values . . . )
supplies starting values for the parameter estimates. In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used. If the START= option specifies more than one starting value for one or more parameters, a grid search is performed over all combinations of the values, and the best combination is used to start the iterations. For more information, see the STARTITER= option.

Options to Control the Estimation Method Used

ADJSMMV
specifies adding the variance adjustment from simulating the moments to the variance-covariance matrix of the parameter estimators. By default, no adjustment is made.

COVBEST=GLS | CROSS | FDA
specifies the variance-covariance estimator used for FIML. COVBEST=GLS selects the generalized least squares estimator. COVBEST=CROSS selects the crossproducts estimator. COVBEST=FDA selects the inverse of the finite difference approximation to the Hessian. The default is COVBEST=CROSS.

DYNAMIC
specifies dynamic estimation of ordinary differential equations. See the section “Ordinary Differential Equations” on page 1174 for more details.

FIML
specifies full information maximum likelihood estimation.

GINV=G2 | G4
specifies the type of generalized inverse to be used when computing the covariance matrix. G4 selects the Moore-Penrose generalized inverse. The default is GINV=G2.

Rather than deleting linearly related rows and columns of the covariance matrix, the Moore-Penrose generalized inverse averages the variance effects between collinear rows. When the option GINV=G4 is used, the Moore-Penrose generalized inverse is used to calculate standard errors and the covariance matrix of the parameters as well as the change vector for the optimization problem. For singular systems, a normal G2 inverse is used to determine the singular rows so that the parameters can be marked in the parameter estimates table. A G2 inverse is calculated by satisfying the first two properties of the Moore-Penrose generalized inverse; that is, $AA^+A = A$ and $A^+AA^+ = A^+$. Whether or not you use a G4 inverse, if the covariance matrix is singular, the parameter estimates are not unique. Refer to Noble and Daniel (1977, pp. 337–340) for more details about generalized inverses.
GENGMMV

specify GMM variance under arbitrary weighting matrix. See the section “Estimation Methods” on page 1119 for more details.

This is the default method for GMM estimation.

GMM

specifies generalized method of moments estimation.

HCCME= 0 | 1 | 2 | 3 | NO

specifies the type of heteroscedasticity-consistent covariance matrix estimator to use for OLS, 2SLS, 3SLS, SUR, and the iterated versions of these estimation methods. The number corresponds to the type of covariance matrix estimator to use as

\[ HC_0 : \hat{\epsilon}_t^2 \]
\[ HC_1 : \frac{n}{n-df}\hat{\epsilon}_t^2 \]
\[ HC_2 : \frac{\hat{\epsilon}_t^2}{(1 - \hat{h}_t)} \]
\[ HC_3 : \frac{\hat{\epsilon}_t^2}{(1 - \hat{h}_t)^2} \]

The default is NO.

ITGMM

specifies iterated generalized method of moments estimation.

ITOLS

specifies iterated ordinary least squares estimation. This is the same as OLS unless there are cross-equation parameter restrictions.

ITSUR

specifies iterated seemingly unrelated regression estimation

IT2SLS

specifies iterated two-stage least squares estimation. This is the same as 2SLS unless there are cross-equation parameter restrictions.

IT3SLS

specifies iterated three-stage least squares estimation.

KERNEL=(PARZEN | BART | QS, c, e)

KERNEL=PARZEN | BART | QS

specifies the kernel to be used for GMM and ITGMM. PARZEN selects the Parzen kernel, BART selects the Bartlett kernel, and QS selects the quadratic spectral kernel. \( e \geq 0 \) and \( c \geq 0 \) are used to compute the bandwidth parameter. The default is KERNEL=(PARZEN, 1, 0.2). See the section “Estimation Methods” on page 1119 for more details.

N2SLS | 2SLS

specifies nonlinear two-stage least squares estimation. This is the default when an INSTRUMENTS statement is used.
N3SLS | 3SLS
specifies nonlinear three-stage least squares estimation.

NDRAW <=number of draws>
requests the simulation method for parameter estimation where the contribution of each observation to the estimation is approximated by using number of draws evaluations of the model program. If number of draws is not specified, the default value of 10 is used.

NOOOLS
NO2SLS
specifies bypassing OLS or 2SLS to get initial parameter estimates for GMM, ITGMM, or FIIML. This is important for certain models that are poorly defined in OLS or 2SLS, or if good initial parameter values are already provided. Note that for GMM, the V matrix is created by using the initial values specified and this might not be consistently estimated.

NO3SLS
specifies not to use 3SLS automatically for FIIML initial parameter starting values.

NOGENGMMV
specifies not to use GMM variance under arbitrary weighting matrix. Use GMM variance under optimal weighting matrix instead. See the section “Estimation Methods” on page 1119 for more details.

NPREOBS =number of obs to initialize
specifies the initial number of observations to run the simulation before the simulated values are compared to observed variables. This option is most useful in cases where the program statements involve lag operations. Use this option to avoid the effect of the starting point on the simulation.

NVDRAW =number of draws for V matrix
specifies \( H' \), the number of draws for V matrix. If this option is not specified, the default \( H' \) is set to 20.

OLS
specifies ordinary least squares estimation. This is the default.

SUR
specifies seemingly unrelated regression estimation.

VARDEF=N | WGT | DF | WDF
specifies the denominator to be used in computing variances and covariances, MSE, root MSE measures, and so on. VARDEF=N specifies that the number of nonmissing observations be used. VARDEF=WGT specifies that the sum of the weights be used. VARDEF=DF specifies that the number of nonmissing observations minus the model degrees of freedom (number of parameters) be used. VARDEF=WDF specifies that the sum of the weights minus the model degrees of freedom be used. The default is VARDEF=DF. For FIIML estimation the VARDEF= option does not affect the calculation of the parameter covariance matrix, which is determined by the COVBEST= option.
Data Set Options

**DATA=SAS-data-set**

specifies the input data set. Values for the variables in the program are read from this data set. If the DATA= option is not specified on the FIT statement, the data set specified by the DATA= option on the PROC MODEL statement is used.

**ESTDATA=SAS-data-set**

specifies a data set whose first observation provides initial values for some or all of the parameters.

**MISSING=PAIRWISE | DELETE**

specifies how missing values are handled. MISSING=PAIRWISE specifies that missing values are tracked on an equation-by-equation basis. MISSING=DELETE specifies that the entire observation is omitted from the analysis when any equation has a missing predicted or actual value for the equation. The default is MISSING=DELETE.

**OUT=SAS-data-set**

names the SAS data set to contain the residuals, predicted values, or actual values from each estimation. The residual values written to the OUT= data set are defined as the actual − predicted, which is the negative of RESID.\_variable as defined in the section “Equation Translations” on page 1264. Only the residuals are output by default.

**OUTACTUAL**

writes the actual values of the endogenous variables of the estimation to the OUT= data set. This option is applicable only if the OUT= option is specified.

**OUTALL**

selects the OUTACTUAL, OUTERRORS, OUTLAGS, OUTPREDICT, and OUTRESID options.

**OUTCOV**

writes the covariance matrix of the estimates to the OUTEST= data set in addition to the parameter estimates. The OUTCOV option is applicable only if the OUTEST= option is also specified.

**OUTEST=SAS-data-set**

names the SAS data set to contain the parameter estimates and optionally the covariance of the estimates.

**OUTLAGS**

writes the observations used to start the lags to the OUT= data set. This option is applicable only if the OUT= option is specified.

**OUTPREDICT**

writes the predicted values to the OUT= data set. This option is applicable only if OUT= is specified.

**OUTRESID**

writes the residual values computed from the parameter estimates to the OUT= data set. The OUT-RESID option is the default if neither OUTPREDICT nor OUTACTUAL is specified. This option is applicable only if the OUT= option is specified. If the h.var equation is specified, the residual values written to the OUT= data set are the normalized residuals, defined as actual − predicted, divided by the square root of the h.var value. If the WEIGHT statement is used, the residual values are calculated as actual − predicted multiplied by the square root of the WEIGHT variable.
OUTS=SAS-data-set
names the SAS data set to contain the estimated covariance matrix of the equation errors. This is the
covariance of the residuals computed from the parameter estimates.

OUTSN=SAS-data-set
names the SAS data set to contain the estimated normalized covariance matrix of the equation errors.
This is valid for multivariate $t$ distribution estimation.

OUTSUSED=SAS-data-set
names the SAS data set to contain the $S$ matrix used in the objective function definition. The
OUTSUSED= data set is the same as the OUTS= data set for the methods that iterate the $S$ matrix.

OUTUNWGTRESID
writes the unweighted residual values computed from the parameter estimates to the OUT= data set.
These are residuals computed as $actual - predicted$ with no accounting for the WEIGHT statement,
the _WEIGHT_ variable, or any variance expressions. This option is applicable only if the OUT=
option is specified.

OUTV=SAS-data-set
names the SAS data set to contain the estimate of the variance matrix for GMM and ITGMM.

SDATA=SAS-data-set
specifies a data set that provides the covariance matrix of the equation errors. The matrix read from
the SDATA= data set is used for the equation covariance matrix ($S$ matrix) in the estimation. (The
SDATA= $S$ matrix is used to provide only the initial estimate of $S$ for the methods that iterate the $S$
matrix.)

TIME=name
specifies the name of the time variable. This variable must be in the data set.

TYPE=name
specifies the estimation type to read from the SDATA= and ESTDATA= data sets. The name specified
in the TYPE= option is compared to the _TYPE_ variable in the ESTDATA= and SDATA= data sets to
select observations to use in constructing the covariance matrices. When the TYPE= option is omitted,
the last estimation type in the data set is used. Valid values are the estimation methods used in PROC
MODEL.

VDATA=SAS-data-set
specifies a data set that contains a variance matrix for GMM and ITGMM estimation. See the section
“Output Data Sets” on page 1217 for details.

Printing Options for FIT Tasks

BREUSCH= ( variable-list )
specifies the modified Breusch-Pagan test, where variable-list is a list of variables used to model the
error variance.
CHOW=obs
CHOW=(obs1 obs2 . . . obsn)

prints the Chow test for break points or structural changes in a model. The argument is the number of
observations in the first sample or a parenthesized list of first sample sizes. If the size of the one of the
two groups in which the sample is partitioned is less than the number of parameters, then a predictive
Chow test is automatically used. See the section “Chow Tests” on page 1189 for details.

COLLIN

prints collinearity diagnostics for the Jacobian crossproducts matrix (XPX) after the parameters have
converged. Collinearity diagnostics are also automatically printed if the estimation fails to converge.

CORR

prints the correlation matrices of the residuals and parameters. Using CORR is the same as using both
CORRB and CORRS.

CORRB

prints the correlation matrix of the parameter estimates.

CORRS

prints the correlation matrix of the residuals.

COV

prints the covariance matrices of the residuals and parameters. Specifying COV is the same as
specifying both COVB and COVS.

COVB

prints the covariance matrix of the parameter estimates.

COVS

prints the covariance matrix of the residuals.

DW <= >

prints Durbin-Watson $d$ statistics, which measure autocorrelation of the residuals. When the residual
series is interrupted by missing observations, the Durbin-Watson statistic calculated is $d'$ as suggested
by Savin and White (1978). This is the usual Durbin-Watson computed by ignoring the gaps. Savin
and White show that it has the same null distribution as the DW with no gaps in the series and can be
used to test for autocorrelation using the standard tables. The Durbin-Watson statistic is not valid for
models that contain lagged endogenous variables.

You can use the DW= option to request higher-order Durbin-Watson statistics. Since the ordinary
Durbin-Watson statistic tests only for first-order autocorrelation, the Durbin-Watson statistics for
higher-order autocorrelation are called generalized Durbin-Watson statistics.

DWPROB

prints the significance level ($p$-values) for the Durbin-Watson tests. Since the Durbin-Watson $p$-values
are computationally expensive, they are not reported by default. In the Durbin-Watson test, the null
hypothesis is that there is autocorrelation at a specific lag.

See the section “Generalized Durbin-Watson Tests” for limitations of the statistic in the Chapter 8,
“The AUTOREG Procedure.”
FSRSQ
prints the first-stage $R^2$ statistics for instrumental estimation methods. These $R^2$ statistics measure
the proportion of the variance retained when the Jacobian columns associated with the parameters are
projected through the instruments space.

GODFREY

GODFREY=$n$
performs Godfrey’s tests for autocorrelated residuals for each equation, where $n$ is the maximum
autoregressive order, and specifies that Godfrey’s tests be computed for lags 1 through $n$. The default
number of lags is one.

HAUSMAN
performs Hausman’s specification test, or $m$-statistics.

NORMAL
performs tests of normality of the model residuals.

PCHOW=$obs$

PCHOW=$(obs1 \ obs2 \ldots \ obsn)$
prints the predictive Chow test for break points or structural changes in a model. The argument is the
number of observations in the first sample or a parenthesized list of first sample sizes. See the section
“Chow Tests” on page 1189 for details.

PRINTALL
specifies the printing options COLLIN, CORRB, CORRS, COVB, COVS, DETAILS, DW, and FSRSQ.

WHITE
specifies White’s test.

Options to Control Iteration Output

Details of the output produced are discussed in the section “Iteration History” on page 1151.

I
prints the inverse of the crossproducts Jacobian matrix at each iteration.

ITALL
specifies all iteration printing-control options (I, ITDETAILS, ITPRINT, and XPX). ITALL also prints
the crossproducts matrix (labeled CROSS), the parameter change vector, and the estimate of the
cross-equation covariance of residuals matrix at each iteration.

ITDETAILS
prints a detailed iteration listing. This includes the ITPRINT information and additional statistics.

ITPRINT
prints the parameter estimates, objective function value, and convergence criteria at each iteration.

XPX
prints the crossproducts Jacobian matrix at each iteration.
**Options to Control the Minimization Process**

The following options can be helpful when you experience a convergence problem:

**CONVERGE=value1**

**CONVERGE=(value1, value2)**

specifies the convergence criteria. The convergence measure must be less than `value1` before convergence is assumed. `value2` is the convergence criterion for the $S$ and $V$ matrices for $S$ and $V$ iterated methods. `value2` defaults to `value1`. See the section “Convergence Criteria” on page 1139 for details. The default value is `CONVERGE=0.001`.

**HESSIAN=CROSS | GLS | FDA**

specifies the Hessian approximation used for FIML. HESSIAN=CROSS selects the crossproducts approximation to the Hessian, HESSIAN=GLS selects the generalized least squares approximation to the Hessian, and HESSIAN=FDA selects the finite difference approximation to the Hessian. HESSIAN=GLS is the default.

**LTEBOUND=n**

specifies the local truncation error bound for the integration. This option is ignored if no ordinary differential equations (ODEs) are specified.

**EPSILON =value**

specifies the tolerance value used to transform strict inequalities into inequalities when restrictions on parameters are imposed. By default, EPSILON=1E–8. See the section “Restrictions and Bounds on Parameters” on page 1184 for details.

**MAXITER=n**

specifies the maximum number of iterations allowed. The default is MAXITER=100.

**MAXSUBITER=n**

specifies the maximum number of subiterations allowed for an iteration. For the GAUSS method, the MAXSUBITER= option limits the number of step halvings. For the MARQUARDT method, the MAXSUBITER= option limits the number of times $\lambda$ can be increased. The default is MAXSUBITER=30. See the section “Minimization Methods” on page 1138 for details.

**METHOD=GAUSS | MARQUARDT**

specifies the iterative minimization method to use. METHOD=GAUSS specifies the Gauss-Newton method, and METHOD=MARQUARDT specifies the Marquardt-Levenberg method. The default is METHOD=GAUSS. If the default GAUSS method fails to converge, the procedure switches to the MARQUARDT method. See the section “Minimization Methods” on page 1138 for details.

**MINTIMESTEP=n**

specifies the smallest allowed time step to be used in the integration. This option is ignored if no ODEs are specified.

**NESTIT**

changes the way the iterations are performed for estimation methods that iterate the estimate of the equation covariance ($S$ matrix). The NESTIT option is relevant only for the methods that iterate the estimate of the covariance matrix (ITGMM, ITOLS, ITSUR, IT2SLS, and IT3SLS). See the section “Details on the Covariance of Equation Errors” on page 1136 for an explanation of NESTIT.
**SINGULAR=** value

specifies the smallest pivot value allowed. The default 1.0E–12.

**STARTITER=n**

specifies the number of minimization iterations to perform at each grid point. The default is \texttt{STARTITER=0}, which implies that no minimization is performed at the grid points. See the section “Using the \texttt{STARTITER} Option” on page 1145 for more details.

**Other Options**

Other options that can be used on the \texttt{FIT} statement include the following that list and analyze the model: \texttt{BLOCK}, \texttt{GRAPH}, \texttt{LIST}, \texttt{LISTCODE}, \texttt{LISTDEP}, \texttt{LISTDER}, and \texttt{XREF}. The following printing control options are also available: \texttt{DETAILS}, \texttt{FLOW}, \texttt{INTGPRINT}, \texttt{MAXERRORS=}, \texttt{NOPRINT}, \texttt{PRINTALL}, and \texttt{TRACE}. For complete descriptions of these options, see the discussion of the \texttt{PROC MODEL} statement options earlier in this chapter.

**ID Statement**

\begin{verbatim}
ID variables ;
\end{verbatim}

The ID statement specifies variables to identify observations in error messages or other listings and in the OUT= data set. The ID variables are normally SAS date or datetime variables. If more than one ID variable is used, the first variable is used to identify the observations; the remaining variables are added to the OUT= data set.

**INCLUDE Statement**

\begin{verbatim}
INCLUDE model-names . . . ;
\end{verbatim}

The INCLUDE statement reads model files and inserts their contents into the current model. However, instead of replacing the current model as the \texttt{RESET MODEL=} option does, the contents of included model files are inserted into the model program at the position that the INCLUDE statement appears.

**INSTRUMENTS Statement**

\begin{verbatim}
INSTRUMENTS variables < _EXOG_ > ;
INSTRUMENTS < variables-list >> < _EXOG_ > < EXCLUDE = ( parameters ) >> < / options > ;
\end{verbatim}

The INSTRUMENTS statement specifies the instrumental variables to be used in the N2SLS, N3SLS, IT2SLS, IT3SLS, GMM, and ITGMM estimation methods.

There are three ways of specifying the INSTRUMENTS statement. The first form of the INSTRUMENTS statement is declared before a FIT statement and defines the default instruments list. The items specified as instruments can be variables or the special keyword \texttt{_EXOG_}. The keyword \texttt{_EXOG_} indicates that all the
model variables declared EXOGENOUS are to be added to the instruments list. If a single INSTRUMENTS statement of the first form is declared before multiple FIT statements, then it serves as the default instruments list for each of the FIT statements. However, if any of these FIT statements are followed by separate INSTRUMENTS statement, then the latter take precedence over the default list. Hence, in the case of multiple FIT statements, the INSTRUMENTS statement for a particular FIT statement is written below the FIT statement if instruments other than the default are required. For a single FIT statement, you can declare the INSTRUMENTS statement of the first form either preceding or following the FIT statement.

The second form of the INSTRUMENTS statement is used only after the FIT statement and before the next RUN statement. The items specified as instruments for the second form can be variables, names of parameters to be estimated, or the special keyword _EXOG_. If you specify the name of a parameter in the instruments list, the partial derivatives of the equations with respect to the parameter (that is, the columns of the Jacobian matrix associated with the parameter) are used as instruments. The parameter itself is not used as an instrument. These partial derivatives should not depend on any of the parameters to be estimated. Only the names of parameters to be estimated can be specified.

Note that an INSTRUMENTS statement of only the first form declared before multiple FIT statements serves as the default instruments list. Hence, in the cases of multiple as well as single FIT statements, you can declare the second form of INSTRUMENTS statements only following the FIT statements.

In the case where a FIT statement is preceded by an INSTRUMENTS statement of the second form in error and not followed by any INSTRUMENTS statement, then the default list is used. This default list is given by the INSTRUMENTS statement of the first form as explained above. If such a list is not declared, all the model variables declared EXOGENOUS comprise the default.

A third form of the INSTRUMENTS statement is used to specify instruments for each equation. No explicit intercept is added, parameters cannot be specified to represent instruments, and the _EXOG_ keyword is not allowed. Equations not explicitly assigned instruments use all the instruments specified for the other equations as well as instruments not assigned specific equations. In the following statements, \(z_1\), \(z_2\), and \(z_3\) are instruments used with equation \(y_1\), and \(z_2\), \(z_3\), and \(z_4\) are instruments used with equation \(y_2\).

```plaintext
proc model data=data_sim;
   exogenous x1 x2;
   parms a b c d e f;
   y1 =a*x1**2 + b*x2**2 + c*x1*x2 ;
   y2 =d*x1**2 + e*x2**2 + f*x1*x2**2;
   fit y1 y2 / 3sls ;
   instruments (y1, z1 z2 z3) (y2,z2 z3 z4);
run;
```

**EXCLUDE=(parameters)** specifies that the derivatives of the equations with respect to all of the parameters to be estimated (except the parameters listed in the EXCLUDE list) be used as instruments, in addition to the other instruments specified. If you use the EXCLUDE= option, you should be sure that the derivatives with respect to the nonexcluded parameters in the estimation are independent of the endogenous variables and not functions of the parameters estimated.

The following options can be specified on the INSTRUMENTS statement following a slash (/):
Chapter 19: The MODEL Procedure

**NOINTERCEPT**

*NOINT*

excludes the constant of 1.0 (intercept) from the instruments list. An intercept is included as an instrument while using the first or second form of the INSTRUMENTS statement unless NOINTERCEPT is specified.

When a FIT statement specifies an instrumental variables estimation method and no INSTRUMENTS statement accompanies the FIT statement, the default instruments are used. If no default instruments list has been specified, all the model variables declared EXOGENOUS are used as instruments. See the section “Choice of Instruments” on page 1192 for more details.

**INTONLY**

specifies that only the intercept be used as an instrument. This option is used for GMM estimation where the moments have been specified explicitly.

---

**LABEL Statement**

```
LABEL variable='label' . . . ;
```

The LABEL statement specifies a label of up to 255 characters for parameters and other variables used in the model program. Labels are used to identify parts of the printout of FIT and SOLVE tasks. The labels are displayed in the output if the LINESIZE= option is large enough.

---

**MOMENT Statement**

```
MOMENT variables = moment specification ;
```

In many scenarios, endogenous variables are observed from data. From the models, you can simulate these endogenous variables based on a fixed set of parameters. The goal of simulated method of moments (SMM) is to find a set of parameters such that the moments of the simulated data match the moments of the observed variables. If there are many moments to match, the code might be tedious. The following MOMENT statement provides a way to generate some commonly used moments automatically. Multiple MOMENT statements can be used.

*variables* can be one or more endogenous variables.

*moment specification* can have the following four types:

- (number list) specifies that the endogenous variable is raised to the power specified by each number in number list. For example,

  ```
  moment y = (2 3);
  ```

  adds the following two equations to be estimated:

  ```
  eq._moment_1 = y**2 - pred.y**2;
  eq._moment_2 = y**3 - pred.y**3;
  ```
• **ABS ( number list )** specifies that the absolute value of the endogenous variable is raised to the power specified by each number in *number list*. For example,

```
moment y = ABS(3);
```

adds the following equation to be estimated:

```
eq._moment_2 = abs(y)**3 - abs(pred.y)**3;
```

• **LAG num ( number list )** specifies that the endogenous variable is multiplied by the *num* th lag of the endogenous variable, and this product is raised to the power specified by each number in *number list*. For example,

```
moment y = LAG4(3);
```

adds the following equation to be estimated:

```
eq._moment_3 = (y*lag4(y))**3 - (pred.y*lag4(pred.y))**3;
```

• **ABS_LAG num ( number list )** specifies that the endogenous variable is multiplied by the *num* th lag of the endogenous variable, and the absolute value of this product is raised to the power specified by each number in *number list*. For example,

```
moment y = ABS_LAG4(3);
```

adds the following equation to be estimated:

```
eq._moment_4 = abs(y*lag4(y))**3 - abs(pred.y*lag4(pred.y))**3;
```

The following PROC MODEL statements use the MOMENT statement to generate 24 moments and fit these moments using SMM.

```
proc model data=_tmpdata list;
  parms a b .5 s 1;
  instrument _exog_ / intonly;
  u = rannor( 10091 );
  z = rannor( 97631 );
  lsigmasq = xlag(sigmasq,exp(a));
  lnsigmasq = a + b * log(lsigmasq) + s * u;
  sigmasq = exp( lnsigmasq );
  y = sqrt(sigmasq) * z;

  moment y = (2 4) abs(1 3) abs_lag1(1 2) abs_lag2(1 2);
  moment y = abs_lag3(1 2) abs_lag4(1 2)
    abs_lag5(1 2) abs_lag6(1 2)
    abs_lag7(1 2) abs_lag8(1 2)
    abs_lag9(1 2) abs_lag10(1 2);

  fit y / gmm npreobs=20 ndraw=10;
  bound s > 0, 1>b>0;
run;
```
OUTVARS Statement

OUTVARS variables ;

The OUTVARS statement specifies additional variables defined in the model program to be output to the OUT= data sets. The OUTVARS statement is not needed unless the variables to be added to the output data set are not referred to by the model, or unless you want to include parameters or other special variables in the OUT= data set. The OUTVARS statement includes additional variables, whereas the KEEP statement excludes variables.

PARAMETERS Statement

PARAMETERS variable < value > < variable < value > > . . . ;

The PARAMETERS statement declares the parameters of a model and optionally sets their initial values. Valid abbreviations are PARMS and PARM.

Each parameter has a single value associated with it, which is the same for all observations. Lagging is not relevant for parameters. If a value is not specified in the PARMS statement (or by the PARMS= option of a FIT statement), the value defaults to 0.0001 for FIT tasks and to a missing value for SOLVE tasks.

Programming Statements

To define the model, you can use most of the programming statements that are allowed in the SAS DATA step. See the SAS Language Reference: Dictionary for more information.

RANGE Statement

RANGE variable < = first > < TO last > ;

The RANGE statement specifies the range of observations to be read from the DATA= data set. For FIT tasks, the RANGE statement controls the period of fit for the estimation. For SOLVE tasks, the RANGE statement controls the simulation period or forecast horizon.

The RANGE variable must be a numeric variable in the DATA= data set that identifies the observations, and the data set must be sorted by the RANGE variable. The first observation in the range is identified by first, and the last observation is identified by last.

PROC MODEL uses the first \( l \) observations prior to first to initialize the lags, where \( l \) is the maximum number of lags needed to evaluate any of the equations to be fit or solved, or the maximum number of lags needed to compute any of the instruments when an instrumental variables estimation method is used. There should be at least \( l \) observations in the data set before first. If last is not specified, all the nonmissing observations starting with first are used.

If first is omitted, the first \( l \) observations are used to initialize the lags, and the rest of the data, until last, is used. If a RANGE statement is used but both first and last are omitted, the RANGE statement variable is used to report the range of observations processed.
The RANGE variable should be nonmissing for all observations. Observations that contain missing RANGE values are deleted.

The following are examples of RANGE statements:

```
range year = 1971 to 1988;  /* yearly data */
range date = '1feb73'd to '1nov82'd;  /* monthly data */
range time = 60.5;  /* time in years */
range year to 1977;  /* use all years through 1977 */
range date;  /* use values of date to report period-of-fit */
```

If no RANGE statements follow multiple FIT statements and if a single RANGE statement is declared before all the FIT statements, estimation in each of the multiple FIT statements is based on the data specified in the single RANGE statement. A single RANGE statement that follows multiple FIT statements affects only the fit immediately preceding it.

If the FIT statement is both followed by and preceded by RANGE statements, the following RANGE statement takes precedence over the preceding RANGE statement.

In the case where a range of data is to be used for a particular SOLVE task, the RANGE statement should be specified following the SOLVE statement in the case of either single or multiple SOLVE statements.

---

**RESET Statement**

```
RESET options;
```

All the options of the PROC MODEL statement can be reset by the RESET statement. In addition, the RESET statement supports one additional option:

**PURGE**

deletes the current model so that a new model can be defined.

When the MODEL= option is used in the RESET statement, the current model is deleted before the new model is read.

---

**RESTRICT Statement**

```
RESTRICT restriction1 < , restriction2 . . . > ;
```

The RESTRICT statement is used to impose linear and nonlinear restrictions either on the parameters in an estimation or on the solution variables that are specified in a solve operation.

Each restriction is written as an optional name, followed by an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

```
< "name" > expression operator expression
```

The optional "name" is a string used to identify the restriction. The operator can be =, <, >, <=, or >=. The operator and second expression are optional. When they are omitted, the default operator is > and the default second expression is 0.
Each RESTRICT statement is associated with the preceding FIT statement or SOLVE statement. When there is no preceding FIT or SOLVE statement, the RESTRICT statement is associated with the following FIT or SOLVE statement. You can specify any number of RESTRICT statements.

### Parameter Estimates

Expressions in RESTRICT statements that apply to the parameters estimated by a FIT statement can be composed of parameter names, arithmetic operators, functions, and constants. Comparison operators (such as = or <) and logical operators (such as &) cannot be used in RESTRICT statement expressions. Parameters that are named in restriction expressions must be among the parameters estimated by the associated FIT statement. Expressions can refer to variables defined in the program.

The restriction expressions can be linear or nonlinear functions of the parameters.

The optional "name" is a string used to identify the restriction in the printed output and in the OUTEST= data set.

The following example shows how to use the RESTRICT statement:

```plaintext
proc model data=one;
   endogenous y1 y2;
   exogenous x1 x2;
   parms a b c;
   restrict b*(b+c) <= a;
   eq.one = -y1/c + a/x2 + b * x1**2 + c * x2**2;
   eq.two = -y2 * y1 + b * x2**2 - c/(2 * x1);
   fit one two / fiml;
run;
```

### Solution Variables

Expressions in RESTRICT statements that apply to the solution variables in a SOLVE statement can be composed of any variables in the model. Unlike restriction expressions that are used in parameter estimation, exogenous model variables can be used in restriction expressions that involve solution variables because each observation is solved independently in a SOLVE statement. To include constraints that are imposed by RESTRICT inequalities in a solution, you must specify the OPTIMIZE option in the SOLVE statement.

The following example illustrates how multiple solutions to a nonlinear system of equations can be found by using a RESTRICT expression that depends on exogenous variables. Two of the four possible solutions are presented in Figure 19.22.

```plaintext
data d;
do i = 0 to 1;
   date=i;
   if i = 0 then r = -1;
   else r = +1;
   output;
end;
run;
```
SOLVE Statement

SOLVE variables < SATISFY= equations > < /options > ;

The SOLVE statement specifies that the model be simulated or forecast for input data values and, optionally, selects the variables to be solved. If the list of variables is omitted, all of the model variables declared ENDOGENOUS are solved. If no model variables are declared ENDOGENOUS, then all model variables are solved.

The following specification can be used in the SOLVE statement:

SATISFY= equation

SATISFY=( equations )

specifies a subset of the model equations that the solution values are to satisfy. If the SATISFY= option is not used, the solution is computed to satisfy all the model equations. Note that the number of equations must equal the number of variables solved.
Data Set Options

**DATA=SAS-data-set**

names the input data set. The model is solved for each observation read from the DATA= data set. If the DATA= option is not specified on the SOLVE statement, the data set specified by the DATA= option in the PROC MODEL statement is used.

**ESTDATA=SAS-data-set**

names a data set whose first observation provides values for some or all of the parameters and whose additional observations (if any) give the covariance matrix of the parameter estimates. The covariance matrix read from the ESTDATA= data set is used to generate multivariate normal pseudo-random shocks to the model parameters when the RANDOM= option requests Monte Carlo simulation.

**OUT=SAS-data-set**

outputs the predicted (solution) values, residual values, actual values, or equation errors from the solution to a data set. The residual values are the actual − predicted values, which is the negative of RESID.variable as defined in the section “Equation Translations” on page 1264. Only the solution values are output by default.

**OUTACTUAL**

outputs the actual values of the solved variables read from the input data set to the OUT= data set. This option is applicable only if the OUT= option is specified.

**OUTALL**

specifies the OUTACTUAL, OUTERRORS, OUTLAGS, OUTPREDICT, and OUTRESID options.

**OUTERRORS**

writes the equation errors to the OUT= data set. These values are normally very close to 0 when a simultaneous solution is computed; they can be used to double-check the accuracy of the solution process. This option applies only if the OUT= option is specified.

**OUTLAGS**

writes the observations that are used to start the lags to the OUT= data set. This option applies only if the OUT= option is specified.

**OUTOBJVALS**

writes the objective function value to the OBJVALS variable in the OUT= data set. The objective function value is computed only when the OPTIMIZE solution method is specified. This value is close to 0 when an unbounded simultaneous solution is computed and can be greater than 0 when bounds are active in the solution. This option applies only if the OUT= option is specified.

**OUTPREDICT**

writes the solution values to the OUT= data set. This option applies only if the OUT= option is specified.

The OUTPREDICT option is the default unless one of the other output options is specified.

**OUTRESID**

writes the residual values that are computed as the actual − predicted values and is not the same as the RESID.variable values. This option applies only if the OUT= option is specified.
OUTVIOLATIONS
writes the equation violations to the OUT= data set. The equation violations are computed only when
the OPTIMIZE solution method is specified. The violations provide information about how much each
equation contributes to the objective function value when bounds are active in the solution. This option
applies only if the OUT= option is specified.

PARMSDATA=SAS-data-set
specifies a data set that contains the parameter estimates. See the section “Input Data Sets” on page 1211
for more details.

RESIDDATA=SAS-data-set
specifies a data set that contains the residuals to be used in the empirical distribution. This data set can
be created using the OUT= option in the FIT statement.

SDATA=SAS-data-set
specifies a data set that provides the covariance matrix of the equation errors. The covariance matrix
that is read from the SDATA= data set is used to generate multivariate normal pseudo-random shocks
to the equations when the RANDOM= option requests Monte Carlo simulation.

TIME=name
specifies the name of the time variable. This variable must be in the data set.

TYPE=name
specifies the estimation type. The name that is specified in the TYPE= option is compared to the
_TYPE_ variable in the ESTDATA= and SDATA= data sets to select observations to use in constructing
the covariance matrices. When TYPE= is omitted, the last estimation type in the data set is used.

Solution Mode Options: Lag Processing

DYNAMIC
specifies a dynamic solution. In the dynamic solution mode, solved values are used by the lagging
functions. DYNAMIC is the default.

NAHEAD=n
specifies a simulation of \( n \)-period-ahead dynamic forecasting. The NAHEAD= option is used to
simulate the process of using the model to produce successive forecasts to a fixed forecast horizon, in
which each forecast uses the historical data available at the time the forecast is made.

Note that NAHEAD=1 produces a static (one-step-ahead) solution. NAHEAD=2 produces a solution
that uses one-step-ahead solutions for the first lag (LAG1 functions return static predicted values) and
actual values for longer lags. NAHEAD=3 produces a solution that uses NAHEAD=2 solutions for
the first lags, NAHEAD=1 solutions for the second lags, and actual values for longer lags. In general,
NAHEAD=n solutions use NAHEAD=n–1 solutions for LAG1, NAHEAD=n–2 solutions for LAG2,
and so forth.

START=s
specifies static solutions until the \( s \)th observation and then changes to dynamic solutions. If the
START=s option is specified, the first observation in the range in which LAGn delivers solved
predicted values is \( s+n \), while LAGn returns actual values for earlier observations.
Chapter 19: The MODEL Procedure

STATIC
specifies a static solution. In static solution mode, actual values of the solved variables from the input data set are used by the lagging functions.

Solution Mode Options: Use of Available Data

FORECAST
specifies that the actual value of a solved variable is used as the solution value (instead of the predicted value from the model equations) whenever nonmissing data are available in the input data set. That is, in FORECAST mode, PROC MODEL solves only for those variables that are missing in the input data set.

SIMULATE
specifies that PROC MODEL always solves for all solution variables as a function of the input values of the other variables, even when actual data for some of the solution variables are available in the input data set. SIMULATE is the default.

Solution Mode Options: Numerical Solution Method

JACOBI
computes a simultaneous solution using a Jacobi iteration.

NEWTON
computes a simultaneous solution by using Newton’s method. When the NEWTON option is selected, the analytic derivatives of the equation errors with respect to the solution variables are computed, and memory-efficient sparse matrix techniques are used for factoring the Jacobian matrix.

The NEWTON option can be used to solve both normalized-form and general-form equations and can compute goal-seeking solutions. NEWTON is the default.

OPTIMIZE
computes a simultaneous solution by minimizing a norm of the equation errors with respect to the solution variables. The OPTIMIZE method obeys constraints on the solution variables that are imposed by the BOUNDS and RESTRICT statements.

SEIDEL
computes a simultaneous solution by using a Gauss-Seidel method.

SINGLE

ONEPASS
specifies a single-equation (nonsimultaneous) solution. The model is executed once to compute predicted values for the variables from the actual values of the other endogenous variables. The SINGLE option can be used only for normalized-form equations and cannot be used for goal-seeking solutions.

For more information about these options, see the section “Solution Modes” on page 1223.
Monte Carlo Simulation Options

**COPULA=(copula-options)**

specifies the copula to be used in the simulation. You can specify the following copula-options:

- CLAYTON(θ), where θ is the Clayton copula parameter
- FRANK(θ), where θ is the Frank copula parameter
- GUMBEL(θ), where θ is the Gumbel copula parameter
- NORMAL
- NORMALMIX( n, p₁ ... pₙ, v₁ ... vₙ ), where pᵢ are the probabilities and vᵢ are the variances
- T(df) < ASYM >, where df is the degrees-of-freedom parameter

The normal (Gaussian) copula is the default. The copula applies to covariance of equation errors.

**PSEUDO=DEFAULT | TWISTER**

specifies which pseudo-number generator to use in generating draws for Monte Carlo simulation. The two pseudo-random number generators that are supported by the MODEL procedure are a default congruential generator that has period $2^{31} - 1$ and a Mersenne-Twister pseudo-random number generator that has an extraordinarily long period $2^{19937} - 1$.

**QUASI=NONE|SOBOL|FAURE**

specifies a pseudo- or quasi-random number generator. Two quasi-random number generators are supported by the MODEL procedure: the Sobol sequence (QUASI=SOBOL) and the Faure sequence (QUASI=FAURE). The default is QUASI=NONE, which is the pseudo-random number generator.

**RANDOM=n**

repeats the solution n times for each BY group, with different random perturbations of the equation errors if the SDATA= option is specified; with different random perturbations of the parameters if the ESTDATA= option is specified and the ESTDATA= data set contains a parameter covariance matrix; and with different values returned from the random number generator functions, if any are used in the model program. If RANDOM=0, the random number generator functions always return zero. See the section “Monte Carlo Simulation” on page 1226 for details. The default is RANDOM=0.

**SEED=n**

specifies an integer to use as the seed in generating pseudo-random numbers to shock the parameters and equations when the ESTDATA= or SDATA= option is specified. If n is negative or 0, the time of day from the computer’s clock is used as the seed. The SEED= option is relevant only if the RANDOM= option is specified. The default is SEED=0.

**WISHART=df**

specifies that a Wishart distribution with degrees of freedom df be used in place of the normal error covariance matrix. This option is used to model the variance of the error covariance matrix when Monte Carlo simulation is selected.

Options for Controlling the Numerical Solution Process

The following options are useful when you have difficulty converging to the simultaneous solution.
CONVERGE=value
specifies the convergence criterion for the simultaneous solution. Convergence of the solution is judged by comparing the CONVERGE= value to the maximum over the equations of
\[
\frac{|\epsilon_i|}{|y_i| + 1E-6}
\]
if they are computable, otherwise
\[
|\epsilon_i|
\]
where \(\epsilon_i\) represents the equation error and \(y_i\) represents the solution variable that corresponds to the \(i\)th equation for normalized-form equations. The default is CONVERGE=1E-8.

MAXITER=n
specifies the maximum number of iterations allowed for computing the simultaneous solution for any observation. The default is MAXITER=50.

MAXSUBITER=n
specifies the maximum number of damping subiterations that are performed in solving a nonlinear system when using the NEWTON solution method. Damping is disabled by setting MAXSUBITER=0. The default is MAXSUBITER=10.

Printing Options

INTGPRIINT
prints between data points integration values for the DERT. variables and the auxiliary variables. If you specify the DETAILS option, the integrated derivative variables are printed as well.

ITPRINT
prints the solution approximation and equation errors at each iteration for each observation. This option can produce voluminous output.

PRINTALL
specifies the printing control options DETAILS, ITPRINT, SOLVEPRINT, STATS, and THEIL.

SOLVEPRINT
prints the solution values and residuals at each observation.

STATS
prints various summary statistics for the solution values.

THEIL
prints tables of Theil inequality coefficients and Theil relative change forecast error measures for the solution values. See the section “Summary Statistics” on page 1242 for more information.

Other Options

Other options that can be used on the SOLVE statement include the following that list and analyze the model: BLOCK, GRAPH, LIST, LISTCODE, LISTDEP, LISTDER, and XREF. The LTEBOUND= and MINTIMESTEP= options can be used to control the integration process. The following printing-control options are also available: DETAILS, FLOW, MAXERRORS=, NOPRINT, and TRACE. For complete descriptions of these options, see the PROC MODEL and FIT statement options described earlier in this chapter.
The TEST statement performs tests of nonlinear hypotheses on the model parameters.

Each TEST statement applies to the parameters estimated by one FIT statement. TEST statements that appear before or after the first FIT statement are associated with the first FIT statement. Subsequent TEST statements are associated with the FIT statement that precedes them. TEST statements that are separated from a FIT statement by an intervening RUN, SOLVE, or RESET statement are ignored. You can specify any number of TEST statements.

If you specify options on the TEST statement, a comma is required before the “/” character that separates the test expressions from the options, because the “/” character can also be used within test expressions to indicate division.

The label lengths for tests and estimate statements are 256 characters. If the labels exceed this length, the label is truncated to 256 characters with a note printed to the log.

Each test is written as an expression optionally followed by an equal sign (=) and a second expression:

```
< expression > < = expression >
```

Test expressions can be composed of parameter names, arithmetic operators, functions, and constants. Comparison operators (such as =) and logical operators (such as &) cannot be used in TEST statement expressions. Parameters named in test expressions must be among the parameters estimated by the associated FIT statement.

If you specify only one expression in a test, that expression is tested against zero. For example, the following two TEST statements are equivalent:

```
test a + b;
test a + b = 0;
```

When you specify multiple tests in the same TEST statement, a joint test is performed. For example, the following TEST statement tests the joint hypothesis that both A and B are equal to zero.

```
test a, b;
```

To perform separate tests rather than a joint test, use separate TEST statements. For example, the following TEST statements test the two separate hypotheses that A is equal to zero and that B is equal to zero.

```
test a;
test b;
```

You can use the following options in the TEST statement.
The **VAR Statement**

```
VAR variables < initial-values> . . . ;
```

The VAR statement declares model variables and optionally provides initial values for the lags of the variables. See the section “Lag Logic” on page 1269 for more information.

The **VARGROUP Statement**

```
VARGROUP label=variable . . . ;
```

The VARGROUP statement applies a group label to the specified list of variables in the model program. Variable groups are used to identify sets of related solve variables. The variable groups can be used by the ANALYZEDEP= option in a subsequent SOLVE statement to help specify and understand the role of groups of solve variables in a SOLVE step. If a variable appears in more than one VARGROUP statement, the label that is specified in the last VARGROUP statement is applied to that variable.

The **WEIGHT Statement**

```
WEIGHT variable ;
```

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters.

If the weight of an observation is nonpositive, that observation is not used for the estimation. `variable` must be a numeric variable in the input data set.
An alternative weighting method is to use an assignment statement to give values to the special variable \_WEIGHT\_. The \_WEIGHT\_ variable must not depend on the parameters being estimated. If both weighting specifications are given, the weights are multiplied together.

**Details: Estimation by the MODEL Procedure**

**Estimation Methods**

Consider the general nonlinear model:

\[
\begin{align*}
\epsilon_t &= q(y_t, x_t, \theta) \\
z_t &= Z(x_t)
\end{align*}
\]

where \(q \in \mathbb{R}^g\) is a real vector valued function of \(y_t \in \mathbb{R}^g, x_t \in \mathbb{R}^l, \theta \in \mathbb{R}^p\), where \(g\) is the number of equations, \(l\) is the number of exogenous variables (lagged endogenous variables are considered exogenous here), \(p\) is the number of parameters, and \(t\) ranges from 1 to \(n\). \(z_t \in \mathbb{R}^k\) is a vector of instruments. \(\epsilon_t\) is an unobservable disturbance vector with the following properties:

\[
\begin{align*}
E(\epsilon_t) &= 0 \\
E(\epsilon_t \epsilon_t') &= \Sigma
\end{align*}
\]

All of the methods implemented in PROC MODEL aim to minimize an objective function. The following table summarizes the objective functions that define the estimators and the corresponding estimator of the covariance of the parameter estimates for each method.

The column labeled “Instruments” identifies the estimation methods that require instruments. The variables used in this table and the remainder of this chapter are defined as follows:
\( n \) = is the number of nonmissing observations.

\( g \) = is the number of equations.

\( k \) = is the number of instrumental variables.

\[
\begin{bmatrix}
  r_1 \\
r_2 \\
  \vdots \\
r_g
\end{bmatrix}
\]
is the \( ng \times 1 \) vector of residuals for the \( g \) equations stacked together.

\[
\begin{bmatrix}
  q_i(y_1, x_1, \theta) \\
  q_i(y_2, x_2, \theta) \\
  \vdots \\
  q_i(y_n, x_n, \theta)
\end{bmatrix}
\]
is the \( n \times 1 \) column vector of residuals for the \( i \)th equation.

\( S \) is a \( g \times g \) matrix that estimates \( \Sigma \), the covariances of the errors across equations (referred to as the \( S \) matrix).

\( X \) is an \( ng \times p \) matrix of partial derivatives of the residual with respect to the parameters.

\( W \) is an \( n \times n \) matrix, \( Z'Z \).

\( Z \) is an \( n \times k \) matrix of instruments.

\( Y \) is a \( gk \times ng \) matrix of instruments. \( Y = I_g \otimes Z' \).

\( \hat{Z} \) is \( \hat{Z} = (\hat{Z}_1, \hat{Z}_2, \ldots, \hat{Z}_p) \) is an \( ng \times p \) matrix. \( \hat{Z}_i \) is a \( ng \times 1 \) column vector obtained from stacking the columns of

\[
U^{-1} \sum_{t=1}^{n} \left( \frac{\partial q(y_t, x_t, \theta)}{\partial y_t} \right)^{-1} \frac{\partial^2 q(y_t, x_t, \theta)}{\partial y_t \partial \theta_t} - Q_i
\]

\( U \) is an \( n \times g \) matrix of residual errors. \( U = \epsilon_1, \epsilon_2, \ldots, \epsilon_n' \).

\( Q \) is the \( n \times g \) matrix \( q(y_1, x_1, \theta), q(y_2, x_2, \theta), \ldots, q(y_n, x_n, \theta) \).

\( Q_i \) is an \( n \times g \) matrix \( \frac{\partial Q}{\partial \theta_i} \).

\( I \) is an \( n \times n \) identity matrix.

\( J_t \) is \( \frac{\partial q(y_t, x_t, \theta)}{\partial \theta_t} \), which is a \( g \times g \) Jacobian matrix.

\( m_n \) is first moment of the crossproduct \( q(y_t, x_t, \theta) \otimes z_t \),

\[
m_n = \frac{1}{n} \sum_{t=1}^{n} q(y_t, x_t, \theta) \otimes z_t
\]

\( z_t \) is a \( k \) column vector of instruments for observation \( t \). \( z_t' \) is also the \( t \)th row of \( Z \).

\( \hat{V} \) is the \( gk \times gk \) matrix that represents the variance of the moment functions.

\( k \) is the number of instrumental variables used.

\( constant \) is the constant \( \frac{ng}{2} (1 + \ln(2\pi)) \).

\( \otimes \) is the notation for a Kronecker product.

All vectors are column vectors unless otherwise noted. Other estimates of the covariance matrix for FIML are also available.
Dependent Regressors and Two-Stage Least Squares

Ordinary regression analysis is based on several assumptions. A key assumption is that the independent variables are in fact statistically independent of the unobserved error component of the model. If this assumption is not true (if the regressor varies systematically with the error), then ordinary regression produces inconsistent results. The parameter estimates are biased.

Regressors might fail to be independent variables because they are dependent variables in a larger simultaneous system. For this reason, the problem of dependent regressors is often called simultaneous equation bias. For example, consider the following two-equation system:

\[
\begin{align*}
y_1 &= a_1 + b_1 y_2 + c_1 x_1 + \epsilon_1 \\
y_2 &= a_2 + b_2 y_1 + c_2 x_2 + \epsilon_2
\end{align*}
\]

In the first equation, \(y_2\) is a dependent, or endogenous, variable. As shown by the second equation, \(y_2\) is a function of \(y_1\), which by the first equation is a function of \(\epsilon_1\), and therefore \(y_2\) depends on \(\epsilon_1\). Likewise, \(y_1\) depends on \(\epsilon_2\) and is a dependent regressor in the second equation. This is an example of a simultaneous equation system; \(y_1\) and \(y_2\) are a function of all the variables in the system.

Using the ordinary least squares (OLS) estimation method to estimate these equations produces biased estimates. One solution to this problem is to replace \(y_1\) and \(y_2\) on the right-hand side of the equations with predicted values, thus changing the regression problem to the following:

\[
\begin{align*}
y_1 &= a_1 + b_1 \hat{y}_2 + c_1 x_1 + \epsilon_1 \\
y_2 &= a_2 + b_2 \hat{y}_1 + c_2 x_2 + \epsilon_2
\end{align*}
\]

This method requires estimating the predicted values \(\hat{y}_1\) and \(\hat{y}_2\) through a preliminary, or “first stage,” instrumental regression. An instrumental regression is a regression of the dependent regressors on a set of instrumental variables, which can be any independent variables useful for predicting the dependent regressors. In this example, the equations are linear and the exogenous variables for the whole system are known. Thus, the best choice for instruments (of the variables in the model) are the variables \(x_1\) and \(x_2\).

This method is known as two-stage least squares or 2SLS, or more generally as the instrumental variables method. The 2SLS method for linear models is discussed in Pindyck and Rubinfeld (1981, pp. 191–192). For nonlinear models this situation is more complex, but the idea is the same. In nonlinear 2SLS, the derivatives of the model with respect to the parameters are replaced with predicted values. See the section “Choice of Instruments” on page 1192 for further discussion of the use of instrumental variables in nonlinear regression.

To perform nonlinear 2SLS estimation with PROC MODEL, specify the instrumental variables with an INSTRUMENTS statement and specify the 2SLS or N2SLS option in the FIT statement. The following statements show how to estimate the first equation in the preceding example with PROC MODEL:

```plaintext
proc model data=in;
  y1 = a1 + b1 * y2 + c1 * x1;
  fit y1 / 2sls;
  instruments x1 x2;
run;
```

The 2SLS or instrumental variables estimator can be computed by using a first-stage regression on the instrumental variables as described previously. However, PROC MODEL actually uses the equivalent but
computationally more appropriate technique of projecting the regression problem into the linear space defined by the instruments. Thus, PROC MODEL does not produce any “first stage” results when you use 2SLS. If you specify the FSRSQ option in the FIT statement, PROC MODEL prints “First-Stage R²” statistic for each parameter estimate.

Formally, the \( \hat{\theta} \) that minimizes

\[
\hat{S}_n = \frac{1}{n} \left( \sum_{t=1}^{n} (q(y_t, x_t, \theta) \otimes z_t) \right) \left( \sum_{t=1}^{n} I \otimes z_t z_t' \right)^{-1} \left( \sum_{t=1}^{n} (q(y_t, x_t, \theta) \otimes z_t) \right)
\]

is the N2SLS estimator of the parameters. The estimate of \( \Sigma \) at the final iteration is used in the covariance of the parameters given in Table 19.2. See Amemiya (1985, p. 250) for details on the properties of nonlinear two-stage least squares.

**Seemingly Unrelated Regression**

If the regression equations are not simultaneous (so there are no dependent regressors), *seemingly unrelated regression* (SUR) can be used to estimate systems of equations with correlated random errors. The large-sample efficiency of an estimation can be improved if these cross-equation correlations are taken into account. SUR is also known as *joint generalized least squares* or *Zellner regression*. Formally, the \( \hat{\theta} \) that minimizes

\[
\hat{S}_n = \frac{1}{n} \sum_{t=1}^{n} q(y_t, x_t, \theta) \hat{\Sigma}^{-1} q(y_t, x_t, \theta)
\]

is the SUR estimator of the parameters.

The SUR method requires an estimate of the cross-equation covariance matrix, \( \Sigma \). PROC MODEL first performs an OLS estimation, computes an estimate, \( \hat{\Sigma} \), from the OLS residuals, and then performs the SUR estimation based on \( \hat{\Sigma} \). The OLS results are not printed unless you specify the OLS option in addition to the SUR option.

You can specify the \( \hat{\Sigma} \) to use for SUR by storing the matrix in a SAS data set and naming that data set in the SDATA= option. You can also feed the \( \hat{\Sigma} \) computed from the SUR residuals back into the SUR estimation process by specifying the ITSUR option. You can print the estimated covariance matrix \( \hat{\Sigma} \) by using the COVS option in the FIT statement.

The SUR method requires estimation of the \( \Sigma \) matrix, and this increases the sampling variability of the estimator for small sample sizes. The efficiency gain that SUR has over OLS is a large sample property, and you must have a reasonable amount of data to realize this gain. For a more detailed discussion of SUR, see Pindyck and Rubinfeld (1981, pp. 331–333).

**Three-Stage Least Squares Estimation**

If the equation system is simultaneous, you can combine the 2SLS and SUR methods to take into account both dependent regressors and cross-equation correlation of the errors. This is called *three-stage least squares* (3SLS).

Formally, the \( \hat{\theta} \) that minimizes

\[
\hat{S}_n = \frac{1}{n} \left( \sum_{t=1}^{n} (q(y_t, x_t, \theta) \otimes z_t) \right) \left( \sum_{t=1}^{n} (\hat{\Sigma} \otimes z_t z_t') \right)^{-1} \left( \sum_{t=1}^{n} (q(y_t, x_t, \theta) \otimes z_t) \right)
\]
is the 3SLS estimator of the parameters. For more details on 3SLS, see Gallant (1987, p. 435).

Residuals from the 2SLS method are used to estimate the $\Sigma$ matrix required for 3SLS. The results of the preliminary 2SLS step are not printed unless the 2SLS option is also specified.

To use the three-stage least squares method, specify an INSTRUMENTS statement and use the 3SLS or N3SLS option in either the PROC MODEL statement or a FIT statement.

**Generalized Method of Moments (GMM)**

For systems of equations with heteroscedastic errors, generalized method of moments (GMM) can be used to obtain efficient estimates of the parameters. See the section “Heteroscedasticity” on page 1160 for alternatives to GMM.

Consider the nonlinear model

$$
\begin{align*}
\epsilon_t & = q(y_t, x_t, \theta) \\
z_t & = Z(x_t)
\end{align*}
$$

where $z_t$ is a vector of instruments and $\epsilon_t$ is an unobservable disturbance vector that can be serially correlated and nonstationary.

In general, the following orthogonality condition is desired:

$$
E(\epsilon_t \otimes z_t) = 0
$$

This condition states that the expected crossproducts of the unobservable disturbances, $\epsilon_t$, and functions of the observable variables are set to 0. The first moment of the crossproducts is

$$
\begin{align*}
m_n &= \frac{1}{n} \sum_{t=1}^{n} m(y_t, x_t, \theta) \\
m(y_t, x_t, \theta) &= q(y_t, x_t, \theta) \otimes z_t
\end{align*}
$$

where $m(y_t, x_t, \theta) \in \mathbb{R}^{gk}$.

The case where $gk > p$ is considered here, where $p$ is the number of parameters.

Estimate the true parameter vector $\theta^0$ by the value of $\hat{\theta}$ that minimizes

$$
S(\theta, V) = [n m_n(\theta)]' V^{-1} [n m_n(\theta)]/n
$$

where

$$
V = \text{Cov} \left( [n m_n(\theta^0)], [n m_n(\theta^0)]' \right)
$$

The parameter vector that minimizes this objective function is the GMM estimator. GMM estimation is requested in the FIT statement with the GMM option.
The variance of the moment functions, $V$, can be expressed as

$$V = E \left( \sum_{t=1}^{n} \epsilon_t \otimes z_t \right) \left( \sum_{s=1}^{n} \epsilon_s \otimes z_s \right)'$$

$$= \sum_{t=1}^{n} \sum_{s=1}^{n} E \left[ (\epsilon_t \otimes z_t)(\epsilon_s \otimes z_s)' \right]$$

$$= nS_n^0$$

where $S_n^0$ is estimated as

$$\hat{S}_n = \frac{1}{n} \sum_{t=1}^{n} \sum_{s=1}^{n} (q(y_t, x_t, \theta) \otimes z_t)(q(y_s, x_s, \theta) \otimes z_s)'$$

Note that $\hat{S}_n$ is a $gk \times gk$ matrix. Because $\text{Var}(\hat{S}_n)$ does not decrease with increasing $n$, you consider estimators of $S_n^0$ of the form:

$$\hat{S}_n(l(n)) = \sum_{\tau=-n+1}^{n} \hat{w}(\frac{\tau}{l(n)}) D \hat{S}_{n,\tau} D$$

$$\hat{S}_{n,\tau} = \begin{cases} \sum_{t=1+\tau}^{n} [q(y_{t+\tau}, x_{t+\tau}, \theta) \otimes z_{t+\tau}][q(y_t, x_t, \theta) \otimes z_t]' & \tau \geq 0 \\ \hat{S}_{n,-\tau} & \tau < 0 \end{cases}$$

$$\hat{w}(\frac{\tau}{l(n)}) = \begin{cases} w(\frac{\tau}{l(n)}) & l(n) > 0 \\ \delta_{\tau,0} & l(n) = 0 \end{cases}$$

where $l(n)$ is a scalar function that computes the bandwidth parameter, $w(\cdot)$ is a scalar valued kernel, and the Kronecker delta function, $\delta_{i,j}$, is 1 if $i = j$ and 0 otherwise. The diagonal matrix $D$ is used for a small sample degrees of freedom correction (Gallant 1987). The initial $\theta^#$ used for the estimation of $\hat{S}_n$ is obtained from a 2SLS estimation of the system. The degrees of freedom correction is handled by the VARDEF= option as it is for the $S$ matrix estimation.

The following kernels are supported by PROC MODEL. They are listed with their default bandwidth functions.

Bartlett: KERNEL=BART

$$w(x) = \begin{cases} 1 - |x| & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

$$l(n) = \frac{1}{2} n^{1/3}$$
Parzen: KERNEL=PARZEN

\[
w(x) = \begin{cases} 
1 - 6|x|^2 + 6|x|^3 & 0 \leq |x| \leq \frac{1}{2} \\
2(1 - |x|)^3 & \frac{1}{2} \leq |x| \leq 1 \\
0 & \text{otherwise}
\end{cases}
\]

\[
l(n) = n^{1/5}
\]

Quadratic spectral: KERNEL=QS

\[
\frac{25}{12\pi^2x^2} \left( \frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right)
\]

\[
l(n) = \frac{1}{2} n^{1/5}
\]

Figure 19.23 Kernels for Smoothing

Details of the properties of these and other kernels are given in Andrews (1991). Kernels are selected with the KERNEL= option; KERNEL=PARZEN is the default. The general form of the KERNEL= option is

\[
\text{KERNEL=} (\text{PARZEN} | \text{QS} | \text{BART, c, e})
\]
where the $e \geq 0$ and $c \geq 0$ are used to compute the bandwidth parameter as

$$l(n) = cn^e$$

The bias of the standard error estimates increases for large bandwidth parameters. A warning message is produced for bandwidth parameters greater than $n^{3/2}$. For a discussion of the computation of the optimal $l(n)$, refer to Andrews (1991).

The “Newey-West” kernel (Newey and West 1987) corresponds to the Bartlett kernel with bandwidth parameter $l(n) = L + 1$. That is, if the “lag length” for the Newey-West kernel is $L$, then the corresponding MODEL procedure syntax is `KERNEL=(bart, L+1, 0)`.

Andrews and Monahan (1992) show that using prewhitening in combination with GMM can improve confidence interval coverage and reduce over rejection of $t$ statistics at the cost of inflating the variance and MSE of the estimator. Prewhitening can be performed by using the `%AR` macros.

For the special case that the errors are not serially correlated— that is,

$$E(e_t \otimes z_t)(e_s \otimes z_s) = 0 \quad t \neq s$$

the estimate for $S^0_n$ reduces to

$$\hat{S}_n = \frac{1}{n} \sum_{t=1}^n [q(y_t, x_t, \theta) \otimes z_t][q(y_t, x_t, \theta) \otimes z_t]'$$

The option `KERNEL=(kernel,0,)` is used to select this type of estimation when using GMM.

### Covariance of GMM estimators

The covariance of GMM estimators, given a general weighting matrix $V^{-1}_G$, is

$$[(YX)'V^{-1}_G(YX)]^{-1}(YX)'V^{-1}_G\hat{V}V^{-1}_G(YX)[(YX)'V^{-1}_G(YX)]^{-1}$$

By default or when `GENGMMV` is specified, this is the covariance of GMM estimators.

If the weighting matrix is the same as $\hat{V}$, then the covariance of GMM estimators becomes

$$[(YX)'\hat{V}^{-1}(YX)]^{-1}$$

If `NOGENGMMMV` is specified, this is used as the covariance estimators.

### Testing Overidentifying Restrictions

Let $r$ be the number of unique instruments times the number of equations. The value $r$ represents the number of orthogonality conditions imposed by the GMM method. Under the assumptions of the GMM method, $r - p$ linearly independent combinations of the orthogonality should be close to zero. The GMM estimates are computed by setting these combinations to zero. When $r$ exceeds the number of parameters to be estimated, the `OBJECTIVE*N`, reported at the end of the estimation, is an asymptotically valid statistic to test the null hypothesis that the overidentifying restrictions of the model are valid. The `OBJECTIVE*N` is distributed as a chi-square with $r - p$ degrees of freedom (Hansen 1982, p. 1049). When the GMM method is selected, the value of the overidentifying restrictions test statistic, also known as Hansen’s $J$ test statistic, and its associated number of degrees of freedom are reported together with the probability under the null hypothesis.
Iterated Generalized Method of Moments (ITGMM)

Iterated generalized method of moments is similar to the iterated versions of 2SLS, SUR, and 3SLS. The variance matrix for GMM estimation is reestimated at each iteration with the parameters determined by the GMM estimation. The iteration terminates when the variance matrix for the equation errors change less than the CONVERGE= value. Iterated generalized method of moments is selected by the ITGMM option on the FIT statement. For some indication of the small sample properties of ITGMM, see Ferson and Foerster (1993).

Simulated Method of Moments (SMM)

The SMM method uses simulation techniques in model inference and estimation. It is appropriate for estimating models in which integrals appear in the objective function, and these integrals can be approximated by simulation. There might be various reasons for integrals to appear in an objective function (for example, transformation of a latent model into an observable model, missing data, random coefficients, heterogeneity, and so on).

This simulation method can be used with all the estimation methods except full information maximum likelihood (FIML) in PROC MODEL. SMM, also known as simulated generalized method of moments (SGMM), is the default estimation method because of its nice properties.

Estimation Details

A general nonlinear model can be described as

$$\epsilon_t = q(y_t, x_t, \theta)$$

where $q \in \mathbb{R}^g$ is a real vector valued function of $y_t \in \mathbb{R}^g$, $x_t \in \mathbb{R}^l$, $\theta \in \mathbb{R}^p$; $g$ is the number of equations; $l$ is the number of exogenous variables (lagged endogenous variables are considered exogenous here); $p$ is the number of parameters; and $t$ ranges from 1 to $n$. $\epsilon_t$ is an unobservable disturbance vector with the following properties:

$$E(\epsilon_t) = 0$$
$$E(\epsilon_t\epsilon_t') = \Sigma$$

In many cases, it is not possible to write $q(y_t, x_t, \theta)$ in a closed form. Instead $q$ is expressed as an integral of a function $f$; that is,

$$q(y_t, x_t, \theta) = \int f(y_t, x_t, \theta, u_t) dP(u)$$

where $f \in \mathbb{R}^g$ is a real vector valued function of $y_t \in \mathbb{R}^g$, $x_t \in \mathbb{R}^l$, $\theta \in \mathbb{R}^p$, and $u_t \in \mathbb{R}^m$, $m$ is the number of stochastic variables with a known distribution $P(u)$. Since the distribution of $u$ is completely known, it is possible to simulate artificial draws from this distribution. Using such independent draws $u_{ht}$, $h = 1, \ldots, H$, and the strong law of large numbers, $q$ can be approximated by

$$\frac{1}{H} \sum_{h=1}^{H} f(y_{ht}, x_{ht}, \theta, u_{ht}).$$
Simulated Generalized Method of Moments (SGMM)

Generalized method of moments (GMM) is widely used to obtain efficient estimates for general model systems. When the moment conditions are not readily available in closed forms but can be approximated by simulation, simulated generalized method of moments (SGMM) can be used. The SGMM estimators have the nice property of being asymptotically consistent and normally distributed even if the number of draws \( H \) is fixed (see McFadden 1989; Pakes and Pollard 1989).

Consider the nonlinear model

\[
\begin{align*}
\epsilon_t & = q(y_t, x_t, \theta) = \frac{1}{H} \sum_{h=1}^{H} f(y_t, x_t, \theta, u_{ht}) \\
Z_t & = Z(x_t)
\end{align*}
\]

where \( Z_t \in \mathbb{R}^k \) is a vector of \( k \) instruments and \( \epsilon_t \) is an unobservable disturbance vector that can be serially correlated and nonstationary. In the case of no instrumental variables, \( Z_t \) is 1. \( q(y_t, x_t, \theta) \) is the vector of moment conditions, and it is approximated by simulation.

In general, theory suggests the following orthogonality condition

\[ E(\epsilon_t \otimes Z_t) = 0 \]

which states that the expected crossproducts of the unobservable disturbances, \( \epsilon_t \), and functions of the observable variables are set to 0. The sample means of the crossproducts are

\[
\begin{align*}
m_n & = \frac{1}{n} \sum_{t=1}^{n} m(y_t, x_t, \theta) \\
m(y_t, x_t, \theta) & = q(y_t, x_t, \theta) \otimes Z_t
\end{align*}
\]

where \( m(y_t, x_t, \theta) \in \mathbb{R}^k \). The case where \( gk > p \), where \( p \) is the number of parameters, is considered here. An estimate of the true parameter vector \( \theta^0 \) is the value of \( \hat{\theta} \) that minimizes

\[ S(\theta, V) = [m_m(\theta)]^T V^{-1} [m_m(\theta)] / n \]

where

\[ V = \text{Cov} \left( m(\theta^0), m(\theta^0) \right) \]

The steps for SGMM are as follows:

1. Start with a positive definite \( \hat{V} \) matrix. This \( \hat{V} \) matrix can be estimated from a consistent estimator of \( \theta \). If \( \hat{\theta} \) is a consistent estimator, then \( u_t \) for \( t = 1, \ldots, n \) can be simulated \( H' \) number of times. A consistent estimator of \( V \) is obtained as

\[
\hat{V} = \frac{1}{n} \sum_{t=1}^{n} \left[ \frac{1}{H'} \sum_{h=1}^{H'} f(y_t, x_t, \hat{\theta}, u_{ht}) \otimes Z_t \right] \left[ \frac{1}{H'} \sum_{h=1}^{H'} f(y_t, x_t, \hat{\theta}, u_{ht}) \otimes Z_t \right]^T
\]

\( H' \) must be large so that this is an consistent estimator of \( V \).

2. Simulate \( H \) number of \( u_t \) for \( t = 1, \ldots, n \). As shown by Gourieroux and Monfort (1993), the number of simulations \( H \) does not need to be very large. For \( H = 10 \), the SGMM estimator achieves 90% of the
efficiency of the corresponding GMM estimator. Find $\hat{\theta}$ that minimizes the quadratic product of the moment conditions again with the weight matrix being $\hat{V}^{-1}$.

$$\min_{\theta} \left[ \frac{1}{n} m_n(\theta)' \hat{V}^{-1} \frac{1}{n} m_n(\theta) \right]$$

3. The covariance matrix of $\sqrt{n}\theta$ is given as (Gourieroux and Monfort 1993)

$$\Sigma_1^{-1} D \hat{V}^{-1} V(\hat{\theta}) \hat{V}^{-1} D' \Sigma_1^{-1} + \frac{1}{H} \Sigma_1^{-1} D \hat{V}^{-1} E [z \otimes \text{Var}(f|x) \otimes z] \hat{V}^{-1} D' \Sigma_1^{-1}$$

where $\Sigma_1 = DV^{-1} D$, $D$ is the matrix of partial derivatives of the residuals with respect to the parameters, $V(\hat{\theta})$ is the covariance of moments from estimated parameters $\hat{\theta}$, and $\text{Var}(f|x)$ is the covariance of moments for each observation from simulation. The first term is the variance-covariance matrix of the exact GMM estimator, and the second term accounts for the variation contributed by simulating the moments.

**Implementation in PROC MODEL**

In PROC MODEL, if the user specifies the GMM and NDRAW options in the FIT statement, PROC MODEL first fits the model by using N2SLS and computes $V$ by using the estimates from N2SLS and $H'$ simulation. If NO2SLS is specified in the FIT statement, $V$ is read from VDATA= data set. If the user does not provide a $V$ matrix, the initial starting value of $\theta$ is used as the estimator for computing the $V$ matrix in step 1. If ITGMM option is specified instead of GMM, then PROC MODEL iterates from step 1 to step 3 until the $V$ matrix converges.

The consistency of the parameter estimates is not affected by the variance correction shown in the second term in step 3. The correction on the variance of parameter estimates is not computed by default. To add the adjustment, use ADJSMMV option on the FIT statement. This correction is of the order of $\frac{1}{H}$ and is small even for moderate $H$.

The following example illustrates how to use SMM to estimate a simple regression model. Suppose the model is

$$y = a + bx + u, u \sim i i d N(0, s^2).$$

First, consider the problem in a GMM context. The first two moments of $y$ are easily derived:

$$E(y) = a + bx$$
$$E(y^2) = (a + bx)^2 + s^2$$

Rewrite the moment conditions in the form similar to the discussion above:

$$\epsilon_{1t} = y_t - (a + bx_t)$$
$$\epsilon_{2t} = y_t^2 - (a + bx_t)^2 - s^2$$

Then you can estimate this model by using GMM with following statements:

```plaintext
proc model data=a;
    parms a b s;
    instrument x;
```
Chapter 19: The MODEL Procedure

\hspace{1cm}

\texttt{eq.m1 = y-(a+b*x);} \\
\texttt{eq.m2 = y*y - (a+b*x)**2 - s*s;} \\
\texttt{bound s > 0;} \\
\texttt{fit m1 m2 / gmm;} \\
\texttt{run;}

Now suppose you do not have the closed form for the moment conditions. Instead you can simulate the moment conditions by generating \(H\) number of simulated samples based on the parameters. Then the simulated moment conditions are

\[
\begin{align*}
\epsilon_{1t} &= \frac{1}{H} \sum_{h=1}^{H} \{ y_t - (a + bx_t + su_{t,h}) \} \\
\epsilon_{2t} &= \frac{1}{H} \sum_{h=1}^{H} \{ y_t^2 - (a + bx_t + su_{t,h})^2 \}
\end{align*}
\]

This model can be estimated by using SGMM with the following statements:

\begin{verbatim}
proc model data=_tmpdata;
  parms a b s;
  instrument x;
  ysim = (a+b*x) + s * rannor( 98711 );
  eq.m1 = y-ysim;
  eq.m2 = y*y - ysim*ysim;
  bound s > 0;
  fit m1 m2 / gmm ndraw=10;
run;
\end{verbatim}

You can use the following MOMENT statement instead of specifying the two moment equations above:

\begin{verbatim}
  moment ysim=(1, 2);
\end{verbatim}

In cases where you require a large number of moment equations, using the MOMENT statement to specify them is more efficient.

Note that the NDRAW= option tells PROC MODEL that this is a simulation-based estimation. Thus, the random number function RANNOR returns random numbers in estimation process. During the simulation, 10 draws of \(m1\) and \(m2\) are generated for each observation, and the averages enter the objective functions just as the equations specified previously.

Other Estimation Methods
The simulation method can be used not only with GMM and ITGMM, but also with OLS, ITOLS, SUR, ITSUR, N2SLS, IT2SLS, N3SLS, and IT3SLS. These simulation-based methods are similar to the corresponding methods in PROC MODEL; the only difference is that the objective functions include the average of the \(H\) simulations.
Full Information Maximum Likelihood Estimation (FIML)

A different approach to the simultaneous equation bias problem is the full information maximum likelihood (FIML) estimation method (Amemiya 1977).

Compared to the instrumental variables methods (2SLS and 3SLS), the FIML method has these advantages and disadvantages:

- FIML does not require instrumental variables.
- FIML requires that the model include the full equation system, with as many equations as there are endogenous variables. With 2SLS or 3SLS, you can estimate some of the equations without specifying the complete system.
- FIML assumes that the equations errors have a multivariate normal distribution. If the errors are not normally distributed, the FIML method might produce poor results. 2SLS and 3SLS do not assume a specific distribution for the errors.
- The FIML method is computationally expensive.

The full information maximum likelihood estimators of $\theta$ and $\sigma$ are the $\hat{\theta}$ and $\hat{\sigma}$ that minimize the negative log-likelihood function:

$$l_n(\theta, \sigma) = \frac{ng}{2} \ln(2\pi) - \sum_{t=1}^{n} \ln \left( \left| \frac{\partial q(y_t, x_t, \theta)}{\partial y_t} \right| \right) + \frac{n}{2} \ln (|\Sigma(\sigma)|)$$

$$+ \frac{1}{2} \text{tr} \left( \Sigma(\sigma)^{-1} \sum_{t=1}^{n} q(y_t, x_t, \theta)q'(y_t, x_t, \theta) \right)$$

The option FIML requests full information maximum likelihood estimation. If the errors are distributed normally, FIML produces efficient estimators of the parameters. If instrumental variables are not provided, the starting values for the estimation are obtained from a SUR estimation. If instrumental variables are provided, then the starting values are obtained from a 3SLS estimation. The log-likelihood value and the $l_2$ norm of the gradient of the negative log-likelihood function are shown in the estimation summary.

**FIML Details**

To compute the minimum of $l_n(\theta, \sigma)$, this function is *concentrated* using the relation

$$\Sigma(\theta) = \frac{1}{n} \sum_{t=1}^{n} q(y_t, x_t, \theta)q'(y_t, x_t, \theta)$$

This results in the concentrated negative log-likelihood function discussed in Davidson and MacKinnon (1993):

$$l_n(\theta) = \frac{ng}{2} (1 + \ln(2\pi)) - \sum_{t=1}^{n} \ln \left| \frac{\partial q(y_t, x_t, \theta)}{\partial y_t} \right| + \frac{n}{2} \ln |\Sigma(\theta)|$$
The gradient of the negative log-likelihood function is
\[ \frac{\partial}{\partial \theta_i} l_n(\theta) = \sum_{t=1}^{n} \nabla_i(t) \]

\[ \nabla_i(t) = -\text{tr}\left( \left( \frac{\partial q(y_t, x_t, \theta)}{\partial y_t} \right)^{-1} \frac{\partial^2 q(y_t, x_t, \theta)}{\partial y_t' \partial \theta_i} \right) \]

\[ + \frac{1}{2} \text{tr}\left( \Sigma(\theta)^{-1} \frac{\partial \Sigma(\theta)}{\partial \theta_i} \right) \left[ I - \Sigma(\theta)^{-1} q(y_t, x_t, \theta) q(y_t, x_t, \theta)' \right] \]

\[ + q(y_t, x_t, \theta') \Sigma(\theta)^{-1} \frac{\partial q(y_t, x_t, \theta)}{\partial \theta_i} \]

where
\[ \frac{\partial \Sigma(\theta)}{\partial \theta_i} = 2 \sum_{t=1}^{n} q(y_t, x_t, \theta) \frac{\partial q(y_t, x_t, \theta)'}{\partial \theta_i} \]

The estimator of the variance-covariance of \( \hat{\theta} \) (COVB) for FIML can be selected with the COVBEST= option with the following arguments:

- **CROSS** selects the crossproducts estimator of the covariance matrix (Gallant 1987, p. 473):
  \[ C = \left( \frac{1}{n} \sum_{t=1}^{n} \nabla(t)\nabla'(t) \right)^{-1} \]
  where \( \nabla(t) = [\nabla_1(t), \nabla_2(t), \ldots, \nabla_p(t)]' \). This is the default.

- **GLS** selects the generalized least squares estimator of the covariance matrix. This is computed as (Dagenais 1978)
  \[ C = [\hat{Z}' (\Sigma(\theta)^{-1} \otimes I) \hat{Z}]^{-1} \]
  where \( \hat{Z} = (\hat{Z}_1, \hat{Z}_2, \ldots, \hat{Z}_p) \) is \( ng \times p \) and each \( \hat{Z}_i \) column vector is obtained from stacking the columns of
  \[ U \frac{1}{n} \sum_{t=1}^{n} \left( \frac{\partial q(y_t, x_t, \theta)}{\partial y} \right)^{-1} \frac{\partial^2 q(y_t, x_t, \theta)}{\partial y' \partial \theta_i} - Q_i \]
  \( U \) is an \( n \times g \) matrix of residuals and \( q_i \) is an \( n \times g \) matrix \( \frac{\partial Q}{\partial \theta_i} \).

- **FDA** selects the inverse of concentrated likelihood Hessian as an estimator of the covariance matrix. The Hessian is computed numerically, so for a large problem this is computationally expensive.

The HESSIAN= option controls which approximation to the Hessian is used in the minimization procedure. Alternate approximations are used to improve convergence and execution time. The choices are as follows:
CROSS  The crossproducts approximation is used.
GLS  The generalized least squares approximation is used (default).
FDA  The Hessian is computed numerically by finite differences.

HESSIAN=GLS has better convergence properties in general, but COVBEST=CROSS produces the most pessimistic standard error bounds. When the HESSIAN= option is used, the default estimator of the variance-covariance of $\hat{\theta}$ is the inverse of the Hessian selected.

**Multivariate t Distribution Estimation**

The multivariate $t$ distribution is specified by using the ERRORMODEL statement with the T option. Other method specifications (FIML and OLS, for example) are ignored when the ERRORMODEL statement is used for a distribution other than normal.

The probability density function for the multivariate $t$ distribution is

$$
P_q = \frac{\Gamma\left(\frac{df+m}{2}\right)}{(\pi * df)^{\frac{m}{2}} * \Gamma\left(\frac{df}{2}\right) \left|\Sigma(\sigma)\right|^\frac{1}{2}} \times \left(1 + \frac{q'(y_t, x_t, \theta) \Sigma(\sigma)^{-1} q(y_t, x_t, \theta)}{df}\right)^{-\frac{df+m}{2}}
$$

where $m$ is the number of equations and $df$ is the degrees of freedom.

The maximum likelihood estimators of $\theta$ and $\sigma$ are the $\hat{\theta}$ and $\hat{\sigma}$ that minimize the negative log-likelihood function:

$$
l_n(\theta, \sigma) = -\frac{1}{2} \sum_{t=1}^{n} \ln \left(\frac{\Gamma\left(\frac{df+m}{2}\right)}{(\pi * df)^{\frac{m}{2}} * \Gamma\left(\frac{df}{2}\right) \left|\Sigma(\sigma)\right|^\frac{1}{2}} \times \left(1 + \frac{q'(y_t, x_t, \theta) \Sigma(\sigma)^{-1} q(y_t, x_t, \theta)}{df}\right)^{-\frac{df+m}{2}}\right)
$$

$$
+ \frac{n}{2} \ln (|\Sigma|) - \sum_{t=1}^{n} \ln \left(\left|\frac{\partial q_t}{\partial y_t'}\right|\right)
$$

The ERRORMODEL statement is used to request the $t$ distribution maximum likelihood estimation. An OLS estimation is done to obtain initial parameter estimates and MSE.var estimates. Use NOOLS to turn off this initial estimation. If the errors are distributed normally, $t$ distribution estimation produces results similar to FIML.

The multivariate model has a single shared degrees-of-freedom parameter, which is estimated. The degrees-of-freedom parameter can also be set to a fixed value. The log-likelihood value and the $l_2$ norm of the gradient of the negative log-likelihood function are shown in the estimation summary.

**t Distribution Details**

Since a variance term is explicitly specified by using the ERRORMODEL statement, $\Sigma(\theta)$ is estimated as a correlation matrix and $q(y_t, x_t, \theta)$ is normalized by the variance. The gradient of the negative log-likelihood function with respect to the degrees of freedom is

$$
\frac{\partial l_n}{\partial df} = \frac{nm}{2df} - \frac{n}{2} \frac{\Gamma'(\frac{df+m}{2})}{\Gamma\left(\frac{df+m}{2}\right)} + \frac{n}{2} \frac{\Gamma'(\frac{df}{2})}{\Gamma\left(\frac{df}{2}\right)} + 0.5 \log\left(1 + \frac{q' \Sigma^{-1} q}{df}\right) - \frac{0.5(df+m) q' \Sigma^{-1} q}{(1 + \frac{q' \Sigma^{-1} q}{df}) df^2}
$$
The gradient of the negative log-likelihood function with respect to the parameters is

\[
\frac{\partial l}{\partial \theta_i} = \frac{0.5(df + m)}{(1 + q^{\Sigma^{-1}q/df})} \left[ \frac{(2q^{\Sigma^{-1}q}d\Sigma^{-1}q)}{df} + q^{\Sigma^{-1}q} \Sigma^{-1}q \right] - \frac{n}{2} \text{trace}(\Sigma^{-1}\frac{\partial \Sigma}{\partial \theta_i})
\]

where

\[
\frac{\partial \Sigma(\theta)}{\partial \theta_i} = \frac{2}{n} \sum_{t=1}^{n} q(y_t, x_t, \theta) \frac{\partial q(y_t, x_t, \theta)^t}{\partial \theta_i}
\]

and

\[
q(y_t, x_t, \theta) = \frac{\epsilon(\theta)}{\sqrt{h(\theta)}} \in R^{m \times n}
\]

The estimator of the variance-covariance of \( \hat{\theta} \) (COVB) for the \( t \) distribution is the inverse of the likelihood Hessian. The gradient is computed analytically, and the Hessian is computed numerically.

**Empirical Distribution Estimation and Simulation**

The following SAS statements fit a model that uses least squares as the likelihood function, but represent the distribution of the residuals with an empirical cumulative distribution function (CDF). The plot of the empirical probability distribution is shown in Figure 19.24.

```sas
data t; /* Sum of two normals */
  format date monyy.;
  do t = 0 to 9.9 by 0.1;
    date = intnx( 'month', '1jun90'd, (t*10)-1 );
    y = 0.1 * (rannor(123)-10) + .5 * (rannor(123)+10);
    output;
  end;
run;
proc model data=t time=t itprint;
  dependent y;
  parm a 5;
  y = a;
  obj = resid.y * resid.y;
  errormodel y ~ general( obj )
       cdf=(empirical=(tails=( normal percent=10)));
  fit y / outsn=s out=r;
  id date;
  solve y / data=t(where=(date='1aug98'd))
        residdata=r sdata=s
        random=200 seed=6789 out=monte;
run;
```
proc kde data=monte;
   univar y / plots=density;
run;

Figure 19.24 Empirical PDF Plot

For simulation, if the CDF for the model is not built in to the procedure, you can use the CDF=EMPIRICAL() option. This uses the sorted residual data to create an empirical CDF. For computing the inverse CDF, the program needs to know how to handle the tails. For continuous data, the tail distribution is generally poorly determined. To counter this, the PERCENT= option specifies the percentage of the observations to use in constructing each tail. The default for the PERCENT= option is 10.

A normal distribution or a t distribution is used to extrapolate the tails to infinity. The standard errors for this extrapolation are obtained from the data so that the empirical CDF is continuous.

Properties of the Estimates

All of the methods are consistent. Small sample properties might not be good for nonlinear models. The tests and standard errors reported are based on the convergence of the distribution of the estimates to a normal distribution in large samples.
These nonlinear estimation methods reduce to the corresponding linear systems regression methods if the model is linear. If this is the case, PROC MODEL produces the same estimates as PROC SYSLIN.

Except for GMM, the estimation methods assume that the equation errors for each observation are identically and independently distributed with a 0 mean vector and positive definite covariance matrix $\Sigma$ consistently estimated by $S$. For FIML, the errors need to be normally distributed. There are no other assumptions concerning the distribution of the errors for the other estimation methods.

The consistency of the parameter estimates relies on the assumption that the $S$ matrix is a consistent estimate of $\Sigma$. These standard error estimates are asymptotically valid, but for nonlinear models they might not be reliable for small samples.

The $S$ matrix used for the calculation of the covariance of the parameter estimates is the best estimate available for the estimation method selected. For $S$-iterated methods, this is the most recent estimation of $\Sigma$. For OLS and 2SLS, an estimate of the $S$ matrix is computed from OLS or 2SLS residuals and used for the calculation of the covariance matrix. For a complete list of the $S$ matrix used for the calculation of the covariance of the parameter estimates, see Table 19.2.

**Missing Values**

An observation is excluded from the estimation if any variable used for FIT tasks is missing, if the weight for the observation is not greater than 0 when weights are used, or if a DELETE statement is executed by the model program. Variables used for FIT tasks include the equation errors for each equation, the instruments, if any, and the derivatives of the equation errors with respect to the parameters estimated. Note that variables can become missing as a result of computational errors or calculations with missing values.

The number of usable observations can change when different parameter values are used; some parameter values can be invalid and cause execution errors for some observations. PROC MODEL keeps track of the number of usable and missing observations at each pass through the data, and if the number of missing observations counted during a pass exceeds the number that was obtained using the previous parameter vector, the pass is terminated and the new parameter vector is considered infeasible. PROC MODEL never takes a step that produces more missing observations than the current estimate does.

The values used to compute the Durbin-Watson, $R^2$, and other statistics of fit are from the observations used in calculating the objective function and do not include any observation for which any needed variable was missing (residuals, derivatives, and instruments).

**Details on the Covariance of Equation Errors**

There are several $S$ matrices that can be involved in the various estimation methods and in forming the estimate of the covariance of parameter estimates. These $S$ matrices are estimates of $\Sigma$, the true covariance of the equation errors. Apart from the choice of instrumental or noninstrumental methods, many of the methods provided by PROC MODEL differ in the way the various $S$ matrices are formed and used.

All of the estimation methods result in a final estimate of $\Sigma$, which is included in the output if the COVS option is specified. The final $S$ matrix of each method provides the initial $S$ matrix for any subsequent estimation.

This estimate of the covariance of equation errors is defined as

$$S = D(R'RD)$$
where $R = (r_1, \ldots, r_g)$ is composed of the equation residuals computed from the current parameter estimates in an $n \times g$ matrix and $D$ is a diagonal matrix that depends on the VARDEF= option.

For VARDEF=N, the diagonal elements of $D$ are $1/\sqrt{n}$, where $n$ is the number of nonmissing observations. For VARDEF=WGT, $n$ is replaced with the sum of the weights. For VARDEF=WDF, $n$ is replaced with the sum of the weights minus the model degrees of freedom. For the default VARDEF=DF, the $i$th diagonal element of $D$ is $1/\sqrt{n - df_i}$, where $df_i$ is the degrees of freedom (number of parameters) for the $i$th equation. Binkley and Nelson (1984) show the importance of using a degrees-of-freedom correction in estimating $\hat{\Sigma}$. Their results indicate that the DF method produces more accurate confidence intervals for N3SLS parameter estimates in the linear case than the alternative approach they tested. VARDEF=N is always used for the computation of the FIML estimates.

For the fixed $S$ methods, the OUTSUSED= option writes the $S$ matrix used in the estimation to a data set. This $S$ matrix is either the estimate of the covariance of equation errors matrix from the preceding estimation, or a prior $\Sigma$ estimate read in from a data set when the SDATA= option is specified. For the diagonal $S$ methods, all of the off-diagonal elements of the $S$ matrix are set to 0 for the estimation of the parameters and for the OUTSUSED= data set, but the output data set produced by the OUTS= option contains the off-diagonal elements. For the OLS and N2SLS methods, there is no previous estimate of the covariance of equation errors matrix, and the option OUTSUSED= saves an identity matrix unless a prior $\Sigma$ estimate is supplied by the SDATA= option. For FIML, the OUTSUSED= data set contains the $S$ matrix computed with VARDEF=N. The OUTS= data set contains the $S$ matrix computed with the selected VARDEF= option. Both versions of the $S$ matrix appear in the printed output for FIML.

If the COVS option is used, the method is not $S$-iterated, $S$ is not an identity, and the OUTSUSED= matrix is included in the printed output.

For the methods that iterate the covariance of equation errors matrix, the $S$ matrix is iteratively re-estimated from the residuals produced by the current parameter estimates. This $S$ matrix estimate iteratively replaces the previous estimate until both the parameter estimates and the estimate of the covariance of equation errors matrix converge. The final OUTS= matrix and OUTSUSED= matrix are thus identical for the $S$-iterated methods.

**Nested Iterations**

By default, for $S$-iterated methods, the $S$ matrix is held constant until the parameters converge once. Then the $S$ matrix is reestimated. One iteration of the parameter estimation algorithm is performed, and the $S$ matrix is again reestimated. This latter process is repeated until convergence of both the parameters and the $S$ matrix. Since the objective of the minimization depends on the $S$ matrix, this has the effect of chasing a moving target.

When the NESTIT option is specified, iterations are performed to convergence for the structural parameters with a fixed $S$ matrix. The $S$ matrix is then reestimated, the parameter iterations are repeated to convergence, and so on until both the parameters and the $S$ matrix converge. This has the effect of fixing the objective function for the inner parameter iterations. It is more reliable, but usually more expensive, to nest the iterations.

**R-Square Statistic**

For unrestricted linear models with an intercept successfully estimated by OLS, $R^2$ is always between 0 and 1. However, nonlinear models do not necessarily encompass the dependent mean as a special case and can
Chapter 19: The MODEL Procedure

produce negative $R^2$ statistics. Negative $R^2$ statistics can also be produced even for linear models when an estimation method other than OLS is used and no intercept term is in the model.

$R^2$ is defined for normalized equations as

$$R^2 = 1 - \frac{SSE}{SSA - \bar{y}^2 \times n}$$

where SSA is the sum of the squares of the actual $y$’s and $\bar{y}$ are the actual means. $R^2$ cannot be computed for models in general form because of the need for an actual $Y$.

Minimization Methods

PROC MODEL currently supports two methods for minimizing the objective function. These methods are described in the following sections.

GAUSS

The Gauss-Newton parameter-change vector for a system with $g$ equations, $n$ nonmissing observations, and $p$ unknown parameters is

$$\Delta = (X'X)^{-1}X'r$$

where $\Delta$ is the change vector, $X$ is the stacked $ng \times p$ Jacobian matrix of partial derivatives of the residuals with respect to the parameters, and $r$ is an $ng \times 1$ vector of the stacked residuals. The components of $X$ and $r$ are weighted by the $S^{-1}$ matrix. When instrumental methods are used, $X$ and $r$ are the projections of the Jacobian matrix and residuals vector in the instruments space and not the Jacobian and residuals themselves. In the preceding formula, $S$ and $W$ are suppressed. If instrumental variables are used, then the change vector becomes:

$$\Delta = (X'(S^{-1} \otimes W)X)^{-1}X'(S^{-1} \otimes W)r$$

This vector is computed at the end of each iteration. The objective function is then computed at the changed parameter values at the start of the next iteration. If the objective function is not improved by the change, the $\Delta$ vector is reduced by one-half and the objective function is reevaluated. The change vector will be halved up to MAXSUBITER= times until the objective function is improved. If the objective function cannot be improved after MAXSUBITER= times, the procedure switches to the MARQUARDT method described in the next section to further improve the objective function.

For FIML, the $X'X$ matrix is substituted with one of three choices for approximations to the Hessian. See the section “Full Information Maximum Likelihood Estimation (FIML)” on page 1131 in this chapter.

MARQUARDT

The Marquardt-Levenberg parameter change vector is

$$\Delta = (X'X + \lambda \text{diag}(X'X))^{-1}X'r$$
where $\Delta$ is the change vector, and $X$ and $r$ are the same as for the Gauss-Newton method, described in the preceding section. Before the iterations start, $\lambda$ is set to a small value ($1E^{-6}$). At each iteration, the objective function is evaluated at the parameters changed by $\Delta$. If the objective function is not improved, $\lambda$ is increased to $10\lambda$ and the step is tried again. $\lambda$ can be increased up to MAXSUBITER= times to a maximum of $1E15$ (whichever comes first) until the objective function is improved. For the start of the next iteration, $\lambda$ is reduced to max($\lambda/10,1E^{-10}$).

**Convergence Criteria**

There are a number of measures that could be used as convergence or stopping criteria. PROC MODEL computes five convergence measures labeled R, S, PPC, RPC, and OBJECT.

When an estimation technique that iterates estimates of $\Sigma$ is used (that is, IT3SLS), two convergence criteria are used. The termination values can be specified with the CONVERGE=(p,s) option in the FIT statement. If the second value, s, is not specified, it defaults to p. The criterion labeled S (described later in the section) controls the convergence of the $S$ matrix. When S is less than s, the $S$ matrix has converged. The criterion labeled R is compared to the $p$-value to test convergence of the parameters.

The R convergence measure cannot be computed accurately in the special case of singular residuals (when all the residuals are close to 0) or in the case of a 0 objective value. When either the trace of the $S$ matrix computed from the current residuals (trace($S$)) or the objective value is less than the value of the SINGULAR= option, convergence is assumed.

The various convergence measures are explained in the following:

**R** is the primary convergence measure for the parameters. It measures the degree to which the residuals are orthogonal to the Jacobian columns, and it approaches 0 as the gradient of the objective function becomes small. $R$ is defined as the square root of

$$ \frac{(r' (S^{-1} \otimes W) X (X' (S^{-1} \otimes W) X)^{-1} X' (S^{-1} \otimes W) r)}{r' (S^{-1} \otimes W) r} $$

where $X$ is the Jacobian matrix and $r$ is the residuals vector. $R$ is similar to the relative offset orthogonality convergence criterion proposed by Bates and Watts (1981).

In the univariate case, the $R$ measure has several equivalent interpretations:

- the cosine of the angle between the residuals vector and the column space of the Jacobian matrix. When this cosine is 0, the residuals are orthogonal to the partial derivatives of the predicted values with respect to the parameters, and the gradient of the objective function is 0.
- the square root of the $R^2$ for the current linear pseudo-model in the residuals
- a norm of the gradient of the objective function, where the normalizing matrix is proportional to the current estimate of the covariance of the parameter estimates. Thus, using $R$, convergence is judged when the gradient becomes small in this norm.
- the prospective relative change in the objective function value expected from the next GAUSS step, assuming that the current linearization of the model is a good local approximation.
In the multivariate case, $R$ is somewhat more complicated but is designed to go to 0 as the gradient of the objective becomes small and can still be given the previous interpretations for the aggregation of the equations weighted by $S^{-1}$.

**PPC** is the prospective parameter change measure. PPC measures the maximum relative change in the parameters implied by the parameter-change vector computed for the next iteration. At the $k$th iteration, PPC is the maximum over the parameters

$$\frac{|\theta_{i}^{k+1} - \theta_{i}^{k}|}{|\theta_{i}^{k}| + 10^{-6}}$$

where $\theta_{i}^{k}$ is the current value of the $i$th parameter and $\theta_{i}^{k+1}$ is the prospective value of this parameter after adding the change vector computed for the next iteration. The parameter with the maximum prospective relative change is printed with the value of PPC, unless the PPC is nearly 0.

**RPC** is the retrospective parameter change measure. RPC measures the maximum relative change in the parameters from the previous iteration. At the $k$th iteration, RPC is the maximum over $i$ of

$$\frac{|\theta_{i}^{k} - \theta_{i}^{k-1}|}{|\theta_{i}^{k-1}| + 10^{-6}}$$

where $\theta_{i}^{k}$ is the current value of the $i$th parameter and $\theta_{i}^{k-1}$ is the previous value of this parameter. The name of the parameter with the maximum retrospective relative change is printed with the value of RPC, unless the RPC is nearly 0.

**OBJECT** measures the relative change in the objective function value between iterations:

$$\frac{|O^{k} - O^{k-1}|}{|O^{k-1}| + 10^{-6}}$$

where $O^{k-1}$ is the value of the objective function ($O^{k}$) from the previous iteration.

**S** measures the relative change in the $S$ matrix. $S$ is computed as the maximum over $i, j$ of

$$\frac{|S_{ij}^{k} - S_{ij}^{k-1}|}{|S_{ij}^{k-1}| + 10^{-6}}$$

where $S_{ij}^{k-1}$ is the previous $S$ matrix. The $S$ measure is relevant only for estimation methods that iterate the $S$ matrix.

An example of the convergence criteria output is shown in Figure 19.25.

The Trace(S) is the trace (the sum of the diagonal elements) of the S matrix computed from the current residuals. This row is labeled MSE if there is only one equation.

Troubleshooting Convergence Problems

As with any nonlinear estimation routine, there is no guarantee that the estimation will be successful for a given model and data. If the equations are linear with respect to the parameters, the parameter estimates always converge in one iteration. The methods that iterate the S matrix must iterate further for the S matrix to converge. Nonlinear models might not necessarily converge.

Convergence can be expected only with fully identified parameters, adequate data, and starting values sufficiently close to solution estimates.

Convergence and the rate of convergence might depend primarily on the choice of starting values for the estimates. This does not mean that a great deal of effort should be invested in choosing starting values. First, try the default values. If the estimation fails with these starting values, examine the model and data and rerun the estimation using reasonable starting values. It is usually not necessary that the starting values be very good, just that they not be very bad; choose values that seem plausible for the model and data.

An Example of Requiring Starting Values

Suppose you want to regress a variable Y on a variable X, assuming that the variables are related by the following nonlinear equation:

\[ y = a + b x^c + \epsilon \]

In this equation, \( Y \) is linearly related to a power transformation of \( X \). The unknown parameters are \( a, b, \) and \( c \). \( \epsilon \) is an unobserved random error. The following SAS statements generate simulated data. In this simulation, \( a = 10, b = 2, \) and the use of the SQRT function corresponds to \( c = .5 \).

```
data test;
  do i = 1 to 20;
    x = 5 * ranuni(1234);
    y = 10 + 2 * sqrt(x) + .5 * rannor(1234);
    output;
  end;
run;
```
The following statements specify the model and give descriptive labels to the model parameters. Then the FIT statement attempts to estimate \(a\), \(b\), and \(c\) by using the default starting value 0.0001.

```
proc model data=test;
  y = a + b * x ** c;
  label a = "Intercept"
     b = "Coefficient of Transformed X"
     c = "Power Transformation Parameter";
  fit y;
run;
```

PROC MODEL prints model summary and estimation problem summary reports and then prints the output shown in Figure 19.26.

By using the default starting values, PROC MODEL is unable to take even the first step in iterating to the solution. The change in the parameters that the Gauss-Newton method computes is very extreme and makes the objective values worse instead of better. Even when this step is shortened by a factor of a million, the objective function is still worse, and PROC MODEL is unable to estimate the model parameters.

The problem is caused by the starting value of \(C\). Using the default starting value \(C=0.0001\), the first iteration attempts to compute better values of \(A\) and \(B\) by what is, in effect, a linear regression of \(Y\) on the 10,000th root of \(X\), which is almost the same as the constant 1. Thus the matrix that is inverted to compute the changes is nearly singular and affects the accuracy of the computed parameter changes.

This is also illustrated by the next part of the output, which displays collinearity diagnostics for the crossproducts matrix of the partial derivatives with respect to the parameters, shown in Figure 19.27.

This output shows that the matrix is singular and that the partials of A, B, and C with respect to the residual are collinear at the point (0.0001, 0.0001, 0.0001) in the parameter space. See the section “Linear Dependencies” on page 1150 for a full explanation of the collinearity diagnostics.

The MODEL procedure next prints the note shown in **Figure 19.28**, which suggests that you try different starting values.

**Figure 19.28** Estimation Failure Note

```
NOTE: The parameter estimation is abandoned. Check your model and data. If the model is correct and the input data are appropriate, try rerunning the parameter estimation using different starting values for the parameter estimates.
PROC MODEL continues as if the parameter estimates had converged.
```

PROC MODEL then produces the usual printout of results for the nonconverged parameter values. The estimation summary is shown in **Figure 19.29**. The heading includes the reminder “(Not Converged)”.

Note that the $R^2$ statistic is negative. An $R^2 < 0$ results when the residual mean squared error for the model is larger than the variance of the dependent variable. Negative $R^2$ statistics might be produced when either the parameter estimates fail to converge correctly, as in this case, or when the correctly estimated model fits the data very poorly.

Controlling Starting Values

To fit the preceding model you must specify a better starting value for C. Avoid starting values of C that are either very large or close to 0. For starting values of A and B, you can specify values, use the default, or have PROC MODEL fit starting values for them conditional on the starting value for C.

Starting values are specified with the START= option of the FIT statement or in a PARM S statement. In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARM SDATA= option. When no starting values for the parameter estimates are specified with BY group processing, the default start value 0.0001 is used for each by group. Again, when no starting values are specified, and a model with a FIT statement is stored by the OUTMODEL=outmodel-filename option in a previous step, the outmodel-filename can be invoked in a subsequent PROC MODEL step by using the MODEL=outmodel-filename option with multiple estimation methods in the second step. In such a case,
the parameter estimates from the `outmodel-filename` are used directly as starting values for OLS, and OLS results from the second step provide starting values for the subsequent estimation method such as 2SLS or SUR, provided that NOOLS is not specified.

For example, the following statements estimate the model parameters by using the starting values $A=0.0001$, $B=0.0001$, and $C=5$.

```sas
proc model data=test;
  y = a + b * x ** c;
  label a = "Intercept"
           b = "Coefficient of Transformed X"
           c = "Power Transformation Parameter";
  fit y start=(c=5);
  run;
```

Using these starting values, the estimates converge in 16 iterations. The results are shown in Figure 19.31. Note that since the START= option explicitly declares parameters, the parameter C is placed first in the table.

![Figure 19.31 Converged Results](image)

### Using the STARTITER Option

PROC MODEL can compute starting values for some parameters conditional on starting values you specify for the other parameters. You supply starting values for some parameters and specify the STARTITER option on the FIT statement.

For example, the following statements set C to 1 and compute starting values for A and B by estimating these parameters conditional on the fixed value of C. With C=1, this is equivalent to computing A and B by linear regression on X. A PARMS statement is used to declare the parameters in alphabetical order. The ITPRINT option is used to print the parameter values at each iteration.
Chapter 19: The MODEL Procedure

proc model data=test;
parms a b c;
y = a + b * x ** c;
label a = "Intercept"
    b = "Coefficient of Transformed X"
    c = "Power Transformation Parameter";
fit y start=(c=1) / startiter itprint;
run;

With better starting values, the estimates converge in only eight iterations. Counting the iteration required to compute the starting values for A and B, this is seven fewer than the 16 iterations required without the STARTITER option. The iteration history listing is shown in Figure 19.32.

NOTE: At OLS Iteration 8 CONVERGE=0.001 Criteria Met.

The results produced in this case are almost the same as the results shown in Figure 19.31, except that the PARMS statement causes the parameter estimates table to be ordered A, B, C instead of C, A, B. They are not exactly the same because the different starting values caused the iterations to converge at a slightly different place. This effect is controlled by changing the convergence criterion with the CONVERGE= option.

By default, the STARTITER option performs one iteration to find starting values for the parameters that are not given values. In this case, the model is linear in A and B, so only one iteration is needed. If A or B were nonlinear, you could specify more than one “starting values” iteration by specifying a number for the STARTITER= option.
Troubleshooting Convergence Problems

Finding Starting Values by Grid Search

PROC MODEL can try various combinations of parameter values and use the combination that produces the smallest objective function value as starting values. (For OLS the objective function is the residual mean square.) This is known as a preliminary grid search. You can combine the STARTITER option with a grid search.

For example, the following statements try five different starting values for C: 1, 0.7, 0.5, 0.3, and 0. For each value of C, values for A and B are estimated. The combination of A, B, and C values that produce the smallest residual mean square is then used to start the iterative process.

```
proc model data=test;
    parms a b c;
    y = a + b * x ** c;
    label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
    fit y start=(c=1 .7 .5 .3 0) / startiter itprint;
run;
```

The iteration history listing is shown in Figure 19.33. Using the best starting values found by the grid search, the OLS estimation only requires two iterations. However, since the grid search required nine iterations, the total iterations in this case is 11.

![Figure 19.33 ITPRINT Listing](image)

Because no initial values for A or B were provided in the PARAMETERS statement or were read in with a PARMSDATA= or ESTDATA= option, A and B were given the default value of 0.0001 for the first iteration.
At the second grid point, C=5, the values of A and B obtained from the previous iterations are used for the initial iteration. If initial values are provided for parameters, the parameters start at those initial values at each grid point.

**Guessing Starting Values from the Logic of the Model**

Example 19.1, which uses a logistic growth curve model of the U.S. population, illustrates the need for reasonable starting values. This model can be written

\[
pop = \frac{a}{1 + \exp(b - c(t - 1790))}
\]

where \(t\) is time in years. The model is estimated by using decennial census data of the U.S. population in millions. If this simple but highly nonlinear model is estimated by using the default starting values, the estimation fails to converge.

To find reasonable starting values, first consider the meaning of \(a\) and \(c\). Taking the limit as time increases, \(a\) is the limiting or maximum possible population. So, as a starting value for \(a\), several times the most recent population known can be used—for example, one billion (1000 million).

Dividing the time derivative by the function to find the growth rate and taking the limit as \(t\) moves into the past, you can determine that \(c\) is the initial growth rate. You can examine the data and compute an estimate of the growth rate for the first few decades, or you can pick a number that sounds like a plausible population growth rate figure, such as 2%.

To find a starting value for \(b\), let \(t\) equal the base year used, 1790, which causes \(c\) to drop out of the formula for that year, and then solve for the value of \(b\) that is consistent with the known population in 1790 and with the starting value of \(a\). This yields \(b = \ln(a/3.9 - 1)\) or about 5.5, where \(a\) is 1000 and 3.9 is roughly the population for 1790 given in the data. The estimates converge using these starting values.

**Convergence Problems**

When estimating nonlinear models, you might encounter some of the following convergence problems.

**Unable to Improve**

The optimization algorithm might be unable to find a step that improves the objective function. If this happens in the Gauss-Newton method, the step size is halved to find a change vector for which the objective improves. In the Marquardt method, \(\lambda\) is increased to find a change vector for which the objective improves. If, after MAXSUBITER= step-size halvings or increases in \(\lambda\), the change vector still does not produce a better objective value, the iterations are stopped and an error message is printed.

Failure of the algorithm to improve the objective value can be caused by a CONVERGE= value that is too small. Look at the convergence measures reported at the point of failure. If the estimates appear to be approximately converged, you can accept the NOT CONVERGED results reported, or you can try rerunning the FIT task with a larger CONVERGE= value.

If the procedure fails to converge because it is unable to find a change vector that improves the objective value, check your model and data to ensure that all parameters are identified and data values are reasonably scaled. Then, rerun the model with different starting values. Also, consider using the Marquardt method if the Gauss-Newton method fails; the Gauss-Newton method can get into trouble if the Jacobian matrix is nearly singular or ill-conditioned. Keep in mind that a nonlinear model may be well-identified and well-conditioned for parameter values close to the solution values but unidentified or numerically ill-conditioned for other parameter values. The choice of starting values can make a big difference.
Nonconvergence
The estimates might diverge into areas where the program overflows or the estimates might go into areas where function values are illegal or too badly scaled for accurate calculation. The estimation might also take steps that are too small or that make only marginal improvement in the objective function and thus fail to converge within the iteration limit.

When the estimates fail to converge, collinearity diagnostics for the Jacobian crossproducts matrix are printed if there are 20 or fewer parameters estimated. See the section “Linear Dependencies” on page 1150 for an explanation of these diagnostics.

Inadequate Convergence Criterion
If convergence is obtained, the resulting estimates approximate only a minimum point of the objective function. The statistical validity of the results is based on the exact minimization of the objective function, and for nonlinear models the quality of the results depends on the accuracy of the approximation of the minimum. This is controlled by the convergence criterion used.

There are many nonlinear functions for which the objective function is quite flat in a large region around the minimum point so that many quite different parameter vectors might satisfy a weak convergence criterion. By using different starting values, different convergence criteria, or different minimization methods, you can produce very different estimates for such models.

You can guard against this by running the estimation with different starting values and different convergence criteria and checking that the estimates produced are essentially the same. If they are not, use a smaller CONVERGE= value.

Local Minimum
You might have converged to a local minimum rather than a global one. This problem is difficult to detect because the procedure appears to have succeeded. You can guard against this by running the estimation with different starting values or with a different minimization technique. The START= option can be used to automatically perform a grid search to aid in the search for a global minimum.

Discontinuities
The computational methods assume that the model is a continuous and smooth function of the parameters. If this is not the case, the methods might not work.

If the model equations or their derivatives contain discontinuities, the estimation usually succeeds, provided that the final parameter estimates lie in a continuous interval and that the iterations do not produce parameter values at points of discontinuity or parameter values that try to cross asymptotes.

One common case of discontinuities causing estimation failure is that of an asymptotic discontinuity between the final estimates and the initial values. For example, consider the following model, which is basically linear but is written with one parameter in reciprocal form:

\[ y = a + b \times x_1 + \frac{x_2}{c}; \]

By placing the parameter C in the denominator, a singularity is introduced into the parameter space at C=0. This is not necessarily a problem, but if the correct estimate of C is negative while the starting value is positive (or vice versa), the asymptotic discontinuity at 0 will lie between the estimate and the starting value. This means that the iterations have to pass through the singularity to get to the correct estimates. The situation is shown in Figure 19.34.
Because of the incorrect sign of the starting value, the C estimate goes off towards positive infinity in a vain effort to get past the asymptote and onto the correct arm of the hyperbola. As the computer is required to work with ever closer approximations to infinity, the numerical calculations break down and an “objective function was not improved” convergence failure message is printed. At this point, the iterations terminate with an extremely large positive value for C. When the sign of the starting value for C is changed, the estimates converge quickly to the correct values.

**Linear Dependencies**

In some cases, the Jacobian matrix might not be of full rank; parameters might not be fully identified for the current parameter values with the current data. When linear dependencies occur among the derivatives of the model, some parameters appear with a standard error of 0 and with the word BIASED printed in place of the \( t \) statistic. When this happens, collinearity diagnostics for the Jacobian crossproducts matrix are printed if the DETAILS option is specified and there are twenty or fewer parameters estimated. Collinearity diagnostics are also printed out automatically when a minimization method fails, or when the COLLIN option is specified.

For each parameter, the proportion of the variance of the estimate accounted for by each *principal component* is printed. The principal components are constructed from the eigenvalues and eigenvectors of the correlation matrix (scaled covariance matrix). When collinearity exists, a principal component is associated with proportion of the variance of more than one parameter. The numbers reported are proportions so they remain between 0 and 1. If two or more parameters have large proportion values associated with the same principal component, then two problems can occur: the computation of the parameter estimates are slow or nonconvergent; and the parameter estimates have inflated variances (Belsley, Kuh, and Welsch 1980, pp. 105–117).
For example, the following cubic model is fit to a quadratic data set:

```plaintext
proc model data=test3;
   exogenous x1;
   parms b1 a1 c1 ;
   y1 = a1 * x1 + b1 * x1 * x1 + c1 * x1 * x1 *x1;
   fit y1 / collin;
run;
```

The collinearity diagnostics are shown in Figure 19.35.

**Figure 19.35** Collinearity Diagnostics

<table>
<thead>
<tr>
<th>Number</th>
<th>Eigenvalue</th>
<th>Condition Number</th>
<th>------Proportion of Variation-----</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>2.942920</td>

<td>81.5801</td>
<td>b1 0.9999, a1 0.9639, c1 0.9850</td>
</tr>
</tbody>
</table>

Notice that the proportions associated with the smallest eigenvalue are almost 1. For this model, removing any of the parameters decreases the variances of the remaining parameters.

In many models, the collinearity might not be clear cut. Collinearity is not necessarily something you remove. A model might need to be reformulated to remove the redundant parameterization, or the limitations on the estimability of the model can be accepted. The GINV=G4 option can be helpful to avoid problems with convergence for models containing collinearities.

Collinearity diagnostics are also useful when an estimation does not converge. The diagnostics provide insight into the numerical problems and can suggest which parameters need better starting values. These diagnostics are based on the approach of Belsley, Kuh, and Welsch (1980).

**Iteration History**

The options ITPRINT, ITDETAILS, XPX, I, and ITALL specify a detailed listing of each iteration of the minimization process.
ITPRINT Option

The ITPRINT information is selected whenever any iteration information is requested. The following information is displayed for each iteration:

- **N** is the number of usable observations.
- **Objective** is the corrected objective function value.
- **Trace(S)** is the trace of the \( S \) matrix.
- **subit** is the number of subiterations required to find a \( \lambda \) or a damping factor that reduces the objective function.
- **R** is the \( R \) convergence measure.

The estimates for the parameters at each iteration are also printed.

ITDETAILS Option

The additional values printed for the ITDETAILS option are:

- **Theta** is the angle in degrees between \( \Delta \), the parameter change vector, and the negative gradient of the objective function.
- **Phi** is the directional derivative of the objective function in the \( \Delta \) direction scaled by the objective function.
- **Stepsize** is the value of the damping factor used to reduce \( \Delta \) if the Gauss-Newton method is used.
- **Lambda** is the value of \( \lambda \) if the Marquardt method is used.
- **Rank(XPX)** is the rank of the \( X'X \) matrix (output if the projected Jacobian crossproducts matrix is singular).

The definitions of PPC and \( R \) are explained in the section “Convergence Criteria” on page 1139. When the values of PPC are large, the parameter associated with the criteria is displayed in parentheses after the value.

XPX and I Options

The XPX and the I options select the printing of the augmented \( X'X \) matrix and the augmented \( X'X \) matrix after a sweep operation (Goodnight 1979) has been performed on it. An example of the output from the following statements is shown in Figure 19.36.

```plaintext
proc model data=test2;
   y1 = a1 * x2 * x2 - exp( d1*x1);
   y2 = a2 * x1 * x1 + b2 * exp( d2*x2);
   fit y1 y2 / itall XPX I ;
run;
```
The first matrix, labeled “Cross Products,” for OLS estimation is

\[
\begin{bmatrix}
X'X & X'r \\
r'X & r'r
\end{bmatrix}
\]

The column labeled Residual in the output is the vector \(X'r\), which is the gradient of the objective function. The diagonal scalar value \(r'r\) is the objective function uncorrected for degrees of freedom. The second matrix, labeled “XPX Inverse,” is created through a sweep operation on the augmented \(X'X\) matrix to get:

\[
\begin{bmatrix}
(X'X)^{-1} & (X'X)^{-1}X'r \\
(X'r)'/(X'X)^{-1} & r'r - (X'r)'/(X'X)^{-1}X'r
\end{bmatrix}
\]

Note that the residual column is the change vector used to update the parameter estimates at each iteration. The corner scalar element is used to compute the R convergence criteria.

**ITALL Option**

The ITALL option, in addition to causing the output of all of the preceding options, outputs the \(S\) matrix, the inverse of the \(S\) matrix, the CROSS matrix, and the swept CROSS matrix. An example of a portion of the CROSS matrix for the preceding example is shown in Figure 19.37.
### Computer Resource Requirements

If you are estimating large systems, you need to be aware of how PROC MODEL uses computer resources (such as memory and the CPU) so they can be used most efficiently.

### Saving Time with Large Data Sets

If your input data set has many observations, the FIT statement performs a large number of model program executions. A pass through the data is made at least once for each iteration and the model program is executed once for each observation in each pass. If you refine the starting estimates by using a smaller data set, the final estimation with the full data set might require fewer iterations.

For example, you could use

```plaintext
proc model;
  /* Model goes here */
  fit / data=a(obs=25);
  fit / data=a;
```
where OBS=25 selects the first 25 observations in A. The second FIT statement produces the final estimates using the full data set and starting values from the first run.

**Fitting the Model in Sections to Save Space and Time**

If you have a very large model (with several hundred parameters, for example), the procedure uses considerable space and time. You might be able to save resources by breaking the estimation process into several steps and estimating the parameters in subsets.

You can use the FIT statement to select for estimation only the parameters for selected equations. Do not break the estimation into too many small steps; the total computer time required is minimized by compromising between the number of FIT statements that are executed and the size of the crossproducts matrices that must be processed.

When the parameters are estimated for selected equations, the entire model program must be executed even though only a part of the model program might be needed to compute the residuals for the equations selected for estimation. If the model itself can be broken into sections for estimation (and later combined for simulation and forecasting), then more resources can be saved.

For example, to estimate the following four equation model in two steps, you could use

```plaintext
proc model data=a outmodel=part1;
  parms a0-a2 b0-b2 c0-c3 d0-d3;
  y1 = a0 + a1*y2 + a2*x1;
  y2 = b0 + b1*y1 + b2*x2;
  y3 = c0 + c1*y1 + c2*y4 + c3*x3;
  y4 = d0 + d1*y1 + d2*y3 + d3*x4;
  fit y1 y2;
  fit y3 y4;
  fit y1 y2 y3 y4;
run;
```

You should try estimating the model in pieces to save time only if there are more than 14 parameters; the preceding example takes more time, not less, and the difference in memory required is trivial.

**Memory Requirements for Parameter Estimation**

PROC MODEL is a large program, and it requires much memory. Memory is also required for the SAS System, various data areas, the model program and associated tables and data vectors, and a few crossproducts matrices. For most models, the memory required for PROC MODEL itself is much larger than that required for the model program, and the memory required for the model program is larger than that required for the crossproducts matrices.

The number of bytes needed for two crossproducts matrices, four \( S \) matrices, and three parameter covariance matrices is

\[
8 \times (2 + k + m + g)^2 + 16 \times g^2 + 12 \times (p + 1)^2
\]

plus lower-order terms, where \( m \) is the number of unique nonzero derivatives of each residual with respect to each parameter, \( g \) is the number of equations, \( k \) is the number of instruments, and \( p \) is the number of parameters. This formula is for the memory required for 3SLS. If you are using OLS, a reasonable estimate of the memory required for large problems (greater than 100 parameters) is to divide the value obtained from the formula in half.
Consider the following model program.

```
proc model data=test2 details;
  exogenous x1 x2;
 parms b1 100 a1 a2 b2 2.5 c2 55;
  y1 = a1 * y2 + b1 * x1 * x1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2;
  fit y1 y2 / n3sls memoryuse;
  inst b1 b2 c2 x1 ;
run;
```

The DETAILS option prints the storage requirements information shown in Figure 19.38.

**Figure 19.38  Storage Requirements Information**

</tbody>
</table>

The matrix \(X'X\) augmented by the residual vector is called the XPX matrix in the output, and it has the size \(m + 1\). The order of the S matrix, 2 for this example, is the value of \(g\). The CROSS matrix is made up of the \(k\) unique instruments, a constant column that represents the intercept terms, followed by the \(m\) unique Jacobian variables plus a constant column that represents the parameters with constant derivatives, followed by the \(g\) residuals.

The size of two CROSS matrices in bytes is

\[
8 \times (2 + k + m + g)^2 + 2 + k + m + g
\]

Note that the CROSS matrix is symmetric, so only the diagonal and the upper triangular part of the matrix is stored. For examples of the CROSS and XPX matrices see the section “Iteration History” on page 1151.

**The MEMORYUSE Option**

The MEMORYUSE option in the FIT, SOLVE, MODEL, or RESET statement can be used to request a comprehensive memory usage summary.

**Figure 19.39** shows an example of the output produced by the MEMORYUSE option.

Definitions of the memory components follow:

- **symbols**: memory used to store information about variables in the model
- **strings**: memory used to store the variable names and labels
- **lists**: space used to hold lists of variables
- **arrays**: memory used by ARRAY statements
- **statements**: memory used for the list of programming statements in the model
- **opcodes**: memory used to store the code compiled to evaluate the expression in the model program
- **parsing**: memory used in parsing the SAS statements
- **executable**: the compiled model program size
- **block option**: memory used by the BLOCK option
- **cross ref.**: memory used by the XREF option
- **flow analysis**: memory used to compute the interdependencies of the variables
- **derivatives**: memory used to compute and store the analytical derivatives
- **data vector**: memory used for the program data vector
- **cross matrix**: memory used for one or more copies of the CROSS matrix
- **X'X matrix**: memory used for one or more copies of the X'X matrix
- **S matrix**: memory used for the covariance matrix
- **GMM memory**: additional memory used for the GMM and ITGMM methods
- **Jacobian**: memory used for the Jacobian matrix for SOLVE and FIML
- **work vectors**: memory used for miscellaneous work vectors
- **overhead**: other miscellaneous memory
Testing for Normality

The NORMAL option in the FIT statement performs multivariate and univariate tests of normality.

The three multivariate tests provided are Mardia’s skewness test and kurtosis test (Mardia 1970) and the Henze-Zirkler $T_{n,\delta}$ test (Henze and Zirkler 1990). The two univariate tests provided are the Shapiro-Wilk $W$ test and the Kolmogorov-Smirnov test. (For details on the univariate tests, refer to “Goodness-of-Fit Tests” section in “The UNIVARIATE Procedure” chapter in the Base SAS Procedures Guide.) The null hypothesis for all these tests is that the residuals are normally distributed.

For a random sample $X_1, \ldots, X_n \in \mathbb{R}^d$, where $d$ is the dimension of $X_i$ and $n$ is the number of observations, a measure of multivariate skewness is

$$b_{1,d} = \frac{1}{n^2} \sum_{i=1}^{n} \sum_{j=1}^{n} [(X_i - \mu)' S^{-1} (X_j - \mu)]^3$$

where $S$ is the sample covariance matrix of $X$. For weighted regression, both $S$ and $(X_i - \mu)$ are computed by using the weights supplied by the WEIGHT statement or the _WEIGHT_ variable.

Mardia showed that under the null hypothesis $\frac{n}{6} b_{1,d}$ is asymptotically distributed as $\chi^2(d(d + 1)(d + 2)/6)$. For small samples, Mardia’s skewness test statistic is calculated with a small sample correction formula, given by $\frac{n^k}{6} b_{1,d}$ where the correction factor $k$ is given by $k = (d + 1)(n + 1)(n + 3)/n(((n + 1)(d + 1)) - 6)$. Mardia’s skewness test statistic in PROC MODEL uses this small sample corrected formula.

A measure of multivariate kurtosis is given by

$$b_{2,d} = \frac{1}{n} \sum_{i=1}^{n} [(X_i - \mu)' S^{-1} (X_i - \mu)]^2$$

Mardia showed that under the null hypothesis, $b_{2,d}$ is asymptotically normally distributed with mean $d(d + 2)$ and variance $8d(d + 2)/n$.

The Henze-Zirkler test is based on a nonnegative functional $D(\ldots)$ that measures the distance between two distribution functions and has the property that

$$D(N_d(0, I_d), Q) = 0$$

if and only if

$$Q = N_d(0, I_d)$$

where $N_d(\mu, \Sigma_d)$ is a $d$-dimensional normal distribution.

The distance measure $D(\ldots)$ can be written as

$$D_\beta(P, Q) = \int_{\mathbb{R}^d} |\hat{P}(t) - \hat{Q}(t)|^2 \varphi_\beta(t) dt$$

where $\hat{P}(t)$ and $\hat{Q}(t)$ are the Fourier transforms of $P$ and $Q$, and $\varphi_\beta(t)$ is a weight or a kernel function. The density of the normal distribution $N_d(0, \beta^2 I_d)$ is used as $\varphi_\beta(t)$

$$\varphi_\beta(t) = (2\pi \beta^2)^{-\frac{d}{2}} \exp\left(-\frac{|t|^2}{2\beta^2}\right), t \in \mathbb{R}^d$$
where $|r| = (r^t r)^{0.5}$.

The parameter $\beta$ depends on $n$ as

$$\beta_d(n) = \frac{1}{\sqrt{2}} \left( \frac{2d + 1}{4} \right)^{1/(d+4)} n^{1/(d+4)}$$

The test statistic computed is called $T_\beta(d)$ and is approximately distributed as a lognormal. The lognormal distribution is used to compute the null hypothesis probability.

$$T_\beta(d) = \frac{1}{n} \sum_{j=1}^{n} \sum_{k=1}^{n} \exp\left(-\frac{\beta^2}{2} |Y_j - Y_k|^2\right)$$

$$- 2(1 + \beta^2)^{-d/2} \sum_{j=1}^{n} \exp\left(-\frac{\beta^2}{2(1 + \beta^2)} |Y_j|^2\right) + n(1 + 2\beta^2)^{-d/2}$$

where

$$|Y_j - Y_k|^2 = (X_j - X_k)' S^{-1} (X_j - X_k)$$

$$|Y_j|^2 = (X_j - \bar{X})' S^{-1} (X_j - \bar{X})$$

Monte Carlo simulations suggest that $T_\beta(d)$ has good power against distributions with heavy tails.

The Shapiro-Wilk $W$ test is computed only when the number of observations ($n$) is less than 2000 while computation of the Kolmogorov-Smirnov test statistic requires at least 2000 observations.

The following is an example of the output produced by the NORMAL option.

```
proc model data=test2;
  y1 = a1 * x2 * x2 - exp( d1*x1);
  y2 = a2 * x1 * x1 + b2 * exp( d2*x2);
  fit y1 y2 / normal ;
run;
```

Heteroscedasticity

One of the key assumptions of regression is that the variance of the errors is constant across observations. If the errors have constant variance, the errors are called homoscedastic. Typically, residuals are plotted to assess this assumption. Standard estimation methods are inefficient when the errors are heteroscedastic or have nonconstant variance.

Heteroscedasticity Tests

The MODEL procedure provides two tests for heteroscedasticity of the errors: White’s test and the modified Breusch-Pagan test.

Both White’s test and the Breusch-Pagan are based on the residuals of the fitted model. For systems of equations, these tests are computed separately for the residuals of each equation.

The residuals of an estimation are used to investigate the heteroscedasticity of the true disturbances.

The WHITE option tests the null hypothesis

\[ H_0 : \sigma_i^2 = \sigma^2 \text{ for all } i \]

White’s test is general because it makes no assumptions about the form of the heteroscedasticity (White 1980). Because of its generality, White’s test might identify specification errors other than heteroscedasticity (Thursby 1982). Thus, White’s test might be significant when the errors are homoscedastic but the model is misspecified in other ways.

White’s test is equivalent to obtaining the error sum of squares for the regression of squared residuals on a constant and all the unique variables in \( J \mathcal{J} \), where the matrix \( J \mathcal{J} \) is composed of the partial derivatives of the equation residual with respect to the estimated parameters. White’s test statistic \( W \) is computed as follows:

\[ W = nR^2 \]

where \( R^2 \) is the correlation coefficient obtained from the above regression. The statistic is asymptotically distributed as chi-squared with \( P-1 \) degrees of freedom, where \( P \) is the number of regressors in the regression, including the constant and \( n \) is the total number of observations. In the example given below, the regressors are constant, income, income*income, income*income*income, and income*income*income*income. income*income occurs twice and one is dropped. Hence, \( P=5 \) with degrees of freedom, \( P-1=4 \).

Note that White’s test in the MODEL procedure is different than White’s test in the REG procedure requested by the SPEC option. The SPEC option produces the test from Theorem 2 on page 823 of White (1980). The WHITE option, on the other hand, produces the statistic discussed in Greene (1993).

The null hypothesis for the modified Breusch-Pagan test is homoscedasticity. The alternate hypothesis is that the error variance varies with a set of regressors, which are listed in the BREUSCH= option.

Define the matrix \( Z \) to be composed of the values of the variables listed in the BREUSCH= option, such that \( z_{i,j} \) is the value of the \( j \)th variable in the BREUSCH= option for the \( i \)th observation. The null hypothesis of the Breusch-Pagan test is

\[ \sigma_i^2 = \sigma^2 (\alpha_0 + \alpha' z_i) \]

\[ H_0 : \alpha = 0 \]

where \( \sigma_i^2 \) is the error variance for the \( i \)th observation and \( \alpha_0 \) and \( \alpha \) are regression coefficients.
The test statistic for the Breusch-Pagan test is

\[ bp = \frac{1}{v} (u - \tilde{u}i)' Z(Z'Z)^{-1} Z' (u - \tilde{u}i) \]

where \( u = (e_1^2, e_2^2, \ldots, e_n^2) \), \( i \) is a \( n \times 1 \) vector of ones, and

\[ v = \frac{1}{n} \sum_{i=1}^{n} (e_i^2 - \frac{1}{n} E^2)^2 \]

This is a modified version of the Breusch-Pagan test, which is less sensitive to the assumption of normality than the original test (Greene 1993, p. 395).

The statements in the following example produce the output in Figure 19.41:

```sas
proc model data=schools;
   parms const inc inc2;
   exp = const + inc * income + inc2 * income * income;
   incsq = income * income;
   fit exp / white breusch=(1 income incsq);
run;
```

**Correcting for Heteroscedasticity**

There are two methods for improving the efficiency of the parameter estimation in the presence of heteroscedastic errors. If the error variance relationships are known, weighted regression can be used or an error model can be estimated. For details about error model estimation, see the section “Error Covariance Structure Specification” on page 1170. If the error variance relationship is unknown, GMM estimation can be used.

**Weighted Regression**

The WEIGHT statement can be used to correct for the heteroscedasticity. Consider the following model, which has a heteroscedastic error term:

\[ y_t = 250(e^{-0.2t} - e^{-0.8t}) + \sqrt{(9/t)}\epsilon_t \]

The data for this model is generated with the following SAS statements.
data test;
    do t=1 to 25;
        y = 250 * (exp( -0.2 * t ) - exp( -0.8 * t )) +
           sqrt( 9 / t ) * rannor(1);
        output;
    end;
run;

If this model is estimated with OLS, as shown in the following statements, the estimates shown in Figure 19.42 are obtained for the parameters.

proc model data=test;
    parms b1 0.1 b2 0.9;
    y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
    fit y;
run;

Figure 19.42  Unweighted OLS Estimates

| Parameter | Estimate | Std Err | t Value | Pr > |t| |
|-----------|----------|---------|---------|------|---|
| b1        | 0.200977 | 0.00101 | 198.60  | <.0001 |
| b2        | 0.826236 | 0.00853 | 96.82   | <.0001 |

If both sides of the model equation are multiplied by $\sqrt{t}$, the model has a homoscedastic error term. This multiplication or weighting is done through the WEIGHT statement. The WEIGHT statement variable operates on the squared residuals as

$$
\epsilon_t'\epsilon_t = \text{weight} \times q_t'q_t
$$

so that the WEIGHT statement variable represents the square of the model multiplier. The following PROC MODEL statements corrects the heteroscedasticity with a WEIGHT statement:

proc model data=test;
    parms b1 0.1 b2 0.9;
    y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
    fit y;
    weight t;
run;

Note that the WEIGHT statement follows the FIT statement. The weighted estimates are shown in Figure 19.43.
Heteroscedasticity

Figure 19.43 Weighted OLS Estimates

The MODEL Procedure
Nonlinear OLS Parameter Estimates

| Parameter | Estimate | Std Err | t Value | Pr > |t| |
|-----------|----------|---------|---------|------|---|
| b1        | 0.200503 | 0.000844| 237.53  | <.0001|
| b2        | 0.816701 | 0.0139  | 58.71   | <.0001|

The weighted OLS estimates are identical to the output produced by the following PROC MODEL example:

```plaintext
proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  _weight_ = t;
  fit y;
run;
```

If the WEIGHT statement is used in conjunction with the _WEIGHT_ variable, the two values are multiplied together to obtain the weight used.

The WEIGHT statement and the _WEIGHT_ variable operate on all the residuals in a system of equations. If a subset of the equations needs to be weighted, the residuals for each equation can be modified through the RESID. variable for each equation. The following example demonstrates the use of the RESID. variable to make a homoscedastic error term:

```plaintext
proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  resid.y = resid.y * sqrt(t);
  fit y;
run;
```

These statements produce estimates of the parameters and standard errors that are identical to the weighted OLS estimates. The reassignment of the RESID.Y variable must be done after Y is assigned; otherwise it would have no effect. Also, note that the residual (RESID.Y) is multiplied by \( \sqrt{t} \). Here the multiplier is acting on the residual before it is squared.

GMM Estimation

If the form of the heteroscedasticity is unknown, generalized method of moments estimation (GMM) can be used. The following PROC MODEL statements use GMM to estimate the example model used in the preceding section:

```plaintext
proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  resid.y = resid.y * sqrt(t);
  fit y;
run;
```
proc model data=test;
parms b1 0.1 b2 0.9;
y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
fit y / gmm;
instruments b1 b2;
run;

GMM is an instrumental method, so instrument variables must be provided.
GMM estimation generates estimates for the parameters shown in Figure 19.44.

Heteroscedasticity-Consistent Covariance Matrix Estimation

Homoscedasticity is required for ordinary least squares regression estimates to be efficient. A nonconstant error variance, heteroscedasticity, causes the OLS estimates to be inefficient, and the usual OLS covariance matrix, $\Sigma$, is generally invalid:

$$\Sigma = \sigma^2 (X'X)^{-1}$$

When the variance of the errors of a classical linear model

$$Y = X\beta + \epsilon$$

is not constant across observations (heteroscedastic), so that $\sigma_i^2 \neq \sigma_j^2$ for some $j > 1$, the OLS estimator

$$\hat{\beta}_{OLS} = (X'X)^{-1}X'Y$$

is unbiased but it is inefficient. Models that take into account the changing variance can make more efficient use of the data. When the variances, $\sigma_i^2$, are known, generalized least squares (GLS) can be used and the estimator

$$\hat{\beta}_{GLS} = (X'\Omega X)^{-1}X'\Omega^{-1}Y$$

where

$$\Omega = \begin{bmatrix} \sigma_1^2 & 0 & 0 & 0 \\ 0 & \sigma_2^2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \sigma_T^2 \end{bmatrix}$$
Heteroscedasticity

is unbiased and efficient. However, GLS is unavailable when the variances, $\sigma_t^2$, are unknown.

To solve this problem White (1980) proposed a heteroscedastic consistent-covariance matrix estimator (HCCME)

$$\hat{\Sigma} = (X'X)^{-1}X'\hat{\Omega}X(X'X)^{-1}$$

that is consistent as well as unbiased, where

$$\hat{\Omega}_0 = \begin{bmatrix}
\epsilon_1^2 & 0 & 0 & 0 \\
0 & \epsilon_2^2 & 0 & 0 \\
0 & 0 & \ddots & 0 \\
0 & 0 & 0 & \epsilon_T^2
\end{bmatrix}$$

and $\epsilon_t = Y_t - X_t\hat{\beta}_{OLS}$.

This estimator is considered somewhat unreliable in finite samples. Therefore, Davidson and MacKinnon (1993) propose three different modifications to estimating $\hat{\Omega}$. The first solution is to simply multiply $\epsilon_t^2$ by $\frac{n}{n-df}$, where $n$ is the number of observations and $df$ is the number of explanatory variables, so that

$$\hat{\Omega}_1 = \begin{bmatrix}
\frac{n}{n-df} \epsilon_1^2 & 0 & 0 & 0 \\
0 & \frac{n}{n-df} \epsilon_2^2 & 0 & 0 \\
0 & 0 & \ddots & 0 \\
0 & 0 & 0 & \frac{n}{n-df} \epsilon_T^2
\end{bmatrix}$$

The second solution is to define

$$\hat{\Omega}_2 = \begin{bmatrix}
\frac{\epsilon_1^2}{1-h_1} & 0 & 0 & 0 \\
0 & \frac{\epsilon_2^2}{1-h_2} & 0 & 0 \\
0 & 0 & \ddots & 0 \\
0 & 0 & 0 & \frac{\epsilon_T^2}{1-h_T}
\end{bmatrix}$$

where $\hat{h}_t = X_t'(X'X)^{-1}X_t'$.

The third solution, called the “jackknife,” is to define

$$\hat{\Omega}_3 = \begin{bmatrix}
\frac{\epsilon_1^2}{(1-h_1)^2} & 0 & 0 & 0 \\
0 & \frac{\epsilon_2^2}{(1-h_2)^2} & 0 & 0 \\
0 & 0 & \ddots & 0 \\
0 & 0 & 0 & \frac{\epsilon_T^2}{(1-h_T)^2}
\end{bmatrix}$$

MacKinnon and White (1985) investigated these three modified HCCMEs, including the original HCCME, based on finite-sample performance of pseudo-$t$ statistics. The original HCCME performed the worst. The first modification performed better. The second modification performed even better than the first, and the third modification performed the best. They concluded that the original HCCME should never be used in finite sample estimation, and that the second and third modifications should be used over the first modification if the diagonals of $\hat{\Omega}$ are available.
Seemingly Unrelated Regression HCCME

Extending the discussion to systems of $g$ equations, the HCCME for SUR estimation is

$$(\tilde{X}'\tilde{X})^{-1}\tilde{X}'\hat{\Omega}\tilde{X}(\tilde{X}'\tilde{X})^{-1}$$

where $\tilde{X}$ is a $n \times g \times k$ matrix with the first $g$ rows representing the first observation, the next $g$ rows representing the second observation, and so on. $\hat{\Omega}$ is now a $n \times g \times g$ block diagonal matrix with typical block $g \times g$

$$\hat{\Omega}_{ij} = \begin{bmatrix} \psi_{1,i} & \psi_{1,i} & \psi_{1,i} & \ldots & \psi_{1,i} & \psi_{g,i} \\ \psi_{2,i} & \psi_{2,i} & \psi_{2,i} & \ldots & \psi_{2,i} & \psi_{g,i} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ \psi_{g,i} & \psi_{g,i} & \psi_{g,i} & \ldots & \psi_{g,i} & \psi_{g,i} \end{bmatrix}$$

where

$$\psi_{j,i} = \epsilon_{j,i} \quad HC_0$$

or

$$\psi_{j,i} = \sqrt{\frac{n}{n - df}} \epsilon_{j,i} \quad HC_1$$

or

$$\psi_{j,i} = \epsilon_{j,i} / \sqrt{1 - \hat{h}_{i}} \quad HC_2$$

or

$$\psi_{j,i} = \epsilon_{j,i} / (1 - \hat{h}_{i}) \quad HC_3$$

Two- and Three-Stage Least Squares HCCME

For two- and three-stage least squares, the HCCME for a $g$ equation system is

$$\text{Cov} F(\hat{\Omega})\text{Cov}$$

where

$$\text{Cov} = \left(\frac{1}{n}X'(I \otimes Z(Z'Z)^{-1}Z')X\right)^{-1}$$

is the normal covariance matrix without the $S$ matrix and

$$F(\hat{\Omega}) = \frac{1}{n} \sum_{i}^{g} \sum_{j}^{g} X'_i Z(Z'Z)^{-1}Z'\hat{\Omega}_{ij}Z(Z'Z)^{-1}Z'X_j$$

where $X_j$ is a $n \times p$ matrix with the $j$th equations regressors in the appropriate columns and zeros everywhere else.

$$\hat{\Omega}_{ij} = \begin{bmatrix} \psi_{i,1} & \psi_{j,1} & 0 & 0 & 0 \\ 0 & \psi_{i,2} & \psi_{j,2} & 0 & 0 \\ 0 & 0 & \ddots & \vdots & 0 \\ 0 & 0 & 0 & \psi_{i,n} & \psi_{j,n} \end{bmatrix}$$
For 2SLS $\hat{\Omega}_{ij} = 0$ when $i \neq j$. The $\epsilon_t$ used in $\hat{\Omega}$ is computed by using the parameter estimates obtained from the instrumental variables estimation.

The leverage value for the $i$th equation used in the HCCME=2 and HCCME=3 methods is computed as conditional on the first stage as

$$h_{ti} = Z_t^t(Z'Z)^{-1}X_i(X' (I \otimes Z(Z' * Z)^{-1}Z')X)^{-1}X_i'Z(Z'Z)^{-1}Z'_t$$

for 2SLS and

$$h_{ti} = Z_t^t(Z'Z)^{-1}X_i(X'(S^{-1} \otimes Z(Z' * Z)^{-1}Z')X)^{-1}X_i'Z(Z'Z)^{-1}Z'_t / S_{ii}$$

for 3SLS.

---

**Testing for Autocorrelation**

The GODFREY= option in the FIT statement produces the Godfrey Lagrange multiplier test for serially correlated residuals for each equation (Godfrey 1978a, b). $n$ is the maximum autoregressive order, and specifies that Godfrey’s tests be computed for lags 1 through $n$. The default number of lags is four.

The tests are performed separately for each equation estimated by the FIT statement. When a nonlinear model is estimated, the test is computed by using a linearized model.

The following is an example of the output produced by the GODFREY=3 option:

**Figure 19.45** Autocorrelation Test Output

<table>
<thead>
<tr>
<th>Equation</th>
<th>Alternative</th>
<th>LM</th>
<th>Pr &gt; LM</th>

<tr>
<td></td>
<td>3</td>
<td>6.96</td>
<td>0.0732</td>
</tr>
</tbody>
</table>

The three variations of the test reported by the GODFREY=3 option are designed to have power against different alternative hypotheses. Thus, if the residuals in fact have only first-order autocorrelation, the lag 1 test has the most power for rejecting the null hypothesis of uncorrelated residuals. If the residuals have second- but not higher-order autocorrelation, the lag 2 test might be more likely to reject; the same is true for third-order autocorrelation and the lag 3 test.

The null hypothesis of Godfrey’s tests is that the equation residuals are white noise. However, if the equation includes autoregressive error model of order $p$ (AR($p$)), then the lag $i$ test, when considered in terms of the structural error, is for the null hypothesis that the structural errors are from an AR($p$) process versus the alternative hypothesis that the errors are from an AR($p + i$) process.
The alternative ARMA($p, i$) process is locally equivalent to the alternative AR($p + i$) process with respect to the null model AR($p$). Thus, the GODFREY= option results are also a test of AR($p$) errors against the alternative hypothesis of ARMA($p, i$) errors. See Godfrey (1978a, b) for more detailed information.

---

### Transformation of Error Terms

In PROC MODEL you can control the form of the error term. By default, the error term is assumed to be additive. This section demonstrates how to specify nonadditive error terms and discusses the effects of these transformations.

#### Models with Nonadditive Errors

The estimation methods used by PROC MODEL assume that the error terms of the equations are independently and identically distributed with zero means and finite variances. Furthermore, the methods assume that the RESID.name equation variable for normalized form equations or the EQ.name equation variable for general form equations contains an estimate of the error term of the true stochastic model whose parameters are being estimated. Details on RESID.name and EQ.name equation variables are in the section “Equation Translations” on page 1264.

To illustrate these points, consider the common loglinear model

\[
y = \alpha x^b \\
\ln y = a + b \ln(x)
\]

Equation (2) is called the log form of the equation in contrast to equation (1), which is called the level form of the equation. Using the SYSLIN procedure, you can estimate equation (2) by specifying

```plaintext
proc syslin data=in;
   model logy=logx;
run;
```

where LOGY and LOGX are the logs of Y and X computed in a preceding DATA step. The resulting values for INTERCEPT and LOGX correspond to $a$ and $b$ in equation (2).

Using the MODEL procedure, you can try to estimate the parameters in the level form (and avoid the DATA step) by specifying

```plaintext
proc model data=in;
   parms alpha beta;
   y = alpha * x ** beta;
   fit y;
run;
```

where ALPHA and BETA are the parameters in equation (1).

Unfortunately, at least one of the preceding is wrong; an ambiguity results because equations (1) and (2) contain no explicit error term. The SYSLIN and MODEL procedures both deal with additive errors; the residual used (the estimate of the error term in the equation) is the difference between the predicted and actual values (of LOGY for PROC SYSLIN and of Y for PROC MODEL in this example). If you perform the regressions discussed previously, PROC SYSLIN estimates equation (3) while PROC MODEL estimates equation (4).
\[ \ln y = a + b \ln(x) + \epsilon \quad (3) \]
\[ y = \alpha x^\beta + \xi \quad (4) \]

These are different statistical models. Equation (3) is the log form of equation (5)
\[ y = \alpha x^\beta \mu \quad (5) \] where \( \mu = e^\epsilon \). Equation (4), on the other hand, cannot be linearized because the error term \( \xi \) (different from \( \mu \)) is additive in the level form.

You must decide whether your model is equation (4) or (5). If the model is equation (4), you should use PROC MODEL. If you linearize equation (1) without considering the error term and apply SYSLIN to MODEL LOGY=LOGX, the results will be wrong. On the other hand, if your model is equation (5) (in practice it usually is), and you want to use PROC MODEL to estimate the parameters in the level form, you must do something to account for the multiplicative error.

PROC MODEL estimates parameters by minimizing an objective function. The objective function is computed using either the RESID.-prefixed equation variable or the EQ.-prefixed equation variable. You must make sure that these prefixed equation variables are assigned an appropriate error term. If the model has additive errors that satisfy the assumptions, nothing needs to be done. In the case of equation (5), the error is nonadditive and the equation is in normalized form, so you must alter the value of RESID.Y.

The following assigns a valid estimate of \( \mu \) to RESID.Y:

\begin{verbatim}
   proc model data=in;
      parms alpha beta;
      y = alpha * x ** beta;
      resid.y = log( actual.y / pred.y );
      fit y;
      run;
\end{verbatim}

However, \( \mu = e^\epsilon \), and therefore \( \mu \), cannot have a mean of zero, and you cannot consistently estimate \( \alpha \) and \( \beta \) by minimizing the sum of squares of an estimate of \( \mu \). Instead, you use \( \epsilon = \ln \mu \).

\begin{verbatim}
   proc model data=in;
      parms alpha beta;
      y = alpha * x ** beta;
      resid.y = actual.y / pred.y;
      fit y;
      run;
\end{verbatim}

If the model was expressed in general form, this transformation becomes

\begin{verbatim}
   proc model data=in;
      parms alpha beta;
      EQ.trans = log( y / (alpha * x ** beta));
      fit trans;
      run;
\end{verbatim}

Both examples produce estimates of \( \alpha \) and \( \beta \) of the level form that match the estimates of \( a \) and \( b \) of the log form. That is, ALPHA=exp(INTERCEPT) and BETA=LOGX, where INTERCEPT and LOGX are the PROC SYSLIN parameter estimates from the MODEL LOGY=LOGX. The standard error reported for ALPHA is different from that for the INTERCEPT in the log form.

The preceding example is not intended to suggest that loglinear models should be estimated in level form but, rather, to make the following points:
Chapter 19: The MODEL Procedure

- Nonlinear transformations of equations involve the error term of the equation, and this should be taken into account when transforming models.

- The RESID.-prefixed and the EQ.-prefixed equation variables for models estimated by the MODEL procedure must represent additive errors with zero means.

- You can use assignments to RESID.-prefixed and EQ.-prefixed equation variables to transform error terms.

- Some models do not have additive errors or zero means, and many such models can be estimated using the MODEL procedure. The preceding approach applies not only to multiplicative models but to any model that can be manipulated to isolate the error term.

Predicted Values of Transformed Models

Nonadditive or transformed errors affect the distribution of the predicted values, as well as the estimates. For the preceding loglinear example, the MODEL procedure produces consistent parameter estimates. However, the predicted values for Y computed by PROC MODEL are not unbiased estimates of the expected values of Y, although they do estimate the conditional median Y values.

In general, the predicted values produced for a model with nonadditive errors are not unbiased estimates of the conditional means of the endogenous value. If the model can be transformed to a model with additive errors by using a monotonic transformation, the predicted values estimate the conditional medians of the endogenous variable.

For transformed models in which the biasing factor is known, you can use programming statements to correct for the bias in the predicted values as estimates of the endogenous means. In the preceding log-linear case, the predicted values are biased by the factor $\exp(\sigma^2/2)$. You can produce approximately unbiased predicted values in this case by writing the model as

```
proc model data=in;
   parms alpha beta;
   y=alpha * x ** beta;
   resid.y = log( actual.y / pred.y );
   fit y;
   run;
```

See Miller (1984) for a discussion of bias factors for predicted values of transformed models.

Note that models with transformed errors are not appropriate for Monte Carlo simulation that uses the SDATA= option. PROC MODEL computes the OUTS= matrix from the transformed RESID.-prefixed equation variables, while it uses the SDATA= matrix to generate multivariate normal errors, which are added to the predicted values. This method of computing errors is inconsistent when the equation variables have been transformed.

Error Covariance Structure Specification

One of the key assumptions of regression is that the variance of the errors is constant across observations. Correcting for heteroscedasticity improves the efficiency of the estimates.
Consider the following general form for models:

\[
\begin{align*}
q(y_t, x_t, \theta) &= \varepsilon_t \\
\varepsilon_t &= H_t \ast \varepsilon_t \\
H_t &= \begin{bmatrix}
\sqrt{h_{t,1}} & 0 & \cdots & 0 \\
0 & \sqrt{h_{t,2}} & \cdots & 0 \\
& \ddots & \ddots & \ddots \\
0 & 0 & \cdots & \sqrt{h_{t,g}}
\end{bmatrix} \\
h_t &= g(y_t, x_t, \phi)
\end{align*}
\]

where \(\varepsilon_t \sim N(0, \Sigma)\).

For models that are homoscedastic,

\[h_t = 1\]

If you have a model that is heteroscedastic with known form, you can improve the efficiency of the estimates by performing a weighted regression. The weight variable, using this notation, would be \(1/\sqrt{h_t}\).

If the errors for a model are heteroscedastic and the functional form of the variance is known, the model for the variance can be estimated along with the regression function.

To specify a functional form for the variance, assign the function to an \(H.var\) variable where \(var\) is the equation variable. For example, if you want to estimate the scale parameter for the variance of a simple regression model

\[y = a \ast x + b\]

you can specify

```plaintext
proc model data=s;
  y = a * x + b;
  h.y = sigma**2;
  fit y;
```

Consider the same model with the following functional form for the variance:

\[h_t = \sigma^2 \ast x^{2\ast\alpha}\]

This would be written as

```plaintext
proc model data=s;
  y = a * x + b;
  h.y = sigma**2 * x**(2*alpha);
  fit y;
```

There are three ways to model the variance in the MODEL procedure: feasible generalized least squares, generalized method of moments, and full information maximum likelihood.
Feasible GLS

A simple approach to estimating a variance function is to estimate the mean parameters \( \theta \) by using some auxiliary method, such as OLS, and then use the residuals of that estimation to estimate the parameters \( \phi \) of the variance function. This scheme is called feasible GLS. It is possible to use the residuals from an auxiliary method for the purpose of estimating \( \phi \) because in many cases the residuals consistently estimate the error terms.

For all estimation methods except GMM and FIML, using the H.var syntax specifies that feasible GLS is used in the estimation. For feasible GLS, the mean function is estimated by the usual method. The variance function is then estimated using pseudo-likelihood (PL) function of the generated residuals. The objective function for the PL estimation is

\[
p_n(\sigma, \theta) = \sum_{i=1}^{n} \left( \frac{(y_i - f(x_i, \hat{\beta}))^2}{\sigma^2 h(z_i, \theta)} + \log[\sigma^2 h(z_i, \theta)] \right)
\]

Once the variance function has been estimated, the mean function is reestimated by using the variance function as weights. If an S-iterated method is selected, this process is repeated until convergence (iterated feasible GLS).

Note that feasible GLS does not yield consistent estimates when one of the following is true:

- The variance is unbounded.
- There is too much serial dependence in the errors (the dependence does not fade with time).
- There is a combination of serial dependence and lag dependent variables.

The first two cases are unusual, but the third is much more common. Whether iterated feasible GLS avoids consistency problems with the last case is an unanswered research question. For more information see: Davidson and MacKinnon (1993, pp. 298–301); Gallant (1987, pp. 124–125); Amemiya (1985, pp. 202–203).

One limitation is that parameters cannot be shared between the mean equation and the variance equation. This implies that certain GARCH models, cross-equation restrictions of parameters, or testing of combinations of parameters in the mean and variance component are not allowed.

Generalized Method of Moments

In GMM, normally the first moment of the mean function is used in the objective function.

\[
q(y_t, x_t, \theta) = \epsilon_t \\
E(\epsilon_t) = 0
\]

To add the second moment conditions to the estimation, add the equation

\[
E(\epsilon_t \cdot \epsilon_t - h_t) = 0
\]

to the model. For example, if you want to estimate \( \sigma \) for linear example above, you can write

```sas
proc model data=s;
  y = a * x + b;
  eq.two = resid.y**2 - sigma**2;
  fit y two/ gmm;
  instruments x;
run;
```

This is a popular way to estimate a continuous-time interest rate processes (see Chan et al. 1992). The H.var syntax automatically generates this system of equations.

To further take advantage of the information obtained about the variance, the moment equations can be modified to

\[
E(\frac{\varepsilon_t}{\sqrt{h_t}}) = 0 \\
E(\varepsilon_t \varepsilon_t - h_t) = 0
\]

For the above example, this can be written as

```sas
proc model data=s;
  y = a * x + b;
  eq.two = resid.y**2 - sigma**2;
  resid.y = resid.y / sigma;
  fit y two/ gmm;
  instruments x;
run;
```

Note that, if the error model is misspecified in this form of the GMM model, the parameter estimates might be inconsistent.

**Full Information Maximum Likelihood**

For FIML estimation of variance functions, the concentrated likelihood below is used as the objective function. That is, the mean function is coupled with the variance function and the system is solved simultaneously.

\[
l_n(\phi) = \frac{ng}{2} \left(1 + \ln(2\pi)\right) - \sum_{t=1}^{n} \ln \left(\left| \frac{\partial q(y_t, x_t, \theta)}{\partial y_t} \right| \right)
+ \frac{1}{2} \sum_{t=1}^{n} \sum_{i=1}^{g} \left(\ln(h_{t,i}) + q_t(y_t, x_t, \theta)^2 / h_{t,i}\right)
\]

where \( g \) is the number of equations in the system.

The HESSIAN=GLS option is not available for FIML estimation that involves variance functions. The matrix used when HESSIAN=CROSS is specified is a crossproducts matrix that has been enhanced by the dual quasi-Newton approximation.
Examples

You can specify a GARCH(1,1) model as follows:

```sas
proc model data=modloc.usd_jpy;
   /* Mean model */
   jpyret = intercept;

   /* Variance model */
   h.jpyret = arch0 + arch1 * xlag( resid.jpyret ** 2, mse.jpyret ) + garch1 * xlag(h.jpyret, mse.jpyret);
   bounds arch0 arch1 garch1 >= 0;

   fit jpyret / method=marquardt fiml;
run;
```

Note that the BOUNDS statement is used to ensure that the parameters are positive, a requirement for GARCH models.

EGARCH models are used because there are no restrictions on the parameters. You can specify an EGARCH(1,1) model as follows:

```sas
proc model data=sasuser.usd_dem;
   /* Mean model */
   demret = intercept;

   /* Variance model */
   if (_OBS_ =1 ) then
     h.demret = exp( earch0 + egarch1 * log(mse.demret) );
   else
     h.demret = exp( earch0 + earch1 * zlag( g) + egarch1 * log(zlag(h.demret)));
   g = - theta * nresid.demret + abs( nresid.demret ) - sqrt(2/3.1415);

   fit demret / method=marquardt fiml maxiter=100 converge=1.0e-6;
run;
```

Ordinary Differential Equations

Ordinary differential equations (ODEs) are also called initial value problems because a time zero value for each first-order differential equation is needed. The following is an example of a first-order system of ODEs:

\begin{align*}
  y' &= -0.1y + 2.5z^2 \\
  z' &= -z \\
  y_0 &= 0 \\
  z_0 &= 1
\end{align*}
Note that you must provide an initial value for each ODE.

As a reminder, any $n$-order differential equation can be modeled as a system of first-order differential equations. For example, consider the differential equations

$$\begin{align*}
y'' &= by' + cy \\
y_0 &= 0 \\
y_0' &= 1
\end{align*}$$

which can be written as the system of differential equations

$$\begin{align*}
y' &= z \\
z' &= by' + cy \\
y_0 &= 0 \\
z_0 &= 1
\end{align*}$$

This differential system can be simulated as follows:

```plaintext
data t;
  time=0; output;
  time=1; output;
  time=2; output;
run;

proc model data=t ;
  dependent y 0 z 1;
  parm b -2 c -4;

  dert.y = z;
  dert.z = b * dert.y + c * y;

  solve y z / dynamic solveprint;
run;
```

The preceding statements produce the output shown in Figure 19.46. These statements produce additional output, which is not shown.

---

**Figure 19.46** Simulation Results for Differential System

<table>
<thead>
<tr>
<th>Observation</th>

<th>Iterations</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>2</td>
<td>-1.000000</td>
<td>0</td>
</tr>
</tbody>
</table>
The differential variables are distinguished by the derivative with respect to time (DERT.) prefix. Once you define the DERT. variable, you can use it on the right-hand side of another equation. The differential equations must be expressed in normal form; implicit differential equations are not allowed, and other terms on the left-hand side are not allowed.

The TIME variable is the implied with respect to variable for all DERT. variables. The TIME variable is also the only variable that must be in the input data set.

You can provide initial values for the differential equations in the data set, in the declaration statement (as in the previous example), or in statements in the program. Using the previous example, you can specify the initial values as

```plaintext
proc model data=t;
    dependent y z;
    parm b -2 c -4;
    if ( time=0 ) then
        do;
            y=0;
            z=1;
        end;
    else
        do;
            dert.y = z;
            dert.z = b * dert.y + c * y;
        end;
    end;
```
solve y z / dynamic solveprint;
run;

If you do not provide an initial value, 0 is used.

**DYNAMIC and STATIC Simulation**

Note that, in the previous example, the DYNAMIC option is specified in the SOLVE statement. The DYNAMIC and STATIC options work the same for differential equations as they do for dynamic systems. In the differential equation case, the DYNAMIC option makes the initial value needed at each observation the computed value from the previous iteration. For a static simulation, the data set must contain values for the integrated variables. For example, if DERT.Y and DERT.Z are the differential variables, you must include Y and Z in the input data set in order to do a static simulation of the model.

If the simulation is dynamic, the initial values for the differential equations are obtained from the data set, if they are available. If the variable is not in the data set, you can specify the initial value in a declaration statement. If you do not specify an initial value, the value of 0.0 is used.

A dynamic solution is obtained by solving one initial value problem for all the data. A graph of a simple dynamic simulation is shown in Figure 19.47. If the time variable for the current observation is less than the time variable for the previous observation, the integration is restarted from this point. This allows for multiple samples in one data file.

**Figure 19.47** Dynamic Solution
In a static solution, \( n-1 \) initial value problems are solved using the first \( n-1 \) data values as initial values. The equations are integrated using the \( i \)th data value as an initial value to the \( i+1 \) data value. Figure 19.48 displays a static simulation of noisy data from a simple differential equation. The static solution does not propagate errors in initial values as the dynamic solution does.

**Figure 19.48** Static Solution

For estimation, the DYNAMIC and STATIC options in the FIT statement perform the same functions as they do in the SOLVE statement. Components of differential systems that have missing values or are not in the data set are simulated dynamically. For example, often in multiple compartment kinetic models, only one compartment is monitored. The differential equations that describe the unmonitored compartments are simulated dynamically.

For estimation, it is important to have accurate initial values for ODEs that are not in the data set. If an accurate initial value is not known, the initial value can be made an unknown parameter and estimated. This allows for errors in the initial values but increases the number of parameters to estimate by the number of equations.

**Estimation of Differential Equations**

Consider the kinetic model for the accumulation of mercury (Hg) in mosquito fish (Matis, Miller, and Allen 1991, p. 177). The model for this process is the one-compartment constant infusion model shown in Figure 19.49.
The differential equation that models this process is

\[
\frac{d\text{conc}}{dt} = k_u - k_e \text{conc} \\
\text{conc}_0 = 0
\]

The analytical solution to the model is

\[
\text{conc} = \left(\frac{k_u}{k_e}\right)(1 - \exp(-k_et))
\]

The data for the model are

```plaintext
data fish;
  input day conc;
datalines;
  0.0 0.0
  1.0 0.15
  2.0 0.2
  3.0 0.26
  4.0 0.32
  6.0 0.33
;```

To fit this model in differential form, use the following statements:

```plaintext
proc model data=fish;
  parm ku ke;
  dert.conc = ku - ke * conc;
  fit conc / time=day;
run;
```

The results from this estimation are shown in Figure 19.50.
To perform a dynamic estimation of the differential equation, add the DYNAMIC option to the FIT statement.

```plaintext
proc model data=fish;
   parm ku .3 ke .3;
   dert.conc = ku - ke * conc;
   fit conc / time = day dynamic;
run;
```

The equation DERT.CONC is integrated from \( \text{conc}(0) = 0 \). The results from this estimation are shown in Figure 19.51:

```
Figure 19.51  Dynamic Estimation Results for Fish Model
```

To perform a dynamic estimation of the differential equation and estimate the initial value, use the following statements:

```plaintext
proc model data=fish;
   parm ku .3 ke .3 conc0 0;
   dert.conc = ku - ke * conc;
   fit conc initial=(conc = conc0) / time = day dynamic;
run;
```

The INITIAL= option in the FIT statement is used to associate the initial value of a differential equation with a parameter. The results from this estimation are shown in Figure 19.52.
Finally, to estimate the fish model by using the analytical solution, use the following statements:

```plaintext
proc model data=fish;
  parm ku .3 ke .3;
  conc = (ku/ ke)*( 1 -exp(-ke * day));
  fit conc;
run;
```

The results from this estimation are shown in Figure 19.53.

A comparison of the results among the four estimations reveals that the two dynamic estimations and the analytical estimation give nearly identical results (identical to the default precision). The two dynamic estimations are identical because the estimated initial value (0.00013071) is very close to the initial value used in the first dynamic estimation (0). Note also that the static model did not require an initial guess for the parameter values. Static estimation, in general, is more forgiving of bad initial values.

The form of the estimation that is preferred depends mostly on the model and data. If a very accurate initial value is known, then a dynamic estimation makes sense. If, additionally, the model can be written analytically, then the analytical estimation is computationally simpler. If only an approximate initial value is known and not modeled as an unknown parameter, the static estimation is less sensitive to errors in the initial value.

The form of the error in the model is also an important factor in choosing the form of the estimation. If the error term is additive and independent of previous error, then the dynamic mode is appropriate. If, on the
other hand, the errors are cumulative, a static estimation is more appropriate. See the section “Monte Carlo Simulation” on page 1226 for an example.

**Auxiliary Equations**

Auxiliary equations can be used with differential equations. These are equations that need to be satisfied with the differential equations at each point between each data value. They are automatically added to the system, so you do not need to specify them in the SOLVE or FIT statement.

Consider the following example.

The Michaelis-Menten equations describe the kinetics of an enzyme-catalyzed reaction. The enzyme is E, and S is called the substrate. The enzyme first reacts with the substrate to form the enzyme-substrate complex ES, which then breaks down in a second step to form enzyme and products P.

The reaction rates are described by the following system of differential equations:

\[
\frac{d[ES]}{dt} = k_1 ([E] - [ES])[S] - k_2 [ES] - k_3 [ES] \\
\frac{d[S]}{dt} = -k_1 ([E] - [ES])[S] + k_2 [ES] \\
[E] = [E]_{tot} - [ES]
\]

The first equation describes the rate of formation of ES from E + S. The rate of formation of ES from E + P is very small and can be ignored. The enzyme is in either the complexed or the uncomplexed form. So if the total ([E]_{tot}) concentration of enzyme and the amount bound to the substrate is known, [E] can be obtained by conservation.

In this example, the conservation equation is an auxiliary equation and is coupled with the differential equations for integration.

**Time Variable**

You must provide a time variable in the data set. The name of the time variable defaults to TIME. You can use other variables as the time variable by specifying the TIME= option in the FIT or SOLVE statement. The time intervals need not be evenly spaced. If the time variable for the current observation is less than the time variable for the previous observation, the integration is restarted.
Differential Equations and Goal Seeking

Consider the following differential equation

\[ y' = ax \]

and the data set

```plaintext
data t2;
y=0; time=0; output;
y=2; time=1; output;
y=3; time=2; output;
run;
```

The problem is to find values for X that satisfy the differential equation and the data in the data set. Problems of this kind are sometimes referred to as goal-seeking problems because they require you to search for values of X that satisfy the goal of Y.

This problem is solved with the following statements:

```plaintext
proc model data=t2;
independent x 0;
dependent y;
parm a 5;
dert.y = a * x;
solve x / out=goaldata;
run;
```

```plaintext
proc print data=goaldata;
run;
```

The output from the PROC PRINT statement is shown in Figure 19.54.

![Figure 19.54 Dynamic Solution](image)

Note that an initial value of 0 is provided for the X variable because it is undetermined at TIME = 0.

In the preceding goal-seeking example, X is treated as a linear function between each set of data points (see Figure 19.55).
If you integrate $y' = ax$ manually, you have

$$x(t) = \frac{t_f - t}{t_f - t_o} x_o + \frac{t - t_o}{t_f - t_o} x_f$$

$$y_f - y_o = \int_{t_o}^{t_f} a x(t) \, dt$$

$$= a \left[ \frac{1}{t_f - t_o} \left( t(t_f x_o - t_o x_f) + \frac{1}{2} t^2(x_f - x_o) \right) \right]_{t_o}^{t_f}$$

For observation 2, this reduces to

$$y_f - y_o = \frac{1}{2} a x_f$$

$$2 = 2.5 x_f$$

So $x = 0.8$ for this observation.

Goal seeking for the TIME variable is not allowed.

---

**Restrictions and Bounds on Parameters**

Using the BOUNDS and RESTRICT statements, PROC MODEL can compute optimal estimates subject to equality or inequality constraints on the parameter estimates.

Equality restrictions can be written as a vector function:

$$h(\theta) = 0$$
Inequality restrictions are either active or inactive. When an inequality restriction is active, it is treated as an equality restriction. All inactive inequality restrictions can be written as a vector function:

\[ F(\theta) \geq 0 \]

Strict inequalities, such as \( f(\theta) > 0 \), are transformed into inequalities as \( f(\theta) \times (1 - \epsilon) - \epsilon \geq 0 \), where the tolerance \( \epsilon \) is controlled by the EPSILON= option in the FIT statement and defaults to \( 10^{-8} \). The \( i \)th inequality restriction becomes active if \( F_i < 0 \) and remains active until its Lagrange multiplier becomes negative. Lagrange multipliers are computed for all the nonredundant equality restrictions and all the active inequality restrictions.

For the following, assume the vector \( h(\theta) \) contains all the current active restrictions. The constraint matrix \( A \) is

\[ A(\hat{\theta}) = \frac{\partial h(\hat{\theta})}{\partial \theta} \]

The covariance matrix for the restricted parameter estimates is computed as

\[ Z(Z'HZ)^{-1}Z' \]

where \( H \) is Hessian or approximation to the Hessian of the objective function \((X'(\text{diag}(S)^{-1} \otimes I)X)\) for OLS), and \( Z \) is the last \((np - nc)\) columns of \( Q \). \( Q \) is from an LQ factorization of the constraint matrix, \( nc \) is the number of active constraints, and \( np \) is the number of parameters. For more details on LQ factorization, see Gill, Murray, and Wright (1981). The covariance column in Table 19.2 summarizes the Hessian approximation used for each estimation method.

The covariance matrix for the Lagrange multipliers is computed as

\[ (AH^{-1}A')^{-1} \]

The \( p \)-value reported for a restriction is computed from a beta distribution rather than a \( t \) distribution because the numerator and the denominator of the \( t \) ratio for an estimated Lagrange multiplier are not independent.

The Lagrange multipliers for the active restrictions are printed with the parameter estimates. The Lagrange multiplier estimates are computed using the relationship

\[ A'\lambda = g \]

where the dimensions of the constraint matrix \( A \) are the number of constraints by the number of parameters, \( \lambda \) is the vector of Lagrange multipliers, and \( g \) is the gradient of the objective function at the final estimates.

The final gradient includes the effects of the estimated \( S \) matrix. For example, for OLS the final gradient would be:

\[ g = X'(\text{diag}(S)^{-1} \otimes I)r \]

where \( r \) is the residual vector. Note that when nonlinear restrictions are imposed, the convergence measure \( R \) might have values greater than one for some iterations.
Tests on Parameters

In general, the hypothesis tested can be written as

\[ H_0 : h(\theta) = 0 \]

where \( h(\theta) \) is a vector-valued function of the parameters \( \theta \) given by the \( r \) expressions specified on the TEST statement.

Let \( \hat{V} \) be the estimate of the covariance matrix of \( \hat{\theta} \). Let \( \hat{\theta} \) be the unconstrained estimate of \( \theta \) and \( \tilde{\theta} \) be the constrained estimate of \( \theta \) such that \( h(\tilde{\theta}) = 0 \). Let

\[ A(\theta) = \frac{\partial h(\theta)}{\partial \theta} \bigg|_{\hat{\theta}} \]

Let \( r \) be the dimension of \( h(\theta) \) and \( n \) be the number of observations. Using this notation, the test statistics for the three kinds of tests are computed as follows.

The Wald test statistic is defined as

\[ W = h' \left( \hat{\theta} \right) \left( A(\hat{\theta})\hat{V}A'(\hat{\theta}) \right)^{-1} h(\hat{\theta}) \]

The Wald test is not invariant to reparameterization of the model (Gregory and Veall 1985; Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

The Lagrange multiplier test statistic is

\[ R = \lambda' A(\tilde{\theta})\tilde{V}A'(\tilde{\theta})\lambda \]

where \( \lambda \) is the vector of Lagrange multipliers from the computation of the restricted estimate \( \tilde{\theta} \).

The Lagrange multiplier test statistic is equivalent to Rao’s efficient score test statistic:

\[ R = (\partial L(\tilde{\theta})/\partial \theta)' \hat{V}(\partial L(\tilde{\theta})/\partial \theta) \]

where \( L \) is the log-likelihood function for the estimation method used. For SUR, 3SLS, GMM, and iterated versions of these methods, the likelihood function is computed as

\[ L = \text{Objective} \times Nobs/2 \]

For OLS and 2SLS, the Lagrange multiplier test statistic is computed as:

\[ R = [(\partial \hat{S}(\tilde{\theta})/\partial \theta)' \hat{V}(\partial \hat{S}(\tilde{\theta})/\partial \theta)]/\hat{S}(\tilde{\theta}) \]

where \( \hat{S}(\tilde{\theta}) \) is the corresponding objective function value at the constrained estimate.

The likelihood ratio test statistic is

\[ T = 2 \left( L(\hat{\theta}) - L(\tilde{\theta}) \right) \]

where \( \tilde{\theta} \) represents the constrained estimate of \( \theta \) and \( L \) is the concentrated log-likelihood value.
For OLS and 2SLS, the likelihood ratio test statistic is computed as:

\[ T = (n - nparms) \times (\hat{S}(\tilde{\theta}) - \hat{S}(\hat{\theta})) / \hat{S}(\hat{\theta}) \]

This test statistic is an approximation from

\[ T = n \times \log \left(1 + \frac{rF}{n - nparms}\right) \]

when the value of \(rF/(n - nparms)\) is small (Greene 2004, p. 421).

The likelihood ratio test is not appropriate for models with nonstationary serially correlated errors (Gallant 1987, p. 139). The likelihood ratio test should not be used for dynamic systems, for systems with lagged dependent variables, or with the FIML estimation method unless certain conditions are met (see Gallant 1987, p. 479).

For each kind of test, under the null hypothesis the test statistic is asymptotically distributed as a \(\chi^2\) random variable with \(r\) degrees of freedom, where \(r\) is the number of expressions in the TEST statement. The \(p\)-values reported for the tests are computed from the \(\chi^2(r)\) distribution and are only asymptotically valid. When both RESTRICT and TEST statements are used in a PROC MODEL step, test statistics are computed by taking into account the constraints imposed by the RESTRICT statement.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation to its small sample distribution than the other two tests. However, the Wald test has the least computational cost, since it does not require computation of the constrained estimate \(\tilde{\theta}\).

The following is an example of using the TEST statement to perform a likelihood ratio test for a compound hypothesis.

\[
\text{test a*exp(-k) = 1-k, d = 0 ,/ lr;}
\]

It is important to keep in mind that although individual \(t\) tests for each parameter are printed by default into the parameter estimates table, they are only asymptotically valid for nonlinear models. You should be cautious in drawing any inferences from these \(t\) tests for small samples.

---

**Hausman Specification Test**

Hausman’s specification test, or \(m\)-statistic, can be used to test hypotheses in terms of bias or inconsistency of an estimator. This test was also proposed by Wu (1973). Hausman’s \(m\)-statistic is as follows.

Given two estimators, \(\hat{\beta}_0\) and \(\hat{\beta}_1\), where under the null hypothesis both estimators are consistent but only \(\hat{\beta}_0\) is asymptotically efficient and under the alternative hypothesis only \(\hat{\beta}_1\) is consistent, the \(m\)-statistic is

\[ m = \hat{q}'(\hat{V}_1 - \hat{V}_0)^{-1}\hat{q} \]

where \(\hat{V}_1\) and \(\hat{V}_0\) represent consistent estimates of the asymptotic covariance matrices of \(\hat{\beta}_1\) and \(\hat{\beta}_0\) respectively, and

\[ q = \hat{\beta}_1 - \hat{\beta}_0 \]
The $m$-statistic is then distributed $\chi^2$ with $k$ degrees of freedom, where $k$ is the rank of the matrix $(\hat{V}_1 - \hat{V}_0)$. A generalized inverse is used, as recommended by Hausman and Taylor (1982).

In the MODEL procedure, Hausman’s $m$-statistic can be used to determine if it is necessary to use an instrumental variables method rather than a more efficient OLS estimation. Hausman’s $m$-statistic can also be used to compare 2SLS with 3SLS for a class of estimators for which 3SLS is asymptotically efficient (similarly for OLS and SUR).

Hausman’s $m$-statistic can also be used, in principle, to test the null hypothesis of normality when comparing 3SLS to FIML. Because of the poor performance of this form of the test, it is not offered in the MODEL procedure. See Fair (1984, pp. 246–247) for a discussion of why Hausman’s test fails for common econometric models.

To perform a Hausman’s specification test, specify the HAUSMAN option in the FIT statement. The selected estimation methods are compared using Hausman’s $m$-statistic.

In the following example, Hausman’s test is used to check the presence of measurement error. Under $H_0$ of no measurement error, OLS is efficient, while under $H_1$, 2SLS is consistent. In the following code, OLS and 2SLS are used to estimate the model, and Hausman’s test is requested.

```
proc model data=one out=fiml2;
   endogenous y1 y2;
   y1 = py2 * y2 + px1 * x1 + interc;
   y2 = py1* y1 + pz1 * z1 + d2;
   fit y1 y2 / ols 2sls hausman;
   instruments x1 z1;
run;
```

The output specified by the HAUSMAN option produces the results shown in Figure 19.56.

![Figure 19.56 Hausman's Specification Test Results](image)

Figure 19.56 indicates that 2SLS is preferred over OLS at 5% level of significance. In this case, the null hypothesis of no measurement error is rejected. Hence, the instrumental variable estimator is required for this example due to the presence of measurement error.
Chow Tests

The Chow test is used to test for break points or structural changes in a model. The problem is posed as a partitioning of the data into two parts of size \( n_1 \) and \( n_2 \). The null hypothesis to be tested is

\[ H_0 : \beta_1 = \beta_2 = \beta \]

where \( \beta_1 \) is estimated by using the first part of the data and \( \beta_2 \) is estimated by using the second part.

The test is performed as follows (see Davidson and MacKinnon 1993, p. 380).

1. The \( p \) parameters of the model are estimated.
2. A second linear regression is performed on the residuals, \( \hat{u} \), from the nonlinear estimation in step one.
   \[ \hat{u} = \hat{X}b + \text{residuals} \]
   where \( \hat{X} \) is Jacobian columns that are evaluated at the parameter estimates. If the estimation is an instrumental variables estimation with matrix of instruments \( W \), then the following regression is performed:
   \[ \hat{u} = P_W\hat{X}b + \text{residuals} \]
   where \( P_W\hat{X} \) is the projection matrix.
3. The restricted SSE (RSSE) from this regression is obtained. An SSE for each subsample is then obtained by using the same linear regression.
4. The \( F \) statistic is then
   \[ f = \frac{(RSSE - SSE_1 - SSE_2)/p}{(SSE_1 + SSE_2)/(n - 2p)} \]
   This test has \( p \) and \( n - 2p \) degrees of freedom.

Chow’s test is not applicable if \( \min(n_1,n_2) < p \), since one of the two subsamples does not contain enough data to estimate \( \beta \). In this instance, the predictive Chow test can be used. The predictive Chow test is defined as

\[ f = \frac{(RSSE - SSE_1)(n_1 - p)}{SSE_1 * n_2} \]

where \( n_1 > p \). This test can be derived from the Chow test by noting that the \( SSE_2 = 0 \) when \( n_2 < = p \) and by adjusting the degrees of freedom appropriately.

You can select the Chow test and the predictive Chow test by specifying the CHOW=arg and the PCHOW=arg options in the FIT statement, where arg is either the number of observations in the first sample or a parenthesized list of first sample sizes. If the size of the one of the two groups in which the sample is partitioned is less than the number of parameters, then a predictive Chow test is automatically used. These tests statistics are not produced for GMM and FIML estimations.

The following is an example of the use of the Chow test.
data exp;
  x=0;
  do time=1 to 100;
    if time=50 then x=1;
    y = 35 * exp( 0.01 * time ) + rannor( 123 ) + x * 5;
    output;
  end;
run;

proc model data=exp;
  parm zo 35 b;
  dert.z = b * z;
  y=z;
  fit y init=(z=zo) / chow =(40 50 60) pchow=90;
run;

The data set introduces an artificial structural change into the model (the structural change effects the intercept parameter). The output from the requested Chow tests are shown in Figure 19.57.

Profile Likelihood Confidence Intervals

Wald-based and likelihood-ratio-based confidence intervals are available in the MODEL procedure for computing a confidence interval on an estimated parameter. A confidence interval on a parameter $\theta$ can be constructed by inverting a Wald-based or a likelihood-ratio-based test.

The approximate $100(1 - \alpha)$ % Wald confidence interval for a parameter $\theta$ is

$$\hat{\theta} \pm z_{1-\alpha/2} \hat{\sigma}$$

where $z_p$ is the 100$p$th percentile of the standard normal distribution, $\hat{\theta}$ is the maximum likelihood estimate of $\theta$, and $\hat{\sigma}$ is the standard error estimate of $\hat{\theta}$.

A likelihood-ratio-based confidence interval is derived from the $\chi^2$ distribution of the generalized likelihood ratio test. The approximate $1 - \alpha$ confidence interval for a parameter $\theta$ is

$$\theta : 2[l(\hat{\theta}) - l(\theta)] \leq \chi^2_{1,1-\alpha} = 2l^*$$
where \( q_{1,1-\alpha} \) is the \((1 - \alpha)\) quantile of the \( \chi^2 \) with one degree of freedom, and \( l(\theta) \) is the log likelihood as a function of one parameter. The endpoints of a confidence interval are the zeros of the function \( l(\theta) - l^* \). Computing a likelihood-ratio-based confidence interval is an iterative process. This process must be performed twice for each parameter, so the computational cost is considerable. Using a modified form of the algorithm recommended by Venzon and Moolgavkar (1988), you can determine that the cost of each endpoint computation is approximately the cost of estimating the original system.

To request confidence intervals on estimated parameters, specify the PRL= option in the FIT statement. By default, the PRL option produces 95% likelihood ratio confidence limits. The coverage of the confidence interval is controlled by the ALPHA= option in the FIT statement.

The following is an example of the use of the confidence interval options.

```plaintext
data exp;
  do time = 1 to 20;
    y = 35 * exp( 0.01 * time ) + 5*rannor( 123 );
  output;
  end;
run;

proc model data=exp;
  parm zo 35 b;
  dert.z = b * z;
  y=z;
  fit y init=(z=zo) / prl=both;
  test zo = 40.475437 ,/ lr;
run;
```

The output from the requested confidence intervals and the TEST statement are shown in Figure 19.58.

**Figure 19.58  Confidence Interval Estimation**

| Parameter | Estimate | Std Err | t Value | Pr > |t| |
|-----------|----------|---------|---------|------|---|
| zo        | 36.58933 | 1.9471  | 18.79   | <.0001 |
| b         | 0.006497 | 0.00464 | 1.40    | 0.1780 |

**Test Results**

</tbody>
</table>
In this example the parameter value used in the likelihood ratio test, $z_0 = 40.475437$, is close to the upper bound computed for the likelihood ratio confidence interval, $z_0 \leq 40.4921$. This coincidence is not germane to the analysis however, since the likelihood ratio test is a test of the null hypothesis $H_0 : z_0 = 40.475437$ and the confidence interval can be viewed as a test of the null hypothesis $H_0 : 32.8381 \leq z_0 \leq 40.4921$.

### Choice of Instruments

Several of the estimation methods supported by PROC MODEL are instrumental variables methods. There is no standard method for choosing instruments for nonlinear regression. Few econometric textbooks discuss the selection of instruments for nonlinear models. See Bowden and Turkington (1984, pp. 180–182) for more information.

The purpose of the instrumental projection is to purge the regressors of their correlation with the residual. For nonlinear systems, the regressors are the partials of the residuals with respect to the parameters.

Possible instrumental variables include the following:

- any variable in the model that is independent of the errors
- lags of variables in the system
- derivatives with respect to the parameters, if the derivatives are independent of the errors
- low-degree polynomials in the exogenous variables
- variables from the data set or functions of variables from the data set

Selected instruments must not have any of the following characteristics:

- depend on any variable endogenous with respect to the equations estimated
- depend on any of the parameters estimated
- be lags of endogenous variables if there is serial correlation of the errors
If the preceding rules are satisfied and there are enough observations to support the number of instruments used, the results should be consistent and the efficiency loss held to a minimum.

You need at least as many instruments as the maximum number of parameters in any equation, or some of the parameters cannot be estimated. Note that *number of instruments* means linearly independent instruments. If you add an instrument that is a linear combination of other instruments, it has no effect and does not increase the effective number of instruments.

You can, however, use too many instruments. In order to get the benefit of instrumental variables, you must have more observations than instruments. Thus, there is a trade-off; the instrumental variables technique completely eliminates the simultaneous equation bias only in large samples. In finite samples, the larger the excess of observations over instruments, the more the bias is reduced. Adding more instruments might improve the efficiency, but after some point efficiency declines as the excess of observations over instruments becomes smaller and the bias grows.

The instruments used in an estimation are printed out at the beginning of the estimation. For example, the following statements produce the instruments list shown in Figure 19.59.

```plaintext
proc model data=test2;
   exogenous x1 x2;
   parms b1 a1 a2 b2 2.5 c2 55;
   y1 = a1 * y2 + b1 * exp(x1);
   y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2;
   fit y1 y2 / n2sls;
   inst b1 b2 c2 x1 ;
run;
```

**Figure 19.59** Instruments Used Message

<table>
<thead>
<tr>
<th>The MODEL Procedure</th>
</tr>
</thead>
<tbody>
<tr>
<td>The 2 Equations to Estimate</td>
</tr>
<tr>
<td>y1 = F(b1, a1(y2))</td>
</tr>
<tr>
<td>y2 = F(a2(y1), b2, c2)</td>
</tr>
<tr>
<td>Instruments 1 x1 @y1/@b1 @y2/@b2 @y2/@c2</td>
</tr>
</tbody>
</table>

This states that an intercept term, the exogenous variable X1, and the partial derivatives of the equations with respect to B1, B2, and C2, were used as instruments for the estimation.

**Examples**

Suppose that Y1 and Y2 are endogenous variables, that X1 and X2 are exogenous variables, and that A, B, C, D, E, F, and G are parameters. Consider the following model:

```plaintext
y1 = a + b * x1 + c * y2 + d * lag(y1);
y2 = e + f * x2 + g * y1;
fit y1 y2;
instruments exclude=(c g);
```

The INSTRUMENTS statement produces X1, X2, LAG(Y1), and an intercept as instruments.
In order to estimate the Y1 equation by itself, it is necessary to include X2 explicitly in the instruments since F, in this case, is not included in the following estimation:

\[
\begin{align*}
y_1 &= a + b \times x_1 + c \times y_2 + d \times \text{lag}(y_1); \\
y_2 &= e + f \times x_2 + g \times y_1;
\end{align*}
\]

fit y1;

instruments x2 exclude=(c);

This produces the same instruments as before. You can list the parameter associated with the lagged variable as an instrument instead of using the EXCLUDE= option. Thus, the following is equivalent to the previous example:

\[
\begin{align*}
y_1 &= a + b \times x_1 + c \times y_2 + d \times \text{lag}(y_1); \\
y_2 &= e + f \times x_2 + g \times y_1;
\end{align*}
\]

fit y1;

instruments x1 x2 d;

For an example of declaring instruments when estimating a model involving identities, consider Klein’s Model I:

```plaintext
proc model data=klien;
   endogenous c p w i x wsum k y;
   exogenous wp g t year;
   parms c0-c3 i0-i3 w0-w3;
   a: c = c0 + c1 * p + c2 * lag(p) + c3 * wsum;
   b: i = i0 + i1 * p + i2 * lag(p) + i3 * lag(k);
   c: w = w0 + w1 * x + w2 * lag(x) + w3 * year;
   x = c + i + g;
   y = c + i + g-t;
   p = x-w-t;
   k = lag(k) + i;
   wsum = w + wp;
run;
```

The three equations to estimate are identified by the labels A, B, and C. The parameters associated with the predetermined terms are C2, I2, I3, W2, and W3 (and the intercepts, which are automatically added to the instruments). In addition, the system includes five identities that contain the predetermined variables G, T, LAG(K), and WP. Thus, the INSTRUMENTS statement can be written as

\[
\begin{align*}
lagk &= \text{lag}(k);
\end{align*}
\]

\[
\begin{align*}
instruments c2 i2 i3 w2 w3 g t wp lagk;
\end{align*}
\]

where LAGK is a program variable used to hold LAG(K). However, this is more complicated than it needs to be. Except for LAG(K), all the predetermined terms in the identities are exogenous variables, and LAG(K) is already included as the coefficient of I3. There are also more parameters for predetermined terms than for endogenous terms, so you might prefer to use the EXCLUDE= option. Thus, you can specify the same instruments list with the simpler statement:

\[
\begin{align*}
\text{instruments } \_\text{exog}\_ \text{exclude}=(c1 c3 i1 w1);
\end{align*}
\]
To illustrate the use of polynomial terms as instrumental variables, consider the following model:

$$y_1 = a + b \cdot \exp(c \cdot x_1) + d \cdot \log(x_2) + e \cdot \exp(f \cdot y_2);$$

The parameters are $A$, $B$, $C$, $D$, $E$, and $F$, and the right-hand-side variables are $X_1$, $X_2$, and $Y_2$. Assume that $X_1$ and $X_2$ are exogenous (independent of the error), while $Y_2$ is endogenous. The equation for $Y_2$ is not specified, but assume that it includes the variables $X_1$, $X_3$, and $Y_1$, with $X_3$ exogenous, so the exogenous variables of the full system are $X_1$, $X_2$, and $X_3$. Using as instruments quadratic terms in the exogenous variables, the model is specified to PROC MODEL as follows:

```plaintext
proc model;
  parms a b c d e f;
  y1 = a + b \cdot \exp(c \cdot x1) + d \cdot \log(x2) + e \cdot \exp(f \cdot y2);
  instruments inst1-inst9;
  inst1 = x1; inst2 = x2; inst3 = x3;
  inst4 = x1 \cdot x1; inst5 = x1 \cdot x2; inst6 = x1 \cdot x3;
  inst7 = x2 \cdot x2; inst8 = x2 \cdot x3; inst9 = x3 \cdot x3;
  fit y1 / 2sls;
run;
```

It is not clear what degree polynomial should be used. There is no way to know how good the approximation is for any degree chosen, although the first-stage $R^2$s might help the assessment.

**First-Stage R-Squares**

When the FSRSQ option is used on the FIT statement, the MODEL procedure prints a column of first-stage $R^2$ (FSRSQ) statistics along with the parameter estimates. The FSRSQ measures the fraction of the variation of the derivative column associated with the parameter that remains after projection through the instruments.

Ideally, the FSRSQ should be very close to 1.00 for exogenous derivatives. If the FSRSQ is small for an endogenous derivative, it is unclear whether this reflects a poor choice of instruments or a large influence of the errors in the endogenous right-hand-side variables. When the FSRSQ for one or more parameters is small, the standard errors of the parameter estimates are likely to be large.

Note that you can make all the FSRSQs larger (or 1.00) by including more instruments, because of the disadvantage discussed previously. The FSRSQ statistics reported are unadjusted $R^2$s and do not include a degrees-of-freedom correction.

**Autoregressive Moving-Average Error Processes**

Autoregressive moving-average error processes (ARMA errors) and other models that involve lags of error terms can be estimated by using FIT statements and simulated or forecast by using SOLVE statements. ARMA models for the error process are often used for models with autocorrelated residuals. The `%AR` macro can be used to specify models with autoregressive error processes. The `%MA` macro can be used to specify models with moving-average error processes.
Autoregressive Errors

A model with first-order autoregressive errors, AR(1), has the form
\[ y_t = f(x_t, \theta) + \mu_t \]
\[ \mu_t = \phi \mu_{t-1} + \epsilon_t \]
while an AR(2) error process has the form
\[ \mu_t = \phi_1 \mu_{t-1} + \phi_2 \mu_{t-2} + \epsilon_t \]
and so forth for higher-order processes. Note that the \( \epsilon_t \)'s are independent and identically distributed and have an expected value of 0.

An example of a model with an AR(2) component is
\[ y = \alpha + \beta x_1 + \mu_t \]
\[ \mu_t = \phi_1 \mu_{t-1} + \phi_2 \mu_{t-2} + \epsilon_t \]
You would write this model as
```plaintext
proc model data=in;
  parms a b p1 p2;
  y = a + b * x1 + p1 * zlag1(y - (a + b * x1)) +
       p2 * zlag2(y - (a + b * x1));
  fit y;
run;
```
or equivalently using the %AR macro as
```plaintext
proc model data=in;
  parms a b;
  y = a + b * x1;
  %ar( y, 2 );
  fit y;
run;
```

Moving-Average Models

A model with first-order moving-average errors, MA(1), has the form
\[ y_t = f(x_t) + \mu_t \]
\[ \mu_t = \epsilon_t - \theta \epsilon_{t-1} \]
where \( \epsilon_t \) is identically and independently distributed with mean zero. An MA(2) error process has the form
\[ \mu_t = \epsilon_t - \theta_1 \epsilon_{t-1} - \theta_2 \epsilon_{t-2} \]
and so forth for higher-order processes.

For example, you can write a simple linear regression model with MA(2) moving-average errors as
proc model data=inma2;
parms a b ma1 ma2;
y = a + b * x + ma1 * zlag1( resid.y ) + ma2 * zlag2( resid.y );
fit;
run;

where MA1 and MA2 are the moving-average parameters.

Note that RESID.Y is automatically defined by PROC MODEL as

$\text{pred.y} = a + b \times x + \text{ma1} \times \text{zlag1 (resid.y)} + \text{ma2} \times \text{zlag2 (resid.y)}$;

$\text{resid.y} = \text{pred.y} - \text{actual.y}$;

Note that RESID.Y is negative of $\epsilon_t$.

The ZLAG function must be used for MA models to truncate the recursion of the lags. This ensures that the lagged errors start at zero in the lag-priming phase and do not propagate missing values when lag-priming period variables are missing, and it ensures that the future errors are zero rather than missing during simulation or forecasting. For details about the lag functions, see the section “Lag Logic” on page 1269.

This model written using the %MA macro is as follows:

proc model data=inma2;
parms a b;
y = a + b * x;
%ma(y, 2);
fit;
run;

**General Form for ARMA Models**

The general ARMA($p,q$) process has the following form

$\mu_t = \phi_1 \mu_{t-1} + \ldots + \phi_p \mu_{t-p} + \epsilon_t - \theta_1 \epsilon_{t-1} - \ldots - \theta_q \epsilon_{t-q}$

An ARMA($p,q$) model can be specified as follows:

```plaintext
yhat = ... compute structural predicted value here ...;
yarma = ar1 * zlag1( y - yhat ) + ... /* ar part */
        + ar(p) * zlag(p)( y - yhat )
        + ma1 * zlag1( resid.y ) + ... /* ma part */
        + ma(q) * zlag(q)( resid.y );
y = yhat + yarma;
```

where AR$i$ and MA$j$ represent the autoregressive and moving-average parameters for the various lags. You can use any names you want for these variables, and there are many equivalent ways that the specification could be written.

Vector ARMA processes can also be estimated with PROC MODEL. For example, a two-variable AR(1) process for the errors of the two endogenous variables Y1 and Y2 can be specified as follows:
Convergence Problems with ARMA Models

ARMA models can be difficult to estimate. If the parameter estimates are not within the appropriate range, a moving-average model’s residual terms grow exponentially. The calculated residuals for later observations can be very large or can overflow. This can happen either because improper starting values were used or because the iterations moved away from reasonable values.

Care should be used in choosing starting values for ARMA parameters. Starting values of 0.001 for ARMA parameters usually work if the model fits the data well and the problem is well-conditioned. Note that an MA model can often be approximated by a high-order AR model, and vice versa. This can result in high collinearity in mixed ARMA models, which in turn can cause serious ill-conditioning in the calculations and instability of the parameter estimates.

If you have convergence problems while estimating a model with ARMA error processes, try to estimate in steps. First, use a FIT statement to estimate only the structural parameters with the ARMA parameters held to zero (or to reasonable prior estimates if available). Next, use another FIT statement to estimate the ARMA parameters only, using the structural parameter values from the first run. Since the values of the structural parameters are likely to be close to their final estimates, the ARMA parameter estimates might now converge. Finally, use another FIT statement to produce simultaneous estimates of all the parameters. Since the initial values of the parameters are now likely to be quite close to their final joint estimates, the estimates should converge quickly if the model is appropriate for the data.

AR Initial Conditions

The initial lags of the error terms of AR(p) models can be modeled in different ways. The autoregressive error startup methods supported by SAS/ETS procedures are the following:

- CLS: conditional least squares (ARIMA and MODEL procedures)
- ULS: unconditional least squares (AUTOREG, ARIMA, and MODEL procedures)
- ML: maximum likelihood (AUTOREG, ARIMA, and MODEL procedures)
- YW: Yule-Walker (AUTOREG procedure only)
- HL: Hildreth-Lu, which deletes the first p observations (MODEL procedure only)

See Chapter 8, “The AUTOREG Procedure,” for an explanation and discussion of the merits of various AR(p) startup methods.

The CLS, ULS, ML, and HL initializations can be performed by PROC MODEL. For AR(1) errors, these initializations can be produced as shown in Table 19.3. These methods are equivalent in large samples.
Table 19.3  Initializations Performed by PROC MODEL: AR(1) ERRORS

<table>
<thead>

</tr>
</tbody>
</table>
| unconditional least squares | \( Y = \text{YHAT} + \text{AR1} \times \text{ZLAG1}(Y - \text{YHAT}); \)  
  IF _OBS_=1 THEN  
  \( \text{RESID.Y} = \sqrt{1 - \text{AR1}^2} \times \text{RESID.Y}; \) |
| maximum likelihood       | \( Y = \text{YHAT} + \text{AR1} \times \text{ZLAG1}(Y - \text{YHAT}); \)  
  \( W = (1 - \text{AR1}^2)^{\frac{-1}{2 \times \_NUSED_}}; \)  
  IF _OBS_=1 THEN  
  \( W \times \text{RESID.Y}; \) |
| Hildreth-Lu             | \( Y = \text{YHAT} + \text{AR1} \times \text{LAG1}(Y - \text{YHAT}); \) |

**MA Initial Conditions**

The initial lags of the error terms of MA\((q)\) models can also be modeled in different ways. The following moving-average error start-up paradigms are supported by the ARIMA and MODEL procedures:

- **ULS**  
  unconditional least squares
- **CLS**  
  conditional least squares
- **ML**  
  maximum likelihood

The conditional least squares method of estimating moving-average error terms is not optimal because it ignores the start-up problem. This reduces the efficiency of the estimates, although they remain unbiased. The initial lagged residuals, extending before the start of the data, are assumed to be 0, their unconditional expected value. This introduces a difference between these residuals and the generalized least squares residuals for the moving-average covariance, which, unlike the autoregressive model, persists through the data set. Usually this difference converges quickly to 0, but for nearly noninvertible moving-average processes the convergence is quite slow. To minimize this problem, you should have plenty of data, and the moving-average parameter estimates should be well within the invertible range.

This problem can be corrected at the expense of writing a more complex program. Unconditional least squares estimates for the MA(1) process can be produced by specifying the model as follows:

```plaintext
yhat = ... compute structural predicted value here ... ;
if _obs_ = 1 then do;
  h = sqrt( 1 + mal ** 2 );
  y = yhat;
  resid.y = ( y - yhat ) / h;
end;
else do;
  g = mal / zlag1( h );
  h = sqrt( 1 + mal ** 2 - g ** 2 );
  y = yhat + g * zlag1( resid.y );
  resid.y = ( ( y - yhat ) - g * zlag1( resid.y ) ) / h;
end;
```
Moving-average errors can be difficult to estimate. You should consider using an AR\(p\) approximation to the moving-average process. A moving-average process can usually be well-approximated by an autoregressive process if the data have not been smoothed or differenced.

**The %AR Macro**

The SAS macro %AR generates programming statements for PROC MODEL for autoregressive models. The %AR macro is part of SAS/ETS software, and no special options need to be set to use the macro. The autoregressive process can be applied to the structural equation errors or to the endogenous series themselves.

The %AR macro can be used for the following types of autoregression:

- univariate autoregression
- unrestricted vector autoregression
- restricted vector autoregression

**Univariate Autoregression**

To model the error term of an equation as an autoregressive process, use the following statement after the equation:

```
%ar( varname, nlags )
```

For example, suppose that \(Y\) is a linear function of \(X1, X2,\) and an AR(2) error. You would write this model as follows:

```
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 2 )
  fit y / list;
run;
```

The calls to %AR must come after all of the equations that the process applies to.

The preceding macro invocation, %AR(y,2), produces the statements shown in the LIST output in Figure 19.60.
Figure 19.60  LIST Option Output for an AR(2) Model

The _PRED__ prefixed variables are temporary program variables used so that the lags of the residuals are the correct residuals and not the ones redefined by this equation. Note that this is equivalent to the statements explicitly written in the section “General Form for ARMA Models” on page 1197.

You can also restrict the autoregressive parameters to zero at selected lags. For example, if you wanted autoregressive parameters at lags 1, 12, and 13, you can use the following statements:

```plaintext
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 13, , 1 12 13 )
  fit y / list;
run;
```

These statements generate the output shown in Figure 19.61.

Figure 19.61  LIST Option Output for an AR Model with Lags at 1, 12, and 13
There are variations on the conditional least squares method, depending on whether observations at the start of the series are used to “warm up” the AR process. By default, the %AR conditional least squares method uses all the observations and assumes zeros for the initial lags of autoregressive terms. By using the M= option, you can request that %AR use the unconditional least squares (ULS) or maximum-likelihood (ML) method instead. For example,

```plaintext
proc model data=in;
  y = a + b * x1 + c * x2;
  %ar( y, 2, m=uls )
  fit y;
run;
```

Discussions of these methods is provided in the section “AR Initial Conditions” on page 1198.

By using the M=CLS \( n \) option, you can request that the first \( n \) observations be used to compute estimates of the initial autoregressive lags. In this case, the analysis starts with observation \( n + 1 \). For example:

```plaintext
proc model data=in;
  y = a + b * x1 + c * x2;
  %ar( y, 2, m=cls2 )
  fit y;
run;
```

You can use the %AR macro to apply an autoregressive model to the endogenous variable, instead of to the error term, by using the TYPE=V option. For example, if you want to add the five past lags of \( Y \) to the equation in the previous example, you could use %AR to generate the parameters and lags by using the following statements:

```plaintext
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 5, type=v )
  fit y / list;
run;
```

The preceding statements generate the output shown in Figure 19.62.

**Figure 19.62** LIST Option Output for an AR model of \( Y \)

<table>

<td>ERROR.y = PRED.y - y;</td>
</tr>
</tbody>
</table>
This model predicts $Y$ as a linear combination of $X_1$, $X_2$, an intercept, and the values of $Y$ in the most recent five periods.

**Unrestricted Vector Autoregression**

To model the error terms of a set of equations as a vector autoregressive process, use the following form of the `%AR` macro after the equations:

```plaintext
%ar( process_name, nlags, variable_list )
```

The `process_name` value is any name that you supply for `%AR` to use in making names for the autoregressive parameters. You can use the `%AR` macro to model several different AR processes for different sets of equations by using different process names for each set. The process name ensures that the variable names used are unique. Use a short `process_name` value for the process if parameter estimates are to be written to an output data set. The `%AR` macro tries to construct parameter names less than or equal to eight characters, but this is limited by the length of `process_name`, which is used as a prefix for the AR parameter names.

The `variable_list` value is the list of endogenous variables for the equations.

For example, suppose that errors for equations $Y_1$, $Y_2$, and $Y_3$ are generated by a second-order vector autoregressive process. You can use the following statements:

```plaintext
proc model data=in;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 2, y1 y2 y3 )
  fit y1 y2 y3;
run;
```

which generate the following for $Y_1$ and similar code for $Y_2$ and $Y_3$:

```plaintext
y1 = pred.y1 + name1_1_1*zlag1(y1-name_y1) +
    name1_1_2*zlag1(y2-name_y2) +
    name1_1_3*zlag1(y3-name_y3) +
    name2_1_1*zlag2(y1-name_y1) +
    name2_1_2*zlag2(y2-name_y2) +
    name2_1_3*zlag2(y3-name_y3);
```

Only the conditional least squares (M=CLS or M=CLS$n$) method can be used for vector processes.

You can also use the same form with restrictions that the coefficient matrix be 0 at selected lags. For example, the following statements apply a third-order vector process to the equation errors with all the coefficients at lag 2 restricted to 0 and with the coefficients at lags 1 and 3 unrestricted:

```plaintext
proc model data=in;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 3, y1 y2 y3, 1 3 )
  fit y1 y2 y3;
```
You can model the three series Y1–Y3 as a vector autoregressive process in the variables instead of in the errors by using the TYPE=V option. If you want to model Y1–Y3 as a function of past values of Y1–Y3 and some exogenous variables or constants, you can use %AR to generate the statements for the lag terms. Write an equation for each variable for the nonautoregressive part of the model, and then call %AR with the TYPE=V option. For example,

```plaintext
proc model data=in;
  parms a1-a3 b1-b3;
  y1 = a1 + b1 * x;
  y2 = a2 + b2 * x;
  y3 = a3 + b3 * x;
  %ar( name, 2, y1 y2 y3, type=v )
  fit y1 y2 y3;
run;
```

The nonautoregressive part of the model can be a function of exogenous variables, or it can be intercept parameters. If there are no exogenous components to the vector autoregression model, including no intercepts, then assign zero to each of the variables. There must be an assignment to each of the variables before %AR is called.

```plaintext
proc model data=in;
  y1=0;
  y2=0;
  y3=0;
  %ar( name, 2, y1 y2 y3, type=v )
  fit y1 y2 y3;
run;
```

This example models the vector Y=(Y1 Y2 Y3)' as a linear function only of its value in the previous two periods and a white noise error vector. The model has 18=(3 × 3 + 3 × 3) parameters.

**Syntax of the %AR Macro**

There are two cases of the syntax of the %AR macro. When restrictions on a vector AR process are not needed, the syntax of the %AR macro has the general form

```plaintext
%AR ( name , nlag <,endolist <, laglist >> <,M= method > <,TYPE= V> ) ;
```

where

- **name** specifies a prefix for %AR to use in constructing names of variables needed to define the AR process. If the *endolist* is not specified, the endogenous list defaults to *name*, which must be the name of the equation to which the AR error process is to be applied. The *name* value cannot exceed 32 characters.

- **nlag** is the order of the AR process.

- **endolist** specifies the list of equations to which the AR process is to be applied. If more than one name is given, an unrestricted vector process is created with the structural residuals of all the equations included as regressors in each of the equations. If not specified, *endolist* defaults to *name*.

- **laglist** specifies the list of lags at which the AR terms are to be added. The coefficients of the terms at lags not listed are set to 0. All of the listed lags must be less than or equal to *nlag*.
and there must be no duplicates. If not specified, the laglist defaults to all lags 1 through nlag.

M=method specifies the estimation method to implement. Valid values of M= are CLS (conditional least squares estimates), ULS (unconditional least squares estimates), and ML (maximum likelihood estimates). M=CLS is the default. Only M=CLS is allowed when more than one equation is specified. The ULS and ML methods are not supported for vector AR models by %AR.

TYPE=V specifies that the AR process is to be applied to the endogenous variables themselves instead of to the structural residuals of the equations.

### Restricted Vector Autoregression

You can control which parameters are included in the process, restricting to 0 those parameters that you do not include. First, use %AR with the DEFER option to declare the variable list and define the dimension of the process. Then, use additional %AR calls to generate terms for selected equations with selected variables at selected lags. For example,

```plaintext
proc model data=d;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 2, y1 y2 y3, defer )
  %ar( name, y1, y1 y2 )
  %ar( name, y2 y3, , 1 )
  fit y1 y2 y3;
run;
```

The error equations produced are as follows:

```plaintext
y1 = pred.y1 + name1_1_1*zlag1(y1-name_y1) +
   name1_1_2*zlag1(y2-name_y2) + name2_1_1*zlag2(y1-name_y1) +
   name2_1_2*zlag2(y2-name_y2) ;

y2 = pred.y2 + name1_2_1*zlag1(y1-name_y1) +
   name1_2_2*zlag1(y2-name_y2) + name1_2_3*zlag1(y3-name_y3) ;

y3 = pred.y3 + name1_3_1*zlag1(y1-name_y1) +
   name1_3_2*zlag1(y2-name_y2) + name1_3_3*zlag1(y3-name_y3) ;
```

This model states that the errors for Y1 depend on the errors of both Y1 and Y2 (but not Y3) at both lags 1 and 2, and that the errors for Y2 and Y3 depend on the previous errors for all three variables, but only at lag 1.

### %AR Macro Syntax for Restricted Vector AR

An alternative use of %AR is allowed to impose restrictions on a vector AR process by calling %AR several times to specify different AR terms and lags for different equations.

The first call has the general form

```plaintext
%AR( name, nlag, endolist , DEFER ) ;
```

where
Chapter 19: The MODEL Procedure

**name** specifies a prefix for %AR to use in constructing names of variables needed to define the vector AR process.

**nlag** specifies the order of the AR process.

**endolist** specifies the list of equations to which the AR process is to be applied.

**DEFER** specifies that %AR is not to generate the AR process but is to wait for further information specified in later %AR calls for the same name value.

The subsequent calls have the general form

```sas
%AR( name, eqlist, varlist, laglist, TYPE= )
```

where

- **name** is the same as in the first call.
- **eqlist** specifies the list of equations to which the specifications in this %AR call are to be applied. Only names specified in the endolist value of the first call for the name value can appear in the list of equations in eqlist.
- **varlist** specifies the list of equations whose lagged structural residuals are to be included as regressors in the equations in eqlist. Only names in the endolist of the first call for the name value can appear in varlist. If not specified, varlist defaults to endolist.
- **laglist** specifies the list of lags at which the AR terms are to be added. The coefficients of the terms at lags not listed are set to 0. All of the listed lags must be less than or equal to the value of nlag, and there must be no duplicates. If not specified, laglist defaults to all lags 1 through nlag.

**The %MA Macro**

The SAS macro %MA generates programming statements for PROC MODEL for moving-average models. The %MA macro is part of SAS/ETS software, and no special options are needed to use the macro. The moving-average error process can be applied to the structural equation errors. The syntax of the %MA macro is the same as the %AR macro except there is no TYPE= argument.

When you are using the %MA and %AR macros combined, the %MA macro must follow the %AR macro. The following SAS/IML statements produce an ARMA(1, (1 3)) error process and save it in the data set MADAT2.

```sas
proc iml;
    phi = { 1 .2 };
    theta = { 1 .3 0 .5 };  
    y = armasim( phi, theta, 0, .1, 200, 32565 );
    create madat2 from y[colname='y'];
    append from y;
quit;
```

The following PROC MODEL statements are used to estimate the parameters of this model by using maximum likelihood error structure:
title 'Maximum Likelihood ARMA(1, (1 3))';
proc model data=madat2;
y=0;
%ar( y, 1, , M=ml )
%ma( y, 3, , 1 3, M=ml ) /* %MA always after %AR */
fit y;
run;
title;

The estimates of the parameters produced by this run are shown in Figure 19.63.

**Syntax of the %MA Macro**

There are two cases of the syntax for the %MA macro. When restrictions on a vector MA process are not needed, the syntax of the %MA macro has the general form

```plaintext
%MA ( name , nlag < , endolist < , laglist >> < , M= method > ) ;
```

where

- **name** specifies a prefix for %MA to use in constructing names of variables needed to define the MA process and is the default `endolist`.
- **nlag** is the order of the MA process.
- **endolist** specifies the equations to which the MA process is to be applied. If more than one name is given, CLS estimation is used for the vector process.
laglist specifies the lags at which the MA terms are to be added. All of the listed lags must be less than or equal to nlag, and there must be no duplicates. If not specified, the laglist defaults to all lags 1 through nlag.

M=method specifies the estimation method to implement. Valid values of M= are CLS (conditional least squares estimates), ULS (unconditional least squares estimates), and ML (maximum likelihood estimates). M=CLS is the default. Only M=CLS is allowed when more than one equation is specified in the endolist.

%MA Macro Syntax for Restricted Vector Moving-Average

An alternative use of %MA is allowed to impose restrictions on a vector MA process by calling %MA several times to specify different MA terms and lags for different equations.

The first call has the general form

\[
\text{%MA( name, nlag, endolist, DEFER ) ;}
\]

where

- name specifies a prefix for %MA to use in constructing names of variables needed to define the vector MA process.
- nlag specifies the order of the MA process.
- endolist specifies the list of equations to which the MA process is to be applied.
- DEFER specifies that %MA is not to generate the MA process but is to wait for further information specified in later %MA calls for the same name value.

The subsequent calls have the general form

\[
\text{%MA( name, eqlist, varlist, laglist )}
\]

where

- name is the same as in the first call.
- eqlist specifies the list of equations to which the specifications in this %MA call are to be applied.
- varlist specifies the list of equations whose lagged structural residuals are to be included as regressors in the equations in eqlist.
- laglist specifies the list of lags at which the MA terms are to be added.

Distributed Lag Models and the %PDL Macro

In the following example, the variable y is modeled as a linear function of x, the first lag of x, the second lag of x, and so forth:

\[
y_t = a + b_0 x_t + b_1 x_{t-1} + b_2 x_{t-2} + b_3 x_{t-3} + \ldots + b_n x_{t-n}
\]
Models of this sort can introduce a great many parameters for the lags, and there may not be enough data to compute accurate independent estimates for them all. Often, the number of parameters is reduced by assuming that the lag coefficients follow some pattern. One common assumption is that the lag coefficients follow a polynomial in the lag length

\[ b_i = \sum_{j=0}^{d} \alpha_j (i)^j \]

where \( d \) is the degree of the polynomial used. Models of this kind are called *Almon lag models, polynomial distributed lag models*, or *PDLs* for short. For example, Figure 19.64 shows the lag distribution that can be modeled with a low-order polynomial. Endpoint restrictions can be imposed on a PDL to require that the lag coefficients be 0 at the 0th lag, or at the final lag, or at both.

**Figure 19.64** Polynomial Distributed Lags

For linear single-equation models, SAS/ETS software includes the PDLREG procedure for estimating PDL models. See Chapter 21, “The PDLREG Procedure,” for a more detailed discussion of polynomial distributed lags and an explanation of endpoint restrictions.

Polynomial and other distributed lag models can be estimated and simulated or forecast with PROC MODEL. For polynomial distributed lags, the %PDL macro can generate the needed programming statements automatically.
The %PDL Macro

The SAS macro %PDL generates the programming statements to compute the lag coefficients of polynomial distributed lag models and to apply them to the lags of variables or expressions.

To use the %PDL macro in a model program, you first call it to declare the lag distribution; later, you call it again to apply the PDL to a variable or expression. The first call generates a PARMS statement for the polynomial parameters and assignment statements to compute the lag coefficients. The second call generates an expression that applies the lag coefficients to the lags of the specified variable or expression. A PDL can be declared only once, but it can be used any number of times (that is, the second call can be repeated).

The initial declaratory call has the general form

```
%PDL ( pdlname, nlags, degree, R=code, OUTEST=dataset );
```

where `pdlname` is a name (up to 32 characters) that you give to identify the PDL, `nlags` is the lag length, and `degree` is the degree of the polynomial for the distribution. The `R=code` is optional for endpoint restrictions. The value of `code` can be FIRST (for upper), LAST (for lower), or BOTH (for both upper and lower endpoints). See Chapter 21, “The PDLREG Procedure,” for a discussion of endpoint restrictions. The option `OUTEST=dataset` creates a data set that contains the estimates of the parameters and their covariance matrix.

The later calls to apply the PDL have the general form

```
%PDL( pdlname, expression )
```

where `pdlname` is the name of the PDL and `expression` is the variable or expression to which the PDL is to be applied. The `pdlname` given must be the same as the name used to declare the PDL.

The following statements produce the output in Figure 19.65:

```plaintext
proc model data=in list;
   parms int pz;
   %pdl(xpdl,5,2);
   y = int + pz * z + %pdl(xpdl,x);
   %ar(y,2,M=ULS);
   id i;
   fit y / out=model1 outresid converge=1e-6;
run;
```
This second example models two variables, Y1 and Y2, and uses two PDLs:

```plaintext
proc model data=in;
  parms int1 int2;
  %pdl( logxpdl, 5, 3 )
  %pdl( zpdl, 6, 4 )
  y1 = int1 + %pdl( logxpdl, log(x) ) + %pdl( zpdl, z );
  y2 = int2 + %pdl( zpdl, z );
  fit y1 y2;
run;
```

A (5,3) PDL of the log of X is used in the equation for Y1. A (6,4) PDL of Z is used in the equations for both Y1 and Y2. Since the same ZPDL is used in both equations, the lag coefficients for Z are the same for the Y1 and Y2 equations, and the polynomial parameters for ZPDL are shared by the two equations. See Example 19.5 for a complete example and comparison with PDLREG.

---

**Input Data Sets**

**DATA= Input Data Set**

For FIT tasks, the DATA= option specifies which input data set to use in estimating parameters. Variables in the model program are looked up in the DATA= data set and, if found, their attributes (type, length, label, and format) are set to be the same as those in the DATA= data set (if not defined otherwise within PROC MODEL).
ESTDATA= Input Data Set

The ESTDATA= option specifies an input data set that contains an observation that gives values for some or all of the model parameters. The data set can also contain observations that give the rows of a covariance matrix for the parameters.

Parameter values read from the ESTDATA= data set provide initial starting values for parameters estimated. Observations that provide covariance values, if any are present in the ESTDATA= data set, are ignored.

The ESTDATA= data set is usually created by the OUTEST= option in a previous FIT statement. You can also create an ESTDATA= data set with a SAS DATA step program. The data set must contain a numeric variable for each parameter to be given a value or covariance column. The name of the variable in the ESTDATA= data set must match the name of the parameter in the model. Parameters with names longer than 32 characters cannot be set from an ESTDATA= data set. The data set must also contain a character variable _NAME_ of length 32. _NAME_ has a blank value for the observation that gives values to the parameters. _NAME_ contains the name of a parameter for observations that define rows of the covariance matrix.

More than one set of parameter estimates and covariances can be stored in the ESTDATA= data set if the observations for the different estimates are identified by the variable _TYPE_. _TYPE_ must be a character variable of length 8. The TYPE= option is used to select for input the part of the ESTDATA= data set for which the _TYPE_ value matches the value of the TYPE= option.

In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used.

The following SAS statements generate the ESTDATA= data set shown in Figure 19.66. The second FIT statement uses the TYPE= option to select the estimates from the GMM estimation as starting values for the FIML estimation.

```sas
/* Generate test data */
data gmm2;
  do t=1 to 50;
    x1 = sqrt(t) ;
    x2 = rannor(10) * 10;
    y1 = -.002 * x2 * x2 - .05 / x2 - 0.001 * x1 * x1;
    y2 = 0.002* y1 + 2 * x2 * x2 + 50 / x2 + 5 * rannor(1);
    y1 = y1 + 5 * rannor(1);
    z1 = 1; z2 = x1 * x1; z3 = x2 * x2; z4 = 1.0/x2;
    output;
  end;
run;
```
proc model data=gmm2;
exogenous x1 x2;
parms a1 a2 b1 2.5 b2 c2 55 d1;
inst b1 b2 c2 x1 x2;
y1 = a1 * y2 + b1 * x1 * x1 + d1;
y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;
fit y1 y2 / 3sls gmm kernel=(qs,1,0.2) outest=gmmest;
run;

proc print data=gmmest;
run;

MISSING=PAIRWISE | DELETE

When missing values are encountered for any one of the equations in a system of equations, the default action is to drop that observation for all of the equations. The new MISSING=PAIRWISE option in the FIT statement provides a different method of handling missing values that avoids losing data for nonmissing equations for the observation. This is especially useful for SUR estimation on equations with unequal numbers of observations.

The option MISSING=PAIRWISE specifies that missing values are tracked on an equation-by-equation basis. The MISSING=DELETE option specifies that the entire observation is omitted from the analysis when any equation has a missing predicted or actual value for the equation. The default is MISSING=DELETE.

When you specify the MISSING=PAIRWISE option, the $S$ matrix is computed as

$$S = D(R'R)D$$

where $D$ is a diagonal matrix that depends on the VARDEF= option, the matrix $R$ is $(r_1, \ldots, r_g)$, and $r_j$ is the vector of residuals for the $i$th equation with $r_{ij}$ replaced with zero when $r_{ij}$ is missing.

For MISSING=PAIRWISE, the calculation of the diagonal element $d_{ij}$ of $D$ is based on $n_j$, the number of nonmissing observations for the $i$th equation, instead of on $n$. Similarly, for VARDEF=WGT or WDF, the calculation is based on the sum of the weights for the nonmissing observations for the $i$th equation instead of...
on the sum of the weights for all observations. See the description of the VARDEF= option for the definition of \( D \).

The degrees-of-freedom correction for a shared parameter is computed by using the average number of observations used in its estimation.

The MISSING=PAIRWISE option is not valid for the GMM and FIML estimation methods.

For the instrumental variables estimation methods (2SLS, 3SLS), when an instrument is missing for an observation, that observation is dropped for all equations, regardless of the MISSING= option.

**PARMSDATA= Input Data Set**

The option PARMSDATA= reads values for all parameters whose names match the names of variables in the PARMSDATA= data set. Values for any or all of the parameters in the model can be reset by using the PARMSDATA= option. The PARMSDATA= option goes in the PROC MODEL statement, and the data set is read before any FIT or SOLVE statements are executed.

In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used. Together, the OUTPARMS= and PARMSDATA= options enable you to change part of a model and recompile the new model program without the need to reestimate equations that were not changed.

Suppose you have a large model with parameters estimated and you now want to replace one equation, \( Y \), with a new specification. Although the model program must be recompiled with the new equation, you don’t need to reestimate all the equations, just the one that changed.

Using the OUTPARMS= and PARMSDATA= options, you could do the following:

```plaintext
proc model model=oldmod outparms=temp; run;
proc model outmodel=newmod parmsdata=temp data=in;
   ... include new model definition with changed y eq. here ...
   fit y;
run;
```

The model file NEWMOD then contains the new model and its estimated parameters plus the old models with their original parameter values.

**SDATA= Input Data Set**

The SDATA= option allows a cross-equation covariance matrix to be input from a data set. The \( S \) matrix read from the SDATA= data set, specified in the FIT statement, is used to define the objective function for the OLS, N2SLS, SUR, and N3SLS estimation methods and is used as the initial \( S \) for the methods that iterate the \( S \) matrix.

Most often, the SDATA= data set has been created by the OUTS= or OUTSUSED= option in a previous FIT statement. The OUTS= and OUTSUSED= data sets from a FIT statement can be read back in by a FIT statement in the same PROC MODEL step.

You can create an input SDATA= data set by using the DATA step. PROC MODEL expects to find a character variable _NAME_ in the SDATA= data set as well as variables for the equations in the estimation or solution. For each observation with a _NAME_ value that matches the name of an equation, PROC MODEL fills the
corresponding row of the $S$ matrix with the values of the names of equations found in the data set. If a row or column is omitted from the data set, a 1 is placed on the diagonal for the row or column. Missing values are ignored, and since the $S$ matrix is symmetric, you can include only a triangular part of the $S$ matrix in the SDATA= data set with the omitted part indicated by missing values. If the SDATA= data set contains multiple observations with the same _NAME_, the last values supplied for the _NAME_ are used. The structure of the expected data set is further described in the section “OUTS= Data Set” on page 1219.

Use the TYPE= option in the PROC MODEL or FIT statement to specify the type of estimation method used to produce the $S$ matrix you want to input.

The following SAS statements are used to generate an $S$ matrix from a GMM and a 3SLS estimation and to store that estimate in the data set GMMS:

```sas
proc model data=gmm2 ;
exogenous x1 x2;
parms a1 a2 b1 2.5 b2 c2 55 d1;
inst b1 b2 c2 x1 x2;
y1 = a1 * y2 + b1 * x1 * x1 + d1;
y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;
fit y1 y2 / 3sls gmm kernel=(qs,1,0.2)
   outest=gmmest outs=gmms;
run;
```

```sas
proc print data=gmms;
run;
```

The data set GMMS is shown in Figure 19.67.

**VDATA= Input data set**

The VDATA= option enables a variance matrix for GMM estimation to be input from a data set. When the VDATA= option is used in the PROC MODEL or FIT statement, the matrix that is input is used to define the objective function and is used as the initial $V$ for the methods that iterate the $V$ matrix.

Normally the VDATA= matrix is created from the OUTV= option in a previous FIT statement. Alternately an input VDATA= data set can be created by using the DATA step. Each row and column of the $V$ matrix is associated with an equation and an instrument. The position of each element in the $V$ matrix can then be indicated by an equation name and an instrument name for the row of the element and an equation name and an instrument name for the column. Each observation in the VDATA= data set is an element in the $V$ matrix.
Chapter 19: The MODEL Procedure

The row and column of the element are indicated by four variables (EQ_ROW, INST_ROW, EQ_COL, and INST_COL) that contain the equation name or instrument name. The variable name for an element is VALUE. Missing values are set to 0. Because the variance matrix is symmetric, only a triangular part of the matrix needs to be input.

The following SAS statements are used to generate a V matrix estimation from GMM and to store that estimate in the data set GMMV:

```sas
proc model data=gmm2;
   exogenous x1 x2;
  parms a1 a2 b2 b1 2.5 c2 55 d1;
   inst b1 b2 c2 x1 x2;
   y1 = a1 * y2 + b1 * x1 * x1 + d1;
   y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;
   fit y1 y2 / gmm outv=gmmv;
run;
proc print data=gmmv(obs=15);
run;
```

The data set GMM2 was generated by the example in the preceding ESTDATA= section. The V matrix stored in GMMV is selected for use in an additional GMM estimation by the following FIT statement:

```sas
fit y1 y2 / gmm vdata=gmmv;
run;
```

A partial listing of the GMMV data set is shown in Figure 19.68. There are a total of 78 observations in this data set. The V matrix is 12 by 12 for this example.

Output Data Sets

OUT= Data Set

For normalized form equations, the OUT= data set specified in the FIT statement contains residuals, actuals, and predicted values of the dependent variables computed from the parameter estimates. For general form equations, actual values of the endogenous variables are copied for the residual and predicted values.

The variables in the data set are as follows:

- BY variables
- RANGE variable
- ID variables
- _ESTYPE_, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, IT2SLS, IT3SLS, GMM, ITGMM, or FIML
- _TYPE_, a character variable of length 8 that identifies the type of observation: RESIDUAL, PREDICT, or ACTUAL
- _WEIGHT_, the weight of the observation in the estimation. The _WEIGHT_ value is 0 if the observation was not used. It is equal to the product of the _WEIGHT_ model program variable and the variable named in the WEIGHT statement, if any, or 1 if weights were not used.
- the WEIGHT statement variable if used
- the model variables. The dependent variables for the normalized form equations in the estimation contain residuals, actuals, or predicted values, depending on the _TYPE_ variable, whereas the model variables that are not associated with estimated equations always contain actual values from the input data set.
- any other variables named in the OUTVARS statement. These can be program variables computed by the model program, CONTROL variables, parameters, or special variables in the model program.

The following SAS statements are used to generate and print an OUT= data set:

```
proc model data=gmm2;
  exogenous x1 x2;
  parms a1 a2 b2 b1 2.5 c2 55 d1;
  inst b1 b2 c2 x1 x2;
  y1 = a1 * y2 + b1 * x1 * x1 + d1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;
  fit y1 y2 / 3sls gmm out=resid outall ;
run;

proc print data=resid(obs=20);
run;
```

The data set GMM2 was generated by the example in the preceding ESTDATA= section above. A partial listing of the RESID data set is shown in Figure 19.69.

OUTEST= Data Set

The OUTEST= data set contains parameter estimates and, if requested, estimates of the covariance of the parameter estimates.

The variables in the data set are as follows:

- **BY variables**
- **_NAME_**, a character variable of length 32, blank for observations that contain parameter estimates or a parameter name for observations that contain covariances
- **_TYPE_**, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, ITSUR, IT2SLS, IT3SLS, GMM, ITGMM, or FIML
- **_STATUS_**, variable that gives the convergence status of estimation. _STATUS_ = 0 when convergence criteria are met, = 1 when estimation converges with a note, = 2 when estimation converges with a warning, and = 3 when estimation fails to converge
- **_NUSED_**, the number of observations used in estimation
- the parameters estimated

If the COVOUT option is specified, an additional observation is written for each row of the estimate of the covariance matrix of parameter estimates, with the _NAME_ values that contain the parameter names for the rows. Parameter names longer than 32 characters are truncated.
**OUTPARMS= Data Set**

The option OUTPARMS= writes all the parameter estimates to an output data set. This output data set contains one observation and is similar to the OUTEST= data set, but it contains all the parameters, is not associated with any FIT task, and contains no covariances. The OUTPARMS= option is used in the PROC MODEL statement, and the data set is written at the end, after any FIT or SOLVE steps have been performed.

**OUTS= Data Set**

The OUTS= SAS data set contains the estimate of the covariance matrix of the residuals across equations. This matrix is formed from the residuals that are computed by using the parameter estimates.

The variables in the OUTS= data set are as follows:

- **BY variables**
- 
  _NAME_, a character variable that contains the name of the equation
- 
  _TYPE_, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, ITSUR, IT2SLS, IT3SLS, GMM, ITGMM, or FIML
- 
  variables with the names of the equations in the estimation

Each observation contains a row of the covariance matrix. The data set is suitable for use with the SDATA= option in a subsequent FIT or SOLVE statement. (See the section “Tests on Parameters” on page 1186 in this chapter for an example of the SDATA= option.)

**OUTSUSED= Data Set**

The OUTSUSED= SAS data set contains the covariance matrix of the residuals across equations that is used to define the objective function. The form of the OUTSUSED= data set is the same as that for the OUTS= data set.

Note that OUTSUSED= is the same as OUTS= for the estimation methods that iterate the S matrix (ITOLS, IT2SLS, ITSUR, and IT3SLS). If the SDATA= option is specified in the FIT statement, OUTSUSED= is the same as the SDATA= matrix read in for the methods that do not iterate the S matrix (OLS, SUR, N2SLS, and N3SLS).

**OUTV= Data Set**

The OUTV= data set contains the estimate of the variance matrix, V. This matrix is formed from the instruments and the residuals that are computed by using the final parameter estimates obtained from the estimation method chosen.

An estimate of V obtained from 2SLS is used in GMM estimation. Hence if you input the dataset obtained from the OUTV statement in 2SLS into the VDATA statement while fitting GMM, you get the same result by fitting GMM directly without specifying the VDATA option.
### ODS Table Names

PROC MODEL assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

#### Table 19.4 ODS Tables Produced in PROC MODEL

The AugGMMCovariance table is the $V$ matrix augmented with the moment vector at iteration zero, produced when the ITALL option is used with the GMM option. If the $V$ matrix to be used in GMM is read in by the VDATA option, then AugGMMCovariance would be the same matrix augmented with the moment vectors. The GMMCovariance ODS output is produced only when you read in a covariance matrix to be used in the GMM method. This table is produced by using DETAILS option with the GMM option.

### ODS Graphics

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the MODEL procedure.

### ODS Graph Names

PROC MODEL assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when you use ODS. The names are listed in Table 19.5.

To request these graphs, ODS Graphics must be enabled.

The solution, given the vector \( k \), of the following nonlinear system of equations is the vector \( u \) that satisfies this equation:

\[
q(u, k, \theta) = 0
\]

A simulation is a set of solutions \( u_t \) for a specific sequence of vectors \( k_t \).

Model simulation can be performed to do the following:

- check how well the model predicts the actual values over the historical period
- investigate the sensitivity of the solution to changes in the input values or parameters
- examine the dynamic characteristics of the model
- check the stability of the simultaneous solution
- estimate the statistical distribution of the predicted values of the nonlinear model using Monte Carlo methods

By combining the various solution modes with different input data sets, model simulation can answer many different questions about the model. This section presents details of model simulation and solution.

### Solution Modes

The following solution modes are commonly used:

- The *dynamic simultaneous forecast* mode is used for forecasting with the model. Collect the historical data on the model variables, the future assumptions of the exogenous variables, and any prior information on the future endogenous values, and combine them in a SAS data set. Use the FORECAST option in the SOLVE statement.

- The *dynamic simultaneous simulation* mode is often called *ex post simulation*, *historical simulation*, or *ex post forecasting*. Use the DYNAMIC option. This mode is the default.

- The *static simultaneous simulation* mode can be used to examine the within-period performance of the model without the complications of previous period errors. Use the STATIC option.

- The *NAHEAD= n* dynamic simultaneous simulation mode can be used to see how well \( n \)-period-ahead forecasting would have performed over the historical period. Use the NAHEAD= \( n \) option.

The different solution modes are explained in detail in the following sections.
Dynamic and Static Simulations

In model simulation, either solved values or actual values from the data set can be used to supply lagged values of an endogenous variable. A dynamic solution refers to a solution obtained by using only solved values for the lagged values. Dynamic mode is used both for forecasting and for simulating the dynamic properties of the model.

A static solution refers to a solution obtained by using the actual values when available for the lagged endogenous values. Static mode is used to simulate the behavior of the model without the complication of previous period errors. Dynamic simulation is the default.

If you want to use static values for lags only for the first \( n \) observations, and dynamic values thereafter, specify the START=\( n \) option. For example, if you want a dynamic simulation to start after observation twenty-four, specify START=24 on the SOLVE statement. If the model being simulated had a value lagged for four time periods, then this value would start using dynamic values when the simulation reached observation number 28.

\( n \)-Period-Ahead Forecasting

Suppose you want to regularly forecast 12 months ahead and produce a new forecast each month as more data becomes available. \( n \)-period-ahead forecasting allows you to test how well you would have done over time if you had been using your model to forecast one year ahead.

To see how well a model predicts \( n \) time periods in the future, perform an \( n \)-period-ahead forecast on real data and compare the forecast values with the actual values.

\( n \)-period-ahead forecasting refers to using dynamic values for the lagged endogenous variables only for lags \( 1 \) through \( n-1 \). For example, one-period-ahead forecasting, specified by the NAHEAD=1 option in the SOLVE statement, is the same as if a static solution had been requested. Specifying NAHEAD=2 produces a solution that uses dynamic values for lag one and static, actual, values for longer lags.

The following example is a two-year-ahead dynamic simulation. The output is shown in Figure 19.70.

```plaintext
data yearly;
  input year x1 x2 x3 y1 y2 y3;

</table>
The preceding two-year-ahead simulation can be emulated without using the NAHEAD= option by the following PROC MODEL statements:

```plaintext
proc model data=yearly model=yearlyModel;
    range year = 87 to 88;
    solve y1 y2 y3 / dynamic solveprint;
run;

    range year = 88 to 89;
    solve y1 y2 y3 / dynamic solveprint;
run;

    range year = 89 to 90;
    solve y1 y2 y3 / dynamic solveprint;
run;

    range year = 90 to 91;
    solve y1 y2 y3 / dynamic solveprint;
run;
```

The totals shown under “Observations Processed” in Figure 19.70 are equal to the sum of the four individual runs.

Simulation and Forecasting

You can perform a simulation of your model or use the model to produce forecasts. Simulation refers to the determination of the endogenous or dependent variables as a function of the input values of the other variables, even when actual data for some of the solution variables are available in the input data set. The simulation mode is useful for verifying the fit of the model parameters. Simulation is selected by the SIMULATE option in the SOLVE statement. Simulation mode is the default.

In forecast mode, PROC MODEL solves only for those endogenous variables that are missing in the data set. The actual value of an endogenous variable is used as the solution value whenever nonmissing data for it is available in the input data set. Forecasting is selected by the FORECAST option in the SOLVE statement.

For example, an econometric forecasting model can contain an equation to predict future tax rates, but tax rates are usually set in advance by law. Thus, for the first year or so of the forecast, the predicted tax rate should really be exogenous. Or, you might want to use a prior forecast of a certain variable from a short-run forecasting model to provide the predicted values for the earlier periods of a longer-range forecast of a long-run model. A common situation in forecasting is when historical data needed to fill the initial lags of a dynamic model are available for some of the variables but have not yet been obtained for others. In this case, the forecast must start in the past to supply the missing initial lags. Clearly, you should use the actual data that are available for the lags. In all the preceding cases, the forecast should be produced by running the model in the FORECAST mode; simulating the model over the future periods would not be appropriate.

Monte Carlo Simulation

The accuracy of the forecasts produced by PROC MODEL depends on four sources of error (Pindyck and Rubinfeld 1981, pp. 405–406):

- The system of equations contains an implicit random error term \( \epsilon \)
  \[
  g(y, x, \hat{\theta}) = \epsilon
  \]
  where \( y, x, g, \hat{\theta}, \) and \( \epsilon \) are vector valued.
The estimated values of the parameters, \( \hat{\theta} \), are themselves random variables.

The exogenous variables might have been forecast themselves and therefore might contain errors.

The system of equations might be incorrectly specified; the model only approximates the process modeled.

The `RANDOM=` option is used to request Monte Carlo (or stochastic) simulations to generate confidence intervals for errors that arise from the first two sources. The Monte Carlo simulations can be performed with \( \epsilon, \theta \), or both vectors represented as random variables. The `SEED=` option is used to control the random number generator for the simulations. `SEED=0` forces the random number generator to use the system clock as its seed value.

In Monte Carlo simulations, repeated simulations are performed on the model for random perturbations of the parameters and the additive error term. The random perturbations follow a multivariate normal distribution with expected value of 0 and covariance described by a covariance matrix of the parameter estimates in the case of \( \theta \), or a covariance matrix of the equation residuals for the case of \( \epsilon \). `PROC MODEL` can generate both covariance matrices or you can provide them.

The `ESTDATA=` option specifies a data set that contains an estimate of the covariance matrix of the parameter estimates to use for computing perturbations of the parameters. The `ESTDATA=` data set is usually created by the `FIT` statement with the `OUTEST=` and `OUTCOV` options. When the `ESTDATA=` option is specified, the matrix read from the `ESTDATA=` data set is used to compute vectors of random shocks or perturbations for the parameters. These random perturbations are computed at the start of each repetition of the solution and added to the parameter values. The perturbed parameters are fixed throughout the solution range. If the covariance matrix of the parameter estimates is not provided, the parameters are not perturbed.

The `SDATA=` option specifies a data set that contains the covariance matrix of the residuals to use for computing perturbations of the equations. The `SDATA=` data set is usually created by the `FIT` statement with the `OUTS=` option. When `SDATA=` is specified, the matrix read from the `SDATA=` data set is used to compute vectors of random shocks or perturbations for the equations. These random perturbations are computed at each observation. The simultaneous solution satisfies the model equations plus the random shocks. That is, the solution is not a perturbation of a simultaneous solution of the structural equations; rather, it is a simultaneous solution of the stochastic equations by using the simulated errors. If the `SDATA=` option is not specified, the random shocks are not used.

The different random solutions are identified by the `_REP_` variable in the `OUT=` data set. An unperturbed solution with `_REP_=0` is also computed when the `RANDOM=` option is used. `RANDOM=n` produces \( n + 1 \) solution observations for each input observation in the solution range. If the `RANDOM=` option is not specified, the `SDATA=` and `ESTDATA=` options are ignored, and no Monte Carlo simulation is performed.

`PROC MODEL` does not have an automatic way of modeling the exogenous variables as random variables for Monte Carlo simulation. If the exogenous variables have been forecast, the error bounds for these variables should be included in the error bounds generated for the endogenous variables. If the models for the exogenous variables are included in `PROC MODEL`, then the error bounds created from a Monte Carlo simulation contain the uncertainty due to the exogenous variables.

Alternatively, if the distribution of the exogenous variables is known, the built-in random number generator functions can be used to perturb these variables appropriately for the Monte Carlo simulation. For example, if you know the forecast of an exogenous variable, \( X \), has a standard error of 5.2 and the error is normally distributed, then the following statements can be used to generate random values for \( X \):
During a Monte Carlo simulation, the random number generator functions produce one value at each observation. It is important to use a different seed value for all the random number generator functions in the model program; otherwise, the perturbations will be correlated. For the unperturbed solution, \(_\text{REP}_-\text{=}0\), the random number generator functions return 0.

PROC UNIVARIATE can be used to create confidence intervals for the simulation (see the Monte Carlo simulation example in the section “Getting Started: MODEL Procedure” on page 1058).

### Multivariate \(t\) Distribution Simulation

To perform a Monte Carlo analysis of models that have residuals distributed as a multivariate \(t\), use the `ERRORMODEL` statement with either the \(\sim t(\text{variance, df})\) option or with the \(\text{CDF}= t(\text{variance, df})\) option. The `CDF=` option specifies the distribution that is used for simulation so that the estimation can be done for one set of distributional assumptions and the simulation for another.

The following is an example of estimating and simulating a system of equations with \(t\) distributed errors by using the `ERRORMODEL` statement.

```sas
/* generate simulation data set */
data five;
	set xfrate end=last;
	if last then do;
	
todate = date +5;
	
do date = date to todate;
	
toutput;
	end;
end;
run;
```

The preceding DATA step generates the data set to request a five-days-ahead forecast. The following statements estimate and forecast the three forward-rate models of the following form.

\[
\begin{align*}
rate_t &= rate_{t-1} + \mu \cdot rate_{t-1} + \nu \\
\nu &= \sigma \cdot rate_{t-1} \cdot \epsilon \\
\epsilon &\sim \text{N}(0, 1)
\end{align*}
\]
title "Daily Multivariate Geometric Brownian Motion Model "
"of D-Mark/USDollar Forward Rates"

proc model data=xfrate;

   parms df 15;    /* Give initial value to df */
   demusd1m = lag(demusd1m) + mu1m * lag(demusd1m);
   var_demusd1m = sigma1m ** 2 * lag(demusd1m **2);
   demusd3m = lag(demusd3m) + mu3m * lag(demusd3m);
   var_demusd3m = sigma3m ** 2 * lag(demusd3m ** 2);
   demusd6m = lag(demusd6m) + mu6m * lag(demusd6m);
   var_demusd6m = sigma6m ** 2 * lag(demusd6m ** 2);

   /* Specify the error distribution */
   errormodel demusd1m demusd3m demusd6m
       ~ t( var_demusd1m var_demusd3m var_demusd6m, df );

   /* output normalized S matrix */
   fit demusd1m demusd3m demusd6m / outsn=s;
   run;
   /* forecast five days in advance */
   solve demusd1m demusd3m demusd6m /
       data=five sdata=s random=1500 out=monte;
   id date;
   run;

   /* select out the last date ---*/
   data monte; set monte;
   if date = '10dec95'd then output;
   run;

   title "Distribution of demusd1m Five Days Ahead";
   proc univariate data=monte noprint;
   var demusd1m;
   histogram demusd1m /
       normal(noprint color=red)
       kernel(noprint color=blue) cfill=ligr;
   run;

The Monte Carlo simulation specified in the preceding example draws from a multivariate \( t \) distribution with constant degrees of freedom and forecasted variance, and it computes future states of DEMUSD1M, DEMUSD3M, and DEMUSD6M. The OUTSN= option in the FIT statement is used to specify the data set for the normalized \( \Sigma \) matrix. That is, the \( \Sigma \) matrix is created by crossing the normally distributed residuals. The normally distributed residuals are created from the \( t \) distributed residuals by using the normal inverse CDF and the \( t \) CDF. This matrix is a correlation matrix.

The distribution of DEMUSD1M on the fifth day is shown in the Figure 19.72. The two curves overlaid on the graph are a kernel density estimation and a normal distribution fit to the results.
Alternate Distribution Simulation

As an alternate to the normal distribution, the ERRORMODEL statement can be used in a simulation to specify other distributions. The distributions available for simulation are Cauchy, chi-squared, $F$, Poisson, $t$, and uniform. An empirical distribution can also be used if the residuals are specified by using the RESIDDATA= option in the SOLVE statement.

Except for the $t$ distribution, all of these alternate distributions are univariate but can be used together in a multivariate simulation. The ERRORMODEL statement applies to solved for equations only. That is, the normal form or general form equation referred to by the ERRORMODEL statement must be one of the equations you have selected in the SOLVE statement.
In the following example, two Poisson distributed variables are used to simulate the calls that arrive at and leave a call center.

```plaintext
data s;  /* Covariance between arriving and leaving */
   arriving = 1; leaving = 0.7; _name_ = "arriving";
   output;
   arriving = 0.7; leaving = 1.0; _name_ = "leaving";
   output;
run;

data calls;
   date = '20mar2001'd;
   output;
run;
```

The first DATA step generates a data set that contains a covariance matrix for the ARRIVING and LEAVING variables. The covariance is

```
|   1   .7 |
| .7  1 |
```

The following statements create the number of waiting clients data:

```plaintext
proc model data=calls;
   arriving = 0;
   errormodel arriving ~ poisson( 10 );
   leaving = 4;
   errormodel leaving ~ poisson( 11 );

   waiting = arriving - leaving;

The distribution of number of waiting clients is shown in Figure 19.73.
Mixtures of Distributions—Copulas

The theory of copulas is what enables the MODEL procedure to combine and simulate multivariate distributions with different marginals. This section provides a brief overview of copulas.

Modeling a system of variables accurately is a difficult task. The underlying, ideal, distributional assumptions for each variable are usually different from each other. An individual variable might be best modeled as a $t$ distribution or as a Poisson process. The correlation of the various variables are very important to estimate as well. A joint estimation of a set of variables would make it possible to estimate a correlation structure but would restrict the modeling to single, simple multivariate distribution (for example, the normal). Even with a simple multivariate distribution, the joint estimation would be computationally difficult and would have to deal with issues of missing data.

By using the MODEL procedure ERRORMODEL statement, you can combine and simulate from models of different distributions. The covariance matrix for the combined model is constructed by using the copula induced by the multivariate normal distribution. A copula is a function that couples joint distributions to their marginal distributions.
By default, the copula used in the MODEL procedure is based on the multivariate normal. This particular multivariate normal has zero mean and covariance matrix $R$. The user provides $R$, which can be created by using the following steps:

1. Each model is estimated separately and their residuals are saved.
2. The residuals for each model are converted to a normal distribution by using their CDFs, $F_i(.)$, using the relationship $\Phi^{-1}(F(\epsilon_{it}))$.
3. These normal residuals are crossed to create a covariance matrix $R$.

If the model of interest can be estimated jointly, such as multivariate T, then the OUTSN= option can be used to generate the correct covariance matrix.

A draw from this mixture of distributions is created by using the following steps that are performed automatically by the MODEL procedure.

1. Independent $N(0, 1)$ variables are generated.
2. These variables are transformed to a correlated set by using the covariance matrix $R$.
3. These correlated normals are transformed to a uniform by using $\Phi(.)$.
4. $F^{-1}()$ is used to compute the final sample value.

**Alternate Copulas**

The Gaussian, $t$, and the normal mixture copula are available in the MODEL procedure. These copulas support asymmetric parameters and can use alternate estimation methods for creating the base covariance matrix.

The normal (Gaussian) copula is the default. A draw from a Gaussian copula is obtained from

$$x = Az$$

where $z \in R^d$ is a vector of independent random normal$(0, 1)$ draws, $A \in R^{d \times d}$ is the square root of the covariance matrix, $R$. For the normal mixture and $t$ copula, a draw is created as

$$x = w\gamma + \sqrt{w}Az$$

where $w$ is a scalar random variable and $\gamma \in R^d$ is a vector of asymmetry parameters. $\gamma$ is specified in the SDATA= data set. If $W \sim$ inverse gamma$(df/2, df/2)$, then $x$ is multivariate $t$ or skewed $t$ if $\gamma$ is provided. When NORMALMIX is specified, $w$ is distributed as a step function with each of the $n$ positive variances, $v_1 \ldots v_n$, having probability $p_1 \ldots p_n$.

The covariance matrix $R = A'A$ is specified with the SDATA= option. The vector of asymmetry parameters, $\gamma$, defaults to zero or is specified in the SDATA= data set with _TYPE_=ASYM. The ASYM option specifies that the nonzero asymmetry vector, $\gamma$, is to be used.

In the event the covariance matrix specified with the SDATA= option is not positive semidefinite the matrix is modified to be positive semidefinite. See Rebonato and Jäckel (1999) for more details.
The actual draw for an individual variable, \( y_i \), depends on the marginal distribution of the variable, \( \tilde{F} \), and the chosen copula \( F \) as
\[
y_i = \tilde{F}_i^{-1} (F(x_i))
\]

**Archimedean Copulas**

The three Archimedean copulas available in the MODEL procedure are the Clayton, Gumbel, and Frank copulas. Archimedean copulas require only a single parameter, \( \theta \), to define the joint distribution’s covariance structure for a simulation problem. Therefore, a covariance matrix is not required to perform simulations that use Archimedean copulas, and the SDATA= option does not have to be specified for these simulations. For more information about Archimedean copulas, including the functional forms of the Clayton, Gumbel, and Frank copulas, see the section “Archimedean Copulas” in Chapter 10, “The COPULA Procedure.”

**Asymmetrical Copula Example**

In this example, an asymmetrical \( t \) copula is used to correlate two uniform distributions. The asymmetrical parameter is varied over a range of values to demonstrate its effect. The resulting graphs is produced by using ODS graphics.

```sas
data histdata;
  do asym = -1.3 to 1.1 by .3;
    date='01aug2007'd;
    y = .5;
    z = .5;
    output;
  end;
run;

/* Add the asymmetric parameter to cov mat */
data asym;
  do asym = -1.3 to 1.1 by .3;
    y = asym;
    z = 0;
    _name_ = ""
    _type_ = "asym";
    output;
    y = 1;
    z = .65;
    _name_ = "y"
    _type_ = "cov";
    output;
    y = .65;
    z = 1;
    _name_ = "z"
    _type_ = "cov";
    output;
  end;
run;
```
proc model out=sim(where=_REP_ > 0) data=histdata sdata=asym;
  y = 0;
  errormodel y ~ Uniform(0,1);

  z = 0;
  errormodel z ~ Uniform(0,1);

  solve y z / random=500 seed=12345 copula=(t(5) asym);
  by asym;
run;

To produce a panel plot of this joint distribution, use the following SAS/GRAPH statements.

ods graphics on / height=800 width=800;
proc template;
  define statgraph myplot.panel;
  BeginGraph;
    entrytitle halign=left halign=center
      textattrs=GRAPHTITLETEXT "t Copula with a Range of Asymmetry";

    layout datapanel classvars=(asym) / rows=3 columns=3
      order=rowmajor height=1024 width=1420
      rowaxisopts=(griddisplay=on label=' ')
      columnaxisopts=(griddisplay=on label=' ');
    layout prototype;
      scatterplot x=z y=y ;
    endlayout;
  endlayout;
EndGraph;
end;
run;

proc sgrender data=sim template='myplot.panel';
run;
Quasi-Random Number Generators

Traditionally high-discrepancy pseudo-random number generators are used to generate innovations in Monte Carlo simulations. Loosely translated, a high-discrepancy pseudo-random number generator is one in which there is very little correlation between the current number generated and the past numbers generated. This property is ideal if indeed independence of the innovations is required. If, on the other hand, the efficient spanning of a multidimensional space is desired, a low discrepancy, quasi-random number generator can be used. A quasi-random number generator produces numbers that have no random component.
A simple one-dimensional quasi-random sequence is the van der Corput sequence. Given a prime number $r \ (r \geq 2)$, any integer has a unique representation in terms of base $r$. A number in the interval $[0,1)$ can be created by inverting the representation base power by base power. For example, consider $r=3$ and $n=1$, $1$ in base $3$ is

$$1_{10} = 1 \cdot 3^0 = 1_3$$

When the powers of $3$ are inverted,

$$\phi(1) = \frac{1}{3}$$

Also, $11$ in base $3$ is

$$11_{10} = 1 \cdot 3^2 + 2 \cdot 3^0 = 102_3$$

When the powers of $3$ are inverted,

$$\phi(11) = \frac{1}{9} + 2 \cdot \frac{1}{3} = \frac{7}{9}$$

The first 10 numbers in this sequence $\phi(1) \ldots \phi(10)$ are provided below

$$0, \frac{1}{3}, \frac{2}{3}, \frac{1}{9}, \frac{4}{9}, \frac{7}{9}, \frac{2}{27}, \frac{5}{27}, \frac{8}{27}, \frac{1}{27}$$

As the sequence proceeds, it fills in the gaps in a uniform fashion.

Several authors have expanded this idea to many dimensions. Two versions supported by the MODEL procedure are the Sobol sequence (QUASI=SOBOL) and the Faure sequence (QUASI=FAURE). The Sobol sequence is based on binary numbers and is generally computationally faster than the Faure sequence. The Faure sequence uses the dimensionality of the problem to determine the number base to use to generate the sequence. The Faure sequence has better distributional properties than the Sobol sequence for dimensions greater than 8.

As an example of the difference between a pseudo-random number and a quasi-random number, consider simulating a bivariate normal with 100 draws.
Figure 19.75  Kernel Density of a Bivariate Normal produced by 100 Faure-Random Draws
The following SAS statements dynamically forecast the solution to a nonlinear equation:

```sas
proc model data=sashelp.citimon;
    parameters a 0.010708  b -0.478849  c 0.929304;
    lhur = 1/(a * ip) + b + c * lag(lhur);
    solve lhur / out=sim forecast dynamic;
run;
```

The first page of output produced by the SOLVE step is shown in Figure 19.77. This is the summary description of the model. The error message states that the simulation was aborted at observation 144 because of missing input values.

Variables Solved For LHUR  

This solution summary table includes the names of the input data set and the output data set followed by a description of the model. The table also indicates that the solution method defaulted to Newton’s method. The remaining output is defined as follows.
Maximum CC is the maximum convergence value accepted by the Newton procedure. This number is always less than the value for the CONVERGE= option.

Maximum Iterations is the maximum number of Newton iterations performed at each observation and each replication of Monte Carlo simulations.

Total Iterations is the sum of the number of iterations required for each observation and each Monte Carlo simulation.

Average Iterations is the average number of Newton iterations required to solve the system at each step.

Solved is the number of observations used times the number of random replications selected plus one, for Monte Carlo simulations. The one additional simulation is the original unperturbed solution. For simulations that do not involve Monte Carlo, this number is the number of observations used.

Summary Statistics

The STATS and THEIL options are used to select goodness-of-fit statistics. Actual values must be provided in the input data set for these statistics to be printed. When the RANDOM= option is specified, the statistics do not include the unperturbed (_REP_=0) solution.

**STATS Option Output**

The following statements show the addition of the STATS and THEIL options to the model in the previous section:

```plaintext
proc model data=sashelp.citimon;
  parameters a 0.010708  b -0.478849  c 0.929304;
  lhur= 1/(a * ip) + b + c * lag(lhur) ;
  solve lhur / out=sim dynamic stats theil;
  range date to '01nov91'd;
run;
```

The STAT OUTPUT in Figure 19.80 and the THEIL output in Figure 19.81 are generated.

  \]

- **\(\hat{y}\)**
  predicted value

- **\(y\)**
  actual value

When the `RANDOM=` option is specified, the statistics do not include the unperturbed (_REP_=0) solution.
THEIL Option Output
The THEIL option specifies that Theil forecast error statistics be computed for the actual and predicted values and for the relative changes from lagged values. Mathematically, the quantities are

\[ \hat{y}c = (\hat{y} - lag(y))/lag(y) \]
\[ yc = (y - lag(y))/lag(y) \]

where \( \hat{y}c \) is the relative change for the predicted value and \( yc \) is the relative change for the actual value.

</tbody>
</table>
Bias (UM) is an indication of systematic error and measures the extent to which the average values of the actual and predicted deviate from each other.

\[
\frac{(E(y) - E(\hat{y}))^2}{\frac{1}{N} \sum_{t=1}^{N} (y_t - \hat{y}_t)^2}
\]

Reg (UR) is defined as \((\sigma_p - \rho \cdot \sigma_a)^2 / \text{MSE}\). Consider the regression

\[y = \alpha + \beta \hat{y}\]

If \(\hat{\beta} = 1\), UR will equal zero.

Dist (UD) is defined as \((1 - \rho^2)\sigma_a^2 / \text{MSE}\) and represents the variance of the residuals obtained by regressing \(y_c\) on \(\hat{y}_c\).

Var (US) is the variance proportion. US indicates the ability of the model to replicate the degree of variability in the endogenous variable.

\[
US = \frac{(\sigma_p - \sigma_a)^2}{\text{MSE}}
\]

Covar (UC) represents the remaining error after deviations from average values and average variabilities have been accounted for.

\[
UC = \frac{2(1 - \rho)\sigma_p \sigma_a}{\text{MSE}}
\]

U1 is a statistic that measures the accuracy of a forecast defined as follows:

\[
U1 = \frac{\sqrt{\text{MSE}}}{\sqrt{\frac{1}{N} \sum_{t=1}^{N} (y_t)^2}}
\]

U is the Theil’s inequality coefficient defined as follows:

\[
U = \frac{\sqrt{\text{MSE}}}{\sqrt{\frac{1}{N} \sum_{t=1}^{N} (y_t)^2} + \sqrt{\frac{1}{N} \sum_{t=1}^{N} (\hat{y}_t)^2}}
\]

MSE is the mean square error. In the case of the relative change Theil statistics, the MSE is computed as follows:

\[
\text{MSE} = \frac{1}{N} \sum_{t=1}^{N} (\hat{y}_c - y_c)^2
\]

More information about these statistics can be found in the references Maddala (1977, pp. 344–347) and Pindyck and Rubinfeld (1981, pp. 364–365).
**Goal Seeking: Solving for Right-Hand-Side Variables**

The process of computing input values that are needed to produce target results is often called *goal seeking*. To compute a goal-seeking solution, use a SOLVE statement that lists the variables you want to solve for and provide a data set that contains values for the remaining variables.

Consider the following demand model for packaged rice

\[
\text{quantity demanded} = \alpha_1 + \alpha_2 \text{price}^{2/3} + \alpha_3 \text{income}
\]

where *price* is the price of the package and *income* is disposable personal income. The only variable the company has control over is the price it charges for rice. This model is estimated by using the following simulated data and PROC MODEL statements:

```sas
data demand;
  do t=1 to 40;
    price = (rannor(10) +5) * 10;
    income = 8000 * t ** (1/8);
    demand = 7200 - 1054 * price ** (2/3) + 7 * income + 100 * rannor(1);
    output;
  end;
run;

data goal;
  demand = 85000;
  income = 12686;
run;
```

The goal is to find the price the company would have to charge to meet a sales target of 85,000 units. To do this, a data set is created with a DEMAND variable set to 85000 and with an INCOME variable set to 12686, the last income value.

The desired price is then determined by using the following PROC MODEL statements:

```sas
proc model data=demand
  outmodel=demandModel;
  demand = a1 - a2 * price ** (2/3) + a3 * income;
  fit demand / outest=demest;
  solve price / estdata=demest data=goal solveprint;
run;
```

The SOLVEPRINT option prints the solution values, number of iterations, and final residuals at each observation. The SOLVEPRINT output from this solve is shown in *Figure 19.82*.

*Figure 19.82*  Goal Seeking, SOLVEPRINT Output

<table>
<thead>
<tr>
<th>Observation</th>
<th>Iterations</th>
<th>CC</th>
<th>ERROR.demand</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>6</td>
<td>0.000000</td>
<td>0.000000</td>
</tr>
</tbody>
</table>
The output indicates that it took six Newton iterations to determine the PRICE of 33.5902, which makes the DEMAND value within 16E–11 of the goal of 85,000 units.

Consider a more ambitious goal of 100,000 units. The output shown in Figure 19.83 indicates that the sales target of 100,000 units is not attainable according to this model.

data goal;
  demand = 100000;
  income = 12686;
run;

proc model model=demandModel;
  solve price / estdata=demest data=goal solveprint;
run;

The program data vector with the error note indicates that even after 10 subiterations, the norm of the residuals could not be reduced. The sales target of 100,000 units are unattainable with the given model. You might need to reformulate your model or collect more data to more accurately reflect the market response.
Numerical Solution Methods

If the SINGLE option is not used, PROC MODEL computes values that simultaneously satisfy the model equations for the variables named in the SOLVE statement. PROC MODEL provides three iterative methods, Newton, Jacobi, and Seidel, for computing a simultaneous solution of the system of nonlinear equations.

Single-Equation Solution

For normalized form equation systems, the solution either can simultaneously satisfy all the equations or can be computed for each equation separately, by using the actual values of the solution variables in the current period to compute each predicted value. By default, PROC MODEL computes a simultaneous solution. The SINGLE option in the SOLVE statement selects single-equation solutions.

Single-equation simulations are often used to produce residuals (which estimate the random terms of the stochastic equations) rather than the predicted values themselves. If the input data and range are the same as those used for parameter estimation, a static single-equation simulation reproduces the residuals of the estimation.

Newton’s Method

The NEWTON option in the SOLVE statement requests Newton’s method to simultaneously solve the equations for each observation. Newton’s method is the default solution method. Newton’s method is an iterative scheme that uses the derivatives of the equations with respect to the solution variables, \( \mathbf{J} \), to compute a change vector as
\[
\Delta y^i = \mathbf{J}^{-1} q(y^i, x, \theta)
\]

PROC MODEL builds and solves \( \mathbf{J} \) by using efficient sparse matrix techniques. The solution variables \( y^i \) at the \( i \)th iteration are then updated as
\[
y^{i+1} = y^i + d \times \Delta y^i
\]
where \( d \) is a damping factor between 0 and 1 chosen iteratively so that
\[
\|q(y^{i+1}, x, \theta)\| < \|q(y^i, x, \theta)\|
\]
The number of subiterations that are allowed for finding a suitable \( d \) is controlled by the MAXSUBITER= option. The number of iterations of Newton’s method that are allowed for each observation is controlled by MAXITER= option. See Ortega and Rheinbolt (1970) for more details.

Optimization Method

The OPTIMIZE option in the SOLVE statement requests that an optimization algorithm be used to minimize a norm of the errors in equations subject to constraints on the solution variables. The OPTIMIZE method is the only solution method that supports constraints on solution variables that are specified using the BOUNDS and RESTRICT statements. Constraints are ignored by the other solution methods. The OPTIMIZE method performs the following optimization:

\[
\begin{align*}
\text{minimize} & \quad \| q(y, x, \theta) \| \\
\text{subject to} & \quad y_l \leq y \leq y_u \\
& \quad f(y) \geq 0
\end{align*}
\]
The norm used in the minimization process is
\[ \|q(y, x, \theta)\| = q(y, x, \theta)' \text{diag}(S)^{-1}q(y, x, \theta) \]

where the S matrix is the covariance of equation errors that is specified by the SDATA= option in the SOLVE statement. If no SDATA= option is specified, the identity matrix is used. Both strict inequality and inequality constraints on the solution variables can be imposed using the BOUNDS or RESTRICT statement. For bounded problems, each lower and upper strict inequality is transformed into an inequality by using the equations
\[
y_l = (y_{\text{lower strict}} + \epsilon)/(1 - \epsilon) \\
y_u = (y_{\text{upper strict}} - \epsilon)/(1 + \epsilon)
\]

When strict inequality expressions are imposed using the RESTRICT statement, these expressions are transformed into an inequality by using the equation
\[ f(y) = (f_{\text{strict}}(y) + \epsilon)/(1 - \epsilon) \]

where \( f_{\text{strict}}(y) \) is a nonlinear strict inequality constraint. The tolerance \( \epsilon \) is controlled by the EPSILON= option in the SOLVE statement and defaults to \( 10^{-8} \). To achieve the best performance from the minimization algorithm, both the first and second analytic derivatives of the equation errors with respect to the solution variables are used to compute the gradient and second derivatives of the objective function, \( \|q(y, x, \theta)\| \). Analytic derivatives of the restriction expressions that are used to specify constraints are also used in the minimization. The gradient of the objective function is
\[
\nabla \|q(y, x, \theta)\| = 2 J' \text{diag}(S)^{-1}q(y, x, \theta)
\]
The matrix of second derivatives of the objective function with respect to the solution variables is
\[
\frac{\partial^2 \|q(y, x, \theta)\|}{\partial y^2} = 2 \left( J' \text{diag}(S)^{-1}J + \sum_{k=1}^{d} \frac{\partial^2 q_k(y, x, \theta)}{\partial y^2} \text{diag}(S)^{-1}q_k(y, x, \theta) \right)
\]

where \( d \) is the number of equations.

The algorithm that is used to find a minimum of \( \|q(y, x, \theta)\| \) subject to bounds on the solution variables employs the interior point technique for nonlinear optimization problems. For further information about this optimization method, see Chapter 9, “The Nonlinear Programming Solver” (SAS/OR User’s Guide: Mathematical Programming).

When constraints are active in a solution, the minimum value of the objective function, \( \|q(y, x, \theta)\| \), is typically greater than 0. The diagnostic quantities that are produced by the OUTOBJVALS and OUTVIOLATIONS options are available to help identify and characterize solutions that have active bounds constraints. The following program contains a boundary constraint that becomes active in steps 6, 8, 10, 12, 13, and 16 of a Monte Carlo simulation:
Chapter 19: The MODEL Procedure

```sas
proc model data=d sdata=s;
  dependent rate stock;
  parms theta 0.2
    kappa 0.002
    sigma 0.4
    sinit 1
    vol .1;
  id i;
  bounds rate >= 0;
  rate = zlag(rate) + kappa*(theta - zlag(rate));
  h.rate = sigma**2 * zlag(rate);
  eq.stock = log(stock/sinit) - (rate + vol*vol/2);
  h.stock = vol**2;
  solve / optimize converge=1e-6 seed=1 random=1 out=o outobjvals outviolations;
quit;
```

```sas
proc print data=o(where=(_objval_>1e-6));
run;
```

Figure 19.84 shows how the OUTOBJVALS option can be used to identify simulation steps with an active bounds constraint, and how the OUTVIOLATIONS option can be used to determine that the RATE equation is not satisfied for those steps.

### Jacobi Method

The JACOBI option in the SOLVE statement selects a matrix-free alternative to Newton’s method. This method is the traditional nonlinear Jacobi method found in the literature. The Jacobi method as implemented in PROC MODEL substitutes predicted values for the endogenous variables and iterates until a fixed point is reached. Then necessary derivatives are computed only for the diagonal elements of the Jacobian, \( J \).
If the normalized form equation is
\[ y = f(y, x, \theta) \]
the Jacobi iteration has the form
\[ y^{i+1} = f(y^i, x, \theta) \]

**Seidel Method**

The Seidel method is an order-dependent alternative to the Jacobi method. You select the Seidel method by specifying the SEIDEL option in the SOLVE statement. The Seidel method is like the Jacobi method, except that in the Seidel method the model is further edited to substitute the predicted values into the solution variables immediately after they are computed. The Seidel method thus differs from the other methods in that the values of the solution variables are not fixed within an iteration. With the other methods, the order of the equations in the model program makes no difference, but the Seidel method might work much differently when the equations are specified in a different sequence. This fixed-point method is the traditional nonlinear Seidel method found in the literature.

The iteration has the form
\[ y^{i+1}_j = f(\hat{y}^i, x, \theta) \]
where \( y^{i+1}_j \) is the \( j \)th equation variable at the \( i \)th iteration and
\[ \hat{y}^i = (y^{i+1}_1, y^{i+1}_2, y^{i+1}_3, \ldots, y^{i+1}_j, y^i_{j+1}, \ldots, y^i_g) \]

If the model is recursive, and if the equations are in recursive order, the Seidel method converges at once. If the model is block-recursive, the Seidel method might converge faster if the equations are grouped by block and the blocks are placed in block-recursive order. The BLOCK option can be used to determine the block-recursive form.

**Jacobi and Seidel Methods with General Form Equations**

Jacobi and Seidel solution methods support general form equations.

There are two cases where derivatives are (automatically) computed. The first case is for equations with the solution variable on the right-hand side and on the left-hand side of the equation
\[ y^i = f(x, y^i) \]
In this case the derivative of ERROR.y with respect to \( y \) is computed, and the new \( y \) approximation is computed as
\[ y^{i+1} = y^i - \frac{f(x, y^i) - y^i}{\partial(f(x, y^i) - y^i)/\partial y} \]

The second case is a system of equations that contains one or more EQ.var equations. In this case, the MODEL procedure assigns a unique solution variable to each equation if such an assignment exists. Use the DETAILS option in the SOLVE statement to print a listing of the assigned variables.
Once the assignment is made, the new $y$ approximation is computed as

$$y^{i+1} = y^i - \frac{f(x, y^i) - y^i}{\partial(f(x, y^i) - y^i)/\partial y}$$

If $k$ is the number of general form equations, then $k$ derivatives are required.

The convergence properties of the Jacobi and Seidel solution methods remain significantly poorer than the default Newton’s method.

**Comparison of Methods**

Newton’s method is the default and should work better than the others for most small- to medium-sized models. The Seidel method is always faster than the Jacobi for recursive models with equations in recursive order. For very large models and some highly nonlinear smaller models, the Jacobi or Seidel methods can sometimes be faster. Newton’s method uses more memory than the Jacobi or Seidel methods.

Both the Newton’s method and the Jacobi method are order-invariant in the sense that the order in which equations are specified in the model program has no effect on the operation of the iterative solution process. In order-invariant methods, the values of the solution variables are fixed for the entire execution of the model program. Assignments to model variables are automatically changed to assignments to corresponding equation variables. Only after the model program has completed execution are the results used to compute the new solution values for the next iteration.

**Troubleshooting Problems**

In solving a simultaneous nonlinear dynamic model you might encounter some of the following problems.

* **Missing Values**
  For SOLVE tasks, there can be no missing parameter values. Missing right-hand-side variables result in missing left-hand-side variables for that observation.

* **Unstable Solutions**
  A solution might exist but be unstable. An unstable system can cause the Jacobi and Seidel methods to diverge.

* **Explosive Dynamic Systems**
  A model might have well-behaved solutions at each observation but be dynamically unstable. The solution might oscillate wildly or grow rapidly with time.

* **Propagation of Errors**
  During the solution process, solution variables can take on values that cause computational errors. For example, a solution variable that appears in a LOG function might be positive at the solution but might be given a negative value during one of the iterations. When computational errors occur, missing values are generated and propagated, and the solution process might collapse.
Convergence Problems

The following items can cause convergence problems:

- There are illegal function values (for example, \( \sqrt{-1} \)).
- There are local minima in the model equation.
- No solution exists.
- Multiple solutions exist.
- Initial values are too far from the solution.
- The CONVERGE= value is too small.

When PROC MODEL fails to find a solution to the system, the current iteration information and the program data vector are printed. The simulation halts if actual values are not available for the simulation to proceed. Consider the following program, which produces the output shown in Figure 19.85:

```plaintext
data test1;
  do t=1 to 50;
    x1 = sqrt(t) ;
    y = .;
    output;
  end;
proc model data=test1;
  exogenous x1 ;
  control a1 -1 b1 -29 c1 -4 ;
  y = a1 * sqrt(y) + b1 * x1 * x1 + c1 * lag(x1);
  solve y / out=sim forecast dynamic ;
run;
```

**Figure 19.85** SOLVE Convergence Problems

The MODEL Procedure
Dynamic Single-Equation Forecast

ERROR: Could not reduce norm of residuals in 10 subiterations.
ERROR: The solution failed because 1 equations are missing or have extreme values for observation 1 at NEWTON iteration 1.
NOTE: Additional information on the values of the variables at this observation, which may be helpful in determining the cause of the failure of the solution process, is printed below.

**Observation 1 Iteration 1 CC -1.000000**
**Missing 1**

Iteration Errors - Missing.
At the first observation, a solution to the following equation is attempted:

\[ y = -\sqrt{Y} - 62 \]

There is no solution to this problem. The iterative solution process got as close as it could to making \( Y \) negative while still being able to evaluate the model. This problem can be avoided in this case by altering the equation.

In other models, the problem of missing values can be avoided by either altering the data set to provide better starting values for the solution variables or by altering the equations.

You should be aware that, in general, a nonlinear system can have any number of solutions and the solution found might not be the one that you want. When multiple solutions exist, the solution that is found is usually determined by the starting values for the iterations. If the value from the input data set for a solution variable is missing, the starting value for it is taken from the solution of the last period (if nonmissing) or else the solution estimate is started at 0.

**Iteration Output**

The iteration output, produced by the ITPRINT option, is useful in determining the cause of a convergence problem. The ITPRINT option forces the printing of the solution approximation and equation errors at each iteration for each observation. A portion of the ITPRINT output from the following statements is shown in Figure 19.86.

```plaintext
proc model data=test1;
  exogenous x1 ;
  control a1 -1 b1 -29 c1 -4 ;
  y = a1 * sqrt(abs(y)) + b1 * x1 * x1 + c1 * lag(x1);
  solve y / out=sim forecast dynamic itprint;
run;
```

For each iteration, the equation with the largest error is listed in parentheses after the Newton convergence criteria measure. From this output you can determine which equation or equations in the system are not converging well.

Numerical Integration

The differential equation system is numerically integrated to obtain a solution for the derivative variables at each data point. The integration is performed by evaluating the provided model at multiple points between each data point. The integration method used is a variable order, variable step-size backward difference scheme; for more detailed information, see Aiken (1985); Byrne and Hindmarsh (1975). The step size or time step is chosen to satisfy a local truncation error requirement. The term truncation error comes from the fact that the integration scheme uses a truncated series expansion of the integrated function to do the integration. Because the series is truncated, the integration scheme is within the truncation error of the true value.

To further improve the accuracy of the integration, the total integration time is broken up into small intervals (time steps or step sizes), and the integration scheme is applied to those intervals. The integration at each time step uses the values computed at the previous time step so that the truncation error tends to accumulate. It is usually not possible to estimate the global error with much precision. The best that can be done is to monitor and control the local truncation error, which is the truncation error committed at each time step relative to

\[ d = \max_{0 \leq t \leq T} (\| y(t) \|_\infty, 1) \]

where \( y(t) \) is the integrated variable. Furthermore, the \( y(t) \)'s are dynamically scaled to within two orders of magnitude of one to keep the error monitoring well-behaved.

The local truncation error requirement defaults to 1.0E–9. You can specify the LTEBOUND= option to modify that requirement. The LTEBOUND= option is a relative measure of accuracy, so a value smaller than 1.0E–10 is usually not practical. A larger bound increases the speed of the simulation and estimation but decreases the accuracy of the results. If the LTEBOUND= option is set too small, the integrator is not able to take time steps small enough to satisfy the local truncation error requirement and still have enough machine precision to compute the results. Since the integrations are scaled to within 1.0E–2 of one, the simulated values should be correct to at least seven decimal places.

There is a default minimum time step of 1.0E–14. This minimum time step is controlled by the MINTIMESTEP= option and the machine epsilon. If the minimum time step is smaller than the machine epsilon times the final time value, the minimum time step is increased automatically.

For the points between each observation in the data set, the values for nonintegrated variables in the data set are obtained from a linear interpolation from the two closest points. Lagged variables can be used with integrations, but their values are discrete and are not interpolated between points. Lagging, therefore, can then be used to input step functions into the integration.

The derivatives necessary for estimation (the gradient with respect to the parameters) and goal seeking (the Jacobian) are computed by numerically integrating analytical derivatives. The accuracy of the derivatives is controlled by the same integration techniques mentioned previously.
Limitations

There are limitations to the types of differential equations that can be solved or estimated. One type is an explosive differential equation (finite escape velocity) for which the following differential equation is an example:

\[ y' = a \times y, \ a > 0 \]

If this differential equation is integrated too far in time, \( y \) exceeds the maximum value allowed on the computer, and the integration terminates.

Likewise, differential systems that are singular cannot be solved or estimated in general. For example, consider the following differential system:

\[
\begin{align*}
x' &= -y' + 2x + 4y + \exp(t) \\
y' &= -x' + y + \exp(4t)
\end{align*}
\]

This system has an analytical solution, but an accurate numerical solution is very difficult to obtain. The reason is that \( y' \) and \( x' \) cannot be isolated on the left-hand side of the equation. If the equation is modified slightly to

\[
\begin{align*}
x' &= -y' + 2x + 4y + \exp(t) \\
y' &= x' + y + \exp(4t)
\end{align*}
\]

the system is nonsingular, but the integration process could still fail or be extremely slow. If the MODEL procedure encounters either system, a warning message is issued.

This system can be rewritten as the following recursive system, which can be estimated and simulated successfully with the MODEL procedure:

\[
\begin{align*}
x' &= 0.5y + 0.5\exp(4t) + x + 1.5y - 0.5\exp(t) \\
y' &= x' + y + \exp(4t)
\end{align*}
\]

Petzold (1982) mentions a class of differential algebraic equations that, when integrated numerically, could produce incorrect or misleading results. An example of such a system is

\[
\begin{align*}
y'_2(t) &= y_1(t) + g_1(t) \\
0 &= y_2(t) + g_2(t)
\end{align*}
\]

The analytical solution to this system depends on \( g \) and its derivatives at the current time only and not on its initial value or past history. You should avoid systems of this and other similar forms mentioned in Petzold (1982).
SOLVE Data Sets

SDATA= Input Data Set

The SDATA= option reads a cross-equation covariance matrix from a data set. The covariance matrix read from the SDATA= data set specified in the SOLVE statement is used to generate random equation errors when the RANDOM= option specifies Monte Carlo simulation.

Typically, the SDATA= data set is created by the OUTS= option in a previous FIT statement. (The OUTS= data set from a FIT statement can be read back in by a SOLVE statement in the same PROC MODEL step.)

You can create an input SDATA= data set by using the DATA step. PROC MODEL expects to find a character variable _NAME_ in the SDATA= data set as well as variables for the equations in the estimation or solution. For each observation with a _NAME_ value that matches the name of an equation, PROC MODEL fills the corresponding row of the S matrix with the values of the names of equations found in the data set. If a row or column is omitted from the data set, an identity matrix row or column is assumed. Missing values are ignored. Since the S matrix is symmetric, you can include only a triangular part of the S matrix in the SDATA= data set with the omitted part indicated by missing values. If the SDATA= data set contains multiple observations with the same _NAME_, the last values supplied for the _NAME_ variable are used. The section “OUTS= Data Set” on page 1219 contains more details on the format of this data set.

Use the TYPE= option to specify the type of estimation method used to produce the S matrix you want to input.

ESTDATA= Input Data Set

The ESTDATA= option specifies an input data set that contains an observation with values for some or all of the model parameters. It can also contain observations with the rows of a covariance matrix for the parameters.

When the ESTDATA= option is used, parameter values are set from the first observation. If the RANDOM= option is used and the ESTDATA= data set contains a covariance matrix, the covariance matrix of the parameter estimates is read and used to generate pseudo-random shocks to the model parameters for Monte Carlo simulation. These random perturbations have a multivariate normal distribution with the covariance matrix read from the ESTDATA= data set.

The ESTDATA= data set is usually created by the OUTEST= option in a FIT statement. The OUTEST= data set contains the parameter estimates produced by the FIT statement and also contains the estimated covariance of the parameter estimates if the OUTCOV option is used. This OUTTEST= data set can be read in by the ESTDATA= option in a SOLVE statement.

You can also create an ESTDATA= data set with a SAS DATA step program. The data set must contain a numeric variable for each parameter to be given a value or covariance column. The name of the variable in the ESTDATA= data set must match the name of the parameter in the model. Parameters with names longer than 32 characters cannot be set from an ESTDATA= data set. The data set must also contain a character variable _NAME_ of length 32. _NAME_ has a blank value for the observation that gives values to the parameters. _NAME_ contains the name of a parameter for observations that define rows of the covariance matrix.

More than one set of parameter estimates and covariances can be stored in the ESTDATA= data set if the observations for the different estimates are identified by the variable _TYPE_. _TYPE_ must be a character
variable of length eight. The TYPE= option is used to select for input the part of the ESTDATA= data set for which the value of the _TYPE_ variable matches the value of the TYPE= option.

**OUT= Data Set**

The OUT= data set contains solution values, residual values, and actual values of the solution variables.

The OUT= data set contains the following variables:

- **BY variables**
- **RANGE variable**
- **ID variables**

  - _TYPE_, a character variable of length eight that identifies the type of observation. The _TYPE_ variable can be PREDICT, RESIDUAL, ACTUAL, or ERROR.

  - _MODE_, a character variable of length eight that identifies the solution mode. _MODE_ takes the value FORECAST or SIMULATE.

  - if lags are used, a numeric variable, _LAG_, that contains the number of dynamic lags that contribute to the solution. The value of _LAG_ is always zero for STATIC mode solutions. _LAG_ is set to a missing value for lag-starting observations.

  - if the RANDOM= option is used, _REP_, a numeric variable that contains the replication number. For example, if RANDOM=10, each input observation results in eleven output observations with _REP_ values 0 through 10. The observations with _REP_=0 are from the unperturbed solution. (The random-number generator functions are suppressed, and the parameter and endogenous perturbations are zero when _REP_=0.)

  - _ERRORS_, a numeric variable that contains the number of errors that occurred during the execution of the program for the last iteration for the observation. If the solution failed to converge, this is counted as one error, and the _ERRORS_ variable is made negative.

  - solution and other variables. The solution variables contain solution or predicted values for _TYPE_=PREDICT observations, residuals for _TYPE_=RESIDUAL observations, or actual values for _TYPE_=ACTUAL observations. The other model variables, and any other variables read from the input data set, are always actual values from the input data set.

  - any other variables named in the OUTVARS statement. These can be program variables computed by the model program, CONTROL variables, parameters, or special variables in the model program. Compound variable names longer than 32 characters are truncated in the OUT= data set.

By default, only the predicted values are written to the OUT= data set. The OUTRESID, OUTACTUAL, and OUTERROR options are used to add the residual, actual, and ERROR_ values, respectively, to the data set.

For examples of the OUT= data set, see Example 19.6.
DATA= Input Data Set

The input data set should contain all of the exogenous variables and should supply nonmissing values for them for each period to be solved.

Solution variables can be supplied in the input data set and are used as follows:

- to supply initial lags. For example, if the lag length of the model is three, three observations are read in to feed the lags before any solutions are computed.

- to evaluate the goodness of fit. Goodness-of-fit measures are computed based on the difference between the solved values and the actual values supplied from the data set.

- to supply starting values for the iterative solution. If the value from the input data set for a solution variable is missing, the starting value for it is taken from the solution of the last period (if nonmissing) or else the solution estimate is started at zero.

- for STATIC mode solutions, actual values from the data set are used by the lagging functions for the solution variables.

- for FORECAST mode solutions, actual values from the data set are used as the solution values when nonmissing.

Programming Language Overview: MODEL Procedure

Variables in the Model Program

Variable names are alphanumeric but must start with a letter. The length is limited to 32 characters.

PROC MODEL uses several classes of variables, and different variable classes are treated differently. The variable class is controlled by declaration statements: the VAR, ENDOGENOUS, and EXOGENOUS statements for model variables, the PARAMETERS statement for parameters, and the CONTROL statement for control class variables. These declaration statements have several valid abbreviations. Various internal variables are also made available to the model program to allow communication between the model program and the procedure. RANGE, ID, and BY variables are also available to the model program. Those variables not declared as any of the preceding classes are program variables.

Some classes of variables can be lagged; that is, their value at each observation is remembered, and previous values can be referred to by the lagging functions. Other classes have only a single value and are not affected by lagging functions. For example, parameters have only one value and are not affected by lagging functions; therefore, if P is a parameter, DIFn (P) is always 0, and LAGn (P) is always the same as P for all values of n.

The different variable classes and their roles in the model are described in the following.
**Model Variables**

Model variables are declared by VAR, ENDOGENOUS, or EXOGENOUS statements, or by FIT and SOLVE statements. The model variables are the variables that the model is intended to explain or predict.

PROC MODEL enables you to use expressions on the left-hand side of the equal sign to define model equations. For example, a log-linear model for Y can be written as

\[
\log( y ) = a + b \times x;
\]

Previously, only a variable name was allowed on the left-hand side of the equal sign.

The text on the left-hand side of the equation serves as the equation name used to identify the equation in printed output, in the OUT= data sets, and in FIT or SOLVE statements. To refer to equations specified by using left-hand side expressions (in the FIT statement, for example), place the left-hand side expression in quotes. For example, the following statements fit a log-linear model to the dependent variable Y:

```plaintext
proc model data=in;
   log( y ) = a + b * x;
   fit "log(y)";
run;
```

The estimation and simulation is performed by transforming the models into general form equations. No actual or predicted value is available for general form equations, so no \( R^2 \) or adjusted \( R^2 \) is computed.

**Equation Variables**

An equation variable is one of several special variables used by PROC MODEL to control the evaluation of model equations. An equation variable name consists of one of the prefixes EQ, RESID, ERROR, PRED, or ACTUAL, followed by a period and the name of a model equation.

Equation variable names can appear in parts of the PROC MODEL printed output, and they can be used in the model program. For example, RESID-prefixed variables can be used in LAG functions to define equations with moving-average error terms. See the section “Autoregressive Moving-Average Error Processes” on page 1195 for details.

The meaning of these prefixes is detailed in the section “Equation Translations” on page 1264.

**Parameters**

Parameters are variables that have the same value for each observation. Parameters can be given values or can be estimated by fitting the model to data. During the SOLVE stage, parameters are treated as constants. If no estimation is performed, the SOLVE stage uses the initial value provided in the ESTDATA= data set, the MODEL= file, or in the PARAMETER statement, as the value of the parameter.

The PARAMETERS statement declares the parameters of the model. Parameters are not lagged, and they cannot be changed by the model program.
Control Variables

Control variables supply constant values to the model program that can be used to control the model in various ways. The CONTROL statement declares control variables and specifies their values. A control variable is like a parameter except that it has a fixed value and is not estimated from the data.

Control variables are not reinitialized before each pass through the data and can thus be used to retain values between passes. You can use control variables to vary the program logic. Control variables are not affected by lagging functions.

For example, if you have two versions of an equation for a variable Y, you could put both versions in the model and, by using a CONTROL statement to select one of them, produce two different solutions to explore the effect the choice of equation has on the model, as shown in the following statements:

```plaintext
select (case);
  when (1) y = ...first version of equation... ;
  when (2) y = ...second version of equation... ;
end;

control case 1;
solve / out=case1;
run;

control case 2;
solve / out=case2;
run;
```

RANGE, ID, and BY Variables

The RANGE statement controls the range of observations in the input data set that is processed by PROC MODEL. The ID statement lists variables in the input data set that are used to identify observations in the printout and in the output data set. The BY statement can be used to make PROC MODEL perform a separate analysis for each BY group. The variable in the RANGE statement, the ID variables, and the BY variables are available for the model program to examine, but their values should not be changed by the program. The BY variables are not affected by lagging functions.

Internal Variables

You can use several internal variables in the model program to communicate with the procedure. For example, if you want PROC MODEL to list the values of all the variables when more than 10 iterations are performed and the procedure is past the 20th observation, you can write

```plaintext
if _obs_ > 20 then if _iter_ > 10 then _list_ = 1;
```

Internal variables are not affected by lagging functions, and they cannot be changed by the model program except as noted. The following internal variables are available. The variables are all numeric except where noted.

`_ERRORS_` is a flag that is set to 0 at the start of program execution and is set to a nonzero value whenever an error occurs. The program can also set the `_ERRORS_` variable.
_ITER_ is the iteration number. For FIT tasks, the value of _ITER_ is negative for preliminary grid-search passes. The iterative phase of the estimation starts with iteration 0. After the estimates have converged, a final pass is made to collect statistics with _ITER_ set to a missing value. Note that at least one pass, and perhaps several subiteration passes as well, is made for each iteration. For SOLVE tasks, _ITER_ counts the iterations used to compute the simultaneous solution of the system.

_LAG_ is the number of dynamic lags that contribute to the solution at the current observation. _LAG_ is always 0 for FIT tasks and for STATIC solutions. _LAG_ is set to a missing value during the lag starting phase.

_LIST_ is a list flag that is set to 0 at the start of program execution. The program can set _LIST_ to a nonzero value to request a listing of the values of all the variables in the program after the program has finished executing.

_METHOD_ is the solution method in use for SOLVE tasks. _METHOD_ is set to a blank value for FIT tasks. _METHOD_ is a character-valued variable. Values are NEWTON, JACOBI, SIEDEL, or ONEPASS.

_MODE_ takes the value ESTIMATE for FIT tasks and the value SIMULATE or FORECAST for SOLVE tasks. _MODE_ is a character-valued variable.

_NMISS_ is the number of missing or otherwise unusable observations during the model estimation. For FIT tasks, _NMISS_ is initially set to 0; at the start of each iteration, _NMISS_ is set to the number of unusable observations for the previous iteration. For SOLVE tasks, _NMISS_ is set to a missing value.

_NUSED_ is the number of nonmissing observations used in the estimation. For FIT tasks, PROC MODEL initially sets _NUSED_ to the number of parameters; at the start of each iteration, _NUSED_ is reset to the number of observations used in the previous iteration. For SOLVE tasks, _NUSED_ is set to a missing value.

_OBS_ counts the observations being processed. _OBS_ is negative or 0 for observations in the lag starting phase.

REP_ is the replication number for Monte Carlo simulation when the RANDOM= option is specified in the SOLVE statement. _REP_ is 0 when the RANDOM= option is not used and for FIT tasks. When _REP_=0, the random-number generator functions always return 0.

_WEIGHT_ is the weight of the observation. For FIT tasks, _WEIGHT_ provides a weight for the observation in the estimation. _WEIGHT_ is initialized to 1.0 at the start of execution for FIT tasks. For SOLVE tasks, _WEIGHT_ is ignored.

**Program Variables**

Variables not in any of the other classes are called program variables. Program variables are used to hold intermediate results of calculations. Program variables are reinitialized to missing values before each observation is processed. Program variables can be lagged. The RETAIN statement can be used to give program variables initial values and enable them to keep their values between observations.
Character Variables

PROC MODEL supports both numeric and character variables. Character variables are not involved in the model specification but can be used to label observations, to write debugging messages, or for documentation purposes. All variables are numeric unless they are the following.

- character variables in a DATA= SAS data set
- program variables assigned a character value
- declared to be character by a LENGTH or ATTRIB statement

Equation Translations

Equations written in normalized form are always automatically converted to general form equations. For example, when a normalized form equation such as

\[ y = a + bx; \]

is encountered, it is translated into the equations

\[
\begin{align*}
\text{PRED}.y &= a + bx; \\
\text{RESID}.y &= \text{PRED}.y - \text{ACTUAL}.y; \\
\text{ERROR}.y &= \text{PRED}.y - y;
\end{align*}
\]

If the same system is expressed as the following general form equation, then this equation is used unchanged.

\[ \text{EQ}.y = y - (a + bx); \]

This makes it easy to solve for arbitrary variables and to modify the error terms for autoregressive or moving average models.

Use the LIST option to see how this transformation is performed. For example, the following statements produce the listing shown in Figure 19.87.

```sas
proc model data=line list;
  y = a1 + b1*x1 + c1*x2;
  fit y;
run;
```
PRED.Y is the predicted value of Y, and ACTUAL.Y is the value of Y in the data set. The predicted value minus the actual value, RESID.Y, is then the error term, $\epsilon$, for the original Y equation. Note that the residuals obtained from the OUTRESID option in the OUT=dataset for both the FIT and SOLVE statements are defined as actual – predicted, the negative of RESID.Y. See the section “Syntax: MODEL Procedure” on page 1072 for details. ACTUAL.Y and Y have the same value for parameter estimation. For solve tasks, ACTUAL.Y is still the value of Y in the data set but Y becomes the solved value; the value that satisfies PRED.Y – Y = 0.

The following are the equation variable definitions.

**EQ.** The value of an EQ.-prefixed equation variable (normally used to define a general form equation) represents the failure of the equation to hold. When the EQ.name variable is 0, the name equation is satisfied.

**RESID.** The RESID.name variables represent the stochastic parts of the equations and are used to define the objective function for the estimation process. A RESID.-prefixed equation variable is like an EQ.-prefixed variable but makes it possible to use or transform the stochastic part of the equation. The RESID. equation is used in place of the ERROR. equation for model solutions if it has been reassigned or used in the equation.

**ERROR.** An ERROR.name variable is like an EQ.-prefixed variable, except that it is used only for model solution and does not affect parameter estimation.

**PRED.** For a normalized form equation (specified by assignment to a model variable), the PRED.name equation variable holds the predicted value, where name is the name of both the model variable and the corresponding equation. (PRED.-prefixed variables are not created for general form equations.)

**ACTUAL.** For a normalized form equation (specified by assignment to a model variable), the ACTUAL.name equation variable holds the value of the name model variable read from the input data set.

**DERT.** The DERT.name variable defines a differential equation. Once defined, it might be used on the right-hand side of another equation.

**H.** The H.name variable specifies the functional form for the variance of the named equation.

**GMM_H.** This is created for H.vars and is the moment equation for the variance for GMM. This variable is used only for GMM.

$$GMM_H.name = RESID.name^{**2} - H.name;$$
MSE. The MSE.$y$ variable contains the value of the mean squared error for $y$ at each iteration. An MSE. variable is created for each dependent/endogenous variable in the model. These variables can be used to specify the missing lagged values in the estimation and simulation of GARCH type models.

```
demret = intercept ;
h.demret = arch0 +
  arch1 * xlag( resid.demret ** 2, mse.demret) +
  garch1 * xlag(h.demret, mse.demret) ;
```

NRESID. This is created for H.$vars$ and is the normalized residual of the variable $<name>$. The formula is

```
NRESID.name = RESID.name/ sqrt(H.name);
```

The three equation variable prefixes, RESID., ERROR., and EQ. allow for control over the objective function for the FIT, the SOLVE, or both the FIT and the SOLVE stages. For FIT tasks, PROC MODEL looks first for a RESID.$name$ variable for each equation. If defined, the RESID.-prefixed equation variable is used to define the objective function for the parameter estimation process. Otherwise, PROC MODEL looks for an EQ.-prefixed variable for the equation and uses it instead.

For SOLVE tasks, PROC MODEL looks first for an ERROR.$name$ variable for each equation. If defined, the ERROR.-prefixed equation variable is used for the solution process. Otherwise, PROC MODEL looks for an EQ.-prefixed variable for the equation and uses it instead. To solve the simultaneous equation system, PROC MODEL computes values of the solution variables (the model variables being solved for) that make all of the ERROR.$name$ and EQ.$name$ variables close to 0.

### Derivatives

Nonlinear modeling techniques require the calculation of derivatives of certain variables with respect to other variables. The MODEL procedure includes an analytic differentiator that determines the model derivatives and generates program code to compute these derivatives. When parameters are estimated, the MODEL procedure takes the derivatives of the equation with respect to the parameters. When the model is solved, Newton’s method requires the derivatives of the equations with respect to the variables solved for.

PROC MODEL uses exact mathematical formulas for derivatives of non-user-defined functions. For other functions, numerical derivatives are computed and used.

The differentiator differentiates the entire model program, including the conditional logic and flow of control statements. Delayed definitions, as when the LAG of a program variable is referred to before the variable is assigned a value, are also differentiated correctly.

The differentiator includes optimization features that produce efficient code for the calculation of derivatives. However, when flow of control statements such as GOTO statements are used, the optimization process is impeded, and less efficient code for derivatives might be produced. Optimization is also reduced by conditional statements, iterative DO loops, and multiple assignments to the same variable.

The table of derivatives is printed with the LISTDER option. The code generated for the computation of the derivatives is printed with the LISTCODE option.
**Derivative Variables**

When the differentiator needs to generate code to evaluate the expression for the derivative of a variable, the result is stored in a special derivative variable. Derivative variables are not created when the derivative expression reduces to a previously computed result, a variable, or a constant. The names of derivative variables, which might sometimes appear in the printed output, have the form @obj/@wrt, where obj is the variable whose derivative is being taken and wrt is the variable that the differentiation is with respect to. For example, the derivative variable for the derivative of \( Y \) with respect to \( X \) is named @\( Y/@X \).

The derivative variables can be accessed or used as part of the model program using the GETDER() function.

- GETDER(\( x, a \)) the derivative of \( x \) with respect to \( a \).
- GETDER(\( x, a, b \)) the second derivative of \( x \) with respect to \( a \) and \( b \).

The main purpose of the GETDER() function is for surfacing the derivatives so they can be stored in a data set for further processing. Only derivatives that are implied by the problem are available to the GETDER() function. When derivatives are requested that aren’t already created, a missing value will be returned. The derivative of the GETDER() function is always zero so the results of the GETDER() function shouldn’t be used in any of the equations in the FIT or the SOLVE statement.

The following example adds the gradient of the PRED.y value with respect to the parameters to the OUT= data set.

```plaintext
proc model data=line ;
y = a1 + b1**2 *x1 + c1*x2;
Dy_a1 = getder(PRED.y,a1);
Dy_b1 = getder(PRED.y,b1);
Dy_c1 = getder(PRED.y,c1);
outvars Dy_a1 Dy_b1 Dy_c1;
fit y / out=grad;
run;
```

**Mathematical Functions**

The following is a brief summary of SAS functions that are useful for defining models. Additional functions and details are in *SAS Language: Reference*. Information about creating new functions can be found in *SAS/BASE Software: Procedure Reference*, Chapter 18, “The FCMP Procedure.”

- **ABS(\( x \))** the absolute value of \( x \)
- **ARCOS(\( x \))** the arccosine in radians of \( x \); \( x \) should be between \(-1\) and \(1\).
- **ARSIN(\( x \))** the arcsine in radians of \( x \); \( x \) should be between \(-1\) and \(1\).
- **ATAN(\( x \))** the arctangent in radians of \( x \)
- **COS(\( x \))** the cosine of \( x \); \( x \) is in radians.
- **COSH(\( x \))** the hyperbolic cosine of \( x \)
- **EXP(\( x \))** \( e^x \)
- **LOG(\( x \))** the natural logarithm of \( x \)
Chapter 19: The MODEL Procedure

LOG10(x) the log base ten of x
LOG2(x) the log base two of x
SIN(x) the sine of x; x is in radians.
SINH(x) the hyperbolic sine of x
SQRT(x) the square root of x
TAN(x) the tangent of x; x is in radians and is not an odd multiple of $\pi/2$.
TANH(x) the hyperbolic tangent of x

Random-Number Functions

The MODEL procedure provides several functions for generating random numbers for Monte Carlo simulation. These functions use the same generators as the corresponding SAS DATA step functions.

The following random number functions are supported: RANBIN, RANCAU, RAND, RANEXP, RANGAM, RANNOR, RANPOI, RANTBL, RANTRI, and RANUNI. For more information, refer to SAS Language: Reference.

Each reference to a random number function sets up a separate pseudo-random sequence. Note that this means that two calls to the same random function with the same seed produce identical results. This is different from the behavior of the random number functions used in the SAS DATA step. For example, the following statements produce identical values for X and Y, but Z is from an independent pseudo-random sequence:

```sas
x=rannor(123);
y=rannor(123);
z=rannor(567);
q=rand('BETA', 1, 12);
```

For FIT tasks, all random number functions always return 0. For SOLVE tasks, when Monte Carlo simulation is requested, a random number function computes a new random number on the first iteration for an observation (if it is executed on that iteration) and returns that same value for all later iterations of that observation. When Monte Carlo simulation is not requested, random number functions always return 0.

Functions across Time

PROC MODEL provides four types of special built-in functions that refer to the values of variables and expressions in previous time periods. These functions have the following forms where $n$ represents the number of periods, $x$ is any expression, and the argument $i$ is a variable or expression that gives the lag length ($0 < i < n$). If the index value $i$ is omitted, the maximum lag length $n$ is used.

LAG$n$ ($<i,>x$) returns the $i$th lag of $x$, where $n$ is the maximum lag;
DIF$n$ ($x$) is the difference of $x$ at lag $n$
ZLAG$n$ ($<i,>x$) returns the $i$th lag of $x$, where $n$ is the maximum lag, with missing lags replaced with zero.
XLAGn (x, y) returns the nth lag of x if x is nonmissing, or y if x is missing.

ZDIFn (x) is the difference with lag length truncated and missing values converted to zero; x is the variable or expression to compute the moving average of.

MOVAVGn(x) is the moving average if Xt denotes the observation at time point t, to ensure compatibility with the number n of observations used to calculate the moving average MOVAVGn, the following definition is used:

\[
MOVAVGn(X_t) = \frac{X_t + X_{t-1} + X_{t-2} + \ldots + X_{t-n+1}}{n}
\]

The moving average calculation for SAS 9.1 and earlier releases is as follows:

\[
MOVAVGn(X_t) = \frac{X_t + X_{t-1} + X_{t-2} + \ldots + X_{t-n}}{n + 1}
\]

Missing values of x are omitted in computing the average.

If you do not specify n, the number of periods is assumed to be one. For example, LAG(X) is the same as LAG1(X). No more than four digits can be used with a lagging function; that is, LAG9999 is the greatest LAG function, ZDIF9999 is the greatest ZDIF function, and so on.

The LAG functions get values from previous observations and make them available to the program. For example, LAG(X) returns the value of the variable X as it was computed in the execution of the program for the preceding observation. The expression LAG2(X+2*Y) returns the value of the expression X+2*Y, computed by using the values of the variables X and Y that were computed by the execution of the program for the observation two periods ago.

The DIF functions return the difference between the current value of a variable or expression and the value of its LAG. For example, DIF2(X) is a short way of writing X–LAG2(X), and DIF15(SQRT(2*Z)) is a short way of writing SQRT(2*Z)–LAG15(SQRT(2*Z)).

The ZLAG and ZDIF functions are like the LAG and DIF functions, but they are not counted in the determination of the program lag length, and they replace missing values with 0s. The ZLAG function returns the lagged value if the lagged value is nonmissing, or 0 if the lagged value is missing. The ZDIF function returns the differenced value if the differenced value is nonmissing, or 0 if the value of the differenced value is missing. The ZLAG function is especially useful for models with ARMA error processes. See the next section for details.

**Lag Logic**

The LAG and DIF lagging functions in the MODEL procedure are different from the queuing functions with the same names in the DATA step. Lags are determined by the final values that are set for the program variables by the execution of the model program for the observation. This can have upsetting consequences for programs that take lags of program variables that are given different values at various places in the program, as shown in the following statements:

```plaintext
temp = x + w;
t = lag(temp);
temp = q - r;
s = lag(temp);
```
The expression LAG(TEMP) always refers to LAG(Q–R), never to LAG(X+W), since Q–R is the final value assigned to the variable TEMP by the model program. If LAG(X+W) is wanted for T, it should be computed as T=LAG(X+W) and not T=LAG(TEMP), as in the preceding example.

Care should also be exercised in using the DIF functions with program variables that might be reassigned later in the program. For example, the program

```plaintext
temp = x;
s = dif(temp);
temp = 3 * y;
```

computes values for S equivalent to

```plaintext
s = x - lag(3 * y);
```

Note that in the preceding examples, TEMP is a program variable, not a model variable. If it were a model variable, the assignments to it would be changed to assignments to a corresponding equation variable.

Note that whereas LAG1(LAG1(X)) is the same as LAG2(X), DIF1(DIF1(X)) is not the same as DIF2(X). The DIF2 function is the difference between the current period value at the point in the program where the function is executed and the final value at the end of execution two periods ago; DIF2 is not the second difference. In contrast, DIF1(DIF1(X)) is equal to DIF1(X)-LAG1(DIF1(X)), which equals X–2*LAG1(X)+LAG2(X), which is the second difference of X.

More information about the differences between PROC MODEL and the DATA step LAG and DIF functions is found in Chapter 3, “Working with Time Series Data.”

**Lag Lengths**

The lag length of the model program is the number of lags needed for any relevant equation. The program lag length controls the number of observations used to initialize the lags.

PROC MODEL keeps track of the use of lags in the model program and automatically determines the lag length of each equation and of the model as a whole. PROC MODEL sets the program lag length to the maximum number of lags needed to compute any equation to be estimated, solved, or needed to compute any instrument variable used.

In determining the lag length, the ZLAG and ZDIF functions are treated as always having a lag length of 0. For example, if Y is computed as

```plaintext
y = lag2(x + zdif3(temp));
```

then Y has a lag length of 2 (regardless of how TEMP is defined). If Y is computed as

```plaintext
y = zlag2(x + dif3(temp));
```

then Y has a lag length of 0.

This is so that ARMA errors can be specified without causing the loss of additional observations to the lag starting phase and so that recursive lag specifications, such as moving-average error terms, can be used. Recursive lags are not permitted unless the ZLAG or ZDIF functions are used to truncate the lag length. For example, the following statement produces an error message:
The program variable \( T \) depends recursively on its own lag, and the lag length of \( T \) is therefore undefined.

In the following equation \( \text{RESID.Y} \) depends on the predicted value for the \( Y \) equation but the predicted value for the \( Y \) equation depends on the \( \text{LAG} \) of \( \text{RESID.Y} \), and thus, the predicted value for the \( Y \) equation depends recursively on its own lag.

\[
y = \text{yhat} + ma \times \text{lag( resid.y )};
\]

The lag length is infinite, and PROC MODEL prints an error message and stops. Since this kind of specification is allowed, the recursion must be truncated at some point. The ZLAG and ZDIF functions do this.

The following equation is valid and results in a lag length for the \( Y \) equation equal to the lag length of \( \text{YHAT} \):

\[
y = \text{yhat} + ma \times \text{zlag( resid.y )};
\]

Initially, the lags of \( \text{RESID.Y} \) are missing, and the ZLAG function replaces the missing residuals with 0s, their unconditional expected values.

The ZLAG0 function can be used to zero out the lag length of an expression. \( \text{ZLAG0}(x) \) returns the current period value of the expression \( x \), if nonmissing, or else returns 0, and prevents the lag length of \( x \) from contributing to the lag length of the current statement.

**Initializing Lags**

At the start of each pass through the data set or \( \text{BY} \) group, the lag variables are set to missing values and an initialization is performed to fill the lags. During this phase, observations are read from the data set, and the model variables are given values from the data. If necessary, the model is executed to assign values to program variables that are used in lagging functions. The results for variables used in lag functions are saved. These observations are not included in the estimation or solution.

If, during the execution of the program for the lag starting phase, a lag function refers to lags that are missing, the lag function returns missing. Execution errors that occur while starting the lags are not reported unless requested. The modeling system automatically determines whether the program needs to be executed during the lag starting phase.

If \( L \) is the maximum lag length of any equation being fit or solved, then the first \( L \) observations are used to prime the lags. If a \( \text{BY} \) statement is used, the first \( L \) observations in the \( \text{BY} \) group are used to prime the lags. If a \( \text{RANGE} \) statement is used, the first \( L \) observations prior to the first observation requested in the \( \text{RANGE} \) statement are used to prime the lags. Therefore, there should be at least \( L \) observations in the data set.

Initial values for the lags of model variables can also be supplied in \( \text{VAR} \), \( \text{ENDOGENOUS} \), and \( \text{EXOGENOUS} \) statements. This feature provides initial lags of solution variables for dynamic solution when initial values for the solution variable are not available in the input data set. For example, the statement

\[
\text{var x 2 3 y 4 5 z 1;}
\]
feeds the initial lags exactly like these values in an input data set:

<table>
<thead>
<tr>
<th>Lag</th>
<th>X</th>
<th>Y</th>
<th>Z</th>
</tr>
</thead>
<tbody>
<tr>
<td>2</td>
<td>3</td>
<td>5</td>
<td>.</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>4</td>
<td>1</td>
</tr>
</tbody>
</table>

If initial values for lags are available in the input data set and initial lag values are also given in a declaration statement, the values in the VAR, ENDOGENOUS, or EXOGENOUS statements take priority.

The RANGE statement is used to control the range of observations in the input data set that are processed by PROC MODEL. In the following statement, ‘01jan1924’ specifies the starting period of the range, and ‘01dec1943’ specifies the ending period:

```plaintext
range date = '01jan1924'd to '01dec1943'd;
```

The observations in the data set immediately prior to the start of the range are used to initialize the lags.

---

**Language Differences**

For the most part, PROC MODEL programming statements work the same as they do in the DATA step as documented in [SAS Language: Reference](#). However, there are several differences that should be noted.

**DO Statement Differences**

The DO statement in PROC MODEL does not allow a character index variable. Thus, the following DO statement is not valid in PROC MODEL, although it is supported in the DATA step:

```plaintext
do i = 'A', 'B', 'C'; /* invalid PROC MODEL code */
```

**IF Statement Differences**

The IF statement in PROC MODEL does not allow a character-valued condition. For example, the following IF statement is not supported by PROC MODEL:

```plaintext
if 'this' then statement;
```

Comparisons of character values are supported in IF statements, so the following IF statement is acceptable:

```plaintext
if 'this' < 'that' then statement;
```

PROC MODEL allows for embedded conditionals in expressions. For example the following two statements are equivalent:

```plaintext
flag = if time = 1 or time = 2 then conc+30/5 + dose*time 
     else if time > 5 then (0=1) else (patient * flag);
```
if time = 1 or time = 2 then flag = conc+30/5 + dose*time;
else if time > 5 then flag = (0=1); else flag = patient*flag;

Note that the ELSE operator involves only the first object or token after it so that the following assignments
are not equivalent:

\[
\begin{align*}
\text{total} &= \text{if sum > 0 then sum else sum + reserve;} \\
\text{total} &= \text{if sum > 0 then sum else (sum + reserve);} \\
\end{align*}
\]

The first assignment makes TOTAL always equal to SUM plus RESERVE.

**PUT Statement Differences**

The PUT statement, mostly used in PROC MODEL for program debugging, supports only some of the
features of the DATA step PUT statement. It also has some new features that the DATA step PUT statement
does not support.

The PROC MODEL PUT statement does not support line pointers, factored lists, iteration factors, overprinting,
the _INFILE_ option, or the colon (:) format modifier.

The PROC MODEL PUT statement does support expressions, but an expression must be enclosed in
parentheses. For example, the following statement prints the square root of x:

```
put (sqrt(x));
```

Subscripted array names must be enclosed in parentheses. For example, the following statement prints the ith
element of the array A:

```
put (a i);
```

However, the following statement is an error:

```
put a i;
```

The PROC MODEL PUT statement supports the print item _PDV_ to print a formatted listing of all the
variables in the program. For example, the following statement prints a much more readable listing of the
variables than does the _ALL_ print item:

```
put _pdv_;
```

To print all the elements of the array A, use the following statement:

```
put a;
```

To print all the elements of A with each value labeled by the name of the element variable, use the following
statement:

```
put a=;```
ABORT Statement Difference

In the MODEL procedure, the ABORT statement does not allow any arguments.

SELECT/WHEN/OTHERWISE Statement Differences

The WHEN and OTHERWISE statements allow more than one target statement. That is, DO groups are not necessary for multiple statement WHENs. For example in PROC MODEL, the following syntax is valid:

```
select;
  when(exp1)
    stmt1;
    stmt2;
  when(exp2)
    stmt3;
    stmt4;
end;
```

The ARRAY Statement

```
ARRAY arrayname < (dimensions) > < $ [length] > < variables and constants> > ;
```

The ARRAY statement is used to associate a name with a list of variables and constants. The array name can then be used with subscripts in the model program to refer to the items in the list.

In PROC MODEL, the ARRAY statement does not support all the features of the DATA step ARRAY statement. Implicit indexing cannot be used; all array references must have explicit subscript expressions. Only exact array dimensions are allowed; lower-bound specifications are not supported. A maximum of six dimensions is allowed.

On the other hand, the ARRAY statement supported by PROC MODEL does allow both variables and constants to be used as array elements. You cannot make assignments to constant array elements. Both dimension specification and the list of elements are optional, but at least one must be supplied. When the list of elements is not given or fewer elements than the size of the array are listed, array variables are created by suffixing element numbers to the array name to complete the element list.

The following are valid PROC MODEL array statements:

```
array x[120]; /* array X of length 120 */
array q[2,2]; /* Two dimensional array Q */
array x xl-x30; /* array X of length 30, X[7] = X7 */
array a[5] (1 2 3 4 5); /* array A initialized to 1,2,3,4,5 */
```

RETAIN Statement

```
RETAIN variables initial-values ;
```

The RETAIN statement causes a program variable to hold its value from a previous observation until the variable is reassigned. The RETAIN statement can be used to initialize program variables.
The RETAIN statement does not work for model variables, parameters, or control variables because the values of these variables are under the control of PROC MODEL and not programming statements. Use the PARMS and CONTROL statements to initialize parameters and control variables. Use the VAR, ENDOGENOUS, or EXOGENOUS statement to initialize model variables.

Storing Programs in Model Files

Models can be saved in and recalled from SAS catalog files as well as XML-based data sets. SAS catalogs are special files that can store many kinds of data structures as separate units in one SAS file. Each separate unit is called an entry, and each entry has an entry type that identifies its structure to the SAS system. Starting with SAS 9.2, model files are being stored as SAS data sets instead of being stored as members of a SAS catalog as in earlier releases. This makes MODEL files more readily extendable in the future and enables Java-based applications to read the MODEL files directly. You can choose between the two formats by specifying a global CMPMODEL option in an OPTIONS statement. Details are given below.

In general, to save a model, use the OUTMODEL= name option in the PROC MODEL statement, where name is specified as libref.catalog.entry, libref.entry, or entry for catalog entry and, starting with SAS 9.2, libref.datasetname or datasetname for XML-based SAS data sets. The libref, catalog, datasetnames and entry names must be valid SAS names no more than 32 characters long. The catalog name is restricted to seven characters on the CMS operating system. If not given, the catalog name defaults to MODELS, and the libref defaults to WORK. The entry type is always MODEL. Thus, OUTMODEL=X writes the model to the file WORK.MODELS.X.MODEL in the SAS catalog or creates a WORK.X XML-based dataset in the WORK library depending on the format chosen by using the CMPMODEL= option. By default, both these formats are chosen.

The CMPMODEL= option can be used in an OPTIONS statement to modify the behavior when reading and writing MODEL files. The values allowed are CMPMODEL= BOTH | XML | CATALOG. For example, the following statements restore the previous behavior:

```sas
options cmpmodel=catalog;
```

The CMPMODEL= option defaults to BOTH in SAS 9.2 and is intended for transitional use. If CMPMODEL=BOOTH, the MODEL procedure writes both formats; when loading model files PROC MODEL attempts to load the XML version first and the CATALOG version second (if the XML version is not found). If CMPMODEL=XML, the MODEL procedure reads and writes only the XML format. If CMPMODEL=CATALOG, only the catalog format is used.

The MODEL= option is used to read in a model. A list of model files can be specified in the MODEL= option, and a range of names with numeric suffixes can be given, as in MODEL=(MODEL1–MODEL10). When more than one model file is given, the list must be placed in parentheses, as in MODEL=(A B C), except in case of a single name. If more than one model file is specified, the files are combined in the order listed in the MODEL= option.
The MODEL procedure continues to read and write catalog MODEL files, and model files created by previous releases of SAS/ETS continue to work, so you should experience no direct impact from this change.

When the MODEL= option is specified in the PROC MODEL statement and model definition statements are also given later in the PROC MODEL step, the model files are read in first, in the order listed, and the model program specified in the PROC MODEL step is appended after the model program read from the MODEL= files. The class that is assigned to a variable, when multiple model files are used, is the last declaration of that variable. For example, if Y1 is declared endogenous in the model file M1 and exogenous in the model file M2, the following statement causes Y1 to be declared exogenous:

```proc model model=(m1 m2);```

The INCLUDE statement can be used to append model code to the current model code. In contrast, when the MODEL= option is specified in the RESET statement, the current model is deleted before the new model is read.

By default, no model file is output if the PROC MODEL step performs any FIT or SOLVE tasks, or if the MODEL= option or the NOSTORE option is specified. However, to ensure compatibility with previous versions of SAS/ETS software, if the PROC MODEL step does nothing but compile the model program, no input model file is read, and the NOSTORE option is not used, then a model file is written. This model file is the default input file for a later PROC SYSLIN or PROC SIMLIN step. The default output model filename in this case is WORK.MODELS._MODEL_.MODEL.

If FIT statements are used to estimate model parameters, the parameter estimates that are written to the output model file are the estimates from the last estimation performed for each parameter.

---

**Macro Return Codes (SYSINFO)**

The MODEL procedure stores a return code in the automatic macro variable SYSINFO upon completion of the PROC MODEL step. In the event any FIT or SOLVE task fails to converge during the completion of a PROC MODEL step, the value 1 is stored in the SYSINFO macro variable. Any subsequent SAS step resets the value of SYSINFO.

---

**Diagnostics and Debugging**

PROC MODEL provides several features to aid in finding errors in the model program. These debugging features are not usually needed; most models can be developed without them.

The example model program that follows is used in the following sections to illustrate the diagnostic and debugging capabilities. This example is the estimation of a segmented model.
/*--- Diagnostics and Debugging ---*/

*---------Fitting a Segmented Model using MODEL----*

  fit y;
run;

Program Listing

The LIST option produces a listing of the model program. The statements are printed one per line with the original line number and column position of the statement.

The program listing from the example program is shown in Figure 19.88.
The LIST option also shows the model translations that PROC MODEL performs. LIST output is useful for understanding the code generated by the %AR and the %MA macros.

Cross-Reference

The XREF option produces a cross-reference listing of the variables in the model program. The XREF listing is usually used in conjunction with the LIST option. The XREF listing does not include derivative (@-prefixed) variables. The XREF listing does not include generated assignments to equation variables, PRED., RESID., and ERROR.-prefixed variables, unless the DETAILS option is used.

The cross-reference from the example program is shown in Figure 19.89.
**Compiler Listing**

The LISTCODE option lists the model code and derivatives tables produced by the compiler. This listing is useful only for debugging and should not normally be needed.

LISTCODE prints the operator and operands of each operation generated by the compiler for each model program statement. Many of the operands are temporary variables generated by the compiler and given names such as #temp1. When derivatives are taken, the code listing includes the operations generated for the derivatives calculations. The derivatives tables are also listed.

A LISTCODE option prints the transformed equations from the example shown in Figure 19.90 and Figure 19.91.

Analyzing the Structure of Large Models

PROC MODEL provides several features to aid in analyzing the structure of the model program. These features summarize properties of the model in various forms.

Simulation Dependency Analysis

During the development of model programs for simulation, misspecification of the equations or variables that compose the systems of nonlinear equations is common. These misspecification errors can occur both in the original formulation of the model and in the encoding of the model into PROC MODEL statements. For large systems these errors can be difficult and time consuming to isolate and repair. Similarly, the process of becoming familiar with an existing simulation model that is encoded in PROC MODEL can be laborious when available documentation is insufficient to understand the model’s implementation. To address these issues, the ANALYZEDEP= option can be applied to SOLVE steps to produce graphical analyses of a model’s structure.

The graphical output that is produced by the ANALYZEDEP= option displays the results of two separate, hierarchical analyses that are both based on the dependence of equations on solve variables in the nonlinear system of equations. First, the system is partitioned to identify which equations overdetermine solve variables, which equations underdetermine solve variables, and which equations consistently determine solve variables. These three partitions of equations and their corresponding three partitions of solve variables are identified in the graphical output and listing produced by the ANALYZEDEP= option. Second, each partition from the first analysis is analyzed to identify subpartitions of equations and solve variables such that all the solve variables within each subpartition depend either directly or indirectly on one another. In the graphical output the subpartitions are represented as blocks in a dependency matrix. The subpartition blocks are ordered so that the matrix of dependencies has a block upper-triangular form.

The first-level partitioning of the system into underdetermined, overdetermined, and consistent systems of equations and variables uses a Dulmage-Mendelsohn (DM) decomposition to define the three partitions, following the work by Dulmage and Mendelsohn (1958); Pothen and Fan (1990). The overdetermining equations in a DM decomposition are the set of all equations that do not have dependent variables on the diagonal of any dependency matrix that contains the maximum possible number of entries on the diagonal. The dependency matrices for a problem consist of the set of pairs of orderings of the problem’s equations and solve variables. Correspondingly, the DM decomposition defines underdetermined variables as the set of all variables that do not appear on the diagonal of any dependency matrix that contains the maximum number of entries on the diagonal. Therefore, the DM decomposition is canonical in the sense that its partitioning of the system is invariant to the order equations and variables are specified in the model program. The following PROC MODEL statements illustrate how to partition a simple model with five equations and five unknowns:

```plaintext
proc model data=_null_;
    endo a b c d e;
    f(a) = 0;
    g(a,b) = 0;
    h(a,b) = 0;
    i(b,d) = 0;
    j(c,d,e) = 0;
    solve / analyzedep=(block);
quit;
```
Figure 19.92 Block Dependency Analysis

Figure 19.92 and Figure 19.93 illustrate which equations and variables belong to each block and which blocks are in each partition. The cells that are marked “Nonzero” in the plot represent a dependency between

</tbody>
</table>
blocks that are above the diagonal in the dependency matrix. The exact functional forms of the equations in this example are not shown; however, the dependency analysis here reveals that this model is structurally singular because it contains overdetermined and underdetermined components. Some modification of the model specification is necessary before a SOLVE step can be executed.

For large systems of equations, the graphical output that the ANALYZEDEP= option produces can be used as a starting point to explore dependency relationships when the models’ programming statement listings and dependency tables are too long to read and comprehend. For example, one econometric model of U.S. agriculture involves thousand of equation and variable dependencies whose structure is difficult to interpret in textual listings of the model. If you examine the block triangular form of its dependency matrix in Figure 19.94, one pattern of dependencies that becomes apparent is the vertical grouping of block dependencies in the middle of the plot. Figure 19.95 shows the dependency matrix for this important subpartition of equations and variables responsible for coupling the vertical grouping of blocks.

Figure 19.94 Block Triangular Form of U.S. Agriculture Model
Compared to the BLOCK and GRAPH options, the ANALYZEDEP= option has the following advantages:

- shows which equations and solve variables are overdetermined, consistent, and underdetermined
- works with any combination of normal form and general form equations
- can display dependency matrices involving many more equations and variables
- can be limited to a subset of the equations and variables in the model
The following Klein’s model program is used to introduce the LISTDEP, BLOCK, and GRAPH options:

```plaintext
proc model out=m data=klein listdep graph block;
  endogenous c p w i x wsum k y;
  exogenous wp g t year;
  parms c0-c3 i0-i3 w0-w3;
  a: c = c0 + c1 * p + c2 * lag(p) + c3 * wsum;
  b: i = i0 + i1 * p + i2 * lag(p) + i3 * lag(k);
  c: w = w0 + w1 * x + w2 * lag(x) + w3 * year;
  x = c + i + g;
  y = c + i + g-t;
  p = x-w-t;
  k = lag(k) + i;
  wsum = w + wp;
  id year;
quit;
```

**Dependency List**

The LISTDEP option produces a dependency list for each variable in the model program. For each variable, a list of variables that depend on it and a list of variables it depends on is given. The dependency list produced by the example program is shown in Figure 19.96.

**BLOCK Listing**

The BLOCK option prints an analysis of the program variables based on the assignments in the model program. The output produced by the example is shown in Figure 19.97.

**Figure 19.97** The BLOCK Output for Klein's Model

```
The MODEL Procedure
Model Structure Analysis
(Based on Assignments to Endogenous Model Variables)

Exogenous Variables    wp  g  t  year
Endogenous Variables   c  p  w  i  x  wsum  k  y

Block Structure of the System
Block 1  c  p  w  i  x  wsum

Dependency Structure of the System
Block 1  Depends On All_Exogenous
k       Depends On Block 1 All_Exogenous
y       Depends On Block 1 All_Exogenous
```

One use for the block output is to put a model in recursive form. Simulations of the model can be done with the SEIDEL method, which is efficient if the model is recursive and if the equations are in recursive order. By examining the block output, you can determine how to reorder the model equations for the most efficient simulation.

**Adjacency Graph**

The GRAPH option displays the same information as the BLOCK option with the addition of an adjacency graph. An X in a column in an adjacency graph indicates that the variable associated with the row depends on the variable associated with the column. The output produced by the example is shown in Figure 19.98.

The first and last graphs are straightforward. The middle graph represents the dependencies of the nonexogenous variables after transitive closure has been performed (that is, A depends on B, and B depends on C, so A depends on C). The preceding transitive closure matrix indicates that K and Y do not directly or indirectly depend on each other.

Examples: MODEL Procedure

Example 19.1: OLS Single Nonlinear Equation

This example illustrates the use of the MODEL procedure for nonlinear ordinary least squares (OLS) regression. The model is a logistic growth curve for the population of the United States. The data is the population in millions recorded at ten-year intervals starting in 1790 and ending in 2000. For an explanation of the starting values given by the START= option, see the section “Troubleshooting Convergence Problems” on page 1141. Portions of the output from the following statements are shown in Output 19.1.1 through Output 19.1.3.

```
title 'Logistic Growth Curve Model of U.S. Population';
data uspop;
  input pop :6.3 @@;
  retain year 1780;

</tbody>
</table>

The adjusted $R^2$ value indicates the model fits the data well. There are only 21 observations and the model is nonlinear, so significance tests on the parameters are only approximate. The significance tests and associated approximate probabilities indicate that all the parameters are significantly different from 0.

The FIT statement included the options OUT=RESID and OUTRESID so that the residuals from the estimation are saved to the data set RESID. The residuals are plotted to check for heteroscedasticity by using PROC SGPLOT as follows.

``` Sas
title2 "Residuals Plot";
proc sgplot data=resid;
   refline 0;
   scatter x=year y=pop / markerattrs=(symbol=circlefilled);
   xaxis values=(1780 to 2000 by 20);
run;
```
The residuals do not appear to be independent, and the model could be modified to explain the remaining nonrandom errors.

Example 19.2: A Consumer Demand Model

This example shows the estimation of a system of nonlinear consumer demand equations based on the translog functional form by using seemingly unrelated regression (SUR). Expenditure shares and corresponding normalized prices are given for three goods.

Since the shares add up to one, the system is singular; therefore, one equation is omitted from the estimation process. The choice of which equation to omit is arbitrary. The nonlinear system is first estimated in unrestricted form by the following statements:
title1 'Consumer Demand--Translog Functional Form';
title2 'Asymmetric Model';

proc model data=tlog1;
   endogenous share1 share2;
   parms a1 a2 b11 b12 b13 b21 b22 b23 b31 b32 b33;

   bm1 = b11 + b21 + b31;
   bm2 = b12 + b22 + b23;
   bm3 = b13 + b23 + b33;
   lp1 = log(p1);
   lp2 = log(p2);
   lp3 = log(p3);
   share1 = (a1 + b11 * lp1 + b12 * lp2 + b13 * lp3) / (-1 + bm1 * lp1 + bm2 * lp2 + bm3 * lp3);
   share2 = (a2 + b21 * lp1 + b22 * lp2 + b23 * lp3) / (-1 + bm1 * lp1 + bm2 * lp2 + bm3 * lp3);

   fit share1 share2
      start=(a1 -.14 a2 -.45 b11 .03 b12 .47 b22 .98 b31 .20
             b32 1.11 b33 .71) / outsused=smatrix sur;
run;

A portion of the printed output produced by this example is shown in Output 19.2.1 through Output 19.2.3.

| Used | Objective | 1.7820 |
| Missing | Objective*N | 78.4097 |

Hypothesis testing requires that the S matrix from the unrestricted model be imposed on the restricted model, as explained in the section “Tests on Parameters” on page 1186. The S matrix saved in the data set SMATRIX is requested by the SDATA= option.

A chi-square test is used to see if the hypothesis of symmetry is accepted or rejected. \((Oc–Ou)\) has a chi-square distribution asymptotically, where \(Oc\) is the constrained OBJECTIVE*N and \(Ou\) is the unconstrained
OBJECTIVE*N. The degrees of freedom is equal to the difference in the number of free parameters in the two models.

In this example, $Ou$ is 76.9697 and $Oc$ is 78.4097, resulting in a difference of 1.44 with 3 degrees of freedom. You can obtain the probability value by using the following statements:

```sas
data _null_; /* probchi( reduced-full, n-restrictions )*/
p = 1-probchi( 1.44, 3 );
put p=;
run;
```

The output from this DATA step run is $p = 0.6961858724$. With this $p$-value you cannot reject the hypothesis of symmetry. This test is asymptotically valid.

---

**Example 19.3: Vector AR(1) Estimation**

This example shows the estimation of a two-variable vector AR(1) error process for the Grunfeld model (Grunfeld and Griliches 1960) by using the %AR macro. First, the full model is estimated. Second, the model is estimated with the restriction that the errors are univariate AR(1) instead of a vector process. The following statements produce Output 19.3.1 through Output 19.3.5.

```sas
data grunfeld;
input year gei gef gec whi whf whc;
label gei = 'Gross Investment GE'
    gec = 'Capital Stock Lagged GE'
    gef = 'Value of Outstanding Shares GE Lagged'
    whi = 'Gross Investment WH'
    whc = 'Capital Stock Lagged WH'
    whf = 'Value of Outstanding Shares Lagged WH';
datalines;
1935 33.1 1170.6 97.8 12.93 191.5 1.8
1936 45.0 2015.8 104.4 25.90 516.0 .8
1937 77.2 2803.3 118.0 35.05 729.0 7.4
... more lines ...
title1 'Example of Vector AR(1) Error Process Using Grunfeld''s Model'; /* Note: GE stands for General Electric
    WH stands for Westinghouse */
proc model outmodel=grunmod;
var gei whi gef gec whf whc;
parms ge_int ge_f ge_c wh_int wh_f wh_c;
label ge_int = 'GE Intercept'
    ge_f = 'GE Lagged Share Value Coef'
    ge_c = 'GE Lagged Capital Stock Coef'
    wh_int = 'WH Intercept'
    wh_f = 'WH Lagged Share Value Coef'
    wh_c = 'WH Lagged Capital Stock Coef';
gei = ge_int + ge_f * gef + ge_c * gec;
whi = wh_int + wh_f * whf + wh_c * whc;
run;
```
The preceding PROC MODEL step defines the structural model and stores it in the model file named GRUNMOD.

The following PROC MODEL step reads in the model, adds the vector autoregressive terms using %AR, and requests SUR estimation by using the FIT statement.

```
title2 'With Unrestricted Vector AR(1) Error Process';
proc model data=grunfeld model=grunmod;
   %ar( ar, 1, gei whi )
   fit gei whi / sur;
run;
```

The final PROC MODEL step estimates the restricted model, as shown in the following statements:

```
title2 'With restricted AR(1) Error Process';
proc model data=grunfeld model=grunmod;
   %ar( gei, 1 )
   %ar( whi, 1)
   fit gei whi / sur;
run;
```

Example 19.4: MA(1) Estimation

This example estimates parameters for an MA(1) error process for the Grunfeld model, using both the unconditional least squares and the maximum likelihood methods. The ARIMA procedure estimates for Westinghouse equation are shown for comparison. The output of the following statements is summarized in Output 19.4.1:
Example 19.4: MA(1) Estimation

```
proc model outmodel=grunmod;
  var gei whi gef gec whf whc;
  parms ge_int ge_f ge_c wh_int wh_f wh_c;
  label ge_int = 'GE Intercept'
    ge_f = 'GE Lagged Share Value Coef'
    ge_c = 'GE Lagged Capital Stock Coef'
    wh_int = 'WH Intercept'
    wh_f = 'WH Lagged Share Value Coef'
    wh_c = 'WH Lagged Capital Stock Coef';
  gei = ge_int + ge_f * gef + ge_c * gec;
  whi = wh_int + wh_f * whf + wh_c * whc;
run;

SBC 152.9873
Number of Residuals 20
The model stored in Example 19.3 is read in by using the MODEL= option and the moving-average terms are added using the %MA macro.

The MA(1) model using maximum likelihood is estimated by using the following statements:

```latex
title2 'MA(1) Error Process Using Maximum Likelihood ';

proc model data=grunfeld model=grunmod;
   %ma(gei,1, m=ml);
   %ma(whi,1, m=ml);
   fit whi gei;
run;
```

For comparison, the model is estimated by using PROC ARIMA as follows:

```latex
title2 'PROC ARIMA Using Maximum Likelihood ';

proc arima data=grunfeld;
   identify var=whi cross=(whf whc) noprint;
   estimate q=1 input=(whf whc) method=ml;
run;
```

PROC ARIMA does not estimate systems, so only one equation is evaluated.

The estimation results are shown in Output 19.4.3 and Output 19.4.4. The small differences in the parameter values between PROC MODEL and PROC ARIMA can be eliminated by tightening the convergence criteria for both procedures.

Example 19.5: Polynomial Distributed Lags by Using %PDL

This example shows the use of the %PDL macro for polynomial distributed lag models. Simulated data is generated so that \( Y \) is a linear function of six lags of \( X \), with the lag coefficients following a quadratic polynomial. The model is estimated by using a fourth-degree polynomial, both with and without endpoint constraints. The example uses simulated data generated from the following model:

\[
y_t = 10 + \sum_{z=0}^{6} f(z)x_{t-z} + \epsilon
\]

\[
f(z) = -5z^2 + 1.5z
\]

The LIST option prints the model statements added by the %PDL macro. The following statements generate simulated data as shown:

```plaintext
/*--------------------------------------------------------------*/
/* Generate Simulated Data for a Linear Model with a PDL on X */
/* y = 10 + x(6,2) + e */
/*--------------------------------------------------------------*/
data pdl;
pdl2=-5.; pdl1=1.5; pdl0=0;
array zz(i) z0-z6;
do i=1 to 7;
z=i-1;
zz=pdl2*z**2 + pdl1*z + pdl0;
end;
do n=-11 to 30;
x =10*ranuni(1234567)-5;
pdl=z0*x + z1*x1 + z2*x12 + z3*x13 + z4*x14 + z5*xl5 + z6*xl6;
e =10*rannor(1234567);
y =10+pdl+e;
if n=1 then output;
xl6=xl5; xl5=xl4; xl4=xl3; xl3=xl2; xl2=xl1; xl1=x;
end;
run;
title1 'Polynomial Distributed Lag Example';
title3 'Estimation of PDL(6,4) Model-- No Endpoint Restrictions';
proc model data=pdl;
  parms int; /* declare the intercept parameter */
  %pdl( xpdl, 6, 4 ) /* declare the lag distribution */
  y = int + %pdl( xpdl, x ); /* define the model equation */
  fit y / list; /* estimate the parameters */
run;
```

The LIST output for the model without endpoint restrictions is shown in Output 19.5.1. The first seven statements in the generated program are the polynomial expressions for lag parameters XPDL_L0 through XPDL_L6. The estimated parameters are INT, XPDL_0, XPDL_1, XPDL_2, XPDL_3, and XPDL_4.

Note that XPDL_0 and XPDL_1 are not shown in the estimate summary. They were used to satisfy the endpoint restrictions analytically by the generated %PDL macro code. Their values can be determined by back substitution.

To estimate the PDL model with one or more of the polynomial terms dropped, specify the largest degree of the polynomial desired with the %PDL macro and use the DROP= option in the FIT statement to remove the unwanted terms. The dropped parameters should be set to 0. The following PROC MODEL statements demonstrate estimation with a PDL of degree 2 without the 0th order term.

```plaintext
title3 'Estimation of PDL(6,2) Model-- With XPDL_0 Dropped';
proc model data=pdl list;
  parms int;          /* declare the intercept parameter */
  %pdl( xpdl, 6, 2 )  /* declare the lag distribution */
  y = int + %pdl( xpdl, x ); /* define the model equation */
  xpdl_0 = 0;
  fit y drop=xpdl_0;   /* estimate the parameters */
run;
```

The results from this estimation are shown in Output 19.5.4.
Example 19.6: General Form Equations

Data for this example are generated. General form equations are estimated and forecast by using PROC MODEL. The system is a basic supply and demand model.

The following statements specify the form of the model:

``` Sas
title1 "General Form Equations for Supply-Demand Model";

proc model outmodel=model;
   var price quantity income unitcost;
   parms d0-d2 s0-s2;
   eq.demand=d0+d1*price+d2*income-quantity;
   eq.supply=s0+s1*price+s2*unitcost-quantity;
run;
```
Three data sets are used in this example. The first data set, HISTORY, is used to estimate the parameters of the model. The ASSUME data set is used to produce a forecast of PRICE and QUANTITY. Notice that the ASSUME data set does not need to contain the variables PRICE and QUANTITY. The HISTORY data set is shown as follows:

```plaintext
data history;
    input year income unitcost price quantity;
datalines;
1976   2221.87   3.31220  0.17903   266.714
1977   2254.77   3.61647  0.06757   276.049
1978   2285.16   2.21601  0.82916   285.858
... more lines ...
```

The ASSUME data set is shown as follows:

```plaintext
data assume;
    input year income unitcost;
datalines;
1986   2571.87   2.31220
1987   2609.12   2.45633
1988   2639.77   2.51647
1989   2667.77   1.65617
1990   2705.16   1.01601
;
```

The third data set, GOAL, used in a forecast of PRICE and UNITCOST as a function of INCOME and QUANTITY is as follows:

```plaintext
data goal;
    input year income quantity;
datalines;
1986   2571.87   371.4
1987   2721.08   416.5
1988   3327.05   597.3
1989   3885.85   764.1
1990   3650.98   694.3
;
```
The following statements fit the model to the HISTORY data set and solve the fitted model for the ASSUME data set.

```
proc model model=model outmodel=model;
/* estimate the model parameters */
    fit supply demand / data=history outest=est n2sls;
instruments income unitcost year;
run;
/* produce forecasts for income and unitcost assumptions */
solve price quantity / data=assume out=pq;
run;
title2 "Parameter Estimates for the System";
proc print data=est;
run;
title2 "Price Quantity Solution";
proc print data=pq;
run;
```

The model summary of the supply and demand model is shown as follows:

Example 19.7: Spring and Damper Continuous System

This model simulates the mechanical behavior of a spring and damper system shown in Figure 19.99.

Figure 19.99  Spring and Damper System Model

A mass is hung from a spring with spring constant $K$. The motion is slowed by a damper with damper constant $C$. The damping force is proportional to the velocity, while the spring force is proportional to the displacement.

This is actually a continuous system; however, the behavior can be approximated by a discrete time model. We approximate the differential equation

$$\frac{\partial disp}{\partial time} = velocity$$

with the difference equation

$$\Delta disp / \Delta time = velocity$$

This is rewritten as

$$\frac{disp - LAG(disp)}{dt} = velocity$$

where $dt$ is the time step used. In PROC MODEL, this is expressed with the program statement

```plaintext
disp = lag(disp) + vel * dt;
```

or
Example 19.7: Spring and Damper Continuous System

dert.disp = vel;

The first statement is simply a computing formula for Euler's approximation for the integral

\[ \text{disp} = \int \text{velocity} \, dt \]

If the time step is small enough with respect to the changes in the system, the approximation is good. Although PROC MODEL does not have the variable step-size and error-monitoring features of simulators designed for continuous systems, the procedure is a good tool to use for less challenging continuous models.

The second form instructs the MODEL procedure to do the integration for you.

This model is unusual because there are no exogenous variables, and endogenous data are not needed. Although you still need a SAS data set to count the simulation periods, no actual data are brought in.

Since the variables DISP and VEL are lagged, initial values specified in the VAR statement determine the starting state of the system. The mass, time step, spring constant, and damper constant are declared and initialized by a CONTROL statement as shown in the following statements:

```sas
title1 'Simulation of Spring-Mass-Damper System';
/*- Data to drive the simulation time periods ---*/
data one;
  do n=1 to 100;
    output;
  end;
run;
proc model data=one outmodel=spring;
  var force -200 disp 10 vel 0 accel -20 time 0;
  control mass 9.2 c 1.5 dt .1 k 20;
  force = -k * disp -c * vel;
  disp = lag(disp) + vel * dt;
  vel = lag(vel) + accel * dt;
  accel = force / mass;
  time = lag(time) + dt;
run;
```

The displacement scale is zeroed at the point where the force of gravity is offset, so the acceleration of the gravity constant is omitted from the force equation. The control variable C and K represent the damper and the spring constants respectively.

The model is simulated three times, and the simulation results are written to output data sets. The first run uses the original initial conditions specified in the VAR statement. In the second run, the initial displacement is doubled; the results show that the period of the motion is unaffected by the amplitude. In the third run, the DERT. syntax is used to do the integration. Notice that the path of the displacement is close to the old path, indicating that the original time step is short enough to yield an accurate solution. These simulations are performed by the following statements:

```sas
...```
Chapter 19: The MODEL Procedure

```sas
proc model data=one model=spring;
  title2 "Simulation of the model for the base case";
  control run '1';
  solve / out=a;
run;

  title2 "Simulation of the model with twice the initial displacement";
  control run '2';
  var disp 20;
  solve / out=b;
run;

data two;
  do time = 0 to 10 by .2; output;end;
run;

  title2 "Simulation of the model using the dert. syntax";
  proc model data=two;
    var force -200 disp 10 vel 0 accel -20 time 0;
    control mass 9.2 c 1.5 dt .1 k 20;
    control run '3';
    force = -k * disp -c * vel;
    dert.disp = vel;
    dert.vel = accel;
    accel = force / mass;
    solve / out=c;
    id time ;
  run;

The output SAS data sets that contain the solution results are merged and the displacement time paths for the three simulations are plotted. The three runs are identified on the plot as 1, 2, and 3. The following statements produce Output 19.7.1 through Output 19.7.5.

```sas
data p;
  set a b c;
run;

  title2 'Overlay Plot of All Three Simulations';
  proc sgplot data=p;
    series x=time y=disp / group=run lineattrs=(pattern=1);
    xaxis values=(0 to 10 by 1);
    yaxis values=(-20 to 20 by 10);
  run;
```

Example 19.8: Nonlinear FIML Estimation

The data and model for this example were obtained from Bard (1974, pp. 133–138). The example is a two-equation econometric model used by Bodkin and Klein to fit U.S. production data for the years 1909–1949. The model is the following:

\[
g_1 = c_1 10^{c_2 z_4} (c_5 z_1^{-c_4} + (1 - c_5) z_2^{-c_4})^{-c_3/c_4} - z_3 = 0
\]

\[
g_2 = [c_5/(1 - c_5)](z_1/z_2)^{1-c_4} - z_5 = 0
\]

where \(z_1\) is capital input, \(z_2\) is labor input, \(z_3\) is real output, \(z_4\) is time in years with 1929 as year zero, and \(z_5\) is the ratio of price of capital services to wage scale. The \(c_i\)'s are the unknown parameters. \(z_1\) and \(z_2\) are considered endogenous variables. A FIML estimation is performed by using the following statements:
Example 19.8: Nonlinear FIML Estimation

data bodkin;
   input z1 z2 z3 z4 z5;
datalines;
1.33135 0.64629 0.4026 -20 0.24447
1.39235 0.66302 0.4084 -19 0.23454
1.41640 0.65272 0.4223 -18 0.23206
... more lines ...
title1 "Nonlinear FIML Estimation";

proc model data=bodkin;
   parms c1-c5;
   endogenous z1 z2;
   exogenous z3 z4 z5;
   eq.g1 = c1 * 10 **(c2 * z4) * (c5*z1**(-c4)+
                   (1-c5)*z2**(-c4))**(-c3/c4) - z3;
   eq.g2 = (c5/(1-c5))*(z1/z2)**(-1-c4) -z5;
   fit g1 g2 / fiml ;
run;

When FIML estimation is selected, the log likelihood of the system is output as the objective value. The results of the estimation are shown in Output 19.8.1.

**Output 19.8.1** FIML Estimation Results for U.S. Production Data

Example 19.9: Circuit Estimation

Consider the nonlinear circuit shown in Figure 19.100.

![Figure 19.100 Nonlinear Resistor Capacitor Circuit](image)

The theory of electric circuits is governed by Kirchhoff’s laws: the sum of the currents flowing to a node is zero, and the net voltage drop around a closed loop is zero. In addition to Kirchhoff’s laws, there are relationships between the current I through each element and the voltage drop V across the elements. For the circuit in Figure 19.100, the relationships are

\[ C \frac{dV}{dt} = I \]

for the capacitor and

\[ V = (R_1 + R_2(1 - \exp(-V)))I \]

for the nonlinear resistor. The following differential equation describes the current at node 2 as a function of time and voltage for this circuit:

\[ C \frac{dV_2}{dt} - \frac{V_1 - V_2}{R_1 + R_2(1 - \exp(-V))} = 0 \]

This equation can be written in the form

\[ \frac{dV_2}{dt} = \frac{V_1 - V_2}{(R_1 + R_2(1 - \exp(-V)))C} \]

Consider the following data.
data circ;
  input v2 v1 time @@;
dataput;
-0.00007 0.0 0.00000000001 0.00912 0.5 0.00000000002

;
You can estimate the parameters in the preceding equation by using the following SAS statements:

title1 'Circuit Model Estimation Example';

proc model data=circ mintimestep=1.0e-23;
  parm R2 2000 R1 4000 C 5.0e-13;
  dert.v2 = (v1-v2)/((r1 + r2*(1-exp( -(v1-v2)))) * C);
  fit v2;
run;

The results of the estimation are shown in Output 19.9.1.

**Output 19.9.1** Circuit Estimation

| Parameter | Estimate  | Std Err | t Value | Pr > |t| |
|-----------|-----------|---------|---------|------|------|
| R2        | 3002.471  | 1517.1  | <-------| Biased |
| R1        | 4984.842  | 1466.8  | <-------| Biased |
| C         | 5E-13     | 0       | <-------| Biased |

NOTE: The model was singular. Some estimates are marked 'Biased'.

In this case, the model equation is such that there is linear dependency that causes biased results and inflated variances. The Jacobian matrix is singular or nearly singular, but eliminating one of the parameters is not a solution in this case.
Chapter 19: The MODEL Procedure

Example 19.10: Systems of Differential Equations

The following is a simplified reaction scheme for the competitive inhibitors with recombinant human renin (Morelock et al. 1995).

**Figure 19.101** Competitive Inhibition of Recombinant Human Renin

In Figure 19.101, \(E\)=enzyme, \(D\)=probe, and \(I\)=inhibitor.

The differential equations that describe this reaction scheme are as follows:

\[
\frac{dD}{dt} = k_{1r}ED - k_{1f}ED + k_{2r}EI - k_{2f}EI
\]

\[
\frac{dED}{dt} = k_{1f}E - k_{1r}ED + k_{2f}EI - k_{2r}EI
\]

\[
\frac{dE}{dt} = k_{1r}ED - k_{1f}ED + k_{2r}EI - k_{2f}EI + k_{2f}EI - k_{2r}EI
\]

\[
\frac{dEI}{dt} = k_{2f}E - k_{2r}EI
\]

For this system, the initial values for the concentrations are derived from equilibrium considerations (as a function of parameters) or are provided as known values.

The experiment used to collect the data was carried out in two ways; preincubation (type='disassoc') and no preincubation (type='assoc'). The data also contain repeated measurements. The data contain values for fluorescence \(F\), which is a function of concentration. Since there are no direct data for the concentrations, all the differential equations are simulated dynamically.

The SAS statements used to fit this model are as follows:
Example 19.10: Systems of Differential Equations Example;

proc sort data=fit;
   by type time;
run;

%let k1f = 6.85e6 ;
%let k1r = 3.43e-4 ;
%let k2f = 1.8e7 ;
%let k2r = 2.1e-2 ;

%let qf = 2.1e8 ;
%let qb = 4.0e9 ;

%let dt = 5.0e-7 ;
%let et = 5.0e-8 ;
%let it = 8.05e-6 ;

proc model data=fit;

parameters qf = 2.1e8
   qb = 4.0e9
   k2f = 1.8e5
   k2r = 2.1e-3
   l   = 0;

   k1f = 6.85e6;
   k1r = 3.43e-4;

   /* Initial values for concentrations */
   control dt 5.0e-7
   et 5.0e-8
   it 8.05e-6;

   /* Association initial values --------------*/
   if type = 'assoc' and time=0 then do;
      ed = 0;
      /* solve quadratic equation ------------*/
      a = 1;
      b = -(&it+&et+(k2r/k2f));
      c = &it*&et;
      ei = (-b-((b**2)-(4*a*c)**.5))/(2*a);
      d = &dt-ed;
      i = &it-ei;
      e = &et-ed-ei;
      end;

   /* Disassociation initial values ------------*/
   if type = 'disassoc' and time=0 then do;
      ei = 0;
      a = 1;
      b = -(&dt+&et+(k1r/&k1f));
      c = &dt*&et;
ed = (-b-((b**2)-(4*a*c))**.5))/(2*a);
d = &dt-ed;
i = &it-ei;
e = &et-ed-ei;
end;

if time ne 0 then do;
   dert.d = klr* ed - klf *e *d;
dert.ed = klf* e *d - klr*ed;
dert.e = klr* ed - klf* e * d + k2r * ei - k2f * e *i;
dert.ei = k2f* e *i - k2r * ei;
dert.i = k2r * ei - k2f* e *i;
end;

/* L - offset between curves */
if type = 'disassoc' then
   F = (qf*(d-ed)) + (qb*ed) -L;
else
   F = (qf*(d-ed)) + (qb*ed);

fit F / method=marquardt;
run;

This estimation requires the repeated simulation of a system of 41 differential equations (5 base differential equations and 36 differential equations to compute the partials with respect to the parameters).

The results of the estimation are shown in Output 19.10.1.

Output 19.10.1  Kinetics Estimation

Example 19.11: Monte Carlo Simulation

This example illustrates how the form of the error in a ODE model affects the results from a static and dynamic estimation. The differential equation studied is

\[ \frac{dy}{dt} = a - ay \]

The analytical solution to this differential equation is

\[ y = 1 - \exp(-at) \]

The first data set contains errors that are strictly additive and independent. The data for this estimation are generated by the following DATA step:

```plaintext
data drive1;
a = 0.5;
do iter=1 to 100;
do time = 0 to 50;
   y = 1 - \exp(-a*time) + 0.1 *rannor(123);
   output;
end;
end;
run;
```

The second data set contains errors that are cumulative in form.

```plaintext
data drive2;
a = 0.5;
yp = 1.0 + 0.01 *rannor(123);
do iter=1 to 100;
do time = 0 to 50;
   y = 1 - \exp(-a)*(1 - yp);
   yp = y + 0.01 *rannor(123);
   output;
end;
end;
run;
```

The following statements perform the 100 static estimations for each data set:
Chapter 19: The MODEL Procedure

**Title:** Monte Carlo Simulation of ODE

```sas
title1 'Monte Carlo Simulation of ODE';

proc model data=drive1 noprint;
   parm a 0.5;
   dert.y = a - a * y;
   fit y / outest=est;
   by iter;
run;
```

Similar statements are used to produce 100 dynamic estimations with a fixed and an unknown initial value. The first value in the data set is used to simulate an error in the initial value. The following PROC UNIVARIATE statements process the estimations:

```sas
proc univariate data=est noprint;
   var a;
   output out=monte mean=mean p5=p5 p95=p95;
run;

proc print data=monte;
run;
```

The results of these estimations are summarized in Table 19.6.

<table>
<thead>
<tr>
<th>Estimation Type</th>
<th>Additive Error</th>
<th>Cumulative Error</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>mean</td>
<td>p95</td>
</tr>

<td>0.63273</td>
</tr>
<tr>
<td>dynamic unknown</td>
<td>0.48518</td>
<td>0.62452</td>
</tr>
</tbody>
</table>

For this example model, it is evident that the static estimation is the least sensitive to misspecification.

---

**Example 19.12: Cauchy Distribution Estimation**

In this example a nonlinear model is estimated by using the Cauchy distribution. Then a simulation is done for one observation in the data.

The following DATA step creates the data for the model.

```sas
/* Generate a Cauchy distributed Y */
data c;
   format date monyy.;
call streaminit(156789);
do t=0 to 20 by 0.1;
   date=intnx('month','01jun90'd,(t*10)-1);
   x=rand('normal');
   e=rand('cauchy') + 10 ;
   y=exp(4*x)+e;
   output;
end;
run;
```
The model to be estimated is

\[ y = e^{-a \cdot x} + \epsilon \]
\[ \epsilon \sim \text{Cauchy}(nc) \]

That is, the residuals of the model are distributed as a Cauchy distribution with noncentrality parameter \( nc \).

The log likelihood for the Cauchy distribution is

\[ ll = -\log \pi (1 + (x - nc)^2) \]

The following SAS statements specify the model and the log-likelihood function.

```sas
title1 'Cauchy Distribution';
proc model data=c ;
  dependent y;
  parm a -2 nc 4;
  y=exp(-a*x);
  /* Likelihood function for the residuals */
  obj = log(constant('pi')*(1+(-resid.y-nc)**2));
  errormodel y ~ general(obj) cdf=cauchy(nc);
  fit y / outsn=s1 method=marquardt;
  solve y / sdata=s1 data=c(obs=1) random=1000
    seed=256789 out=out1;
run;

title 'Distribution of Y';
proc sgplot data=out1;
  histogram y;
run;
```

The FIT statement uses the OUTSN= option to output the \( \Sigma \) matrix for residuals from the normal distribution. The \( \Sigma \) matrix is \( 1 \times 1 \) and has value 1.0 because it is a correlation matrix. The OUTS= matrix is the scalar 2989.0. Because the distribution is univariate (no covariances), the OUTS= option would produce the same simulation results. The simulation is performed by using the SOLVE statement.

The distribution of \( y \) is shown in the following output.
Example 19.13: Switching Regression Example

Take the usual linear regression problem

\[ y = X\beta + u \]

where \( Y \) denotes the \( n \) column vector of the dependent variable, \( X \) denotes the \( (n \times k) \) matrix of independent variables, \( \beta \) denotes the \( k \) column vector of coefficients to be estimated, \( n \) denotes the number of observations \( (i = 1, 2, \ldots, n) \), and \( k \) denotes the number of independent variables.
You can take this basic equation and split it into two regimes, where the $i$th observation on $y$ is generated by one regime or the other:

$$
y_i = \sum_{j=1}^{k} \beta_{1j} x_{ji} + u_{1i} = x_i' \beta_1 + u_{1i}
$$

$$
y_i = \sum_{j=1}^{k} \beta_{2j} x_{ji} + u_{2i} = x_i' \beta_2 + u_{2i}
$$

where $x_{hi}$ and $x_{hj}$ are the $i$th and $j$th observations, respectively, on $x_h$. The errors, $u_{1i}$ and $u_{2i}$, are assumed to be distributed normally and independently with mean zero and constant variance. The variance for the first regime is $\sigma_1^2$, and the variance for the second regime is $\sigma_2^2$. If $\sigma_1^2 \neq \sigma_2^2$ and $\beta_1 \neq \beta_2$, the regression system given previously is thought to be switching between the two regimes.

The problem is to estimate $\beta_1$, $\beta_2$, $\sigma_1$, and $\sigma_2$ without knowing a priori which of the $n$ values of the dependent variable, $y$, was generated by which regime. If it is known a priori which observations belong to which regime, a simple Chow test can be used to test $\sigma_1^2 = \sigma_2^2$ and $\beta_1 = \beta_2$.

Using Goldfeld and Quandt’s D-method for switching regression, you can solve this problem. Assume that observations exist on some exogenous variables $z_{1i}$, $z_{2i}$, ..., $z_{pi}$, where $z$ determines whether the $i$th observation is generated from one equation or the other. The equations are given as follows:

$$
y_i = x_i' \beta_1 + u_{1i} \quad \text{if } \sum_{j=1}^{p} \pi_j z_{ji} \leq 0$
$$
y_i = x_i' \beta_2 + u_{2i} \quad \text{if } \sum_{j=1}^{p} \pi_j z_{ji} > 0
$$

where $\pi_j$ are unknown coefficients to be estimated. Define $d(z_i)$ as a continuous approximation to a step function. Replacing the unit step function with a continuous approximation by using the cumulative normal integral enables a more practical method that produces consistent estimates.

$$
d(z_i) = \frac{1}{\sqrt{2\pi} \sigma} \int_{-\infty}^{\sum_{j=1}^{p} \pi_j z_{ji}} \exp \left[ -\frac{1}{2} \frac{\xi^2}{\sigma^2} \right] d\xi
$$

$D$ is the $n$-dimensional diagonal matrix consisting of $d(z_i)$:

$$
D = \begin{bmatrix}
d(z_1) & 0 & 0 & 0 \\
0 & d(z_2) & 0 & 0 \\
0 & 0 & \ddots & 0 \\
0 & 0 & 0 & d(z_n)
\end{bmatrix}
$$

The parameters to estimate are now the $k \beta_1$’s, the $k \beta_2$’s, $\sigma_1^2$, $\sigma_2^2$, $p \pi$’s, and the $\sigma$ introduced in the $d(z_i)$ equation. The $\sigma$ can be considered as given a priori, or it can be estimated, in which case, the estimated magnitude provides an estimate of the success in discriminating between the two regimes (Goldfeld and Quandt 1976). Given the preceding equations, the model can be written as:

$$
Y = (I - D) X \beta_1 + DX \beta_2 + W
$$
where \( W = (I - D)U_1 + DU_2 \), and \( W \) is a vector of unobservable and heteroscedastic error terms. The covariance matrix of \( W \) is denoted by \( \Omega \), where \( \Omega = (I - D)^2 \sigma_1^2 + D^2 \sigma_2^2 \). The maximum likelihood parameter estimates maximize the following log-likelihood function.

\[
\log L = - \frac{n}{2} \log 2\pi - \frac{1}{2} \log |\Omega| - \frac{1}{2} \left[ (Y - (I - D)X\beta_1 - DX\beta_2)' \Omega^{-1} [Y - (I - D)X\beta_1 - DX\beta_2] \right]
\]

As an example, you now can use this switching regression likelihood to develop a model of housing starts as a function of changes in mortgage interest rates. The data for this example are from the U.S. Census Bureau and cover the period from January 1973 to March 1999. The hypothesis is that there are different coefficients on your model based on whether the interest rates are going up or down.

So the model for \( z_i \) is

\[
z_i = p \times (\text{rate}_i - \text{rate}_{i-1})
\]

where \( \text{rate}_i \) is the mortgage interest rate at time \( i \) and \( p \) is a scale parameter to be estimated.

The regression model is

\[
\begin{align*}
\text{starts}_i &= \text{intercept}_1 + a_1 \times \text{starts}_{i-1} + \text{djf}_1 \times \text{decjanfeb} & z_i < 0 \\
\text{starts}_i &= \text{intercept}_2 + a_2 \times \text{starts}_{i-1} + \text{djf}_2 \times \text{decjanfeb} & z_i \geq 0
\end{align*}
\]

where \( \text{starts}_i \) is the number of housing starts at month \( i \) and \( \text{decjanfeb} \) is a dummy variable that indicates that the current month is one of December, January, or February.

This model is written by using the following SAS statements:

```sas
title1 'Switching Regression Example';
proc model data=switch;
parms sig1=10 sig2=10 int1 b11 b13 int2 b21 b23 p;
bounds 0.0001 < sig1 sig2;
decjanfeb = ( month(date) = 12 | month(date) <= 2 );
a = p*dif(rate); /* Upper bound of integral */
d = probnorm(a); /* Normal CDF as an approx of switch */
/* Regime 1 */
y1 = int1 + zlag(starts)*b11 + decjanfeb *b13 ;
/* Regime 2 */
y2 = int2 + zlag(starts)*b21 + decjanfeb *b23 ;
/* Composite regression equation */
starts = (1 - d)*y1 + d*y2;
/* Resulting log-likelihood function */
logL = (1/2)*( (log(2*3.1415)) +
log( (sig1**2)*((1-d)**2)+(sig2**2)*((d*2) )
+ (resid.starts* 1/ ( (sig1**2)*((1-d)**2)+
```

(sig2**2)*(d**2) ) )*resid.starts) ) ;

errormodel starts ~ general(logL);

fit starts / method=marquardt converge=1.0e-5;

    /* Test for significant differences in the parms */
    test int1 = int2 ,/ lm;
    test b11 = b21 ,/ lm;
    test b13 = b23 ,/ lm;
    test sig1 = sig2 ,/ lm;

run;

Four TEST statements are added to test the hypothesis that the parameters are the same in both regimes. The parameter estimates and ANOVA table from this run are shown in Output 19.13.1.

**Example 19.14: Simulating from a Mixture of Distributions**

This example illustrates how to perform a multivariate simulation by using models that have different error distributions. Three models are used. The first model has \( t \) distributed errors. The second model is a GARCH\((1,1)\) model with normally distributed errors. The third model has a noncentral Cauchy distribution.

The following SAS statements generate the data for this example. The \( t \) and the CAUCHY data sets use a common seed so that those two series are correlated.

```sas
/* set distribution parameters */
%let df = 7.5;
%let sig1 = .5;
%let var2 = 2.5;

data t;
  format date monyy.;
  do date='1jun2001'd to '1nov2002'd;
    /* t-distribution with df,sig1 */
    t = .05 * date + 5000 + &sig1 * tinv(ranuni(1234),&df);
    output;
  end;
run;

data normal;
  format date monyy.;
  le = &var2;
  lv = &var2;
  do date='1jun2001'd to '1nov2002'd;
    /* Normal with GARCH error structure */
    v = 0.0001 + 0.2 * le**2 + .75 * lv;
    e = sqrt( v) * rannor(12345) ;
    normal = 25 + e;
    le = e;
    lv = v;
    output;
  end;
run;
```
Example 19.14: Simulating from a Mixture of Distributions

data cauchy;
  format date monyy.;
  PI = 3.1415926;
  do date='1jun2001'd to '1nov2002'd;
    cauchy = -4 + tan((ranuni(1234) - 0.5) * PI);
    output;
  end;
run;

Since the multivariate joint likelihood is unknown, the models must be estimated separately. The residuals for each model are saved by using the OUT= option. Also, each model is saved by using the OUTMODEL= option. The ID statement is used to provide a variable in the residual data set to merge by. The XLAG function is used to model the GARCH(1,1) process. The XLAG function returns the lag of the first argument if it is nonmissing, otherwise it returns the second argument.

title1 't-distributed Errors Example';
proc model data=t outmod=tModel;
  parms df 10 vt 4;
  t = a * date + c;
  errormodel t ~ t( vt, df );
  fit t / out=tresid;
  id date;
run;

title1 'GARCH-distributed Errors Example';
proc model data=normal outmodel=normalModel;
  normal = b0 ;
  h.normal = arch0 + arch1 * xlag(resid.normal **2 , mse.normal)
          + GARCH1 * xlag(h.normal, mse.normal);
  fit normal /fiml out=nresid;
  id date;
run;

title1 'Cauchy-distributed Errors Example';
proc model data=cauchy outmod=cauchyModel;
  parms nc = 1;
  /* nc is noncentrality parm to Cauchy dist */
  cauchy = nc;
  obj = log(1+resid.cauchy**2 * 3.1415926);
  errormodel cauchy ~ general(obj) cdf=cauchy(nc);
  fit cauchy / out=cresid;
  id date;
run;

The simulation requires a covariance matrix created from normal residuals. The following DATA step statements use the inverse CDFs of the t and Cauchy distributions to convert the residuals to the normal distribution. The CORR procedure is used to create a correlation matrix that uses the converted residuals.
/* Merge and normalize the 3 residual data sets */
data c; merge tresid nresid cresid; by date;
t = probit(cdf("T", t/sqrt(0.2789), 16.58 ));
cauchy = probit(cdf("CAUCHY", cauchy, -4.0623));
run;

proc corr data=c out=s;
  var t normal cauchy;
run;

Now the models can be simulated together by using the MODEL procedure SOLVE statement. The data set created by the CORR procedure is used as the correlation matrix.

    title 'Simulating Equations with Different Error Distributions';

    /* Create one observation driver data set */
data sim; merge t normal cauchy; by date;
data sim; set sim(firstobs = 519 );

    proc model data=sim model=( tModel normalModel cauchyModel );
      errormodel t ~ t( vt, df );
      errormodel cauchy ~ cauchy(nc);
      solve t cauchy normal / random=2000 seed=1962 out=monte
                      sdata=s(where=_type_="CORR"));
    run;

An estimation of the joint density of the $t$ and Cauchy distribution is created by using the KDE procedure. Bounds are placed on the Cauchy dimension because of its fat tail behavior. The joint PDF is shown in Output 19.14.1.

Example 19.15: Simulated Method of Moments—Simple Linear Regression

This example illustrates how to use SMM to estimate a simple linear regression model for the following process:

\[ y = a + bx + \epsilon, \epsilon \sim iid N(0, \sigma^2) \]

In the following SAS statements, \( y_{sim} \) is simulated, and the first moment and the second moment of \( y_{sim} \) are compared with those of the observed endogenous variable \( y \).

```
title "Simple regression model";

data regdata;
  do i=1 to 500;
    x = rannor( 1013 );
    Y = 2 + 1.5 * x + 1.5 * rannor( 1013 );
    output;
  end;
run;
```
Example 19.15: Simulated Method of Moments—Simple Linear Regression

```
proc model data=regdata;
  parms a b s;
  instrument x;

  ysim = (a+b*x) + s * rannor( 8003 );
  y = ysim;
  eq.ysq = y*y - ysim*ysim;

  fit y ysq / gmm ndraw;
  bound s > 0;
run;
```

Alternatively, the MOMENT statement can be used to specify the moments using the following syntax:

```
proc model data=regdata;
  parms a b s;
  instrument x;

  ysim = (a+b*x) + s * rannor( 8003 );
  y = ysim;
  moment y = (2);

  fit y / gmm ndraw;
  bound s > 0;
run;
```

The output of the MODEL procedure is shown in Output 19.15.1:

Example 19.16: Simulated Method of Moments—AR(1) Process

This example illustrates how to use SMM to estimate an AR(1) regression model for the following process:

\[
\begin{align*}
y_t &= a + bx_t + u_t \\
u_t &= \alpha u_{t-1} + \epsilon_t \\
\epsilon_t &\sim iid N(0, s^2)
\end{align*}
\]

In the following SAS statements, \( \text{ysim} \) is simulated by using this model, and the endogenous variable \( y \) is set to be equal to \( \text{ysim} \). The MOMENT statement creates two more moments for the estimation. One is the second moment, and the other is the first-order autocovariance. The NPREOBS=10 option instructs PROC MODEL to run the simulation 10 times before \( \text{ysim} \) is compared to the first observation of \( y \). Because the initial zlag\( (u) \) is zero, the first \( \text{ysim} \) is \( a + b \times x + s \times \text{rannor}(8003) \). Without the NPREOBS option, this \( \text{ysim} \) is matched with the first observation of \( y \). With NPREOBS, this \( \text{ysim} \) and the next nine \( \text{ysim} \) are thrown away, and the moment match starts with the eleventh \( \text{ysim} \) with the first observation of \( y \). This way, the initial values do not exert a large influence on the simulated endogenous variables.

```sas
%let nobs=500;
data ardata;
  lu =0;
do i=-10 to &nobs;
    x = rannor( 1011 );
    e = rannor( 1011 );
    u = .6 * lu + 1.5 * e;
    Y = 2 + 1.5 * x + u;
    lu = u;
    if i > 0 then output;
  end;
run;
title1 'Simulated Method of Moments for AR(1) Process';

proc model data=ardata ;
  parms a b s 1 alpha .5;
  instrument x;
  
  u = alpha * zlag(u) + s * rannor( 8003 );
```

ysim = a + b * x + u;
y = ysim;
moment y = (2) lag1(1); 

    fit y / gmm npreobs=10 ndraw=10;
    bound s > 0, 1 > alpha > 0;
    run;

Example 19.17: Simulated Method of Moments—Stochastic Volatility Model

This example illustrates how to use SMM to estimate a stochastic volatility model as in Andersen and Sorensen (1996):

\[
\begin{align*}
   y_t & = \sigma_t z_t \\
   \log(\sigma_t^2) & = a + b \log(\sigma_{t-1}^2) + su_t \\
   (z_t, u_t) & \sim iid N(0, I_2)
\end{align*}
\]

This model is widely used in modeling the return process of stock prices and foreign exchange rates. This is called the stochastic volatility model because the volatility is stochastic as the random variable \(u_t\) appears in the volatility equation. The following SAS statements use three moments: absolute value, the second-order moment, and absolute value of the first-order autoregressive moment. Note the ADJSMMV option in the FIT statement to request the SMM covariance adjustment for the parameter estimates. Although these moments have closed form solution as shown by Andersen and Sorensen (1996), the simulation approach significantly simplifies the moment conditions.

```sas
%let nobs=1000;
data _tmpdata;
a = -0.736; b=0.9; s=0.363;
ll=sqrt( exp(a/(1-b)));

**Example 19.18: Duration Data Model with Unobserved Heterogeneity**

All of the previous three models actually have closed-form moment conditions, so the simulation approach is not necessarily required for the estimation. This example illustrates how to use SMM to estimate a model for which there is no closed-form solution for the moments and thus the traditional GMM method does not apply. The model is the duration data model with unobserved heterogeneity in Gourieroux and Monfort (1993):

\[
\begin{align*}
    y_i &= -exp(-bx_i - \sigma u_i) log(v_i) \\
    u_i &\sim N(0, 1) \quad v_i \sim U_{[0,1]}
\end{align*}
\]

The SAS statements are:

Example 19.19: EMM Estimation of a Stochastic Volatility Model

The efficient method of moments (EMM) (Bansal et al. 1993, 1995; Gallant and Tauchen 2001), can be
considered a variant of SMM. The idea is to match the efficiency of the maximum likelihood (ML) estimation
with the flexibility of the SMM procedure. ML itself can be interpreted as a method of moments procedure,
where the score vector, the vector of derivatives of the log-likelihood function with respect to the parameters,
provides the exactly identifying moment conditions. EMM employs an auxiliary (or pseudo) model that
closely matches the true model. The score vector of the auxiliary model provides the moment conditions in
the SMM step.

This example uses the SMM feature of PROC MODEL to estimate the simple stochastic volatility (SV) model
of Example 19.17 with the EMM method.

Suppose that your data are the time series \( \{y_1, y_2, \ldots, y_n\} \), and the model that you want to estimate, or the
structural model, is characterized by the vector of parameters \( \theta \). For the SV model, \( \theta \) is given by \( \{a, b, s\} \).

The first step of the EMM method is to fit the data with an auxiliary model (or score generator) that has
transition density \( f(y_t|Y_{t-1}, \eta) \), parameterized by the pseudo parameter \( \eta \), where \( Y_{t-1} = \{y_{t-1}, \ldots, y_1\} \).
The auxiliary model must approximate the true data-generating process as closely as possible and be such
that ML estimation is feasible.

The only identification requirement is that the dimension of the pseudo parameter \( \eta \) be greater than or equal
to that of the structural parameter \( \theta \).

Andersen, Chung, and Sorensen (1999) showed that the GARCH(1,1) is an appropriate auxiliary model that
leads to a good performance of the EMM estimator for the SV model.

The analytical expression for the GARCH(1,1) model with mean zero is

\[
\begin{align*}
y_t & = \sigma_t z_t \\
\sigma_t^2 & = \omega + \alpha y_{t-1} + \beta \sigma_{t-1}^2
\end{align*}
\]
The pseudo parameter vector $\eta$ is given by $(\omega, \alpha, \beta)$.

One advantage of such a class of models is that the conditional density of $y_t$ is Gaussian—that is,

$$f(y_t|Y_{t-1}, \eta) \propto \frac{1}{\sigma_t} \exp \left( -\frac{y_t^2}{2\sigma_t^2} \right)$$

Therefore the score vector can easily be computed analytically.

The AUTOREG procedure provides the ML estimates, $\hat{\eta}_n$. The estimates are stored in the garchest data set.

```sas
title1 'Efficient Method of Moments for Stochastic Volatility Model';
/* estimate GARCH(1,1) model */
proc autoreg data=svdata(keep=y)
    outest=garchest
    noprint covout;
model y = / noint garch=(q=1,p=1,type=nonneg);
run;
```

If the pseudo model is close enough to the structural model, in a suitable sense, Gallant and Long (1997) showed that a consistent estimator of the asymptotic covariance matrix of the sample pseudo-score vector can be obtained from the formula

$$\hat{V}_n = \frac{1}{n} \sum_{t=1}^{n} s_f(Y_t, \hat{\eta}_n)s_f(Y_t, \hat{\eta}_n)'$$

where $s_f(Y_t, \hat{\eta}_n) = (\partial/\partial \eta_n) \log f(y_t|Y_{t-1}, \hat{\eta}_n)$ denotes the score function of the auxiliary model computed at the ML estimates.

The ML estimates of the GARCH(1,1) model are used in the following SAS statements to compute the variance-covariance matrix $\hat{V}_n$.

```sas
/* compute the V matrix */
data vvalues;
    set scores;
    array score{*} dlldw dllda dlldb;
    array v_t{*} v_t_1-v_t_6;
    array v{*} v_1-v_6;

    /* compute external product of score vector */
    do i=1 to 3;
        do j=i to 3;
            v_t{j*(j-1)/2 + i} = score{i}*score{j};
        end;
    end;

    /* average them over t */
    do s=1 to 6;
        v{s}+ v_t{s}/&nobs;
    end;
run;
```

The $\hat{V}$ matrix must be formatted to be used with the VDATA= option of the MODEL procedure. See the section “VDATA= Input data set” on page 1215 for more information about the VDATA= data set.
/* Create a VDATA dataset acceptable to PROC MODEL */
/* Transpose the last obs in the dataset */
proc transpose data=vvalues(firstobs=&nobs keep=v_1-v_6)
   out=tempv;
run;
/* Add eq and inst labels */
data vhat;
   set tempv(drop=_name_);
   value = col1;
   drop col1;
   input _type_ $ eq_row $ eq_col $ inst_row $ inst_col $; *$;
datalines;
gmm m1 m1 1 1 /* intcpt is the only inst we use */
gmm m1 m2 1 1
   gmm m2 m2 1 1
   gmm m1 m3 1 1
   gmm m2 m3 1 1
   gmm m3 m3 1 1;

The last step of the EMM procedure is to estimate $\theta$ by using SMM, where the moment conditions are given by the scores of the auxiliary model.

Given a fixed value of the parameter vector $\theta$ and an arbitrarily large $T$, one can simulate a series $\{\hat{y}_1(\theta), \hat{y}_2(\theta), \ldots, \hat{y}_T(\theta)\}$ from the structural model. The EMM estimator is the value $\hat{\theta}_n$ that minimizes the quantity

$$ m_T(\theta, \hat{\eta}_n) V_n^{-1} m_T(\theta, \hat{\eta}_n) $$

where

$$ m_T(\theta, \hat{\eta}_n) = \frac{1}{T} \sum_{k=1}^{T} s_f(\hat{y}_k(\theta), \hat{\eta}_n) $$

is the sample moment condition evaluated at the fixed estimated pseudo parameter $\hat{\eta}_n$. Note that the target function depends on the parameter $\theta$ only through the simulated series $\hat{y}_k$.

The following statements generate a data set that contains $T = 20,000$ replicates of the estimated pseudo parameter $\hat{\eta}_n$ and that is then input to the MODEL procedure. The EMM estimates are found by using the SMM option of the FIT statement. The $V_n$ matrix computed above serves as weighting matrix by using the VDATA= option, and the scores of the GARCH(1,1) auxiliary model evaluated at the ML estimates are the moment conditions in the GMM step.

Since the number of structural parameters to estimate (3) is equal to the number of moment equations (3) times the number of instruments (1), the model is exactly identified and the objective function has value zero at the minimum.

For simplicity, the starting values are set to the true values of the parameters.
/* USE SMM TO FIND EMM ESTIMATES */

Overview: PANEL Procedure

The PANEL procedure analyzes a class of linear econometric models that commonly arise when time series and cross-sectional data are combined. This type of pooled data on time series cross-sectional bases is often referred to as panel data. Typical examples of panel data include observations over time on households, countries, firms, trade, and so on. For example, in the case of survey data on household income, the panel is created by repeatedly surveying the same households in different time periods (years).

The panel data models can be grouped into several categories depending on the structure of the error term. The PANEL procedure uses the following error structures and the corresponding methods to analyze data:

- one-way and two-way models
- fixed-effects and random-effects models
- autoregressive models
- moving average models
A one-way model depends only on the cross section to which the observation belongs. A two-way model depends on both the cross section and the time period to which the observation belongs.

Apart from the possible one-way or two-way nature of the effect, the other dimension of difference between the possible specifications is the nature of the cross-sectional or time-series effect. The models are referred to as fixed-effects models if the effects are nonrandom and as random-effects models otherwise.

If the effects are fixed, the models are essentially regression models with dummy variables that correspond to the specified effects. For fixed-effects models, ordinary least squares (OLS) estimation is the best linear unbiased estimator. Random-effects models use a two-stage approach. In the first stage, variance components are calculated by using methods described by: Fuller and Battese (1974); Wansbeek and Kapteyn (1989); Wallace and Hussain (1969); Nerlove (1971). In the second stage, variance components are used to standardize the data, and ordinary least squares (OLS) regression is performed.

Two types of models in the PANEL procedure accommodate an autoregressive structure: The Parks method estimates a first-order autoregressive model with contemporaneous correlation, and the dynamic panel estimator estimates an autoregressive model with lagged dependent variable.

The Da Silva method estimates a mixed variance-component moving-average error process. The regression parameters are estimated by using a two-step generalized least squares (GLS)-type estimator.

The PANEL procedure enhances the features that were implemented in the TSCSREG procedure. The following list shows the most important additions.

- New estimation methods include between estimators, pooled estimators, and dynamic panel estimators that use the generalized method of moments (GMM). The variance components for random-effects models can be calculated for both balanced and unbalanced panels by using the methods described by: Fuller and Battese (1974); Wansbeek and Kapteyn (1989); Wallace and Hussain (1969); Nerlove (1971).
- The CLASS statement creates classification variables that are used in the analysis.
- The TEST statement includes new options for Wald, Lagrange multiplier, and the likelihood ratio tests.
- The new RESTRICT statement specifies linear restrictions on the parameters.
- The FLATDATA statement enables the data to be in a compressed form.
- Several methods that produce heteroscedasticity-consistent (HCCME) and heteroscedasticity- and Autocorrelation-Consistent (HAC) covariance matrices are added because the presence of heteroscedasticity and autocorrelation can result in inefficient and biased estimates of the covariance matrix in the OLS framework.
- Tests are added for poolability, panel stationarity, the existence of cross sectional and time effects, autocorrelation, and cross sectional dependence.
- The LAG statement can generate a large number of missing values, depending on lag order. Typically, it is difficult to create lagged variables in the panel setting. If lagged variables are created in a DATA step, several programming steps that include loops are often needed. By including the LAG statement, the PANEL procedure makes the creation of lagged values easy. The missing values can be replaced with zeros, overall mean, time mean, or cross section mean by using the LAG, ZLAG, XLAG, SLAG, and CLAG statements.
- The OUTPUT statement enables you to output data and estimates that can be used in other analyses.
Chapter 20: The PANEL Procedure

Getting Started: PANEL Procedure

The following statements use the cost function data from Greene (1990) to estimate the variance components model. The variable PRODUCTION is the log of output in millions of kilowatt-hours, and COST is the log of cost in millions of dollars. See Greene (1990) for details.

data greene;
  input firm year production cost @@;
datalines;
  1 1955 5.36598 1.14867 1 1960 6.03787 1.45185
  1 1965 6.37673 1.52257 1 1970 6.93245 1.76627
  2 1965 7.40245 2.09519 2 1970 7.82644 2.39480
  3 1955 8.07153 2.94628 3 1960 8.47679 3.25967

... more lines ...

You decide to fit the following model to the data:

$$C_{it} = \text{Intercept} + \beta P_{it} + v_i + e_t + \epsilon_{it} \quad i = 1, \ldots, N; \quad t = 1, \ldots, T$$

where $C_{it}$ and $P_{it}$ represent the cost and production, and $v_i$, $e_t$ and $\epsilon_{it}$ are the cross-sectional, time series, and error variance components.

If you assume that the time and cross-sectional effects are random, you are left with four possible estimators for the variance components. You choose Fuller-Battese.

The following statements fit this model.

```sas
proc sort data=greene;
  by firm year;
run;

proc panel data=greene;
  model cost = production / rantwo vcomp = fb;
  id firm year;
run;
```

The PANEL procedure output is shown in Figure 20.1. A model description is printed first, which reports the estimation method used and the number of cross sections and time periods. The variance components estimates are printed next. Finally, the table of regression parameter estimates shows the estimates, standard errors, and $t$ tests.

**PROC PANEL Statement**

PROC PANEL options ;

The following options can be specified on the PROC PANEL statement.

**DATA=SAS-data-set**

names the input data set. The input data set must be sorted by cross section and by time period within cross section. If you omit the DATA= option, the most recently created SAS data set is used.

**OUTEST=SAS-data-set**

names an output data set to contain the parameter estimates. When the OUTEST= option is not specified, the OUTEST= data set is not created. See the section “OUTEST= Data Set” on page 1454 for details about the structure of the OUTEST= data set.

**OUTTRANS=SAS-data-set**

names an output data set to contain the transformed series for further analysis and computation of models with time observations greater than two. See the section “OUTTRANS= Data Set” on page 1455 for details about the structure of the OUTTRANS= data set.
OUTCOV
COVOUT
writes the standard errors and covariance matrix of the parameter estimates to the OUTEST= data set. See the section “OUTEST= Data Set” on page 1454 for details.

OUTCORR
CORROUT
writes the correlation matrix of the parameter estimates to the OUTEST= data set. See the section “OUTEST= Data Set” on page 1454 for details.

PLOTS < (global-plot-options < (NCROSS=value) > ) > < = (specific-plot-options) >

Global Plot Options
The following global-plot-options are supported:

ONLY
suppresses the default plots. Only the plots specifically requested are produced.

UNPACKPANEL
UNPACK
displays each graph separately. (By default, some graphs can appear together in a single panel.)

NCROSS=value
specifies the number of cross sections to be combined into one time series plot.

Specific Plot Options
The following specific-plot-options are supported:

ACTSURFACE
produces a surface plot of actual values.

ALL
produces all appropriate plots.

FITPLOT
plots the predicted and actual values.

NONE
suppresses all plots.

PREDSDSURFACE
produces a surface plot of predicted values.

QQ
produces a QQ plot of residuals.

RESIDSTACK RESSTACK
produces a stacked plot of residuals.

RESIDSURFACE
produces a surface plot of residual values.

RESIDUAL RES
plots the residuals.

RESIDUALHISTOGRAM RESIDHISTOGRAM
plots the histogram of residuals.
For more details, see the section “Creating ODS Graphics” on page 1453.

In addition, any of the following MODEL statement options can be specified in the PROC PANEL statement: CORRB, COVB, FIXONE, FIXONETIME, FIXTWO, BTWNG, BTWNT, POOLED, RANONE, RANTWO, PARKS, DASILVA, NOINT, NOPRINT, PRINTFIXED, M=, PHI, RHO, VCOMP=, and SINGULAR=. When specified in the PROC PANEL statement, these options are equivalent to specifying the options for every MODEL statement. See the section “MODEL Statement” on page 1386 for a complete description of each of these options.

---

**BY Statement**

```
BY variables;
```

A BY statement obtains separate analyses on observations in groups that are defined by the BY variables. When a BY statement appears, the input data set must be sorted both by the BY variables and by cross section and time period within the BY groups.

The following statements show an example:

```
proc sort data=a;
   by byvar1 byvar2 csid tsid;
run;

proc panel data=a;
   by byvar1 byvar2;
      id csid tsid;
   ...;
run;
```

---

**CLASS Statement**

```
CLASS variables / out= SAS-data-set;
```

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric.

In PROC PANEL, the CLASS statement enables you to output class variables to a data set that contains a copy of the original data.

---

**FLATDATA Statement**

```
FLATDATA options / out= SAS-data-set;
```

The following options must be specified in the FLATDATA statement:
**BASE=** \((\text{variable, variable, \ldots, variable})\)

specifies the variables that are to be transformed into a proper PROC PANEL format. All variables to be transformed must be named according to the convention: basename_timeperiod. You supply just the basename, and the procedure extracts the appropriate variables to transform. If some year’s data are missing for a variable, then PROC PANEL detects this and fills in with missing values.

**INDID=** \(\text{variable}\)

names the variable in the input data set that uniquely identifies each individual. The INDID variable can be a character or numeric variable.

**KEEP=** \((\text{variable, variable, \ldots, variable})\)

specifies the variables that are to be copied without any transformation. These variables remain constant with respect to time when the data are converted to PROC PANEL format. This is an optional item.

**TSNAME=** \(\text{name}\)

specifies a name for the generated time identifier. The name must satisfy the requirements for the name of a SAS variable. The name can be quoted, but it must not be the name of a variable in the input data set.

The following options can be specified on the FLATDATA statement after the slash (/):

**OUT =** \(\text{SAS-data-set}\)

saves the converted flat data set to a PROC PANEL formatted data set.

---

**ID Statement**

\[ \text{ID cross-section-id time-series-id ;} \]

The ID statement is used to specify variables in the input data set that identify the cross section and time period for each observation.

When an ID statement is used, the PANEL procedure verifies that the input data set is sorted by the cross section ID variable and by the time series ID variable within each cross section. The PANEL procedure also verifies that the time series ID values are the same for all cross sections.

To make sure the input data set is correctly sorted, use PROC SORT to sort the input data set with a BY statement with the variables listed exactly as they are listed in the ID statement, as shown in the following statements:

```sas
proc sort data=a;
   by csid tsid;
run;

proc panel data=a;
   id csid tsid;
   ... etc. ...
run;
```
Chapter 20: The PANEL Procedure

INSTRUMENTS Statement

INSTRUMENTS options ;

The INSTRUMENTS statement denotes which variables are used in the moment condition equations of the dynamic panel estimator. The following options can be used with the INSTRUMENTS statement.

**CONSTANT**
includes an intercept (column of ones) as an uncorrelated exogenous instrument.

**CORRELATED=(variable, variable, . . . , variable)**
specifies a list of variables correlated with the unobserved individual effects. These variables are correlated with the error terms in the level equations so they are not used in forming moment conditions from those equations.

**DEPVAR<(LEVEL | DIFF | DIFFERENCE | BOTH )>**
specifies instruments related to the dependent variable. With LEVEL, the lagged dependent variables are included as instruments for differenced equations. With DIFFERENCE, the differenced dependent variable is included as instruments for equations. With BOTH or nothing specified, both level and differenced dependent variables are included in the instrument matrix.

**EXOGENOUS=(variable, variable, . . . , variable)**
specifies a list of variables that are not correlated with the disturbances given the unobserved individual effects.

**PREDETERMINED=(variable, variable, . . . , variable)**
specifies a list of variables whose future realizations can be correlated with the disturbances but whose present and past realizations are not conditional on the individual effects.

Because a variable can be used as an instrument only if it is either exogenous or predetermined, the variables listed in the CORRELATED= option must be included in either the EXOGENOUS= list or the PREDETERMINED= list. If a variable listed in the EXOGENOUS= list is not included in the CORRELATED= list, then it is considered to be uncorrelated to the error term in the level equations, which consist only of the individual effects and the disturbances. Moreover, it is uncorrelated with the error term in the differenced equations, which consist only of the disturbances. For example, in the following statements, the exogenous instruments are Z1, Z2 and X1. Because Z1 is an instrument that is correlated to the individual fixed effects, it is included in the level equations but not in the differenced equations. Because Z2 is not correlated with either the individual effects or the disturbances, it is included in both the level equations and the differenced equations.

```plaintext
proc panel data=a;
    inst exogenous=(Z1 Z2 X1)
    correlated = (Z1) constant depvar;
    model Y = X1 X2 X3 / gmm1;
run;
```

For a detailed discussion of the model set up and the use of the INSTRUMENTS statement, see “Dynamic Panel Estimator” on page 1423.

Note that for each MODEL statement, one INSTRUMENT statement is required. In other words, if there are two models to be estimated by using GMM1 within one PANEL procedure, then there should be two INSTRUMENT statements. For example,
LAG, ZLAG, XLAG, SLAG, or CLAG Statement

LAG var1( lag1 lag2 ... lagT ), ..., varN( lag1 lag2 ... lagT ) < / OUT=SAS-data-set > ;

Generally, creating lags of variables in a panel setting is a tedious process in which you must generate many DATA step statements. The PANEL procedure now enables you to generate lags of any series without jumping across the boundary of any individual series. The LAG statement is a data set generation tool. Using the data created by a LAG statement requires a subsequent PROC PANEL call. You can specify more than one LAG statement in each call to PROC PANEL.

You must specify the OUT= option in the LAG statement. The output data set includes all variables in the input set, plus the lags that are denoted with the convention var_lag. The LAG statement tends to generate many missing values in the data. This can be problematic, because the number of usable observations diminishes with the lag length. Therefore, PROC PANEL offers the following alternatives to the LAG statement. The following statements can be used instead of LAG with otherwise identical syntax:

CLAG var1( lag1 lag2 ... lagT ), ..., varN( lag1 lag2 ... lagT ) < / OUT=SAS-data-set > ;

replaces missing values with the cross section mean for that variable in that cross section. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

SLAG var1( lag1 lag2 ... lagT ), ..., varN( lag1 lag2 ... lagT ) < / OUT=SAS-data-set > ;

replaces missing values with the time mean for that variable in that time period. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

XLAG var1( lag1 lag2 ... lagT ), ..., varN( lag1 lag2 ... lagT ) < / OUT=SAS-data-set > ;

replaces missing values with the overall mean for that variable. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

ZLAG var1( lag1 lag2 ... lagT ), ..., varN( lag1 lag2 ... lagT ) < / OUT=SAS-data-set > ;

replaces missing values with 0 for that variable. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

Assume that data set A has been sorted by cross section and by time period within cross section (or that the FLATDATA statement has been specified) and that the variables are Y, X1, X2, and X3. The following PROC PANEL statements generate a series with lags 1 and 3 of the X1 variable; lags 3, 6, and 9 of the X2 variable; and lag 2 of the X3 variable.

```plaintext
proc panel data=A;
  id i t;
  lag X1(1 3) X2(3 6 9) X3(2) / out=A_lag;
run;
```
If you want a zeroing instead of missing values, then you specify the following:

```plaintext
proc panel data=A;
   id i t;
   zlag X1(1 3) X2(3 6 9) X3(2) / out=A_zlag;
run;
```

Similarly, you can specify XLAG to replace with overall means, SLAG to replace with time means, and CLAG to replace with cross section means.

---

**MODEL Statement**

```plaintext
MODEL response = regressors < / options> ;
```

The MODEL statement specifies the regression model and the error structure assumed for the regression residuals. The response variable on the left side of the equal sign is regressed on the independent variables listed after the equal sign. Any number of MODEL statements can be used. For each model statement, only one response variable can be specified on the left side of the equal sign.

The error structure is specified by the PARKS, DASILVA, FIXONE, FIXONETIME, FIXTWO, RANONE, RANTWO, GMM1, GMM2, and ITGMM options. More than one of these options can be used, in which case the analysis is repeated for each error structure model specified.

Models can be given labels. Model labels are used in the printed output to identify the results for different models. If no label is specified, the response variable name is used as the label for the model. The model label is specified as follows:

```plaintext
label : MODEL . . ;
```

The following *options* can be specified in the MODEL statement after a slash (/).

- **ARTEST=integer**
  specifies the maximum order of the test for the presence of AR effects in the residual in the dynamic panel model. The acceptable range of values for this option is 1 to \( t - 3 \).

- **ATOL=number**
  specifies the convergence criterion for iterated GMM when convergence of the method is determined by convergence in the weighting matrix. The convergence criterion must be positive. The default option is the BTOL= option unless the ATOL= option is specified. See the section “Dynamic Panel Estimator” on page 1423 for details.

- **BANDOPT=TRAILING | CENTERED | LEADING**
  specifies which observations are included in the instrument list when the MAXBAND= option is specified. This option should be used only for exogenous instruments. BANDOPT=TRAILING is the default. See the section “Dynamic Panel Estimator” on page 1423 for details.

- **BP**
  requests the Breusch-Pagan one-way test for random effects.
BP2
requests the Breusch-Pagan two-way test for random effects.

BTOL=number
specifies the convergence criterion for iterated GMM when convergence of the method is determined by convergence in the parameter matrix. The convergence criterion must be positive. The default is BTOL=1E–8. See the section “Dynamic Panel Estimator” on page 1423 for details.

BTWNG
specifies that a between-groups model be estimated.

BTWNT
specifies that a between-time-periods model be estimated.

CLUSTER
specifies the cluster correction for the covariance matrix. The cluster correction can be requested with HCCME=0, 1, 2 or 3.

CORRB
CORR
prints the matrix of estimated correlations between the parameter estimates.

COVB
VAR
prints the matrix of estimated covariances between the parameter estimates.

DASILVA
specifies that the model be estimated by using the Da Silva method, which assumes a mixed variance-component moving average model for the error structure. See the section “Da Silva Method (Variance-Component Moving Average Model)” on page 1421 for details.

FIXONE
specifies that a one-way fixed-effects model be estimated with the one-way model corresponding to cross-sectional effects only.

FIXONETIME
specifies that a one-way fixed-effects model be estimated with the one-way model corresponding to time effects only.

FIXTWO
specifies that a two-way fixed-effects model be estimated.

GINV= G2 | G4
specifies what type of generalized inverse to use. The default is a G2 inverse. The G4 inverse is generally more desirable except that it is a more numerically intensive methodology.

GMM1
requests that the model be estimated in a single step by using the dynamic panel estimator method, which allows for autoregressive processes. When you specify this option, you must specify one INSTRUMENT statement for each MODEL statement. For more information, see the section “Dynamic Panel Estimator” on page 1423.
GMM2 requests that the model be estimated in two steps by using the dynamic panel estimator method. An initial first step is used to form an estimator for the weighting matrix that is used in the second step. For more information, see the section “Dynamic Panel Estimator” on page 1423.

HAC < (hac-options) > specifies the heteroscedasticity- and autocorrelation-consistent (HAC) covariance matrix estimator. This option is not available for between models and cannot be specified with the HCCME option. When you specify this option, you can also specify the following hac-options within parentheses:

**KERNEL=**value specifies the type of kernel function. You can specify the following values:

- BARTLETT specifies the Bartlett kernel function.
- PARZEN specifies the Parzen kernel function.
- QS specifies the quadratic spectral kernel function.
- TH specifies the Turkey-Hanning kernel function.
- TRUNCATED specifies the truncated kernel function.

The default is KERNEL=TRUNCATED.

**KERNELLB=**number specifies the lower bound of the kernel weight value. Any kernel weight less than this lower bound is regarded as 0, which accelerates the calculation for big samples, especially for the quadratic spectral kernel function. By default, KERNELLB=0.

**BANDWIDTH=**value specifies the fixed bandwidth value or bandwidth selection method which is used in the kernel function. You can specify the following values:

**NEWEYWEST94<(C=number)>**

NW94 <(C=number)> specifies the Newey and West (1994) bandwidth selection method. The C= option can be specified within parentheses for the calculation of lag selection parameter; the default is C=12.

**SAMPLESIZE<(option-list)>**

SS<(option-list)> specifies that the bandwidth be calculated according to the following equation based on the sample size

\[ b = \gamma T^r + c \]

where \( b \) is the bandwidth parameter, \( T \) is the sample size, and \( \gamma, r \) and \( c \) are values specified by the following options within parentheses and separated by commas.
GAMMA=number
specifies the coefficient $\gamma$ in the equation. The default is $\gamma = 0.75$.

RATE=number
specifies the growth rate $r$ in the equation. The default is $r = 0.3333$.

CONSTANT=number
specifies the constant $c$ in the equation. The default is $c = 0.5$.

INT
specifies that the bandwidth parameter must be integer; that is, $b = \lfloor \gamma T + c \rfloor$, where \( \lfloor x \rfloor \) denotes the largest integer less than or equal to $x$.

number
specifies the fixed value of the bandwidth parameter.

The default is BANDWIDTH=ANDREWS91.

PREWHITENING
specifies that prewhitening is required in the covariance calculation.

ADJUSTDF
specifies that the adjustment of degrees of freedom is required in the covariance calculation.

See the section “Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrices” on page 1436 for details.

HCCME= NO | number
specifies the type of HCCME covariance matrix requested. If you specify HCCME=NO, the covariance matrix is not corrected. The value number can be any integer from 0 to 4, inclusive. See the section “Heteroscedasticity-Corrected Covariance Matrices” on page 1433 for details. By default, HCCME=NO.

ITGMM
specifies that the model be estimated by using the dynamic panel estimator method, but that PROC PANEL keep updating the weighting matrix until either the parameter vector converges or the weighting matrix converges. See the section “Dynamic Panel Estimator” on page 1423 for details.

ITPRINT
prints out the iteration history of the parameter and transformed sum of error squared.

M=number
specifies the order of the moving-average process in the Da Silva method. The value of the M=option must be less than $T - 1$. The default is M=1.

MAXBAND=integer
specifies the maximum number of time periods (per instrumental variable) that are allowed into the moment condition. The acceptable range of values for this option is 1 to $T - 1$. If BANDOPT=LEADING or CENTERED, then the default value of MAXBAND is 2. If BANDOPT=TRAILING, then the default value of MAXBAND is 1. If no BANDOPT option is specified such as when no exogenous instruments are used, then the default value of MAXBAND is 1. See the section “Dynamic Panel Estimator” on page 1423 for details.
**MAXITER=integer**

specifies the maximum number of iterations allowed for the iterated GMM option. The default value is MAXITER=200. See the section “Dynamic Panel Estimator” on page 1423 for details.

**NEWEYWEST=<(option-list)>**

specifies the well-known Newey-West estimator, a special HAC estimator with (1) the Bartlett kernel, (2) the bandwidth parameter determined by the equation based on the sample size, \( b = \lfloor \gamma T^r + c \rfloor \), and (3) no adjustment for degrees of freedom and no prewhitening. By default the bandwidth parameter for Newey-West estimator is \( 0.75T^{0.3333} + 0.5 \), as shown in the equation (15.17) in Stock and Watson (2002). When you specify COVEST=NEWEYWEST, you can specify the following options in parentheses and separate them with commas:

**GAMMA= number**

specifies the coefficient \( \gamma \) in the equation. The default is \( \gamma = 0.75 \).

**RATE= number**

specifies the growth rate \( r \) in the equation. The default is \( r = 0.3333 \).

**CONSTANT= number**

specifies the constant \( c \) in the equation. The default is \( c = 0.5 \).

**NODIFFS**

specifies that the dynamic panel model be estimated without moment conditions from the difference equations. See the section “Dynamic Panel Estimator” on page 1423 for details.

**NOESTIM**

limits the estimation of a FIXONE, FIXONETIME, RANONE model to the generation of the transformed series. This option is intended for use with an OUTTRANS= data set.

**NOINT**

suppresses the intercept parameter from the model.

**NOLEVELS**

specifies that the dynamic panel model be estimated without moment conditions from the level equations. See the section “Dynamic Panel Estimator” on page 1423 for details.

**NOPRINT**

suppresses the normal printed output.

**PARKS**

specifies that the model be estimated by using the Parks method, which assumes a first-order autoregressive model for the error structure. See the section “Parks Method (Autoregressive Model)” on page 1418 for details.

**PHI**

prints the \( \Phi \) matrix of estimated covariances of the observations for the Parks method. The PHI option is relevant only when the PARKS option is used. See the section “Parks Method (Autoregressive Model)” on page 1418 for details.
POOLED
specifies that a pooled (OLS) model be estimated.

POOLTEST
requests poolability tests for one-way fixed effects and pooled models.

PRINTFIXED
prints the fixed effects.

RANONE
specifies that a one-way random-effects model be estimated.

RANTWO
specifies that a two-way random-effects model be estimated.

RHO
prints the estimated autocorrelation coefficients for the Parks method.

ROBUST
specifies that the robust weighting matrix be used in the calculation of the covariance matrix of the single-step, two-step and iterated GMM dynamic panel estimator. See the section “Dynamic Panel Estimator” on page 1423 for details.

SINGULAR=number
specifies a singularity criterion for the inversion of the matrix. The default depends on the precision of the computer system.

TIME
specifies that the model be estimated by using the dynamic panel estimator method, but that PROC PANEL includes time dummy variables to model any time effects present in the data. See the section “Dynamic Panel Estimator” on page 1423 for details.

UROOTTEST(test1< (test-options), test2< (test-options)> . . . < option1 < option2 . . . > )
STATIONARITY(test1< (test-options), test2< (test-options)> . . . < option1 < option2 . . . > )
specifies tests of stationarity or unit root for panel data and the options for each test. The panel unit root test (or stationarity test) will test the existence of unit root for the dependent variables only. Six tests are available. You can specify all or some of these tests, separated by commas. If you specify one or more test-options (separated by spaces) inside the parentheses after a particular test, they apply only to that test. If you specify one or more options separated by spaces after you specify the tests, they apply to all the tests. If you specify both test-options and options, the test-options override the options.

ALL
requests that all panel unit root and stationarity tests be performed.

BREITUNG< (test-options) >
requests Breitung’s unbiased test, t test and GLS t test that are robust to cross-sectional dependence. The tests are described in Breitung and Meyer (1994); Breitung (2000); Breitung and Das (2005). The following test-options are available for this test:
DETAIL
requests that intermediate results (lag order) be printed.

LAGS=type | value
specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regressions. You can specify a value for the order of lags. If the specified lag order is too big to run linear regression (LAGS > T – k, where T is the number of observations and k is the number of parameters), then the lag order is set to \[12(T/100)^{1/4}\] or \(T – k – 1\), whichever is smaller. Alternatively, you can specify one of the following types:

GS
selects the order of lags by Hall’s (1994) sequential testing method: from the most general model (maximum lags) to lower order of lag terms.

SG
selects the order of lags by Hall’s (1994) sequential testing method: from no lag term to maximum allowed lags.

AIC
selects the order of lags by AIC.

SBC
SIC
SBIC
selects the order of lags by Bayesian information criterion (or Schwarz criterion).

HQIC
selects the order of lags by the Hannan-Quinn information criterion.

MAIC
selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is LAGS=MAIC.

MAXLAGS=value
specifies the maximum lag order that the model allows. The default value is \[12(T/100)^{1/4}\]. If value is larger than 0 and larger than \(T – k\), then the maximum lag order is set to be the default value of \[12(T/100)^{1/4}\] or \(T – k – 1\), whichever is smaller. This option is ignored if you specify LAGS=value.

COMBINATION < (test-options) >
FISHER < (test-options) >
specifies combination tests proposed by Choi (2001); Maddala and Wu (1999). Fisher’s test, as proposed by Maddala and Wu (1999), is a special case of combination tests. You can specify one or more of the following test-options:

TEST=ADF | PP
selects the time series unit root test for combination tests (Fisher’s test). ADF specifies the augmented Dickey-Fuller (ADF) test, and ignores the BANDWIDTH and KERNEL options for the combination tests. PP specifies the Phillips and Perron (1988) unit root test. When
you specifies TEST = PP, the LAGS and MAXLAGS options are ignored for the combination
tests.
The default is TEST=PP.

**KERNEL=value**
specifies the type of kernel function. You can specify the following values:

- BARTLETT specifies the Bartlett kernel function.
- PARZEN specifies the Parzen kernel function.
- QS specifies the quadratic spectral kernel function.
- TH specifies the Turkey-Hanning kernel function.
- TRUNCATED specifies the truncated kernel function.

The default is KERNEL=QS.

**BANDWIDTH=ANDREWS | number**
specifies the bandwidth for the kernel. If you specify BANDWIDTH=ANDREWS, the
bandwidth is selected by the Andrews method. If you specify a nonnegative number, the
bandwidth is set to that value. The default is BANDWIDTH=ANDREWS.

**DETAIL**
requests that intermediate results (lag order and long-run variance for each cross section) be
printed.

**LAGS=type | value**
specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regres-
sions. You can specify a value for the order of lags. If the specified lag order is too big to
run linear regression (LAGS > T – k, where T is the number of observations and k is the
number of parameters), then the lag order is set to \( \left\lfloor \frac{12(T/100)^{1/4}}{1} \right\rfloor \) or \( T – k – 1 \), whichever
is smaller. Alternatively, you can specify one of the following types:

- **GS**
  selects the order of lags by Hall’s (1994) sequential testing method: from the most
general model (maximum lags) to lower order of lag terms.

- **SG**
  selects the order of lags by Hall’s (1994) sequential testing method: from no lag term to
maximum allowed lags.

- **AIC**
  selects the order of lags by AIC.

- **SBC**

- **SIC**

- **SBIC**
  selects the order of lags by Bayesian information criterion (or Schwarz criterion).
**HQIC**
selects the order of lags by the Hannan-Quinn information criterion.

**MAIC**
selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is LAGS=MAIC.

**MAXLAGS=value**
specifies the maximum lag order that the model allows. The default value is \( \left\lfloor \frac{12(T/100)^{1/4}}{1} \right\rfloor \). If value is larger than 0 and larger than \( T - k \), then the maximum lag order is set to be the default value of \( \left\lfloor \frac{12(T/100)^{1/4}}{1} \right\rfloor \) or \( T - k - 1 \), whichever is smaller. This option is ignored if you specify LAGS=value.

**HADRI < (test-options) >**
specifies Hadri’s (2000) panel stationarity test. You can specify the following test-options:

- **DETAIL**
  requests that intermediate results (lag order and long-run variance for each cross section) be printed.

- **KERNEL=value**
  specifies the type of kernel function. You can specify the following values:

  - **BARTLETT**
    specifies the Bartlett kernel function.

  - **PARZEN**
    specifies the Parzen kernel function.

  - **QS**
    specifies the quadratic spectral kernel function.

  - **TH**
    specifies the Turkey-Hanning kernel function.

  - **TRUNCATED**
    specifies the truncated kernel function.

  The default is KERNEL=QS.

- **BANDWIDTH=ANDREWS | number**
  specifies the bandwidth for the kernel. If you specify BANDWIDTH=ANDREWS, the bandwidth is selected with the Andrews method. If you specify a nonnegative number, the bandwidth is set to that value. The default is BANDWIDTH=ANDREWS.

**HT**
specifies Harris and Tzavalis (1999) panel unit root test. No options are available for this test.

**IPS < (test-options) >**
specifies the Im, Pesaran, and Shin (2003) panel unit root test. You can specify the following test-options:

- **DETAIL**
  requests that intermediate results (lag order) be printed.
LAGS= type | value
specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regressions. You can specify a value for the order of lags. If the specified lag order is too big to run linear regression (LAGS > T – k, where T is the number of observations and k is the number of parameters), then the lag order is set to \( \left\lfloor 12(T/100)^{1/4} \right\rfloor \) or \( T – k – 1 \), whichever is smaller. Alternatively, you can specify one of the following types:

**GS**
selects the order of lags by Hall’s (1994) sequential testing method: from the most general model (maximum lags) to lower order of lag terms.

**SG**
selects the order of lags by Hall’s (1994) sequential testing method: from no lag term to maximum allowed lags.

**AIC**
selects the order of lags by AIC.

**SBC**

**SIC**

**SBIC**
selects the order of lags by Bayesian information criterion (or Schwarz criterion).

**HQIC**
selects the order of lags by the Hannan-Quinn information criterion.

**MAIC**
selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is LAGS=MAIC.

MAXLAGS= value
specifies the maximum lag order that the model allows. The default value is \( \left\lfloor 12(T/100)^{1/4} \right\rfloor \). If value is larger than 0 and larger than \( T – k \), then the maximum lag order is set to the default value of \( \left\lfloor 12(T/100)^{1/4} \right\rfloor \) or \( T – k – 1 \), whichever is smaller. This option is ignored if you specify LAGS=value.

LLC < (test-options) >
specifies the Levin, Lin, and Chu (2002) panel unit root test. You can specify the following test-options:

**DETAIL**
requests that intermediate results (lag order and long-run variance for each cross section) be printed.

**KERNEL=value**
specifies the type of kernel function. You can specify the following values:
BARTLETT specifies the Bartlett kernel function.

PARZEN specifies the Parzen kernel function.

QS specifies the quadratic spectral kernel function.

TH specifies the Turkey-Hanning kernel function.

TRUNCATED specifies the truncated kernel function.

The default is KERNEL=QS.

**BANDWIDTH=ANDREWS | number**
specifies the bandwidth for the kernel. If you specify BANDWIDTH=ANDREWS, the bandwidth is selected with the Andrews method. If you specify a nonnegative number, the bandwidth is set to that value. The default is BANDWIDTH=LLCBAND, where the bandwidth is set to be 

\[ \hat{k} = \left\lfloor 3.21T^{\frac{1}{3}} \right\rfloor \]

according to Levin, Lin, and Chu (2002).

**LAGS=type | value**
specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regressions. You can specify a value for the order of lags. If the specified lag order is too big to run linear regression (LAGS > T - k, where T is the number of observations and k is the number of parameters), then the lag order is set to \( \left\lfloor 12(T/100)^{1/4} \right\rfloor \) or \( T - k - 1 \), whichever is smaller. Alternatively, you can specify one of the following types:

- **GS**
  selects the order of lags by Hall’s (1994) sequential testing method: from the most general model (maximum lags) to lower order of lag terms.

- **SG**
  selects the order of lags by Hall’s (1994) sequential testing method: from no lag term to maximum allowed lags.

- **AIC**
  selects the order of lags by AIC.

- **SBC**

- **SIC**

- **SBIC**
  selects the order of lags by Bayesian information criterion (or Schwarz criterion).

- **HQIC**
  selects the order of lags by the Hannan-Quinn information criterion.

- **MAIC**
  selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is LAGS=MAIC.

**MAXLAGS=value**
specifies the maximum lag order that the model allows. The default value is \( \left\lfloor 12(T/100)^{1/4} \right\rfloor \). If value is larger than 0 and larger than \( T - k \), then the maximum lag order is set to be the default value of \( \left\lfloor 12(T/100)^{1/4} \right\rfloor \) or \( T - k - 1 \), whichever is smaller. This option is ignored if you specify LAGS=value.
Two tests, LLC and BREITUNG’s, are specified in the following UROOTTEST option specification:

```
uroottest = (llc=(kernel=parzen lags=aic), breitung= (lags=gs ) maxlags=2 kernel=bartlett)
```

For the LLC test, the lag order is selected by AIC with maximum lag order 2, and the kernel is specified as Parzen (overriding Bartlett). For the BREITUNG’s test, the lag order is GS with a maximum lag order 2. The KERNEL option is ignored by BREITUNG’s test because it is not a valid option.

**VCOMP=FB | NL | WH | WK**

specifies the type of variance component estimate to use. The default is VCOMP=FB for balanced data and VCOMP=WK for unbalanced data. See the section “One-Way Random-Effects Model” on page 1410 and “Two-Way Random-Effects Model” on page 1413 for details.

**OUTPUT Statement**

```
OUTPUT OUT=SAS-data-set < = options . . . > ;
```

The OUTPUT statement creates an output SAS data set as specified by the following options:

**OUT=SAS-data-set**

names the output SAS data set to contain the predicted and transformed values. If the OUT= option is not specified, the new data set is named according to the DATA$n convention.

**PREDICTED=name**

writes the predicted values to the output data set.

**RESIDUAL=name**

writes the residuals from the predicted values based on both the structural and time series parts of the model to the output data set.

**RESTRICT Statement**

```
RESTRICT < "string"> equation < ,equation2 . . . > ;
```

The RESTRICT statement specifies linear equality restrictions on the parameters in the previous model statement. There can be as many unique restrictions as the number of parameters in the preceding model statement. Multiple RESTRICT statements are understood as joint restrictions on a model’s parameters. Restrictions on the intercept are obtained by the use of the keyword INTERCEPT.

Currently, only linear equality restrictions are permitted in PROC PANEL. Tests and restriction expressions can only be composed of algebraic operations that involve the addition symbol (+), subtraction symbol (–), and multiplication symbol (*).

The RESTRICT statement accepts labels that are produced in the printed output. RESTRICT statement can be labeled in two ways. A RESTRICT statement can be preceded by a label followed by a colon. This is
illustrated in `rest1` in the example below. Alternatively, the keyword RESTRICT can be followed by a quoted string.

The following statements illustrate the use of the RESTRICT statement:

```plaintext
proc panel;
  model y = x1 x2 x3;
  restrict x1 = 0, x2 * .5 + 2 * x3 = 0;
  rest1: restrict x2 = 0, x3 = 0;
  restrict "rest2" intercept=1;
run;
```

Note that a restrict statement cannot include a division sign in its formulation.

---

**TEST Statement**

```
TEST < "string"> equation < , equation2... > < / options > ;
```

The TEST statement performs Wald, LaGrange multiplier and likelihood ratio tests of linear hypotheses about the regression parameters in the preceding MODEL statement. TEST and RESTRICT statements before the first MODEL statement are automatically associated with the first MODEL statement, in addition to any TEST and RESTRICT statements that follow it but precede subsequent MODEL statements. Each equation specifies a linear hypothesis to be tested. All hypotheses in one TEST statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. The keyword INTERCEPT refers to the coefficient of the intercept.

The following options can be specified on the TEST statement after the slash (/):

- **ALL**
  - specifies Wald, LaGrange multiplier and likelihood ratio tests.

- **WALD**
  - specifies the WALD test.

- **LM**
  - specifies the LaGrange multiplier test.

- **LR**
  - specifies the likelihood ratio test.

The Wald test is performed by default.

The following statements illustrate the use of the TEST statement:

```plaintext
proc panel;
  id csid tsid;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0;
  test_int: test intercept = 0, x3 = 0;
run;
```
The first test investigates the joint hypothesis that

$$\beta_1 = 0$$

and

$$0.5\beta_2 + 2\beta_3 = 0$$

Currently, only linear equality restrictions and tests are permitted in PROC PANEL. Tests and restriction expressions can be composed only of algebraic operations that involve the addition symbol (+), subtraction symbol (−), and multiplication symbol (*).

The TEST statement accepts labels that are produced in the printed output. The TEST statement can be labeled in two ways. A TEST statement can be preceded by a label followed by a colon. Alternatively, the keyword TEST can be followed by a quoted string. If both are presented, PROC PANEL uses the quoted string. In the event no label is present, PROC PANEL automatically labels the tests. If both a TEST and a RESTRICT statement are specified, the test is run with restrictions applied.

Note that for the DaSilva method, only the WALD test is available.

---

**Details: PANEL Procedure**

### Specifying the Input Data

The PANEL procedure is similar to other regression procedures in SAS. Suppose you want to regress the variable Y on regressors X1 and X2. Cross sections are identified by the variable STATE, and time periods are identified by the variable DATE. The input data set used by PROC PANEL must be sorted by cross section and by time within each cross section. Therefore, the first step in PROC PANEL is to make sure that the input data set is sorted. The following statements sort the data set A appropriately:

```plaintext
proc sort data=a;
   by state date;
run;
```

The next step is to invoke the PANEL procedure and specify the cross section and time series variables in an ID statement. The following statements shows the correct syntax:

```plaintext
proc panel data=a;
   id state date;
   model y = x1 x2;
run;
```

Alternatively, PROC PANEL has the capability to read “flat” data. Say that you are using the data set A, which has observations on states. Specifically, the data are composed of observations on Y, X1, and X2. Unlike the previous case, the data is not recorded with a PROC PANEL structure. Instead, you have all of a state’s information on a single row. You have variables to denote the name of the state (say state). The
time observations for the $Y$ variable are recorded horizontally. So the variable $Y_{-1}$ is the first period’s time observation, $Y_{-10}$ is the tenth period’s observation for some state. The same holds for the other variables. You have variables $X1_{-1}$ to $X1_{-10}$, $X2_{-1}$ to $X2_{-10}$, and $X3_{-1}$ to $X3_{-10}$ for others. With such data, PROC PANEL could be called by using the following syntax:

```plaintext
proc panel data=a;
  flatdata indid = state base = (Y X1 X2) tsname = t;
  id state t;
  model Y = X1 X2;
run;
```

See “FLATDATA Statement” on page 1382 and Example 20.2 for more information about the use of the FLATDATA statement.

**Specifying the Regression Model**

The MODEL statement in PROC PANEL is specified like the MODEL statement in other SAS regression procedures: the dependent variable is listed first, followed by an equal sign, followed by the list of regressor variables, as shown in the following statements:

```plaintext
proc panel data=a;
  id state date;
  model y = x1 x2;
run;
```

The major advantage of using PROC PANEL is that you can incorporate a model for the structure of the random errors. It is important to consider what kind of error structure model is appropriate for your data and to specify the corresponding option in the MODEL statement.

The error structure options supported by the PANEL procedure are FIXONE, FIXONETIME, FIXTWO, RANONE, RANTWO, PARKS, DASILVA, GMM1, GMM2, and ITGMM (iterated GMM). See the following sections for more information about these methods and the error structures they assume. The following statements fit a Fuller-Battese one-way random-effects model:

```plaintext
proc panel data=a;
  id state date;
  model y = x1 x2 / ranone vcomp=fb;
run;
```

You can specify more than one error structure option in the MODEL statement; the analysis is repeated using each specified method. You can use any number of MODEL statements to estimate different regression models or estimate the same model by using different options. See Example 20.1 for more information.

To aid in model specification within this class of models, PROC PANEL provides two specification test statistics. The first is an $F$ statistic that tests the null hypothesis that the fixed-effects parameters are all 0. The second is a Hausman $m$ statistic that provides information about the appropriateness of the random-effects specification. The $m$ statistic is based on the idea that, under the null hypothesis of no correlation between the effects variables and the regressors, OLS and GLS are consistent. However, OLS is inefficient. Hence, a test
can be based on the result that the covariance of an efficient estimator with its difference from an inefficient estimator is 0. Rejection of the null hypothesis might suggest that the fixed-effects model is more appropriate.

The PANEL procedure also provides the Buse R-square measure. This number is interpreted as a measure of the proportion of the transformed sum of squares of the dependent variable that is attributable to the influence of the independent variables. In the case of OLS estimation, the Buse R-square measure is equivalent to the usual R-square measure.

Unbalanced Data

For fixed-effects models, random-effects models, between estimators, and dynamic panel estimators, the PANEL procedure can process data with different numbers of time series observations across different cross sections. The Parks and Da Silva methods cannot be used with unbalanced data. The missing time series observations are recognized by the absence of time series ID variable values in some of the cross sections in the input data set. Moreover, if an observation with a particular time series ID value and cross-sectional ID value is present in the input data set, but one or more of the model variables are missing, that time series point is treated as missing for that cross section.

Missing Values

Any observation in the input data set with a missing value for one or more of the regressors is ignored by PROC PANEL and is not used in the model fit.

If there are observations in the input data set with missing dependent variable values but with nonmissing regressors, PROC PANEL can compute predicted values and store them in an output data set by using the OUTPUT statement. Note that the presence of such observations with missing dependent variable values does not affect the model fit because these observations are excluded from the calculation.

If either some regressors or the dependent variable values are missing, the model is estimated as unbalanced where the number of time series observations across different cross sections does not have to be equal. The Parks and Da Silva methods cannot be used with unbalanced data.

Computational Resources

The more parameters there are to be estimated, the more memory and time are required to estimate the model. Also affecting these resources are the estimation method chosen and the method to calculate variance components. If the model has $p$ parameters including the intercept, there are at least $p + [p * (p + 1)]/2$ numbers being held in the memory.

If the Arellano and Bond GMM approach is used, the amount of memory grows proportionately to the number of instruments in the INSTRUMENT statement. If the ITGMM (iterated GMM) option is selected, the computation time also depends on the convergence criteria selected and the maximum number of iterations allowed.
Chapter 20: The PANEL Procedure

Restricted Estimates

A consequence of estimating a linear model with a restriction is that the error degrees of freedom increase by the number of restrictions. PROC PANEL produces the LaGrange multiplier associated with each restriction.

Say that you are interested in linear regression in which there are \( r \) restrictions. A linear restriction implies the following set of equations that relate the regression coefficients:

\[
\begin{align*}
R_{1,1}\beta_1 + R_{1,2}\beta_2 + \cdots + R_{1,p}\beta_p &= q_1 \\
R_{2,1}\beta_1 + R_{2,2}\beta_2 + \cdots + R_{2,p}\beta_p &= q_2 \\
& \quad \vdots \\
R_{r,1}\beta_1 + R_{r,2}\beta_2 + \cdots + R_{r,p}\beta_p &= q_r
\end{align*}
\]

To economize on notation, you can represent the restriction structure in the following matrix notation \( R\beta = q \).

The restricted \( \beta \) estimator is given by:

\[
\beta^* = \beta - (X'X)^{-1}X'(R(X'X)^{-1}R')^{-1}(R\beta - q)
\]

The LaGrange multipliers are given as:

\[
\lambda_* = (R(X'X)^{-1}R')^{-1}(R\beta - q)
\]

The standard errors of the LaGrange Multipliers are calculated from the following relationship:

\[
\text{Var}(\lambda_*) = (R(X'X)^{-1}R')^{-1}\text{Var}(\beta)R'(R(X'X)^{-1}R')^{-1}
\]

A significant LaGrange multiplier implies that you can reject the null hypothesis that the restrictions are not binding.

Note that in the special case of the fixed-effects models, the NOINT option and RESTRICT INTERCEPT=0 option give different estimates. This is not an error; it reflects two perspectives on the same issue. In the FIXONE case, the intercept is the last cross section’s fixed effect (or the last time affecting the case of FIXONETIME). Specifying the NOINT option removes the intercept, but allows the last effect in. The NOINT command simply reclassifies the effects. The dummy variables become true cross section effects. If you specify the NOINT option with the FIXTWO option, the restriction is imposed that the last time effect is zero. A RESTRICT INTERCEPT=0 statement suppresses the estimation of the last effect in the FIXONE and FIXONETIME case. A RESTRICT INTERCEPT=0 has similar effects on the FIXTWO estimator. In general, restricting the intercept to zero is not recommended because OLS loses its unbiased nature.

Notation

The following notation represents the usual panel structure, with the specification of \( u_{it} \) dependent on the particular model:

\[
y_{it} = \sum_{k=1}^{K} x_{itk}\beta_k + u_{it} \quad i = 1, \ldots, N; t = 1, \ldots, T_i
\]

The total number of observations \( M = \sum_{i=1}^{N} T_i \). For the balanced data case, \( T_i = T \) for all \( i \). The \( M \times M \) covariance matrix of \( u_{it} \) is denoted by \( V \). Let \( X \) and \( y \) be the independent and dependent variables arranged by cross section and by time within each cross section. Let \( X_s \) be the \( X \) matrix without the intercept. All other notation is specific to each section.
One-Way Fixed-Effects Model

The specification for the one-way fixed-effects model is

\[ u_{it} = \gamma_i + \epsilon_{it} \]

where the \( \gamma_i \)s are nonrandom parameters to be estimated.

Let \( Q_0 = \text{diag}(E_{T_i}) \), with \( \tilde{J}_{T_i} = J_{T_i} / T_i \) and \( E_{T_i} = I_{T_i} - \tilde{J}_{T_i} \), where \( J_{T_i} \) is a matrix of \( T_i \) ones.

The matrix \( Q_0 \) represents the within transformation. In the one-way model, the within transformation is the conversion of the raw data to deviations from a cross section’s mean. The vector \( \tilde{x}_{it} \) is a row of the general matrix \( X_s \), where the subscripted \( s \) implies the constant (column of ones) is missing.

Let \( \tilde{X}_s = Q_0 X_s \) and \( \tilde{y} = Q_0 y \). The estimator of the slope coefficients is given by

\[ \tilde{\beta}_s = (\tilde{X}_s' \tilde{X}_s)^{-1} \tilde{X}_s' \tilde{y} \]

Once the slope estimates are in hand, the estimation of an intercept or the cross-sectional fixed effects is handled as follows. First, you obtain the cross-sectional effects:

\[ \gamma_i = \tilde{y}_i - \tilde{\beta}_s \tilde{x}_i \quad \text{for} \quad i = 1 \ldots N \]

If the NOINT option is specified, then the dummy variables’ coefficients are set equal to the fixed effects. If an intercept is desired, then the \( i \)th dummy variable is obtained from the following expression:

\[ D_i = \gamma_i - \gamma_N \quad \text{for} \quad i = 1 \ldots N - 1 \]

The intercept is the \( N \)th fixed effect \( \gamma_N \).

The within model sum of squared errors is:

\[ \text{SSE} = \sum_{i=1}^{N} \sum_{t=1}^{T_i} (y_{it} - \gamma_i - X_s \tilde{\beta}_s)^2 \]

The estimated error variance can be written:

\[ \hat{\sigma}_e^2 = \text{SSE} / (M - N - (K - 1)) \]

Alternatively, an equivalent way to express the error variance is

\[ \hat{\sigma}_e^2 = \tilde{u}' Q_0 \tilde{u} / (M - N - (K - 1)) \]

where the residuals \( \tilde{u} \) are given by \( \tilde{u} = (I_M - j_M j_M' / M)(y - X_s \tilde{\beta}_s) \) if there is an intercept and by \( \tilde{u} = (y - X_s \tilde{\beta}_s) \) if there is not. The drawback is that the formula changes (but the results do not) with the inclusion of a constant.

The variance covariance matrix of \( \tilde{\beta}_s \) is given by:

\[ \text{Var} \left[ \tilde{\beta}_s \right] = \hat{\sigma}_e^2 (\tilde{X}_s' \tilde{X}_s)^{-1} \]

The covariance of the dummy variables and the dummy variables with the \( \tilde{\beta}_s \) is dependent on whether the intercept is included in the model.
• no intercept:

\[
\text{Var}[\gamma_i] = \text{Var}[D_i] = \frac{\hat{\sigma}_e^2}{T_i} + \bar{x}_i \text{Var} [\tilde{\beta}_s] \bar{x}_i.
\]

\[
\text{Cov}[\gamma_i, \gamma_j] = \text{Cov}[D_i, D_j] = \bar{x}_i \text{Var} [\tilde{\beta}_s] \bar{x}_j.
\]

\[
\text{Cov}[\gamma_i, \tilde{\beta}_s] = \text{Cov}[D_i, \tilde{\beta}_s] = -\bar{x}_i \text{Var} [\tilde{\beta}_s]
\]

• intercept:

\[
\text{Var}[D_i] = \frac{\hat{\sigma}_e^2}{T_i} + \frac{\hat{\sigma}_\tau^2}{T_N} + (\bar{x}_i - \bar{x}_N) \text{Var} [\tilde{\beta}_s] (\bar{x}_j - \bar{x}_N).
\]

\[
\text{Cov}[D_i, D_j] = \frac{\hat{\sigma}_e^2}{T_N} + (\bar{x}_i - \bar{x}_N) \text{Var} [\tilde{\beta}_s] (\bar{x}_j - \bar{x}_N).
\]

\[
\text{Var}[\text{Intercept}] = \text{Var}[\gamma_N] = \frac{\hat{\sigma}_e^2}{T_N} + \bar{x}_N \text{Var} [\tilde{\beta}_s] \bar{x}_N.
\]

\[
\text{Cov}[D_i, \tilde{\beta}_s] = -(\bar{x}_i - \bar{x}_N) \text{Var} [\tilde{\beta}_s]
\]

\[
\text{Cov}[\text{Intercept}, D_i] = \frac{\hat{\sigma}_\tau^2}{T_i} + \bar{x}_N \text{Var} [\tilde{\beta}_s] (\bar{x}_i - \bar{x}_N)
\]

\[
\text{Cov}[\text{Intercept}, \tilde{\beta}_s] = -\bar{x}_N \text{Var} [\tilde{\beta}_s]
\]

Alternatively, the model option FIXONETIME estimates a one-way model where the heterogeneity comes from time effects. This option is analogous to re-sorting the data by time and then by cross section and running a FIXONE model. The advantage of using the FIXONETIME option is that sorting is avoided and the model remains labeled correctly.

**Two-Way Fixed-Effects Model**

The specification for the two-way fixed-effects model is

\[
u_{it} = \gamma_i + \alpha_t + \epsilon_{it}\]

where the \(\gamma_i\)s and \(\alpha_t\)s are nonrandom parameters to be estimated.

If you do not specify the NOINT option, which suppresses the intercept, the estimates for the fixed effects are reported under the restriction that \(\gamma_N = 0\) and \(\alpha_T = 0\). If you specify the NOINT option to suppress the intercept, only the restriction \(\alpha_T = 0\) is imposed.
Assume that the data are balanced (for example, all cross sections have $T$ observations). Then you can write the following:

$$\tilde{y}_{it} = y_{it} - \bar{y}_i - \bar{y}_t + \bar{y}$$
$$\tilde{x}_{it} = x_{it} - \bar{x}_i - \bar{x}_t + \bar{x}$$

where the symbols:

$y_{it}$ and $x_{it}$ are the dependent variable (a scalar) and the explanatory variables (a vector whose columns are the explanatory variables not including a constant), respectively

$\bar{y}_i$ and $\bar{x}_i$ are cross section means

$\bar{y}_t$ and $\bar{x}_t$ are time means

$\bar{y}$ and $\bar{x}$ are the overall means

The two-way fixed-effects model is simply a regression of $\tilde{y}_{it}$ on $\tilde{x}_{it}$. Therefore, the two-way $\beta$ is given by:

$$\hat{\beta}_s = \left( \tilde{X}' \tilde{X} \right)^{-1} \tilde{X}' \tilde{y}$$

The calculations of cross section dummy variables, time dummy variables, and intercepts follow in a fashion similar to that used in the one-way model.

First, you obtain the net cross-sectional and time effects. Denote the cross-sectional effects by $\gamma$ and the time effects by $\alpha$. These effects are calculated from the following relations:

$$\hat{\gamma}_i = (\bar{y}_i - \bar{y}) - \hat{\beta}_s (\bar{x}_i - \bar{x})$$
$$\hat{\alpha}_t = (\bar{y}_t - \bar{y}) - \hat{\beta}_s (\bar{x}_t - \bar{x})$$

Denote the cross-sectional dummy variables and time dummy variables with the superscript $C$ and $T$. Under the NOINT option the following equations give the dummy variables:

$$D^C_i = \hat{\gamma}_i + \hat{\alpha}_T$$
$$D^T_t = \hat{\alpha}_t - \hat{\alpha}_T$$

When an intercept is specified, the equations for dummy variables and intercept are:

$$D^C_i = \hat{\gamma}_i - \hat{\gamma}_N$$
$$D^T_t = \hat{\alpha}_t - \hat{\alpha}_T$$

Intercept = $\hat{\gamma}_N + \hat{\alpha}_T$

The sum of squared errors is:

$$\text{SSE} = \sum_{i=1}^{N} \sum_{t=1}^{T_i} \left( y_{it} - \gamma_i - \alpha_t - X_s \hat{\beta}_s \right)^2$$

The estimated error variance is:

$$\hat{\sigma}_e^2 = \text{SSE}/(M-N-T-(K-1))$$

With or without a constant, the variance covariance matrix of $\hat{\beta}_s$ is given by:

$$\text{Var} \left[ \hat{\beta}_s \right] = \hat{\sigma}_e^2 (\tilde{X}' \tilde{X})^{-1}$$
Variance Covariance of Dummy Variables with No Intercept

The variances and covariances of the dummy variables are given with the NOINT specification as follows:

\[
\text{Var} \left( D^C_i \right) = \hat{\sigma}_\varepsilon^2 \left( \frac{1}{T} + \frac{1}{N} - \frac{1}{NT} \right) + \left( \bar{\mathbf{x}}_i + \bar{\mathbf{x}}_T - \bar{\mathbf{x}} \right)' \text{Var} \left[ \mathbf{b}_s \right] \left( \bar{\mathbf{x}}_i + \bar{\mathbf{x}}_T - \bar{\mathbf{x}} \right)
\]

\[
\text{Var} \left( D^T_t \right) = \frac{2\hat{\sigma}_\varepsilon^2}{N} + (\bar{\mathbf{x}}_t - \bar{\mathbf{x}}_T)' \text{Var} \left[ \mathbf{b}_s \right] (\bar{\mathbf{x}}_t - \bar{\mathbf{x}}_T)
\]

\[
\text{Cov} \left( D^C_i , D^C_j \right) = \hat{\sigma}_\varepsilon^2 \left( \frac{1}{N} - \frac{1}{NT} \right) + \left( \bar{\mathbf{x}}_i + \bar{\mathbf{x}}_T - \bar{\mathbf{x}} \right)' \text{Var} \left[ \mathbf{b}_s \right] \left( \bar{\mathbf{x}}_j + \bar{\mathbf{x}}_T - \bar{\mathbf{x}} \right)
\]

\[
\text{Cov} \left( D^T_t , D^T_u \right) = \frac{\hat{\sigma}_\varepsilon^2}{N} + (\bar{\mathbf{x}}_t - \bar{\mathbf{x}}_T)' \text{Var} \left[ \mathbf{b}_s \right] (\bar{\mathbf{x}}_u - \bar{\mathbf{x}}_T)
\]

\[
\text{Cov} \left( D^C_i , D^T_t \right) = -\frac{\hat{\sigma}_\varepsilon^2}{N} + (\bar{\mathbf{x}}_i + \bar{\mathbf{x}}_T - \bar{\mathbf{x}})' \text{Var} \left[ \mathbf{b}_s \right] (\bar{\mathbf{x}}_t - \bar{\mathbf{x}}_T)
\]

\[
\text{Cov} \left( D^C_i , \mathbf{b} \right) = -\left( \bar{\mathbf{x}}_i + \bar{\mathbf{x}}_T - \bar{\mathbf{x}} \right)' \text{Var} \left[ \mathbf{b}_s \right]
\]

\[
\text{Cov} \left( D^T_t , \mathbf{b} \right) = -\left( \bar{\mathbf{x}}_t - \bar{\mathbf{x}}_T \right)' \text{Var} \left[ \mathbf{b}_s \right]
\]
Variance Covariance of Dummy Variables with Intercept

The variances and covariances of the dummy variables are given when the intercept is included as follows:

\[
\text{Var} \left( D_i^C \right) = \frac{2\hat{\sigma}^2}{T} + (\bar{x}_i - \bar{x}_N) \left( \bar{x}_i - \bar{x}_N \right) \text{Var} \left[ \tilde{\beta}_s \right]
\]

\[
\text{Var} \left( D_t^C \right) = \frac{2\hat{\sigma}^2}{N} + (\bar{x}_t - \bar{x}_T) \left( \bar{x}_t - \bar{x}_T \right) \text{Var} \left[ \tilde{\beta}_s \right]
\]

\[
\text{Var} \left( \text{Intercept} \right) = \frac{\hat{\sigma}^2}{T} \left( \frac{1}{T} + \frac{1}{N} - \frac{1}{N T} \right) + \left( \bar{x}_N + \bar{x}_T - \bar{x} \right) \text{Var} \left[ \tilde{\beta}_s \right]
\]

\[
\text{Cov} \left( D_i^C, D_j^C \right) = \frac{2\hat{\sigma}^2}{T} + (\bar{x}_i - \bar{x}_N) \left( \bar{x}_j - \bar{x}_N \right) \text{Var} \left[ \tilde{\beta}_s \right]
\]

\[
\text{Cov} \left( D_t^C, D_s^C \right) = \frac{2\hat{\sigma}^2}{N} + (\bar{x}_t - \bar{x}_T) \left( \bar{x}_s - \bar{x}_T \right) \text{Var} \left[ \tilde{\beta}_s \right]
\]

\[
\text{Cov} \left( D_i^C, \text{Intercept} \right) = - \left( \frac{\hat{\sigma}^2}{T} \right) + (\bar{x}_i - \bar{x}_N) \left( \bar{x}_N + \bar{x}_T - \bar{x} \right) \text{Var} \left[ \tilde{\beta}_s \right]
\]

\[
\text{Cov} \left( D_t^C, \text{Intercept} \right) = - \left( \frac{\hat{\sigma}^2}{N} \right) + (\bar{x}_t - \bar{x}_T) \left( \bar{x}_N + \bar{x}_T - \bar{x} \right) \text{Var} \left[ \tilde{\beta}_s \right]
\]

\[
\text{Cov} \left( \text{Intercept}, \tilde{\beta} \right) = - (\bar{x}_N + \bar{x}_T - \bar{x}) \text{Var} \left[ \tilde{\beta}_s \right]
\]

\[
\text{Cov} \left( \text{Intercept}, \tilde{\beta} \right) = - (\bar{x}_N + \bar{x}_T - \bar{x}) \text{Var} \left[ \tilde{\beta}_s \right]
\]

Unbalanced Panels

Let \( X_s \) and \( y_s \) be the independent and dependent variables arranged by time and by cross section within each time period. (Note that the input data set used by the PANEL procedure must be sorted by cross section and then by time within each cross section.) Let \( M_t \) be the number of cross sections observed in year \( t \) and let \( \sum_t M_t = M \). Let \( D_t \) be the \( M_t \times N \) matrix obtained from the \( N \times N \) identity matrix from which rows that correspond to cross sections not observed at time \( t \) have been omitted. Consider

\[
Z = (Z_1, Z_2)
\]

where \( Z_1 = (D_1', D_2', \ldots, D_T') \) and \( Z_2 = \text{diag}(D_1jN, D_2jN, \ldots, D_TjN) \). The matrix \( Z \) gives the dummy variable structure for the two-way model.

Let

\[
\Delta_N = Z_1' Z_1
\]

\[
\Delta_T = Z_2' Z_2
\]

\[
A = Z_2 Z_1
\]

\[
\bar{Z} = Z_2 - Z_1 \Delta_N^{-1} A'
\]

\[
Q = \Delta_T - A \Delta_N^{-1} A'
\]

\[
P = (I_M - Z_1 \Delta_N^{-1} Z_1') - \bar{Z} Q^{-1} \bar{Z} '
\]
Chapter 20: The PANEL Procedure

The estimate of the regression slope coefficients is given by

$$\tilde{\beta}_s = (X'_{s*}PX_{s*})^{-1}X'_{s*}Py_*$$

where $X_{s*}$ is the $X_*$ matrix without the vector of 1s.

The estimator of the error variance is

$$\hat{\sigma}_e^2 = \tilde{\mu}'P\tilde{\mu}/(M - T - N + 1 - (K - 1))$$

where the residuals are given by $\tilde{u} = (I_M - \tilde{J}_M'M/M)(y_* - X_{s*}\tilde{\beta}_s)$ if there is an intercept in the model and by $\tilde{u} = y_* - X_{s*}\tilde{\beta}_s$ if there is no intercept.

The actual implementation is quite different from the theory. The PANEL procedure transforms all series using the $P$ matrix.

$$\tilde{v} = Pv$$

The variable being transformed is $v$, which could be $y$ or any column of $X$. After the data are properly transformed, OLS is run on the resulting series.

Given $\tilde{\beta}_s$, the next step is estimating the cross-sectional and time effects. Given that $\gamma$ is the column vector of cross-sectional effects and $\alpha$ is the column vector of time effects,

$$\tilde{\alpha} = Q^{-1}\tilde{Z}'\gamma - Q^{-1}\tilde{Z}'X_s\tilde{\beta}_s$$

$$\tilde{\gamma} = (\Theta_1 + \Theta_2 - \Theta_3)\gamma - (\Theta_1 + \Theta_2 - \Theta_3)X_s\tilde{\beta}_s$$

$$\Theta_1 = \Delta_N^{-1}\tilde{Z}'_1$$

$$\Theta_2 = \Delta_N^{-1}A'Q^{-1}\tilde{Z}'_2$$

$$\Theta_3 = \Delta_N^{-1}A'Q^{-1}A\Delta_N^{-1}\tilde{Z}'_1$$

Given the cross-sectional and time effects, the next step is to derive the associated dummy variables. Using the NOINT option, the following equations give the dummy variables:

$$D^C_i = \tilde{\gamma}_i + \tilde{\alpha}_T$$

$$D^T_t = \tilde{\alpha}_t - \tilde{\alpha}_T$$

When an intercept is desired, the equations for dummy variables and intercept are:

$$D^C_i = \tilde{\gamma}_i - \tilde{\gamma}_N$$

$$D^T_t = \tilde{\alpha}_t - \tilde{\alpha}_T$$

Intercept = $\tilde{\gamma}_N + \tilde{\alpha}_T$

The calculation of the covariance matrix is as follows:

$$\text{Var} [\tilde{\gamma}] = \hat{\sigma}_e^2 (\Delta_N^{-1} - \Sigma_1 + \Sigma_2)$$

$$+ (\Theta_1 + \Theta_2 - \Theta_3)\text{Var} [\tilde{\beta}_s] (\Theta_1 + \Theta_2 - \Theta_3)'$$
where
\[
\Sigma_1 = \Delta_N^{-1} A' Q^{-1} \Delta_N^{-1} A' Q^{-1} A \Delta_N^{-1}
\]
\[
\Sigma_2 = \Delta_N^{-1} A' Q^{-1} \Delta_T Q^{-1} A \Delta_N
\]
\[
\text{Var}[\tilde{\alpha}] = \delta_\epsilon^2 \left( Q^{-1} \tilde{Z} Q^{-1} \right) + \left( Q^{-1} \tilde{Z} X_s \right) \text{Var}\left[\tilde{\beta}_s\right] \left( X_s' \tilde{Z} Q^{-1} \right)
\]
\[
\text{Cov}[\tilde{\alpha}, \hat{\gamma}] = \delta_\epsilon^2 \Delta_N^{-1} \left[ A' Q^{-1} \Delta_T - A' Q^{-1} A \Delta_N^{-1} A' \right] Q^{-1}
\]
\[
+ (\Theta_1 + \Theta_2 - \Theta_3) \text{Var}\left[\tilde{\beta}_s\right] \left( X_s' \tilde{Z} Q^{-1} \right)
\]
\[
\text{Cov}[\hat{\gamma}, \tilde{\beta}] = (\Theta_1 + \Theta_2 - \Theta_3) \text{Var}\left[\tilde{\beta}_s\right]
\]
\[
\text{Cov}[\tilde{\alpha}, \tilde{\beta}] = \left( Q^{-1} \tilde{Z} X_s \right) \text{Var}\left[\tilde{\beta}_s\right]
\]

Now you work out the variance covariance estimates for the dummy variables.

**Variance Covariance of Dummy Variables with No Intercept**

The variances and covariances of the dummy variables are given under the NOINT selection as follows:

\[
\text{Cov}\left(D_i^C, D_j^C\right) = \text{Cov}\left(\hat{y}_i, \hat{y}_j\right) + \text{Cov}\left(\hat{y}_i, \hat{\alpha}_T\right) + \text{Cov}\left(\hat{y}_j, \hat{\alpha}_T\right) + \text{Var}\left(\hat{\alpha}_T\right)
\]
\[
\text{Cov}\left(D_i^C, D_u^u\right) = \text{Cov}\left(\hat{\alpha}_i, \hat{\alpha}_u\right) - \text{Cov}\left(\hat{\alpha}_i, \hat{\alpha}_T\right) - \text{Cov}\left(\hat{\alpha}_u, \hat{\alpha}_T\right) + \text{Var}\left(\hat{\alpha}_T\right)
\]
\[
\text{Cov}\left(D_i^C, D_i^T\right) = \text{Cov}\left(\hat{y}_i, \hat{\alpha}_i\right) + \text{Cov}\left(\hat{y}_i, \hat{\alpha}_T\right) - \text{Cov}\left(\hat{y}_i, \hat{\alpha}_T\right) - \text{Var}\left(\hat{\alpha}_T\right)
\]
\[
\text{Cov}\left(D_i^C, \tilde{\beta}\right) = -\text{Cov}\left(\hat{y}_i, \tilde{\beta}\right) - \text{Cov}\left(\hat{\alpha}_T, \tilde{\beta}\right)
\]
\[
\text{Cov}\left(D_i^T, \tilde{\beta}\right) = -\text{Cov}\left(\hat{\alpha}_i, \tilde{\beta}\right) + \text{Cov}\left(\hat{\alpha}_T, \tilde{\beta}\right)
\]

**Variance Covariance of Dummy Variables with Intercept**

The variances and covariances of the dummy variables are given as follows when the intercept is included:

\[
\text{Cov}\left(D_i^C, D_j^C\right) = \text{Cov}\left(\hat{y}_i, \hat{y}_j\right) - \text{Cov}\left(\hat{y}_i, \hat{\gamma}_N\right) - \text{Cov}\left(\hat{y}_j, \hat{\gamma}_N\right) + \text{Var}\left(\hat{\gamma}_N\right)
\]
\[
\text{Cov}\left(D_i^C, D_u^u\right) = \text{Cov}\left(\hat{\alpha}_i, \hat{\alpha}_u\right) - \text{Cov}\left(\hat{\alpha}_i, \hat{\alpha}_T\right) - \text{Cov}\left(\hat{\alpha}_u, \hat{\alpha}_T\right) + \text{Var}\left(\hat{\alpha}_T\right)
\]
\[
\text{Cov}\left(D_i^C, D_i^T\right) = \text{Cov}\left(\hat{y}_i, \hat{\alpha}_i\right) - \text{Cov}\left(\hat{y}_i, \hat{\alpha}_T\right) - \text{Cov}\left(\hat{y}_N, \hat{\alpha}_i\right) + \text{Cov}\left(\hat{\gamma}_N, \hat{\alpha}_T\right)
\]
\[
\text{Cov}\left(D_i^C, \text{Intercept}\right) = \text{Cov}\left(\hat{y}_i, \hat{\gamma}_N\right) + \text{Cov}\left(\hat{y}_i, \hat{\alpha}_T\right) - \text{Cov}\left(\hat{y}_j, \hat{\alpha}_T\right) - \text{Var}\left(\hat{\gamma}_N\right)
\]
\[
\text{Cov}\left(D_i^T, \text{Intercept}\right) = \text{Cov}\left(\hat{\alpha}_i, \hat{\alpha}_T\right) + \text{Cov}\left(\hat{\alpha}_i, \hat{\gamma}_N\right) - \text{Cov}\left(\hat{\alpha}_T, \hat{\gamma}_N\right) - \text{Var}\left(\hat{\alpha}_T\right)
\]
\[
\text{Cov}\left(D_i^C, \tilde{\beta}\right) = -\text{Cov}\left(\hat{y}_i, \tilde{\beta}\right) - \text{Cov}\left(\hat{\gamma}_N, \tilde{\beta}\right)
\]
\[
\text{Cov}\left(D_i^T, \tilde{\beta}\right) = -\text{Cov}\left(\hat{\alpha}_i, \tilde{\beta}\right) + \text{Cov}\left(\hat{\alpha}_T, \tilde{\beta}\right)
\]
\[
\text{Cov}\left(\text{Intercept, } \tilde{\beta}_f\right) = -\text{Cov}\left(\hat{\alpha}_T, \tilde{\beta}\right) - \text{Cov}\left(\hat{\gamma}_N, \tilde{\beta}\right)
\]
Between Estimators

The between-groups estimator is the regression of the cross section means of $y$ on the cross section means of $\bar{X}_s$. In other words, you fit the following regression:

$$\tilde{y}_i = \bar{X}_i \beta_{BG} + \eta_i$$

The between-time-periods estimator is the regression of the time means of $y$ on the time means of $\bar{X}_s$. In other words, you fit the following regression:

$$\tilde{y}_t = \bar{X}_t \beta_{BT} + \xi_t$$

In either case, the error is assumed to be normally distributed with mean zero and a constant variance.

Pooled Estimator

PROC PANEL allows you to pool time series cross-sectional data and run regressions on the data. Pooling is admissible if there are no fixed effects or random effects present in the data. This feature is included to aid in analysis and comparison across model types and to give you access to HCCME standard errors and other panel diagnostics. In general, this model type should not be used with time series cross-sectional data.

One-Way Random-Effects Model

The specification for the one-way random-effects model is

$$u_{it} = v_i + \epsilon_{it}$$

Let $Z_0 = \text{diag}(J_T)$, $P_0 = \text{diag}(J_T)$, and $Q_0 = \text{diag}(E_T)$, with $\tilde{J}_T = J_T / T_i$ and $E_T = I_T - \tilde{J}_T$. Define $\bar{X}_s = Q_0 X_s$ and $\bar{y} = Q_0 y$ and $J$ as a vector of ones $T_i$ long.

In the one-way model, estimation proceeds in a two-step fashion. First, you obtain estimates of the variance of the $\sigma^2_\epsilon$ and $\sigma^2_{\epsilon\eta}$. There are multiple ways to derive these estimates; PROC PANEL provides four options. All four options are valid for balanced or unbalanced panels. Once these estimates are in hand, they are used to form a weighting factor $\theta$, and estimation proceeds via OLS on partial deviations from group means.

PROC PANEL gives the following options for variance component estimators.

Fuller and Battese’s Method

The Fuller and Battese method for estimating variance components can be obtained with the option VCOMP = FB and the option RANONE. The variance components are given by the following equations (For the approach in the two-way model, see Baltagi and Chang (1994); Fuller and Battese (1974)). Let

$$R(\nu) = y'Z_0(Z_0'Z_0)^{-1}Z_0'y$$

$$R(\beta|\nu) = ((\bar{X}_s'\bar{X}_s)^{-1}\bar{X}_s'\bar{y}(\bar{X}_s')^{-1}\bar{X}_s'\bar{y})$$
One-Way Random-Effects Model

\[ R(\beta) = (X' \beta)'(X' \beta)^{-1}X' \beta \]
\[ R(\nu|\beta) = R(\beta|\nu) + R(\nu) - R(\beta) \]

The estimator of the error variance is given by
\[ \hat{\sigma}_\epsilon^2 = (y' y - R(\beta|\nu) - R(\nu))/(M - N - (K - 1)) \]

If the NOINT option is specified, the estimator is
\[ \hat{\sigma}_\epsilon^2 = (y' y - R(\beta|\nu) - R(\nu))/(M - N - K) \]

The estimator of the cross-sectional variance component is given by
\[ \hat{\sigma}_\nu^2 = (R(\nu|\beta) - (N - 1)\hat{\sigma}_\epsilon^2)/(M - \text{tr}(Z_0'X_\epsilon(X_\epsilon'X_\epsilon)^{-1}X_\epsilon'Z_0)) \]

Note that the error variance is the variance of the residual of the within estimator.

According to Baltagi and Chang (1994), the Fuller and Battese method is appropriate to apply to both balanced and unbalanced data. The Fuller and Battese method is the default for estimation of one-way random-effects models with balanced panels. However, the Fuller and Battese method does not always obtain nonnegative estimates for the cross section (or group) variance. In the case of a negative estimate, a warning is printed and the estimate is set to zero.

Wansbeek and Kapteyn’s Method

The Wansbeek and Kapteyn method for estimating variance components can be obtained by setting VCOMP = WK (together with the option RANONE). The estimation of the one-way unbalanced data model is performed by using a specialization (Baltagi and Chang 1994) of the approach used by Wansbeek and Kapteyn (1989) for unbalanced two-way models. The Wansbeek and Kapteyn method is the default for unbalanced data. If just RANONE is specified, without the VCOMP= option, PROC PANEL estimates the variance component under Wansbeek and Kapteyn’s method.

The estimation of the variance components is performed by using a quadratic unbiased estimation (QUE) method. This involves focusing on quadratic forms of the centered residuals, equating their expected values to the realized quadratic forms, and solving for the variance components.

Let
\[ q_1 = \hat{u}'Q_0\hat{u} \]
\[ q_2 = \hat{u}'P_0\hat{u} \]

where the residuals \( \hat{u} \) are given by \( \hat{u} = (I_M - jM_j'^M/M)(y - X_\epsilon(\bar{X}_\epsilon'\bar{X}_\epsilon)^{-1}\bar{X}_\epsilon'y) \) if there is an intercept and by \( \hat{u} = y - X_\epsilon(\bar{X}_\epsilon'\bar{X}_\epsilon)^{-1}\bar{X}_\epsilon'y \) if there is not. A vector of \( M \) ones is represented by \( j \).

Consider the expected values
\[ E(q_1) = (M - N - (K - 1))\sigma_\epsilon^2 \]
\[ E(q_2) = (N - 1 + \text{tr}([X_\epsilon'Q_0X_\epsilon]^{-1}X_\epsilon'P_0X_\epsilon) - \text{tr}([X_\epsilon'Q_0X_\epsilon]^{-1}X_\epsilon'\bar{X}_\epsilon'MX_\epsilon)]\sigma_\nu^2 \]
\[ [M - \sum_i T_i^2/M]\sigma_\nu^2 \]

where \( \hat{\sigma}_\epsilon^2 \) and \( \hat{\sigma}_\nu^2 \) are obtained by equating the quadratic forms to their expected values.

The estimator of the error variance is the residual variance of the within estimate. The Wansbeek and Kapteyn method can also generate negative variance components estimates.
Wallace and Hussain's Method

The Wallace and Hussain method for estimating variance components can be obtained by setting VCOMP = WH (together with the option RANONE). Wallace-Hussain estimates start from OLS residuals on a data that are assumed to exhibit groupwise heteroscedasticity. As in the Wansbeek and Kapteyn method, you start with

\[ q_1 = \hat{u}_{OLS}^T Q_0 \hat{u}_{OLS} \]
\[ q_2 = \hat{u}_{OLS}^T P_0 \hat{u}_{OLS} \]

However, instead of using the 'true' errors, you substitute the OLS residuals. You solve the system

\[ E(q_1) = E(\hat{u}_{OLS}^T Q_0 \hat{u}_{OLS}) = \delta_{11} \hat{\sigma}_\epsilon^2 + \delta_{12} \hat{\sigma}_v^2 \]
\[ E(q_2) = E(\hat{u}_{OLS}^T P_0 \hat{u}_{OLS}) = \delta_{21} \hat{\sigma}_v^2 + \delta_{22} \hat{\sigma}_\epsilon^2 \]

The constants \( \delta_{11}, \delta_{12}, \delta_{21}, \delta_{22} \) are given by

\[ \delta_{11} = \text{tr} \left( (X'X)^{-1} X' Z_0' Z_0 X \right) - \text{tr} \left( (X'X)^{-1} X' P_0 X (X'X)^{-1} X' Z_0 Z_0 X \right) \]
\[ \delta_{12} = M - N - K + \text{tr} \left( (X'X)^{-1} X' P_0 X \right) \]
\[ \delta_{21} = M - 2 \text{tr} \left( (X'X)^{-1} X' Z_0' Z_0 X \right) + \text{tr} \left( (X'X)^{-1} X' P_0 X \right) \]
\[ \delta_{22} = N - \text{tr} \left( (X'X)^{-1} X' P_0 X \right) \]

where \( \text{tr}() \) is the trace operator on a square matrix.

Solving this system produces the variance components. This method is applicable to balanced and unbalanced panels. However, there is no guarantee of positive variance components. Any negative values are fixed equal to zero.

Nerlove's Method

The Nerlove method for estimating variance components can be obtained by setting VCOMP = NL. The Nerlove method (see Baltagi 1995, p. 17) is assured to give estimates of the variance components that are always positive. Furthermore, it is simple in contrast to the previous estimators.

If \( \gamma_i \) is the \( i \)th fixed effect, Nerlove’s method uses the variance of the fixed effects as the estimate of \( \hat{\sigma}_v^2 \). You have

\[ \hat{\sigma}_v^2 = \frac{1}{N} \sum_{i=1}^{N} (\gamma_i - \bar{\gamma})^2, \]

where \( \bar{\gamma} \) is the mean fixed effect. The estimate of \( \sigma_\epsilon^2 \) is simply the residual sum of squares of the one-way fixed-effects regression divided by the number of observations.

Transformation and Estimation

After you calculate the variance components from any method, the next task is to estimate the regression model of interest. For each individual, you form a weight \( (\theta_i) \) as

\[ \theta_i = 1 - \sigma_\epsilon^2 / w_i \]
\[ w_i^2 = T_i \sigma_v^2 + \sigma_\epsilon^2 \]
where $T_i$ is the $i$th cross section’s time observations.

Taking the $\theta_i$, you form the partial deviations,

$$\tilde{y}_{it} = y_{it} - \theta_i \bar{y}_i.$$  
$$\tilde{x}_{it} = x_{it} - \theta_i \bar{x}_i.$$  

where $\bar{y}_i$ and $\bar{x}_i$ are cross-sectional means of the dependent variable and independent variables (including the constant if any), respectively.

The random effects $\beta$ is then the result of simple OLS on the transformed data.

---

**Two-Way Random-Effects Model**

The specification for the two-way random-effects model is

$$u_{it} = v_i + e_t + \epsilon_{it}$$

As in the one-way random-effects model, the PANEL procedure provides four options for variance component estimators. Unlike the one-way random-effects model, unbalanced panels present some special concerns. Let $X_*$ and $y_*$ be the independent and dependent variables arranged by time and by cross section within each time period. (Note that the input data set used by the PANEL procedure must be sorted by cross section and then by time within each cross section.) Let $M_t$ be the number of cross sections observed in time $t$ and $\sum_t M_t = M$. Let $D_t$ be the $M_t \times N$ matrix obtained from the $N \times N$ identity matrix from which rows that correspond to cross sections not observed at time $t$ have been omitted. Consider

$$Z = (Z_1, Z_2)$$

where $Z_1 = (D'_1, D'_2, \ldots, D'_T)^T$ and $Z_2 = \text{diag}(D_{1jN}, D_{2jN}, \ldots, D_{TjN})$.

The matrix $Z$ gives the dummy variable structure for the two-way model.

For notational ease, let

$$\Delta_N = Z'_1 Z_1, \Delta_T = Z'_2 Z_2, A = Z'_2 Z_1$$

$$\bar{Z} = Z_2 - Z_1 \Delta_N^{-1} A'$$

$$\bar{\Delta}_1 = I_M - Z_1 \Delta_N^{-1} Z'_1$$

$$\bar{\Delta}_2 = I_M - Z_2 \Delta_T^{-1} Z'_2$$

$$Q = \Delta_T - A \Delta_N^{-1} A'$$

$$P = (I_M - Z_1 \Delta_N^{-1} Z'_1) - \bar{Z} Q^{-1} \bar{Z}$$
Chapter 20: The PANEL Procedure

Fuller and Battese’s Method

The Fuller and Battese method for estimating variance components can be obtained by setting VCOMP = FB (with the option RANTWO). FB is the default method for a RANTWO model with balanced panel. If RANTWO is requested without specifying the VCOMP= option, PROC PANEL proceeds under the Fuller and Battese method.

Following the discussion in Baltagi, Song, and Jung (2002), the Fuller and Battese method forms the estimates as follows.

The estimator of the error variance is

\[ \hat{\sigma}^2 = \hat{u}'P\hat{u}/(M - T - N + 1 - (K - 1)) \]

where \( P \) is the Wansbeek and Kapteyn within estimator for unbalanced (or balanced) panel in a two-way setting.

The estimation of the variance components is performed by using a quadratic unbiased estimation (QUE) method that involves computing on quadratic forms of the residuals \( \hat{u} \), equating their expected values to the realized quadratic forms, and solving for the variance components.

Wansbeek and Kapteyn’s Method

The Wansbeek and Kapteyn method for estimating variance components can be obtained by setting VCOMP = WK. The following methodology, outlined in Wansbeek and Kapteyn (1989) is used to handle both balanced and unbalanced data. The Wansbeek and Kapteyn method is the default for a RANTWO model with unbalanced panel. If RANTWO is requested without specifying the VCOMP= option, PROC PANEL proceeds under the Wansbeek and Kapteyn method if the panel is unbalanced.

The estimator of the error variance is

\[ \hat{\sigma}^2 = \hat{u}'P\hat{u}/(M - T - N + 1 - (K - 1)) \]

where the \( \hat{u} \) are given by \( \hat{u} = (I_M - j_M'j_M/M)/(y_* - X_{*5}(X'_{*5}PX_{*5})^{-1}X_{*5}/Py_*) \) if there is an intercept and by \( \hat{u} = (y_* - X_{*5}(X'_{*5}PX_{*5})^{-1}X'_{*5}Py_*) \) if there is not.
Let
\[ q_N = \tilde{u}'Z_2\Delta_T^{-1}Z'_2\tilde{u} \]
\[ q_T = \tilde{u}'Z_1\Delta_N^{-1}Z'_1\tilde{u} \]
The expected values are
\[ E(q_N) = (T + k_N - (1 + k_0))\sigma^2 + (T - \frac{\lambda_1}{M})\sigma_v^2 + (M - \frac{\lambda_2}{M})\sigma_e^2 \]
\[ E(q_T) = (N + k_T - (1 + k_0))\sigma^2 + (M - \frac{\lambda_1}{M})\sigma_v^2 + (N - \frac{\lambda_2}{M})\sigma_e^2 \]
where
\[ k_0 = j'MX_{ss}(X'_{ss}PX_{ss})^{-1}X'_{ss}j_M/M \]
\[ k_N = \text{tr}((X'_{ss}PX_{ss})^{-1}X'_{ss}Z_2\Delta_T^{-1}Z'_2X_{ss}) \]
\[ k_T = \text{tr}((X'_{ss}PX_{ss})^{-1}X'_{ss}Z_1\Delta_N^{-1}Z'_1X_{ss}) \]
\[ \lambda_1 = j'Z_1Z'_1j_M \]
\[ \lambda_2 = j'Z_2Z'_2j_M \]
The quadratic unbiased estimators for \( \sigma_v^2 \) and \( \sigma_e^2 \) are obtained by equating the expected values to the quadratic forms and solving for the two unknowns.

When the NOINT option is specified, the variance component equations change slightly. In particular, the following is true (Wansbeek and Kapteyn 1989):
\[ E(q_N) = (T + k_N)\sigma^2 + T\sigma_v^2 + M\sigma_e^2 \]
\[ E(q_T) = (N + k_T)\sigma^2 + M\sigma_v^2 + N\sigma_e^2 \]

**Wallace and Hussain’s Method**

The Wallace and Hussain method for estimating variance components can be obtained by setting VCOMP = WH. Wallace and Hussain’s method is by far the most computationally intensive. It uses the OLS residuals to estimate the variance components. In other words, the Wallace and Hussain method assumes that the following holds:
\[ q_e = \tilde{u}'_{OLS}P\tilde{u}_{OLS} \]
\[ q_N = \tilde{u}'_{OLS}Z_2\Delta_T^{-1}Z'_2\tilde{u}_{OLS} \]
\[ q_T = \tilde{u}'_{OLS}Z_1\Delta_N^{-1}Z'_1\tilde{u}_{OLS} \]
Taking expectations yields
\[ E(q_e) = E(\tilde{u}'_{OLS}P\tilde{u}_{OLS}) = \delta_{11}\sigma_e^2 + \delta_{12}\sigma_v^2 + \delta_{13}\sigma_e^2 \]
where the $\delta_{js}$ constants are defined by

$$
\delta_{11} = M - N - T + 1 - \text{tr} \left( X'PX \left( X'X \right)^{-1} \right) \\
\delta_{12} = \text{tr} \left( X'Z_2X'X \left( X'X \right)^{-1} \left( X'PX \left( X'X \right)^{-1} \right) \right) \\
\delta_{13} = \text{tr} \left( X'Z_2X'X \left( X'X \right)^{-1} \left( X'PX \left( X'X \right)^{-1} \right) \right) \\
\delta_{21} = T - \text{tr} \left( X'Z_2\Delta_T^{-1}Z'_1X \left( X'X \right)^{-1} \right)
$$

$$
\delta_{22} = T - 2\text{tr} \left( X'Z_2\Delta_T^{-1}Z_1Z'_1X \left( X'X \right)^{-1} \right) + \text{tr} \left( X'Z_2\Delta_T^{-1}Z_1'X \left( X'X \right)^{-1} X'Z_1Z'_1X \left( X'X \right)^{-1} \right)
$$

$$
\delta_{23} = T - 2\text{tr} \left( X'Z_2X \left( X'X \right)^{-1} \right) + \text{tr} \left( X'Z_2\Delta_T^{-1}Z_2X \left( X'X \right)^{-1} X'Z_2Z'_2X \left( X'X \right)^{-1} \right)
$$

$$
\delta_{31} = N - \text{tr} \left( X'Z_1\Delta_N^{-1}Z'_1X \left( X'X \right)^{-1} \right)
$$

$$
\delta_{32} = M - 2\text{tr} \left( X'Z_1Z'_1X \left( X'X \right)^{-1} \right) + \text{tr} \left( X'Z_1\Delta_N^{-1}Z'_1X \left( X'X \right)^{-1} X'Z_1Z'_1X \left( X'X \right)^{-1} \right)
$$

$$
\delta_{33} = N - 2\text{tr} \left( X'Z_1\Delta_N^{-1}Z'_1Z_2Z'_2X \left( X'X \right)^{-1} \right) + \text{tr} \left( X'Z_1\Delta_N^{-1}Z'_1X \left( X'X \right)^{-1} X'Z_2Z'_2X \left( X'X \right)^{-1} \right)
$$

The PANEL procedure solves this system for the estimates $\hat{\sigma}_e$, $\hat{\sigma}_v$, and $\hat{\sigma}_e$. Some of the estimated variance components can be negative. Negative components are set to zero and estimation proceeds.
Nerlove’s Method

The Nerlove method for estimating variance components can be obtained with by setting VCOMP = NL.

The estimator of the error variance is

\[ \hat{\sigma}_e^2 = \bar{u}' \bar{P} \bar{u} / M \]

The variance components for cross section and time effects are:

\[ \hat{\sigma}_p^2 = \sum_{i=1}^{N} \frac{(\gamma_i - \bar{\gamma})^2}{N - 1} \text{ where } \gamma_i \text{ is the } i \text{th cross section effect} \]

and

\[ \hat{\sigma}_t^2 = \sum_{i=1}^{T} \frac{(\alpha_t - \bar{\alpha})^2}{T - 1} \text{ where } \alpha_i \text{ is the } t \text{th time effect} \]

Transformation and Estimation

After you calculate the estimates of the variance components, you can proceed to the final estimation. If the panel is balanced, partial mean deviations are used:

\[ \bar{y}_{it} = y_{it} - \theta_1 \bar{y}_i - \theta_2 \bar{y}_t + \theta_3 \bar{y} . \]
\[ \bar{x}_{it} = x_{it} - \theta_1 \bar{x}_i - \theta_2 \bar{x}_t + \theta_3 \bar{x} . \]

The \( \theta \) estimates are obtained from:

\[ \theta_1 = 1 - \frac{\sigma_e}{\sqrt{T\sigma_p^2 + \sigma_e^2}} \]
\[ \theta_2 = 1 - \frac{\sigma_e}{\sqrt{N\sigma_e^2 + \sigma_e^2}} \]
\[ \theta_3 = \theta_1 + \theta_2 + \frac{\sigma_e}{\sqrt{T\sigma_p^2 + N\sigma_e^2 + \sigma_e^2}} - 1; \]

With these partial deviations, PROC PANEL uses OLS on the transformed series (including an intercept if you want).

The case of an unbalanced panel is somewhat more complicated. You could naively substitute the variance components in the equation below:

\[ \Omega = \sigma_e^2 I_M + \sigma_p^2 Z_1 Z'_1 + \sigma_e^2 Z_2 Z'_2 \]

After inverting the expression for \( \Omega \), it is possible to do GLS on the data (even if the panel is unbalanced). However, the inversion of \( \Omega \) is no small matter because the dimension is at least \( M(M+1) \).

Wansbeek and Kapteyn show that the inverse of \( \Omega \) can be written as

\[ \sigma_e^2 \Omega^{-1} = V - VZ_2 \bar{P}^{-1} Z'_2 V \]
Chapter 20: The PANEL Procedure

with the following:

\[
\begin{align*}
V &= I_M - Z_1 \hat{\Delta}_N^{-1} Z'_1 \\
\tilde{P} &= \hat{\Delta}_T - \Lambda \hat{\Delta}_N^{-1} \Lambda' \\
\hat{\Delta}_N &= \Delta_N + \left( \frac{\sigma^2}{\hat{\sigma}^2} \right) I_N \\
\hat{\Delta}_T &= \Delta_T + \left( \frac{\sigma^2}{\hat{\sigma}^2} \right) I_T
\end{align*}
\]

Computationally, this is a much less intensive approach.

By using the inverse of the covariance matrix of the error, it becomes possible to complete GLS on the unbalanced panel.

---

**Parks Method (Autoregressive Model)**

Parks (1967) considered the first-order autoregressive model in which the random errors \( u_{it}, i = 1, 2, \ldots, N, \) and \( t = 1, 2, \ldots, T \) have the structure

\[
\begin{align*}
E(u_{it}^2) &= \sigma_i (\text{heteroscedasticity}) \\
E(u_{it}u_{jt}) &= \sigma_{ij} (\text{contemporaneously correlated}) \\
u_{it} &= \rho_i u_{i,t-1} + \epsilon_{it} (\text{autoregression})
\end{align*}
\]

where

\[
\begin{align*}
E(\epsilon_{it}) &= 0 \\
E(u_{i,t-1}\epsilon_{jt}) &= 0 \\
E(\epsilon_{it}\epsilon_{jt}) &= \phi_{ij} \\
E(\epsilon_{it}\epsilon_{js}) &= 0 (s \neq t) \\
E(u_{i0}) &= 0 \\
E(u_{i0}u_{j0}) &= \sigma_{ij} = \phi_{ij} / (1 - \rho_i \rho_j)
\end{align*}
\]

The model assumed is first-order autoregressive with contemporaneous correlation between cross sections. In this model, the covariance matrix for the vector of random errors \( \mathbf{u} \) can be expressed as

\[
E(\mathbf{uu}') = V = \begin{bmatrix}
\sigma_{11} P_{11} & \sigma_{12} P_{12} & \ldots & \sigma_{1N} P_{1N} \\
\sigma_{21} P_{21} & \sigma_{22} P_{22} & \ldots & \sigma_{2N} P_{2N} \\
\vdots & \vdots & \ddots & \vdots \\
\sigma_{N1} P_{N1} & \sigma_{N2} P_{N2} & \ldots & \sigma_{NN} P_{NN}
\end{bmatrix}
\]
where

\[
P_{ij} = \begin{bmatrix}
1 & \rho_j & \rho_j^2 & \ldots & \rho_j^{T-1} \\
\rho_i & 1 & \rho_j & \ldots & \rho_j^{T-2} \\
\rho_i^2 & \rho_i & 1 & \ldots & \rho_j^{T-3} \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
\rho_i^{T-1} & \rho_i^{T-2} & \rho_i^{T-3} & \ldots & 1
\end{bmatrix}
\]

The matrix \( V \) is estimated by a two-stage procedure, and \( \beta \) is then estimated by generalized least squares. The first step in estimating \( V \) involves the use of ordinary least squares to estimate \( \beta \) and obtain the fitted residuals, as follows:

\[
\hat{u} = y - X\hat{\beta}_{OLS}
\]

A consistent estimator of the first-order autoregressive parameter is then obtained in the usual manner, as follows:

\[
\hat{\rho}_i = \left( \sum_{t=2}^{T} \hat{u}_{it} \hat{u}_{i,t-1} \right) / \left( \sum_{t=2}^{T} \hat{u}_{i,t-1}^2 \right) \quad i = 1, 2, \ldots, N
\]

Finally, the autoregressive characteristic of the data is removed (asymptotically) by the usual transformation of taking weighted differences. That is, for \( i = 1, 2, \ldots, N \),

\[
y_{i1} \sqrt{1 - \hat{\rho}_i^2} = \sum_{k=1}^{p} X_{i1k} \cdot \sqrt{1 - \hat{\rho}_i^2} + u_{i1} \sqrt{1 - \hat{\rho}_i^2}
\]

\[
y_{it} - \hat{\rho}_i y_{i,t-1} = \sum_{k=1}^{p} (X_{itk} - \hat{\rho}_i X_{i,t-1,k}) \beta_k + u_{it} - \hat{\rho}_i u_{i,t-1} \quad t = 2, \ldots, T
\]

which is written

\[
y_{it}^* = \sum_{k=1}^{p} X_{itk}^* \beta_k + u_{it}^* \quad i = 1, 2, \ldots, N; \quad t = 1, 2, \ldots, T
\]

Notice that the transformed model has not lost any observations (Seely and Zyskind 1971).

The second step in estimating the covariance matrix \( V \) is applying ordinary least squares to the preceding transformed model, obtaining

\[
\hat{u}^* = y^* - X^* \beta_{OLS}^*
\]

from which the consistent estimator of \( \sigma_{ij} \) is calculated as follows:

\[
s_{ij} = \frac{\hat{\phi}_{ij}}{(1 - \hat{\rho}_i \hat{\rho}_j)}
\]
where

\[ \hat{\phi}_{ij} = \frac{1}{(T - p)} \sum_{t=1}^{T} \tilde{u}_{it}^* \tilde{u}_{jt}^* \]

Estimated generalized least squares (EGLS) then proceeds in the usual manner,

\[ \hat{\beta}_P = (X'\hat{V}^{-1}X)^{-1}X'\hat{V}^{-1}y \]

where \( \hat{V} \) is the derived consistent estimator of \( V \). For computational purposes, \( \hat{\beta}_P \) is obtained directly from the transformed model,

\[ \hat{\beta}_P = (X'^*(\hat{\Phi}^{-1} \otimes I_T)X'^*)^{-1}X'^*(\hat{\Phi}^{-1} \otimes I_T)y^* \]

where \( \hat{\Phi} = [\hat{\phi}_{ij}]_{i,j=1,...,N} \).

The preceding procedure is equivalent to Zellner’s two-stage methodology applied to the transformed model (Zellner 1962).

Parks demonstrates that this estimator is consistent and asymptotically, normally distributed with

\[ \text{Var}(\hat{\beta}_P) = (X'V^{-1}X)^{-1} \]

**Standard Corrections**

For the PARKS option, the first-order autocorrelation coefficient must be estimated for each cross section. Let \( \rho \) be the \( N \times 1 \) vector of true parameters and \( R = (r_1, \ldots, r_N)' \) be the corresponding vector of estimates. Then, to ensure that only range-preserving estimates are used in PROC PANEL, the following modification for \( R \) is made:

\[ r_i = \begin{cases} r_i & \text{if } |r_i| < 1 \\ \max(.95, r_{\text{max}}) & \text{if } r_i \geq 1 \\ \min(-.95, r_{\text{min}}) & \text{if } r_i \leq -1 \end{cases} \]

where

\[ r_{\text{max}} = \begin{cases} 0 & \text{if } r_i < 0 \text{ or } r_i \geq 1 \forall i \\ \max_j [r_j : 0 \leq r_j < 1] & \text{otherwise} \end{cases} \]

and

\[ r_{\text{min}} = \begin{cases} 0 & \text{if } r_i > 0 \text{ or } r_i \leq -1 \forall i \\ \max_j [-1 < r_j \leq 0] & \text{otherwise} \end{cases} \]

Whenever this correction is made, a warning message is printed.
Da Silva Method (Variance-Component Moving Average Model)

The Da Silva method assumes that the observed value of the dependent variable at the \( t \)th time point on the \( i \)th cross-sectional unit can be expressed as

\[
y_{it} = \mathbf{x}'_{it} \beta + a_i + b_t + e_{it} \quad i = 1, \ldots, N; t = 1, \ldots, T
\]

where

- \( \mathbf{x}'_{it} = (x_{it1}, \ldots, x_{itp}) \) is a vector of explanatory variables for the \( t \)th time point and \( i \)th cross-sectional unit
- \( \beta = (\beta_1, \ldots, \beta_p)' \) is the vector of parameters
- \( a_i \) is a time-invariant, cross-sectional unit effect
- \( b_t \) is a cross-sectionally invariant time effect
- \( e_{it} \) is a residual effect unaccounted for by the explanatory variables and the specific time and cross-sectional unit effects

Since the observations are arranged first by cross sections, then by time periods within cross sections, these equations can be written in matrix notation as

\[
y = \mathbf{X}\beta + \mathbf{u}
\]

where

- \( \mathbf{u} = (\mathbf{a} \otimes \mathbf{1}_T) + (\mathbf{1}_N \otimes \mathbf{b}) + \mathbf{e} \)
- \( \mathbf{y} = (y_{11}, \ldots, y_{1T}, y_{21}, \ldots, y_{NT})' \)
- \( \mathbf{X} = (\mathbf{x}_{11}, \ldots, \mathbf{x}_{1T}, \mathbf{x}_{21}, \ldots, \mathbf{x}_{NT})' \)
- \( \mathbf{a} = (a_1 \ldots a_N)' \)
- \( \mathbf{b} = (b_1 \ldots b_T)' \)
- \( \mathbf{e} = (e_{11}, \ldots, e_{1T}, e_{21}, \ldots, e_{NT})' \)

Here \( \mathbf{1}_N \) is an \( N \times 1 \) vector with all elements equal to 1, and \( \otimes \) denotes the Kronecker product.

The following conditions are assumed:

1. \( x_{it} \) is a sequence of nonstochastic, known \( p \times 1 \) vectors in \( \mathbb{R}^p \) whose elements are uniformly bounded in \( \mathbb{R}^p \). The matrix \( \mathbf{X} \) has a full column rank \( p \).
2. \( \beta \) is a \( p \times 1 \) constant vector of unknown parameters.
3. \( \mathbf{a} \) is a vector of uncorrelated random variables such that \( E(a_i) = 0 \) and \( \text{var}(a_i) = \sigma_a^2 \), \( \sigma_a^2 > 0, i = 1, \ldots, N \).
4. \( \mathbf{b} \) is a vector of uncorrelated random variables such that \( E(b_t) = 0 \) and \( \text{var}(b_t) = \sigma_b^2 \) where \( \sigma_b^2 > 0 \) and \( t = 1, \ldots, T \).
5. $e_i = (e_{i1}, \ldots, e_{iT})'$ is a sample of a realization of a finite moving-average time series of order $m < T - 1$ for each $i$; hence,

$$e_{it} = \alpha_0 e_{it} + \alpha_1 e_{i,t-1} + \ldots + \alpha_m e_{i,t-m} \quad t = 1, \ldots, T; i = 1, \ldots, N$$

where $\alpha_0, \alpha_1, \ldots, \alpha_m$ are unknown constants such that $\alpha_0 \neq 0$ and $\alpha_m \neq 0$, and $\{e_{ij}\}_{j=-\infty}^{\infty}$ is a white noise process for each $i$—that is, a sequence of uncorrelated random variables with $E(e_i) = 0$, $E(e_i^2) = \sigma_e^2$, and $\sigma_e^2 > 0$. $\{e_{ij}\}_{j=-\infty}^{\infty}$ for $i = 1, \ldots, N$ are mutually uncorrelated.

6. The sets of random variables $\{a_i\}_{i=1}^{N}$, $\{b_t\}_{t=1}^{T}$, and $\{e_{it}\}_{t=1}^{T}$ for $i = 1, \ldots, N$ are mutually uncorrelated.

7. The random terms have normal distributions $a_i \sim N(0, \sigma_a^2)$, $b_t \sim N(0, \sigma_b^2)$, and $e_{t-k} \sim N(0, \sigma_e^2)$, for $i = 1, \ldots, N; t = 1, \ldots, T$; and $k = 1, \ldots, m$.

If assumptions 1–6 are satisfied, then

$$E(y) = X\beta$$

and

$$\text{var}(y) = \sigma_a^2 (I_N \otimes J_T) + \sigma_b^2 (J_N \otimes I_T) + (I_N \otimes \Psi_T)$$

where $\Psi_T$ is a $T \times T$ matrix with elements $\psi_{ts}$ as follows:

$$\text{Cov}(e_{it}e_{is}) = \begin{cases} \psi(|t-s|) & \text{if } |t-s| \leq m \\ 0 & \text{if } |t-s| > m \end{cases}$$

where $\psi(k) = \sigma_e^2 \sum_{j=0}^{m-k} \alpha_j \alpha_{j+k}$ for $k = |t-s|$. For the definition of $I_N$, $I_T$, $J_N$, and $J_T$, see the section “Fuller and Battese’s Method” on page 1410.

The covariance matrix, denoted by $V$, can be written in the form

$$V = \sigma_a^2 (I_N \otimes J_T) + \sigma_b^2 (J_N \otimes I_T) + \sum_{k=0}^{m} \psi(k)(I_N \otimes \Psi_T^{(k)})$$

where $\Psi_T^{(0)} = I_T$, and, for $k = 1, \ldots, m$, $\Psi_T^{(k)}$ is a band matrix whose $k$th off-diagonal elements are 1’s and all other elements are 0’s.

Thus, the covariance matrix of the vector of observations $y$ has the form

$$\text{Var}(y) = \sum_{k=1}^{m+3} v_k V_k$$

where

$$v_1 = \sigma_a^2$$

$$v_2 = \sigma_b^2$$

$$v_k = \psi(k-3)k = 3, \ldots, m + 3$$

$$V_1 = I_N \otimes J_T$$

$$V_2 = J_N \otimes I_T$$

$$V_k = I_N \otimes \Psi_T^{(k-3)}k = 3, \ldots, m + 3$$
The estimator of \( \beta \) is a two-step GLS-type estimator—that is, GLS with the unknown covariance matrix replaced by a suitable estimator of \( V \). It is obtained by substituting Seely estimates for the scalar multiples \( v_k, k = 1, 2, \ldots, m + 3 \).

Seely (1969) presents a general theory of unbiased estimation when the choice of estimators is restricted to finite dimensional vector spaces, with a special emphasis on quadratic estimation of functions of the form \( \sum_{i=1}^{n} \delta_i v_i \).

The parameters \( v_i \) \((i = 1, \ldots, n)\) are associated with a linear model \( E(y_i) = X \beta \) with covariance matrix \( \sum_{i=1}^{n} v_i V_i \) where \( V_i \) \((i = 1, \ldots, n)\) are real symmetric matrices. The method is also discussed by Seely (1970b, a); Seely and Zyskind (1971). Seely and Soong (1971) consider the MINQUE principle, using an approach along the lines of Seely (1969).

\[ y_{it} = \sum_{\text{maxlag}}^{1} \phi_l y_{i(t-l)} + \sum_{k=1}^{K} \beta_k x_{itk} + \gamma_i + \alpha_t + \epsilon_{it} \]

The \( x \) variables can include ones that are correlated or uncorrelated to the individual effects, predetermined, or strictly exogenous. The variable \( x_{it}^p \) is defined as predetermined in the sense that \( E(x_{it}^p \epsilon_{is}) \neq 0 \) for \( s < t \) and zero otherwise. The variable \( x_{it}^e \) is defined as strictly exogenous if \( E(x_{it}^e \epsilon_{is}) = 0 \) for all \( s \) and \( t \). The \( \gamma_i \) and \( \alpha_t \) are cross-sectional and time series fixed effects, respectively. Arellano and Bond (1991) show that it is possible to define conditions that should result in a consistent estimator.

Consider the simple case of an autoregression in a panel setting (with only individual effects):

\[ y_{it} = \phi y_{i(t-1)} + \gamma_i + \epsilon_{it} \]

Differencing the preceding relationship results in:

\[ \Delta y_{it} = \phi \Delta y_{i(t-1)} + \nu_{it} \]

where \( \nu_{it} = \epsilon_{it} - \epsilon_{it-1} \).

Obviously, \( y_{it} \) is not exogenous. However, Arellano and Bond (1991) show that it is still useful as an instrument, if properly lagged. This instrument is required with the option DEPV AR(LEVEL).

For \( t = 2 \) (assuming the first observation corresponds to time period 1) you have,

\[ \Delta y_{i2} = \phi \Delta y_{i1} + \nu_{i2} \]

Using \( y_{i1} \) as an instrument is not a good idea since \( \text{Cov}(\epsilon_{i1}, \nu_{i2}) \neq 0 \). Therefore, since it is not possible to form a moment restriction, you discard this observation.

For \( t = 3 \) you have,

\[ \Delta y_{i3} = \phi \Delta y_{i2} + \nu_{i3} \]
Clearly, you have every reason to suspect that \( \text{Cov}(\epsilon_{it}, v_{it}) = 0 \). This condition forms one restriction.

For \( t = 4 \), both \( \text{Cov}(\epsilon_{i1}, v_{i4}) = 0 \) and \( \text{Cov}(\epsilon_{i2}, v_{i4}) = 0 \) must hold.

Proceeding in that fashion, you have the following matrix of instruments,

\[
Z_i = \begin{pmatrix}
y_{i1} & 0 & 0 & \cdots & 0 & 0 & 0 & 0 & 0 \\
0 & y_{i1} & y_{i2} & 0 & \cdots & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & y_{i1} & y_{i2} & y_{i3} & 0 & \cdots & 0 \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
0 & 0 & 0 & 0 & 0 & 0 & y_{i1} & \cdots & y_{i(T-2)}
\end{pmatrix}
\]

Using the instrument matrix, you form the weighting matrix \( A_N \) as

\[
A_N = \left( \frac{1}{N} \sum_i Z_i' H_i Z_i \right)^{-1}
\]

The initial weighting matrix is

\[
H_i = \begin{pmatrix}
2 & -1 & 0 & \cdots & 0 & 0 & 0 & 0 & 0 \\
-1 & 2 & -1 & 0 & \cdots & 0 & 0 & 0 & 0 \\
0 & -1 & 2 & -1 & 0 & \cdots & 0 & 0 & 0 \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
0 & 0 & 0 & 0 & 0 & -1 & 2 & -1 & 2
\end{pmatrix}
\]

Note that the maximum size of the \( H_i \) matrix is \( T-2 \). The origins of the initial weighting matrix are the expected error covariances. Notice that on the diagonals,

\[
E(v_{it}v_{it}) = E(\epsilon_{it}^2 - 2\epsilon_{it}\epsilon_{i(t-1)} + \epsilon_{i(t-1)}^2) = 2\sigma_\epsilon^2
\]

and off diagonals,

\[
E(v_{it}v_{i(t-1)}) = E(\epsilon_{it}\epsilon_{i(t-1)} - \epsilon_{it}\epsilon_{i(t-2)} - \epsilon_{i(t-1)}\epsilon_{i(t-1)} + \epsilon_{i(t-1)}\epsilon_{i(t-2)}) = -\sigma_\epsilon^2
\]

If you let the vector of lagged differences (in the series \( y_{it} \)) be denoted as \( \Delta y_{i-} \) and the dependent variable as \( \Delta y_i \), then the optimal GMM estimator is

\[
\phi = \left( \sum_i \Delta y_{i-} Z_i \right) A_N \left( \sum_i Z_i' \Delta y_{i-} \right)^{-1} \left( \sum_i \Delta y_{i-} Z_i \right) A_N \left( \sum_i Z_i' \Delta y_i \right)
\]

Using the estimate, \( \hat{\phi} \), you can obtain estimates of the errors, \( \hat{\epsilon} \), or the differences, \( \hat{v} \). From the errors, the variance is calculated as,

\[
\sigma^2 = \frac{\hat{\epsilon}' \hat{\epsilon}}{M - 1}
\]
where \( M = \sum_{i=1}^{N} T_i \) is the total number of observations. With differenced equations, since we lose the first two observations, \( M = \sum_{i=1}^{N} (T_i - 2) \).

Furthermore, you can calculate the variance of the parameter as,

\[
\sigma^2 \left[ \left( \sum_i \Delta y'_i - Z_i \right) A_N \left( \sum_i Z'_i \Delta y_i - \right) \right]^{-1}
\]

Alternatively, you can view the initial estimate of the \( \phi \) as a first step. That is, by using \( \hat{\phi} \), you can improve the estimate of the weight matrix, \( A_N \).

Instead of imposing the structure of the weighting, you form the \( H_i \) matrix through the following:

\[
H_i = \hat{\psi}_i \hat{\psi}'_i
\]

You then complete the calculation as previously shown. The PROC PANEL option GMM2 specifies this estimation.

The case of multiple right-hand-side variables illustrates more clearly the power of Arellano and Bond (1991); Arellano and Bover (1995).

Considering the general case you have:

\[
y_{it} = \sum_{l=1}^{\text{maxlag}} \phi_l y_{i(t-l)} + \beta X_i + \gamma_i + \alpha_t + \epsilon_{it}
\]

It is clear that lags of the dependent variable are both not exogenous and correlated to the fixed effects. However, the independent variables can fall into one of several categories. An independent variable can be correlated and exogenous, uncorrelated and exogenous, correlated and predetermined, and uncorrelated and predetermined. The category in which an independent variable is found influences when or whether it becomes a suitable instrument. Note, however, that neither PROC PANEL nor Arellano and Bond require that a regressor be an instrument or that an instrument be a regressor.

First, suppose that the variables are all correlated with the individual effects \( \gamma_i \). Consider the question of exogenous or predetermined. An exogenous variable is not correlated with the error term \( \epsilon_{it} - \epsilon_{it-1} \) in the differenced equations. Therefore, all observations (on the exogenous variable) become valid instruments at all time periods. If the model has only one instrument and it happens to be exogenous, then the optimal instrument matrix looks like,

\[
Z_i = \begin{pmatrix}
X_{i1} \cdots X_{iT}
0
0
0
0
X_{i1} \cdots X_{iT}
0
0
0
0
X_{i1} \cdots X_{iT}
\vdots
\vdots
\vdots
\vdots
0
0
0
0
X_{i1} \cdots X_{iT}
\end{pmatrix}
\]

The situation for the predetermined variables becomes a little more difficult. A predetermined variable is one whose future realizations can be correlated to current shocks in the dependent variable. With such an

\[1\]In this section, “correlated” means correlated with the individual effects and “uncorrelated” means uncorrelated with the individual effects.
understanding, it is admissible to allow all current and lagged realizations as instruments. In other words you have,

\[
Z_i = \begin{pmatrix}
x_{i1} & 0 & 0 & 0 & 0 \\
0 & x_{i1} x_{i2} & 0 & 0 & 0 \\
0 & 0 & x_{i1} \cdots x_{i\beta} & 0 & 0 \\
\vdots & \vdots & \vdots & \vdots & \vdots \\
0 & 0 & 0 & 0 & x_{i1} \cdots x_{i(T-1)} \\
\end{pmatrix}
\]

When the data contain a mix of endogenous, exogenous, and predetermined variables, the instrument matrix is formed by combining the three. The third observation would have one observation on the dependent variable as an instrument, three observations on the predetermined variables as instruments, and all observations on the exogenous variables.

Now consider some variables, denoted as \(x_{1it}\), that are not correlated with the individual effects \(\gamma_i\). There is yet another set of moment restrictions that can be used. An uncorrelated variable means that the variable’s level is not affected by the individual specific effect. You write the preceding general model as

\[
y_{it} = \sum_{l=1}^{\text{maxlag}} \phi_l y_{i(t-l)} + \sum_{k=1}^{K} \beta_k x_{itk} + \alpha_i + \mu_{it}
\]

where \(\mu_{it} = \gamma_i + \epsilon_{it}\).

Because the variables are uncorrelated with \(\gamma_i\) and thus uncorrelated with the error term \(\mu_{it}\) in the level equations, you can use the difference and level equations to perform a system estimation. That is, the uncorrelated variables imply moment restrictions on the level equations. Given the previously used restrictions for the equations in first differences, there are \(T\) extra restrictions. For predetermined variables, Arellano and Bond (1991) use the extra restrictions \(E(\mu_{i2}x_{1it}) = 0\) and \(E(\mu_{it}x_{1it}^p) = 0\) for \(t = 2, \ldots, T\). The instrument matrix becomes

\[
Z_i^* = \begin{pmatrix}
Z_i & 0 & 0 & 0 & \cdots & 0 \\
0 & x_{i1}^p & x_{i2}^p & 0 & \cdots & 0 \\
0 & 0 & 0 & x_{i1}^p & \cdots & 0 \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
0 & 0 & 0 & 0 & \cdots & x_{i1T}^p \\
\end{pmatrix}
\]

For exogenous variables \(x_{1it}^e\) Arellano and Bond (1991) use \(E(T^{-1} \sum_{s=1}^{T} \mu_{is} x_{1it}^e) = 0\). PROC PANEL uses the same ones as the predetermined variables—that is, \(E(\mu_{i2} x_{1i1}^e) = 0\) and \(E(\mu_{it} x_{1i1}^e) = 0\) for \(t = 2, \ldots, T\). If you denote the new instrument matrix by using the full complement of instruments available by an asterisk and if both \(x^p\) and \(x^e\) are uncorrelated, then you have

\[
Z_i^* = \begin{pmatrix}
Z_i & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & x_{i1}^p & x_{i2}^p & x_{i1}^e & x_{i2}^e & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & x_{i3}^p & x_{i3}^e & 0 & 0 \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
0 & 0 & 0 & 0 & 0 & \cdots & x_{i1T}^p & x_{i1T}^e \\
\end{pmatrix}
\]

When the lagged dependent variable is included as the explanatory variable (as in the dynamic panel data models), Blundell and Bond (1998) suggest the system GMM to use \(T - 2\) extra-moment restrictions, which
use the lagged differences as the instruments for the level:

\[ E(\mu_{it} \Delta y_{i,t-1}) = 0 \quad \text{for } t = 3, \ldots, T \]

This additional set of moment conditions are required by DEPVAR(DIFF) option. The corresponding instrument matrix is

\[
Z_{it}^* = \begin{pmatrix}
0 & 0 & 0 & \cdots & 0 \\
0 & \Delta y_{i2} & 0 & \cdots & 0 \\
0 & 0 & \Delta y_{i3} & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & \Delta y_{i(T-1)}
\end{pmatrix}
\]

Blundell and Bond (1998) argue that the system GMM that uses these extra conditions significantly increases the efficiency of the estimator, especially under strong serial correlation in the dependent variables\(^2\).

The formation of the initial weighting matrix becomes somewhat problematic. If you denote the new weighting matrix with an asterisk, then you can write the following:

\[
A_N^* = \left( \frac{1}{N} \sum_i S_i^* H_i^* Z_i^* \right)^{-1}
\]

where

\[
H_i^* = \begin{pmatrix}
H_i & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & 1
\end{pmatrix}
\]

To finish, you write out the two equations (or two stages) that are estimated.

\[
\begin{align*}
\Delta y_{it} &= \beta^* S_{it} + \alpha_t - \alpha_{t-1} + \nu_{it} \\
y_{it} &= \beta^* S_{it} + \gamma_i + \alpha_t + \epsilon_{it}
\end{align*}
\]

where \(S_{it}\) is the matrix of all explanatory variables, lagged endogenous, exogenous, and predetermined.

Let \(y_{it}^*\) be given by

\[
y_{it}^* = \begin{pmatrix}
\Delta y_{it} \\
y_{it}
\end{pmatrix} \quad \beta^* = \begin{pmatrix}
\phi & \beta
\end{pmatrix} \quad S_{it}^* = \begin{pmatrix}
\Delta S_{it} \\
S_{it}
\end{pmatrix} \quad e_{it}^* = \begin{pmatrix}
\nu_i \\
\mu_i = \epsilon_i + \gamma_i
\end{pmatrix}
\]

Using the information above, we can get the one-step GMM estimator,

\[
\hat{\beta}_1^* = \left( \sum_i S_i^* Z_i^* \right) A_N^* \left( \sum_i Z_i^* S_i \right)^{-1} \left( \sum_i S_i^* Z_i^* \right) A_N^* \left( \sum_i Z_i^* y_i^* \right)
\]

If the GMM2 or ITGMM option is not requested, estimation terminates here. If it terminates, you can obtain the following information.

\(^2\)This happens when \(\phi \to 1\) or as \(\sigma_{\gamma}^2 / \sigma_{\nu}^2 \to \infty\). In this case, the lagged dependent variables \(y_{i(t-1)}\) become weak instruments for the differenced variables \(\Delta y_{it}\).
Variance of the error term comes from the second stage (level) equations—that is,

\[ \sigma^2 = \frac{\hat{\mu}' \hat{\mu}}{M - p} = \frac{(y_{it} - \hat{\beta}_1^* S_{it})'}{(y_{it} - \hat{\beta}_1^* S_{it})} \]

where \( p \) is the number of regressors and \( M \) is the number of observations as defined before.

The variance covariance matrix can be obtained from

\[ \left[ \left( \sum_i S_i^* Z_i^* \right) A_N^* \left( \sum_i Z_i^* S_i^* \right) \right]^{-1} \sigma^2 \]

Alternatively, a robust estimate of the variance covariance matrix can be obtained by specifying the ROBUST option. Without further reestimation of the model, the \( H_i^* \) matrix is recalculated as follows:

\[ H_{i,2}^* = \begin{pmatrix} \hat{\nu}_i \hat{\nu}_i' & 0 \\ 0 & \hat{\epsilon}_i \hat{\epsilon}_i' \end{pmatrix} \]

And the weighting matrix becomes

\[ A_N^* (\hat{\beta}_1^*) = \left( \frac{1}{N} \sum_i Z_i^* H_{i,2}^* Z_i^* \right)^{-1} \]

Using the preceding information, you construct the robust covariance matrix from the following:

Let \( G \) denote a temporary matrix:

\[ G = \left[ \left( \sum_i S_i^* Z_i^* \right) A_N^* \left( \sum_i Z_i^* S_i^* \right) \right]^{-1} \left( \sum_i S_i^* Z_i^* \right) A_N^* \]

The robust covariance estimate of \( \hat{\beta}_1^* \) is

\[ V^r (\hat{\beta}_1^*) = GA_N^* \left( \hat{\beta}_1^* \right) G' \]

Alternatively, you can use the new weighting matrix to form an updated estimate of the regression parameters, as requested by the GMM2 option. In short,

\[ \hat{\beta}_2^* = \left[ \left( \sum_i S_i^* Z_i^* \right) A_N^* (\hat{\beta}_1^*) \left( \sum_i Z_i^* s_i^* \right) \right]^{-1} \left( \sum_i S_i^* Z_i^* \right) A_N^* (\hat{\beta}_1^*) \left( \sum_i Z_i^* y_i^* \right) \]

The covariance estimate of the two-step \( \hat{\beta}_2^* \) becomes

\[ V (\hat{\beta}_2^*) = \left[ \left( \sum_i S_i^* Z_i^* \right) A_N^* (\hat{\beta}_1^*) \left( \sum_i Z_i^* s_i^* \right) \right]^{-1} \]
Similarly, you construct the robust covariance matrix from the following:

Let $G_2$ denote a temporary matrix.

$$
G_2 = \left[ \left( \sum_i S_i^* Z_i^* \right) A_N^* \left( \sum_i Z_i^* S_i^* \right) \right]^{-1} \left( \sum_i S_i^* Z_i^* \right) A_N^* \left( \hat{\beta}^*_1 \right)
$$

The robust covariance estimate of $\hat{\beta}^*_2$ is

$$
V^r \left( \hat{\beta}^*_2 \right) = G_2 A_N^{-1} \left( \hat{\beta}^*_2 \right) G_2'
$$

As a final note, it possible to iterate more than twice by specifying the ITGMM option. At each iteration, the parameter estimates and its variance-covariance matrix (standard or robust) can be constructed as the one-step and/or two-step GMM estimators. Such a multiple iteration should result in a more stable estimate of the covariance estimate. PROC PANEL allows two convergence criteria. Convergence can occur in the parameter estimates or in the weighting matrices. Let $A_{N,k+1}^*$ denote the robust covariance matrix from iteration $k$, which is used as the weighting matrix in iteration $k + 1$. Iterate until

$$
\max_{i,j \leq \dim(A_{N,k}^*)} \left| A_{N,k+1}^*(i,j) - A_{N,k}^*(i,j) \right| \leq ATOL
$$

or

$$
\max_{i \leq \dim(\hat{\beta}^*_k)} \left| \hat{\beta}^*_{k+1}(i) - \hat{\beta}^*_k(i) \right| \leq BTOL
$$

where ATOL is the tolerance for convergence in the weighting matrix and BTOL is the tolerance for convergence in the parameter estimate matrix. The default convergence criteria is BTOL = 1E–8 for PROC PANEL.

**Specification Testing For Dynamic Panel**

Specification tests under the GMM in PROC PANEL follow Arellano and Bond (1991) very generally. The first test available is a Sargan/Hansen test of over-identification. The test for a one-step estimation is constructed as

$$
\left( \sum_i \eta_i^* Z_i^* \right) A_N^* \left( \sum_i Z_i^* \eta_i \right) \sigma^2
$$

where $\eta_i$ is the stacked error term (of the differenced equation and level equation).

When the robust weighting matrix is used, the test statistic is computed as

$$
\left( \sum_i \eta_i^* Z_i^* \right) A_{N,2}^* \left( \sum_i Z_i^* \eta_i \right)
$$

This definition of the Sargan test is used for all iterated estimations. The Sargan test is distributed as a $\chi^2$ with degrees of freedom equal to the number of moment conditions minus the number of parameters.
In addition to the Sargan test, PROC PANEL tests for autocorrelation in the residuals. These tests are distributed as standard normal. PROC PANEL tests the hypothesis that the autocorrelation of the \( l \)th lag is significant.

Define \( \omega_l \) as the lag of the differenced error, with zero padding for the missing values generated. Symbolically,

\[
\omega_{l,i} = \begin{pmatrix}
0 \\
\vdots \\
0 \\
\nu_{l,2} \\
\vdots \\
\nu_{l,T-1-l}
\end{pmatrix}
\]

You define the constant \( k_0 \) as

\[
k_0 (l) = \sum_i \omega_{l,i} \nu_i
\]

You next define the constant \( k_1 \) as

\[
k_1 (l) = \sum_i \omega_{l,i} H_l \omega_{l,i}
\]

Note that the choice of \( H_l \) is dependent on the stage of estimation. If the estimation is first stage, then you would use the matrix with twos along the main diagonal, and minus ones along the primary subdiagonals. In a robust estimation or multi-step estimation, this matrix would be formed from the outer product of the residuals (from the previous step).

Define the constant \( k_2 \) as

\[
 k_2 (l) = -2 \left( \sum_i \omega_{l,i}^* \Delta S_i \right) G \left( \sum_i \Delta S_i^* Z_i \right) A_{N,k} \left( \sum_i Z_i^* H_l \omega_{l,i} \right)
\]

The matrix \( G \) is defined as

\[
 G = \left[ \left( \sum_i \Delta S_{i}^* Z_{i}^* \right) A_{N,k}^* \left( \sum_i Z_{i}^* \Delta S_{i}^* \right) \right]^{-1}
\]

The constant \( k_3 \) is defined as

\[
k_3 (l) = \left( \sum_i \omega_{l,i}^* \Delta S_i \right) V \left( \beta^* \right) \left( \sum_i \Delta S_i^* \omega_{l,i} \right)
\]

Using the four quantities, the test for autoregressive structure in the differenced residual is

\[
m (l) = \frac{k_0 (l)}{\sqrt{k_1 (l) + k_2 (l) + k_3 (l)}}
\]

The \( m \) statistic is distributed as a normal random variable with mean zero and standard deviation of one.
Instrument Choice

Arellano and Bond’s technique is a very useful method for dealing with any autoregressive characteristics in the data. However, there is one caveat to consider. Too many instruments bias the estimator to the within estimate. Furthermore, many instruments make this technique not scalable. The weighting matrix becomes very large, so every operation that involves it becomes more computationally intensive. The PANEL procedure enables you to specify a bandwidth for instrument selection. For example, specifying MAXBAND=10 means that at most there will be ten time observations for each variable that enters as an instrument. The default is to follow the Arellano-Bond methodology.

In specifying a maximum bandwidth, you can also specify the selection of the time observations. There are three possibilities: leading, trailing (default), and centered. The exact consequence of choosing any of those possibilities depends on the variable type (correlated, exogenous, or predetermined) and the time period of the current observation.

If the MAXBAND option is specified, then the following is true under any selection criterion (let $t$ be the time subscript for the current observation). The first observation for the endogenous variable (as instrument) is $\max(t - \text{MAXBAND}, 1)$ and the last instrument is $t - 2$. The first observation for a predetermined variable is $\max(t - \text{MAXBAND}, 1)$ and the last is $t - 1$. The first and last observation for an exogenous variable is given in the following list:

- **Trailing**: If $t < \text{MAXBAND}$, then the first instrument is for the first time period and the last observation is $\text{MAXBAND}$. Otherwise, if $t \geq \text{MAXBAND}$, then the first observation is $t - \text{MAXBAND} + 1$ and the last instrument to enter is $t$.

- **Centered**: If $t \leq \frac{\text{MAXBAND}}{2}$, then the first observation is the first time period and the last observation is $\text{MAXBAND}$. If $t > \frac{T - \text{MAXBAND}}{2}$, then the first instrument included is $T - \text{MAXBAND} + 1$ and the last observation is $T$. If $\frac{\text{MAXBAND}}{2} < t \leq T - \frac{\text{MAXBAND}}{2}$, then the first included instrument is $t - \frac{\text{MAXBAND}}{2} + 1$ and the last observation is $t + \frac{\text{MAXBAND}}{2}$. If the MAXBAND value is an odd number, the procedure decrements by one.

- **Leading**: If $t > T - \text{MAXBAND}$, then the first instrument corresponds to time period $T - \text{MAXBAND} + 1$ and the last observation is $T$. Otherwise, if $t \leq T - \text{MAXBAND}$, then the first observation is $t$ and the last observation is $t + \text{MAXBAND} + 1$.

The PANEL procedure enables you to include dummy variables to deal with the presence of time effects that are not captured by including the lagged dependent variable. The dummy variables directly affect the level equations. However, this implies that the difference of the dummy variable for time period $t$ and $t - 1$ enters the difference equation. The first usable observation occurs at $t = 3$. If the level equation is not used in the estimation, then there is no way to identify the dummy variables. Selecting the TIME option gives the same result as that which would be obtained by creating dummy variables in the data set and using those in the regression.

The PANEL procedure gives you several options when it comes to missing values and unbalanced panel. By default, any time period for which there are missing values is skipped. The corresponding rows and columns of $\mathbf{H}$ matrices are zeroed, and the calculation is continued. Alternatively, you can elect to replace missing values and missing observations with zeros (ZERO), the overall mean of the series (OAM), the cross-sectional mean (CSM), or the time series mean (TSM).
Linear Hypothesis Testing

For a linear hypothesis of the form $R \beta = r$ where $R$ is $J \times K$ and $r$ is $J \times 1$, the $F$-statistic with $J, M - K$ degrees of freedom is computed as

$$(R \beta - r)' [R \hat{V}R']^{-1} (R \beta - r)$$

However, it is also possible to write the $F$ statistic as

$$F = \frac{(\hat{u}_*^\prime \hat{u}_* - \hat{u}^\prime \hat{u})/J}{\hat{u}^\prime \hat{u}/(M - K)}$$

where

- $\hat{u}_*$ is the residual vector from the restricted regression
- $\hat{u}$ is the residual vector from the unrestricted regression
- $J$ is the number of restrictions
- $(M - K)$ are the degrees of freedom, $M$ is the number of observations, and $K$ is the number of parameters in the model

The Wald, likelihood ratio (LR) and LaGrange multiplier (LM) tests are all related to the $F$ test. You use this relationship of the $F$ test to the likelihood ratio and LaGrange multiplier tests. The Wald test is calculated from its definition.

The Wald test statistic is:

$$W = (R \beta - r)' [R \hat{V}R']^{-1} (R \beta - r)$$

The advantage of calculating Wald in this manner is that it enables you to substitute a heteroscedasticity-corrected covariance matrix for the matrix $V$. PROC PANEL makes such a substitution if you request the HCCME option in the MODEL statement.

The likelihood ratio is:

$$LR = M \ln \left[ 1 + \frac{1}{M - K} JF \right]$$

The LaGrange multiplier test statistic is:

$$LM = M \left[ \frac{JF}{M - K + JF} \right]$$

where $JF$ represents the number of restrictions multiplied by the result of the $F$ test.

Note that only the Wald is changed when the HCCME option is selected. The LR and LM tests are unchanged.

The distribution of these test statistics is the $\chi^2$ with degrees of freedom equal to the number of restrictions imposed ($J$). The three tests are asymptotically equivalent, but they have differing small sample properties. Greene (2000, p. 392) and Davidson and MacKinnon (1993, pp. 456–458) discuss the small sample properties of these statistics.
Heteroscedasticity-Corrected Covariance Matrices

The HCCME= option in the MODEL statement selects the type of heteroscedasticity-consistent covariance matrix. In the presence of heteroscedasticity, the covariance matrix has a complicated structure that can result in inefficiencies in the OLS estimates and biased estimates of the covariance matrix. The variances for cross-sectional and time dummy variables and the covariances with or between the dummy variables are not corrected for heteroscedasticity in the one-way and two-way models. Whether or not HCCME is specified, they are the same. For the two-way models, the variance and the covariances for the intercept are not corrected.3

Consider the simple linear model:

\[ y = X\beta + \epsilon \]

This discussion parallels the discussion in Davidson and MacKinnon 1993, pp. 548–562. For panel data models, we apply HCCME on the transformed data (\( \bar{y} \) and \( \bar{X} \)). In other words, we first remove the random or fixed effects through transforming/demean the data4, then correct heteroscedasticity (also auto-correlation with HAC option) in the residual. The assumptions that make the linear regression best linear unbiased estimator (BLUE) are \( E(\epsilon) = 0 \) and \( E(\epsilon \epsilon') = \Omega \), where \( \Omega \) has the simple structure \( \sigma^2 I \). Heteroscedasticity results in a general covariance structure, so that it is not possible to simplify \( \Omega \). The result is the following:

\[
\hat{\beta} = (X' X)^{-1} X' y = (X' X)^{-1} X' (X\beta + \epsilon) = \beta + (X' X)^{-1} X' \epsilon
\]

As long as the following is true, then you are assured that the OLS estimate is consistent and unbiased:

\[
\text{plim}_{n \to \infty} \left( \frac{1}{n} X' \epsilon \right) = 0
\]

If the regressors are nonrandom, then it is possible to write the variance of the estimated \( \beta \) as the following:

\[
\text{Var} (\hat{\beta} - \beta) = (X' X)^{-1} X' \Omega X (X' X)^{-1}
\]

The effect of structure in the covariance matrix can be ameliorated by using generalized least squares (GLS), provided that \( \Omega^{-1} \) can be calculated. Using \( \Omega^{-1} \), you premultiply both sides of the regression equation,

\[
L^{-1} y = L^{-1} X\beta + L^{-1} \epsilon
\]

where \( L \) denotes the Cholesky root of \( \Omega \). (that is, \( \Omega = LL' \) with \( L \) lower triangular).

The resulting GLS \( \hat{\beta} \) is

\[
\hat{\beta} = (X' \Omega^{-1} X)^{-1} X' \Omega^{-1} y
\]

3The dummy variables are removed by the within transformations, so their variances and covariances cannot be calculated the same way as the other regressors. They are recovered by the formulas listed in the sections “One-Way Fixed-Effects Model” on page 1403 and “Two-Way Fixed-Effects Model” on page 1404. The formulas assume homoscedasticity, so they do not apply when HCCME is specified. Therefore, standard errors, variances, and covariances are reported only when the HCCME option is ignored. HCCME standard errors for dummy variables and intercept can be calculated by the dummy variable approach with the pooled model.

Using the GLS $\beta$, you can write

$$
\hat{\beta} = (X'\Omega^{-1}X)^{-1}X'\Omega^{-1}y \\
= (X'\Omega^{-1}X)^{-1}X'(\Omega^{-1}X_0 + \Omega^{-1}\epsilon) \\
= \beta + (X'\Omega^{-1}X)^{-1}X'\Omega^{-1}\epsilon
$$

The resulting variance expression for the GLS estimator is

$$
\text{Var}(\beta - \hat{\beta}) = (X'\Omega^{-1}X)^{-1}X'\Omega^{-1}\epsilon\epsilon'\Omega^{-1}X(X'\Omega^{-1}X)^{-1} \\
= (X'\Omega^{-1}X)^{-1}X'\Omega^{-1}\Omega^{-1}X(X'\Omega^{-1}X)^{-1} \\
= (X'\Omega^{-1}X)^{-1}
$$

The difference in variance between the OLS estimator and the GLS estimator can be written as

$$(X'X)^{-1}X'\Omega(X'X)^{-1} - (X'\Omega^{-1}X)^{-1}$$

By the Gauss-Markov theorem, the difference matrix must be positive definite under most circumstances (zero if OLS and GLS are the same, when the usual classical regression assumptions are met). Thus, OLS is not efficient under a general error structure. It is crucial to realize that OLS does not produce biased results. It would suffice if you had a method for estimating a consistent covariance matrix and you used the OLS $\beta$. Estimation of the $\Omega$ matrix is certainly not simple. The matrix is square and has $M^2$ elements; unless some sort of structure is assumed, it becomes an impossible problem to solve. However, the heteroscedasticity can have quite a general structure. White (1980) shows that it is not necessary to have a consistent estimate of $\Omega$. On the contrary, it suffices to calculate an estimate of the middle expression. That is, you need an estimate of:

$$\Lambda = X'\Omega X$$

This matrix, $\Lambda$, is easier to estimate because its dimension is $K$. PROC PANEL provides the following classical HCCME estimators for $\Lambda$:

The matrix is approximated by:

- **HCCME=N0:**
  $$\sigma^2X'X$$
  This is the simple OLS estimator. If you do not specify the HCCME= option, PROC PANEL defaults to this estimator.

- **HCCME=0:**
  $$\sum_{i=1}^{N} \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 x_{it}x_{it}'$$
  where $N$ is the number of cross sections and $T_i$ is the number of observations in $i$th cross section. The $x_{it}'$ is from the $r$th observation in the $i$th cross section, constituting the $(\sum_{j=1}^{i-1} T_j + t)$th row of the matrix $X$. If the CLUSTER option is specified, one extra term is added to the preceding equation so that the estimator of matrix $\Lambda$ is
  $$\sum_{i=1}^{N} \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 x_{it}x_{it}' + \sum_{i=1}^{N} \sum_{t=1}^{T_i} \sum_{s=1}^{T_i} \hat{\epsilon}_{it} \hat{\epsilon}_{is} (x_{it}x_{is}' + x_{is}x_{it}')$$
• HCCME=1:

\[ M \frac{N}{M - K} \sum_{i=1}^{N} \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 x_{it}' x_{it} \]

where \( M \) is the total number of observations, \( \sum_{j=1}^{N} T_j \), and \( K \) is the number of parameters. With the CLUSTER option, the estimator becomes

\[ M \frac{N}{M - K} \sum_{i=1}^{N} \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 x_{it}' x_{it}' + \frac{2M}{M - K} \sum_{i=1}^{N} \sum_{t=1}^{T_i} \sum_{s=1}^{T_i} \hat{\epsilon}_{is} \hat{\epsilon}_{is} x_{it}' x_{is}' \]

• HCCME=2:

\[ \sum_{i=1}^{N} \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{1 - \hat{h}_{it}} x_{it}' x_{it}' \]

The \( \hat{h}_{it} \) term is the \((\sum_{j=1}^{i-1} T_j + t)\)th diagonal element of the hat matrix. The expression for \( \hat{h}_{it} \) is \( x_{it}'(X'X)^{-1}x_{it} \). The hat matrix attempts to adjust the estimates for the presence of influence or leverage points. With the CLUSTER option, the estimator becomes

\[ \sum_{i=1}^{N} \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{1 - \hat{h}_{it}} x_{it}' x_{it}' + 2 \sum_{i=1}^{N} \sum_{t=1}^{T_i} \sum_{s=1}^{T_i} \frac{\hat{\epsilon}_{is}}{\sqrt{1 - \hat{h}_{it}}} \frac{\hat{\epsilon}_{is}}{\sqrt{1 - \hat{h}_{is}}} x_{it}' x_{is}' \]

• HCCME=3:

\[ \sum_{i=1}^{N} \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{(1 - \hat{h}_{it})^2} x_{it}' x_{it}' \]

With the CLUSTER option, the estimator becomes

\[ \sum_{i=1}^{N} \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{(1 - \hat{h}_{it})^2} x_{it}' x_{it}' + 2 \sum_{i=1}^{N} \sum_{t=1}^{T_i} \sum_{s=1}^{T_i} \frac{\hat{\epsilon}_{is}}{1 - \hat{h}_{it}} \frac{\hat{\epsilon}_{is}}{1 - \hat{h}_{is}} x_{it}' x_{is}' \]

• HCCME=4: PROC PANEL includes this option for the calculation of the Arellano (1987) version of the White (1980) HCCME in the panel setting. Arellano’s insight is that there are \( N \) covariance matrices in a panel, and each matrix corresponds to a cross section. Forming the White HCCME for each panel, you need to take only the average of those \( N \) estimators that yield Arellano. The details of the estimation follow. First, you arrange the data such that the first cross section occupies the first \( T_i \) observations. You treat the panels as separate regressions with the form:

\[ y_i = \alpha_i + X_{is}' \tilde{\beta} + \epsilon_i \]

The parameter estimates \( \tilde{\beta} \) and \( \alpha_i \) are the result of least squares dummy variables (LSDV) or within estimator regressions, and \( i \) is a vector of ones of length \( T_i \). The estimate of the \( i \)th cross section’s \( X'\Omega X \) matrix (where the \( s \) subscript indicates that no constant column has been suppressed to avoid confusion) is \( X_{is}'\Omega X_i \). The estimate for the whole sample is:

\[ X_s'\Omega X_s = \sum_{i=1}^{N} X_i'\Omega X_i \]
The Arellano standard error is in fact a White-Newey-West estimator with constant and equal weight on each component. In the between estimators, selecting HCCME=4 returns the HCCME=0 result since there is no ‘other’ variable to group by.

In their discussion, Davidson and MacKinnon (1993, p. 554) argue that HCCME=1 should always be preferred to HCCME=0. Although HCCME=3 is generally preferred to 2 and 2 is preferred to 1, the calculation of HCCME=1 is as simple as the calculation of HCCME=0. Therefore, it is clear that HCCME=1 is preferred when the calculation of the hat matrix is too tedious.

All HCCME estimators have well-defined asymptotic properties. The small sample properties are not well-known, and care must exercised when sample sizes are small.

The HCCME estimator of $\text{Var}(\hat{\beta})$ is used to drive the covariance matrices for the fixed effects and the LaGrange multiplier standard errors. Robust estimates of the covariance matrix for $\beta$ imply robust covariance matrices for all other parameters.

### Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrices

The HAC option in the MODEL statement selects the type of heteroscedasticity- and autocorrelation-consistent covariance matrix. As with the HCCME option, an estimator of the middle expression $\Lambda$ in sandwich form is needed. With the HAC option, it is estimated as

$$
\Lambda_{\text{HAC}} = a \sum_{i=1}^{N} \sum_{t=1}^{T_i} \hat{e}_{it} \hat{x}_{it} \hat{x}_{it}^t + a \sum_{i=1}^{N} \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} k\left(\frac{s-1}{b}\right) \hat{e}_{it} \hat{e}_{is} \left(\hat{x}_{it} \hat{x}_{is}^t + \hat{x}_{is} \hat{x}_{it}^t\right)
$$

, where $k(.)$ is the real-valued kernel function\(^5\), $b$ is the bandwidth parameter, and $a$ is the adjustment factor of small sample degrees of freedom (that is, $a = 1$ if the ADJUSTDF option is not specified and otherwise $a = NT/(NT - k)$, where $k$ is the number of parameters including dummy variables). The types of kernel functions are listed in Table 20.2.

</tbody>
</table>

Let $\{g_{ait}\}$ denote each series in $\{g_{it} = \hat{e}_{it}x_{it}\}$, and let $(\rho_a, \sigma_a^2)$ denote the corresponding estimates of the autoregressive and innovation variance parameters of the AR(1) model on $\{g_{ait}\}$, $a = 1, \ldots, k$, where the AR(1) model is parameterized as $g_{ait} = \rho g_{ait-1} + \epsilon_{ait}$ with $Var(\epsilon_{ait}) = \sigma_a^2$. The $\alpha(1)$ and $\alpha(2)$ are estimated with the following formulas:

$$
\alpha(1) = \frac{\sum_{a=1}^{k} 4\rho_a^2 \sigma_a^4}{\sum_{a=1}^{k} \frac{\sigma_a^4}{(1-\rho_a)^2}}, \quad \alpha(2) = \frac{\sum_{a=1}^{k} 4\rho_a^2 \sigma_a^4}{\sum_{a=1}^{k} \frac{\sigma_a^4}{(1-\rho_a)^4}}
$$

When you specify BANDWIDTH=NEWEYWEST94, according to Newey and West (1994) the bandwidth parameter is estimated as shown in Table 20.4.

<table>
<thead>
<tr>

<td>$b = 1.7462({s_1/s_0}^2 T)^{1/5}$</td>
</tr>
</tbody>
</table>

The $s_1$ and $s_0$ are estimated with the following formulas:

$$
s_1 = 2 \sum_{j=1}^{n} j \sigma_j, \quad s_0 = \sigma_0 + 2 \sum_{j=1}^{n} \sigma_j
$$

where $n$ is the lag selection parameter and is determined by kernels, as listed in Table 20.5.
### Table 20.5  Lag Selection Parameter Estimation

<table>
<thead>
<tr>
<th>Kernel Name</th>
<th>Lag Selection Parameter</th>

</tr>
</tbody>
</table>

The \( c \) in Table 20.5 is specified by the \( \text{C=} \) option; by default, \( \text{C=}12 \).

The \( \sigma_j \) is estimated with the equation

\[
\sigma_j = T^{-1} \sum_{t=j+1}^{T} \left( \sum_{a=i}^{k} \sum_{a=i}^{k} g_{at} - j \right) \cdot j = 0, \ldots, n
\]

where \( g_{at} \) is the same as in the Andrews method and \( i \) is 1 if the NOINT option in the MODEL statement is specified, and 2 otherwise.

When you specify \( \text{BANDWIDTH=SAMPLESIZE} \), the bandwidth parameter is estimated with the equation

\[
b = \begin{cases} 
\lfloor \gamma T^r + c \rfloor & \text{if \( \text{BANDWIDTH=SAMPLESIZE(INT)} \) option is specified} \\
\gamma T^r + c & \text{otherwise} 
\end{cases}
\]

where \( T \) is the sample size, \( \lfloor x \rfloor \) is the largest integer less than or equal to \( x \), and \( \gamma, r, \) and \( c \) are values specified by \( \text{BANDWIDTH=SAMPLESIZE(GAMMA=} \), \( \text{RATE=} \), \( \text{CONSTANT=} \) \) options, respectively.

If the \( \text{PREWHITENING} \) option is specified in the MODEL statement, \( g_{it} \) is prewhitened by the VAR(1) model,

\[
g_{it} = A_i g_{i,t-1} + w_{it}
\]

Then \( \Lambda_{\text{HAC}} \) is calculated by

\[
\Lambda_{\text{HAC}} = \sigma \sum_{i=1}^{N} \left( (I - A_i)^{-1} \right)^{\prime} \left( \sum_{t=1}^{T_i} w_{it} w_{it}^{\prime} + \sum_{t=1}^{T_i} \sum_{s=1}^{T_i} k\left( \frac{s-t}{b} \right) \left( w_{it} w_{is}^{\prime} + w_{is} w_{it}^{\prime} \right) \right) (I - A_i)^{-1}
\]

**R-Square**

The conventional R-square measure is inappropriate for all models that the PANEL procedure estimates by using GLS because a number outside the \([0,1]\) range might be produced. Hence, a generalization of the R-square measure is reported. The following goodness-of-fit measure (Buse 1973) is reported:

\[
R^2 = 1 - \frac{\hat{\mathbf{u}}^{\prime} \hat{\mathbf{V}}^{-1} \hat{\mathbf{u}}}{y^{\prime} \hat{\mathbf{V}}^{-1} \hat{\mathbf{V}}^{-1} \hat{\mathbf{y}}}
\]
where \( \hat{u} \) are the residuals of the transformed model, \( \hat{u} = y - X(\hat{\Sigma}^{-1}X)^{-1}X\hat{\Sigma}^{-1}y \), and 

\[
D = I_M - jM_i'\left(\frac{\hat{\Sigma}^{-1}}{jM_i'\hat{\Sigma}^{-1}jM_i}\right).
\]

This is a measure of the proportion of the transformed sum of squares of the dependent variable that is attributable to the influence of the independent variables.

If there is no intercept in the model, the corresponding measure (Theil 1961) is

\[
R^2 = 1 - \frac{\hat{u}'\hat{\Sigma}^{-1}\hat{u}}{y'\hat{\Sigma}^{-1}y}
\]

However, the fixed-effects models are somewhat different. In the case of a fixed-effects model, the choice of including or excluding an intercept becomes merely a choice of classification. Suppressing the intercept in the FIXONE or FIXONETIME case merely changes the name of the intercept to a fixed effect. It makes no sense to redefine the R-square measure since nothing material changes in the model. Similarly, for the FIXTWO model there is no reason to change the R-square measure. In the case of the FIXONE, FIXONETIME, and FIXTWO models, the R-square is defined as the Theil (1961) R-square as shown in the preceding equation. This makes intuitive sense since you are regressing a transformed (demeaned) series on transformed regressors, excluding a constant. In other words, you are looking at 1 minus the sum of squared errors divided by the sum of squares of the (transformed) dependent variable.

In the case of OLS estimation, both of the R-square formulas given here reduce to the usual R-square formula.

### Specification Tests

The PANEL procedure outputs the results of one specification test for fixed effects and two specification tests for random effects.

For fixed effects, let \( \beta_f \) be the \( n \) dimensional vector of fixed-effects parameters. The specification test reported is the conventional \( F \) statistic for the hypothesis \( \beta_f = 0 \). The \( F \) statistic with \( n, M - K \) degrees of freedom is computed as

\[
\hat{\beta}_f \hat{S}_f^{-1}/n
\]

where \( \hat{S}_f \) is the estimated covariance matrix of the fixed-effects parameters.

Hausman (1978) specification test or \( m \) statistic can be used to test hypotheses in terms of bias or inconsistency of an estimator. This test was also proposed by Wu (1973) and further extended in Hausman and Taylor (1982). Hausman’s \( m \) statistic is as follows.

Consider two estimators, \( \hat{\beta}_a \) and \( \hat{\beta}_b \), which under the null hypothesis are both consistent, but only \( \hat{\beta}_a \) is asymptotically efficient. Under the alternative hypothesis, only \( \hat{\beta}_b \) is consistent. The \( m \) statistic is

\[
m = (\hat{\beta}_b - \hat{\beta}_a)'(\hat{S}_b - \hat{S}_a)^{-1}(\hat{\beta}_b - \hat{\beta}_a)
\]

where \( \hat{S}_b \) and \( \hat{S}_a \) are consistent estimates of the asymptotic covariance matrices of \( \hat{\beta}_b \) and \( \hat{\beta}_a \). Then \( m \) is distributed \( \chi^2 \) with \( k \) degrees of freedom, where \( k \) is the dimension of \( \hat{\beta}_a \) and \( \hat{\beta}_b \).

In the random-effects specification, the null hypothesis of no correlation between effects and regressors implies that the OLS estimates of the slope parameters are consistent and inefficient but the GLS estimates of
the slope parameters are consistent and efficient. This facilitates a Hausman specification test. The reported $\chi^2$ statistic has degrees of freedom equal to the number of slope parameters. If the null hypothesis holds, the random-effects specification should be used.

Breusch and Pagan (1980) lay out a LaGrange multiplier test for random effects based on the simple OLS (pooled) estimator. If $\hat{u}_{it}$ is the $i$th residual from the OLS regression, then the Breusch-Pagan (BP) test for one-way random effects is

$$BP = \frac{NT}{2(T-1)} \left[ \frac{\sum_{i=1}^{N} \left( \sum_{t=1}^{T} \hat{u}_{it} \right)^2}{\sum_{i=1}^{N} \sum_{t=1}^{T} \hat{u}_{it}^2} - 1 \right]^2$$

The BP test generalizes to the case of a two-way random-effects model (Greene 2000, p. 589). Specifically,

$$BP2 = \frac{NT}{2(T-1)} \left[ \frac{\sum_{i=1}^{N} \left( \sum_{t=1}^{T} \hat{u}_{it} \right)^2}{\sum_{i=1}^{N} \sum_{t=1}^{T} \hat{u}_{it}^2} - 1 \right]^2 + \frac{NT}{2(N-1)} \left[ \frac{\sum_{t=1}^{T} \left( \sum_{i=1}^{N} \hat{u}_{it} \right)^2}{\sum_{i=1}^{N} \sum_{t=1}^{T} \hat{u}_{it}^2} - 1 \right]^2$$

is distributed as a $\chi^2$ statistic with two degrees of freedom. Since the BP2 test generalizes (nests the BP test) the test for random effects, the absence of random effects (nonrejection of the null of no random effects) in the BP2 is a fairly clear indication that there will probably not be any one-way effects either. In both cases (BP and BP2), the residuals are obtained from a pooled regression. There is very little extra cost in selecting both the BP and BP2 test. Notice that in the case of just groupwise heteroscedasticity, the BP2 test approaches BP. In the case of time based heteroscedasticity, the BP2 test reduces to a BP test of time effects. In the case of unbalanced panels, neither the BP nor BP2 statistics are valid.

Finally, you should be aware that the BP option generates different results depending on whether the estimation is FIXONE or FIXONETIME. Specifically, under the FIXONE estimation technique, the BP tests for cross-sectional random effects. Under the FIXONETIME estimation, the BP tests for time random effects.

While the Hausman statistic is automatically generated, you request Breusch-Pagan via the BP or BP2 option (see Baltagi 1995 for details).

---

**Panel Data Poolability Test**

The null hypothesis of poolability assumes homogeneous slope coefficients. An $F$ test can be applied to test for the poolability across cross sections in panel data models.

**F Test**

For the unrestricted model, run a regression for each cross section and save the sum of squared residuals as $SSE_u$. For the restricted model, save the sum of squared residuals as $SSE_r$. If the test applies to all coefficients (including the constant), then the restricted model is the pooled model (OLS); if the test applies
Panel Data Unit Root Tests

Levin, Lin, and Chu (2002)

Levin, Lin, and Chu (2002) propose a panel unit root test for the null hypothesis of unit root against a homogeneous stationary hypothesis. The model is specified as

$$\Delta y_{it} = \delta y_{it-1} + \sum_{L=1}^{P_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mt} + \varepsilon_{it} \quad m = 1, 2, 3$$

Three models are considered: (1) $d_{1t} = \emptyset$ (the empty set) with no individual effects, (2) $d_{2t} = \{1\}$ in which the series $y_{it}$ has an individual-specific mean but no time trend, and (3) $d_{3t} = \{1, t\}$ in which the series $y_{it}$ has an individual-specific mean and linear and individual-specific time trend. The panel unit root test evaluates the null hypothesis of $H_0: \delta = 0$, for all $i$, against the alternative hypothesis $H_1: \delta < 0$ for all $i$. The lag order $p_i$ is unknown and is allowed to vary across individuals. It can be selected by the methods that are described in the section “Lag Order Selection in the ADF Regression” on page 1443. Denote the selected lag orders as $\hat{p}_i$. The test is implemented in three steps.

**Step 1** The ADF regressions are implemented for each individual $i$, and then the orthogonalized residuals are generated and normalized. That is, the following model is estimated:

$$\Delta y_{it} = \delta_i y_{it-1} + \sum_{L=1}^{\hat{p}_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mt} + \varepsilon_{it} \quad m = 1, 2, 3$$

For the unbalanced panel, the number of time series $T_i$ might be different. The number of observations needs to be redefined accordingly.

---

6For the unbalanced panel, the number of time series $T_i$ might be different. The number of observations needs to be redefined accordingly.
The two orthogonalized residuals are generated by the following two auxiliary regressions:

\[
\Delta y_{it} = \sum_{L=1}^{L} \theta_{iL} \Delta y_{it-L} + \alpha_m d_{mi} + \varepsilon_{it}
\]

\[
y_{it-1} = \sum_{L=1}^{L} \hat{\theta}_{iL} \Delta y_{it-L} + \alpha_m d_{mi} + \hat{v}_{it-1}
\]

The residuals are saved at \( \hat{e}_{it} \) and \( \hat{v}_{it-1} \), respectively. To remove heteroscedasticity, the residuals \( \hat{e}_{it} \) and \( \hat{v}_{it-1} \) are normalized by the regression standard error from the ADF regression. Denote the standard error as \( \hat{\sigma}_{ei} \), and normalize residuals as

\[
\tilde{e}_{it} = \frac{\hat{e}_{it}}{\hat{\sigma}_{ei}}, \quad \tilde{v}_{it-1} = \frac{\hat{v}_{it-1}}{\hat{\sigma}_{ei}}
\]

**Step 2** The ratios of long-run to short-run standard deviations of \( \Delta y_{it} \) are estimated. Denote the ratios and the long-run variances as \( s_i \) and \( \sigma_{yi} \), respectively. The long-run variances are estimated by the HAC (heteroscedasticity- and autocorrelation-consistent) estimators, which are described in the section "Long-Run Variance Estimation" on page 1443. Then the ratios are estimated by \( \hat{s}_i = \hat{\sigma}_{yi} / \hat{\sigma}_{ei} \). Let the average standard deviation ratio be \( \hat{S}_N = (1 / N) \sum_{i=1}^{N} \hat{s}_i \), and let its estimator be \( \hat{S}_N = (1 / N) \sum_{i=1}^{N} \hat{s}_i \).

**Step 3** The panel test statistics are calculated. To calculate the \( t \) statistic and the adjusted \( t \) statistic, the following equation is estimated:

\[
\hat{e}_{it} = \delta \hat{v}_{it-1} + \tilde{e}_{it}
\]

The total number of observations is \( NT \), with \( \bar{p} = \sum_{i=1}^{N} \hat{p}_i / N, \bar{T} = T - \bar{p} - 1 \). The standard \( t \) statistic for testing \( \delta = 0 \) is \( t_\delta = \hat{\delta} / STD(\hat{\delta}) \), with OLS estimator \( \hat{\delta} \) and standard deviation \( STD(\hat{\delta}) \). However, the standard \( t \) statistic diverges to negative infinity for models (2) and (3). Let \( \hat{\sigma}_\tilde{e} \) be the root mean square error from the step 3 regression, and denote it as

\[
\hat{\sigma}_\tilde{e}^2 = \left[ \frac{1}{NT} \sum_{i=1}^{N} \sum_{t=2/\bar{p}_i}^{T} (\tilde{e}_{it} - \hat{\delta} \hat{v}_{it-1})^2 \right]
\]

Levin, Lin, and Chu (2002) propose the following adjusted \( t \) statistic:

\[
t^*_\delta = \frac{\hat{\delta} - \bar{T} \hat{S}_N \hat{\sigma}_\tilde{e}^{-2} STD(\hat{\delta}) \mu^*_m \bar{T}}{\sigma^*_m \bar{T}}
\]

The mean and standard deviation adjustments \( (\mu^*_m, \sigma^*_m) \) depend on the time series dimension \( \bar{T} \) and model specification \( m \), which can be found in Table 2 of Levin, Lin, and Chu (2002). The adjusted \( t \) statistic converges to the standard normal distribution. Therefore, the standard normal critical values are used in hypothesis testing.
**Lag Order Selection in the ADF Regression**

The methods for selecting the individual lag orders in the ADF regressions can be divided into two categories: selection based on information criteria and selection via sequential testing.

**Lag Selection Based on Information Criteria** In this method, the following information criteria can be applied to lag order selection: AIC, SBC, HQIC (HQC), and MAIC. As with other model selection applications, the lag order is selected from 0 to the maximum $p_{max}$ to minimize the objective function, plus a penalty term, which is a function of the number of parameters in the regression. Let $k$ be the number of parameters and $T_o$ be the number of effective observations. For regression models, the objective function is $T_o \log \frac{SSR}{T_o} = \sum_{t=p_{max}+2}^{T} y_{t-1}^2$, where $\hat{\delta}$ is the estimated coefficient of the lagged dependent variable $y_{t-1}$ in the ADF regression.

**Lag Selection via Sequential Testing** In this method, the lag order estimation is based on the statistical significance of the estimated AR coefficients. Hall (1994) proposed general-to-specific (GS) and specific-to-general (SG) strategies. Levin, Lin, and Chu (2002) recommend the first strategy, following Campbell and Perron (1991). In the GS modeling strategy, starting with the maximum lag order $p_{max}$, the $t$ test for the largest lag order in $\hat{\theta}_L$ is performed to determine whether a smaller lag order is preferred. Specifically, when the null of $\hat{\theta}_L = 0$ is not rejected given the significance level (5%), a smaller lag order is preferred. This procedure continues until a statistically significant lag order is reached. On the other hand, the SG modeling strategy starts with lag order 0 and moves toward the maximum lag order $p_{max}$.

**Long-Run Variance Estimation**

The long-run variance of $\Delta y_{it}$ is estimated by a HAC-type estimator. For model (1), given the lag truncation parameter $\tilde{K}$ and kernel weights $w_{KL}$, the formula is

$$\hat{\sigma}^2_{y_L} = \frac{1}{T-1} \sum_{t=2}^{T} \Delta y_{it}^2 + 2 \sum_{L=1}^{\tilde{K}} w_{KL} \left[ \frac{1}{T-1} \sum_{t=2+L}^{T} \Delta y_{it} \Delta y_{it-L} \right]$$

To achieve consistency, the lag truncation parameter must satisfy $\tilde{K}/T \to 0$ and $\tilde{K} \to \infty$ as $T \to \infty$. Levin, Lin, and Chu (2002) suggest $\tilde{K} = \left[ 3.21T^{1/3} \right]$. The weights $w_{KL}$ depend on the kernel function. Andrews (1991) proposes data-driven bandwidth (lag truncation parameter + 1 if integer-valued) selection procedures to minimize the asymptotic mean squared error (MSE) criterion. For details about the kernel functions and Andrews (1991) data-driven bandwidth selection procedure, see the section “Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrices” on page 1436 for details. Because Levin, Lin, and Chu (2002) truncate the bandwidth as an integer, when LLCBAND is specified as the BANDWIDTH option, it corresponds to BANDWIDTH = $\left[ 3.21T^{1/3} \right] + 1$. Furthermore, kernel weights $w_{KL} = k(L/(\tilde{K} + 1))$ with kernel function $k(\cdot)$.

---

7In practice $c$ is set to 1, following the literature (Hannan and Quinn 1979; Hall 1994).
For model (2), the series $\Delta y_{it}$ is demeaned individual by individual first. Therefore, $\Delta y_{it}$ is replaced by $\Delta y_{it} - \bar{y}_{it}$, where $\bar{y}_{it}$ is the mean of $\Delta y_{it}$ for individual $i$. For model (3) with individual fixed effects and time trend, both the individual mean and trend should be removed before the long-run variance is estimated. That is, first regress $\Delta y_{it}$ on $\{1, t\}$ for each individual and save the residual $\bar{y}_{it}$, and then replace $\Delta y_{it}$ with the residual.

**Cross-Sectional Dependence via Time-Specific Aggregate Effects**

The Levin, Lin, and Chu (2002) testing procedure is based on the assumption of cross-sectional independence. It is possible to relax this assumption and allow for a limited degree of dependence via time-specific aggregate effects. Let $\theta_i$ denote the time-specific aggregate effects; then the data generating process (DGP) becomes

$$\Delta y_{it} = \delta y_{it-1} + \sum_{L=1}^{P_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mt} + \theta_t + \epsilon_{it} \quad m = 1, 2, 3$$

By subtracting the cross-sectional averages $\bar{y}_t = \sum_{i=1}^{N} y_{it}$ from the observed dependent variable $y_{it}$, or equivalently, by including the time-specific intercepts $\theta_t$ in the ADF regression, the cross-sectional dependence is removed. The impact of a single aggregate common factor that has an identical impact on all individuals but changes over time can also be removed in this way. After cross-sectional dependence is removed, the three-step procedure is applied to calculate the Levin, Lin, and Chu (2002) adjusted $t$ statistic.

**Deterministic Variables**

Three deterministic variables can be included in the model for the first-stage estimation: CS_FixedEffects (cross-sectional fixed effects), TS_FixedEffects (time series fixed effects), and TimeTrend (individual linear time trend). When a linear time trend is included, the individual fixed effects are also included. Otherwise the time trend is not identified. Moreover, if the time fixed effects are included, the time trend is not identified either. Therefore, we have 5 identified models: model (1), no deterministic variables; model (2), CS_FixedEffects; model (3), CS_FixedEffects and TimeTrend; model (4), TS_FixedEffects; model (5), CS_FixedEffects TS_FixedEffects. PROC PANEL outputs the test results for all 5 model specifications.

**Im, Pesaran, and Shin (2003)**

To test for the unit root in heterogeneous panels, Im, Pesaran, and Shin (2003) propose a standardized $t$-bar test statistic based on averaging the (augmented) Dickey-Fuller statistics across the groups. The limiting distribution is standard normal. The stochastic process $y_{it}$ is generated by the first-order autoregressive process. If $\Delta y_{it} = y_{it} - y_{it-1}$, the data generating process can be expressed as in LLC:

$$\Delta y_{it} = \beta_i y_{it-1} + \sum_{j=1}^{P_i} \rho_{ij} \Delta y_{i,t-j} + \alpha_{mi} d_{mt} + \epsilon_{it} \quad m = 1, 2, 3$$

Unlike the DGP in LLC, $\beta_i$ is allowed to differ across groups. The null hypothesis of unit roots is $H_0 : \beta_i = 0$ for all $i$ against the heterogeneous alternative,

$$H_1 : \beta_i < 0 \quad \text{for } i = 1, \ldots, N_1, \quad \beta_i = 0 \quad \text{for } i = N_1 + 1, \ldots, N$$

The Im, Pesaran, and Shin test also allows for some (but not all) of the individual series to have unit roots under the alternative hypothesis. But the fraction of the individual processes that are stationary is positive,
When \(N \to \infty\) \(N_1/N = \delta \in (0, 1]\). The \(t\)-bar statistic, denoted by \(t\)-bar\(_{NT}\), is formed as a simple average of the individual \(t\) statistics for testing the null hypothesis of \(\beta_i = 0\). If \(t_{iT} (p_i, \rho_i)\) is the standard \(t\) statistic, then

\[
t\text{-bar}_{NT} = \frac{1}{N} \sum_{i=1}^{N} t_{iT} (p_i, \rho_i)
\]

If \(T \to \infty\), then for each \(i\) the \(t\) statistic (without time trend) converges to the Dickey-Fuller distribution, \(\eta_i\), defined by

\[
\eta_i = \frac{1}{2} \int_0^1 \frac{W_i(1)^2 - W_i(u)}{W_i(u)^2} du
\]

where \(W_i\) is the standard Brownian motion. The limiting distribution is different when a time trend is included in the regression (Hamilton 1994, p. 499). The mean and variance of the limiting distributions are reported in Nabeya (1999). The standardized \(t\)-bar statistic satisfies

\[
Z_{t\text{-bar}} (p, \rho) = \frac{\sqrt{N} \{t\text{-bar}_{NT} - E(\eta)\}}{\sqrt{\text{Var}(\eta)}} \implies \mathcal{N}(0, 1)
\]

where the standard normal is the sequential limit with \(T \to \infty\) followed by \(N \to \infty\). To obtain better finite sample approximations, Im, Pesaran, and Shin (2003) propose standardizing the \(t\)-bar statistic by means and variances of \(t_{iT}(p_i, 0)\) under the null hypothesis \(\beta_i = 0\). The alternative standardized \(t\)-bar statistic is

\[
W_{t\text{-bar}} (p, \rho) = \frac{\sqrt{N} \{t\text{-bar}_{NT} - \sum_{i=1}^{N} E[t_{iT}(p_i, 0)|\beta_i = 0]/N\}}{\sqrt{\sum_{i=1}^{N} \text{Var}[t_{iT}(p_i, 0)|\beta_i = 0]/N}} \implies \mathcal{N}(0, 1)
\]

Im, Pesaran, and Shin (2003) simulate the values of \(E[t_{iT}(p_i, 0)|\beta_i = 0]\) and \(\text{Var}[t_{iT}(p_i, 0)|\beta_i = 0]\) for different values of \(T\) and \(p\). The lag order in the ADF regression can be selected by the same method as in Levin, Lin, and Chu (2002). See the section “Lag Order Selection in the ADF Regression” on page 1443 for details.

When \(T\) is fixed, Im, Pesaran, and Shin (2003) assume serially uncorrelated errors, \(p_i = 0\; t_{iT}\) is likely to have finite second moment, which is not established in the paper. The \(t\) statistic is modified by imposing the null hypothesis of a unit root. Denote \(\hat{\sigma}_{iT}\) as the estimated standard error from the restricted regression \((\beta_i = 0)\),

\[
\tilde{t}\text{-bar}_{NT} = \sum_{i=1}^{N} \frac{i_{TT}}{N} = \sum_{i=1}^{N} \left[ \hat{\beta}_{iT} \left( y'_{i,-1} M_{i} y_{i,-1} \right)^{1/2} / \hat{\sigma}_{iT} \right] / N
\]

where \(\hat{\beta}_{iT}\) is the OLS estimator of \(\beta_i\) (unrestricted model), \(\tau_T = (1, 1, \ldots, 1)'\), \(M_{i} = I_T - \tau_T \tau_T'\), and \(y_{i,-1} = (y_{i0}, y_{i1}, \ldots, y_{i,T-1})'\) Under the null hypothesis, the standardized \(\tilde{t}\)-bar statistic converges to a standard normal variate,

\[
Z_{\tilde{t}\text{-bar}} = \frac{\sqrt{N} \{\tilde{t}\text{-bar}_{NT} - E(\tilde{t}_{iT})\}}{\sqrt{\text{Var}(\tilde{t}_{iT})}} \implies \mathcal{N}(0, 1)
\]

where \(E(\tilde{t}_{iT})\) and \(\text{Var}(\tilde{t}_{iT})\) are the mean and variance of \(\tilde{t}_{iT}\), respectively. The limit is taken as \(N \to \infty\) and \(T\) is fixed. Their values are simulated for finite samples without a time trend. The \(Z_{\tilde{t}\text{-bar}}\) is also likely to converge to standard normal.

When \(N\) and \(T\) are both finite, an exact test that assumes no serial correlation can be used. The critical values of \(t\)-bar\(_{NT}\) and \(\tilde{t}\)-bar\(_{NT}\) are simulated.
Combination Tests (Experimental)

Combining the observed significance levels \((p\)-values\) from \(N\) independent tests of the unit root null hypothesis was proposed by Maddala and Wu (1999); Choi (2001). Suppose \(G_i\) is the test statistic to test the unit root null hypothesis for individual \(i = 1, \ldots, N\), and \(F(\cdot)\) is the cdf (cumulative distribution function) of the asymptotic distribution as \(T \to \infty\). Then the asymptotic \(p\)-value is defined as

\[
p_i = F(G_i)
\]

There are different ways to combine these \(p\)-values. The first one is the inverse chi-square test (Fisher 1932); this test is referred to as \(P\) test in Choi (2001) and \(\lambda\) in Maddala and Wu (1999):

\[
Chi - Square = -2 \sum_{i=1}^{N} \ln(p_i)
\]

When the test statistics \(\{G_i\}_{i=1}^{N}\) are continuous, \(\{p_i\}_{i=1}^{N}\) are independent uniform \((0, 1)\) variables. Therefore, \(P \Rightarrow \chi^2(2N)\) as \(T \to \infty\) and \(N\) fixed. But as \(N \to \infty\), \(P\) diverges to infinity in probability. Therefore, it is not applicable for large \(N\). To derive a nondegenerate limiting distribution, the \(P\) test (Fisher test with \(N \to \infty\)) should be modified to

\[
P_m = FI = \sum_{i=1}^{N} (-2\ln(p_i) - 2) / 2\sqrt{N} = -\sum_{i=1}^{N} (\ln(p_i) + 1) / \sqrt{N}
\]

Under the null as \(T_i \to \infty^8\) and then \(N \to \infty\), \(P_m \Rightarrow N(0, 1)^9\).

The second way of combining individual \(p\)-values is the inverse normal test,

\[
Z = \sum_{i=1}^{N} \Phi^{-1}(p_i)
\]

where \(\Phi(\cdot)\) is the standard normal cdf. When \(T_i \to \infty\), \(Z \Rightarrow N(0, 1)\) as \(N\) is fixed. When \(N\) and \(T_i\) are both large, the sequential limit is also standard normal if \(T_i \to \infty\) first and \(N \to \infty\) next.

The third way of combining \(p\)-values is the logit test,

\[
L^* = \sqrt{k} L = \sqrt{k} \sum_{i=1}^{N} \ln \left( \frac{p_i}{1 - p_i} \right)
\]

where \(k = 3(5N + 4) / (\pi^2 N (5N + 2))\). When \(T_i \to \infty\) and \(N\) is fixed, \(L^* \Rightarrow t_{5N+4}\). In other words, the limiting distribution is the \(t\) distribution with degree of freedom \(5N + 4\). The sequential limit is \(L^* \Rightarrow N(0, 1)\) as \(T_i \to \infty\) and then \(N \to \infty\). Simulation results in Choi (2001) suggest that the \(Z\) test outperforms other combination tests. For the time series unit root test \(G_i\), Maddala and Wu (1999) apply the augmented Dickey-Fuller test. According to Choi (2006), the Elliott, Rothenberg, and Stock (1996) Dickey-Fuller generalized least squares (DF-GLS) test brings significant size and power advantages in finite samples.

---

\(^8\)The time series length \(T\) is subindexed by \(i = 1, \ldots, N\) because the panel can be unbalanced.

\(^9\)Choi (2001) also points out that the joint limit result where \(N\) and \(\{T_i\}_{i=1}^{N}\) go to infinity simultaneously is the same as the sequential limit, but it requires more moment conditions.
Breitung’s Unbiased Tests

To account for the nonzero mean of the $t$ statistic in the OLS detrending case, bias-adjusted $t$ statistics were proposed by: Levin, Lin, and Chu (2002); Im, Pesaran, and Shin (2003). The bias corrections imply a severe loss of power. Breitung and associates take an alternative approach to avoid the bias, by using alternative estimates of the deterministic terms (Breitung and Meyer 1994; Breitung 2000; Breitung and Das 2005). The DGP is the same as in the Im, Pesaran, and Shin approach. When serial correlation is absent, for model (2) with individual specific means, the constant terms are estimated by the initial values $y_{i1}$. Therefore, the series $y_{it}$ is adjusted by subtracting the initial value. The equation becomes

$$\Delta y_{it} = \delta^* (y_{i,t-1} - y_{i1}) + v_{it}$$

For model (3) with individual specific means and time trends, the time trend can be estimated by $\hat{\beta}_i = (T - 1)^{-1} (y_{i,T} - y_{i1})$. The levels can be transformed as

$$\hat{y}_{it} = y_{it} - y_{i1} - \hat{\beta}_it = y_{it} - y_{i1} - t (y_{i,T} - y_{i1}) / (T - 1)$$

The Helmert transformation is applied to the dependent variable to remove the mean of the differenced variable:

$$\Delta y_{it}^* = \sqrt{\frac{T - t}{T - t + 1}} [\Delta y_{it} - (\Delta y_{i,t+1} + \ldots + \Delta y_{iT}) / (T - t)]$$

The transformed model is

$$\Delta y_{it}^* = \delta^* \hat{y}_{i,t-1} + v_{it}$$

The pooled $t$ statistic has a standard normal distribution. Therefore, no adjustment is needed for the $t$ statistic.

To adjust for heteroscedasticity across cross sections, Breitung (2000) proposes a UB (unbiased) statistic based on the transformed data,

$$UB = \frac{\sum_{i=1}^{N} \sum_{t=2}^{T} \Delta y_{it}^* \hat{y}_{i,t-1} / \sigma_i^2}{\sqrt{\sum_{i=1}^{N} \sum_{t=2}^{T} \hat{y}_{i,t-1}^2 / \sigma_i^2}}$$

where $\sigma_i^2 = E (\Delta y_{it} - \beta_1)^2$. When $\sigma_i^2$ is unknown, it can be estimated as

$$\hat{\sigma}_i^2 = \sum_{t=2}^{T} (\Delta y_{it} - \sum_{t=2}^{T} \Delta y_{it} / (T - 1))^2 / (T - 2)$$

The $UB$ statistic has a standard normal limiting distribution as $T \to \infty$ followed by $N \to \infty$ sequentially.

To account for the short-run dynamics, Breitung and Das (2005) suggest applying the test to the prewhitened series, $\hat{y}_{it}$. For model (1) and model (2) (constant-only case), they suggested the same method as in step 1 of Levin, Lin, and Chu (2002). For model (3) (with a constant and linear time trend), the prewhitened series can be obtained by running the following restricted ADF regression under the null hypothesis of a unit root ($\delta = 0$) and no intercept and linear time trend ($\mu_i = 0, \beta_i = 0$):

$$\Delta y_{it} = \sum_{L=1}^{\hat{p}_i} \theta_{iL} \Delta y_{i,t-L} + \mu_i + \varepsilon_{it}$$

10See the section “Levin, Lin, and Chu (2002)” on page 1441 for details. The only difference is the standard error estimate $\hat{\sigma}_{\epsilon_i}^2$. Breitung suggests using $T - p_i - 2$ instead of $T - p_i - 1$ as in LLC to normalize the standard error.
where \( \hat{p}_i \) is a consistent estimator of the true lag order \( p_i \) and can be estimated by the procedures listed in the section “Lag Order Selection in the ADF Regression” on page 1443. For LLC and IPS tests, the lag orders are selected by running the ADF regressions. But for Breitung and his coauthors’ tests, the restricted ADF regressions are used to be consistent with the prewhitening method. Let \( \widehat{\mu}_i, \widehat{\theta}_{iL} \) be the estimated coefficients. The prewhitened series can be obtained by

\[
\Delta \widehat{y}_{it} = \Delta y_{it} - \sum_{L=1}^{\hat{p}_i} \hat{\theta}_{iL} \Delta y_{it-L}
\]

and

\[
\hat{y}_{it} = y_{it} - \sum_{L=1}^{\hat{p}_i} \hat{\theta}_{iL} y_{it-L}
\]

The transformed series are random walks under the null hypothesis,

\[
\Delta \hat{y}_{it} = \delta \hat{y}_{it-1} + v_{it}
\]

where \( y_{it} = 0 \) for \( s < 0 \). When the cross-section units are independent, the \( t \) statistic converges to standard normal under the null, as \( T \rightarrow \infty \) followed by \( N \rightarrow \infty \),

\[
t_{OLS} = \frac{\sum_{t=1}^{N} \sum_{s=2}^{T} y_{is,t-1} \Delta y_{is,t}}{\hat{\sigma} \sqrt{\sum_{i=1}^{N} \sum_{s=2}^{T} y_{is,t}^2}} \quad \Rightarrow \quad N(0, 1)
\]

where \( \hat{\sigma}^2 = \sum_{i=1}^{N} \sum_{s=2}^{T} (\Delta y_{is,t} - \hat{\delta} \hat{y}_{is,t-1})^2 / N (T - 1) \) with OLS estimator \( \hat{\delta} \).

To take account for cross-sectional dependence, Breitung and Das (2005) propose the robust \( t \) statistic and a GLS version of the test statistic. Let \( v_t = (v_{1t}, \ldots, v_{Nt})' \) be the error vector for time \( t \), and let \( \Omega = E (v_t v_t') \) be a positive definite matrix with eigenvalues \( \lambda_1 \geq \ldots \geq \lambda_N \). Let \( y_t = (y_{1t}, \ldots, y_{Nt})' \) and \( \Delta y_t = (\Delta y_{1t}, \ldots, \Delta y_{Nt})' \). The model can be written as a SUR-type system of equations,

\[
\Delta y_t = \delta \hat{y}_{it-1} + v_t
\]

The unknown covariance matrix \( \Omega \) can be estimated by its sample counterpart,

\[
\hat{\Omega} = \frac{1}{T} \sum_{t=2}^{T} (\Delta y_{it} - \hat{\delta} \hat{y}_{it-1}) (\Delta y_{it} - \hat{\delta} \hat{y}_{it-1})' / (T - 1)
\]

The sequential limit \( T \rightarrow \infty \) followed by \( N \rightarrow \infty \) of the standard \( t \) statistic \( t_{OLS} \) is normal with mean 0 and variance \( v_\Omega = \lim_{N \rightarrow \infty} \text{tr} (\Omega^2 / N) / (\text{tr} \Omega / N)^2 \). The variance \( v_\Omega \) can be consistently estimated by

\[
\hat{v}_\delta = \frac{1}{\sum_{t=2}^{T} y_{it-1}' \hat{\Omega} y_{it-1}} \frac{\sum_{t=2}^{T} y_{it-1}' \Delta y_{it} (\Delta y_{it} - \hat{\delta} \hat{y}_{it-1})' (\Delta y_{it} - \hat{\delta} \hat{y}_{it-1})}{(T - 1)}
\]

Thus the robust \( t \) statistic can be calculated as

\[
t_{rob} = \frac{\delta}{\hat{v}_\delta} = \frac{\sum_{t=2}^{T} y_{it-1}' \Delta y_{it}}{\sqrt{\sum_{t=2}^{T} y_{it-1}' \hat{\Omega} y_{it-1}}} \quad \Rightarrow \quad N(0, 1)
\]

\( ^{11} \)Breitung (2000) suggests the approach in step 1 of Levin, Lin, and Chu (2002), while Breitung and Das (2005) suggest the prewhitening method as described above. In Breitung’s code, to be consistent with the papers, different approaches are adopted for model (2) and (3). Meanwhile, for the order of variable transformation and prewhitening, in model (2), the initial values are deducted (variable transformation) first, and then the prewhitening was applied. For model (3), the order is reversed. The series is prewhitened and then transformed to remove the mean and linear time trend.
Panel Data Unit Root Tests

as $T \to \infty$ followed by $N \to \infty$ under the null hypothesis of random walk. Since the finite sample distribution can be quite different, Breitung and Das (2005) list the 1%, 5%, and 10% critical values for different $N$’s.

When $T > N$, a (feasible) GLS estimator is applied; it is asymptotically more efficient than the OLS estimator. The data are transformed by multiplying $\hat{\Omega}^{-1/2}$ as defined before, $\hat{z}_t = \hat{\Omega}^{-1/2}y_t$. Thus the model is transformed into

$$\Delta \hat{z}_t = \delta \hat{z}_{t-1} + e_t$$

The feasible GLS (FGLS) estimator of $\delta$ and the corresponding $t$ statistic are obtained by estimating the transformed model by OLS and denoted by $\hat{\delta}_{GLS}$ and $t_{GLS}$, respectively:

$$t_{GLS} = \frac{\sum_{t=2}^{T} y'_{t-1} \hat{\Omega}^{-1} \Delta y_t}{\sqrt{\sum_{t=2}^{T} y'_{t-1} \hat{\Omega}^{-1} y_{t-1}}} \rightarrow N(0, 1)$$

Hadri (2000) Stationarity Tests

Hadri (2000) adopts a component representation where an individual time series is written as a sum of a deterministic trend, a random walk, and a white-noise disturbance term. Under the null hypothesis of stationary, the variance of the random walk equals 0. Specifically, two models are considered:

- For model (1), the time series $y_{it}$ is stationary around a level $r_{i0}$,
  $$y_{it} = r_{it} + \epsilon_{it} \quad i = 1, \ldots, N, \quad t = 1, \ldots, T$$

- For model (2), $y_{it}$ is trend stationary,
  $$y_{it} = r_{it} + \beta_it + \epsilon_{it} \quad i = 1, \ldots, N, \quad t = 1, \ldots, T$$

where $r_{it}$ is the random walk component,

$$r_{it} = r_{it-1} + u_{it} \quad i = 1, \ldots, N, \quad t = 1, \ldots, T$$

The initial values of the random walks, $\{r_{i0}\}_{i=1}^{N}$, are assumed to be fixed unknowns and can be considered as heterogeneous intercepts. The errors $\epsilon_{it}$ and $u_{it}$ satisfy $\epsilon_{it} \sim iid \mathcal{N}(0, \sigma^2_e)$, $u_{it} \sim iid \mathcal{N}(0, \sigma^2_u)$ and are mutually independent.

The null hypothesis of stationarity is $H_0 : \sigma_u^2 = 0$ against the alternative random walk hypothesis $H_1 : \sigma_u^2 > 0$.

In matrix form, the models can be written as

$$y_i = X_i \beta_i + e_i$$

where $y'_i = (y_{i1}, \ldots, y_{iT})$, $e'_i = (e_{i1}, \ldots, e_{iT})$ with $e_{it} = \sum_{j=1}^{t} u_{ij} + \epsilon_{it}$, and $X_i = (t_i, a_T)$ with $t_i$ being a $T \times 1$ vector of ones, $a'_T = (1, \ldots, T)$, and $\beta_i = (r_{i0}, \beta_i)$.

Let $\hat{e}_{it}$ be the residuals from the regression of $y_i$ on $X_i$; then the LM statistic is

$$LM = \frac{1}{N} \sum_{i=1}^{N} \frac{1}{T} \sum_{t=1}^{T} S_{it}^2$$
where $S_{it} = \sum_{j=1}^{t} \hat{\varepsilon}_{ij}$ is the partial sum of the residuals and $\hat{\sigma}_{\varepsilon}^2$ is a consistent estimator of $\sigma_{\varepsilon}^2$ under the null hypothesis of stationarity. With some regularity conditions,

$$LM \overset{p}{\to} E \left[ \int_0^1 V^2 (r) \, dr \right]$$

where $V (r)$ is a standard Brownian bridge in model (1) and a second-level Brownian bridge in model (2). Let $W (r)$ be a standard Wiener process (Brownian motion),

$$V (r) = \begin{cases} W (r) - rW (1) & \text{for model (1)} \\ W (r) + (2r - 3r^2) W (1) + 6r (r - 1) \int_0^1 W (s) \, ds & \text{for model (2)} \end{cases}$$

The mean and variance of the random variable $\int V^2$ can be calculated by using the characteristic functions,

$$\xi = E \left[ \int_0^1 V^2 (r) \, dr \right] = \begin{cases} \frac{1}{6} & \text{for model (1)} \\ \frac{1}{15} & \text{for model (2)} \end{cases}$$

and

$$\xi^2 = \text{var} \left[ \int_0^1 V^2 (r) \, dr \right] = \begin{cases} \frac{1}{3} & \text{for model (1)} \\ \frac{1}{6} & \text{for model (2)} \end{cases}$$

The LM statistics can be standardized to obtain the standard normal limiting distribution,

$$Z = \frac{\sqrt{N} (LM - \xi)}{\xi} \implies \mathcal{N} (0, 1)$$

**Consistent Estimator of $\sigma_{\varepsilon}^2$**

Hadri’s (2000) test can be applied to the general case of heteroscedasticity and serially correlated disturbance errors. Under homoscedasticity and serially uncorrelated errors, $\sigma_{\varepsilon}^2$ can be estimated as

$$\hat{\sigma}_{\varepsilon}^2 = \frac{1}{N} \sum_{i=1}^{N} \sum_{t=1}^{T} \hat{\varepsilon}_{it}^2 / (T - k)$$

where $k$ is the number of regressors. Therefore, $k = 1$ for model (1) and $k = 2$ for model (2).

When errors are heteroscedastic across individuals, the standard errors $\sigma_{\varepsilon,i}^2$ can be estimated by $\hat{\sigma}_{\varepsilon,i}^2 = \sum_{t=1}^{T} \hat{\varepsilon}_{it}^2 / (T - k)$ for each individual $i$ and the LM statistic needs to be modified to

$$LM = \frac{1}{N} \sum_{i=1}^{N} \left( \frac{1}{T^2} \sum_{t=1}^{T} S_{it}^2 / \hat{\sigma}_{\varepsilon,i}^2 \right)$$

To allow for temporal dependence over $t$, $\sigma_{\varepsilon}^2$ has to be replaced by the long-run variance of $\varepsilon_{it}$, which is defined as $\sigma^2 = \sum_{i=1}^{N} \lim_{T \to \infty} T^{-1} \left( S_{iT}^2 \right) / N$. A HAC estimator can be used to consistently estimate the long-run variance $\sigma^2$. For more information, see the section “Long-Run Variance Estimation” on page 1443.
Harris and Tzavalis (1999) **Panel Unit Root Tests (Experimental)**

Harris and Tzavalis (1999) derive the panel unit root test under fixed $T$ and large $N$. Three models are considered as in Levin, Lin, and Chu (2002). Model (1) is the homogeneous panel,

$$y_{it} = \varphi y_{i,t-1} + v_{it}$$

Under the null hypothesis, $\varphi = 0$. For model (2), each series is a unit root process with a heterogeneous drift,

$$y_{it} = \alpha_i + \varphi y_{i,t-1} + v_{it}$$

Model (3) includes heterogeneous drifts and linear time trends,

$$y_{it} = \alpha_i + \beta_i t + \varphi y_{i,t-1} + v_{it}$$

Under the null hypothesis $H_0 : \varphi = 1$, $\beta_i = 0$, so the series is random walks with drift.

Let $\hat{\varphi}$ be the OLS estimator of $\varphi$; then

$$\hat{\varphi} - 1 = \left[ \sum_{i=1}^{N} y'_{i,-1} Q_T y_{i,-1} \right]^{-1} \left[ \sum_{i=1}^{N} y'_{i,-1} Q_T v_{i} \right]$$

where $y_{i,-1} = (y_{i0}, \ldots, y_{iT-1})$, $y'_{i} = (v_{i1}, \ldots, v_{iT})$, and $Q_T$ is the projection matrix. For model (1), there are no regressors other than the lagged dependent value, so $Q_T$ is the identity matrix $I_T$. For model (2), a constant is included, so $Q_T = I_T - e_T e'_T / T$ with $e_T$ a $T \times 1$ column of ones. For model (3), a constant and time trend are included. Thus $Q_T = I_T - Z_T (Z'_T Z_T)^{-1} Z'_T / T$, where $Z_T = (e_T, \tau_T)$ and $\tau_T = (1, \ldots, T)$.

When $y_{i0} = 0$ in model (1) under the null hypothesis,

$$\sqrt{N T (T - 1) / 2} (\hat{\varphi} - 1) \overset{y_{i0}=0,H_0}{\sim} \mathcal{N}(0, 1)$$

As $T \rightarrow \infty$, it becomes $T \sqrt{N} (\hat{\varphi} - 1) \overset{H_0}{\Rightarrow} \mathcal{N}(0, 1)$.

When the drift is absent in model (2) under the null hypothesis, $\alpha_i = 0$,

$$\sqrt{5N (T + 1)^3 (T - 1) / 3 (17T^2 - 20T + 17)} \left( \hat{\varphi} - 1 - \frac{3}{T + 1} \right) \overset{H_0}{\Rightarrow} \mathcal{N}(0, 1)$$

As $T$ grows large, $\left( T \sqrt{N} (\hat{\varphi} - 1) + 3 \sqrt{N} \right) / \sqrt{51/5} \overset{H_0}{\Rightarrow} \mathcal{N}(0, 1)$.

When the time trend is absent in model (3) under the null hypothesis, $\beta_i = 0$,

$$\sqrt{112N (T + 2)^3 (T - 2) / 15 (193T^2 - 728T + 1147)} \left( \hat{\varphi} - 1 - \frac{15}{2 (T + 2)} \right) \overset{H_0}{\Rightarrow} \mathcal{N}(0, 1)$$

When $T$ is sufficiently large, it implies $\left( T \sqrt{N} (\hat{\varphi} - 1) + 7.5 \sqrt{N} \right) / \sqrt{2895/112} \overset{H_0}{\Rightarrow} \mathcal{N}(0, 1)$. 

Troubleshooting

You need to follow some guidelines when you use PROC PANEL for analysis. For each cross section, PROC PANEL requires at least two time series observations that have nonmissing values for all model variables. There should be at least two cross sections for each time point in the data. If these two conditions are not met, then an error message is printed in the log that states that there is only one cross section or time series observation and further computations will be terminated. You must provide adequate data for an estimation method to produce results, and you should check the log for any errors that are related to data.

If PROC PANEL uses the Parks method and the number of cross sections is greater than the number of time series observations per cross section, then PROC PANEL produces an error message that states that the $\phi$ matrix is singular. This is analogous to seemingly unrelated regression that has fewer observations than equations in the model. To avoid the problem, reduce the number of cross sections.

Your data set could have multiple observations for each time ID within a particular cross section. However, you can use PROC PANEL only in cases where you have only a single observation for each time ID within each cross section. In such a case, after you have sorted the data, an error warning is printed in the log that states that the data have not been sorted in ascending sequence with respect to time series ID.

The cause of the error is due to multiple observations for each time ID for a given cross section. PROC PANEL allows only one observation for each time ID within each cross section.

The following data set shown in Figure 20.2 illustrates the preceding instance with the correct representation.

**Figure 20.2** Single Observation for Each Time Series

<table>
<thead>
<tr>
<th>Obs</th>
<th>firm</th>
<th>year</th>
<th>production</th>
<th>cost</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>1955</td>
<td>5.36598</td>
<td>1.14867</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>1960</td>
<td>6.03787</td>
<td>1.45185</td>
</tr>
<tr>
<td>3</td>
<td>1</td>
<td>1965</td>
<td>6.37673</td>
<td>1.52257</td>
</tr>
<tr>
<td>4</td>
<td>1</td>
<td>1970</td>
<td>6.93245</td>
<td>1.76627</td>
</tr>
<tr>
<td>5</td>
<td>2</td>
<td>1955</td>
<td>6.54535</td>
<td>1.35041</td>
</tr>
<tr>
<td>6</td>
<td>2</td>
<td>1960</td>
<td>6.69827</td>
<td>1.71109</td>
</tr>
<tr>
<td>7</td>
<td>2</td>
<td>1965</td>
<td>7.40245</td>
<td>2.09519</td>
</tr>
<tr>
<td>8</td>
<td>2</td>
<td>1970</td>
<td>7.82644</td>
<td>2.39480</td>
</tr>
</tbody>
</table>

In this case, you can observe that there are no multiple observations with respect to a given time series ID within a cross section. This is the correct representation of a data set where PROC PANEL is applicable.

If for state ID 1 you have two observations for the year=1955, then PROC PANEL produces the following error message:

“The data set is not sorted in ascending sequence with respect to time series ID. The current time period has year=1955 and the previous time period has year=1955 in cross section firm=1.”

A data set similar to the previous example with multiple observations for the year=1955 is shown in Figure 20.3; this data set results in an error message due to multiple observations while using PROC PANEL.
Figure 20.3 Multiple Observations for Each Time Series

<td>8</td>
<td>2</td>
<td>1970</td>
<td>7.82644</td>
<td>2.39480</td>
</tr>
</tbody>
</table>

In order to use PROC PANEL, you need to aggregate the data so that you have unique time ID values within each cross section. One possible way to do this is to run a PROC MEANS on the input data set and compute the mean of all the variables by FIRM and YEAR, and then use the output data set.

### Creating ODS Graphics

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the PANEL procedure. The table below lists the graph names, the plot descriptions, and the options used.

Chapter 20: The PANEL Procedure

**OUTPUT OUT= Data Set**

PROC PANEL writes the initial data of the estimated model, predicted values, and residuals to an output data set when the OUTPUT OUT= statement is specified. The OUT= data set contains the following variables:

- `_MODELL_` is a character variable that contains the label for the MODEL statement if a label is specified.
- `_METHOD_` is a character variable that identifies the estimation method.
- `_MODLNO_` is the number of the model estimated.
- `_ACTUAL_` contains the value of the dependent variable.
- `_WEIGHT_` contains the weighing variable.
- `_CSID_` is the value of the cross section ID.
- `_TSID_` is the value of the time period in the dynamic model.
- `name` regressors are the values of regressor variables specified in the MODEL statement.

If PRED= `name1` and/or RESIDUAL= `name2` options are specified, then `name1` and `name2` are the columns of predicted values of dependent variable and residuals of the regression, respectively.

**OUTEST= Data Set**

PROC PANEL writes the parameter estimates to an output data set when the OUTEST= option is specified. The OUTEST= data set contains the following variables:

- `_MODEL_` is a character variable that contains the label for the MODEL statement if a label is specified.
- `_METHOD_` is a character variable that identifies the estimation method.
- `_TYPE_` is a character variable that identifies the type of observation. Values of the `_TYPE_` variable are CORRB, COVB, CSPARMS, STD, and the type of model estimated. The CORRB observation contains correlations of the parameter estimates, the COVB observation contains covariances of the parameter estimates, the CSPARMS observation contains cross-sectional parameter estimates, the STD observation indicates the row of standard deviations of the corresponding coefficients, and the type of model estimated observation contains the parameter estimates.
- `_NAME_` is a character variable that contains the name of a regressor variable for COVB and CORRB observations and is left blank for other observations. The `_NAME_` variable is used in conjunction with the `_TYPE_` values COVB and CORRB to identify rows of the correlation or covariance matrix.
- `_DEPVAR_` is a character variable that contains the name of the response variable.
- `_MSE_` is the mean square error of the transformed model.
_CSID_ is the value of the cross section ID for CSPARMS observations. The _CSID_ variable is used with the _TYPE_ value CSPARMS to identify the cross section for the first-order autoregressive parameter estimate contained in the observation. The _CSID_ variable is missing for observations with other _TYPE_ values. (Currently, only the _A_1 variable contains values for CSPARMS observations.)

_VARCS_ is the variance component estimate due to cross sections. The _VARCS_ variable is included in the OUTEST= data set when a one-way or two-way random effects models is estimated.

_VARTS_ is the variance component estimate due to time series. The _VARTS_ variable is included in the OUTEST= data set when a two-way random effects model is estimated.

_VARERR_ is the variance component estimate due to error. The _VARERR_ variable is included in the OUTEST= data set when a one-way or two-way random effects models is estimated.

_A_1 is the first-order autoregressive parameter estimate. The _A_1 variable is included in the OUTEST= data set when the PARKS option is specified. The values of _A_1 are cross-sectional parameters, meaning that they are estimated for each cross section separately. The _A_1 variable has a value only for _TYPE_=CSPARMS observations. The cross section to which the estimate belongs is indicated by the _CSID_ variable.

Intercept is the intercept parameter estimate. (Intercept is missing for models when the NOINT option is specified.)

regressors are the regressor variables specified in the MODEL statement. The regressor variables in the OUTEST= data set contain the corresponding parameter estimates for the model identified by _MODEL_ for _TYPE_=PARMS observations, and the corresponding covariance or correlation matrix elements for _TYPE_=COVB and _TYPE_=CORRB observations. The response variable contains the value–1 for the _TYPE_=PARMS observation for its model.

**OUTTRANS=. Data Set**

PROC PANEL writes the transformed series to an output data set. That is, if the user selects FIXONE, FIXONETIME, or RANONE and supplies the OUTTRANS = option, the transformed dependent variable and independent variables are written out to a SAS data set; other variables in the input data set are copied unchanged.

Say that your data set contains variables y, x1, x2, x3, and z2. The following statements result in a SAS data set:

```sas
proc panel data=datain outtrans=dataout;
   id cs ts;
   model y = x1 x2 x3 / fixone;
run;
```

First, z2 is copied over. Then _Int, x1, x2, y, and x3, are replaced with their mean deviates (from cross sections). Furthermore, two new variables are created.
_MODELL_ is the model’s label (if it exists).

_METHOD_ is the model’s transformation type. In the FIXONE case, this is _FIXONE_ or _FIXONE-TIME_. If the model RANONE model is selected, the _METHOD_ variable is either _Ran1FB_, _Ran1WK_, _Ran1WH_, or _Ran1NL_, depending on the variance component estimators chosen.

**Printed Output**

For each MODEL statement, the printed output from PROC PANEL includes the following:

- a model description, which gives the estimation method used, the model statement label if specified, the number of cross sections and the number of observations in each cross section, and the order of moving average error process for the DASILVA option. For fixed-effects model analysis, an F test for the absence of fixed effects is produced, and for random-effects model analysis, a Hausman test is used for the appropriateness of the random-effects specification.

- the estimates of the underlying error structure parameters

- the regression parameter estimates and analysis. For each regressor, this includes the name of the regressor, the degrees of freedom, the parameter estimate, the standard error of the estimate, a t statistic for testing whether the estimate is significantly different from 0, and the significance probability of the t statistic.

Optionally, PROC PANEL prints the following:

- the covariance and correlation of the resulting regression parameter estimates for each model and assumed error structure

- the $\Phi$ matrix that is the estimated contemporaneous covariance matrix for the PARKS option

**ODS Table Names**

PROC PANEL assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 20.7.

Example: PANEL Procedure

Example 20.1: Analyzing Demand for Liquid Assets

In this example, the demand equations for liquid assets are estimated. The demand function for the demand deposits is estimated under three error structures while demand equations for time deposits and savings and loan (S&L) association shares are calculated using the Parks method. The data for seven states (CA, DC, FL, IL, NY, TX, and WA) are selected out of 49 states. See Feige (1964) for data description. All variables were transformed via natural logarithm. The data set A is shown below.

```plaintext
data a;
  length state $ 2;
  input state $ year d t s y rd rt rs;
  label d = 'Per Capita Demand Deposits'
     t = 'Per Capita Time Deposits'
     s = 'Per Capita S & L Association Shares'
     y = 'Permanent Per Capita Personal Income'
     rd = 'Service Charge on Demand Deposits'
     rt = 'Interest on Time Deposits'
     rs = 'Interest on S & L Association Shares';
datalines;
CA  1949  6.2785  6.1924  4.4998  7.2056 -1.0700  0.1080  1.0664
CA  1950  6.4019  6.2106  4.6821  7.2889 -1.0106  0.1501  1.0767
CA  1951  6.5058  6.2729  4.8598  7.3827 -1.0024  0.4008  1.1291
CA  1952  6.4785  6.2971  5.0039  7.4000 -0.9970  0.4492  1.1227
CA  1953  6.4118  6.2538  5.1761  7.4200 -0.8916  0.4662  1.2110
CA  1954  6.4520  6.2971  5.3613  7.4478 -0.6951  0.4756  1.1924
...
```

As shown in the following statements, the SORT procedure is used to sort the data into the required time series cross-sectional format; then PROC PANEL analyzes the data.

```plaintext
proc sort data=a;
  by state year;
run;

proc panel data=a;
  model d = y rd rt rs / fuller parks dasilva m=7;
  model t = y rd rt rs / parks;
  model s = y rd rt rs / parks;
  id state year;
run;
```
The income elasticities for liquid assets are greater than 1 except for the demand deposit income elasticity (0.692757) estimated by the Da Silva method. In Output 20.1.1, Output 20.1.2, and Output 20.1.3, the coefficient estimates (−0.29094, −0.43591, and −0.27736) of demand deposits (RD) imply that demand deposits increase significantly as the service charge is reduced. The price elasticities (0.227152 and 0.408066) for time deposits (RT) and S&L association shares (RS) have the expected sign. Thus an increase in the interest rate on time deposits or S&L shares will increase the demand for the corresponding liquid asset. Demand deposits and S&L shares appear to be substitutes (see Output 20.1.2, Output 20.1.3, and Output 20.1.5). Time deposits are also substitutes for S&L shares in the time deposit demand equation (see Output 20.1.4), while these liquid assets are independent of each other in Output 20.1.5 (insignificant coefficient estimate of RT, −0.02705). Demand deposits and time deposits appear to be weak complements in Output 20.1.3 and Output 20.1.4, while the cross elasticities between demand deposits and time deposits are not significant in Output 20.1.2 and Output 20.1.5.

Example 20.2: The Airline Cost Data: Fixtwo Model

The Christenson Associates airline data are a frequently cited data set (see Greene 2000). The data measure costs, prices of inputs, and utilization rates for six airlines over the time span 1970–1984. This example analyzes the log transformations of the cost, price and quantity, and the raw (not logged) capacity utilization measure. You speculate the following model:

\[
\ln\left(\frac{TC_{it}}{D}\right) = \alpha_N + \gamma_T + (\alpha_i - \alpha_N) + (\gamma_t - \gamma_T) + \beta_1 \ln(Q_{it}) + \beta_2 \ln(PF_{it}) + \beta_3 LF_{it} + \epsilon_{it}
\]

where the \(\alpha\) are the pure cross-sectional effects and \(\gamma\) are the time effects. The actual model speculated is highly nonlinear in the original variables. It would look like the following:

\[
TC_{it} = \exp(\alpha_i + \gamma_t + \beta_3 LF_{it} + \epsilon_{it}) Q_{it}^{\beta_1} PF_{it}^{\beta_2}
\]

The data and preliminary SAS statements are:

```sas
data airline;
input Obs I T C Q PF LF;
label Obs = "Observation number";
label I = "Firm Number (CSID)";
label T = "Time period (TSID)";
label Q = "Output in revenue passenger miles (index)";
label C = "Total cost, in thousands";
label PF = "Fuel price";
label LF = "Load Factor (utilization index)";
datalines;
1 1 1 1140640 0.95276 106650 0.53449

... more lines ...
```
data airline;
  set airline;
  lC = log(C);
  lQ = log(Q);
  lpF = log(PF);
  label lC = "Log transformation of costs";
  label lQ = "Log transformation of quantity";
  label lpF= "Log transformation of price of fuel";
run;

The following statements fit the model.

proc panel data=airline printfixed;
  id i t;
  model lC = lQ lpF LF / fixtwo;
run;

First, you see the model’s description in Output 20.2.1. The model is a two-way fixed-effects model. There are six cross sections and fifteen time observations.

**Output 20.2.1** The Airline Cost Data—Model Description

<table>

</tr>
</tbody>
</table>

The R-square and degrees of freedom can be seen in Table 20.2.2. On the whole, you see a large R-square, so there is a reasonable fit. The degrees of freedom of the estimate are 90 minus 14 time dummy variables minus 5 cross section dummy variables and 4 regressors.

The $F$ test for fixed effects is shown in Table 20.2.3. Testing the hypothesis that there are no fixed effects, you easily reject the null of poolability. There are group effects, or time effects, or both. The test is highly significant. OLS would not give reasonable results.

Looking at the parameters, you see a more complicated pattern. Most of the cross-sectional effects are highly significant (with the exception of CS2). This means that the cross sections are significantly different from the sixth cross section. Many of the time effects show significance, but this is not uniform. It looks like the significance might be driven by a large 16th period effect, since the first six time effects are negative and of similar magnitude. The time dummy variables taper off in size and lose significance from time period 12 onward. There are many causes to which you could attribute this decay of time effects. The time period of the data spans the OPEC oil embargoes and the dissolution of the Civil Aeronautics Board (CAB). These two forces are two possible reasons to observe the decay and parameter instability. As for the regression parameters, you see that quantity affects cost positively, and the price of fuel has a positive effect, but load factors negatively affect the costs of the airlines in this sample. The somewhat disturbing result is that the fuel cost is not significant. If the time effects are proxies for the effect of the oil embargoes, then an insignificant fuel cost parameter would make some sense. If the dummy variables proxy for the dissolution of the CAB, then the effect of load factors is also not being precisely estimated.

ODS Graphics Plots

ODS graphics plots can be obtained to graphically analyze the results. The following statements show how to generate the plots. If the PLOTS=ALL option is specified, all available plots are produced in two panels. For a complete list of options, see the section “Creating ODS Graphics” on page 1453.

```plaintext
proc panel data=airline;
   id i t;
   model lC = lQ lPF LF / fixtwo plots = all;
run;
```

The preceding statements result in plots shown in Output 20.2.5 and Output 20.2.6.

**Output 20.2.5** Diagnostic Panel 1

![Diagnostic Panel 1](image)

**Observations** 90  **MSE** 0.002639  **Model DF** 67
The UNPACK and ONLY options produce individual detail images of paneled plots. The graph shown in Output 20.2.7 shows a detail plot of residuals by cross section. The packed version always puts all cross sections on one plot while the unpacked one shows the cross sections in groups of ten to avoid loss of detail.

```
proc panel data=airline;
  id i t;
  model lC = lQ lPF LF / fixtwo plots(unpack only) = residsurface;
run;
```
Example 20.3: The Airline Cost Data: Further Analysis

Using the same data as in Example 20.2, you further investigate the ‘true’ effect of fuel prices. Specifically, you run the FixOne model, ignoring time effects. You specify the following statements in PROC PANEL to run this model:

```
proc panel data=airline;
   id i t;
   model lC = lQ lPF LF / fixone;
run;
```

The preceding statements result in Output 20.3.1. The fit seems to have deteriorated somewhat. The SSE rises from 0.1768 to 0.2926.

The parameters change somewhat dramatically as shown in **Output 20.3.3**. The effect of fuel costs comes in very strong and significant. The load factor’s coefficient increases, although not as dramatically. This suggests that the fixed time effects might be proxies for both the oil shocks and deregulation.

**Output 20.3.3** The Airline Cost Data—Parameter Estimates

Example 20.4: The Airline Cost Data: Random-Effects Models

This example continues to use the Christenson Associates airline data, which measures costs, prices of inputs, and utilization rates for six airlines over the time span 1970–1984. There are six cross sections and fifteen time observations. Here, you examine the different estimates generated from the one-way random-effects and two-way random-effects models, by using four different methods to estimate the variance components: Fuller and Battese, Wansbeek and Kapteyn, Wallace and Hussain, and Nerlove.

The data for this example is created by the PROC PANEL statements shown in Example 20.2. The PROC PANEL statements necessary to generate the estimates are as follows:

```sas
proc panel data=airline outest=estimates;
    id I T;
    RANONE: model lC = lQ lPF lF / ranone vcomp=fb;
    RANONEwk: model lC = lQ lPF lF / ranone vcomp=wk;
    RANONEwh: model lC = lQ lPF lF / ranone vcomp=wh;
    RANONEnl: model lC = lQ lPF lF / ranone vcomp=nl;
    RANTWO: model lC = lQ lPF lF / rantwo vcomp=fb;
    RANTWOwk: model lC = lQ lPF lF / rantwo vcomp=wk;
    RANTWOwh: model lC = lQ lPF lF / rantwo vcomp=wh;
    RANTWOnl: model lC = lQ lPF lF / rantwo vcomp=nl;
    POOLED: model lC = lQ lPF lF / pooled;
    BTWNG: model lC = lQ lPF lF / btwng;
    BTWNT: model lC = lQ lPF lF / btwnt;
run;

data table;
    set estimates;
    VarCS = round(_VARCS_,.00001);
    VarTS = round(_VARTS_,.00001);
    VarErr = round(_VARERR_,.00001);
    Int = round(Intercept,.0001);
    lQ2 = round(lQ,.0001);
    lPF2 = round(lPF,.0001);
    lF2 = round(lF,.0001);
    if _n_ >= 9 then do;
        VarCS = .;
        VarTS = .;
        Int = .;
        lQ2 = .;
        lPF2 = .;
        lF2 = .;
    end;
    keep _MODEL_ _METHOD_ VarCS VarTS VarErr Int lQ2 lPF2 lF2;
run;
```

The parameter estimates and variance components for both models are reported in Output 20.4.1 and Output 20.4.2.

</table>

In the random-effects model, individual constant terms are viewed as randomly distributed across cross-sectional units and not as parametric shifts of the regression function, as in the fixed-effects model. This is appropriate when the sampled cross-sectional units are drawn from a large population. Clearly, in this example, the six airlines are a sample of all the airlines in the industry and not an exhaustive, or nearly exhaustive, list.

There are four ways of computing the variance components in the one-way random-effects model. The method by Fuller and Battese (1974) (FB), uses a “fitting of constants” methods to estimate them. The Wansbeek and Kapteyn (1989) (WK) method uses the true disturbances, while the Wallace and Hussain (WH) method uses ordinary least squares residuals.
Example 20.5: Using the FLATDATA Statement

Sometimes the data can be found in compressed form, where each line consists of all observations for the dependent and independent variables for the cross section. To illustrate, suppose you have a data set with 20 cross sections where each cross section consists of observations for six time periods. Each time period has values for dependent and independent variables $Y_1 \ldots Y_6$ and $X_1 \ldots X_6$. The $cs$ and $num$ variables represent other character and numeric variables that are constant across each cross section.

The observations for first five cross sections along with other variables are shown in Output 20.5.1. In this example, $i$ represents the cross section. The time period is identified by the subscript on the $Y$ and $X$ variables; it ranges from 1 to 6.

</tr>
</tbody>
</table>

Since the PANEL procedure cannot work directly with the data in compressed form, the FLATDATA statement can be used to transform the data. The OUT= option can be used to output transformed data to a data set.

```
proc panel data=flattest;
  flatdata indid=i tsname="t" base=(X Y)
    keep=( cs num seed ) / out=flat_out;
  id i t;
  model y = x / fixone noint;
run;
```

First, six observations for the uncompressed data set and results for the one-way fixed-effects model fitted are shown in Output 20.5.2 and Output 20.5.3.

Example 20.6: The Cigarette Sales Data: Dynamic Panel Estimation with GMM

In this example, a dynamic panel demand model for cigarette sales is estimated. It illustrates the application of the method described in the section “Dynamic Panel Estimator” on page 1423. The data are a panel from 46 American states over the period 1963–92. For data description see: Baltagi and Levin (1992); Baltagi (1995). All variables were transformed by taking the natural logarithm. The data set CIGAR is shown in the following statements.

data cigar;
  input state year price pop pop_16 cpi ndi sales pimin;
  label
    state = 'State abbreviation'
    year = 'YEAR'
    price = 'Price per pack of cigarettes'
    pop = 'Population'
    pop_16 = 'Population above the age of 16'
    cpi = 'Consumer price index with (1983=100)'
    ndi = 'Per capita disposable income'
    sales = 'Cigarette sales in packs per capita'
    pimin = 'Minimum price in adjoining states per pack of cigarettes';
datalines;
  ... more lines ...
The following statements sort the data by STATE and YEAR variables.

```sas
proc sort data=cigar;
   by state year;
run;
```

Next, logarithms of the variables required for regression estimation are calculated, as shown in the following statements:

```sas
data cigar;
   set cigar;
   lsales = log(sales);
   lprice = log(price);
   lndi = log(ndi);
   lpimin = log(pimin);
   label lprice = 'Log price per pack of cigarettes';
   label lndi = 'Log per capita disposable income';
   label lsales = 'Log cigarette sales in packs per capita';
   label lpimin = 'Log minimum price in adjoining states per pack of cigarettes';
run;
```

The following statements create the CIGAR_LAG data set with lagged variable for each cross section.

```sas
proc panel data=cigar;
   id state year;
   clag lsales(1) / out=cigar_lag;
run;
```

```sas
data cigar_lag;
   set cigar_lag;
   label lsales_1 = 'Lagged log cigarette sales in packs per capita';
run;
```

Finally, the model is estimated by a two step GMM method. Five lags (MAXBAND=5) of the dependent variable are used as instruments. NOLEVELS options is specified to avoid use of level equations, as shown in the following statements:

```sas
proc panel data=cigar_lag;
   inst depvar;
   model lsales = lsales_1 lprice lndi lpimin
      / gmm2 nolevels maxband=5 noint;
   id state year;
run;
```

Overview: PDLREG Procedure

The PDLREG procedure estimates regression models for time series data in which the effects of some of the regressor variables are distributed across time. The distributed lag model assumes that the effect of an input variable X on an output Y is distributed over time. If you change the value of X at time t, Y will experience some immediate effect at time t, and it will also experience a delayed effect at times t + 1, t + 2, and so on up to time t + p for some limit p.

The regression model supported by PROC PDLREG can include any number of regressors with distribution lags and any number of covariates. (Simple regressors without lag distributions are called covariates.) For example, the two-regressor model with a distributed lag effect for one regressor is written

\[ y_t = \alpha + \sum_{i=0}^{p} \beta_i x_{t-i} + \gamma z_t + u_t \]
Here, \( x_t \) is the regressor with a distributed lag effect, \( z_t \) is a simple covariate, and \( u_t \) is an error term.

The distribution of the lagged effects is modeled by Almon lag polynomials. The coefficients \( b_i \) of the lagged values of the regressor are assumed to lie on a polynomial curve. That is,

\[
b_i = \alpha_0 + \sum_{j=1}^{d} \alpha_j i^j
\]

where \( d(\leq p) \) is the degree of the polynomial. For the numerically efficient estimation, the PDLREG procedure uses orthogonal polynomials. The preceding equation can be transformed into orthogonal polynomials:

\[
b_i = \alpha_0 + \sum_{j=1}^{d} \alpha_j f_j(i)
\]

where \( f_j(i) \) is a polynomial of degree \( j \) in the lag length \( i \), and \( \alpha_j \) is a coefficient estimated from the data.

The PDLREG procedure supports endpoint restrictions for the polynomial. That is, you can constrain the estimated polynomial lag distribution curve so that \( b_{-1} = 0 \) or \( b_{p+1} = 0 \), or both. You can also impose linear restrictions on the parameter estimates for the covariates.

You can specify a minimum degree and a maximum degree for the lag distribution polynomial, and the procedure fits polynomials for all degrees in the specified range. (However, if distributed lags are specified for more than one regressor, you can specify a range of degrees for only one of them.)

The PDLREG procedure can also test for autocorrelated residuals and perform autocorrelated error correction by using the autoregressive error model. You can specify any order autoregressive error model and can specify several different estimation methods for the autoregressive model, including exact maximum likelihood.

The PDLREG procedure computes generalized Durbin-Watson statistics to test for autocorrelated residuals. For models with lagged dependent variables, the procedure can produce Durbin \( h \) and Durbin \( t \) statistics. You can request significance level \( p \)-values for the Durbin-Watson, Durbin \( h \), and Durbin \( t \) statistics. See Chapter 8, “The AUTOREG Procedure,” for details about these statistics.

The PDLREG procedure assumes that the input observations form a time series. Thus, the PDLREG procedure should be used only for ordered and equally spaced time series data.

---

**Getting Started: PDLREG Procedure**

Use the MODEL statement to specify the regression model. The PDLREG procedure’s MODEL statement is written like MODEL statements in other SAS regression procedures, except that a regressor can be followed by a lag distribution specification enclosed in parentheses.

For example, the following MODEL statement regresses \( Y \) on \( X \) and \( Z \) and specifies a distributed lag for \( X \):

```plaintext
model y = x(4,2) z;
```

The notation \( X(4,2) \) specifies that the model includes \( X \) and 4 lags of \( X \), with the coefficients of \( X \) and its lags constrained to follow a second-degree (quadratic) polynomial. Thus, the regression model specified by this MODEL statement is

\[
y_t = a + b_0 x_t + b_1 x_{t-1} + b_2 x_{t-2} + b_3 x_{t-3} + b_4 x_{t-4} + cz_t + u_t
\]
\[ b_i = \alpha_0 + \alpha_1 f_1(i) + \alpha_2 f_2(i) \]

where \( f_1(i) \) is a polynomial of degree 1 in \( i \) and \( f_2(i) \) is a polynomial of degree 2 in \( i \).

Lag distribution specifications are enclosed in parentheses and follow the name of the regressor variable. The general form of the lag distribution specification is

\[
\text{regressor-name ( length, degree, minimum-degree, end-constraint )}
\]

where

- **length** is the length of the lag distribution—that is, the number of lags of the regressor to use.
- **degree** is the degree of the distribution polynomial.
- **minimum-degree** is an optional minimum degree for the distribution polynomial.
- **end-constraint** is an optional endpoint restriction specification, which can have the value FIRST, LAST, or BOTH.

If the *minimum-degree* option is specified, the PDLREG procedure estimates models for all degrees between *minimum-degree* and *degree*.

**Introductory Example**

The following statements generate simulated data for variables \( Y \) and \( X \). \( Y \) depends on the first three lags of \( X \), with coefficients .25, .5, and .25. Thus, the effect of changes of \( X \) on \( Y \) takes effect 25% after one period, 75% after two periods, and 100% after three periods.

```r
data test;
  xl1 = 0; xl2 = 0; xl3 = 0;
  do t = -3 to 100;
    x = ranuni(1234);
    y = 10 + .25 * xl1 + .5 * xl2 + .25 * xl3
      + .1 * rannor(1234);
    if t > 0 then output;
    xl3 = xl2; xl2 = xl1; xl1 = x;
  end;
run;
```

The following statements use the PDLREG procedure to regress \( Y \) on a distributed lag of \( X \). The length of the lag distribution is 4, and the degree of the distribution polynomial is specified as 3.

```r
proc pdlreg data=test;
  model y = x( 4, 3 );
run;
```

The PDLREG procedure first prints a table of statistics for the residuals of the model, as shown in Figure 21.1. See Chapter 8, “The AUTOREG Procedure,” for an explanation of these statistics.

The PDLREG procedure next prints a table of parameter estimates, standard errors, and \( t \) tests, as shown in Figure 21.2.

Figure 21.2 Parameter Estimates

| Variable | DF | Estimate | Standard Error | t Value | Pr > |t| |
|----------|----|----------|----------------|---------|------|------|
| Intercept| 1  | 10.0030  | 0.0431         | 231.87  | <.0001 |
| X**0     | 1  | 0.4406   | 0.0378         | 11.66   | <.0001 |
| X**1     | 1  | 0.0113   | 0.0336         | 0.34    | 0.7377 |
| X**2     | 1  | -0.4108  | 0.0322         | -12.75  | <.0001 |
| X**3     | 1  | 0.0331   | 0.0392         | 0.84    | 0.4007 |

The table in Figure 21.2 shows the model intercept and the estimated parameters of the lag distribution polynomial. The parameter labeled X**0 is the constant term, \( \alpha_0 \), of the distribution polynomial. X**1 is the linear coefficient, \( \alpha_1 \); X**2 is the quadratic coefficient, \( \alpha_2 \); and X**3 is the cubic coefficient, \( \alpha_3 \).

The parameter estimates for the distribution polynomial are not of interest in themselves. Since the PDLREG procedure does not print the orthogonal polynomial basis that it constructs to represent the distribution polynomial, these coefficient values cannot be interpreted.

However, because these estimates are for an orthogonal basis, you can use these results to test the degree of the polynomial. For example, this table shows that the X**3 estimate is not significant; the \( p \)-value for its \( t \) ratio is 0.4007, while the X**2 estimate is highly significant (\( p < .0001 \)). This indicates that a second-degree polynomial might be more appropriate for this data set.

The PDLREG procedure next prints the lag distribution coefficients and a graphical display of these coefficients, as shown in Figure 21.3.
The lag distribution coefficients are the coefficients of the lagged values of X in the regression model. These coefficients lie on the polynomial curve defined by the parameters shown in Figure 21.2. Note that the estimated values for X(1), X(2), and X(3) are highly significant, while X(0) and X(4) are not significantly different from 0. These estimates are reasonably close to the true values used to generate the simulated data.

The graphical display of the lag distribution coefficients plots the estimated lag distribution polynomial reported in Figure 21.2. The roughly quadratic shape of this plot is another indication that a third-degree distribution curve is not needed for this data set.

Syntax: PDLREG Procedure

The following statements can be used with the PDLREG procedure:

```plaintext
PROC PDLREG option ;
   BY variables ;
   MODEL dependents = effects / options ;
   OUTPUT OUT= SAS-data-set keyword = variables ;
   RESTRICT restrictions ;
```
Functional Summary

The statements and options used with the PDLREG procedure are summarized in the following table.

PROC PDLREG Statement

PROC PDLREG option ;

The PROC PDLREG statement has the following option:

DATA= SAS-data-set

specifies the name of the SAS data set containing the input data. If you do not specify the DATA= option, the most recently created SAS data set is used.

In addition, you can place any of the following MODEL statement options in the PROC PDLREG statement, which is equivalent to specifying the option for every MODEL statement: ALL, COEF, CONVERGE=, CORRB, COVB, DW=, DWPROB, GINV, ITPRINT, MAXITER=, METHOD=, NOINT, NOPRINT, and PARTIAL.

BY Statement

BY variables ;

A BY statement can be used with PROC PDLREG to obtain separate analyses on observations in groups defined by the BY variables.

MODEL Statement

MODEL dependent = effects / options ;

The MODEL statement specifies the regression model. The keyword MODEL is followed by the dependent variable name, an equal sign, and a list of independent effects. Only one MODEL statement is allowed.

Every variable in the model must be a numeric variable in the input data set. Specify an independent effect with a variable name optionally followed by a polynomial lag distribution specification.
Specifying Independent Effects

The general form of an effect is

\[
\text{variable ( length, degree, minimum-degree, constraint )}
\]

The term in parentheses following the variable name specifies a polynomial distributed lag (PDL) for the variable. The PDL specification is as follows:

- **length**: specifies the number of lags of the variable to include in the lag distribution.
- **degree**: specifies the maximum degree of the distribution polynomial. If not specified, the degree defaults to the lag length.
- **minimum-degree**: specifies the minimum degree of the polynomial. By default, **minimum-degree** is the same as **degree**.
- **constraint**: specifies endpoint restrictions on the polynomial. The value of **constraint** can be FIRST, LAST, or BOTH. If a value is not specified, there are no endpoint restrictions.

If you do not specify the **degree** or **minimum-degree** parameter, but you do specify endpoint restrictions, you must use commas to show which parameter, **degree** or **minimum-degree**, is left out.

MODEL Statement Options

The following options can appear in the MODEL statement after a slash (/).

- **ALL**: prints all the matrices computed during the analysis of the model.
- **COEF**: prints the transformation coefficients for the first \( p \) observations. These coefficients are formed from a scalar multiplied by the inverse of the Cholesky root of the Toeplitz matrix of autocovariances.
- **CORRB**: prints the matrix of estimated correlations between the parameter estimates.
- **COVB**: prints the matrix of estimated covariances between the parameter estimates.
- **DW= \( j \)**: prints the generalized Durbin-Watson statistics up to the order of \( j \). The default is DW=1. When you specify the LAGDEP or LAGDEP=\( \text{name} \) option, the Durbin-Watson statistic is not printed unless you specify the DW= option.
- **DWPROB**: prints the marginal probability of the Durbin-Watson statistic.
- **CONVERGE= \( \text{value} \)**: sets the convergence criterion. If the maximum absolute value of the change in the autoregressive parameter estimates between iterations is less than this amount, then convergence is assumed. The default is CONVERGE=.001.
**GINV**

prints the inverse of the Toeplitz matrix of autocovariances for the Yule-Walker solution.

**I**

prints \((X'X)^{-1}\), the inverse of the crossproducts matrix for the model; or, if restrictions are specified, it prints \((X'X)^{-1}\) adjusted for the restrictions.

**ITPRINT**

prints information on each iteration.

**LAGDEP**

**LAGDV**

prints the \(t\) statistic for testing residual autocorrelation when regressors contain lagged dependent variables.

**LAGDEP= name**

**LAGDV= name**

prints the Durbin \(h\) statistic for testing the presence of first-order autocorrelation when regressors contain the lagged dependent variable whose name is specified as LAGDEP= name. When the \(h\) statistic cannot be computed, the asymptotically equivalent \(t\) statistic is given.

**MAXITER= number**

sets the maximum number of iterations allowed. The default is MAXITER=50.

**METHOD= value**

specifies the type of estimates for the autoregressive component. The values of the METHOD= option are as follows:

- **METHOD=ML** specifies the maximum likelihood method.
- **METHOD=ULS** specifies unconditional least squares.
- **METHOD=YW** specifies the Yule-Walker method.
- **METHOD=ITYW** specifies iterative Yule-Walker estimates.

The default is METHOD=ML if you specified the LAGDEP or LAGDEP= option; otherwise, METHOD=YW is the default.

**NLAG= m**

**NLAG= ( number-list )**

specifies the order of the autoregressive process or the subset of autoregressive lags to be fit. If you do not specify the NLAG= option, PROC PDLREG does not fit an autoregressive model.

**NOINT**

suppresses the intercept parameter from the model.

**NOPRINT**

suppresses the printed output.
PARTIAL
prints partial autocorrelations if the NLAG= option is specified.

STB
prints standardized parameter estimates. Sometimes known as a standard partial regression coefficient, a *standardized parameter estimate* is a parameter estimate multiplied by the standard deviation of the associated regressor and divided by the standard deviation of the regressed variable.

XPX
prints the crossproducts matrix, $X'X$, used for the model. $X$ refers to the transformed matrix of regressors for the regression.

---

**OUTPUT Statement**

**OUTPUT OUT= SAS-data-set keyword= option . . . ;**

The OUTPUT statement creates an output SAS data set with variables as specified by the following keyword options. See the section “Predicted Values” in Chapter 8, “The AUTOREG Procedure,” for a description of the associated computations for these options.

**ALPHACL= number**
sets the confidence limit size for the estimates of future values of the current realization of the response time series to number, where number is less than one and greater than zero. The resulting confidence interval has 1-number confidence. The default value for number is 0.05, corresponding to a 95% confidence interval.

**ALPHACLM= number**
sets the confidence limit size for the estimates of the structural or regression part of the model to number, where number is less than one and greater than zero. The resulting confidence interval has 1-number confidence. The default value for number is 0.05, corresponding to a 95% confidence interval.

**OUT= SAS-data-set**
names the output data.

The following specifications are of the form **KEYWORD=names**, where **KEYWORD=** specifies the statistic to include in the output data set and **names** gives names to the variables that contain the statistics.

**CONSTANT= variable**
writes the transformed intercept to the output data set.

**LCL= name**
requests that the lower confidence limit for the predicted value (specified in the PREDICTED= option) be added to the output data set under the name given.
LCLM= name
requests that the lower confidence limit for the structural predicted value (specified in the PREDICTEDM= option) be added to the output data set under the name given.

PREDICTED= name
P= name
stores the predicted values in the output data set under the name given.

PREDICTEDM= name
PM= name
stores the structural predicted values in the output data set under the name given. These values are formed from only the structural part of the model.

RESIDUAL= name
R= name
stores the residuals from the predicted values based on both the structural and time series parts of the model in the output data set under the name given.

RESIDUALM= name
RM= name
requests that the residuals from the structural prediction be given.

TRANSFORM= variables
requests that the specified variables from the input data set be transformed by the autoregressive model and put in the output data set. If you need to reproduce the data suitable for reestimation, you must also transform an intercept variable. To do this, transform a variable that only takes the value 1 or use the CONSTANT= option.

UCL= name
stores the upper confidence limit for the predicted value (specified in the PREDICTED= option) in the output data set under the name given.

UCLM= name
stores the upper confidence limit for the structural predicted value (specified in the PREDICTEDM= option) in the output data set under the name given.

For example, the SAS statements

```sas
proc pdlreg data=a;
   model y=x1 x2;
   output out=b p=yhat r=resid;
run;
```

create an output data set named B. In addition to the input data set variables, the data set B contains the variable YHAT, whose values are predicted values of the dependent variable Y, and RESID, whose values are the residual values of Y.
RESTRICT Statement

RESTRICT equation , . . . , equation ;

The RESTRICT statement places restrictions on the parameter estimates for covariates in the preceding MODEL statement. A parameter produced by a distributed lag cannot be restricted with the RESTRICT statement.

Each restriction is written as a linear equation. If you specify more than one restriction in a RESTRICT statement, the restrictions are separated by commas.

You can refer to parameters by the name of the corresponding regressor variable. Each name used in the equation must be a regressor in the preceding MODEL statement. Use the keyword INTERCEPT to refer to the intercept parameter in the model.

RESTRICT statements can be given labels. You can use labels to distinguish results for different restrictions in the printed output. Labels are specified as follows:

label : RESTRICT ...

The following is an example of the use of the RESTRICT statement, in which the coefficients of the regressors X1 and X2 are required to sum to 1:

```
proc pdlreg data=a;
   model y = x1 x2;
   restrict x1 + x2 = 1;
run;
```

Parameter names can be multiplied by constants. When no equal sign appears, the linear combination is set equal to 0. Note that the parameters associated with the variables are restricted, not the variables themselves. Here are some examples of valid RESTRICT statements:

```
restrict x1 + x2 = 1;
restrict x1 + x2 - 1;
restrict 2 * x1 = x2 + x3 , intercept + x4 = 0;
restrict x1 = x2 = x3 = 1;
restrict 2 * x1 - x2;
```

Restricted parameter estimates are computed by introducing a Lagrangian parameter $\lambda$ for each restriction (Pringle and Rayner 1971). The estimates of these Lagrangian parameters are printed in the parameter estimates table. If a restriction cannot be applied, its parameter value and degrees of freedom are listed as 0.

The Lagrangian parameter, $\lambda$, measures the sensitivity of the SSE to the restriction. If the restriction is changed by a small amount $\epsilon$, the SSE is changed by $2\lambda\epsilon$.

The $t$ ratio tests the significance of the restrictions. If $\lambda$ is zero, the restricted estimates are the same as the unrestricted ones.

You can specify any number of restrictions in a RESTRICT statement, and you can use any number of RESTRICT statements. The estimates are computed subject to all restrictions specified. However, restrictions should be consistent and not redundant.
Details: PDLREG Procedure

Missing Values

The PDLREG procedure skips any observations at the beginning of the data set that have missing values. The procedure uses all observations with nonmissing values for all the independent and dependent variables such that the lag distribution has sufficient nonmissing lagged independent variables.

Polynomial Distributed Lag Estimation

The simple finite distributed lag model is expressed in the form

$$y_t = \alpha + \sum_{i=0}^{p} \beta_i x_{t-i} + \epsilon_t$$

When the lag length ($p$) is long, severe multicollinearity can occur. Use the Almon or polynomial distributed lag model to avoid this problem, since the relatively low-degree $d$ ($\leq p$) polynomials can capture the true lag distribution. The lag coefficient can be written in the Almon polynomial lag

$$\beta_i = \alpha_0^* + \sum_{j=1}^{d} \alpha_j^* i^j$$

Emerson (1968) proposed an efficient method of constructing orthogonal polynomials from the preceding polynomial equation as

$$\beta_i = \alpha_0 + \sum_{j=1}^{d} \alpha_j f_j(i)$$

where $f_j(i)$ is a polynomial of degree $j$ in the lag length $i$. The polynomials $f_j(i)$ are chosen so that they are orthogonal:

$$\sum_{i=1}^{n} w_i f_j(i) f_k(i) = \begin{cases} 1 & \text{if } j = k \\ 0 & \text{if } j \neq k \end{cases}$$

where $w_i$ is the weighting factor, and $n = p + 1$. PROC PDLREG uses the equal weights ($w_i = 1$) for all $i$. To construct the orthogonal polynomials, the following recursive relation is used:

$$f_j(i) = (A_j i + B_j) f_{j-1}(i) - C_j f_{j-2}(i) j = 1, \ldots, d$$
The constants $A_j$, $B_j$, and $C_j$ are determined as follows:

$$A_j = \left\{ \sum_{i=1}^{n} w_i i^2 f_{j-1}^2(i) - \left( \sum_{i=1}^{n} w_i if_{j-1}^2(i) \right)^2 \right\}^{-1/2}$$

$$B_j = -A_j \sum_{i=1}^{n} w_i if_{j-1}^2(i)$$

$$C_j = A_j \sum_{i=1}^{n} w_i if_{j-1}^2(i) f_{j-2}(i)$$

where $f_{-1}(i) = 0$ and $f_0(i) = 1/\sqrt{\sum_{i=1}^{n} w_i}.$

PROC PDLREG estimates the orthogonal polynomial coefficients, $\alpha_0, \ldots, \alpha_d$, to compute the coefficient estimate of each independent variable ($X$) with distributed lags. For example, if an independent variable is specified as $X(9,3)$, a third-degree polynomial is used to specify the distributed lag coefficients. The third-degree polynomial is fit as a constant term, a linear term, a quadratic term, and a cubic term. The four terms are constructed to be orthogonal. In the output produced by the PDLREG procedure for this case, parameter estimates with names $X**0$, $X**1$, $X**2$, and $X**3$ correspond to $\alpha_0$, $\alpha_1$, $\alpha_2$, and $\alpha_3$, respectively. A test using the $t$ statistic and the approximate $p$-value (“Approx Pr $> |t|$”) associated with $X**3$ can determine whether a second-degree polynomial rather than a third-degree polynomial is appropriate. The estimates of the 10 lag coefficients associated with the specification $X(9,3)$ are labeled $X(0)$, $X(1)$, $X(2)$, $X(3)$, $X(4)$, $X(5)$, $X(6)$, $X(7)$, $X(8)$, and $X(9)$.

**Autoregressive Error Model Estimation**

The PDLREG procedure uses the same autoregressive error model estimation methods as the AUTOREG procedure. These two procedures share the same computational resources for computing estimates. See Chapter 8, “The AUTOREG Procedure,” for details about estimation methods for autoregressive error models.

**OUT= Data Set**

The OUT= data set produced by the PDLREG procedure’s OUTPUT statement is similar in form to the OUT= data set produced by the AUTOREG procedure. See Chapter 8, “The AUTOREG Procedure,” for details on the OUT= data set.
The PDLREG procedure prints the following items:

1. the name of the dependent variable
2. the ordinary least squares (OLS) estimates
3. the estimates of autocorrelations and of the autocovariance, and if line size permits, a graph of the autocorrelation at each lag. The autocorrelation for lag 0 is 1. These items are printed if you specify the NLAG= option.
4. the partial autocorrelations if the PARTIAL and NLAG= options are specified. The first partial autocorrelation is the autocorrelation for lag 1.
5. the preliminary mean square error, which results from solving the Yule-Walker equations if you specify the NLAG= option
6. the estimates of the autoregressive parameters, their standard errors, and the ratios of estimates to standard errors ($t$) if you specify the NLAG= option
7. the statistics of fit for the final model if you specify the NLAG= option. These include the error sum of squares (SSE), the degrees of freedom for error (DFE), the mean square error (MSE), the root mean square error (Root MSE), the mean absolute error (MAE), the mean absolute percentage error (MAPE), the Schwarz information criterion (SBC), the Akaike’s information criterion (AIC), Akaike’s information criterion corrected (AICC), the regression $R^2$ (Regress R-Square), the total $R^2$ (Total R-Square), and the Durbin-Watson statistic (Durbin-Watson). See Chapter 8, “The AUTOREG Procedure,” for details of the regression $R^2$ and the total $R^2$.
8. the parameter estimates for the structural model (B), a standard error estimate, the ratio of estimate to standard error ($t$), and an approximation to the significance probability for the parameter being 0 (“Approx Pr > |t|”)
9. a plot of the lag distribution (estimate of lag distribution)
10. the covariance matrix of the parameter estimates if the COVB option is specified

### ODS Graphics

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.
PROC PDLREG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

### Table 21.2 ODS Tables Produced in PROC PDLREG

Example 21.1: Industrial Conference Board Data

In this example, a second-degree Almon polynomial lag model is fit to a model with a five-period lag, and dummy variables are used for quarter effects. The PDL model is estimated using capital appropriations data series for the period 1952 to 1967. The estimation model is written

\[
CE_t = a_0 + b_1Q1_t + b_2Q2_t + b_3Q3_t + c_0CA_t + c_1CA_{t-1} + \ldots + c_5CA_{t-5}
\]

where CE represents capital expenditures and CA represents capital appropriations.

```

The following statements use the REG procedure to fit the same polynomial distributed lag model. A DATA step computes lagged values of the regressor X, and RESTRICT statements are used to impose the polynomial lag distribution. Refer to Judge et al. (1985, pp. 357–359) for the restricted least squares estimation of the Almon distributed lag model.

```sas
data b;
  set a;
  ca_1 = lag( ca );
  ca_2 = lag2( ca );
  ca_3 = lag3( ca );
  ca_4 = lag4( ca );
  ca_5 = lag5( ca );
run;

proc reg data=b;
  model ce = q1 q2 q3 ca ca_1 ca_2 ca_3 ca_4 ca_5;
  restrict - ca + 5*ca_1 - 10*ca_2 + 10*ca_3 - 5*ca_4 + ca_5;
  restrict ca - 3*ca_1 + 2*ca_2 + 2*ca_3 - 3*ca_4 + ca_5;
  restrict -5*ca + 7*ca_1 + 4*ca_2 - 4*ca_3 - 7*ca_4 + 5*ca_5;
run;
```

The REG procedure output is shown in Output 21.1.2.

Example 21.2: Money Demand Model

This example estimates the demand for money by using the following dynamic specification:

\[ m_t = a_0 + b_0 m_{t-1} + \sum_{i=0}^{5} c_i y_{t-i} + \sum_{i=0}^{2} d_i r_{t-i} + \sum_{i=0}^{3} f_i p_{t-i} + u_t \]

where

- \( m_t \) = log of real money stock (M1)
- \( y_t \) = log of real GNP
- \( r_t \) = interest rate (commercial paper rate)
- \( p_t \) = inflation rate
- \( c_i, d_i, \) and \( f_i \) (i > 0) are coefficients for the lagged variables
Example 21.2: Money Demand Model

The following DATA step reads the data and transforms the real money and real GNP variables using the natural logarithm. Refer to Balke and Gordon (1986) for a description of the data.

data a;
  input m1 gnp gdf r @@;
  m = log( 100 * m1 / gdf );
  lags = lag( m );
  y = log( gnp );
  p = log( gdf / lag( gdf ) );
  date = intnx( 'qtr', '1jan1968'd, _n_-1 );
  format date yyqc6.;
  label m = 'Real Money Stock (M1)'
    lags = 'Lagged Real Money Stock'
    y = 'Real GNP'
    r = 'Commercial Paper Rate'
    p = 'Inflation Rate';
datalines;

Overview: QLIM Procedure

The QLIM (qualitative and limited dependent variable model) procedure analyzes univariate and multivariate limited dependent variable models in which dependent variables take discrete values or in which dependent variables are observed only in a limited range of values. These models include logit, probit, tobit, selection, and multivariate models. The multivariate model can contain discrete choice and limited endogenous variables in addition to continuous endogenous variables.

The QLIM procedure supports the following models:

- linear regression model with heteroscedasticity
- Box-Cox regression with heteroscedasticity
- probit with heteroscedasticity
- logit with heteroscedasticity
- tobit (censored and truncated) with heteroscedasticity
- bivariate probit
- bivariate tobit
- sample selection and switching regression models
- multivariate limited dependent variables
- stochastic frontier production and cost models
In the linear regression models with heteroscedasticity, the assumption that error variance is constant across observations is relaxed. The QLIM procedure allows for a number of different linear and nonlinear variance specifications. Another way to make the linear model more appropriate to fit the data and reduce skewness is to apply Box-Cox transformation. If the nature of the data is such that the dependent variable is discrete and it takes only two possible values, ordinary least squares (OLS) estimates are inconsistent. The QLIM procedure offers probit and logit models to overcome these estimation problems. Assumptions about the error variance can also be relaxed in order to estimate probit or logit with heteroscedasticity.

The QLIM procedure also offers a class of models in which the dependent variable is censored or truncated from below or above or both. When a continuous dependent variable is observed only within a certain range and values outside this range are not available, the QLIM procedure offers a class of models that adjust for truncation. In some cases, the dependent variable is continuous only in a certain range and all values outside this range are reported as being on its boundary. For example, if it is not possible to observe negative values, the value of the dependent variable is reported as equal to 0. Because the data are censored, OLS results are inconsistent, and it cannot be guaranteed that the predicted values from the model fall in the appropriate region.

Most of the models in the QLIM procedure can be extended to accommodate bivariate and multivariate scenarios. The assumption that one variable is observed only if another variable takes on certain values lead to the introduction of sample selection models. If the dependent variables are mutually exclusive and observed only for certain ranges of the selection variable, the sample selection can be extended to include cases of switching regression. Stochastic frontier production and cost models allow for random shocks of the production or cost. They include a systematic positive component in the error term that adjusts for technological or cost inefficiency.

The QLIM procedure can use the maximum likelihood method and the Bayesian method for both univariate and multivariate models. Initial starting values for the nonlinear optimizations are typically calculated by OLS.

---

**Getting Started: QLIM Procedure**

The QLIM procedure is similar in use to the other regression or simultaneous equations model procedures in the SAS System. For example, the following statements are used to estimate a binary choice model by using the probit probability function:

```sas
proc qlim data=a;
   model y = x1;
   endogenous y ~ discrete;
run;
```

The response variable, y, is numeric and has discrete values. PROC QLIM enables the user to specify the type of endogenous variables in the ENDOGENOUS statement. The binary probit model can be also specified as follows:

```sas
model y = x1 / discrete;
```
When multiple endogenous variables are specified in the QLIM procedure, these equations are estimated as a system. Multiple endogenous variables can be specified with one MODEL statement in the QLIM procedure when these models have the same exogenous variables:

\[
\text{model } y_1 \ y_2 = x_1 \ x_2 / \text{discrete};
\]

The preceding specification is equivalent to the following statements:

```
proc qlim data=a;
  model y1 = x1 x2;
  model y2 = x1 x2;
  endogenous y1 y2 ~ discrete;
run;
```

Some equations in multivariate models can be continuous while other equations can be discrete. A bivariate model with a discrete and a continuous equation is specified as follows:

```
proc qlim data=a;
  model y1 = x1 x2;
  model y2 = x3 x4;
  endogenous y1 ~ discrete;
run;
```

The standard tobit model is estimated by specifying the endogenous variable to be truncated or censored. The limits of the dependent variable can be specified with the CENSORED or TRUNCATED option in the ENDOGENOUS or MODEL statement when the data are limited by specific values or variables. For example, the two-limit censored model requires two variables that contain the lower (bottom) and upper (top) bound:

```
proc qlim data=a;
  model y = x1 x2 x3;
  endogenous y ~ censored(lb=bottom ub=top);
run;
```

The bounds can be numbers if they are fixed for all observations in the data set. For example, the standard tobit model can be specified as follows:

```
proc qlim data=a;
  model y = x1 x2 x3;
  endogenous y ~ censored(lb=0);
run;
```

---

**Introductory Example: Binary Probit and Logit Models**

The following example illustrates the use of PROC QLIM. The data were originally published by Mroz (1987) and downloaded from Wooldridge (2002). This data set is based on a sample of 753 married white women. The dependent variable is a discrete variable of labor force participation (inlf). Explanatory variables
are the number of children ages 5 or younger (\texttt{kidslt6}) , the number of children ages 6 to 18 (\texttt{kidsge6}) , the woman’s age (\texttt{age}) , the woman’s years of schooling (\texttt{educ}) , wife’s labor experience (\texttt{exper}) , square of experience (\texttt{expersq}) , and the family income excluding the wife’s wage (\texttt{nwifeinc}). The program (with data values omitted) is as follows:

```plaintext
/*-- Binary Probit --*/
proc qlim data=mroz plots=predicted;
   model inlf = nwifeinc educ exper expersq
                  age kidslt6 kidsge6 / discrete;
run;
```

Results of this analysis are shown in the following four figures. In the first table, shown in Figure 22.1, PROC QLIM provides frequency information about each choice. In this example, 428 women participate in the labor force (\texttt{inlf}=1).

### Figure 22.1 Choice Frequency Summary

<table>
<thead>
<tr>
<th>Index</th>
<th>Value</th>
<th>Total Frequency</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0</td>
<td>325</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>428</td>
</tr>
</tbody>
</table>

The second table is the estimation summary table shown in Figure 22.2. Included are the number of dependent variables, names of dependent variables, the number of observations, the log-likelihood function value, the maximum absolute gradient, the number of iterations, AIC, and Schwarz criterion.
Goodness-of-fit measures are displayed in Figure 22.3. All measures except McKelvey-Zavoina’s definition are based on the log-likelihood function value. The likelihood ratio test statistic has chi-square distribution conditional on the null hypothesis that all slope coefficients are zero. In this example, the likelihood ratio statistic is used to test the hypothesis that \( \text{kidslt6} = \text{kidge6} = \text{age} = \text{educ} = \text{exper} = \text{expersq} = \text{nwifeinc} = 0. \)

The parameter estimates and standard errors are shown in Figure 22.4.
**Figure 22.4** Parameter Estimates of Binary Probit

| Parameter | DF | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----|----------|----------------|---------|-------|---|
| Intercept | 1  | 0.270077 | 0.508590       | 0.53    | 0.5954|
| nwifeinc  | 1  | -0.012024| 0.004840       | -2.48   | 0.0130|
| educ      | 1  | 0.130905 | 0.025255       | 5.18    | <.0001|
| exper     | 1  | 0.123348 | 0.018720       | 6.59    | <.0001|
| expersq   | 1  | -0.001887| 0.000600       | -3.14   | 0.0017|
| age       | 1  | -0.052853| 0.008477       | -6.24   | <.0001|
| kidslt6   | 1  | -0.868329| 0.118519       | -7.33   | <.0001|
| kidage6   | 1  | 0.036005 | 0.043477       | 0.83    | 0.4076|

Finally, the QLIM procedure profiles the predicted outcome with respect to the regressors. For example, *Output 22.5* shows the predicted values profiled with respect to *nwifeinc*, *educ*, *exper*, *expersq*, *age*, and *kidslt6*.

**Figure 22.5** Predictions by Regressors: nwifeinc, educ, exper, expersq, age, and kidslt6
When the error term has a logistic distribution, the binary logit model is estimated. To specify a logistic distribution, add D=LOGIT option as follows:

```sas
/*** Binary Logit ***/
proc qlim data=mroz;
   model inlf = nwifeinc educ exper expersq
               age kidslt6 kidsge6 / discrete(d=logit);
run;
```

The estimated parameters are shown in Figure 22.6.

**Figure 22.6** Parameter Estimates of Binary Logit

| Parameter  | DF | Estimate | Standard Error | t Value | Pr > |t| |
|------------|----|----------|----------------|---------|------|---|
| Intercept  | 1  | 0.425452 | 0.860365       | 0.49    | 0.6210|
| nwifeinc   | 1  | -0.021345| 0.008421       | -2.53   | 0.0113|
| educ       | 1  | 0.221170 | 0.043441       | 5.09    | <.0001|
| exper      | 1  | 0.205870 | 0.032070       | 6.42    | <.0001|
| expersq    | 1  | -0.003154| 0.001017       | -3.10   | 0.0019|
| age        | 1  | -0.088024| 0.014572       | -6.04   | <.0001|
| kidslt6    | 1  | -1.443354| 0.203575       | -7.09   | <.0001|
| kidsge6    | 1  | 0.060112 | 0.074791       | 0.80    | 0.4215|

The heteroscedastic logit model can be estimated using the HETERO statement. If the variance of the logit model is a function of the family income level excluding wife’s income (nwifeinc), the variance can be specified as

$$\text{Var}(\epsilon_i) = \sigma^2 \exp(y^*\text{nwifeinc}_i)$$

where \(\sigma^2\) is normalized to 1 because the dependent variable is discrete. The following SAS statements estimate the heteroscedastic logit model:

```sas
/*** Binary Logit with Heteroscedasticity ***/
proc qlim data=mroz;
   model inlf = nwifeinc educ exper expersq
               age kidslt6 kidsge6 / discrete(d=logit);
   hetero inlf ~ nwifeinc / noconst;
run;
```

The parameter estimate, \(\gamma\), of the heteroscedasticity variable is listed as \(_H.nwifeinc\); see Figure 22.7.
Syntax: QLIM Procedure

The QLIM procedure is controlled by the following statements:

PROC QLIM options ;
   BAYES < options> ;
   BOUNDS bound1 < , bound2 . . . > ;
   BY variables ;
   CLASS variables ;
   FREQ variable ;
   ENDogenous variables ~ options ;
   HETERO dependent variables ~ exogenous variables / options ;
   INIT initvalue1 < , initvalue2 . . . > ;
   MODEL dependent variables = regressors / options ;
   NLOPTIONS options ;
   OUTPUT options ;
   PRIOR variables ~ distributions ;
   RESTRICT restriction1 < , restriction2 . . . > ;
   TEST options ;
   WEIGHT variable ;

At least one MODEL statement is required. If more than one MODEL statement is used, the QLIM procedure estimates a system of models. If a FREQ or WEIGHT statement is specified more than once, the variable specified in the first instance is used. Main effects and higher-order terms can be specified in the MODEL statement, as in the GLM procedure and PROBIT procedure in SAS/STAT. If a CLASS statement is used, it must precede the MODEL statement.

Figure 22.7  Parameter Estimates of Binary Logit with Heteroscedasticity

| Parameter       | DF | Estimate  | Standard Error | t Value | Pr > |t| |
|-----------------|----|-----------|----------------|---------|------|---|
| Intercept       | 1  | 0.510445  | 0.983538       | 0.52    | 0.6038 |
| nwifeinc        | 1  | -0.026778 | 0.012108       | -2.21   | 0.0270 |
| educ            | 1  | 0.255547  | 0.061728       | 4.14    | <.0001 |
| exper           | 1  | 0.234105  | 0.046639       | 5.02    | <.0001 |

### PROC QLIM Statement

PROC QLIM options;  

The following options can be used in the PROC QLIM statement.
Data Set Options

**DATA=SAS-data-set**
specifies the input SAS data set. If the DATA= option is not specified, PROC QLIM uses the most recently created SAS data set.

Output Data Set Options

**OUTEST=SAS-data-set**
writes the parameter estimates to an output data set.

**COVOUT**
writes the covariance matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

**CORROUT**
writes the correlation matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

Printing Options

**NOPRINT**
suppresses the normal printed output but does not suppress error listings. If NOPRINT option is set, then any other print option is turned off.

**PRINTALL**
turns on all the printing-control options. The options set by PRINTALL are COVB and CORRB.

**CORRB**
prints the correlation matrix of the parameter estimates.

**COVB**
prints the covariance matrix of the parameter estimates.

**ITPRINT**
prints the initial parameter estimates, convergence criteria, and all constraints of the optimization. At each iteration, objective function value, step size, maximum gradient, and slope of search direction are printed as well.

Model Estimation Options

**COVEST=covariance-option**
specifies the method to calculate the covariance matrix of parameter estimates. The supported covariance types are as follows:

- **OP** specifies the covariance from the outer product matrix.
- **HESSIAN** specifies the covariance from the inverse Hessian matrix.
- **QML** specifies the covariance from the outer product and Hessian matrices (the quasi-maximum likelihood estimates).

The default is COVEST=HESSIAN.
HECKIT < (heckit-options) >
requests that the selection model be estimated by Heckman’s two-step estimation method. You must specify exactly two MODEL statements when you use the HECKIT option. One of the models must be a binary probit model; therefore, you must specify the DISCRETE option in the MODEL or ENDOGENOUS statement. You base the selection on the binary probit model for the second model; therefore, you must specify the SELECT option for this model.

You can specify one or both of the following heckit-options:

SECONDSTAGE=OLS | ML
specifies the estimation method of the second stage of Heckman’s two-step method. SECONDSTAGE=OLS requests the ordinary least squares method for the second stage. If you specify SECONDSTAGE=OLS, then the model of interest—that is, the model that uses the SELECT option—must be linear and contain a continuous dependent variable. Therefore, you cannot specify the DISCRETE, CENSORED, or TRUNCATED option along with the SELECT option for the model of interest. When you specify the SECONDSTAGE=OLS option, you cannot test or restrict the parameters of the model of interest. However, you can test or restrict the parameters of the selection model—that is, the model that defines the selection rule.

If you specify SECONDSTAGE=ML, then PROC QLIM uses the maximum likelihood method in the second stage, as it does in the first stage. When you specify SECONDSTAGE=ML, the model of interest can be nonlinear. Moreover, you can also use the TEST or RESTRICT statement to test or restrict the parameters of the model of interest.

By default, SECONDSTAGE=OLS.

UNCORRECTED
requests the conventional OLS standard errors when the second-stage estimation method is the ordinary least squares method. If you do not specify the UNCORRECTED option, PROC QLIM reports the corrected OLS standard errors. For more information about the corrected standard errors, see the section “Heckman’s Two-Step Selection Method” on page 1553.

If you specify both the UNCORRECTED and SECONDSTAGE=ML options, PROC QLIM ignores the UNCORRECTED option, because the UNCORRECTED option is related to the OLS standard errors.

NDRAW=value
specifies the number of draws for Monte Carlo integration.

SEED=value
specifies a seed for pseudo-random number generation in Monte Carlo integration.

Optimization Process Control Options
PROC QLIM uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. You can use any of the NLO options in the NLOPTIONS statement. For more information, see Chapter 6, “Nonlinear Optimization Methods.”

METHOD=value
specifies the optimization method. If this option is specified, it overwrites the TECH= option in NLOPTIONS statement. Valid values are as follows:
CONGRA performs a conjugate-gradient optimization
DBLDOG performs a version of double-dogleg optimization
NMSIMP performs a Nelder-Mead simplex optimization
NEWRAP performs a Newton-Raphson optimization combining a line-search algorithm with ridging
NRRIDG performs a Newton-Raphson optimization with ridging
QUANEW performs a quasi-Newton optimization
TRUREG performs a trust region optimization

The default method is METHOD=QUANEW.

Plotting Options

PLOTS< (global-plot-options) > = plot-request | (plot-requests)
controls the display of plots. By default, the plots are displayed in panels unless the UNPACK global-plot-option is specified. When you specify only one plot-request, you can omit the parentheses around the plot-request.

Global Plot Options
You can specify the following global-plot-options:

ONLY
displays only the requested plot.

PRIOR
displays the prior predictive graph that is associated with the requested posterior predictive plot BAYESPRED. This option is available only for Bayesian analysis.

UNPACK PANEL
UNPACK
specifies that all paneled plots be unpacked, meaning that each plot in a panel is displayed separately.

Plot Requests
You can specify the following plot-requests:

ALL
specifies all types of available plots.

AUTOCORR< (LAGS=n) >
displays the autocorrelation function plots for the parameters. This plot-request is available only for Bayesian analysis. The optional LAGS= suboption the number (up to lag n) of autocorrelations to be plotted in the AUTOCORR plot. If this suboption is not specified, autocorrelations are plotted up to lag 50.
BAYESDIAG displays the TRACE, AUTOCORR, and DENSITY plots. This plot-request is available only for Bayesian analysis.

BAYESPRED displays the predictive analysis. The predictive analysis takes into account the variability of the error term, whereas the PREDICTED plot-request does not. The BAYESPRED plot-request is available only for Bayesian analysis.

BAYESSUM displays the posterior distribution, the prior distribution, and the maximum likelihood estimates. This plot-request is available only for Bayesian analysis.

CONDITIONAL displays the conditional expected values for continuous endogenous variables. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This plot-request is not available for Bayesian analysis.

DENSITY< (FRINGE) >= displays the kernel density plots for the parameters. This plot-request is available only for Bayesian analysis. If you specify the FRINGE suboption, a fringe plot is created on the X axis of the kernel density plot. This plot-request is available only for Bayesian analysis.

ERRSTD displays the error standard deviation versus observed regressors when you also specify a HETERO statement. This plot-request is not available for Bayesian analysis.

EXPECTED displays the expected values for continuous endogenous variables. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This plot-request is not available for Bayesian analysis.

MARGINAL displays the marginal effects. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This plot-request is not available for Bayesian analysis.

MILLS displays the inverse Mills ratio. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This plot-request is not available for Bayesian analysis.

NONE suppresses all diagnostic plots.

PREDICTED displays the model predicted values. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This plot-request is not available for Bayesian analysis.

PROB displays the predicted response probability. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This plot-request is not available for Bayesian analysis.
**PROBALL**

displays the predicted probabilities for each level of the response. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

**PROFLIK**

displays the profiled log likelihood. Each profiled graph is obtained by setting all the parameters to their maximum likelihood estimate except for the profiling parameter. The profiling parameter takes values on a predefined grid that is determined by the maximum likelihood estimate of the corresponding standard deviation.

**RESIDUAL**

displays the residuals versus observed regressors. This *plot-request* is not available for Bayesian analysis.

**TE1**

displays the technical efficiency for the stochastic frontier model as suggested by Battese and Coelli (1988). Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

**TE2**

displays the technical efficiency for the stochastic frontier model as suggested by Jondrow et al. (1982). Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

**TRACE< (SMOOTH) >**

displays the trace plots for the parameters. This *plot-request* is available only for Bayesian analysis. The SMOOTH suboption displays a fitted penalized B-spline curve for each TRACE plot.

**XBETA**

displays the structural part on the right-hand side of the model. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This is not available for Bayesian analysis.

---

**BAYES Statement**

```
BAYES <options> ;
```

The BAYES statement controls the Metropolis sampling scheme that is used to obtain samples from the posterior distribution of the underlying model and data.

**DIAGNOSTICS=ALL | NONE | (keyword-list)**

controls which diagnostics are produced. All the following diagnostics are produced with DIAGNOSTICS=ALL. If you do not want any of these diagnostics, specify DIAGNOSTICS=NONE. If you want some but not all of the diagnostics, or if you want to change certain settings of these diagnostics, specify a subset of the following keywords. By default, DIAGNOSTICS=NONE.
AUTOCORR < (LAGS= numeric-list) >
computes the autocorrelations at lags that are specified in the numeric-list. Elements in the numeric-list are truncated to integers, and repeated values are removed. If the LAGS= option is not specified, autocorrelations of lags 1, 5, 10, and are computed.

ESS
computes Carlin’s estimate of the effective sample size, the correlation time, and the efficiency of the chain for each parameter.

GEWEKE < (geweke-options) >
computes the Geweke spectral density diagnostics, which are essentially a two-sample t test between the first $f_1$ portion and the last $f_2$ portion of the chain. The default is $f_1 = 0.1$ and $f_2 = 0.5$, but you can choose other fractions by using the following geweke-options:

FRAC1=value
specifies the fraction $f_1$ for the first window.

FRAC2=value
specifies the fraction $f_2$ for the second window.

HEIDELBERGER < (heidel-options) >
computes the Heidelberger and Welch diagnostic for each variable, which consists of a stationarity test of the null hypothesis that the sample values form a stationary process. If the stationarity test is not rejected, a halfwidth test is then carried out. Optionally, you can specify one or more of the following heidel-options:

SALPHA=value
specifies the $\alpha$ level ($0 < \alpha < 1$) for the stationarity test.

HALPHA=value
specifies the $\alpha$ level ($0 < \alpha < 1$) for the halfwidth test.

EPS=value
specifies a positive number $\epsilon$ such that if the halfwidth is less than $\epsilon$ times the sample mean of the retained iterates, the halfwidth test is passed.

MCSE
MCERROR
computes the Monte Carlo standard error for each parameter. The Monte Carlo standard error, which measures the simulation accuracy, is the standard error of the posterior mean estimate and is calculated as the posterior standard deviation divided by the square root of the effective sample size.

RAFTERY < (raftery-options) >
computes the Raftery and Lewis diagnostics, which evaluate the accuracy of the estimated quantile ($\hat{\theta}_Q$ for a given $Q \in (0, 1)$) of a chain. $\hat{\theta}_Q$ can achieve any degree of accuracy when the chain is allowed to run for a long time. The computation is stopped when the estimated probability $\hat{P}_Q = \Pr(\theta \leq \hat{\theta}_Q)$ reaches within $\pm R$ of the value $Q$ with probability $S$; that is, $\Pr(Q - R \leq \hat{P}_Q \leq Q + R) = S$. The following raftery-options enable you to specify $Q, R, S$, and a precision level $\epsilon$ for the test:
**QUANTILE | Q=value**
specifies the order (a value between 0 and 1) of the quantile of interest. The default is 0.025.

**ACCURACY | R=value**
specifies a small positive number as the margin of error for measuring the accuracy of estimation of the quantile. The default is 0.005.

**PROBABILITY | S=value**
specifies the probability of attaining the accuracy of the estimation of the quantile. The default is 0.95.

**EPSILON | EPS=value**
specifies the tolerance level (a small positive number) for the stationary test. The default is 0.001.

**MINTUNE=number**
specifies the minimum number of tuning phases. The default is 2.

**MAXTUNE=number**
specifies the maximum number of tuning phases. The default is 24.

**NBI=number**
specifies the number of burn-in iterations before the chains are saved. The default is 1,000.

**NMC=number**
specifies the number of iterations after the burn-in. The default is 1,000.

**NMCPRIOR=number**
specifies the number of samples for the prior predictive analysis when `PLOTS(PRIOR)=BAYESPRED` is requested. The default is 10,000.

**NTRDS=number**

**THREADS=number**
specifies the number of threads to be used. The number of threads cannot exceed the number of computer cores available. Each core samples the number of iterations that is specified by the NMC option. The default is 1.

**NTU=number**
specifies the number of samples for each tuning phase. The default is 500.

**OUTPOST=SAS-data-set**
names the SAS data set to contain the posterior samples. Alternatively, you can create the output data set by specifying an ODS OUTPUT statement as follows:

```plaintext
ODS OUTPUT POSTERIORSAMPLE = <SAS-data-set> ;
```

**OUTPRIOR=SAS-data-set**
names the SAS data set to contain the prior samples used to generate the prior predictive analysis when you request the prior predictive plots. Alternatively, you can create the output data set by specifying an ODS OUTPUT statement as follows:

```plaintext
ODS OUTPUT PRIORSAMPLE = <SAS-data-set> ;
```
PROPCOV=value
specifies the method used in constructing the initial covariance matrix for the Metropolis-Hastings algorithm. The QUANEW and NMSIMP methods find numerically approximated covariance matrices at the optimum of the posterior density function with respect to all continuous parameters. The tuning phase starts at the optimized values; in some problems, this can greatly increase convergence performance. If the approximated covariance matrix is not positive definite, then an identity matrix is used instead. You can specify the following values:

**CONGRA**
- performs a conjugate-gradient optimization.

**DBLDOG**
- performs a version of double-dogleg optimization.

**NEWRAP**
- performs a Newton-Raphson optimization that combines a line-search algorithm with ridging.

**NMSIMP**
- performs a Nelder-Mead simplex optimization.

**NRRIDG**
- performs a Newton-Raphson optimization with ridging.

**QUANEW**
- performs a quasi-Newton optimization.

**TRUREG**
- performs a trust-region optimization.

SAMPLING=MULTIMETROPOLIS | UNIMETROPOLIS | MODELMETROPOLIS
specifies how to sample from the posterior distribution. SAMPLING=MULTIMETROPOLIS implements a Metropolis sampling scheme on a single block that contains all the parameters of the model. SAMPLING=MODELMETROPOLIS implements a Metropolis sampling scheme on multiple blocks: one block for each model (all the parameters of the model) plus a block for all the correlation parameters across the models. SAMPLING=UNIMETROPOLIS implements a Metropolis sampling scheme on multiple blocks, one for each parameter of the model. By default, SAMPLING=MULTIMETROPOLIS.

SEED=number
specifies an integer seed in the range 1 to $2^{31} - 1$ for the random number generator in the simulation. Specifying a seed enables you to reproduce identical Markov chains for the same specification. If you do not specify the SEED= option, or if you specify a nonpositive seed, a random seed is derived from the time of day.

SIMTIME
prints the time required for the MCMC sampling.

STATISTICS < (global-options) > = ALL | NONE | keyword | (keyword-list)
STATS < (global-options) > = ALL | NONE | keyword | (keyword-list)
controls the number of posterior statistics produced. Specifying STATISTICS=ALL is equivalent to specifying STATISTICS= (CORR COV INTERVAL PRIOR SUMMARY). If you do not want any posterior statistics, specify STATISTICS=NONE. The default is STATISTICS=(SUMMARY INTERVAL). You can specify the following global-options:
ALPHA=numeric-list
controls the probabilities of the credible intervals. The ALPHA= values must be between 0 and 1. Each ALPHA= value produces a pair of $100(1-\text{ALPHA})\%$ equal-tail and HPD intervals for each parameter. The default is ALPHA=0.05, which yields the 95% credible intervals for each parameter.

PERCENT=numeric-list
requests the percentile points of the posterior samples. The PERCENT= values must be between 0 and 100. The default is PERCENT=25, 50, 75, which yields the 25th, 50th, and 75th percentile points, respectively, for each parameter.

You can specify the following keywords:

CORR
produces the posterior correlation matrix.

COV
produces the posterior covariance matrix.

INTERVAL
produces equal-tail credible intervals and HPD intervals. The default is to produce the 95% equal-tail credible intervals and 95% HPD intervals, but you can use the ALPHA= global-option to request intervals of any probabilities.

NONE
suppresses printing of all summary statistics.

PRIOR
produces a summary table of the prior distributions used in the Bayesian analysis.

SUMMARY
produces the means, standard deviations, and percentile points (25th, 50th, and 75th) for the posterior samples. You can use the global PERCENT= global-option to request specific percentile points.

THIN=number
THINNING=number
controls the thinning of the Markov chain. Only one in every $k$ samples is used when THIN=$k$, and if NBI=$n_0$ and NMC=$n$, the number of samples that are kept is

$$\left\lfloor \frac{n_0 + n}{k} \right\rfloor - \left\lfloor \frac{n_0}{k} \right\rfloor$$

where $[a]$ represents the integer part of the number $a$. The default is THIN=1.
The BOUNDS statement imposes simple boundary constraints on the parameter estimates. BOUNDS statement constraints refer to the parameters estimated by the QLIM procedure. Any number of BOUNDS statements can be specified.

Each bound is composed of parameters and constants and inequality operators. Parameters associated with regressor variables are referred to by the names of the corresponding regressor variables:

\[
\text{item operator item} < \text{operator item} < \text{operator item} \ldots > >
\]

Each item is a constant, the name of a parameter, or a list of parameter names. See the section “Naming of Parameters” on page 1574 for more details on how parameters are named in the QLIM procedure. Each operator is '<', '>', '<=', or '>='.

Both the BOUNDS statement and the RESTRICT statement can be used to impose boundary constraints; however, the BOUNDS statement provides a simpler syntax for specifying these kinds of constraints. See the “RESTRICT Statement” on page 1537 for more information.

The following BOUNDS statement constrains the estimates of the parameters associated with the variable ttime and the variables x1 through x10 to be between 0 and 1. This example illustrates the use of parameter lists to specify boundary constraints.

\[
\text{bounds } 0 < \text{ttime } x1-\text{x10} < 1;
\]

The following BOUNDS statement constrains the estimates of the correlation (_RHO) and sigma (_SIGMA) in the bivariate model:

\[
\text{bounds } _\text{rho} \geq 0, _\text{sigma.y1} > 1, _\text{sigma.y2} < 5;
\]

The BOUNDS statement is not supported if a BAYES statement is also specified. In Bayesian analysis, the restrictions on parameters are usually introduced through the prior distribution.

---

**BY Statement**

\[
\text{BY } \text{variables } ;
\]

A BY statement can be used with PROC QLIM to obtain separate analyses on observations in groups defined by the BY variables.

---

**CLASS Statement**

\[
\text{CLASS } \text{variables } ;
\]

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric.

Class levels are determined from the formatted values of the CLASS variables. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in *SAS Language Reference: Dictionary* for details.
The ENDOGENOUS statement specifies the type of dependent variables that appear on the left-hand side of the equation. Endogenous variables listed refer to the dependent variables that appear on the left-hand side of the equation.

Discrete Variable Options

**DISCRETE** *(discrete-options)*

specifies that the endogenous variables in this statement are discrete. Valid *discrete-options* are as follows:

- **ORDER=DATA | FORMATTED | FREQ | INTERNAL**
  
specifies the sorting order for the levels of the discrete variables specified in the ENDOGENOUS statement. This ordering determines which parameters in the model correspond to each level in the data. The following table shows how PROC QLIM interprets values of the ORDER= option.

<table>
<thead>
<tr>
<th>Value of ORDER=</th>
<th>Levels Sorted By</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA</td>
<td>Order of appearance in the input data set</td>
</tr>
<tr>
<td>FORMATTED</td>
<td>Formatted value</td>
</tr>
<tr>
<td>FREQ</td>
<td>Descending frequency count; levels with the most observations come first in the order</td>
</tr>
<tr>
<td>INTERNAL</td>
<td>Unformatted value</td>
</tr>
</tbody>
</table>

By default, ORDER=FORMATTED. For the values FORMATTED and INTERNAL, the sort order is machine dependent. For more information about sorting order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide*.

**DISTRIBUTION=NORMAL | LOGISTIC**

specifies the cumulative distribution function used to model the response probabilities. DISTRIBUTION=NORMAL specifies the normal distribution for the probit model. DISTRIBUTION=LOGISTIC specifies the logistic distribution for the logit model.

By default, DISTRIBUTION=NORMAL.

If a multivariate model is specified, logistic distribution is not allowed. Only normal distribution is supported.

Censored Variable Options

**CENSORED** *(censored-options)*

specifies that the endogenous variables in this statement be censored. Valid *censored-options* are as follows:
\textbf{LB=} value or variable

\textbf{LOWERBOUND=} value or variable

specifies the lower bound of the censored variables. If \textit{value} is missing or the value in \textit{variable} is missing, no lower bound is set. By default, no lower bound is set.

\textbf{UB=} value or variable

\textbf{UPPERBOUND=} value or variable

specifies the upper bound of the censored variables. If \textit{value} is missing or the value in \textit{variable} is missing, no upper bound is set. By default, no upper bound is set.

\textbf{Truncated Variable Options}

\textbf{TRUNCATED (truncated-options )}

specifies that the endogenous variables in this statement be truncated. Valid \textit{truncated-options} are as follows:

\textbf{LB=} value or variable

\textbf{LOWERBOUND=} value or variable

specifies the lower bound of the truncated variables. If \textit{value} is missing or the value in \textit{variable} is missing, no lower bound is set. By default, no lower bound is set.

\textbf{UB=} value or variable

\textbf{UPPERBOUND=} value or variable

specifies the upper bound of the truncated variables. If \textit{value} is missing or the value in \textit{variable} is missing, no upper bound is set. By default, no upper bound is set.

\textbf{Stochastic Frontier Variable Options}

\textbf{FRONTIER < (frontier-options ) >}

specifies that the endogenous variable in this statement follow a production or cost frontier. Valid \textit{frontier-options} are as follows:

\textbf{TYPE=} \textbf{HALF} | \textbf{EXPONENTIAL} | \textbf{TRUNCATED}

specifies the model type:

\begin{itemize}
  \item HALF specifies a half-normal model.
  \item EXPONENTIAL specifies an exponential model.
  \item TRUNCATED specifies a truncated normal model.
\end{itemize}

\textbf{PRODUCTION}

specifies that the model estimated be a production function.

\textbf{COST}

specifies that the model estimated be a cost function.

If neither PRODUCTION nor COST option is specified, production function is estimated by default.
Selection Options

**SELECT** *(select-option)*

specifies selection criteria for sample selection model. The BAYES statement does not support the SELECT option. The **select-option** specifies the condition for the endogenous variable to be selected. It is written as a variable name, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a number:

*variable operator number*

The **variable** is the endogenous variable that the selection is based on. The **operator** can be =, <, >, <=, or >=. Multiple **select-options** can be combined with the logic operators: AND, OR. The following example illustrates the use of the SELECT option:

```
endogenous y1 ~ select(z=0);
endogenous y2 ~ select(z=1 or z=2);
```

The SELECT option can be used together with the DISCRETE, CENSORED, or TRUNCATED option. For example:

```
endogenous y1 ~ select(z=0) discrete;
endogenous y2 ~ select(z=1) censored (lb=0);
endogenous y3 ~ select(z=1 or z=2) truncated (ub=10);
```

For more information about selection models with censoring or truncation, see the section “Selection Models” on page 1551.

Endogeneity and Overidentification Test Options

**ENDOTEST** *(regressors)*

requests the test of endogeneity for a list of regressors in the model. More specifically, this option tests the null hypothesis that the specified regressors are exogenous. Each of these regressors must also have a model of its own. The former model is considered the structural model, and the latter models are considered reduced form models.

The following example illustrates the use of the ENDOTEST option by testing whether the regressors y2 and y3 are endogenous in the model for y1:

```
proc qlim;
  model y1 = y2 y3 x1;
  model y2 = x1 x2 x3 x4 x5;
  model y3 = x1 x2 x3 x4 x5;
  endogenous y1 ~ endotest(y2 y3);
run;
```

The ENDOTEST option is not available when you specify the SELECT or FRONTIER option. You can specify the ENDOTEST option only once for each ENDOGENOUS statement.

For more information about the test for endogeneity, see the section “Test for Endogeneity” on page 1561.
OVERID (variables)
requests the overidentification test for a list of variables. These variables are the overidentifying
instrumental variables that you provide from the reduced form models. For more information, see the
section “Overidentification Test” on page 1562.

The following example illustrates the use of the OVERID option:

```
proc qlim;
   model y1 = y2 y3 x1;
   model y2 = x1 x2 x3 x4 x5;
   model y3 = x1 x2 x3 x4 x5;
   endogenous y1 ~ overid(y2.x4 y3.x5);
run;
```

The regressors y2 and y3 in the model for y1 are the endogenous variables. Therefore, each of
these variables has its own models, which are considered reduced form models. The overidentifying
instrumental variables are x4 and x5. If you specify the OVERID option as

```
endogenous y1 ~ overid(y2.x4 y2.x5);
```

then you consider only the regressor y2 to be endogenous, and the model for y3 is ignored during the
testing process.

The OVERID option is not available when you specify the SELECT or FRONTIER option. You can
specify the OVERID option only once for each ENDOGENOUS statement.

FREQ Statement

```
FREQ variable ;
```

The FREQ statement identifies a variable that contains the frequency of occurrence of each observation.
PROC QLIM treats each observation as if it appears n times, where n is the value of the FREQ variable for
the observation. If it is not an integer, the frequency value is truncated to an integer. If the frequency value
is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not
specified, each observation is assigned a frequency of 1. If you specify more than one FREQ statement, then
the first FREQ statement is used.

HETERO Statement

```
HETERO dependent variables ~ exogenous variables < / options > ;
```

The HETERO statement specifies variables that are related to the heteroscedasticity of the residuals and the
way these variables are used to model the error variance. The heteroscedastic regression model supported by
PROC QLIM is

\[ y_i = x'_i \beta + \epsilon_i \]
\[ \epsilon_i \sim N(0, \sigma_i^2) \]

See the section “Heteroscedasticity” on page 1549 for more details on the specification of functional forms.
LINK=\textit{value}

The functional form can be specified using the LINK= option. The following option values are allowed:

- **EXP** specifies the exponential link function
  \[
  \sigma^2_i = \sigma^2 (1 + \exp(z_i' \gamma))
  \]

- **LINEAR** specifies the linear link function
  \[
  \sigma^2_i = \sigma^2 (1 + z_i' \gamma)
  \]

When the LINK= option is not specified, the exponential link function is specified by default.

**NOCONST**

specifies that there be no constant in the exponential heteroscedasticity model.

\[
\sigma^2_i = \sigma^2 \exp(z_i' \gamma)
\]

**SQUARE**

estimates the model by using the square of linear heteroscedasticity function. For example, you can specify the following heteroscedasticity function:

\[
\sigma^2_i = \sigma^2 (1 + (z_i' \gamma)^2)
\]

\texttt{model y = x1 x2 / discrete;}
\texttt{hetero y ~ z1 / link=linear square;}

The option SQUARE does not apply to exponential heteroscedasticity function because the square of an exponential function of \(z_i' \gamma\) is the same as the exponential of \(2z_i' \gamma\). Hence the only difference is that all \(\gamma\) estimates are divided by two.

You can use the HETERO statement within a Bayesian framework, but you should do this carefully because convergence can be slower than in the homoscedastic case. For more information see “Priors for Heteroscedastic Models” on page 1566.

**INIT Statement**

\texttt{INIT initvalue1 < , initvalue2 \ldots > ;}

The INIT statement sets initial values for parameters in the optimization. You can specify any number of INIT statements.

Each \textit{initvalue} is written as a parameter or parameter list, followed by an optional equality operator (=), followed by a number:

\texttt{parameter <= number}

If you also specify the BAYES statement, the INIT statement also initializes the Markov chain Monte Carlo (MCMC) algorithm. In particular, the INIT statement does one of the following:

- It initializes the tuning phase (this also includes the PROPCOV option).
- It initializes the sampling phase, if there is no tuning phase.
MODEL Statement

MODEL dependent = regressors < / options > ;

The MODEL statement specifies the dependent variable and independent regressor variables for the regression model.

You can specify the following options after a slash (/).

LIMIT1=ZERO | VARYING
specifies the restriction of the threshold value of the first category when the ordinal probit or logit model is estimated. LIMIT1=ZERO is the default option. When LIMIT1=VARYING is specified, the threshold value is estimated.

NOINT
suppresses the intercept parameter.

Endogenous Variable Options

The endogenous variable options are the same as the options that you can specify in the ENDOGENOUS statement. If you specify an ENDOGENOUS statement, all endogenous options in the MODEL statement are ignored.

Endogeneity and Overidentification Test Options

The endogeneity and overidentification test options are the same as the options that you can specify in the ENDOGENOUS statement. If you specify an ENDOGENOUS statement, all endogeneity and overidentification test options in the MODEL statement are ignored.

BOXCOX Estimation Options

BOXCOX (option-list )
specifies options that are used for Box-Cox regression or regressor transformation. For example, the Box-Cox regression is specified as

model y = x1 x2 / boxcox(y=lambda, x1 x2)

PROC QLIM estimates the following Box-Cox regression model:

\[ y_i^{(\lambda)} = \beta_0 + \beta_1 x_1^{(\lambda_1)} + \beta_2 x_2^{(\lambda_2)} + \epsilon_i \]

The option-list takes the form variable-list < = varname > separated by commas. The variable-list specifies that the list of variables have the same Box-Cox transformation; varname specifies the name of this Box-Cox coefficient. If varname is not specified, the coefficient is called _Lambda_i, where i increments sequentially.
Variable Selection Options

**SELECTVAR <=(selectvar-option) =>**

enables variable selection. The `selectvar-option` specifies a variable selection method based on an information criterion. For more information, see the section “Variable Selection” on page 1555. You can specify the following `selectvar-options`:

- **DIRECTION=FORWARD | BACKWARD**
  specifies the searching algorithm to use in the variable selection method. By default, DIRECTION=FORWARD.

- **CRITER=AIC | SBC**
  specifies the information criterion to use for the variable selection. By default, CRITER=AIC.

- **MAXSTEPS=value**
  specifies the maximum number of steps that are allowed in the search algorithm. The default is infinite; that is, the algorithm does not stop until the stopping criterion is satisfied.

- **LSTOP=value**
  specifies the stopping criterion. The `value` represents the percentage of decrease or increase in the AIC or SBC that is required for the algorithm to proceed; it must be a positive number less than 1. The default is 0.

- **RETAIN(regressors)**
  specifies a list of regressors that are to be retained in any model that the variable selection process considers.

The following rules apply to how regressors are handled when you specify more than one MODEL statement and use the SELECTVAR option:

- If you do not specify the SELECTVAR option in a particular MODEL statement, then all regressors in the original model are included in any model that the variable selection algorithm considers. In other words, omitting the SELECTVAR option is equivalent to providing the option: SELECTVAR=(RETAIN(all-regressors)).
- If you specify the SELECTVAR option without any `=(option)` clause in a MODEL statement, then all regressors in that model (other than the intercept, if present) are eligible for potential exclusion as the variable selection process is executed.

The following example specifies 10 possible regressor candidates, out of which five are selected using the AIC criterions:

```sql
proc qlim data=one;
  model y = x1-x10 /selectvar=(direction=forward criter=AIC maxsteps=5);
run;
```

---

**NLOPTIONS Statement**

NLOPTIONS `<options>`;

PROC QLIM uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. For a list of all the options of the NLOPTIONS statement, see Chapter 6, “Nonlinear Optimization Methods.”
OUTPUT Statement

```plaintext
OUTPUT < OUT=SAS-data-set > < output-options > ;
```

The OUTPUT statement creates a new SAS data set containing all variables in the input data set and, optionally, the estimates of $x'\beta$, predicted value, residual, marginal effects, probability, standard deviation of the error, expected value, conditional expected value, technical efficiency measures, and inverse Mills ratio. When the response values are missing for the observation, all output estimates except residual are still computed as long as none of the explanatory variables is missing. This enables you to compute these statistics for prediction. You can specify only one OUTPUT statement.

Details on the specifications in the OUTPUT statement are as follows:

**CONDITIONAL**
- outputs estimates of conditional expected values of continuous endogenous variables.

**ERRSTD**
- outputs estimates of $\sigma_j$, the standard deviation of the error term.

**EXPECTED**
- outputs estimates of expected values of continuous endogenous variables.

**MARGINAL**
- outputs marginal effects.

**MILLS**
- outputs estimates of inverse Mills ratios of censored or truncated continuous, binary discrete, and selection endogenous variables.

**OUT=SAS-data-set**
- names the output data set.

**PREDICTED**
- outputs estimates of predicted endogenous variables.

**PROB**
- outputs estimates of probability of discrete endogenous variables taking the current observed responses.

**PROBALL**
- outputs estimates of probability of discrete endogenous variables for all possible responses.

**RESIDUAL**
- outputs estimates of residuals of continuous endogenous variables.

**XBETA**
- outputs estimates of $x'\beta$.

**TE1**
- outputs estimates of technical efficiency for each producer in the stochastic frontier model suggested by Battese and Coelli (1988).
TE2

outputs estimates of technical efficiency for each producer in the stochastic frontier model suggested by Jondrow et al. (1982).

PRIOR Statement

PRIOR _REGRESSORS | parameter-list ~ distribution ;

The PRIOR statement specifies the prior distribution of the model parameters. You must specify a single parameter or a list of parameter, a tilde ~, and then a distribution with its parameters. Multiple PRIOR statements are allowed.

You can specify the following distributions:

NORMAL(MEAN=μ, VAR=σ²)

specifies a normal distribution with parameters MEAN and VAR.

GAMMA(SHAPE=a, SCALE=b)

specifies a gamma distribution with parameters SHAPE and SCALE.

IGAMMA(SHAPE=a, SCALE=b)

specifies an inverse gamma distribution with parameters SHAPE and SCALE.

UNIFORM(MIN=m, MAX=M)

specifies a uniform distribution that is defined between MIN and MAX.

BETA(SHAPE1=a, SHAPE2=b, MIN=m, MAX=M)

specifies a beta distribution with parameters SHAPE1 and SHAPE2 and defined between MIN and MAX.

T(LOCATION=μ, DF=ν)

specifies a noncentral t distribution with DF degrees of freedom and location parameter equal to LOCATION.

See the section “Standard Distributions” on page 1567 for details about how to specify distributions.

You can specify the special keyword REGRESSORS to select all the parameters used in the linear regression component of the model.

RESTRICT Statement

RESTRICT restriction1 <, restriction2 . . . > ;

The RESTRICT statement is used to impose linear restrictions on the parameter estimates. Any number of RESTRICT statements can be specified, but the number of restrictions imposed is limited by the number of regressors.

Each restriction is written as an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:
expression operator expression

The operator can be =, <, >, <=, or >=. The operator and second expression are optional.

Restriction expressions can be composed of parameter names, multiplication (*), addition (+) and substitution (−) operators, and constants. Parameters named in restriction expressions must be among the parameters estimated by the model. Parameters associated with a regressor variable are referred to by the name of the corresponding regressor variable. The restriction expressions must be a linear function of the parameters.

The following is an example of the use of the RESTRICT statement:

```plaintext
proc qlim data=one;
  model y = x1-x10 / discrete;
  restrict x1*2 <= x2 + x3;
run;
```

The RESTRICT statement can also be used to impose cross-equation restrictions in multivariate models. The following RESTRICT statement imposes an equality restriction on coefficients of x1 in equation y1 and x1 in equation y2:

```plaintext
proc qlim data=one;
  model y1 = x1-x10;
  model y2 = x1-x4;
  endogenous y1 y2 ~ discrete;
  restrict y1.x1=y2.x1;
run;
```

The RESTRICT statement is not supported if a BAYES statement is also specified. In Bayesian analysis, the restrictions on parameters are usually introduced through the prior distribution.

---

**TEST Statement**

```plaintext
<'label'> TEST <'string'> equation [,equation...] / options ;
```

The TEST statement performs Wald, Lagrange multiplier, and likelihood ratio tests of linear hypotheses about the regression parameters in the preceding MODEL statement. Each equation specifies a linear hypothesis to be tested. All hypotheses in one TEST statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. The keyword INTERCEPT refers to the coefficient of the intercept.

The following options can be specified in the TEST statement after the slash (/):

- **ALL**
  - requests Wald, Lagrange multiplier, and likelihood ratio tests.

- **WALD**
  - requests the Wald test.
requests the Lagrange multiplier test.

requests the likelihood ratio test.

The following illustrates the use of the TEST statement:

```
proc qlim;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0;
  test _int: test intercept = 0, x3 = 0;
run;
```

The first test investigates the joint hypothesis that

\[
\beta_1 = 0
\]

and

\[
0.5\beta_2 + 2\beta_3 = 0
\]

In case there is more than one MODEL statement in one QLIM procedure, then TEST statement is capable of testing cross-equation restrictions. Each parameter reference should be preceded by the name of the dependent variable of the particular model and the dot sign. For example,

```
proc qlim;
  model y1 = x1 x2 x3;
  model y2 = x3 x5 x6;
  test y1.x1 + y2.x6 = 1;
run;
```

This cross-equation test investigates the null hypothesis that

\[
\beta_{1,1} + \beta_{2,3} = 1
\]

in the system of equations

\[
\begin{align*}
y_{1,i} &= \alpha_1 + \beta_{1,1}x_{1,i} + \beta_{1,2}x_{2,i} + \beta_{1,3}x_{3,i} \\
y_{2,i} &= \alpha_2 + \beta_{2,1}x_{3,i} + \beta_{2,2}x_{5,i} + \beta_{2,3}x_{6,i}
\end{align*}
\]

Only linear equality restrictions and tests are permitted in PROC QLIM. Tests expressions can be composed only of algebraic operations involving the addition symbol (+), subtraction symbol (-), and multiplication symbol (*).

The TEST statement accepts labels that are reproduced in the printed output. TEST statement can be labeled in two ways. A TEST statement can be preceded by a label followed by a colon. Alternatively, the keyword TEST can be followed by a quoted string. If both are present, PROC QLIM uses the label preceding the colon. In the event no label is present, PROC QLIM automatically labels the tests.

You cannot specify both the TEST statement and the BAYES statement.
WEIGHT Statement

WEIGHT variable < / option> ;

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters. The log likelihood for each observation is multiplied by the corresponding weight variable value.

If the weight of an observation is nonpositive, that observation is not used in the estimation.

The following option can be added to the WEIGHT statement after a slash (/).

NONORMALIZE

specifies that the weights are required to be used as is. When this option is not specified, the weights are normalized so that they add up to the actual sample size. Weights $w_i$ are normalized by multiplying them by $\frac{n}{\sum_{i=1}^{n} w_i}$, where $n$ is the sample size.

Details: QLIM Procedure

Ordinal Discrete Choice Modeling

Binary Probit and Logit Model

The binary choice model is

$$y_i^* = x_i^t \beta + \epsilon_i$$

where value of the latent dependent variable, $y_i^*$, is observed only as follows:

$$y_i = 1 \quad \text{if} \quad y_i^* > 0$$
$$y_i = 0 \quad \text{otherwise}$$

The disturbance, $\epsilon_i$, of the probit model has standard normal distribution with the distribution function (CDF)

$$\Phi(x) = \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} \exp(-t^2/2) dt$$

The disturbance of the logit model has standard logistic distribution with the CDF

$$\Lambda(x) = \frac{\exp(x)}{1 + \exp(x)} = \frac{1}{1 + \exp(-x)}$$

The binary discrete choice model has the following probability that the event $\{y_i = 1\}$ occurs:

$$P(y_i = 1) = F(x_i^t \beta) = \begin{cases} \Phi(x_i^t \beta) & \text{(probit)} \\ \Lambda(x_i^t \beta) & \text{(logit)} \end{cases}$$
The log-likelihood function is

\[ \ell = \sum_{i=1}^{N} \left\{ y_i \log[F(x'_i \beta)] + (1 - y_i) \log[1 - F(x'_i \beta)] \right\} \]

where the CDF \( F(x) \) is defined as \( \Phi(x) \) for the probit model while \( F(x) = \Lambda(x) \) for logit. The first order derivatives of the logit model are

\[ \frac{\partial \ell}{\partial \beta} = \sum_{i=1}^{N} (y_i - \Lambda(x'_i \beta)) x_i \]

The probit model has more complicated derivatives

\[ \frac{\partial \ell}{\partial \beta} = \sum_{i=1}^{N} \left[ \frac{(2y_i - 1)\phi(x'_i \beta)}{\Phi(x'_i \beta)} \right] x_i = \sum_{i=1}^{N} r_i x_i \]

where

\[ r_i = \frac{(2y_i - 1)\phi(x'_i \beta)}{\Phi(x'_i \beta)} \]

Note that the logit maximum likelihood estimates are \( \frac{\pi^2}{3} \) times greater than probit maximum likelihood estimates, since the probit parameter estimates, \( \beta \), are standardized, and the error term with logistic distribution has a variance of \( \frac{\pi^2}{3} \).

**Ordinal Probit/Logit**

When the dependent variable is observed in sequence with \( M \) categories, binary discrete choice modeling is not appropriate for data analysis. McKelvey and Zavoina (1975) proposed the ordinal (or ordered) probit model.

Consider the following regression equation:

\[ y^*_i = x'_i \beta + \epsilon_i \]

where error disturbances, \( \epsilon_i \), have the distribution function \( F \). The unobserved continuous random variable, \( y^*_i \), is identified as \( M \) categories. Suppose there are \( M + 1 \) real numbers, \( \mu_0, \cdots, \mu_M \), where \( \mu_0 = -\infty \), \( \mu_1 = 0 \), \( \mu_M = \infty \), and \( \mu_0 \leq \mu_1 \leq \cdots \leq \mu_M \). Define

\[ R_{i,j} = \mu_j - x'_i \beta \]

The probability that the unobserved dependent variable is contained in the \( j \)th category can be written as

\[ P[\mu_{j-1} < y^*_i \leq \mu_j] = F(R_{i,j}) - F(R_{i,j-1}) \]

The log-likelihood function is

\[ \ell = \sum_{i=1}^{N} \sum_{j=1}^{M} d_{ij} \log \left[ F(R_{i,j}) - F(R_{i,j-1}) \right] \]
where

\[
d_{ij} = \begin{cases} 
1 & \text{if } \mu_{j-1} < y_i \leq \mu_j \\
0 & \text{otherwise}
\end{cases}
\]

The first derivatives are written as

\[
\frac{\partial \ell}{\partial \beta} = \sum_{i=1}^{N} \sum_{j=1}^{M} d_{ij} \left[ \frac{f(R_{i,j-1}) - f(R_{i,j})}{F(R_{i,j}) - F(R_{i,j-1})} x_i \right]
\]

\[
\frac{\partial \ell}{\partial \mu_k} = \sum_{i=1}^{N} \sum_{j=1}^{M} d_{ij} \left[ \frac{\delta_{j,k} f(R_{i,j}) - \delta_{j-1,k} f(R_{i,j-1})}{F(R_{i,j}) - F(R_{i,j-1})} \right]
\]

where \( f(x) = \frac{dF(x)}{dx} \) and \( \delta_{j,k} = 1 \) if \( j = k \), and \( \delta_{j,k} = 0 \) otherwise. When the ordinal probit is estimated, it is assumed that \( F(R_{i,j}) = \Phi(R_{i,j}) \). The ordinal logit model is estimated if \( F(R_{i,j}) \neq \Lambda(R_{i,j}) \). The first threshold parameter, \( \mu_1 \), is estimated when the LIMIT1=VARYING option is specified. By default (LIMIT1=ZERO), so that \( M-2 \) threshold parameters (\( \mu_2, \ldots, \mu_{M-1} \)) are estimated.

The ordered probit models are analyzed by Aitchison and Silvey (1957), and Cox (1970) discussed ordered response data by using the logit model. They defined the probability that \( y_i \) belongs to \( j \)th category as

\[
P[\mu_{j-1} < y_i \leq \mu_j] = F(\mu_j + x_i^\prime \theta) - F(\mu_{j-1} + x_i^\prime \theta)
\]

where \( \mu_0 = -\infty \) and \( \mu_M = \infty \). Therefore, the ordered response model analyzed by Aitchison and Silvey can be estimated if the LIMIT1=VARYING option is specified. Note that \( \theta = -\beta \).

**Goodness-of-Fit Measures**

The goodness-of-fit measures discussed in this section apply only to discrete dependent variable models.

McFadden (1974) suggested a likelihood ratio index that is analogous to the \( R^2 \) in the linear regression model:

\[
R^2_M = 1 - \frac{\ln L}{\ln L_0}
\]

where \( L \) is the value of the maximum likelihood function and \( L_0 \) is the value of a likelihood function when regression coefficients except an intercept term are zero. It can be shown that \( L_0 \) can be written as

\[
L_0 = \sum_{j=1}^{M} N_j \ln \left( \frac{N_j}{N} \right)
\]

where \( N_j \) is the number of responses in category \( j \).

Estrella (1998) proposes the following requirements for a goodness-of-fit measure to be desirable in discrete choice modeling:

- The measure must take values in \([0, 1]\), where 0 represents no fit and 1 corresponds to perfect fit.
- The measure should be directly related to the valid test statistic for significance of all slope coefficients.
• The derivative of the measure with respect to the test statistic should comply with corresponding
derivatives in a linear regression.

Estrella’s (1998) measure is written

$$R_{E1}^2 = 1 - \left( \frac{\ln L}{\ln L_0} \right)^{-\frac{2}{N}} \ln L_0$$

An alternative measure suggested by Estrella (1998) is

$$R_{E2}^2 = 1 - \left[ \frac{(\ln L - K)}{\ln L_0} \right]^{-\frac{2}{N}} \ln L_0$$

where $\ln L_0$ is computed with null slope parameter values, $N$ is the number observations used, and $K$
represents the number of estimated parameters.

Other goodness-of-fit measures are summarized as follows:

$$R_{CU1}^2 = 1 - \left( \frac{L_0}{L} \right)^{\frac{2}{N}}$$ (Cragg – Uhler1)

$$R_{CU2}^2 = \frac{1 - (L_0/L)^{\frac{2}{N}}}{1 - L_0^{\frac{2}{N}}}$$ (Cragg – Uhler2)

$$R_A^2 = \frac{2(\ln L - \ln L_0)}{2(\ln L - \ln L_0) + N}$$ (Aldrich – Nelson)

$$R_{VZ}^2 = R_A^2 \frac{2\ln L_0 - N}{2\ln L_0}$$ (Veall – Zimmermann)

$$R_{MZ}^2 = \frac{\sum_{i=1}^{N}(\hat{y}_i - \bar{\tilde{y}})^2}{N + \sum_{i=1}^{N}(\hat{y}_i - \hat{y})^2}$$ (McKelvey – Zavoina)

where $\hat{y}_i = x'_i \hat{\beta}$ and $\tilde{y}_i = \sum_{i=1}^{N} \hat{y}_i / N$.

---

### Limited Dependent Variable Models

#### Censored Regression Models

When the dependent variable is censored, values in a certain range are all transformed to a single value. For
example, the standard tobit model can be defined as

$$y_i^* = x'_i \beta + \epsilon_i$$

$$y_i = \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases}$$

where $\epsilon_i \sim i.i.d. N(0, \sigma^2)$. The log-likelihood function of the standard censored regression model is

$$\ell = \sum_{i \in \{y_i = 0\}} \ln[1 - \Phi(x'_i \beta / \sigma)] + \sum_{i \in \{y_i > 0\}} \ln \left[ \phi \left( \frac{y_i - x'_i \beta}{\sigma} \right) / \sigma \right]$$
where $\Phi(\cdot)$ is the cumulative density function of the standard normal distribution and $\phi(\cdot)$ is the probability density function of the standard normal distribution.

The tobit model can be generalized to handle observation-by-observation censoring. The censored model on both of the lower and upper limits can be defined as

$$y_i = \begin{cases} R_i & \text{if } y_i^* \geq R_i \\ y_i^* & \text{if } L_i < y_i^* < R_i \\ L_i & \text{if } y_i^* \leq L_i \end{cases}$$

The log-likelihood function can be written as

$$\ell = \sum_{i \in \{L_i < y_i < R_i\}} \ln \left[ \phi(\frac{y_i - x_i'\beta}{\sigma})/\sigma \right] + \sum_{i \in \{y_i = R_i\}} \ln \left[ \Phi(-\frac{R_i - x_i'\beta}{\sigma}) \right] + \sum_{i \in \{y_i = L_i\}} \ln \left[ \Phi(\frac{L_i - x_i'\beta}{\sigma}) \right]$$

Log-likelihood functions of the lower- or upper-limit censored model are easily derived from the two-limit censored model. The log-likelihood function of the lower-limit censored model is

$$\ell = \sum_{i \in \{y_i > L_i\}} \ln \left[ \phi(\frac{y_i - x_i'\beta}{\sigma})/\sigma \right] + \sum_{i \in \{y_i = L_i\}} \ln \left[ \Phi(\frac{L_i - x_i'\beta}{\sigma}) \right]$$

The log-likelihood function of the upper-limit censored model is

$$\ell = \sum_{i \in \{y_i < R_i\}} \ln \left[ \phi(\frac{y_i - x_i'\beta}{\sigma})/\sigma \right] + \sum_{i \in \{y_i = R_i\}} \ln \left[ 1 - \Phi(\frac{R_i - x_i'\beta}{\sigma}) \right]$$

Types of Tobit Models

Amemiya (1984) classified Tobit models into five types based on characteristics of the likelihood function. For notational convenience, let $P$ denote a distribution or density function, $y_{ji}^*$ is assumed to be normally distributed with mean $x_{ji}'\beta_j$ and variance $\sigma_j^2$.

**Type 1 Tobit**

The Type 1 Tobit model was already discussed in the preceding section.

$$y_{1i}^* = x_{1i}'\beta_1 + u_{1i}$$

$$y_{1i} = y_{1i}^* \text{ if } y_{1i}^* > 0$$

$$= 0 \text{ if } y_{1i}^* \leq 0$$

The likelihood function is characterized as $P(y_1 < 0)P(y_1)$. 
**Type 2 Tobit**

The Type 2 Tobit model is defined as

\[
\begin{align*}
y_{1i}^* &= x'_{1i} \beta_1 + u_{1i} \\
y_{2i}^* &= x'_{2i} \beta_2 + u_{2i} \\
y_{1i} &= 1 \text{ if } y_{1i}^* > 0 \\
&= 0 \text{ if } y_{1i}^* \leq 0 \\
y_{2i} &= y_{2i}^* \text{ if } y_{1i}^* > 0 \\
&= 0 \text{ if } y_{1i}^* \leq 0
\end{align*}
\]

where \((u_{1i}, u_{2i}) \sim N(0, \Sigma)\). The likelihood function is described as \(P(y_1 < 0) P(y_1 > 0, y_2)\).

**Type 3 Tobit**

The Type 3 Tobit model is different from the Type 2 Tobit in that \(y_{1i}^*\) of the Type 3 Tobit is observed when \(y_{1i}^* > 0\).

\[
\begin{align*}
y_{1i}^* &= x'_{1i} \beta_1 + u_{1i} \\
y_{2i}^* &= x'_{2i} \beta_2 + u_{2i} \\
y_{1i} &= y_{1i}^* \text{ if } y_{1i}^* > 0 \\
&= 0 \text{ if } y_{1i}^* \leq 0 \\
y_{2i} &= y_{2i}^* \text{ if } y_{1i}^* > 0 \\
&= 0 \text{ if } y_{1i}^* \leq 0
\end{align*}
\]

where \((u_{1i}, u_{2i})' \sim i i d N(0, \Sigma)\).

The likelihood function is characterized as \(P(y_1 < 0) P(y_1, y_2)\).

**Type 4 Tobit**

The Type 4 Tobit model consists of three equations:

\[
\begin{align*}
y_{1i}^* &= x'_{1i} \beta_1 + u_{1i} \\
y_{2i}^* &= x'_{2i} \beta_2 + u_{2i} \\
y_{3i}^* &= x'_{3i} \beta_3 + u_{3i} \\
y_{1i} &= y_{1i}^* \text{ if } y_{1i}^* > 0 \\
&= 0 \text{ if } y_{1i}^* \leq 0 \\
y_{2i} &= y_{2i}^* \text{ if } y_{1i}^* > 0 \\
&= 0 \text{ if } y_{1i}^* \leq 0 \\
y_{3i} &= y_{3i}^* \text{ if } y_{1i}^* \leq 0 \\
&= 0 \text{ if } y_{1i}^* > 0
\end{align*}
\]

where \((u_{1i}, u_{2i}, u_{3i})' \sim i i d N(0, \Sigma)\). The likelihood function of the Type 4 Tobit model is characterized as \(P(y_1 < 0, y_3) P(y_1, y_2)\).
Type 5 Tobit

The Type 5 Tobit model is defined as follows:

\[
\begin{align*}
    y_{1i}^* &= x_{1i}'\beta_1 + u_{1i} \\
    y_{2i}^* &= x_{2i}'\beta_2 + u_{2i} \\
    y_{3i}^* &= x_{3i}'\beta_3 + u_{3i} \\
    y_{1i} &= 1 \text{ if } y_{1i}^* > 0 \\
    &= 0 \text{ if } y_{1i}^* \leq 0 \\
    y_{2i} &= y_{1i}^* \text{ if } y_{1i}^* > 0 \\
    &= 0 \text{ if } y_{1i}^* \leq 0 \\
    y_{3i} &= y_{1i}^* \text{ if } y_{1i}^* \leq 0 \\
    &= 0 \text{ if } y_{1i}^* > 0
\end{align*}
\]

where \((u_{1i}, u_{2i}, u_{3i})'\) are from iid trivariate normal distribution. The likelihood function of the Type 5 Tobit model is characterized as \(P(y_1 < 0, y_3)P(y_1 > 0, y_2)\).

Code examples for these models can be found in “Example 22.6: Types of Tobit Models” on page 1588.

Truncated Regression Models

In a truncated model, the observed sample is a subset of the population where the dependent variable falls in a certain range. For example, when neither a dependent variable nor exogenous variables are observed for \(y_i^* \leq 0\), the truncated regression model can be specified.

\[
\ell = \sum_{i \in \{y_i > 0\}} \left\{ -\ln \Phi(x_i'\beta/\sigma) + \ln \left( \frac{\phi((y_i - x_i'\beta)/\sigma)}{\sigma} \right) \right\}
\]

Two-limit truncation model is defined as

\[
y_i = y_i^* \text{ if } L_i < y_i^* < R_i
\]

The log-likelihood function of the two-limit truncated regression model is

\[
\ell = \sum_{i=1}^{N} \left\{ \ln \left( \frac{\phi((y_i - x_i'\beta)/\sigma)}{\sigma} \right) - \ln \left( \Phi\left(\frac{R_i - x_i'\beta}{\sigma}\right) - \Phi\left(\frac{L_i - x_i'\beta}{\sigma}\right) \right) \right\}
\]

The log-likelihood functions of the lower- and upper-limit truncation model are

\[
\ell = \sum_{i=1}^{N} \left\{ \ln \left( \frac{\phi((y_i - x_i'\beta)/\sigma)}{\sigma} \right) - \ln \left( 1 - \Phi\left(\frac{L_i - x_i'\beta}{\sigma}\right) \right) \right\} \quad \text{(lower)}
\]

\[
\ell = \sum_{i=1}^{N} \left\{ \ln \left( \frac{\phi((y_i - x_i'\beta)/\sigma)}{\sigma} \right) - \ln \left( \Phi\left(\frac{R_i - x_i'\beta}{\sigma}\right) \right) \right\} \quad \text{(upper)}
\]
Stochastic Frontier Production and Cost Models

Stochastic frontier production models were first developed by Aigner, Lovell, and Schmidt (1977); Meeusen and van den Broeck (1977). Specification of these models allow for random shocks of the production or cost but also include a term for technological or cost inefficiency. Assuming that the production function takes a log-linear Cobb-Douglas form, the stochastic frontier production model can be written as

$$\ln(y_i) = \beta_0 + \sum_n \beta_n \ln(x_{ni}) + \epsilon_i$$

where $\epsilon_i = v_i - u_i$. The $v_i$ term represents the stochastic error component and $u_i$ is the nonnegative, technology inefficiency error component. The $v_i$ error component is assumed to be distributed iid normal and independently from $u_i$. If $u_i > 0$, the error term, $\epsilon_i$, is negatively skewed and represents technology inefficiency. If $u_i < 0$, the error term $\epsilon_i$ is positively skewed and represents cost inefficiency. PROC QLIM models the $u_i$ error component as a half normal, exponential, or truncated normal distribution.

The Normal-Half Normal Model

In case of the normal-half normal model, $v_i$ is iid $N(0, \sigma_v^2)$, $u_i$ is iid $N^+(0, \sigma_u^2)$ with $v_i$ and $u_i$ independent of each other. Given the independence of error terms, the joint density of $v$ and $u$ can be written as

$$f(u, v) = \frac{2}{2\pi \sigma_u \sigma_v} \exp \left\{ -\frac{u^2}{2\sigma_u^2} - \frac{v^2}{2\sigma_v^2} \right\}$$

Substituting $v = \epsilon + u$ into the preceding equation gives

$$f(u, \epsilon) = \frac{2}{2\pi \sigma_u \sigma_v} \exp \left\{ -\frac{u^2}{2\sigma_u^2} - \frac{(\epsilon + u)^2}{2\sigma_v^2} \right\}$$

Integrating $u$ out to obtain the marginal density function of $\epsilon$ results in the following form:

$$f(\epsilon) = \int_0^\infty f(u, \epsilon) du$$

$$= \frac{2}{\sqrt{2\pi} \sigma} \left[ 1 - \Phi \left( \frac{\epsilon \sigma}{\sigma_u} \right) \right] \exp \left\{ -\frac{\epsilon^2}{2\sigma^2} \right\}$$

$$= \frac{2}{\sigma} \phi \left( \frac{\epsilon}{\sigma} \right) \Phi \left( \frac{\epsilon \sigma}{\sigma_u} \right)$$

where $\lambda = \sigma_u / \sigma_v$ and $\sigma = \sqrt{\sigma_u^2 + \sigma_v^2}$.

In the case of a stochastic frontier cost model, $v = \epsilon - u$ and

$$f(\epsilon) = \frac{2}{\sigma} \phi \left( \frac{\epsilon}{\sigma} \right) \Phi \left( \frac{\epsilon \sigma}{\sigma_v} \right)$$

The log-likelihood function for the production model with $N$ producers is written as

$$\ln L = \text{constant} - N \ln \sigma + \sum_i \ln \Phi \left( -\frac{\epsilon_i \sigma}{\sigma_u} \right) - \frac{1}{2\sigma^2} \sum_i \epsilon_i^2$$
The Normal-Exponential Model

Under the normal-exponential model, \( v_i \) is iid \( N(0, \sigma_v^2) \) and \( u_i \) is iid exponential with scale parameter \( \sigma_u \). Given the independence of error term components \( u_i \) and \( v_i \), the joint density of \( v \) and \( u \) can be written as

\[
f(u, v) = \frac{1}{\sqrt{2\pi \sigma_u \sigma_v}} \exp \left\{ -\frac{u}{\sigma_u} - \frac{v^2}{2\sigma_v^2} \right\}
\]

The marginal density function of \( \epsilon \) for the production function is

\[
f(\epsilon) = \int_0^\infty f(u, \epsilon) \, du = \left( \frac{1}{\sigma_u} \right) \Phi \left( -\frac{\epsilon}{\sigma_v} - \frac{\sigma_v}{\sigma_u} \right) \exp \left\{ -\frac{\epsilon}{\sigma_u} + \frac{\sigma_v^2}{2\sigma_u^2} \right\}
\]

and the marginal density function for the cost function is equal to

\[
f(\epsilon) = \left( \frac{1}{\sigma_u} \right) \Phi \left( \frac{\epsilon}{\sigma_v} - \frac{\sigma_v}{\sigma_u} \right) \exp \left\{ -\frac{\epsilon}{\sigma_u} + \frac{\sigma_v^2}{2\sigma_u^2} \right\}
\]

The log-likelihood function for the normal-exponential production model with \( N \) producers is

\[
\ln L = \text{constant} - N \ln \sigma_u + N \left( \frac{\sigma_v^2}{2\sigma_u^2} \right) + \sum_i \frac{\epsilon_i}{\sigma_u} + \sum_i \ln \Phi \left( -\frac{\epsilon_i}{\sigma_v} - \frac{\sigma_v}{\sigma_u} \right)
\]

The Normal-Truncated Normal Model

The normal-truncated normal model is a generalization of the normal-half normal model by allowing the mean of \( u_i \) to differ from zero. Under the normal-truncated normal model, the error term component \( v_i \) is iid \( N(0, \sigma_v^2) \) and \( u_i \) is iid \( N^+(\mu, \sigma_u^2) \). The joint density of \( v_i \) and \( u_i \) can be written as

\[
f(u, v) = \frac{1}{2\pi \sigma_u \sigma_v \Phi(\mu/\sigma_u)} \exp \left\{ -\frac{(u - \mu)^2}{2\sigma_u^2} - \frac{v^2}{2\sigma_v^2} \right\}
\]

The marginal density function of \( \epsilon \) for the production function is

\[
f(\epsilon) = \int_0^\infty f(u, \epsilon) \, du = \frac{1}{\sqrt{2\pi \sigma \Phi(\mu/\sigma_u)}} \Phi \left( \frac{\mu - \epsilon \lambda}{\sigma} \right) \exp \left\{ -\frac{(\epsilon + \mu)^2}{2\sigma^2} \right\}
\]

and the marginal density function for the cost function is

\[
f(\epsilon) = \frac{1}{\sigma \Phi(\epsilon/\lambda)} \Phi \left( \frac{\mu + \epsilon \lambda}{\sigma u} \right) \left[ \Phi \left( \frac{\mu}{\sigma u} \right) \right]^{-1}
\]
The log-likelihood function for the normal-truncated normal production model with $N$ producers is

$$
\ln L = \text{constant} - N \ln \sigma - N \ln \Phi \left( \frac{\mu}{\sigma u} \right) + \sum_i \ln \Phi \left( \frac{\mu_i - \epsilon_i}{\sigma} \right) - \frac{1}{2} \sum_i \left( \frac{\epsilon_i + \mu_i}{\sigma} \right)^2
$$

For more detail on normal-half normal, normal-exponential, and normal-truncated models, see Kumbhakar and Lovell (2000); Coelli, Prasada Rao, and Battese (1998).

### Heteroscedasticity and Box-Cox Transformation

#### Heteroscedasticity

If the variance of regression disturbance, $(\epsilon_i)$, is heteroscedastic, the variance can be specified as a function of variables

$$E(\epsilon_i^2) = \sigma_i^2 = f(x_i', y)
$$

The following table shows various functional forms of heteroscedasticity and the corresponding options to request each model.

<table>
<thead>
<tr>
<th>No.</th>
<th>Model</th>
<th>Options</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>$f(x_i', y) = \sigma_i^2(1 + \exp(z_i', \gamma))$</td>
<td>LINK=EXP (default)</td>
</tr>
<tr>
<td>2</td>
<td>$f(x_i', y) = \sigma_i^2 \exp(z_i', \gamma)$</td>
<td>LINK=EXP NOCONST</td>
</tr>
<tr>
<td>3</td>
<td>$f(x_i', y) = \sigma_i^2(1 + \sum_{l=1}^{L} y_l z_{li})$</td>

<tr>
<td>4</td>
<td>$f(x_i', y) = \sigma_i^2(1 + (\sum_{l=1}^{L} y_l z_{li})^2)$</td>
<td>LINK=LINEAR SQUARE</td>
</tr>
</tbody>
</table>

For discrete choice models, $\sigma_i^2$ is normalized ($\sigma_i^2 = 1$) since this parameter is not identified. Note that in models 3 and 5, it may be possible that variances of some observations are negative. Although the QLIM procedure assigns a large penalty to move the optimization away from such region, it is possible that the optimization cannot improve the objective function value and gets locked in the region. Signs of such outcome include extremely small likelihood values or missing standard errors in the estimates. In models 2 and 6, variances are guaranteed to be greater or equal to zero, but it may be possible that variances of some observations are very close to zero. In these scenarios, standard errors may be missing. Models 1 and 4 do not have such problems. Variances in these models are always positive and never close to zero.

The heteroscedastic regression model is estimated using the following log-likelihood function:

$$
\ell = -\frac{N}{2} \ln(2\pi) - \sum_{i=1}^{N} \frac{1}{2} \ln(\sigma_i^2) - \frac{1}{2} \sum_{i=1}^{N} \left( \frac{e_i}{\sigma_i} \right)^2
$$

where $e_i = y_i - x_i' \beta$. 
Box-Cox Modeling

The Box-Cox transformation on \( x \) is defined as
\[
  x^{(\lambda)} = \begin{cases} 
    \frac{x^{\lambda} - 1}{\lambda} & \text{if } \lambda \neq 0 \\
    \ln(x) & \text{if } \lambda = 0 
  \end{cases}
\]

The Box-Cox regression model with heteroscedasticity is written as
\[
  y_i^{(\lambda_0)} = \beta_0 + \sum_{k=1}^{K} \beta_k x_i^{(\lambda_k)} + \epsilon_i = \mu_i + \epsilon_i
\]

where \( \epsilon_i \sim N(0, \sigma_i^2) \) and transformed variables must be positive. In practice, too many transformation parameters cause numerical problems in model fitting. It is common to have the same Box-Cox transformation performed on all the variables — that is, \( \lambda_0 = \lambda_1 = \cdots = \lambda_K \). It is required for the magnitude of transformed variables to be in the tolerable range if the corresponding transformation parameters are \( |\lambda| > 1 \).

The log-likelihood function of the Box-Cox regression model is written as
\[
  \ell = -\frac{N}{2} \ln(2\pi) - \sum_{i=1}^{N} \ln(\sigma_i) - \frac{1}{2\sigma_i^2} \sum_{i=1}^{N} e_i^2 + (\lambda_0 - 1) \sum_{i=1}^{N} \ln(y_i)
\]

where \( e_i = y_i^{(\lambda_0)} - \mu_i \).

When the dependent variable is discrete, censored, or truncated, the Box-Cox transformation can be applied only to explanatory variables.

Bivariate Limited Dependent Variable Modeling

The generic form of a bivariate limited dependent variable model is
\[
  \begin{align*}
    y_{1i}^* &= x_{1i}' \beta_1 + \epsilon_{1i} \\
    y_{2i}^* &= x_{2i}' \beta_2 + \epsilon_{2i}
  \end{align*}
\]

where the disturbances, \( \epsilon_{1i} \) and \( \epsilon_{2i} \), have joint normal distribution with zero mean, standard deviations \( \sigma_1 \) and \( \sigma_2 \), and correlation of \( \rho \). \( y_{1i}^* \) and \( y_{2i}^* \) are latent variables. The dependent variables \( y_1 \) and \( y_2 \) are observed if the latent variables \( y_1^* \) and \( y_2^* \) fall in certain ranges:
\[
  \begin{align*}
    y_1 &= y_{1i} \text{ if } y_{1i}^* \in D_1(y_{1i}) \\
    y_2 &= y_{2i} \text{ if } y_{2i}^* \in D_2(y_{2i})
  \end{align*}
\]

\( D \) is a transformation from \((y_{1i}^*, y_{2i}^*)\) to \((y_{1i}, y_{2i})\). For example, if \( y_1 \) and \( y_2 \) are censored variables with lower bound 0, then
\[
  \begin{align*}
    y_1 &= y_{1i} \text{ if } y_{1i}^* > 0, & y_1 &= 0 \text{ if } y_{1i}^* \leq 0 \\
    y_2 &= y_{2i} \text{ if } y_{2i}^* > 0, & y_2 &= 0 \text{ if } y_{2i}^* \leq 0
  \end{align*}
\]
There are three cases for the log likelihood of \( y_{1i}, y_{2i} \). The first case is that \( y_{1i} = y_{1i}^* \) and \( y_{2i} = y_{2i}^* \). That is, this observation is mapped to one point in the space of latent variables. The log likelihood is computed from a bivariate normal density,

\[
\ell_i = \ln \left( \phi_2(\frac{y_{1i} - x_{1i}' \beta_1}{\sigma_1}, \frac{y_{2i} - x_{2i}' \beta_2}{\sigma_2}, \rho) \right) - \ln \sigma_1 - \ln \sigma_2
\]

where \( \phi_2(u, v, \rho) \) is the density function for standardized bivariate normal distribution with correlation \( \rho \),

\[
\phi_2(u, v, \rho) = \frac{e^{-(1/2)(u^2 + v^2 - 2\rho uv)/(1 - \rho^2)}}{2\pi(1 - \rho^2)^{1/2}}
\]

The second case is that one observed dependent variable is mapped to a point of its latent variable and the other dependent variable is mapped to a segment in the space of its latent variable. For example, in the bivariate censored model specified, if observed \( y_{1i} > 0 \) and \( y_{2i} = 0 \), then \( y_{1i}^* = y_{1i} \) and \( y_{2i}^* \in (-\infty, 0] \). In general, the log likelihood for one observation can be written as follows (the subscript \( i \) is dropped for simplicity):

\[
\ell_i = \ln \left[ \phi \left( \frac{y_{1i} - x_{1i}' \beta_1}{\sigma_1} \right) \right] - \ln \sigma_1 + \ln \left[ \Phi \left( \frac{R_2 - x_{2i}' \beta_2 - \rho \frac{y_{1i} - x_{1i}' \beta_1}{\sigma_1}}{\sigma_2} \right) - \Phi \left( \frac{L_2 - x_{2i}' \beta_2 - \rho \frac{y_{1i} - x_{1i}' \beta_1}{\sigma_1}}{\sigma_2} \right) \right]
\]

where \( \phi \) and \( \Phi \) are the density function and the cumulative probability function for standardized univariate normal distribution.

The third case is that both dependent variables are mapped to segments in the space of latent variables. For example, in the bivariate censored model specified, if observed \( y_{1i} = 0 \) and \( y_{2i} = 0 \), then \( y_{1i}^* \in (-\infty, 0] \) and \( y_{2i}^* \in (-\infty, 0] \). In general, if \( D_1(y_1) = [L_1, R_1] \) and \( D_2(y_2) = [L_2, R_2] \), the log likelihood is

\[
\ell_i = \ln \int_{L_1 - x_{1i}' \beta_1 \sigma_1}^{R_1 - x_{1i}' \beta_1 \sigma_1} \int_{L_2 - x_{2i}' \beta_2 \sigma_2}^{R_2 - x_{2i}' \beta_2 \sigma_2} \phi_2(u, v, \rho) \, du \, dv
\]

Selection Models

In sample selection models, one or several dependent variables are observed when another variable takes certain values. For example, the standard Heckman selection model can be defined as

\[
z_{1i}^* = w_{1i}' y + u_{1i}
\]

\[
z_{i} = \begin{cases} 
1 & \text{if } z_{1i}^* > 0 \\
0 & \text{if } z_{1i}^* \leq 0 
\end{cases}
\]

\[
y_{i} = x_{i}' \beta + \epsilon_{i} \quad \text{if } z_{i} = 1
\]

where \( u_{1i} \) and \( \epsilon_{i} \) are jointly normal with 0 mean, standard deviations of 1 and \( \sigma_u \), respectively, and correlation of \( \rho \). Selection is based on the variable \( z \), and \( y \) is observed when \( z \) has a value of 1. Least squares regression
that uses the observed data of $y$ produces inconsistent estimates of $\beta$. The maximum likelihood method is used to estimate selection models. It is also possible to estimate these models by using Heckman’s method, which is more computationally efficient. But it can be shown that the resulting estimates, although consistent, are not asymptotically efficient under a normality assumption. Moreover, this method often violates the constraint on the correlation coefficient $|\rho| \leq 1$.

The log-likelihood function of the Heckman selection model is written as

$$
\ell = \sum_{i \in \{z_i = 0\}} \ln[1 - \Phi(w_i'y)] + \sum_{i \in \{z_i = 1\}} \left\{ \ln \phi \left( \frac{y_i - x_i'\beta}{\sigma} \right) - \ln \sigma + \ln \Phi \left( \frac{w_i'y + \rho \frac{y_i - x_i'\beta}{\sigma}}{\sqrt{1 - \rho^2}} \right) \right\}
$$

The selection can be based on only one variable, but the selection can lead to several variables. For example, selection is based on the variable $z$ in the following switching regression model:

$$
z_i^* = w_i'y + u_i
$$

$$
z_i = \begin{cases} 
1 & \text{if } z_i^* > 0 \\
0 & \text{if } z_i^* \leq 0
\end{cases}
$$

$$
y_{1i} = x_{1i}'\beta_1 + \epsilon_{1i} \quad \text{if } z_i = 0
$$

$$
y_{2i} = x_{2i}'\beta_2 + \epsilon_{2i} \quad \text{if } z_i = 1
$$

If $z = 0$, then $y_1$ is observed. If $z = 1$, then $y_2$ is observed. Because $y_1$ and $y_2$ are never observed at the same time, the correlation between $y_1$ and $y_2$ cannot be estimated. Only the correlation between $z$ and $y_1$ and the correlation between $z$ and $y_2$ can be estimated. This estimation uses the maximum likelihood method.

A brief example of the SAS statements for this model can be found in “Example 22.4: Sample Selection Model” on page 1584.

The Heckman selection model can include censoring or truncation. For a brief example of the SAS statements for these models see “Example 22.5: Sample Selection Model with Truncation and Censoring” on page 1585. The following example shows a variable $y_i$ that is censored from below at zero:

$$
z_i^* = w_i'y + u_i
$$

$$
z_i = \begin{cases} 
1 & \text{if } z_i^* > 0 \\
0 & \text{if } z_i^* \leq 0
\end{cases}
$$

$$
y_{i}^* = x_{i}'\beta + \epsilon_i \quad \text{if } z_i = 1
$$

$$
y_i = \begin{cases} 
y_{i}^* & \text{if } y_{i}^* > 0 \\
0 & \text{if } y_{i}^* \leq 0
\end{cases}
$$
In this case, the log-likelihood function of the Heckman selection model needs to be modified as follows to include the censored region:

\[
\ell = \sum_{i \mid z_i = 0} \ln[1 - \Phi(w_i'y)]
+ \sum_{i \mid z_i = 1, y_i = y_i^*} \left\{ \ln \left[ \phi\left( \frac{y_i - x_i'\beta}{\sigma} \right) \right] - \ln \sigma + \ln \left[ \Phi\left( \frac{w_i'y + \rho \frac{y_i - x_i'\beta}{\sigma}}{\sqrt{1 - \rho^2}} \right) \right] \right\}
+ \sum_{i \mid z_i = 1, y_i = 0} \int_{-\infty}^{\infty} \int_{-w_i'y}^{\infty} \phi_2(u, v, \rho) \, du \, dv
\]

In case \( y_i \) is truncated from below at 0 instead of censored, the likelihood function can be written as

\[
\ell = \sum_{i \mid z_i = 0} \ln[1 - \Phi(w_i'y)]
+ \sum_{i \mid z_i = 1} \left\{ \ln \left[ \phi\left( \frac{y_i - x_i'\beta}{\sigma} \right) \right] - \ln \sigma + \ln \left[ \Phi\left( \frac{w_i'y + \rho \frac{y_i - x_i'\beta}{\sigma}}{\sqrt{1 - \rho^2}} \right) \right] - \ln \left[ \Phi(x_i'\beta/\sigma) \right] \right\}
\]

**Heckman’s Two-Step Selection Method**

Sample selection bias arises from nonrandom selection of the sample from the population. A classic example is using a sample of market wages for working women to estimate female labor supply function. This sample is nonrandom because it includes only the wages of women whose market wage exceeds their home wage at zero hours of work.

A simple selection model can be written as the latent model

\[
z_i^* = w_i'y + u_i
\]

\[
z_i = \begin{cases} 
1 & \text{if } z_i^* > 0 \\
0 & \text{if } z_i^* \leq 0
\end{cases}
\]

\[
y_i = x_i'\beta + \epsilon_i \quad \text{if } z_i = 1
\]

where \( u_i \) and \( \epsilon_i \) are jointly normal with 0 mean, standard deviations of 1 and \( \sigma \), respectively, and correlation of \( \rho \). The dependent variable \( y_i \) (wage) is observed if the latent variable \( z_i^* \) (the difference between market wage and reservation wage) is positive or if the indicator variable \( z_i \) (labor force participation) is 1.

The model of interest that applies to the observations in the selected sample can be written as

\[
E(y_i|x_i, z_i = 1) = x_i'\beta + \rho \sigma \lambda(w_i'y)
\]

where \( \lambda(w_i'y) = \phi(w_i'y) / \Phi(w_i'y) \). Hence, the following regression equation is valid for the observations for which \( z_i = 1 \):

\[
y_i = x_i'\beta + \rho \sigma \lambda(w_i'y) + v_i
\]
Therefore, estimates of \( \beta \) that are obtained from the OLS regression of \( y \) on \( x \) by using the selected sample (that is, the sample for which \( z_i = 1 \)) suffer from omitted variable bias if selection bias is really the case. Although maximum likelihood estimation of \( \beta \) is consistent and efficient, Heckman's two-step method is more frequently used. Heckman's two-step method can be requested by specifying the HECKIT option of the QLIM statement.

Heckman's two-step method is as follows:

1. Obtain \( \hat{\lambda} \), the estimate of the parameters of the probability that \( z_i^* > 0 \), by using regressors \( w_i \) and the binary dependent variable \( z_i \) by probit analysis for the full sample. Compute \( \hat{\lambda}_i = \lambda(w_i' \hat{\lambda}) \).

2. Obtain \( \hat{\beta} \) and \( \hat{\beta}_{\lambda} \), the estimates of \( \beta \) and \( \rho \), by least squares regression of \( y_i \) on \( x_i \) and \( \hat{\lambda}_i \) by using observations on the selected subsample.

The standard least squares estimators of the population variance \( \sigma^2 \) and the variances of the estimated coefficients are incorrect. To test hypotheses, the correct ones need to be calculated. An estimator of \( \sigma^2 \) is

\[
\hat{\sigma}^2 = \frac{1}{N_1} \sum_{i=1}^{N_1} e_i^2 + \hat{\rho}_\lambda^2 \frac{1}{N_1} \sum_{i=1}^{N_1} \delta_i
\]

where \( N_1 \) is the selected subsample size, \( e_i \) is the residual for the \( i \)th observation obtained from step 2, and \( \delta_i = \hat{\lambda}_i^2 + \hat{\lambda}_i w_i' \hat{\lambda} \). Let \( X_* \) be an \( N_1 \times (K + 1) \) matrix with \( i \)th row \( [x_i' \ \lambda_i] \), and define \( W \) similarly with \( i \)th row \( w_i' \). Then the estimator of the asymptotic covariance of \( [\hat{\beta}, \hat{\beta}_{\lambda}] \) is

\[
\text{EstAsyVar}[\hat{\beta}, \hat{\beta}_{\lambda}] = \hat{\sigma}^2 [X_*' X_*]^{-1} [X_*' (I - \hat{\rho}^2 \hat{\Delta}) X_* + Q][X_*' X_*]^{-1}
\]

where \( \hat{\rho}^2 = \hat{\rho}_\lambda^2 / \hat{\sigma}^2 \), \( \hat{\Delta} = \text{diag}(\delta_i) \), and

\[
Q = \hat{\sigma}^2 (X_*' \hat{\Delta} W)\text{Est.Asy.Var}(\hat{\lambda})(W' \hat{\Delta} X_*)
\]

where \( \text{Est.Asy.Var}(\hat{\lambda}) \) is the estimator of the asymptotic covariance of the probit coefficients that are obtained in step 1. When you specify the HECKIT option, PROC QLIM uses a numerical estimated asymptotic variance.

When the HECKIT option is specified, PROC QLIM reports the corrected standard errors for \( [\hat{\beta}, \hat{\beta}_{\lambda}] \) automatically. However, if you need the conventional OLS standard errors, you can specify the HECKIT(UNCORRECTED) option.

In the selected regression model, when the coefficient of \( \lambda(w_i' y) \) is 0, you do not need Heckman’s two-step estimation method; a simple regression of \( y \) on \( x \) produces consistent estimates for \( \beta \), and the OLS standard errors are correct. Thus, a standard \( t \) test on \( \hat{\beta}_{\lambda} \) (which uses the estimate from step 2 and the uncorrected standard errors) is a valid test of the null hypothesis of no selection bias.

Although Heckman’s two-step method uses the OLS method in the second stage, you can request the ML method by specifying the HECKIT(SECONDSTAGE=ML) option. When the second-stage method is the ML method, the model for \( y_i \) can be nonlinear.
Multivariate Limited Dependent Models

The multivariate model is similar to bivariate models. The generic form of the multivariate limited dependent variable model is

\[
\begin{align*}
  y_{1i}^* &= x_{1i}' \beta_1 + \epsilon_{1i} \\
  y_{2i}^* &= x_{2i}' \beta_2 + \epsilon_{2i} \\
  \vdots \\
  y_{mi}^* &= x_{mi}' \beta_m + \epsilon_{mi}
\end{align*}
\]

where \( m \) is the number of models to be estimated. The vector \( \epsilon \) has multivariate normal distribution with mean 0 and variance-covariance matrix \( \Sigma \). Similar to bivariate models, the likelihood may involve computing multivariate normal integrations. This is done using Monte Carlo integration. (See Genz (1992); Hajivassiliou and McFadden (1998).)

When the number of equations, \( N \), increases in a system, the number of parameters increases at the rate of \( N^2 \) because of the correlation matrix. When the number of parameters is large, sometimes the optimization converges but some of the standard deviations are missing. This usually means that the model is over-parameterized. The default method for computing the covariance is to use the inverse Hessian matrix. The Hessian is computed by finite differences, and in over-parameterized cases, the inverse cannot be computed. It is recommended that you reduce the number of parameters in such cases. Sometimes using the outer product covariance matrix (COVEST=OP option) may also help.

Variable Selection

Variable Selection

Variable selection uses either Akaike’s information criterion (AIC) or the Schwartz Bayesian criterion (SBC) and either a forward selection method or a backward elimination method.

Forward selection starts from a small subset of variables. In each step, the variable that gives the largest decrease in the value of the information criterion specified in the CRITER= option (AIC or SBC) is added. The process stops when the next candidate to be added does not reduce the value of the information criterion by more than the amount specified in the LSTOP= option in the MODEL statement.

Backward elimination starts from a larger subset of variables. In each step, one variable is dropped based on the information criterion that is chosen.

Tests on Parameters

Tests on Parameters

In general, the hypothesis tested can be written as

\[ H_0 : h(\theta) = 0 \]
where \( h(\theta) \) is an \( r \) by 1 vector valued function of the parameters \( \theta \) given by the \( r \) expressions specified in the TEST statement.

Let \( \hat{V} \) be the estimate of the covariance matrix of \( \hat{\theta} \). Let \( \hat{\theta} \) be the unconstrained estimate of \( \theta \) and \( \tilde{\theta} \) be the constrained estimate of \( \theta \) such that \( h(\tilde{\theta}) = 0 \). Let

\[
A(\theta) = \frac{\partial h(\theta)}{\partial \theta} \bigg|_{\hat{\theta}}
\]

Using this notation, the test statistics for the three kinds of tests are computed as follows.

The Wald test statistic is defined as

\[
W = h'(\hat{\theta}) \left( A(\hat{\theta}) \hat{V} A'(\hat{\theta}) \right)^{-1} h(\hat{\theta})
\]

The Wald test is not invariant to reparameterization of the model (Gregory and Veall 1985, Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

The Lagrange multiplier test statistic is

\[
LM = \lambda' A(\hat{\theta}) \hat{V} A'(\hat{\theta}) \lambda
\]

where \( \lambda \) is the vector of Lagrange multipliers from the computation of the restricted estimate \( \tilde{\theta} \).

The likelihood ratio test statistic is

\[
LR = 2 \left( L(\hat{\theta}) - L(\tilde{\theta}) \right)
\]

where \( \tilde{\theta} \) represents the constrained estimate of \( \theta \) and \( L \) is the concentrated log-likelihood value.

For each kind of test, under the null hypothesis the test statistic is asymptotically distributed as a \( \chi^2 \) random variable with \( r \) degrees of freedom, where \( r \) is the number of expressions in the TEST statement. The \( p \)-values reported for the tests are computed from the \( \chi^2(r) \) distribution and are only asymptotically valid.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation to its small sample distribution than that of the other two tests. However, the Wald test has the lowest computational cost, since it does not require computation of the constrained estimate \( \tilde{\theta} \).

The following is an example of using the TEST statement to perform a likelihood ratio test:

```
proc qlim;
    model y = x1 x2 x3;
    test x1 = 0, x2 * .5 + 2 * x3 = 0 /lr;
run;
```

**Endogeneity and Instrumental Variables**

The PROC QLIM models such as qualitative response or limited dependent variable models assume that the errors are independent of the explanatory variables. If this assumption fails to hold, the distributional form that the likelihood is based on is misspecified and the obtained coefficients are inconsistent.
To begin, consider a linear model

\[ y_i = y_i^* = \beta_0 + \beta_1 x_{1i} + \cdots + \beta_k x_{ki} + u_i \]

Assume that \( E(u) = 0, \text{Cov}(x_j, u) = 0 \) for \( j = 1, \ldots, k - 1 \), and \( \text{Cov}(x_k, u) = \rho \neq 0 \). Therefore, \( x_k \) is endogenous. The endogeneity comes from many sources, such as \( x_k \) having measurement error or omitting a variable that is correlated with \( x_k \). If you ignore the endogeneity, you can estimate this model in PROC QLIM as follows (assuming \( k = 4 \)):

```plaintext
proc qlim data=a;
  model y = x1 x2 x3 x4;
run;
```

However, this approach produces inconsistent maximum likelihood estimates. To obtain consistent maximum likelihood estimates, you should consider the joint density of the dependent variable and the endogenous variables. To do this in PROC QLIM, you need at least one instrument—that is, an observable variable, \( z_1 \)—that is not in the structural equation and that satisfies two conditions: \( z_1 \) is exogenous (that is, \( \text{Cov}(z_1, u) = 0 \)), and \( z_1 \) must be correlated with the endogenous regressor \( x_k \). Then, you can model \( x_k \) as

\[ x_{ki} = \pi_0 + \pi_1 x_{1i} + \cdots + \pi_{k-1} x_{(k-1)i} + \theta z_{1i} + \epsilon_i \]

You can now write this reduced form equation along with the structural equation to obtain the consistent maximum likelihood estimates as follows:

```plaintext
proc qlim data=a;
  model y = x1 x2 x3 x4;
  model x4 = x1 x2 x3 z1;
run;
```

Estimating the structural model together with the reduced form models for the endogenous explanatory variables gives you the full information maximum likelihood (FIML) estimates. Because of the linearity of the model, you can estimate it efficiently and more simply by using the two-stage least squares estimator. However, PROC QLIM handles nonlinear models such as qualitative response and limited dependent variable models, and in their estimation it maximizes the corresponding joint likelihood function. In the case of endogeneity, when the reduced form models for the endogenous explanatory variables are written along with the structural model, PROC QLIM maximizes the likelihood function that is obtained from the joint density of the response variable and the endogenous explanatory variables. For example, consider the following censored regression model in which one of the explanatory variables is a continuous endogenous variable:

\[
\begin{align*}
  y_{1i}^* &= \alpha y_{2i} + \beta' x_{1i} + u_i \\
  y_{2i} &= \beta' x_{1i} + \epsilon_i \\
  y_{1i} &= \begin{cases} 
  y_{1i}^* & \text{if } y_{1i}^* > 0 \\
  0 & \text{if } y_{1i}^* \leq 0
  \end{cases}
\end{align*}
\]

The exogenous explanatory variables are \( z_{1i} \), and the continuous endogenous explanatory variable is \( y_{2i} \). The likelihood function to maximize is

\[
L = \prod_{i \in \{y_{1i} > 0\}} f(y_{1i}, y_{2i}) \cdot \prod_{i \in \{y_{1i} = 0\}} \int_{-\infty}^{0} f(y_{1i}^*, y_{2i}) dy_{1i}^*
\]
where \( f(y_i^*, y_{2i}) \) is the joint density of \( y_i^* \) and \( y_{2i} \). Note that \( y_{1i} \) is substituted for \( y_i^* \) when \( y_{1i} > 0 \). If you assume \((u_i, \epsilon_i)^{iid} \sim N(0, \Sigma)\) with \( \Sigma = \begin{bmatrix} \sigma_u^2 & \eta \\ \eta & \sigma_e^2 \end{bmatrix} \), then, by using \( f(y_i^*, y_{2i}) = f(y_i^* | y_{2i}) \cdot f(y_{2i}) \), you can write the likelihood function for each \( i \) as a multiplication of two parts. The first part is the probability density function of the normal distribution with mean \( \alpha y_{2i} + \mu_1 \) and variance \( \sigma_e^2 \), and the second part follows a Tobit model that has latent mean \( \alpha y_{2i} + \mu_1 y_{2i} + \eta y_{2i} - \mu \) and variance \( \sigma_u^2 - \eta^2 \sigma_e^2 \). Then, you can obtain the log-likelihood function by taking the log of this multiplication and summing over \( i \) (for more information, see Wooldridge (2002, chapter 16)). This is the log-likelihood function that PROC QLIM maximizes. The parameters \( (\alpha, \beta, \mu, \sigma_u^2, \sigma_e^2, \eta) \) that are obtained from this maximization are the FIML estimators. Assuming that the latent model includes two instrumental variables and two exogenous explanatory variables, you can estimate this model in PROC QLIM as follows:

```plaintext
proc qlim data=a;
  model y1 = y2 z11 z12 / censored(lb=0);
  model y2 = z11 z12 z21 z22;
run;
```

For simple examples like the preceding ones, you can derive the likelihood function easily. However, as the number of endogenous explanatory variables increases, if these variables have a discontinuous nature, if simultaneity among equations exists, or if a combination of these occurs, then the derivation of the likelihood function becomes cumbersome, or, in some cases, the likelihood function does not even have a closed analytical form.

PROC QLIM can handle endogeneity regardless of the nature of the endogenous explanatory variables for a single structural model. In the case of one endogenous explanatory variable, PROC QLIM reports the FIML estimates that are calculated by using the analytical likelihood function that is obtained from the joint distribution of the dependent variable and the endogenous variable. When there is more than one endogenous explanatory variable, the analytical form of the likelihood function is usually not available; in this case PROC QLIM reports the simulated maximum likelihood estimates. For the simulated maximum likelihood estimation method, PROC QLIM uses the Geweke-Hajivassiliou-Keane (GHK) simulator (see, among others, Hajivassiliou, McFadden, and Ruud (1996)) to simulate the joint distribution of the dependent variable and the endogenous variables. The simulation is facilitated by assuming that the error terms in the latent models for the dependent variable and the endogenous explanatory variables are distributed as multivariate normal.

When you estimate a model in PROC QLIM, you can take the endogeneity into account by writing the structural model along with the reduced form models for each endogenous variable. Examples are provided in the following sections.

**Probit Model with a Continuous Endogenous Explanatory Variable**

Consider a probit model that contains a single endogenous explanatory variable in addition to two instruments and two exogenous explanatory variables. The model is

\[
\begin{align*}
y_{1i}^* &= \alpha_1 y_{2i} + \beta_1 z_{1i} + \beta_2 z_{2i} + u_i \\
y_{2i}^* &= \pi_1 z_{1i} + \pi_2 z_{2i} + \pi_3 z_{3i} + \pi_4 z_{4i} + \epsilon_i \\
y_{1i} &= \begin{cases} 1 & \text{if } y_{1i}^* > 0 \\ 0 & \text{if } y_{1i}^* \leq 0 \end{cases} \\
y_{2i} &= y_{2i}^* 
\end{align*}
\]

where \( \text{Cov}(u, \epsilon) = \eta \). You can estimate this model by using the following statements:
Probit Model with a Binary Endogenous Explanatory Variable

Consider a probit model that contains a single binary endogenous explanatory variable in addition to two instruments and two exogenous explanatory variables. The model is

\[
\begin{align*}
y^*_1 &= \alpha_1 y_{2i} + \beta_1 z_{1i} + \beta_2 z_{2i} + u_i \\
y^*_2 &= \pi_1 z_{1i} + \pi_2 z_{2i} + \pi_3 z_{3i} + \pi_4 z_{4i} + \epsilon_i \\
y_{1i} &= \begin{cases} 1 & \text{if } y^*_1 > 0 \\ 0 & \text{if } y^*_1 \leq 0 \end{cases} \\
y_{2i} &= \begin{cases} 1 & \text{if } y^*_2 > 0 \\ 0 & \text{if } y^*_2 \leq 0 \end{cases}
\end{align*}
\]

where \( \text{Cov}(u, \epsilon) = \eta \). You can estimate this model by using the following statements:

```sql
proc qlim data=a;
  model y1 = y2 z1 z2 / discrete;
  model y2 = z1 z2 z3 z4 / discrete;
run;
```

Probit Model with a Censored Endogenous Explanatory Variable

Consider a probit model that contains a single censored (below zero) endogenous explanatory variable in addition to two instruments and two exogenous explanatory variables. The model is

\[
\begin{align*}
y^*_1 &= \alpha_1 y_{2i} + \beta_1 z_{1i} + \beta_2 z_{2i} + u_i \\
y^*_2 &= \pi_1 z_{1i} + \pi_2 z_{2i} + \pi_3 z_{3i} + \pi_4 z_{4i} + \epsilon_i \\
y_{1i} &= \begin{cases} 1 & \text{if } y^*_1 > 0 \\ 0 & \text{if } y^*_1 \leq 0 \end{cases} \\
y_{2i} &= \begin{cases} y^*_{2i} & \text{if } y^*_{2i} > 0 \\ 0 & \text{if } y^*_{2i} \leq 0 \end{cases}
\end{align*}
\]

where \( \text{Cov}(u, \epsilon) = \eta \). You can estimate this model by using the following statements:

```sql
proc qlim data=a;
  model y1 = y2 z1 z2 / discrete;
  model y2 = z1 z2 z3 z4 / censored(lb=0);
run;
```
Censored Regression Model with a Binary Endogenous Explanatory Variable

Consider a Type 1 Tobit model that contains a single binary endogenous explanatory variable in addition to two instruments and two exogenous explanatory variables. The model is

\[
\begin{align*}
y_{1i}^* & = \alpha_1 y_{2i} + \beta_1 z_{1i} + \beta_2 z_{2i} + u_i \\
y_{2i}^* & = \pi_1 z_{1i} + \pi_2 z_{2i} + \pi_3 z_{3i} + \pi_4 z_{4i} + \epsilon_i \\
y_{1i} & = \begin{cases} y_{1i}^* & \text{if } y_{1i}^* > 0 \\ 0 & \text{if } y_{1i}^* \leq 0 \end{cases} \\
y_{2i} & = \begin{cases} 1 & \text{if } y_{2i}^* > 0 \\ 0 & \text{if } y_{2i}^* \leq 0 \end{cases}
\end{align*}
\]

where \( \text{Cov}(u, \epsilon) = \eta \). You can estimate this model by using the following statements:

```
proc qlim data=a;
  model y1 = y2 z1 z2 / censored(lb=0);
  model y2 = z1 z2 z3 z4 / discrete;
run;
```

Censored Regression Model with Binary and Continuous Endogenous Explanatory Variables

Consider a Type 1 Tobit model that contain binary and continuous endogenous explanatory variables in addition to two instruments and two exogenous explanatory variables. The model is

\[
\begin{align*}
y_{1i}^* & = \alpha_1 y_{21i} + \alpha_2 y_{22i} + \beta_1 z_{1i} + \beta_2 z_{2i} + u_i \\
y_{21i}^* & = \pi_{11} z_{1i} + \pi_{12} z_{2i} + \pi_{13} z_{3i} + \pi_{14} z_{4i} + \epsilon_{1i} \\
y_{22i}^* & = \pi_{21} z_{1i} + \pi_{22} z_{2i} + \pi_{23} z_{3i} + \pi_{24} z_{4i} + \epsilon_{2i} \\
y_{1i} & = \begin{cases} y_{1i}^* & \text{if } y_{1i}^* > 0 \\ 0 & \text{if } y_{1i}^* \leq 0 \end{cases} \\
y_{21i} & = \begin{cases} 1 & \text{if } y_{21i}^* > 0 \\ 0 & \text{if } y_{21i}^* \leq 0 \end{cases} \\
y_{22i} & = y_{22i}^*
\end{align*}
\]

where \( \text{Cov}(u, \epsilon_1, \epsilon_2) = \eta \). You can estimate this model by using the following statements:

```
proc qlim data=a;
  model y1 = y21 y22 z1 z2 / censored(lb=0);
  model y21 = z1 z2 z3 z4 / discrete;
  model y22 = z1 z2 z3 z4;
run;
```
**Probit Model with Binary, Censored, and Truncated Endogenous Explanatory Variables**

Consider a probit model that contains binary, censored (below zero), and truncated (below zero) endogenous explanatory variables. The model is

\[
\begin{align*}
  y_{1i}^* &= \alpha_1 y_{21i} + \alpha_2 y_{22i} + \alpha_3 y_{23i} + \epsilon_i \\
  y_{21i}^* &= \pi_{11} z_{1i} + \pi_{12} z_{2i} + \pi_{13} z_{3i} + \pi_{14} z_{4i} + \epsilon_{1i} \\
  y_{22i}^* &= \pi_{21} z_{1i} + \pi_{22} z_{2i} + \pi_{23} z_{3i} + \pi_{24} z_{4i} + \epsilon_{2i} \\
  y_{23i}^* &= \pi_{31} z_{1i} + \pi_{32} z_{2i} + \pi_{33} z_{3i} + \pi_{34} z_{4i} + \epsilon_{3i} \\
  y_{1i} &= \begin{cases} 
  1 & \text{if } y_{1i}^* > 0 \\
  0 & \text{if } y_{1i}^* \leq 0 
\end{cases} \\
  y_{21i} &= \begin{cases} 
  1 & \text{if } y_{21i}^* > 0 \\
  0 & \text{if } y_{21i}^* \leq 0 
\end{cases} \\
  y_{22i} &= \begin{cases} 
  y_{22i}^* & \text{if } y_{22i}^* > 0 \\
  0 & \text{if } y_{22i}^* \leq 0 
\end{cases} \\
  y_{23i} &= \begin{cases} 
  y_{23i}^* & \text{if } y_{23i}^* > 0 
\end{cases}
\end{align*}
\]

where \(z_1, \ldots, z_4\) are the instrumental variables that are independent of the errors. You can estimate this model by using the following statements:

```r
proc qlim data=a;
  model y1 = y21 y22 y23 / discrete;
  model y21 = z1 z2 z3 z4 / discrete;
  model y22 = z1 z2 z3 z4 / censored(lb=0);
  model y23 = z1 z2 z3 z4 / truncated(lb=0);
run;
```

Note that the dependent variable \(y_1\) should not occur in the models for the endogenous explanatory variables, because this causes inconsistent coefficient estimates. In other words, you should write the models for the endogenous explanatory variables as reduced form models. PROC QLIM does not handle simultaneous equations models.

**Test for Endogeneity**

PROC QLIM has two ways to test the null hypothesis that an endogenous explanatory variable (EEV) is in fact exogenous. In the case of a single EEV, the first testing method involves a likelihood ratio test of \(H_0 : \rho_0 = 0\). For example, consider the probit model with a binary endogenous explanatory variable that was considered earlier; \(y_2\) is exogenous if the error term in the model for \(y_1^*\) is uncorrelated with the error term in the model for \(y_2^*\). Therefore, testing to determine whether this correlation is 0 or not provides an endogeneity test for \(y_2\). You can do this in PROC QLIM as follows:

```r
proc qlim data=a;
  model y1 = y2 z1 z2 / discrete;
  model y2 = z1 z2 z3 z4 / discrete;
  test _rho = 0 / LR;
run;
```
Failing to reject the null hypothesis favors the decision that \( y_2 \) is exogenous in the model for \( y_1 \).

When there are two or more EEVs, the test becomes the joint likelihood ratio test of whether corresponding correlations are 0 or not.

The second testing method is similar to the approach of Rivers and Vuong (1988). Considering the same model, you can write

\[
 u_i = \theta \epsilon_i + e_i
\]

where \( \theta = \eta / \sigma_e^2 \) and \( e \) is independent of \( z \)s and \( \epsilon \). You can now write

\[
 y_{1i}^* = \alpha y_{2i} + \beta_1 z_{1i} + \beta_2 z_{2i} + \theta \epsilon_i + e_i
\]

Testing \( H_0 : \theta = 0 \) is the same as testing whether \( u_i \) is correlated with \( \epsilon_i \) or testing whether \( y_{2i} \) is endogenous or not. Because \( \epsilon_i \) are unobserved, you can replace them with the OLS residuals from the model for \( y_{2i}^* \) and apply a robust \( t \) test. Note that even though \( y_{2i} \) is binary (or censored), the test is still correct under \( H_0 \).

This approach can be summarized as a two-step procedure. In the first step, generated regressors—that is, the OLS residuals from the models for each of the EEVs—are obtained. In the second step, the structural model that includes the generated regressors as additional explanatory variables is estimated by the maximum likelihood method and the joint significance of these generated regressors is tested by the Wald test.

In PROC QLIM, you can apply the second method for the same test that was considered previously as follows:

```plaintext
proc qlim data=a;
  model y1 = y2 z1 z2 / discrete endotest(y2);
  model y2 = z1 z2 z3 z4 / discrete;
run;
```

**Overidentification Test**

In PROC QLIM you can test the validity of instrumental variables (IVs) by specifying the OVERID option in the ENDOGENOUS or MODEL statement. The OVERID test is a maximum likelihood version of the overidentifying restrictions test in the IV framework. If you have more IVs than are necessary for identification—that is, overidentifying IVs—you can use them to test the validity of your IVs. When you use the OVERID option to specify the overidentifying IVs, it applies the likelihood ratio test of the joint significance of these IVs, included as additional explanatory variables in the structural model that it estimates by the MLE jointly with the reduced form models. In effect, you test whether the overidentifying IVs are correlated with the error term in the structural model. You specify the reduced form models through the overidentifying IVs. The structural model is the model that includes the OVERID option. For example, consider the probit model that contains a continuous endogenous explanatory variable. You can consider \( z_3 \) or \( z_4 \) in the model for \( y_2 \) as an overidentifying IV; therefore, you can specify the OVERID test as follows:

```plaintext
proc qlim data=a;
  model y1 = y2 z1 z2 / discrete overid(y2.z4);
  model y2 = z1 z2 z3 z4;
run;
```

In this case, PROC QLIM estimates the structural model $y_1$, including the overidentifying IV $z_4$ as an additional explanatory variable in this model, jointly with the reduced form model $y_2$. Then it uses the likelihood ratio test to test the hypothesis that the overidentifying IV is insignificant. Rejecting this hypothesis raises doubts about the validity of the instruments $z_3$ and $z_4$.

Note that, as long as you have continuous endogenous explanatory variables, the test result is invariant to which overidentifying IVs you specify in the test.

---

**Bayesian Analysis**

To perform Bayesian analysis, you must specify a BAYES statement. Unless otherwise stated, all options in this section are options in the BAYES statement.

By default, PROC QLIM uses the random walk Metropolis algorithm to obtain posterior samples. For the implementation details of the Metropolis algorithm in PROC QLIM, such as the blocking of the parameters and tuning of the covariance matrices, see the sections “Blocking of Parameters” on page 1563 and “Tuning the Proposal Distribution” on page 1563.

The Bayes theorem states that

$$p(\theta | y) \propto \pi(\theta) L(y | \theta)$$

where $\theta$ is a parameter or a vector of parameters and $\pi(\theta)$ is the product of the prior densities that are specified in the PRIOR statement. The term $L(y | \theta)$ is the likelihood associated with the MODEL statement.

---

**Blocking of Parameters**

In a multivariate parameter model, all the parameters are updated in one single block (by default or when you specify the SAMPLING=MULTIMETROPOLIS option). This could be inefficient, especially when parameters have vastly different scales. As an alternative, you could update the parameters one at a time (by specifying SAMPLING=UNIMETROPOLIS).

---

**Tuning the Proposal Distribution**

One key factor in achieving high efficiency of a Metropolis-based Markov chain is finding a good proposal distribution for each block of parameters. This process is called tuning. The tuning phase consists of a number of loops controlled by the options MINTUNE and MAXTUNE. The MINTUNE= option controls the minimum number of tuning loops and has a default value of 2. The MAXTUNE= option controls the maximum number of tuning loops and has a default value of 24. Each loop is iterated the number of times specified by the NTU= option, which has a default of 500. At the end of every loop, PROC QLIM examines the acceptance probability for each block. The acceptance probability is the percentage of NTU proposed values that have been accepted. If this probability does not fall within the acceptance tolerance range (see the following section), the proposal distribution is modified before the next tuning loop.

A good proposal distribution should resemble the actual posterior distribution of the parameters. Large sample theory states that the posterior distribution of the parameters approaches a multivariate normal distribution (see Gelman et al. 2004, Appendix B; Schervish 1995, Section 7.4). That is why a normal proposal distribution often works well in practice. The default proposal distribution in PROC QLIM is the normal distribution.
**Scale Tuning**

The acceptance rate is closely related to the sampling efficiency of a Metropolis chain. For a random walk Metropolis, a high acceptance rate means that most new samples occur right around the current data point. Their frequent acceptance means that the Markov chain is moving rather slowly and not exploring the parameter space fully. A low acceptance rate means that the proposed samples are often rejected; hence the chain is not moving much. An efficient Metropolis sampler has an acceptance rate that is neither too high nor too low. The scale \( c \) in the proposal distribution \( q(\cdot | \cdot) \) effectively controls this acceptance probability. Roberts, Gelman, and Gilks (1997) show that if both the target and proposal densities are normal, the optimal acceptance probability for the Markov chain should be around 0.45 in a one-dimension problem and should asymptotically approach 0.234 in higher-dimension problems. The corresponding optimal scale is 2.38, which is the initial scale that is set for each block.

Because of the nature of stochastic simulations, it is impossible to fine-tune a set of variables so that the Metropolis chain has exactly the desired acceptance rate that you want. In addition, Roberts and Rosenthal (2001) empirically demonstrate that an acceptance rate between 0.15 and 0.5 is at least 80% efficient, so there is really no need to fine-tune the algorithms to reach an acceptance probability that is within a small tolerance of the optimal values. PROC QLIM works with a probability range, determined by TargetAcceptance \( \pm 0.075 \). If the observed acceptance rate in a given tuning loop is less than the lower bound of the range, the scale is reduced; if the observed acceptance rate is greater than the upper bound of the range, the scale is increased. During the tuning phase, a scale parameter in the normal distribution is adjusted as a function of the observed acceptance rate and the target acceptance rate. PROC QLIM uses the following updating scheme:

\[
 c_{\text{new}} = \frac{c_{\text{cur}} \cdot \Phi^{-1}(p_{\text{opt}}/2)}{\Phi^{-1}(p_{\text{cur}}/2)}
\]

where \( c_{\text{cur}} \) is the current scale, \( p_{\text{cur}} \) is the current acceptance rate, and \( p_{\text{opt}} \) is the optimal acceptance probability.

**Covariance Tuning**

To tune a covariance matrix, PROC QLIM takes a weighted average of the old proposal covariance matrix and the recent observed covariance matrix, based on the number samples (as specified by the NTU= option) NTU samples in the current loop. The formula to update the covariance matrix is:

\[
 \text{COV}_{\text{new}} = 0.75 \text{COV}_{\text{cur}} + 0.25 \text{COV}_{\text{old}}
\]

There are two ways to initialize the covariance matrix:

- The default is an identity matrix that is multiplied by the initial scale of 2.38 and divided by the square root of the number of estimated parameters in the model. A number of tuning phases might be required before the proposal distribution is tuned to its optimal stage, because the Markov chain needs to spend time to learn about the posterior covariance structure. If the posterior variances of your parameters vary by more than a few orders of magnitude, if the variances of your parameters are much different from 1, or if the posterior correlations are high, then the proposal tuning algorithm might have difficulty forming an acceptable proposal distribution.

---

\[^{1}\text{Roberts and associates demonstrate that the relationship between acceptance probability and scale in a random walk Metropolis scheme is } p = 2\Phi\left(-\sqrt{tc}/2\right), \text{ where } c \text{ is the scale, } p \text{ is the acceptance rate, } \Phi \text{ is the CDF of a standard normal, and } t = E_{f}\left[\left(f'(x)/f(x)\right)^2\right], f(x) \text{ is the density function of samples (Roberts, Gelman, and Gilks 1997; Roberts and Rosenthal 2001). This relationship determines the updating scheme, with } I \text{ replaced by the identity matrix to simplify calculation.}\]
• Alternatively, you can use a numerical optimization routine, such as the quasi-Newton method, to find a starting covariance matrix. The optimization is performed on the joint posterior distribution, and the covariance matrix is a quadratic approximation at the posterior mode. In some cases this is a better and more efficient way of initializing the covariance matrix. However, there are cases, such as when the number of parameters is large, where the optimization could fail to find a matrix that is positive definite. In those cases, the tuning covariance matrix is reset to the identity matrix.

A by-product of the optimization routine is that it also finds the maximum a posteriori (MAP) estimates with respect to the posterior distribution. The MAP estimates are used as the initial values of the Markov chain. For more information, see the section “INIT Statement” on page 1533.

Initial Values of the Markov Chains

You can assign initial values to any parameters. (For more information, see the INIT statement.) If you use the optimization option PROPCOV=, then PROC QLIM starts the tuning at the optimized values. This option overwrites the provided initial values.

Prior Distributions

The PRIOR statement is used to specify the prior distribution of the model parameters. You must specify a list of parameters, a tilde ~, and then a distribution with its parameters. You can specify multiple PRIOR statements to define independent priors. Parameters that are associated with a regressor variable are referred to by the name of the corresponding regressor variable.

You can specify the special keyword _REGRESSORS to consider all the regressors of a model. If multiple prior statements affect the same parameter, the prior that is specified is used. For example, in a regression with three regressors (X1, X2, X3) the following statements imply that the prior on X1 is NORMAL(MEAN=0, VAR=1), the prior on X2 is GAMMA(SHAPE=3, SCALE=4), and the prior on X3 is UNIFORM(MIN=0, MAX=1):

...  
prior _Regressors ~ uniform(min=0, max=1);  
prior X1 X2 ~ gamma(shape=3, scale=4);  
prior X1 ~ normal(mean=0, var=1);  
...  

If a parameter is not associated with a PRIOR statement or if some of the prior hyperparameters are missing, then the following default choices are considered:

<table>
<thead>

See the section “Standard Distributions” on page 1567 for density specification.

**Priors for Heteroscedastic Models**

The choice of the prior distribution for a heteroscedastic model is particularly interesting. Based on the notation provided in section “HETERO Statement” on page 1532, you need to provide a prior for $\gamma$. This prior is enough to induce different $\sigma_i^2$ into the analysis. The resulting inference is a compromise between two cases: the inference based on the entire sample and the inference based on a single unit $z_i$. The degree of compromise is determined by $\pi(\gamma)$.

This type of modeling is similar to a method called “hierarchical Bayes,” in which the prior is characterized by two levels: one for each individual $\pi(\sigma_i^2|\gamma)$ and one for the entire population $\pi(\gamma)$. In this scenario the degree of compromise between the information provided by a unit and the information provided by the entire sample is determined by the data.

The choice of the prior might not be straightforward, and it can heavily affect sampling performance. Depending on how the heteroscedastic effects are modeled, the default priors are

\[
\begin{align*}
\text{if } & \left[1 + \exp(z_i'y) \right], \quad \pi(\gamma_j) = \text{normal} \left\{ \text{mean} = \frac{1}{\tilde{z}_j J} \left[ \log \left( \frac{\epsilon^4}{1 + \epsilon^2} \right) \right], \text{var} = \frac{1}{\tilde{z}_j^2 J} \left[ \log \left( \frac{1 + \epsilon^2}{\epsilon^2} \right) \right] \right\} \\
\text{if } & \left[\exp(z_i'y)\right], \quad \pi(\gamma_j) = \text{normal} \left\{ \text{mean} = \frac{1}{\tilde{z}_j J} \left[ \log \left( \frac{1}{2} \right) \right], \text{var} = \frac{1}{\tilde{z}_j^2 J} \left[ \log (2) \right] \right\} \\
\text{if } & \left(1 + z_i'y\right), \quad \pi(\gamma_j) = \text{normal} \left\{ \text{mean} = 0, \text{var} = \frac{1}{\tilde{z}_j^2 J} \right\} \\
\text{if } & \left[1 + (z_i'y)^2\right], \quad \pi(\gamma_j) = \text{normal} \left\{ \text{mean} = \frac{(\epsilon^2 - 1/2)^{1/4}}{\tilde{z}_j J}, \text{var} = \frac{\epsilon - (\epsilon^2 - 1/2)^{1/2}}{\tilde{z}_j^2 J} \right\}
\end{align*}
\]

where $\tilde{z}_j = \frac{1}{J} \sum_{i=1}^n z_{ij}$, $\forall j$, and $\epsilon$ is a small number (by default, $\epsilon = 0.1$ for the EXPONENTIAL link function and $\epsilon = 0.71$ for the QUADRATIC link function).

The priors for the EXPONENTIAL and QUADRATIC link functions are not straightforward. To understand the choices, do the following:

1. Assume that
\[
z_i'y = z_{i1} \gamma_1 + \ldots + z_{iJ} \gamma_J \approx \tilde{z}_1 \gamma_1 + \ldots + \tilde{z}_J \gamma_J, \quad \forall i
\]

2. Set the priors according to the link function type:
   - For the EXPONENTIAL link function, set
   \[
   E \left[ \exp(z_i'y) \right] \approx E \left[ \exp(\tilde{z}_1 \gamma_1) \right] \times \ldots \times E \left[ \exp(\tilde{z}_J \gamma_J) \right] = \epsilon
   \]
   \[
   \text{Var} \left[ \exp(z_i'y) \right] \approx E \left[ \exp(2\tilde{z}_1 \gamma_1) \right] \times \ldots \times E \left[ \exp(2\tilde{z}_J \gamma_J) \right] - \epsilon^2 = 1
   \]
   Assume a normal prior for $\pi(\gamma_j)$, and set
   \[
   E \left[ \exp(\tilde{z}_j \gamma_j) \right] = \epsilon^{\frac{1}{2}} \cdot \forall j
   \]
   \[
   E \left[ \exp(2\tilde{z}_j \gamma_j) \right] = (1 + \epsilon^2)^{\frac{1}{2}} \cdot \forall j
   \]
Based on the properties of the lognormal distribution, the prior hyperparameters for $\gamma_j$ can be derived. Notice that $J$ is the number of regressors that are used in the heterogeneous regression. If the intercept is excluded, then $\varepsilon = 1$.

- For the QUADRATIC link function, set
  \[
  E \left[ \left( z_j^2 \right) \right] \approx \frac{E[\tilde{z}_1 \gamma_1 + \ldots + \tilde{z}_J \gamma_J]^2 + V[\tilde{z}_1 \gamma_1 + \ldots + \tilde{z}_J \gamma_J]}{\varepsilon} = \varepsilon
  \]
  \[
  V \left[ \left( z_j^2 \right) \right] \approx \frac{E[(\tilde{z}_1 \gamma_1 + \ldots + \tilde{z}_J \gamma_J)^4] - \varepsilon^2 = 1}{\varepsilon}
  \]
  Assume a normal prior for $\pi(\gamma_j)$. Based on the properties of the normal distribution, the preceding expressions return
  \[
  E[\tilde{z}_1 \gamma_1 + \ldots + \tilde{z}_J \gamma_J] = (\varepsilon^2 - 1/2)^{1/4}
  \]
  \[
  V[\tilde{z}_1 \gamma_1 + \ldots + \tilde{z}_J \gamma_J] = \varepsilon - (\varepsilon^2 - 1/2)^{1/2}
  \]
  \[
  \varepsilon > (1/2)^{1/2}
  \]
  The prior hyperparameters for $\gamma_j$ can be derived by setting
  \[
  E[\tilde{z}_j \gamma_j] = \frac{(\varepsilon^2 - 1/2)^{1/4}}{J}, \forall j
  \]
  \[
  V[\tilde{z}_j \gamma_j] = \frac{\varepsilon - (\varepsilon^2 - 1/2)^{1/2}}{J}, \forall j
  \]
  Notice that $J$ is the number of regressors that are used in the heterogeneous regression. It is important to emphasize that the restriction $\varepsilon > (1/2)^{1/2} \approx 0.71$ is likely to introduce some distortion because $\varepsilon$ cannot be any “small” number.

**Standard Distributions**

Table 22.3 through Table 22.8 show all the distribution density functions that PROC QLIM recognizes. You specify these distribution densities in the PRIOR statement.

**Output to SAS Data Set**

**XBeta, Predicted, Residual**

Xbeta is the structural part on the right-hand side of the model. Predicted value is the predicted dependent variable value. For censored variables, if the predicted value is outside the boundaries, it is reported as the closest boundary. For discrete variables, it is the level whose boundaries Xbeta falls between. Residual is defined only for continuous variables and is defined as

\[
\text{Residual} = \text{Observed} - \text{Predicted}
\]
Error Standard Deviation

Error standard deviation is $\sigma_i$ in the model. It varies only when the HETERO statement is used.

Marginal Effects

Marginal effect is defined as a contribution of one control variable to the response variable. For the binary choice model with two response categories, $\mu_0 = -\infty$, $\mu_1 = 0$, $\mu_2 = \infty$; and ordinal response model with $M$ response categories, $\mu_0, \ldots, \mu_M$, define

$$R_{i,j} = \mu_j - x_i'\beta$$

The probability that the unobserved dependent variable is contained in the $j$th category can be written as

$$P[\mu_{j-1} < y_i^* \leq \mu_j] = F(R_{i,j}) - F(R_{i,j-1})$$

The marginal effect of changes in the regressors on the probability of $y_i = j$ is then

$$\frac{\partial P_{rob}[y_i = j]}{\partial x} = [f(\mu_{j-1} - x_i'\beta) - f(\mu_j - x_i'\beta)]\beta$$

where $f(x) = \frac{dF(x)}{dx}$ In particular,

$$f(x) = \frac{dF(x)}{dx} = \begin{cases} \frac{1}{\sqrt{2\pi}} e^{-x^2/2} & \text{(probit)} \\ \frac{1}{\sqrt{1+e^{-x^2}}} & \text{(logit)} \end{cases}$$

The marginal effects in the Box-Cox regression model are

$$\frac{\partial E[y_i]}{\partial x} = \beta \frac{x^\lambda_k - 1}{y^\lambda_0 - 1}$$

The marginal effects in the truncated regression model are

$$\frac{\partial E[y_i | L_i < y_i^* < R_i]}{\partial x} = \beta \left[ 1 - \frac{(\phi(a_i) - \Phi(b_i))^2}{(\Phi(b_i) - \Phi(a_i))^2} + \frac{a_i \phi(a_i) - b_i \phi(b_i)}{\Phi(b_i) - \Phi(a_i)} \right]$$

where $a_i = \frac{L_i - x_i'\beta}{\sigma_i}$ and $b_i = \frac{R_i - x_i'\beta}{\sigma_i}$.

The marginal effects in the censored regression model are

$$\frac{\partial E[y | x_i]}{\partial x} = \beta \times P_{rob}[L_i < y_i^* < R_i]$$

Inverse Mills Ratio, Expected and Conditionally Expected Values

Expected and conditionally expected values are computed only for continuous variables. The inverse Mills ratio is computed for censored or truncated continuous, binary discrete, and selection endogenous variables.

Let $L_i$ and $R_i$ be the lower boundary and upper boundary, respectively, for the $y_i$. Define $a_i = \frac{L_i - x_i'\beta}{\sigma_i}$ and $b_i = \frac{R_i - x_i'\beta}{\sigma_i}$. Then the inverse Mills ratio is defined as

$$\lambda = \frac{(\phi(a_i) - \phi(b_i))}{(\Phi(b_i) - \Phi(a_i))}$$
for a continuous variable and defined as
\[ \lambda = \frac{\phi(x_i' \beta)}{\Phi(x_i' \beta)} \]
for a binary discrete variable.

The expected value is the unconditional expectation of the dependent variable. For a censored variable, it is
\[ E[y_i] = \Phi(a_i)L_i + (x_i' \beta + \lambda \sigma_i)(\Phi(b_i) - \Phi(a_i)) + (1 - \Phi(b_i))R_i \]
For a left-censored variable \( (R_i = \infty) \), this formula is
\[ E[y_i] = \Phi(a_i)L_i + (x_i' \beta + \lambda \sigma_i)(1 - \Phi(a_i)) \]
where \( \lambda = \frac{\phi(a_i)}{1 - \Phi(a_i)} \).
For a right-censored variable \( (L_i = -\infty) \), this formula is
\[ E[y_i] = (x_i' \beta + \lambda \sigma_i)\Phi(b_i) + (1 - \Phi(b_i))R_i \]
where \( \lambda = -\frac{\phi(b_i)}{\Phi(b_i)} \).
For a noncensored variable, this formula is
\[ E[y_i] = x_i' \beta \]

The conditional expected value is the expectation given that the variable is inside the boundaries:
\[ E[y_i | L_i < y_i < R_i] = x_i' \beta + \lambda \sigma_i \]

**Probability**

Probability applies only to discrete responses. It is the marginal probability that the discrete response is taking the value of the observation. If the PROBALL option is specified, then the probability for all of the possible responses of the discrete variables is computed.

**Technical Efficiency**

Technical efficiency for each producer is computed only for stochastic frontier models.

In general, the stochastic production frontier can be written as
\[ y_i = f(x_i; \beta) \exp\{v_i\}TE_i \]
where \( y_i \) denotes producer \( i \)'s actual output, \( f(\cdot) \) is the deterministic part of production frontier, \( \exp\{v_i\} \) is a producer-specific error term, and \( TE_i \) is the technical efficiency coefficient, which can be written as
\[ TE_i = \frac{y_i}{f(x_i; \beta) \exp\{v_i\}} \]
In the case of a Cobb-Douglas production function, \( TE_i = \exp\{-u_i\} \), See the section “Stochastic Frontier Production and Cost Models” on page 1547.
Cost frontier can be written in general as

\[ E_i = c(y_i, w_i; \beta) \exp\{v_i\} / CE_i \]

where \( w_i \) denotes producer \( i \)'s input prices, \( c(\cdot) \) is the deterministic part of cost frontier, \( \exp\{v_i\} \) is a producer-specific error term, and \( CE_i \) is the cost efficiency coefficient, which can be written as

\[ CE_i = \frac{c(x_i, w_i; \beta) \exp\{v_i\}}{E_i} \]

In the case of a Cobb-Douglas cost function, \( CE_i = \exp\{-u_i\} \). See the section “Stochastic Frontier Production and Cost Models” on page 1547. Hence, both technical and cost efficiency coefficients are the same. The estimates of technical efficiency are provided in the following subsections.

**Normal-Half Normal Model**

Define \( \mu_* = -\epsilon \sigma_v^2 / \sigma^2 \) and \( \sigma_*^2 = \sigma_u^2 \sigma_v^2 / \sigma^2 \). Then, as it is shown by Jondrow et al. (1982), conditional density is as follows:

\[ f(u|\epsilon) = \frac{f(u, \epsilon)}{f(\epsilon)} = \frac{1}{\sqrt{2\pi} \sigma_*} \exp\left\{ -\frac{(u - \mu_*)^2}{2\sigma_*^2} \right\} \bigg/ \left[ 1 - \Phi\left( -\frac{\mu_*}{\sigma_*} \right) \right] \]

Hence, \( f(u|\epsilon) \) is the density for \( N^+(\mu_* , \sigma_*^2) \).

Using this result, it follows that the estimate of technical efficiency (Battese and Coelli 1988) is

\[ TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \frac{1 - \Phi(\sigma_* - \mu_* / \sigma_*)}{1 - \Phi(-\mu_* / \sigma_*)} \exp\left\{ -\mu_* + \frac{1}{2}\sigma_*^2 \right\} \]

The second version of the estimate (Jondrow et al. 1982) is

\[ TE2_i = \exp\{-E(u_i|\epsilon_i)\} \]

where

\[ E(u_i|\epsilon_i) = \mu_* + \sigma_* \left[ \frac{\phi(-\mu_* / \sigma_*)}{1 - \Phi(-\mu_* / \sigma_*)} \right] = \sigma_* \left[ \frac{\phi(\epsilon_i \lambda / \sigma)}{1 - \Phi(\epsilon_i \lambda / \sigma)} - \left( \frac{\epsilon_i \lambda}{\sigma} \right) \right] \]

**Normal-Exponential Model**

Define \( A = -\tilde{\mu} / \sigma_v \) and \( \tilde{\mu} = -\epsilon \sigma_v^2 / \sigma_u \). Then, as it is shown by Kumbhakar and Lovell (2000), conditional density is as follows:

\[ f(u|\epsilon) = \frac{1}{\sqrt{2\pi} \sigma_v} \Phi(-\tilde{\mu} / \sigma_v) \exp\left\{ -\frac{(u - \tilde{\mu})^2}{2\sigma_v^2} \right\} \]

Hence, \( f(u|\epsilon) \) is the density for \( N^+(\tilde{\mu}, \sigma_v^2) \).

Using this result, it follows that the estimate of technical efficiency is

\[ TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \frac{1 - \Phi(\sigma_v - \tilde{\mu}_i / \sigma_v)}{1 - \Phi(-\tilde{\mu}_i / \sigma_v)} \exp\left\{ -\tilde{\mu}_i + \frac{1}{2}\sigma_v^2 \right\} \]

The second version of the estimate is

\[ TE2_i = \exp\{-E(u_i|\epsilon_i)\} \]
where

\[ E(u_i|\epsilon_i) = \bar{\mu}_i + \sigma_v \left[ \frac{\phi(-\mu_i/\sigma_v)}{1 - \Phi(-\mu_i/\sigma_v)} \right] = \sigma_v \left[ \frac{\Phi(A)}{\Phi(-A)} - A \right] \]

**Normal-Truncated Normal Model**

Define \( \bar{\mu} = (-\sigma_u^2 \epsilon_i + \mu_\sigma^2)/\sigma^2 \) and \( \sigma_*^2 = \sigma_u^2 \sigma_v^2/\sigma^2 \). Then, as it is shown by Kumbhakar and Lovell (2000), conditional density is as follows:

\[ f(u|\epsilon) = \frac{1}{\sqrt{2\pi}\sigma_*[1 - \Phi(-\bar{\mu}/\sigma_*)]} \exp \left\{ -\frac{(u - \bar{\mu})^2}{2\sigma_*^2} \right\} \]

Hence, \( f(u|\epsilon) \) is the density for \( N^+ (\bar{\mu}, \sigma_*^2) \).

Using this result, it follows that the estimate of technical efficiency is

\[ TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \frac{1 - \Phi(\sigma_* - \mu_i/\sigma_*)}{1 - \Phi(-\bar{\mu}_i/\sigma_*^2)} \exp \left\{ -\bar{\mu}_i + \frac{1}{2} \sigma_*^2 \right\} \]

The second version of the estimate is

\[ TE2_i = \exp\{-E(u_i|\epsilon_i)\} \]

where

\[ E(u_i|\epsilon_i) = \bar{\mu}_i + \sigma_* \left[ \frac{\phi(\mu_i/\sigma_*)}{1 - \Phi(-\bar{\mu}_i/\sigma_*^2)} \right] \]

---

**OUTEST= Data Set**

The OUTEST= data set contains all the parameters estimated in a MODEL statement. The OUTEST= option can be used when the PROC QLIM call contains one MODEL statement:

```plaintext
proc qlim data=a outest=e;
   model y = x1 x2 x3;
   endogenous y ~ censored(lb=0);
run;
```

Each parameter contains the estimate for the corresponding parameter in the corresponding model. In addition, the OUTEST= data set contains the following variables:

- **_NAME_** the name of the independent variable
- **_TYPE_** type of observation. PARM indicates the row of coefficients; STD indicates the row of standard deviations of the corresponding coefficients.
- **_STATUS_** convergence status for optimization
The rest of the columns correspond to the explanatory variables.

The OUTTEST= data set contains one observation for the MODEL statement, giving the parameter estimates for that model. If the COVOUT option is specified, the OUTTEST= data set includes additional observations for the MODEL statement, giving the rows of the covariance matrix of parameter estimates. For covariance observations, the value of the _TYPE_ variable is COV, and the _NAME_ variable identifies the parameter associated with that row of the covariance matrix. If the CORROUT option is specified, the OUTTEST= data set includes additional observations for the MODEL statement, giving the rows of the correlation matrix of parameter estimates. For correlation observations, the value of the _TYPE_ variable is CORR, and the _NAME_ variable identifies the parameter associated with that row of the correlation matrix.

**Naming**

**Naming of Parameters**

When there is only one equation in the estimation, parameters are named in the same way as in other SAS procedures such as REG, PROBIT, and so on. The constant in the regression equation is called Intercept. The coefficients on independent variables are named by the independent variables. The standard deviation of the errors is called _Sigma. If there are Box-Cox transformations, the coefficients are named _Lambda/, where i increments from 1, or as specified by the user. The limits for the discrete dependent variable are named _Limit/. If the LIMIT=varying option is specified, then _Limit/ starts from 1. If the LIMIT=varying option is not specified, then _Limit/1 is set to 0 and the limit parameters start from i = 2. If the HETERO statement is included, the coefficients of the independent variables in the hetero equation are called _H.*x, where x is the name of the independent variable. If the parameter name includes interaction terms, it needs to be enclosed in quotation marks followed by _N. The following example restricts the parameter that includes the interaction term to be greater than zero:

```
proc qlim data=a;
   model y = x1|x2;
   endogenous y ~ discrete;
   restrict "x1*x2"N>0;
run;
```

When there are multiple equations in the estimation, the parameters in the main equation are named in the format of y.x, where y is the name of the dependent variable and x is the name of the independent variable. The standard deviation of the errors is called _Sigma.y. The correlation of the errors is called _Rho for bivariate model. For the model with three variables it is _Rho.y1,y2, _Rho.y1,y3, _Rho.y2,y3. The construction of correlation names for multivariate models is analogous. Box-Cox parameters are called _Lambda/y and limit variables are called _Limit/y. Parameters in the HETERO statement are named as _H.y.x. In the OUTEST= data set, all variables are changed from '.' to '_'.

**Naming of Output Variables**

The following table shows the option in the OUTPUT statement, with the corresponding variable names and their explanation.
<table>
<thead>
<tr>
<th>Option</th>
<th>Name</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>PREDICTED</td>

</tr>
</tbody>
</table>

If you prefer to name the output variables differently, you can use the RENAME option in the data set. For example, the following statements rename the residual of y as Resid:

```plaintext
proc qlim data=one;
    model y = x1-x10 / censored;
    output out=outds(rename=(resid_y=resid)) residual;
run;
```

**ODS Table Names**

PROC QLIM assigns a name to each table it creates. You can use these names to denote the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the Table 22.9.

## ODS Graphics

You can reference every graph that is produced through ODS Graphics with a name. The names of the graphs that PROC QLIM generates are listed in Table 22.10 for the frequentist approach and in Table 22.11 for the Bayesian approach.

**Examples: QLIM Procedure**

**Example 22.1: Ordered Data Modeling**

Cameron and Trivedi (1986, 1998) studied the number of doctor visits from the Australian Health Survey 1977-78. In the following data set, the dependent variable, DVISITS, contains the number of doctor visits in the past 2 weeks (0, 1, or more than 2). The explanatory variables are: SEX indicates if the patient is female; AGE is the age in years divided by 100; INCOME is the annual income ($10,000); LEVYPLUS indicates if the patient has private health insurance; FREPOOR indicates free government health insurance due to low income; FREEREPA indicates free government health insurance for other reasons; ILLNESS is the number of illnesses in the past 2 weeks; ACTDAYS is the number of days the illness caused reduced activity; HSCORE is a questionnaire score; CHCOND1 indicates a chronic condition that does not limit activity; and CHCOND2 indicates a chronic condition that limits activity.

```plaintext
data docvisit;
  input sex age agesq income levyplus freepoor freerepa illness actdays hscore chcond1 chcond2 dvisits;
y = (dvisits > 0);
  if ( dvisits > 8 ) then dvisits = 8;
datalines;
1 0.19 0.0361 0.55 1 0 0 1 4 1 0 0 1 0.19 0.0361 0.45 1 0 0 1 2 1 0 0 0
1 0.37 0.1369 0.25 0 0 0 1 1 0 1 0 0 1 0.52 0.2704 0.65 0 0 0 0 0 0 0 0 0 0.72 0.5184 0.25 0 0 1 0 0 0 0 0 0
;
```

---

---
The dependent variable, dvisits, has nine ordered values. The following SAS statements estimate the ordinal probit model:

```sas
/*-- Ordered Discrete Responses --*/
proc qlim data=docvisit;
  model dvisits = sex age agesq income levyplus
                   freepoor freerepa illness actdays hscore
                   chcond1 chcond2 / discrete;
run;
```

The output of the QLIM procedure for ordered data modeling is shown in **Output 22.1.1**.

</tbody>
</table>

By default, ordinal probit/logit models are estimated assuming that the first threshold or limit parameter ($\mu_1$) is 0. However, this parameter can also be estimated when the LIMIT1=VARYING option is specified. The probability that $y_i^*$ belongs to the $j$th category is defined as

$$P[\mu_{j-1} < y_i^* < \mu_j] = F(\mu_j - x_i^* \beta) - F(\mu_{j-1} - x_i^* \beta)$$

where $F(\cdot)$ is the logistic or standard normal CDF, $\mu_0 = -\infty$ and $\mu_9 = \infty$. Output 22.1.2 lists ordinal probit estimates computed in the following program. Note that the intercept term is suppressed for model identification when $\mu_1$ is estimated.
Example 22.2: Tobit Analysis

The following statements show a subset of the Mroz (1987) data set. In these data, Hours is the number of hours the wife worked outside the household in a given year, Yrs_Ed is the years of education, and Yrs_Exp is the years of work experience. A Tobit model will be fit to the hours worked with years of education and experience as covariates.

By the nature of the data it is clear that there are a number of women who committed some positive number of hours to outside work ($y_i > 0$ is observed). There are also a number of women who did not work at all ($y_i = 0$ is observed). This gives us the following model:

$$y_i^* = x_i \beta + \epsilon_i$$
\[ y_i = \begin{cases} \ y_i^* & \text{if } y_i^* > 0 \\ \ 0 & \text{if } y_i^* \leq 0 \end{cases} \]

where \( \epsilon_i \sim iidN(0, \sigma^2) \). The set of explanatory variables is denoted by \( x_i \).

title1 'Estimating a Tobit model';

data subset;
   input Hours Yrs_Ed Yrs_Exp @@;
   if Hours eq 0 then Lower=.;
   else Lower=Hours;
 dataplines;
   0 8 9 0 8 12 0 9 10 0 10 15 0 11 4 0 11 6

   3686 14 11 1920 14 38 0 15 14 1728 16 3
   1568 16 19 1316 17 7 0 17 15
; /*-- Tobit Model --*/
proc qlim data=subset;
   model hours = yrs_ed yrs_exp;
   endogenous hours ~ censored(lb=0);
run;

The output of the QLIM procedure is shown in Output 22.2.1.

### Output 22.2.1 Tobit Analysis Results

| Parameter       | DF | Estimate     | Standard Error | t Value | Pr > |t| |
|-----------------|----|--------------|----------------|---------|------|---|
| Intercept       | 1  | -5598.295129 | 27.692220      | -202.16 | <.0001 |
| Yrs_Ed          | 1  | 373.123254   | 53.988877      | 6.91    | <.0001 |
| Yrs_Exp         | 1  | 63.336247    | 36.551299      | 1.73    | 0.0831 |
| _Sigma          | 1  | 1582.859635  | 390.076480     | 4.06    | <.0001 |
In the “Parameter Estimates” table there are four rows. The first three of these rows correspond to the vector estimate of the regression coefficients $\beta$. The last one is called _Sigma, which corresponds to the estimate of the error variance $\sigma$.

---

Example 22.3: Bivariate Probit Analysis

This example shows how to estimate a bivariate probit model. Note the INIT statement in the following program, which sets the initial values for some parameters in the optimization:

```plaintext
data a;
  keep y1 y2 x1 x2;
  do i = 1 to 500;
    x1 = rannor( 19283 );
    x2 = rannor( 19283 );
    u1 = rannor( 19283 );
    u2 = rannor( 19283 );
    y1l = 1 + 2 * x1 + 3 * x2 + u1;
    y2l = 3 + 4 * x1 - 2 * x2 + u1*.2 + u2;
    if ( y1l > 0 ) then y1 = 1;
    else    y1 = 0;
    if ( y2l > 0 ) then y2 = 1;
    else    y2 = 0;
    output;
  end;
run;

/*--- Bivariate Probit ---*/
proc qlim data=a method=qn;
  init y1.x1 2.8, y1.x2 2.1, _rho .1;
  model y1 = x1 x2;
  model y2 = x1 x2;
  endogenous y1 y2 ~ discrete;
run;
```

The output of the QLIM procedure is shown in Output 22.3.1.
Output 22.3.1 Bivariate Probit Analysis Results

Estimating a Tobit model

The QLIM Procedure

Model Fit Summary

| Parameter       | DF | Estimate | Standard Error | t Value | Pr > |t| |
|-----------------|----|----------|----------------|---------|------|---|

| _Rho            | 1  | 0.144097 | 0.336459       | 0.43    | 0.6685 |

Example 22.4: Sample Selection Model

This example illustrates the use of PROC QLIM for sample selection models. The data set is the same one from Mroz (1987). The goal is to estimate a wage offer function for married women, accounting for potential selection bias. Of the 753 women, the wage is observed for 428 working women. The labor force participation equation estimated in the introductory example is used for selection. The wage equation uses log wage (lwage) as the dependent variable. The explanatory variables in the wage equation are the woman’s years of schooling (educ), wife’s labor experience (exper), and square of experience (expersq). The program is as follows:

```sas
/*-- Sample Selection --*/
proc qlim data=mroz;
   model inlf = nwifeinc educ exper expersq
             age kidslt6 kidsge6 / discrete;
   model lwage = educ exper expersq / select(inlf=1);
run;
```

The output of the QLIM procedure is shown in Output 22.4.1.
Example 22.5: Sample Selection Model with Truncation and Censoring

Note the correlation estimate is insignificant. This indicates that selection bias is not a big problem in the estimation of wage equation.

Example 22.5: Sample Selection Model with Truncation and Censoring

In this example the data are generated such that the selection variable is discrete and the variable Y is truncated from below by zero. The program follows, with the results shown in Output 22.5.1:
data trunc;
  keep z y x1 x2;
  do i = 1 to 500;
    x1 = rannor( 19283 );
    x2 = rannor( 19283 );
    u1 = rannor( 19283 );
    u2 = rannor( 19283 );
    zl = 1 + 2 * x1 + 3 * x2 + u1;
    y = 3 + 4 * x1 - 2 * x2 + u1*.2 + u2;
    if ( zl > 0 ) then z = 1;
    else z = 0;
    if y>=0 then output;
  end;
run;
/*-- Sample Selection with Truncation --*/
proc qlim data=trunc method=qn;
  model z = x1 x2 / discrete;
  model y = x1 x2 / select(z=1) truncated(lb=0);
run;

Output 22.5.1 Sample Selection with Truncation

Example 22.6: Types of Tobit Models

The following five examples show how to estimate different types of Tobit models (see “Types of Tobit Models” on page 1544). Output 22.6.1 through Output 22.6.5 show the results of the corresponding programs.

Type 1 Tobit

data a1;
  keep y x;
  do i = 1 to 500;
    x = rannor( 19283 );
    u = rannor( 19283 );
    yl = 1 + 2 * x + u;
    if ( yl > 0 ) then y = yl;
    else y = 0;
  output;
  end;
run;

/*-- Type 1 Tobit --*/
proc qlim data=a1 method=qn;
  model y = x;
  endogenous y ~ censored(lb=0);
run;

Output 22.6.1 Type 1 Tobit

Example 22.7: Stochastic Frontier Models

This example illustrates the estimation of stochastic frontier production and cost models.

First, a production function model is estimated. The data for this example were collected by Christensen Associates; they represent a sample of 125 observations on inputs and output for 10 airlines between 1970 and 1984. The explanatory variables (inputs) are fuel (LF), materials (LM), equipment (LE), labor (LL), and property (LP), and (LQ) is an index that represents passengers, charter, mail, and freight transported.

The following statements create the dataset:

```latex
\begin{verbatim}
title1 'Stochastic Frontier Production Model';
data airlines;
  input TS FIRM NI LQ LF LM LE LL LP;
datalines;

The following statements estimate a stochastic frontier exponential production model that uses Christensen Associates data:

```latex
\begin{verbatim}
/**** Stochastic Frontier Production Model *****/
proc qlim data=airlines;
  model LQ=LF LM LE LL LP;
  endogenous LQ ~ frontier (type=exponential production);
run;
\end{verbatim}
```
Figure 22.7.1 shows the results from this production model.

**Output 22.7.1 Stochastic Frontier Production Model**

| Parameter       | DF | Estimate | Standard Error | t Value | Pr > |t| |
|-----------------|----|----------|----------------|---------|------|---|
| Intercept       | 1  | -0.085048| 0.024528       | -3.47   | 0.0005 |
| LF              | 1  | -0.115802| 0.124178       | -0.93   | 0.3511 |
| LM              | 1  | 0.756253 | 0.078755       | 9.60    | <.0001|
| LE              | 1  | 0.424916 | 0.081893       | 5.19    | <.0001|
| LL              | 1  | -0.136421| 0.089702       | -1.52   | 0.1283 |
| LP              | 1  | 0.098967 | 0.042776       | 2.31    | 0.0207 |
| _Sigma_v        | 1  | 0.108688 | 0.010063       | 10.80   | <.0001|
| _Sigma_u        | 1  | 0.060611 | 0.017603       | 3.44    | 0.0006|

Similarly, the stochastic frontier production function can be estimated with (type=half) or (type=truncated) options that represent half-normal and truncated normal production models.

In the next step, stochastic frontier cost function is estimated. The data for the cost model are provided by Christensen and Greene (1976). The data describe costs and production inputs of 145 U.S. electricity producers in 1955. The model being estimated follows the nonhomogeneous version of the Cobb-Douglas cost function:

\[
\log \left( \frac{\text{Cost}}{\text{FPrice}} \right) = \beta_0 + \beta_1 \log \left( \frac{\text{KPrice}}{\text{FPrice}} \right) + \beta_2 \log \left( \frac{\text{LPrice}}{\text{FPrice}} \right) + \beta_3 \log (\text{Output}) + \beta_4 \frac{1}{2} \log (\text{Output})^2 + \epsilon
\]

All dollar values are normalized by fuel price. The quadratic log of the output is added to capture nonlinearities due to scale effects in cost functions. New variables, log_C_PF, log_PK_PF, log_PL_PF, log_y, and log_y_sq, are created to reflect transformations. The following statements create the data set and transformed variables:

If no (Production) or (Cost) option is specified, the stochastic frontier production model is estimated by default.

Example 22.8: Bayesian Modeling

This example illustrates how to use the QLIM procedure to perform Bayesian analysis. The generated data mimic a hypothetical scenario in which you study the number of tickets sold for a sports event given the probability of the hosting team winning and the price of the tickets. The following statements create the dataset:
title1 'Bayesian Analysis';
ods graphics on;
data test;
do i=1 to 200;
e1 = rannor(8726)*2000;
WinChance = ranuni(8772);
Price = 10+ranexp(8773)*4;
y = 48000 + 5000*WinChance - 100 * price + e1;
if y>50000 then TicketSales = 50000;
if y<=50000 then TicketSales = y;
output;
end;
keep WinChance price y TicketSales;
run;
The following statements perform Bayesian analysis of a Tobit model:
proc qlim data=test plots(prior)=all;
model TicketSales = WinChance price;
endogenous TicketSales ~ censored(lb=0 ub= 50000);
prior intercept~normal(mean=48000);
prior WinChance~normal(mean=5000);
prior Price~normal(mean=-100);
bayes NBI=10000 NMC=30000 THIN=1 ntrds=1 DIAG=ALL STATS=ALL seed=2; run;

Output 22.8.1 shows the results from the maximum likelihood estimation and the Bayesian analysis with diffuse prior of this Tobit model.

Overview: SEVERITY Procedure

The SEVERITY procedure estimates parameters of any arbitrary continuous probability distribution that is used to model the magnitude (severity) of a continuous-valued event of interest. Some examples of such events are loss amounts paid by an insurance company and demand of a product as depicted by its sales. PROC SEVERITY is especially useful when the severity of an event does not follow typical distributions such as the normal distribution that are often assumed by standard statistical methods.

PROC SEVERITY provides a default set of probability distribution models that includes the Burr, exponential, gamma, generalized Pareto, inverse Gaussian (Wald), lognormal, Pareto, Tweedie, and Weibull distributions. In the simplest form, you can estimate the parameters of any of these distributions by using a list of severity values that are recorded in a SAS data set. You can optionally group the values by a set of BY variables. PROC SEVERITY computes the estimates of the model parameters, their standard errors, and their covariance structure by using the maximum likelihood method for each of the BY groups.

PROC SEVERITY can fit multiple distributions at the same time and choose the best distribution according to a selection criterion that you specify. You can use seven different statistics of fit as selection criteria. They are log likelihood, Akaike’s information criterion (AIC), corrected Akaike’s information criterion (AICC), Schwarz Bayesian information criterion (BIC), Kolmogorov-Smirnov statistic (KS), Anderson-Darling statistic (AD), and Cramér-von Mises statistic (CvM).

You can request the procedure to output the status of the estimation process, the parameter estimates and their standard errors, the estimated covariance structure of the parameters, the statistics of fit, estimated cumulative distribution function (CDF) for each of the specified distributions, and the empirical distribution function (EDF) estimate (which is used to compute the KS, AD, and CvM statistics of fit).

A high-performance version of PROC SEVERITY is available as the HPSEVERITY procedure in the SAS High-Performance Econometrics product. The following key features make PROC SEVERITY and PROC HPSEVERITY unique among SAS procedures that can estimate continuous probability distributions:

- Both procedures enable you to fit a distribution model when the severity values are truncated or censored or both. You can specify any combination of the following types of censoring and truncation effects: left-censoring, right-censoring, left-truncation, or right-truncation. This is especially useful in applications with an insurance-type model where a severity (loss) is reported and recorded only if it is greater than the deductible amount (left-truncation) and where a severity value greater than or equal to the policy limit is recorded at the limit (right-censoring). Another useful application is that of interval-censored data, where you know both the lower limit (right-censoring) and upper limit (left-censoring) on the severity, but you do not know the exact value.
Getting Started: SEVERITY Procedure

PROC SEVERITY also enables you to specify a probability of observability for the left-truncated data, which is a probability of observing values greater than the left-truncation threshold. This additional information can be useful in certain applications to more correctly model the distribution of the severity of events.

Both procedures use an appropriate estimator of the empirical distribution function (EDF). EDF is required to compute the KS, AD, and CvM statistics-of-fit. The procedures also provide the EDF estimates to your custom parameter initialization method. When you specify truncation or censoring, the EDF is estimated by using either Kaplan-Meier’s product-limit estimator or Turnbull’s estimator. The former is used by default when you specify only one form of censoring effect (right-censoring or left-censoring), whereas the latter is used by default when you specify both left-censoring and right-censoring effects. PROC SEVERITY also computes the standard errors for the EDF estimates.

• Both procedures enable you to define any arbitrary continuous parametric distribution model and to estimate its parameters. You just need to define the key components of the distribution, such as its probability density function (PDF) and cumulative distribution function (CDF), as a set of functions and subroutines written with the FCMP procedure, which is part of Base SAS software. As long as the functions and subroutines follow certain rules, the SEVERITY and HPSEVERITY procedures can fit the distribution model defined by them.

• Both procedures can model the effect of exogenous or regressor variables on a probability distribution, as long as the distribution has a scale parameter. A linear combination of the regressor variables is assumed to affect the scale parameter via an exponential link function.

If a distribution does not have a scale parameter, then either it needs to have another parameter that can be derived from a scale parameter by using a supported transformation or it needs to be reparameterized to have a scale parameter. If neither of these is possible, then regression effects cannot be modeled.

• Both procedures enable you to specify your own objective function to be optimized for estimating the parameters of a model. You can write SAS programming statements to specify the contribution of each observation to the objective function. You can use keyword functions such as _PDF_ and _CDF_ to generalize the objective function to any distribution. If you do not specify your own objective function, then the parameters of a model are estimated by maximizing the likelihood function of the data.

• Both procedures enable you to create scoring functions that offer a convenient way to evaluate any distribution function, such as PDF, CDF, QUANTILE, or your custom distribution function, for a fitted model on new observations.

• Both procedures use multithreading to significantly reduce the time it takes to fit a distribution model.

Getting Started: SEVERITY Procedure

This section outlines the use of the SEVERITY procedure to fit continuous probability distribution models. Three examples illustrate different features of the procedure.
A Simple Example of Fitting Predefined Distributions

The simplest way to use PROC SEVERITY is to fit all the predefined distributions to a set of values and let the procedure identify the best fitting distribution.

Consider a lognormal distribution, whose probability density function (PDF) $f$ and cumulative distribution function (CDF) $F$ are as follows, respectively, where $\Phi$ denotes the CDF of the standard normal distribution:

$$f(x; \mu, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x) - \mu}{\sigma}\right)^2} \quad \text{and} \quad F(x; \mu, \sigma) = \Phi\left(\frac{\log(x) - \mu}{\sigma}\right)$$

The following DATA step statements simulate a sample from a lognormal distribution with population parameters $\mu = 1.5$ and $\sigma = 0.25$, and store the sample in the variable $Y$ of a data set Work.Test_sev1:

```plaintext
/*------------- Simple Lognormal Example -------------*/
data test_sev1(keep=y label='Simple Lognormal Sample');
call streaminit(45678);
label y='Response Variable';
Mu = 1.5;
Sigma = 0.25;
do n = 1 to 100;
   y = exp(Mu) * rand('LOGNORMAL')**Sigma;
   output;
end;
run;
```

The following statements fit all the predefined distribution models to the values of $Y$ and identify the best distribution according to the corrected Akaike’s information criterion (AICC):

```plaintext
proc severity data=test_sev1 crit=aicc;
   loss y;
   dist _predefined_;
run;
```

The PROC SEVERITY statement specifies the input data set along with the model selection criterion, the LOSS statement specifies the variable to be modeled, and the DIST statement with the _PREDEFINED_ keyword specifies that all the predefined distribution models be fitted.
Some of the default output displayed by this step is shown in Figure 23.1 through Figure 23.5. First, information about the input data set is displayed followed by the “Model Selection Table”, as shown in Figure 23.1. The model selection table displays the convergence status, the value of the selection criterion, and the selection status for each of the candidate models. The Converged column indicates whether the estimation process for a given distribution model has converged, might have converged, or failed. The Selected column indicates whether a given distribution has the best fit for the data according to the selection criterion. For this example, the lognormal distribution model is selected, because it has the lowest value for the selection criterion.

Next, two comparative plots are prepared. These plots enable you to visually verify how the models differ from each other and from the nonparametric estimates. The plot in Figure 23.2 displays the cumulative distribution function (CDF) estimates of all the models and the estimates of the empirical distribution function (EDF). The CDF plot indicates that the Exp (exponential), Pareto, and Gpd (generalized Pareto) distributions are a poor fit as compared to the EDF estimate. The Weibull distribution is also a poor fit, although not as poor as exponential, Pareto, and Gpd. The other four distributions seem to be quite close to each other and to the EDF estimate.
The plot in Figure 23.3 displays the probability density function (PDF) estimates of all the models and the nonparametric kernel and histogram estimates. The PDF plot enables better visual comparison between the Burr, Gamma, Igauss (inverse Gaussian), and Logn (lognormal) models. The Burr and Gamma differ significantly from the Igauss and Logn distributions in the central portion of the range of Y values, while the latter two fit the data almost identically. This provides a visual confirmation of the information in the “Model Selection Table” of Figure 23.1, which indicates that the AICC values of Igauss and Logn distributions are very close.
The comparative plots are followed by the estimation information for each of the candidate models. The information for the lognormal model, which is the best fitting model, is shown in Figure 23.4. The first table displays a summary of the distribution. The second table displays the convergence status. This is followed by a summary of the optimization process which indicates the technique used, the number of iterations, the number of times the objective function was evaluated, and the log likelihood attained at the end of the optimization. Since the model with lognormal distribution has converged, PROC SEVERITY displays its statistics of fit and parameter estimates. The estimates of $\mu=1.49605$ and $\sigma=0.26243$ are quite close to the population parameters of $\mu=1.5$ and $\sigma=0.25$ from which the sample was generated. The $p$-value for each estimate indicates the rejection of the null hypothesis that the estimate is 0, implying that both the estimates are significantly different from 0.

**An Example with Left-Truncation and Right-Censoring**

PROC SEVERITY enables you to specify that the response variable values are left-truncated or right-censored. The following DATA step expands the data set of the previous example to simulate a scenario that is typically encountered by an automobile insurance company. The values of the variable \(Y\) represent the loss values on claims that are reported to an auto insurance company. The variable THRESHOLD records the deductible on the insurance policy. If the actual value of \(Y\) is less than or equal to the deductible, then it is unobservable and does not get recorded. In other words, THRESHOLD specifies the left-truncation of \(Y\). LIMIT records the policy limit. If the value of \(Y\) is equal to or greater than the recorded value, then the observation is right-censored.

```sas
/*----- Lognormal Model with left-truncation and censoring -----*/
data test_sev2(keep=y threshold limit label='A Lognormal Sample With Censoring and Truncation');
  set test_sev1;
  label y='Censored & Truncated Response';
  if _n_ = 1 then call streaminit(45679);
  /* make about 20% of the observations left-truncated */
  if (rand('UNIFORM') < 0.2) then
      threshold = y * (1 - rand('UNIFORM'));
  else
      threshold = .;
  /* make about 15% of the observations right-censored */
  iscens = (rand('UNIFORM') < 0.15);
  if (iscens) then
      limit = y;
  else
      limit = .;
run;
```
The following statements use the AICC criterion to analyze which of the four predefined distributions (lognormal, Burr, gamma, and Weibull) has the best fit for the data:

```sas
proc severity data=test_sev2 crit=aicc
   print=all plots=(cdfperdist pp qq);
   loss y / lt=threshold rc=limit;
   dist logn burr gamma weibull;
run;
```

The LOSS statement specifies the left-truncation and right-censoring variables. The DIST statement specifies the candidate distributions. The PRINT= option in the PROC SEVERITY statement requests that all the displayed output be prepared. The PLOTS= option in the PROC SEVERITY statement requests that the CDF plot, P-P plot, and Q-Q plot be prepared for each candidate distribution in addition to the default plots.

Some of the key results prepared by PROC SEVERITY are shown in Figure 23.6 through Figure 23.13. In addition to the estimates of the range, mean, and standard deviation of $Y$, the “Descriptive Statistics for $Y$” table shown in Figure 23.6 also indicates the number of observations that are left-truncated or right-censored. The “Model Selection Table” in Figure 23.6 shows that models with all the candidate distributions have converged and that the Logn (lognormal) model has the best fit for the data according to the AICC criterion.

PROC SEVERITY also prepares a table that shows all the fit statistics for all the candidate models. It is useful to see which model would be the best fit according to each of the criteria. The “All Fit Statistics Table” prepared for this example is shown in Figure 23.7. It indicates that the lognormal model is chosen by all the criteria.

</tbody>
</table>

Note: The asterisk (*) marks the best model according to each column's criterion.

The plot that compares EDF and CDF estimates is shown in Figure 23.8. When you specify left-truncation, both the EDF and CDF estimates are conditional on the response variable being greater than the smallest left-truncation threshold in the sample.
When you specify the PLOTS=CDFPERDIST option, PROC SEVERITY prepares a plot that compares the nonparametric EDF estimates with the parametric CDF estimates for each distribution. These plots for lognormal and Weibull distributions are shown in Figure 23.9. These plots also contain the lower and upper confidence limits of EDF for the specified confidence level. Because no confidence level is specified in the EDFALPHA= option in the PROC SEVERITY statement, a default confidence level of 95% is used, which is equivalent to specifying EDFALPHA=0.05. If the CDF estimates lie entirely within the EDF confidence interval, then you can be 95% confident that the parametric and nonparametric estimates are in agreement.
There are two additional ways to compare nonparametric (empirical) and parametric estimates for each model that has not failed to converge:

- A P-P plot is a scatter plot of the EDF and the CDF estimates. The model for which the points are scattered closer to the unit-slope reference line is a better fit. The P-P plot for the lognormal distribution is shown in Figure 23.10. It indicates that the EDF and the CDF match very closely. In contrast, the P-P plot for the Weibull distribution, also shown in Figure 23.10, indicates a poor fit.

Figure 23.10  P-P Plots for Lognormal and Weibull Models Fitted to Truncated and Censored Data

- A Q-Q plot is a scatter plot of empirical quantiles and the quantiles of a parametric distribution. Like the P-P plot, points scattered closer to the unit-slope reference line indicate a better fit. The Q-Q plots of lognormal and Weibull distributions are shown in Figure 23.11, which confirm the conclusions arrived at by comparing the P-P plots.
Specifying Initial Values for Parameters

All the predefined distributions have parameter initialization functions built into them. For the current example, Figure 23.12 shows the initial values that are obtained by the predefined method for the Burr distribution. It also shows the summary of the optimization process and the final parameter estimates.

**Figure 23.12** Burr Model Summary for the Truncated and Censored Data

</tr>
</tbody>
</table>

**Optimization Summary**

- Optimization Technique: Trust Region
- Iterations: 8
- Function Calls: 23
- Log Likelihood: -148.20614
You can specify a different set of initial values if estimates are available from fitting the distribution to similar
data. For this example, the parameters of the Burr distribution can be initialized with the final parameter
estimates of the Burr distribution that were obtained in the first example (shown in Figure 23.5). One of the
ways in which you can specify the initial values is as follows:

```plaintext
/*------ Specifying initial values using INIT= option -------*/
proc severity data=test_sev2 crit=aicc print=all plots=none;
   loss y / lt=threshold rc=limit;
   dist burr(init=(theta=4.62348 alpha=1.15706 gamma=6.41227));
run;
```

The names of the parameters that are specified in the INIT option must match the parameter names in the
definition of the distribution. The results obtained with these initial values are shown in Figure 23.13. These
results indicate that new set of initial values causes the optimizer to reach the same solution with fewer
iterations and function evaluations as compared to the default initialization.

**Figure 23.13** Burr Model Optimization Summary for the Truncated and Censored Data

| Parameter | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----------|----------------|---------|------|---|
| Theta     | 4.76980  | 0.62492        | 7.63    | <.0001 |
| Alpha     | 1.16363  | 0.58859        | 1.98    | 0.0509 |
| Gamma     | 5.94081  | 1.05004        | 5.66    | <.0001 |
An Example of Modeling Regression Effects

Consider a scenario in which the magnitude of the response variable might be affected by some regressor (exogenous or independent) variables. The SEVERITY procedure enables you to model the effect of such variables on the distribution of the response variable via an exponential link function. In particular, if you have \( k \) random regressor variables denoted by \( x_j \) \( (j = 1, \ldots, k) \), then the distribution of the response variable \( Y \) is assumed to have the form

\[
Y \sim \exp\left( \sum_{j=1}^{k} \beta_j x_j \right) \cdot \mathcal{F}(\Theta)
\]

where \( \mathcal{F} \) denotes the distribution of \( Y \) with parameters \( \Theta \) and \( \beta_j (j = 1, \ldots, k) \) denote the regression parameters (coefficients). For the effective distribution of \( Y \) to be a valid distribution from the same parametric family as \( \mathcal{F} \), it is necessary for \( \mathcal{F} \) to have a scale parameter. The effective distribution of \( Y \) can be written as

\[
Y \sim \mathcal{F}(\theta, \Omega)
\]

where \( \theta \) denotes the scale parameter and \( \Omega \) denotes the set of nonscale parameters. The scale \( \theta \) is affected by the regressors as

\[
\theta = \theta_0 \cdot \exp\left( \sum_{j=1}^{k} \beta_j x_j \right)
\]

where \( \theta_0 \) denotes a base value of the scale parameter.

Given this form of the model, PROC SEVERITY allows a distribution to be a candidate for modeling regression effects only if it has an untransformed or a log-transformed scale parameter.

All the predefined distributions, except the lognormal distribution, have a direct scale parameter (that is, a parameter that is a scale parameter without any transformation). For the lognormal distribution, the parameter \( \mu \) is a log-transformed scale parameter. This can be verified by replacing \( \mu \) with a parameter \( \theta = e^\mu \), which results in the following expressions for the PDF \( f \) and the CDF \( F \) in terms of \( \theta \) and \( \sigma \), respectively, where \( \Phi \) denotes the CDF of the standard normal distribution:

\[
f(x; \theta, \sigma) = \frac{1}{x \sigma \sqrt{2\pi}} e^{-\frac{1}{2} \left( \frac{\log(x) - \log(\theta)}{\sigma} \right)^2} \quad \text{and} \quad F(x; \theta, \sigma) = \Phi\left( \frac{\log(x) - \log(\theta)}{\sigma} \right)
\]

With this parameterization, the PDF satisfies the \( f(x; \theta, \sigma) = \frac{1}{\sigma} f\left( \frac{x}{\theta}; 1, \sigma \right) \) condition and the CDF satisfies the \( F(x; \theta, \sigma) = F\left( \frac{x}{\theta}; 1, \sigma \right) \) condition. This makes \( \theta \) a scale parameter. Hence, \( \mu = \log(\theta) \) is a log-transformed scale parameter and the lognormal distribution is eligible for modeling regression effects.

The following DATA step simulates a lognormal sample whose scale is decided by the values of the three regressors \( X1, X2, \) and \( X3 \) as follows:

\[
\mu = \log(\theta) = 1 + 0.75 \times X1 - X2 + 0.25 \times X3
\]
An Example of Modeling Regression Effects

/*---------------- Lognormal Model with Regressors ----------------*/
data test_sev3(keep=y x1-x3
   label='A Lognormal Sample Affected by Regressors');
array x{*} x1-x3;
array b{4} _TEMPORARY_ (1 0.75 -1 0.25);
call streaminit(45678);
label y='Response Influenced by Regressors';
Sigma = 0.25;
do n = 1 to 100;
   Mu = b(1); /* log of base value of scale */
   do i = 1 to dim(x);
      x(i) = rand('UNIFORM');
      Mu = Mu + b(i+1) * x(i);
   end;
y = exp(Mu) * rand('LOGNORMAL')**Sigma;
output;
end;
run;

The following PROC SEVERITY step fits the lognormal, Burr, and gamma distribution models to this data. The regressors are specified in the SCALEMODEL statement. The DFMIXTURE= option in the SCALEMODEL statement specifies the method of computing the CDF estimates that are used to compute the EDF-based statistics of fit.

    proc severity data=test_sev3 crit=aicc print=all;
      loss y;
      scalemodel x1-x3 / dfmixture=full;
      dist logn burr gamma;
    run;

Some of the key results prepared by PROC SEVERITY are shown in Figure 23.14 through Figure 23.18. The descriptive statistics of all the variables are shown in Figure 23.14.

The comparison of the fit statistics of all the models is shown in Figure 23.15. It indicates that the lognormal model is the best model according to each of the likelihood-based statistics, whereas the gamma model is the best model according to two of the three EDF-based statistics.

Figure 23.15 Comparison of Statistics of Fit for the Regression Example

The distribution information and the convergence results of the lognormal model are shown in Figure 23.16. The iteration history gives you a summary of how the optimizer is traversing the surface of the log-likelihood function in its attempt to reach the optimum. Both the change in the log likelihood and the maximum gradient of the objective function with respect to any of the parameters typically approach 0 if the optimizer converges.

The final parameter estimates of the lognormal model are shown in Figure 23.17. All the estimates are significantly different from 0. The estimate that is reported for the parameter $\mu$ is the base value for the log-transformed scale parameter $\mu$. Let $x_i (1 \leq i \leq 3)$ denote the observed value for regressor $X_i$. If the lognormal distribution is chosen to model $Y$, then the effective value of the parameter $\mu$ varies with the observed values of regressors as

$$\mu = 1.04047 + 0.65221 x_1 - 0.91116 x_2 + 0.16243 x_3$$

These estimated coefficients are reasonably close to the population parameters (that is, within one or two standard errors).
The estimates of the gamma distribution model, which is the best model according to a majority of the EDF-based statistics, are shown in Figure 23.18. The estimate that is reported for the parameter \( \Theta \) is the base value for the scale parameter \( \theta \). If the gamma distribution is chosen to model \( Y \), then the effective value of the scale parameter is \( \theta = 0.14293 \exp(0.64562 x_1 - 0.89831 x_2 + 0.14901 x_3) \).

PROC SEVERITY Statement

PROC SEVERITY options ;

The PROC SEVERITY statement invokes the procedure. You can specify two types of options in the PROC SEVERITY statement. One set of options controls input and output. The other set of options controls the model estimation and selection process.

The following options control the input data sets used by PROC SEVERITY and various forms of output generated by PROC SEVERITY. The options are listed in alphabetical order:

**COVOUT**

specifies that the OUTEST= data set contain the estimate of the covariance structure of the parameters. This option has no effect if you do not specify the OUTEST= option. For more information about how the covariance is reported in the OUTEST= data set, see the section “OUTEST= Data Set” on page 1709.

**DATA=SAS-data-set**

names the input data set. If you do not specify the DATA= option, then the most recently created SAS data set is used.

**INEST=SAS-data-set**

names the input data set that contains the initial values of the parameter estimates to start the optimization process. The initial values that you specify in the INIT= option in the DIST statement take precedence over any initial values that you specify in the INEST= data set. For more information about the variables in this data set, see the section “INEST= Data Set” on page 1707.

**NOPRINT**

turns off all displayed and graphical output. If you specify this option, then any value that you specify for the PRINT= and PLOTS= options is ignored.

**OUTCDF=SAS-data-set**

names the output data set to contain estimates of the cumulative distribution function (CDF) value at each of the observations. The information is output for each specified model whose parameter estimation process converges. The data set also contains the estimates of the empirical distribution function (EDF). For more information about the variables in this data set, see the section “OUTCDF= Data Set” on page 1708.

**OUTEST=SAS-data-set**

names the output data set to contain estimates of the parameter values and their standard errors for each model whose parameter estimation process converges. For more information about the variables in this data set, see the section “OUTEST= Data Set” on page 1709.

**OUTMODELINFO=SAS-data-set**

names the output data set to contain the information about each candidate distribution. For more information about the variables in this data set, see the section “OUTMODELINFO= Data Set” on page 1710.
OUTSTAT=SAS-data-set
names the output data set to contain the values of statistics of fit for each model whose parameter estimation process converges. For more information about the variables in this data set, see the section “OUTSTAT= Data Set” on page 1711.

PLOTS < (global-plot-options) >= plot-request-option>

PLOTS < (global-plot-options) > < = (plot-request-option . . . plot-request-option) >
specifies the desired graphical output. If you specify more than one global-plot-option, then separate them with spaces and enclose them in parentheses. If you specify more than one plot-request-option, then separate them with spaces and enclose them in parentheses.

The following global-plot-options are available:

HISTOGRAM
plots the histogram of the response variable on the PDF plots.

KERNEL
plots the kernel estimate of the probability density of the response variable on the PDF plots.

ONLY
turns off the default graphical output and prepares only the requested plots.

The following plot-request-options are available:

ALL
displays all the graphical output.

CDF
prepares a plot that compares the cumulative distribution function (CDF) estimates of all the candidate distribution models and the empirical distribution function (EDF) estimate. The plot does not contain CDF estimates for models whose parameter estimation process does not converge.

CDFPERDIST
prepares a plot of the CDF estimates of each candidate distribution model. A plot is not prepared for models whose parameter estimation process does not converge.

NONE
displays none of the graphical output. If you specify this option, then it overrides all the other plot request options. The default graphical output is also suppressed.

PDF
prepares a plot that compares the probability density function (PDF) estimates of all the candidate distribution models. The plot does not contain PDF estimates for models whose parameter estimation process does not converge.

PDFPERDIST
prepares a plot of the PDF estimates of each candidate distribution model. A plot is not prepared for models whose parameter estimation process does not converge.
prepares the probability-probability plot (known as the P-P plot), which compares the CDF estimate of each candidate distribution model against the empirical distribution function (EDF). The data shown in this plot are used for computing the EDF-based statistics of fit.

prepares the quantile-quantile plot (known as the Q-Q plot), which compares the empirical quantiles against the quantiles of each candidate distribution model.

If you do not specify the PLOTS= option or if you do not specify the ONLY global-plot-option, then the default graphical output is equivalent to specifying PLOTS=(CDF PDF).

specifies the desired displayed output. If you specify more than one display-option, then separate them with spaces and enclose them in parentheses.

The following global-display-option is available:

ONLY

turns off the default displayed output and displays only the requested output.

The following display-options are available:

ALL

displays all the output.

ALLFITSTATS

displays the comparison of all the statistics of fit for all the models in one table. The table does not include the models whose parameter estimation process does not converge.

CONVSTATUS

displays the convergence status of the parameter estimation process.

DESCSTATS

displays the descriptive statistics for the response variable. If you specify the SCALEMODEL statement, then this option also displays the descriptive statistics for the regressor variables.

DISTINFO

displays the information about each specified distribution. For each distribution, the information includes the name, description, validity status, and number of distribution parameters.

ESTIMATES | PARMEST

displays the final estimates of parameters. The estimates are not displayed for models whose parameter estimation process does not converge.

INITIALVALUES

displays the initial values and bounds used for estimating each model.
NLOHISTORY
  displays the iteration history of the nonlinear optimization process used for estimating the parameters.

NLOSUMMARY
  displays the summary of the nonlinear optimization process used for estimating the parameters.

NONE
  displays none of the output. If you specify this option, then it overrides all other display options. The default displayed output is also suppressed.

SELECTION | SELECT
  displays the model selection table.

STATISTICS | FITSTATS
  displays the statistics of fit for each model. The statistics of fit are not displayed for models whose parameter estimation process does not converge.

If you do not specify the PRINT= option or if you do not specify the ONLY global-display-option, then the default displayed output is equivalent to specifying PRINT=(SELECTION CONVSTATUS NLOSUMMARY STATISTICS ESTIMATES).

VARDEF=option
  specifies the denominator to use for computing the covariance estimates. You can specify one of the following values for option:

  DF
    specifies that the number of nonmissing observations minus the model degrees of freedom (number of parameters) be used.

  N
    specifies that the number of nonmissing observations be used.

For more information about the covariance estimation, see the section “Estimating Covariance and Standard Errors” on page 1662.

VERBOSE=verbosity-level
  specifies the amount of messages printed to the SAS log by PROC SEVERITY. A higher number prints messages with the same or more detail.

The following options control the model estimation and selection process:

CRITERION | CRITERIA | CRIT=criterion-option
  specifies the model selection criterion.

If you specify two or more candidate models for estimation, then the one with the best value for the selection criterion is chosen as the best model. If you specify the OUTSTAT= data set, then the best model’s observation has a value of 1 for the _SELECTED_ variable. You can specify one of the following criterion-options:
AD
specifies the Anderson-Darling (AD) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

AIC
specifies the Akaike’s information criterion (AIC) as the selection criterion. A lower value is deemed better.

AICC
specifies the finite-sample corrected Akaike’s information criterion (AICC) as the selection criterion. A lower value is deemed better.

BIC
specifies Schwarz Bayesian information criterion (BIC) as the selection criterion. A lower value is deemed better.

CUSTOM
specifies the custom objective function as the selection criterion. You can specify this only if you also specify the OBJECTIVE= option. A lower value is deemed better.

CVM
specifies the Cramér-von Mises (CvM) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

KS
specifies the Kolmogorov-Smirnov (KS) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

LOGLIKELIHOOD | LL
specifies \(-2 \log(L)\) as the selection criterion, where \(L\) is the likelihood of the data. A lower value is deemed better. This is the default.

For more information about these criterion-options, see the section “Statistics of Fit” on page 1675.

EMPIRICALCDF | EDF=method
specifies the method to use for computing the nonparametric or empirical estimate of the cumulative distribution function of the data. You can specify one of the following values for method:

AUTOMATIC | AUTO
specifies that the method be chosen automatically based on the data specification. This option is the default.

If you do not specify censoring or truncation, then the standard empirical estimation method (STANDARD) is chosen. If you specify both right-censoring and left-censoring, then Turnbull’s estimation method (TURNBULL) is chosen. For all other combinations of censoring and truncation, the Kaplan-Meier method (KAPLANMEIER) is chosen.

KAPLANMEIER | KM
specifies that the product limit estimator proposed by Kaplan and Meier (1958) be used. Specification of this method has no effect when you specify both right-censoring and left-censoring.
MODIFIEDKM | MKM <(options)>
specifies that the modified product limit estimator be used. Specification of this method has no
effect when you specify both right-censoring and left-censoring.

This method allows Kaplan-Meier’s product limit estimates to be more robust by ignoring the
contributions to the estimate due to small risk-set sizes. The risk set is the set of observations at
the risk of failing, where an observation is said to fail if it has not been processed yet and might
experience censoring or truncation. You can specify the minimum risk-set size that makes it
eligible to be included in the estimation either as an absolute lower bound on the size (RSLB=)
option) or a relative lower bound determined by the formula \( cn^\alpha \) proposed by Lai and Ying
(1991). You can specify the values of \( c \) and \( \alpha \) by using the C= and ALPHA= options, respectively.
By default, the relative lower bound is used with values of \( c = 1 \) and \( \alpha = 0.5 \). However, you
can modify the default by using the following options:

**ALPHA | A=number**

specifies the value to use for \( \alpha \) when the lower bound on the risk set size is defined as \( cn^\alpha \).
This value must satisfy \( 0 < \alpha < 1 \).

**C=number**

specifies the value to use for \( c \) when the lower bound on the risk set size is defined as \( cn^\alpha \).
This value must satisfy \( c > 0 \).

**RSLB=number**

specifies the absolute lower bound on the risk set size to be included in the estimate.

STANDARD | STD

specifies that the standard empirical estimation method be used. If you specify both right-
censoring and left-censoring, then the specification of this method has no effect. If you specify
any other combination of censoring or truncation effects, then this method ignores such effects,
and can thus result in estimates that are more biased than those obtained with other methods that
are more suitable for censored or truncated data.

TURNBULL | EM <(options)>
specifies that the Turnbull’s method be used. This method is used when you specify both right-
censoring and left-censoring. An iterative expectation-maximization (EM) algorithm proposed
by Turnbull (1976) is used to compute the empirical estimates. If you also specify truncation,
then the modification suggested by Frydman (1994) is used. You can modify the default behavior
of the EM algorithm by using the following options:

**ENSUREMLE**

specifies that the final EDF estimates be maximum likelihood estimates. The Kuhn-Tucker
conditions are computed for the likelihood maximization problem and checked to ensure
that EM algorithm converges to maximum likelihood estimates. The method generalizes
the method proposed by Gentleman and Geyer (1994) by taking into account any truncation
information that you might specify.

**EPS=number**

specifies the maximum relative error to be allowed between estimates of two consecutive
iterations. This criterion is used to check the convergence of the algorithm. If you do not
specify this option, then PROC SEVERITY uses a default value of 1.0E–8.
BY Statement

A BY statement can be used in the SEVERITY procedure to process the input data set in groups of observations defined by the BY variables.

When a BY statement appears, the procedure expects the input data set to be sorted in the order of the BY variables.

DIST Statement

DIST distribution-name-or-keyword < (distribution-option) < distribution-name-or-keyword < (distribution-option) > > ... > </ preprocess-options> ;

The DIST statement specifies candidate distributions to be estimated by the SEVERITY procedure. You can specify multiple DIST statements, and each statement can contain one or more distribution specifications.

MAXITER=number
specifies the maximum number of iterations to attempt to find the empirical estimates. If you do not specify this option, then PROC SEVERITY uses a default value of 500.

ZEROPROB=number
specifies the threshold below which an empirical estimate of the probability is considered zero. This option is used to decide if the final estimate is a maximum likelihood estimate. This option does not have an effect if you do not specify the ENSUREMLE option. If you specify the ENSUREMLE option, but do not specify this option, then PROC SEVERITY uses a default value of 1.0E–8.

For more information about each of the methods, see the section “Empirical Distribution Function Estimation Methods” on page 1669.

EDFALPHA=confidence-level
specifies the confidence level in the (0,1) range that is used for computing the confidence intervals for the EDF estimates. The lower and upper confidence limits that correspond to this level are reported in the OUTCDF= data set, if specified, and displayed in the plot that is prepared when you specify the PLOTS=CDFPERDIST option.

If you do not specify this option, then PROC SEVERITY uses a default value of 0.05.

OBJECTIVE=symbol-name
names the symbol that represents the objective function in the SAS programming statements that you specify. For each model to be estimated, PROC SEVERITY executes the programming statements to compute the value of this symbol for each observation. The values are added across all observations to obtain the value of the objective function. The optimization algorithm estimates the model parameters such that the objective function value is minimized. A separate optimization problem is solved for each candidate distribution. If you specify a BY statement, then a separate optimization problem is solved for each candidate distribution within each BY group.

For more information about writing SAS programming statements to define your own objective function, see the section “Custom Objective Functions” on page 1703.
For your convenience, PROC SEVERITY provides the following 10 different predefined distributions (the name in the parentheses is the name to use in the DIST statement): Burr (BURR), exponential (EXP), gamma (GAMMA), generalized Pareto (GPD), inverse Gaussian or Wald (IGAUSS), lognormal (LOGN), Pareto (PARETO), Tweedie (TWEEDIE), scaled Tweedie (STWEEDIE), and Weibull (WEIBULL). These are described in detail in the section “Predefined Distributions” on page 1649.

You can specify any of the predefined distributions or any distribution that you have defined. If a distribution that you specify is not a predefined distribution, then you must submit the CMPLIB= system option with appropriate libraries before you submit the PROC SEVERITY step to enable the procedure to find the functions associated with your distribution. The predefined distributions are defined in the Sashelp.Svrtdist library. However, you are not required to specify this library in the CMPLIB= system option. For more information about defining your own distributions, see the section “Defining a Distribution Model with the FCMP Procedure” on page 1679.

As a convenience, you can also use a shortcut keyword to indicate a list of distributions. You can specify one or more of the following keywords:

_ALL_

specifies all the predefined distributions and the distributions that you have defined in the libraries that you specify in the CMPLIB= system option. In addition to the eight predefined distributions included by the _PREDEFINED_ keyword, this list also includes the Tweedie and scaled Tweedie distributions that are defined in the Sashelp.Svrtdist library.

_PREDEFINED_

specifies the list of eight predefined distributions: BURR, EXP, GAMMA, GPD, IGAUSS, LOGN, PARETO, and WEIBULL. Although the TWEEDIE and STWEEDIE distributions are available in the Sashelp.Svrtdist library along with these eight distributions, they are not included by this keyword. If you want to fit the TWEEDIE and STWEEDIE distributions, then you must specify them explicitly or use the _ALL_ keyword.

_USER_

specifies the list of all the distributions that you have defined in the libraries that you specify in the CMPLIB= system option. This list does not include the distributions defined in the Sashelp.Svrtdist library, even if you specify the Sashelp.Svrtdist library in the CMPLIB= option.

The use of these keywords, especially _ALL_, can result in a large list of distributions, which might take a longer time to estimate. A warning is printed to the SAS log if the number of total distribution models to estimate exceeds 10.

If you specify the OUTCDF= option or request a CDF plot and you do not specify any DIST statement, then PROC SEVERITY does not fit any distributions and produces the empirical estimates of the cumulative distribution function.

The following distribution-option values can be used in the DIST statement for a distribution name that is not a shortcut keyword:

_INIT=(name=value . . . name=value)

specifies the initial values to be used for the distribution parameters to start the parameter estimation process. You must specify the values by parameter names and the parameter names must match the names used in the model definition.
For example, let a model M’s definition contain a M_PDF function with following signature:

```
function M_PDF(x, alpha, beta);
```

For this model, the names `alpha` and `beta` must be used for the INIT option. The names are case-insensitive. If you do not specify initial values for some parameters in the INIT statement, then a default value of 0.001 is assumed for those parameters. If you specify an incorrect parameter, PROC SEVERITY prints a warning to the SAS log and does not fit the model. All specified values must be nonmissing.

If you are modeling regression effects, then the initial value of the first distribution parameter (`alpha` in the preceding example) should be the initial `base` value of the scale parameter or log-transformed scale parameter. For more information, see the section “Estimating Regression Effects” on page 1664.

The use of INIT= option is one of the three methods available for initializing the parameters. For more information, see the section “Parameter Initialization” on page 1663. If none of the initialization methods is used, then PROC SEVERITY initializes all parameters to 0.001.

You can specify the following `preprocess-options` in the DIST statement:

- **LISTONLY**
  - specifies that the list of all candidate distributions be printed to the SAS log without doing any further processing on them. This option is especially useful when you use a shortcut keyword to include a list of distributions. It enables you to find out which distributions are included by the keyword.

- **VALIDATEONLY**
  - specifies that all candidate distributions be checked for validity without doing any further processing on them. If a distribution is invalid, the reason for invalidity is written to the SAS log. If all distributions are valid, then the distribution information is written to the SAS log. The information includes name, description, validity status (valid or invalid), and number of distribution parameters. The information is not written to the SAS log if you specify an OUTMODELINFO= data set or the PRINT=DISTINFO or PRINT=ALL option in the PROC SEVERITY statement. This option is especially useful when you specify your own distributions or when you specify the _USER_ or _ALL_ keywords in the DIST statement. It enables you to check whether your custom distribution definitions satisfy PROC SEVERITY’s requirements for the specified modeling task. It is recommended that you specify the SCALMODEL statement if you intend to fit a model with regression effects, because the SCALMODEL statement instructs PROC SEVERITY to perform additional checks to validate whether regression effects can be modeled on each candidate distribution.

---

**LOSS Statement**

```
LOSS < response-variable-name > < / censoring-truncation-options >;
```

The LOSS statement specifies the name of the response or loss variable whose distribution needs to be modeled. You can also specify additional options to indicate any truncation or censoring of the response. The specification of response variable is optional if you specify at least one type of censoring. You must specify a response variable if you do not specify any censoring. If you specify more than one LOSS statement, then the first statement is used.
All the analysis variables that you specify in this statement must be present in the input data set that you specify by using the DATA= option in the PROC SEVERITY statement. The response variable is expected to have nonmissing values. If the variable has a missing value in an observation, then a warning is written to the SAS log and that observation is ignored.

The following censoring-truncation-options can be used in the LOSS statement:

**LEFTCENSORED | LC=variable-name**

**LEFTCENSORED | LC=number**

specifies the left-censoring variable or a global left-censoring limit.

You can use the variable-name argument to specify a data set variable that contains the left-censoring limit. If the value of this variable is missing, then PROC SEVERITY assumes that such observations are not left-censored.

Alternatively, you can use the number argument to specify a left-censoring limit value that applies to all the observations in the data set. This limit must be a nonzero positive number.

By definition of left-censoring, an exact value of the response is not known when it is less than or equal to the left-censoring limit. If you specify the response variable and the value of that variable is less than or equal to the value of the left-censoring limit for some observations, then PROC SEVERITY treats such observations as left-censored and the value of the response variable is ignored. If you specify the response variable and the value of that variable is greater than the value of the left-censoring limit for some observations, then PROC SEVERITY assumes that such observations are not left-censored and the value of the left-censoring limit is ignored.

If you specify both right-censoring and left-censoring limits, then the left-censoring limit must be greater than or equal to the right-censoring limit. If both limits are identical, then the observation is assumed to be uncensored.

For more information about left-censoring, see the section “Censoring and Truncation” on page 1659.

**LEFTTRUNCATED | LT=variable-name < (left-truncation-option) >**

**LEFTTRUNCATED | LT=number < (left-truncation-option) >**

specifies the left-truncation variable or a global left-truncation threshold.

You can use the variable-name argument to specify a data set variable that contains the left-truncation threshold. If the value of this variable is missing or 0 for some observations, then PROC SEVERITY assumes that such observations are not left-truncated.

Alternatively, you can use the number argument to specify a left-truncation threshold that applies to all the observations in the data set. This threshold must be a nonzero positive number.

It is assumed that the response variable contains the observed values. By definition of left-truncation, you can observe only a value that is greater than the left-truncation threshold. If a response variable value is less than or equal to the left-truncation threshold, a warning is printed to the SAS log, and the observation is ignored. For more information about left-truncation, see the section “Censoring and Truncation” on page 1659.

You can specify the following left-truncation-option for an alternative interpretation of the left-truncation threshold:
PROBOBSERVED | POBS=number

specifies the probability of observability, which is defined as the probability that the underlying severity event is observed (and recorded) for the specified left-threshold value.

The specified number must lie in the (0.0, 1.0] interval. A value of 1.0 is equivalent to specifying that there is no left-truncation, because it means that no severity events can occur with a value less than or equal to the threshold. If you specify value of 1.0, PROC SEVERITY prints a warning to the SAS log and proceeds by assuming that LEFTTRUNCATED= option is not specified.

For more information, see the section “Probability of Observability” on page 1660.

RIGHTCENSORED | RC=variable-name

RIGHTCENSORED | RC=number

specifies the right-censoring variable or a global right-censoring limit.

You can use the variable-name argument to specify a data set variable that contains the right-censoring limit. If the value of this variable is missing, then PROC SEVERITY assumes that such observations are not right-censored.

Alternatively, you can use the number argument to specify a right-censoring limit value that applies to all the observations in the data set. This limit must be a nonzero positive number.

By definition of right-censoring, an exact value of the response is not known when it is greater than or equal to the right-censoring limit. If you specify the response variable and the value of that variable is greater than or equal to the value of the right-censoring limit for some observations, then PROC SEVERITY treats such observations as right-censored and the value of the response variable is ignored. If you specify the response variable and the value of that variable is less than the value of the right-censoring limit for some observations, then PROC SEVERITY assumes that such observations are not right-censored and the value of the right-censoring limit is ignored.

If you specify both right-censoring and left-censoring limits, then the left-censoring limit must be greater than or equal to the right-censoring limit. If both limits are identical, then the observation is assumed to be uncensored.

For more information about right-censoring, see the section “Censoring and Truncation” on page 1659.

RIGHTTRUNCATED | RT=variable-name

RIGHTTRUNCATED | RT=number

specifies the right-truncation variable or a global right-truncation threshold.

You can use the variable-name argument to specify a data set variable that contains the right-truncation threshold. If the value of this variable is missing for some observations, then PROC SEVERITY assumes that such observations are not right-truncated.

Alternatively, you can use the number argument to specify a right-truncation threshold that applies to all the observations in the data set. This threshold must be a nonzero positive number.

It is assumed that the response variable contains the observed values. By definition of right-truncation, you can observe only a value that is less than or equal to the right-truncation threshold. If a response variable value is greater than the right-truncation threshold, a warning is printed to the SAS log, and the observation is ignored. For more information about right-truncation, see the section “Censoring and Truncation” on page 1659.
NLOPTIONS Statement

NLOPTIONS options;

The SEVERITY procedure uses the nonlinear optimization (NLO) subsystem to perform the nonlinear
optimization of the likelihood function to obtain the estimates of distribution and regression parameters.
You can use the NLOPTIONS statement to control different aspects of this optimization process. For most
problems, the default settings of the optimization process are adequate. However, in some cases it might be
useful to change the optimization technique or to change the maximum number of iterations. The following
statement uses the MAXITER= option to set the maximum number of iterations to 200 and uses the TECH=
option to change the optimization technique to the double-dogleg optimization (DBLDOG) rather than the
default technique, the trust region optimization (TRUREG), used in the SEVERITY procedure:

nloptions tech=dbldog maxiter=200;

A discussion of the full range of options that can be used with the NLOPTIONS statement is given in
Chapter 6, “Nonlinear Optimization Methods.” The SEVERITY procedure supports all of those options
except the options that are related to displaying the optimization information. You can use the PRINT=
option in the PROC SEVERITY statement to request the optimization summary and iteration history. If you
specify more than one NLOPTIONS statement, then the first statement is used.

OUTSCORELIB Statement (Experimental)

OUTSCORELIB OUTLIB= fcmp-library-name options;

The OUTSCORELIB statement specifies the library to write scoring functions to. Scoring functions enable
you to easily execute a distribution function on the fitted parameters of the distribution without going through
a potentially complex process of extracting the fitted parameter estimates from other output such as the
OUTEST= data set that is created by PROC SEVERITY.

You must specify the following option as the first option in the statement:

OUTLIB=fcmp-library-name

names the FCMP library to contain the scoring functions. PROC SEVERITY writes the scoring
functions to the FCMP library named fcmp-library-name. If a library or data set named fcmp-library-
name already exists, PROC SEVERITY deletes it before proceeding.

This option is similar to the OUTLIB= option that you would specify in a PROC FCMP statement,
except that fcmp-library-name must be a two-level name whereas the OUTLIB= option in the PROC
FCMP statement requires a three-level name. The third level of a three-level name specifies the package
to which the functions belong. You do not need to specify the package name in the fcmp-library-name,
because PROC SEVERITY automatically creates the package for you. By default, a separate package
is created for each distribution that has not failed to converge. Each package is named for a distribution.
For example, if you define and fit a distribution named `mydist`, and if `mydist` does not fail to converge, then PROC SEVERITY creates a package named `mydist` in the OUTLIB= library that you specify. Further, let the definition of the `mydist` distribution contain three distribution functions, `mydist_PDF(x, Parm1, Parm2)`, `mydist_LOGCDF(x, Parm1, Parm2)`, and `mydist_XYZ(x, Parm1, Parm2)`. If you specify the OUTSCORELIB statement

```plaintext
outscorelib outlib=sasuser.scorefunc;
```

then the Sasuser.Scorefunc library contains the following three functions in a package named `mydist`: `SEV_PDF(x)`, `SEV_LOGCDF(x)`, and `SEV_XYZ(x)`.

The key feature of scoring functions is that they do not require the parameter arguments (`Parm1` and `Parm2` in this example). The fitted parameter estimates are encoded inside the scoring function so that you can compute or score the value of each function for a given value of the loss variable without having to know or extract the parameter estimates through some other means.

For convenience, you can omit the OUTLIB= portion of the specification and just specify the name, as in the following example:

```plaintext
outscorelib sasuser.scorefunc;
```

When the SEVERITY procedure executes successfully, the `fcmp-library-name` is appended to the CMPLIB system option, so you can immediately start using the scoring functions in a DATA step or PROC FCMP step.

You can specify the following options in the OUTSCORELIB statement:

- **COMMONPACKAGE**
  - requests that only one common package be created to contain all the scoring functions.

  If you specify this option, then all the scoring functions are created in a package called `sevfit`. For each distribution function that has the name `distribution_suffix`, the name of the corresponding scoring function is formed as `SEV_suffix_distribution`. For example, the scoring function of the distribution function `MYDIST_BAR` is named `SEV_BAR_MYDIST`.

  If you do not specify this option, then all scoring functions for a distribution are created in a package that has the same name as the distribution, and for each distribution function that has the name `distribution_suffix`, the name of the corresponding scoring function is formed as `SEV_suffix`. For example, the scoring function of the distribution function `MYDIST_BAR` is named `SEV_BAR`.

- **OUTBYID=SAS-data-set**
  - names the output data set to contain the unique identifier for each BY group. This unique identifier is used as part of the name of the package or scoring function for each distribution. This is a required option when you specify a BY statement in PROC SEVERITY.

  The OUTBYID= data set contains one observation per BY group and a variable named `_ID_` in addition to the BY variables that you specify in the BY statement. The `_ID_` variable contains the unique identifier for each BY group. The identifier of the BY group is the decimal representation of the sequence number of the BY group. The first BY group has an identifier of 1, the second BY group has an identifier of 2, the tenth BY group has an identifier of 10, and so on.
If you do not specify the COMMONPACKAGE option in the OUTSCORELIB statement, then for each distribution, PROC SEVERITY creates as many packages as the number of BY groups. The unique BY-group identifier is used as a suffix for the package name. For example, if your DATA= data set has three BY groups and if you specify the OUTSCORELIB statement

```plaintext
outscorelib outlib=sasuser.byscorefunc outbyid=sasuser.byid;
```

then for the distribution ‘MYDIST’, the Sasuser.Byscorefunc library contains the three packages ‘MYDIST1’, ‘MYDIST2’, and ‘MYDIST3’, and each package contains one scoring function named ‘SEV_BAR’ for each distribution function named ‘MYDIST_BAR’.

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, PROC SEVERITY creates as many versions of the distribution function as the number of BY groups. The unique BY-group identifier is used as a suffix for the function name. Extending the previous example, if you specify the OUTSCORELIB statement with the COMMONPACKAGE option,

```plaintext
outscorelib outlib=sasuser.byscorefunc outbyid=sasuser.byid commonpackage;
```

then for the distribution function ‘MYDIST_BAR’ of the distribution ‘MYDIST’, the Sasuser.Byscorefunc library contains the following three scoring functions: ‘SEV_BAR_MYDIST1’, ‘SEV_BAR_MYDIST2’, and ‘SEV_BAR_MYDIST3’. All the scoring functions are created in one common package named `sevfit`.

For both the preceding examples, the Sasuser.Byid data set contains three observations, one for each BY group. The value of the _ID_ variable is 1 for the first BY group, 2 for the second BY group, and 3 for the third BY group.

For more information about scoring functions, see the section “Scoring Functions (Experimental)” on page 1696.

---

**SCALEMODEL Statement**

```
SCALEMODEL regressor-variable-list < / scalemodel-options> ;
```

The SCALEMODEL statement specifies regression variables. All the variables that you specify in this statement must be present in the input data set that you specify by using the DATA= option in the PROC SEVERITY statement. The scale parameter of each candidate distribution is linked to a linear combination of these regression variables along with an intercept. If a distribution does not have a scale parameter, then a model based on that distribution is not estimated. If you specify more than one SCALEMODEL statement, then the first statement is used.

The regressor variables are expected to have nonmissing values. If any of the variables has a missing value in an observation, then a warning is written to the SAS log and that observation is ignored.

For more information about modeling regression effects, see the section “Estimating Regression Effects” on page 1664.
You can specify the following `scalemodel-options` in the SCALEMODEL statement:

DFMIXTURE=`method-name < (method-options)>`

specifies the method for computing representative estimates of the cumulative distribution function (CDF) and the probability density function (PDF).

When you specify regression variables, the scale of the distribution depends on the values of the regressors. For a given distribution family, each observation in the input data set implies a different scaled version of the distribution. To compute estimates of CDF and PDF that are comparable across different distribution families, PROC SEVERITY needs to construct a single representative distribution from all such distributions. You can specify one of the following `method-name` values to specify the method that is used to construct the representative distribution. For more information about each of the methods, see the section “CDF and PDF Estimates with Regression Effects” on page 1667.

**FULL**

specifies that the representative distribution be the mixture of $N$ distributions such that each distribution has a scale value that is implied by each of the $N$ observations that are used for estimation. This method is the slowest.

**MEAN**

specifies that the representative distribution be the one-point mixture of the distribution whose scale value is the mean of the $N$ scale values that are implied by the $N$ observations that are used for estimation. If you do not specify the DFMIXTURE= option, then this method is used by default. This is also the fastest method.

**QUANTILE < (K=q)>**

specifies that the representative distribution be the mixture of a fixed number of distributions whose scale values are the quantiles from the sample of $N$ scale values that are implied by the $N$ observations in the current BY group (or in the entire DATA= data set if you do not specify the BY statement).

You can use the K= option to specify the number of distributions in the mixture. If you specify $K=q$, then the mixture contains $(q-1)$ distributions such that each distribution has as its scale one of the $(q-1)$-quantiles.

If you do not specify the K= option, then PROC SEVERITY uses the default of 2, which implies the use of a one-point mixture with a distribution whose scale value is the median of all scale values.

**RANDOM < (random-method-options)>**

specifies that the representative distribution be the mixture of a fixed number of distributions whose scale values are the scale values that are implied by a randomly chosen subset of the set of all observations in the current BY group (or in the entire DATA= data set if you do not specify the BY statement). The same subset of observations is used for each distribution family.

You can specify the following `random-method-options` to specify how the subset is chosen:

`K=r`

specifies the number of distributions to include in the mixture. If you do not specify this option, then PROC SEVERITY uses the default of 15.
**SEED=**number

specifies the seed that is used to generate the uniform random sample of observation indices. If you do not specify this option, then PROC SEVERITY generates a seed internally that is based on the current value of the system clock.

**OFFSET=**offset-variable-name

specifies the name of the offset variable in the scale regression model. An offset variable is a regressor variable whose regression coefficient is known to be 1. For more information, see the section “Offset Variable” on page 1665.

---

**WEIGHT Statement**

```
WEIGHT variable-name;
```

The WEIGHT statement specifies the name of a variable whose values represent the weight of each observation. PROC SEVERITY associates a weight of $w$ to each observation, where $w$ is the value of the WEIGHT variable for the observation. If the weight value is missing or less than or equal to 0, then the observation is ignored and a warning is written to the SAS log. When you do not specify the WEIGHT statement, each observation is assigned a weight of 1. If you specify more than one WEIGHT statement, then the last statement is used.

The weights are normalized so that they add up to the actual sample size. In particular, weight of each observation is multiplied by $\frac{N}{\sum_{i=1}^{N} w_i}$, where $N$ is the sample size.

---

**Programming Statements**

You can use a series of programming statements that use variables in the input data set that you specify in the DATA= option in the PROC SEVERITY statement to assign a value to an objective function symbol. You must specify the objective function symbol by using the OBJECTIVE= option in the PROC SEVERITY statement. If you do not specify the OBJECTIVE= option in the PROC SEVERITY statement, then the programming statements are ignored and models are estimated using the maximum likelihood method.

You can use most DATA step statements and functions in your program. Any additional functions, restrictions, and differences are listed in the section “Custom Objective Functions” on page 1703.
Details: SEVERITY Procedure

Predefined Distributions

PROC SEVERITY assumes the following model for the response variable $Y$

$$Y \sim \mathcal{F}(\Theta)$$

where $\mathcal{F}$ is a continuous probability distribution with parameters $\Theta$. The model hypothesizes that the observed response is generated from a stochastic process that is governed by the distribution $\mathcal{F}$. This model is typically referred to as the error model. Given a representative input sample of response variable values, PROC SEVERITY estimates the model parameters for any distribution $\mathcal{F}$ and computes the statistics of fit for each model. This enables you to find the distribution that is most likely to generate the observed sample.

A set of predefined distributions is provided with the SEVERITY procedure. A summary of the distributions is provided in Table 23.2. For each distribution, the table lists the name of the distribution that should be used in the DIST statement, the parameters of the distribution along with their bounds, and the mathematical expressions for the probability density function (PDF) and cumulative distribution function (CDF) of the distribution.

All the predefined distributions, except LOGN and TWEEDIE, are parameterized such that their first parameter is the scale parameter. For LOGN, the first parameter $\mu$ is a log-transformed scale parameter. TWEEDIE does not have a scale parameter. The presence of scale parameter or a log-transformed scale parameter enables you to use all of the predefined distributions, except TWEEDIE, as a candidate for estimating regression effects.

A distribution model is associated with each predefined distribution. You can also define your own distribution model, which is a set of functions and subroutines that you define by using the FCMP procedure. See the section “Defining a Distribution Model with the FCMP Procedure” on page 1679 for more information.
Table 23.2 Predefined SEVERITY Distributions

<table>
<thead>
<tr>
<th>Name</th>
<th>Distribution</th>
<th>Parameters</th>
<th>PDF ((f)) and CDF ((F))</th>
</tr>
</thead>
</table>
| BURR    | Burr         | \(\theta > 0, \alpha > 0, \gamma > 0\) | \(f(x) = \frac{\alpha \gamma x^\gamma}{x(1+x\gamma)^{\alpha+1}}\)  
\(F(x) = 1 - \left(\frac{1}{1+x\gamma}\right)\alpha\) |
| EXP     | Exponential  | \(\theta > 0\) | \(f(x) = \frac{1}{\theta} e^{-\frac{x}{\theta}}\)  
\(F(x) = 1 - e^{-\frac{x}{\theta}}\) |
| GAMMA   | Gamma        | \(\theta > 0, \alpha > 0\) | \(f(x) = \frac{z^\alpha e^{-z}}{x \Gamma(\alpha)}\)  
\(F(x) = \frac{1}{\gamma} \left[\int_0^x \frac{1}{\gamma} e^{-\frac{t}{\gamma}} dt\right]\) |
| GPD     | Generalized Pareto | \(\theta > 0, \xi > 0\) | \(f(x) = \frac{1}{\theta} (1 + \xi z)^{-1-1/\xi}\)  
\(F(x) = 1 - (1 + \xi z)^{-1/\xi}\) |
| IGAUSS  | Inverse Gaussian | \(\theta > 0, \alpha > 0\) | \(f(x) = \frac{1}{\theta} \sqrt{\frac{\alpha}{2\pi z^3}} e^{-\frac{\alpha(z-1)^2}{2z}}\)

| LOGN    | Lognormal    | \(\mu\) (no bounds), \(\sigma > 0\) | \(f(x) = \frac{1}{x \sigma \sqrt{2\pi e}} e^{-\frac{1}{2\sigma^2} \left(\frac{\log(x) - \mu}{\sigma}\right)^2}\)  
\(F(x) = \Phi\left(\frac{\log(x) - \mu}{\sigma}\right)\) |
| PARETO  | Pareto       | \(\theta > 0, \alpha > 0\) | \(f(x) = \frac{\alpha^\alpha}{(x+\theta)^{\alpha+1}}\)  
\(F(x) = 1 - \left(\frac{\theta}{x+\theta}\right)^\alpha\) |
| TWEEDIE | Tweedie\(^6\) | \(p > 1, \mu > 0, \phi > 0\) | \(f(x) = a(x, \phi) \exp\left[\frac{1}{\phi} \left(\frac{x \mu - p}{1-p} - \kappa(\mu, p)\right)\right]\)  
\(F(x) = \int_0^x f(t) dt\) |
| STWEEDIE| Scaled Tweedie\(^6\) | \(\theta > 0, \lambda > 0, 1 < p < 2\) | \(f(x) = a(x, \theta, \lambda, p) \exp\left(-\frac{x}{\theta} - \lambda\right)\)  
\(F(x) = \int_0^x f(t) dt\) |
| WEIBULL | Weibull      | \(\theta > 0, \tau > 0\) | \(f(x) = \frac{1}{\tau} \tau z e^{-\frac{x}{\tau}}\)  
\(F(x) = 1 - e^{-\frac{x}{\tau}}\) |

Notes:
1. \(z = x/\theta\), wherever \(z\) is used.
2. \(\theta\) denotes the scale parameter for all the distributions. For LOGN, \(\log(\theta) = \mu\).
3. Parameters are listed in the order in which they are defined in the distribution model.
4. \(\gamma(a, b) = \int_0^b t^{a-1} e^{-t} dt\) is the lower incomplete gamma function.
5. \(\Phi(y) = \frac{1}{2} \left(1 + \text{erf}\left(\frac{y}{\sqrt{2}}\right)\right)\) is the standard normal CDF.
6. See the section “Tweedie Distributions” on page 1651 for more information.
Tweedie Distributions

Tweedie distributions are a special case of the exponential dispersion family (Jørgensen 1987) with a property that the variance of the distribution is equal to $\phi \mu^p$, where $\mu$ is the mean of the distribution, $\phi$ is a dispersion parameter, and $p$ is an index parameter as discovered by Tweedie (1984). The distribution is defined for all values of $p$ except for values of $p$ in the open interval $(0, 1)$. Many important known distributions are a special case of Tweedie distributions including normal ($p=0$), Poisson ($p=1$), gamma ($p=2$), and the inverse Gaussian ($p=3$). Apart from these special cases, the probability density function (PDF) of the Tweedie distribution does not have an analytic expression. For $p > 1$, it has the form (Dunn and Smyth 2005),

$$f(x; \mu, \phi, p) = a(x, \phi) \exp \left[ \frac{1}{\phi} \left( \frac{x \mu^{1-p}}{1-p} - \kappa(\mu, p) \right) \right]$$

where $\kappa(\mu, p) = \mu^{2-p}/(2-p)$ for $p \neq 2$ and $\kappa(\mu, p) = \log(\mu)$ for $p = 2$. The function $a(x, \phi)$ does not have an analytical expression. It is typically evaluated using series expansion methods described in Dunn and Smyth (2005).

For $1 < p < 2$, the Tweedie distribution is a compound Poisson-gamma mixture distribution, which is the distribution of $S$ defined as

$$S = \sum_{i=1}^{N} X_i$$

where $N \sim \text{Poisson}(\lambda)$ and $X_i \sim \text{gamma}(\alpha, \theta)$ are iid gamma random variables with shape parameter $\alpha$ and scale parameter $\theta$. At $X = 0$, the density is a probability mass that is governed by the Poisson distribution, and for values of $X > 0$, it is a mixture of gamma variates with Poisson mixing probability. The parameters $\lambda$, $\alpha$ and $\theta$ are related to the natural parameters $\mu$, $\phi$, and $p$ of the Tweedie distribution as

$$\lambda = \frac{\mu^{2-p}}{\phi(2-p)}$$
$$\alpha = \frac{2-p}{p-1}$$
$$\theta = \phi(p-1)\mu^{p-1}$$

The mean of a Tweedie distribution is positive for $p > 1$.

Two predefined versions of the Tweedie distribution are provided with the SEVERITY procedure. The first version, named TWEEDIE and defined for $p > 1$, has the natural parameterization with parameters $\mu$, $\phi$, and $p$. The second version, named STWEEDIE and defined for $1 < p < 2$, is the version with a scale parameter. It corresponds to the compound Poisson-gamma distribution with gamma scale parameter $\theta$, Poisson mean parameter $\lambda$, and the index parameter $p$. The index parameter decides the shape parameter $\alpha$ of the gamma distribution as

$$\alpha = \frac{2-p}{p-1}$$

The parameters $\theta$ and $\lambda$ of the STWEEDIE distribution are related to the parameters $\mu$ and $\phi$ of the TWEEDIE distribution as

$$\mu = \lambda \theta \alpha$$
$$\phi = \frac{(\lambda \theta \alpha)^{2-p}}{\lambda(2-p)} = \frac{\theta}{(p-1)(\lambda \theta \alpha)^{p-1}}$$
You can fit either version when there are no regression variables. Each version has its own merits. If you fit the TWEEDIE version, you have the direct estimate of the overall mean of the distribution. If you are interested in the most practical range of the index parameter $1 < p < 2$, then you can fit the STWEEDIE version, which provides you direct estimates of the Poisson and gamma components that comprise the distribution (an estimate of the gamma shape parameter $\alpha$ is easily obtained from the estimate of $p$).

If you want to estimate the effect of exogenous (regression) variables on the distribution, then you must use the STWEEDIE version, because PROC SEVERITY requires a distribution to have a scale parameter in order to estimate regression effects. See the section “Estimating Regression Effects” on page 1664 for more information. The gamma scale parameter $\theta$ is the scale parameter of the STWEEDIE distribution. If you are interested in determining the effect of regression variables on the mean of the distribution, you can do so by first fitting the STWEEDIE distribution to determine the effect of the regression variables on the scale parameter $\theta$. Then, you can easily estimate how the mean of the distribution is affected by the regression variables using the relationship $\mu = c\theta$, where $c = \lambda\alpha = \lambda(2 - p)/(p - 1)$. The estimates of the regression parameters remain the same, whereas the estimate of the intercept parameter is adjusted by the estimates of the $\alpha$ and $p$ parameters.

**Parameter Initialization for Predefined Distributions**

The parameters are initialized by using the method of moments for all the distributions, except for the gamma and the Weibull distributions. For the gamma distribution, approximate maximum likelihood estimates are used. For the Weibull distribution, the method of percentile matching is used.

Given $n$ observations of the severity value $y_i$ ($1 \leq i \leq n$), the estimate of $k$th raw moment is denoted by $m_k$ and computed as

$$m_k = \frac{1}{n} \sum_{i=1}^{n} y_i^k$$

The 100$p$th percentile is denoted by $\pi_p$ ($0 \leq p \leq 1$). By definition, $\pi_p$ satisfies

$$F(\pi_p) - p \leq F(\pi_p)$$

where $F(\pi_p) = \lim_{h \downarrow 0} F(\pi_p - h)$. PROC SEVERITY uses the following practical method of computing $\pi_p$. Let $\hat{F}_n(y)$ denote the empirical distribution function (EDF) estimate at a severity value $y$. Let $y_p^-$ and $y_p^+$ denote two consecutive values in the ascending sequence of $y$ values such that $\hat{F}_n(y_p^-) < p$ and $\hat{F}_n(y_p^+) \geq p$. Then, the estimate $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = y_p^- + \frac{p - \hat{F}_n(y_p^-)}{\hat{F}_n(y_p^+) - \hat{F}_n(y_p^-)}(y_p^+ - y_p^-)$$

Let $\epsilon$ denote the smallest double-precision floating-point number such that $1 + \epsilon > 1$. This machine precision constant can be obtained by using the CONSTANT function in Base SAS software.

The details of how parameters are initialized for each predefined distribution are as follows:

**BURR**

The parameters are initialized by using the method of moments. The $k$th raw moment of the Burr distribution is:

$$E[X^k] = \frac{\theta^k \Gamma(1 + k/\gamma) \Gamma(\alpha - k/\gamma)}{\Gamma(\alpha)}, -\gamma < k < \alpha\gamma$$
Three moment equations \( E[X^k] = m_k \) \((k = 1, 2, 3)\) need to be solved for initializing the three parameters of the distribution. In order to get an approximate closed form solution, the second shape parameter \( \gamma \) is initialized to a value of 2. If \( 2m_3 - 3m_1 m_2 > 0 \), then simplifying and solving the moment equations yields the following feasible set of initial values:

\[
\hat{\theta} = \sqrt{\frac{m_2 m_3}{2m_3 - 3m_1 m_2}}, \quad \hat{\alpha} = 1 + \frac{m_3}{2m_3 - 3m_1 m_2}, \quad \hat{\gamma} = 2
\]

If \( 2m_3 - 3m_1 m_2 < 0 \), then the parameters are initialized as follows:

\[
\hat{\theta} = \sqrt{m_2}, \quad \hat{\alpha} = 2, \quad \hat{\gamma} = 2
\]

EXP

The parameters are initialized by using the method of moments. The \( k \)th raw moment of the exponential distribution is:

\[
E[X^k] = \theta^k \Gamma(k + 1), \quad k > -1
\]

Solving \( E[X] = m_1 \) yields the initial value of \( \hat{\theta} = m_1 \).

GAMMA

The parameter \( \alpha \) is initialized by using its approximate maximum likelihood (ML) estimate. For a set of \( n \) iid observations \( y_i \) \((1 \leq i \leq n)\), drawn from a gamma distribution, the log likelihood, \( l \), is defined as follows:

\[
l = \sum_{i=1}^{n} \log \left( y_i^{\alpha-1} \frac{e^{-y_i/\theta}}{\theta^{\alpha} \Gamma(\alpha)} \right)
\]

\[
= (\alpha - 1) \sum_{i=1}^{n} \log(y_i) - \frac{1}{\theta} \sum_{i=1}^{n} y_i - n\alpha \log(\theta) - n \log(\Gamma(\alpha))
\]

Using a shorter notation of \( \sum \) to denote \( \sum_{i=1}^{n} \) and solving the equation \( \partial l / \partial \theta = 0 \) yields the following ML estimate of \( \theta \):

\[
\hat{\theta} = \frac{\sum y_i}{n\alpha} = \frac{m_1}{\alpha}
\]

Substituting this estimate in the expression of \( l \) and simplifying gives

\[
l = (\alpha - 1) \sum \log(y_i) - n\alpha - n\alpha \log(m_1) + n\alpha \log(\alpha) - n \log(\Gamma(\alpha))
\]

Let \( d \) be defined as follows:

\[
d = \log(m_1) - \frac{1}{n} \sum \log(y_i)
\]

Solving the equation \( \partial l / \partial \alpha = 0 \) yields the following expression in terms of the digamma function, \( \psi(\alpha) \):

\[
\log(\alpha) - \psi(\alpha) = d
\]

The digamma function can be approximated as follows:

\[
\hat{\psi}(\alpha) \approx \log(\alpha) - \frac{1}{\alpha} \left( 0.5 + \frac{1}{12\alpha + 2} \right)
\]
This approximation is within 1.4% of the true value for all the values of $\alpha > 0$ except when $\alpha$ is arbitrarily close to the positive root of the digamma function (which is approximately 1.461632). Even for the values of $\alpha$ that are close to the positive root, the absolute error between true and approximate values is still acceptable ($|\psi(\alpha) - \psi(\alpha)| < 0.005$ for $\alpha > 1.07$). Solving the equation that arises from this approximation yields the following estimate of $\alpha$:

$$\hat{\alpha} = \frac{3 - \mu + \sqrt{(d - 3)^2 + 24d}}{12d}$$

If this approximate ML estimate is infeasible, then the method of moments is used. The $k$th raw moment of the gamma distribution is:

$$E[X^k] = \theta^k \frac{\Gamma(\alpha + k)}{\Gamma(\alpha)}, \quad k > -\alpha$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial value for $\alpha$:

$$\hat{\alpha} = \frac{m_1^2}{m_2 - m_1^2}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance), then $\alpha$ is initialized as follows:

$$\hat{\alpha} = 1$$

After computing the estimate of $\alpha$, the estimate of $\theta$ is computed as follows:

$$\hat{\theta} = \frac{m_1}{\hat{\alpha}}$$

Both the maximum likelihood method and the method of moments arrive at the same relationship between $\hat{\alpha}$ and $\hat{\theta}$.

**GPD**

The parameters are initialized by using the method of moments. Notice that for $\xi > 0$, the CDF of the generalized Pareto distribution (GPD) is:

$$F(x) = 1 - \left(1 + \frac{\xi x}{\theta}\right)^{-1/\xi}$$

$$= 1 - \left(\frac{\theta/\xi}{x + \theta/\xi}\right)^{1/\xi}$$

This is equivalent to a Pareto distribution with scale parameter $\theta_1 = \theta/\xi$ and shape parameter $\alpha = 1/\xi$. Using this relationship, the parameter initialization method used for the PARETO distribution is used to get the following initial values for the parameters of the GPD distribution:

$$\hat{\theta} = \frac{m_1 m_2}{2(m_2 - m_1^2)}, \quad \hat{\xi} = \frac{m_2 - 2m_1^2}{2(m_2 - m_1^2)}$$
If \( m_2 - m_1^2 < \epsilon \) (almost zero sample variance) or \( m_2 - 2m_1^2 < \epsilon \), then the parameters are initialized as follows:

\[
\hat{\theta} = \frac{m_1}{2}, \quad \hat{\alpha} = \frac{1}{2}
\]

**IGAUSS**

The parameters are initialized by using the method of moments. Note that the standard parameterization of the inverse Gaussian distribution (also known as the Wald distribution), in terms of the location parameter \( \mu \) and shape parameter \( \lambda \), is as follows (Klugman, Panjer, and Willmot 1998, p. 583):

\[
f(x) = \sqrt{\frac{\lambda}{2\pi x^3}} \exp \left( -\frac{\lambda(x - \mu)^2}{2\mu^2x} \right)
\]

\[
F(x) = \Phi \left( \frac{1}{\mu} \sqrt{\frac{\lambda}{x}} \right) + \Phi \left( -\left( \frac{x}{\mu} + 1 \right) \sqrt{\frac{\lambda}{x}} \right) \exp \left( \frac{2\lambda}{\mu} \right)
\]

For this parameterization, it is known that the mean is \( E[X] = \mu \) and the variance is \( Var[X] = \mu^2/\lambda \), which yields the second raw moment as \( E[X^2] = \mu^2(1 + \mu/\lambda) \) (computed by using \( E[X^2] = Var[X] + (E[X])^2 \)).

The predefined IGAUSS distribution in PROC SEVERITY uses the following alternate parameterization to allow the distribution to have a scale parameter, \( \theta \):

\[
f(x) = \sqrt{\frac{\alpha \theta}{2\pi x^3}} \exp \left( -\frac{\alpha(x - \theta)^2}{2x\theta} \right)
\]

\[
F(x) = \Phi \left( \frac{x}{\theta} - 1 \right) \sqrt{\frac{\alpha \theta}{x}} + \Phi \left( -\left( \frac{x}{\theta} + 1 \right) \sqrt{\frac{\alpha \theta}{x}} \right) \exp (2\alpha)
\]

The parameters \( \theta \) (scale) and \( \alpha \) (shape) of this alternate form are related to the parameters \( \mu \) and \( \lambda \) of the preceding form such that \( \theta = \mu \) and \( \alpha = \lambda/\mu \). Using this relationship, the first and second raw moments of the IGAUSS distribution are:

\[
E[X] = \theta
\]

\[
E[X^2] = \theta^2 \left( 1 + \frac{1}{\alpha} \right)
\]

Solving \( E[X] = m_1 \) and \( E[X^2] = m_2 \) yields the following initial values:

\[
\hat{\theta} = m_1, \quad \hat{\alpha} = \frac{m_1^2}{m_2 - m_1^2}
\]

If \( m_2 - m_1^2 < \epsilon \) (almost zero sample variance), then the parameters are initialized as follows:

\[
\hat{\theta} = m_1, \quad \hat{\alpha} = 1
\]
LOGN The parameters are initialized by using the method of moments. The $k$th raw moment of the lognormal distribution is:

$$E[X^k] = \exp \left( k\mu + \frac{k^2\sigma^2}{2} \right)$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial values:

$$\hat{\mu} = 2 \log(m_1) - \frac{\log(m_2)}{2}, \quad \hat{\sigma} = \sqrt{\log(m_2) - 2 \log(m_1)}$$

PARETO The parameters are initialized by using the method of moments. The $k$th raw moment of the Pareto distribution is:

$$E[X^k] = \frac{\theta^k \Gamma(k + 1) \Gamma(\alpha - k)}{\Gamma(\alpha)}, -1 < k < \alpha$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial values:

$$\hat{\theta} = \frac{m_1 m_2}{m_2 - 2m_1^2}, \quad \hat{\alpha} = \frac{2(m_2 - m_1^2)}{m_2 - 2m_1^2}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance) or $m_2 - 2m_1^2 < \epsilon$, then the parameters are initialized as follows:

$$\hat{\theta} = m_1, \quad \hat{\alpha} = 2$$

TWEEDIE The parameter $p$ is initialized by assuming that the sample is generated from a gamma distribution with shape parameter $\alpha$ and by computing $\hat{p} = \frac{\hat{\alpha} + 2}{\hat{\alpha} + 1}$. The initial value $\hat{\alpha}$ is obtained from using the method previously described for the GAMMA distribution. The parameter $\mu$ is the mean of the distribution. Hence, it is initialized to the sample mean as

$$\hat{\mu} = m_1$$

Variance of a Tweedie distribution is equal to $\phi \mu^p$. Thus, the sample variance is used to initialize the value of $\phi$ as

$$\hat{\phi} = \frac{m_2 - m_1^2}{\hat{\mu}^p}$$
STWEEDIE

STWEEDIE is a compound Poisson-gamma mixture distribution with mean $\mu = \lambda \theta \alpha$, where $\alpha$ is the shape parameter of the gamma random variables in the mixture and the parameter $p$ is determined solely by $\alpha$. First, the parameter $p$ is initialized by assuming that the sample is generated from a gamma distribution with shape parameter $\alpha$ and by computing $\hat{p} = \frac{\hat{\alpha} + 2}{\hat{\alpha} + 1}$. The initial value $\hat{\alpha}$ is obtained from using the method previously described for the GAMMA distribution. As done for initializing the parameters of the TWEEDIE distribution, the sample mean and variance are used to compute the values $\hat{\mu}$ and $\hat{\phi}$ as

$$
\hat{\mu} = m_1 \\
\hat{\phi} = \frac{m_2 - m_1^2}{\hat{\mu} \hat{p}}
$$

Based on the relationship between the parameters of TWEEDIE and STWEEDIE distributions described in the section “Tweedie Distributions” on page 1651, values of $\theta$ and $\lambda$ are initialized as

$$
\hat{\theta} = \hat{\phi}(\hat{p} - 1)\hat{\mu}^{p-1} \\
\hat{\lambda} = \frac{\hat{\mu}}{\hat{\theta} \hat{\alpha}}
$$

WEIBULL

The parameters are initialized by using the percentile matching method. Let $q_1$ and $q_3$ denote the estimates of the 25th and 75th percentiles, respectively. Using the formula for the CDF of Weibull distribution, they can be written as

$$
1 - \exp\left(-\left(\frac{q_1}{\theta}\right)^r\right) = 0.25 \\
1 - \exp\left(-\left(\frac{q_3}{\theta}\right)^r\right) = 0.75
$$

Simplifying and solving these two equations yields the following initial values:

$$
\hat{\theta} = \exp\left(\frac{r \log(q_1) - \log(q_3)}{r - 1}\right), \quad \hat{r} = \frac{\log(\log(4))}{\log(q_3) - \log(\theta)}
$$

where $r = \log(\log(4))/\log(\log(4/3))$. These initial values agree with those suggested in Klugman, Panjer, and Willmot (1998).

A summary of the initial values of all the parameters for all the predefined distributions is given in Table 23.3. The table also provides the names of the parameters to use in the INIT= option in the DIST statement if you want to provide a different initial value.

### Censoring and Truncation

One of the key features of PROC SEVERITY is that it enables you to specify whether the severity event’s magnitude is observable and if it is observable, then whether the exact value of the magnitude is known. If an event is unobservable when the magnitude is in certain intervals, then it is referred to as a truncation effect. If the exact magnitude of the event is not known, but it is known to have a value in a certain interval, then it is referred to as a censoring effect.

PROC SEVERITY allows a severity event to be subject to any combination of the following four censoring and truncation effects:

- **Left-truncation:** An event is said to be left-truncated if it is observed only when $Y > T^l$, where $Y$ denotes the random variable for the magnitude and $T^l$ denotes a random variable for the truncation threshold. You can specify left-truncation using the `LEFTTRUNCATED=` option in the LOSS statement.

- **Right-truncation:** An event is said to be right-truncated if it is observed only when $Y \leq T^r$, where $Y$ denotes the random variable for the magnitude and $T^r$ denotes a random variable for the truncation threshold. You can specify right-truncation using the `RIGHTTRUNCATED=` option in the LOSS statement.

- **Left-censoring:** An event is said to be left-censored if it is known that the magnitude is $Y \leq C^l$, but the exact value of $Y$ is not known. $C^l$ is a random variable for the censoring limit. You can specify left-censoring using the `LEFTCENSORED=` option in the LOSS statement.

- **Right-censoring:** An event is said to be right-censored if it is known that the magnitude is $Y > C^r$, but the exact value of $Y$ is not known. $C^r$ is a random variable for the censoring limit. You can specify right-censoring using the `RIGHTCENSORED=` option in the LOSS statement.

For each effect, you can specify a different threshold or limit for each observation or specify a single threshold or limit that applies to all the observations.

If all the four types of effects are present on an event, then the following relationship holds: $T^l < C^r \leq C^l \leq T^r$. PROC SEVERITY checks these relationships and write a warning to the SAS log if any is violated.

If you specify the response variable in the LOSS statement, then PROC SEVERITY also checks whether each observation satisfies the definitions of the specified censoring and truncation effects. If you specify left-truncation, then PROC SEVERITY ignores observations where $Y \leq T^l$, because such observations are not observable by definition. Similarly, if you specify right-truncation, then PROC SEVERITY ignores observations where $Y > T^r$. If you specify left-censoring, then PROC SEVERITY treats an observation with $Y > C^l$ as uncensored and ignores the value of $C^l$. The observations with $Y \leq C^l$ are considered as left-censored, and the value of $Y$ is ignored. If you specify right-censoring, then PROC SEVERITY treats an observation with $Y \leq C^r$ as uncensored and ignores the value of $C^r$. The observations with $Y > C^r$ are considered as right-censored, and the value of $Y$ is ignored. If you specify both left-censoring and right-censoring, it is referred to as interval-censoring. If $C^r < C^l$ is satisfied for an observation, then it is considered as interval-censored and the value of the response variable is ignored. If $C^r = C^l$ for an observation, then PROC SEVERITY assumes that observation to be uncensored. If all the observations in a data set are censored in some form, then the specification of the response variable in the LOSS statement is optional, because the actual value of the response variable is not required for the purposes of estimating a model.
Specification of censoring and truncation affects the likelihood of the data (see the section “Likelihood Function” on page 1661) and how the empirical distribution function (EDF) is estimated (see the section “Empirical Distribution Function Estimation Methods” on page 1669).

Probability of Observability

For left-truncated data, PROC SEVERITY also enables you to provide additional information in the form of probability of observability by using the PROBOBSERVED= option. It is defined as the probability that the underlying severity event gets observed (and recorded) for the specified left-truncation threshold value. For example, if you specify a value of 0.75, then for every 75 observations recorded above a specified threshold, 25 more events have happened with a severity value less than or equal to the specified threshold. Although the exact severity value of those 25 events is not known, PROC SEVERITY can use the information about the number of those events.

In particular, for each left-truncated observation, PROC SEVERITY assumes a presence of \( (1 - p)/p \) additional observations with \( y_i = t_i \). These additional observations are then used for computing the likelihood (see the section “Probability of Observability and Likelihood” on page 1662) and an unconditional estimate of the empirical distribution function (see the section “EDF Estimates and Truncation” on page 1673).

Truncation and Conditional CDF Estimates

If you specify left-truncation without the probability of observability or if you specify right-truncation, then the EDF estimates that are computed by all methods except the STANDARD method are conditional on the truncation information. See the section “EDF Estimates and Truncation” on page 1673 for more information. In such cases, PROC SEVERITY uses conditional estimates of the CDF whenever they are used for computational or visual comparison with the EDF estimates.

Let \( t_{i \min}^l \) be the smallest value of the left-truncation threshold (\( t_i^l \) is the left-truncation threshold for observation \( i \)) and \( t_{i \max}^r \) be the largest value of the right-truncation threshold (\( t_i^r \) is the right-truncation threshold for observation \( i \)). If \( \hat{F}(y) \) denotes the unconditional estimate of the CDF at \( y \), then the conditional estimate \( \hat{F}^c(y) \) is computed as follows:

- If you do not specify the probability of observability, then the EDF estimates are conditional on the left-truncation information. If an observation is both left-truncated and right-truncated, then

\[
\hat{F}^c(y) = \frac{\hat{F}(y) - \hat{F}(t_{i \min}^l)}{\hat{F}(t_{i \max}^r) - \hat{F}(t_{i \min}^l)}
\]

If an observation is left-truncated but not right-truncated, then

\[
\hat{F}^c(y) = \frac{\hat{F}(y) - \hat{F}(t_{i \min}^l)}{1 - \hat{F}(t_{i \min}^l)}
\]

If an observation is right-truncated but not left-truncated, then

\[
\hat{F}^c(y) = \frac{\hat{F}(y)}{\hat{F}(t_{i \max}^r)}
\]

- If you specify the probability of observability, then EDF estimates are not conditional on the left-truncation information. If an observation is not right-truncated, then the conditional estimate is the
same as the unconditional estimate. If an observation is right-truncated, then the conditional estimate is computed as

\[ \hat{F}^c(y) = \frac{\hat{F}(y)}{\hat{F}(t_{\text{max}})} \]

If you specify regressors, then \( \hat{F}(y) \), \( \hat{F}(t_{\text{min}}) \), and \( \hat{F}(t_{\text{max}}) \) are all computed from a mixture distribution, as described in the section “CDF and PDF Estimates with Regression Effects” on page 1667.

---

**Parameter Estimation Method**

If you do not specify a custom objective function by specifying programming statements and the **OBJECTIVE=** option in the PROC SEVERITY statement, then PROC SEVERITY uses the maximum likelihood (ML) method to estimate the parameters of each model. A nonlinear optimization process is used to maximize the log of the likelihood function. If you specify a custom objective function, then PROC SEVERITY uses a nonlinear optimization algorithm to estimate the parameters of each model that minimize the value of your specified objective function. For more information, see the section “Custom Objective Functions” on page 1703.

**Likelihood Function**

Let \( f_\Theta(x) \) and \( F_\Theta(x) \) denote the PDF and CDF, respectively, evaluated at \( x \) for a set of parameter values \( \Theta \). Let \( Y \) denote the random response variable, and let \( y \) denote its value recorded in an observation in the input data set. Let \( T_l \) and \( T_r \) denote the random variables for the left-truncation and right-truncation threshold, respectively, and let \( t_l \) and \( t_r \) denote their values for an observation, respectively. If there is no left-truncation, then \( t_l = \tau_l \), where \( \tau_l \) is the smallest value in the support of the distribution; so \( F(\tau_l) = 0 \). If there is no right-truncation, then \( t_r = \tau_h \), where \( \tau_h \) is the largest value in the support of the distribution; so \( F(\tau_h) = 1 \). Let \( C_l \) and \( C_r \) denote the random variables for the left-censoring and right-censoring limit, respectively, and let \( c_l \) and \( c_r \) denote their values for an observation, respectively. If there is no left-censoring, then \( c_l = \tau_h \), so \( F(c_l) = 1 \). If there is no right-censoring, then \( c_r = \tau_l \), so \( F(c_r) = 0 \).

The set of input observations can be categorized into the following four subsets within each BY group:

- **\( E \)** is the set of uncensored and untruncated observations. The likelihood of an observation in \( E \) is
  \[
  l_E = \Pr(Y = y) = f_\Theta(y)
  \]

- **\( E_t \)** is the set of uncensored observations that are truncated. The likelihood of an observation in \( E_t \) is
  \[
  l_{E_t} = \Pr(y | t_l < Y \leq t_r) = \frac{f_\Theta(y)}{F_\Theta(t_r) - F_\Theta(t_l)}
  \]

- **\( C \)** is the set of censored observations that are not truncated. The likelihood of an observation \( C \) is
  \[
  l_C = \Pr(c_r < Y \leq c_l) = F_\Theta(c_l) - F_\Theta(c_r)
  \]

- **\( C_t \)** is the set of censored observations that are truncated. The likelihood of an observation \( C_t \) is
  \[
  l_{C_t} = \Pr(c_r < Y \leq c_l | t_l < Y \leq t_r) = \frac{F_\Theta(c_l) - F_\Theta(c_r)}{F_\Theta(t_r) - F_\Theta(t_l)}
  \]
Note that \((E \cup E_t) \cap (C \cup C_t) = \emptyset\). Also, the sets \(E_t\) and \(C_t\) are empty when you do not specify truncation, and the sets \(C\) and \(C_t\) are empty when you do not specify censoring.

Given this, the likelihood of the data \(L\) is as follows:

\[
L = \prod_{E} f_{\Theta}(y) \prod_{E_t, t^l = t^l} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r)} \prod_{E_t, t^l > t^l} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r)} \prod_{C} F_{\Theta}(c^l) - F_{\Theta}(c^r) \prod_{C_t, t^l = t^l} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r)} \prod_{C_t, t^l > t^l} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r)} \frac{1-p}{p}
\]

The maximum likelihood procedure used by PROC SEVERITY finds an optimal set of parameter values \(\hat{\Theta}\) that maximizes \(\log(L)\) subject to the boundary constraints on parameter values. For a distribution \(\text{dist}\), you can specify such boundary constraints by using the \text{dist}_\text{LOWERBOUNDS} and \text{dist}_\text{UPPERBOUNDS} subroutines. See the section “Defining a Distribution Model with the FCMP Procedure” on page 1679 for more information. Some aspects of the optimization process can be controlled by using the NLOPTIONS statement.

**Probability of Observability and Likelihood**

If you specify the probability of observability for the left-truncation, then PROC SEVERITY uses a modified likelihood function for each truncated observation. If the probability of observability is \(p \in (0.0, 1.0]\), then for each left-truncated observation with truncation threshold \(t^l\), there exist \((1-p)/p\) observations with a response variable value less than or equal to \(t^l\). Each such observation has a probability of \(P(Y \leq t^l) = F_{\Theta}(t^l)\). The right-truncation and censoring information does not apply to these added observations. Thus, following the notation of the section “Likelihood Function” on page 1661, the likelihood of the data is as follows:

\[
L = \prod_{E} f_{\Theta}(y) \prod_{E_t, t^l = t^l} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r)} \prod_{E_t, t^l > t^l} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r)} \frac{1-p}{p} \prod_{C} F_{\Theta}(c^l) - F_{\Theta}(c^r) \prod_{C_t, t^l = t^l} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r)} \prod_{C_t, t^l > t^l} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r)} \frac{1-p}{p}
\]

Note that the likelihood of the observations that are not left-truncated (observations in sets \(E\) and \(C\), and observations in sets \(E_t\) and \(C_t\) for which \(t^l = t^l\)) is not affected.

If you specify a custom objective function, then PROC SEVERITY accounts for the probability of observability only while computing the empirical distribution function estimate. The parameter estimates are affected only by your custom objective function.

**Estimating Covariance and Standard Errors**

PROC SEVERITY computes an estimate of the covariance matrix of the parameters by using the asymptotic theory of the maximum likelihood estimators (MLE). If \(N\) denotes the number of observations used for estimating a parameter vector \(\Theta\), then the theory states that as \(N \to \infty\), the distribution of \(\hat{\Theta}\), the estimate of \(\Theta\), converges to a normal distribution with mean \(\Theta\) and covariance \(\hat{C}\) such that \(I(\Theta) \cdot \hat{C} \to 1\), where \(I(\Theta) = -E \left[ \nabla^2 \log(L(\Theta)) \right]\) is the information matrix for the likelihood of the data, \(L(\Theta)\). The covariance estimate is obtained by using the inverse of the information matrix.
In particular, if $G = \nabla^2(-\log(L(\theta)))$ denotes the Hessian matrix of the negative of log likelihood, then the covariance estimate is computed as

$$\hat{C} = \frac{N}{d} G^{-1}$$

where $d$ is a denominator that is determined by the VARDEF= option. If VARDEF=N, then $d = N$, which yields the asymptotic covariance estimate. If VARDEF=DF, then $d = N - k$, where $k$ is number of parameters (the model’s degrees of freedom). The VARDEF=DF option is the default, because it attempts to correct the potential bias introduced by the finite sample.

The standard error $s_i$ of the parameter $\theta_i$ is computed as the square root of the $i$th diagonal element of the estimated covariance matrix; that is, $s_i = \sqrt{\hat{C}_{ii}}$.

If you specify a custom objective function, then the covariance matrix of the parameters is still computed by inverting the information matrix, except that the Hessian matrix $G$ is computed as $G = \nabla^2 \log(U(\theta))$, where $U$ denotes your custom objective function that is minimized by the optimizer.

Covariance and standard error estimates might not be available if the Hessian matrix is found to be singular at the end of the optimization process. This can especially happen if the optimization process stops without converging.

Parameter Initialization

PROC SEVERITY enables you to initialize parameters of a model in different ways. There can be two kinds of parameters in a model: distribution parameters and regression parameters.

The distribution parameters can be initialized by using one of the following three methods:

- INIT= option You can use the INIT= option in the DIST statement.
- INEST= data set You can use the INEST= data set.
- PARMINIT subroutine You can define a dist_PARMINIT subroutine in the distribution model. See the section “Defining a Distribution Model with the FCMP Procedure” on page 1679 for more information.

Note that only one of the initialization methods is used. You cannot combine them. They are used in the following order:

- The method that uses the INIT= option takes the highest precedence. If you use the INIT= option to provide an initial value for at least one parameter, then other initialization methods (INEST= and PARMINIT) are not used. If you specify initial values for some but not all the parameters by using the INIT= option, then the uninitialized parameters are initialized to the default value of 0.001.

  If you use this option and if you specify the regression effects, then the value of the first distribution parameter must be related to the initial value for the base value of the scale or log-transformed scale parameter. See the section “Estimating Regression Effects” on page 1664 for more information.

- The method that uses the INEST= data set takes the second precedence. If you specify a nonmissing value for even one distribution parameter, then the PARMINIT method is not used and any uninitialized parameters are initialized to the default value of 0.001.
• If none of the distribution parameters are initialized by using the INIT= option or the INEST= data set, but the distribution model defines a PARMINIT subroutine, then PROC SEVERITY invokes that subroutine with appropriate inputs to initialize the parameters. If the PARMINIT subroutine returns missing values for some parameters, then those parameters are initialized to the default value of 0.001.

• If none of the initialization methods are used, each distribution parameter is initialized to the default value of 0.001.

See the section “Estimating Regression Effects” on page 1664 for more information about regression models and initialization of regression parameters.

---

**Estimating Regression Effects**

The SEVERITY procedure enables you to estimate the effects of regressor (exogenous) variables while fitting a distribution if the distribution has a scale parameter or a log-transformed scale parameter.

Let \( x_j \) \((j = 1, \ldots, k)\) denote the \( k \) regressor variables. Let \( \beta_j \) denote the regression parameter that corresponds to the regressor \( x_j \). If you do not specify regression effects, then the model for the response variable \( Y \) is of the form

\[
Y \sim \mathcal{F}(\Theta)
\]

where \( \mathcal{F} \) is the distribution of \( Y \) with parameters \( \Theta \). This model is typically referred to as the error model. The regression effects are modeled by extending the error model to the following form:

\[
Y \sim \exp\left(\sum_{j=1}^{k} \beta_j x_j\right) \cdot \mathcal{F}(\Theta)
\]

Under this model, the distribution of \( Y \) is valid and belongs to the same parametric family as \( \mathcal{F} \) if and only if \( \mathcal{F} \) has a scale parameter. Let \( \theta \) denote the scale parameter and \( \Omega \) denote the set of nonscale distribution parameters of \( \mathcal{F} \). Then the model can be rewritten as

\[
Y \sim \mathcal{F}(\theta, \Omega)
\]

such that \( \theta \) is affected by the regressors as

\[
\theta = \theta_0 \cdot \exp\left(\sum_{j=1}^{k} \beta_j x_j\right)
\]

where \( \theta_0 \) is the *base* value of the scale parameter. Thus, the scale regression model consists of the following parameters: \( \theta_0, \Omega, \) and \( \beta_j (j = 1, \ldots, k) \).

Given this form of the model, distributions without a scale parameter cannot be considered when regression effects are to be modeled. If a distribution does not have a direct scale parameter, then PROC SEVERITY accepts it only if it has a log-transformed scale parameter — that is, if it has a parameter \( p = \log(\theta) \).
Offset Variable

You can specify that an offset variable be included in the scale regression model by specifying it in the OFFSET= option of the SCALEMODEL statement. The offset variable is a regressor whose regression coefficient is known to be 1. If \( x_o \) denotes the offset variable, then the scale regression model becomes

\[
\theta = \theta_0 \cdot \exp(x_o + \sum_{j=1}^{k} \beta_j x_j)
\]

The regression coefficient of the offset variable is fixed at 1 and not estimated, so it is not reported in the ParameterEstimates ODS table. However, if you specify the OUTEST= data set, then the regression coefficient is added as a variable to that data set. The value of the offset variable in OUTEST= data set is equal to 1 for the estimates row (_TYPE_='EST') and is equal to a special missing value (.F) for the standard error (_TYPE_='STDERR') and covariance (_TYPE_='COV') rows.

An offset variable is useful to model the scale parameter per unit of some measure of exposure. For example, in the automobile insurance context, measure of exposure can be the number of car-years insured or the total number of miles driven by a fleet of cars at a rental car company. For worker’s compensation insurance, if you want to model the expected loss per enterprise, then you can use the number of employees or total employee salary as the measure of exposure. For epidemiological data, measure of exposure can be the number of people who are exposed to a certain pathogen when you are modeling the loss associated with an epidemic. In general, if \( e \) denotes the value of the exposure measure and if you specify \( x_o = \log(e) \) as the offset variable, then you are modeling the effect of other regressors \( x_j \) on the size of the scale of the distribution per unit of exposure.

Another use for an offset variable is when you have a priori knowledge of the effect of some exogenous variables that cannot be included in the SCALEMODEL statement. You can model the combined effect of such variables as an offset variable in order to correct for the omitted variable bias.

Parameter Initialization for Regression Models

The regression parameters are initialized either by using the values that you specify or by the default method.

- If you provide initial values for the regression parameters, then you must provide valid, nonmissing initial values for \( \theta_0 \) and \( \beta_j \) parameters for all \( j \).

  You can specify the initial value for \( \theta_0 \) by using either the INEST= data set or the INIT= option in the DIST statement. If the distribution has a direct scale parameter (no transformation), then the initial value for the first parameter of the distribution is used as an initial value for \( \theta_0 \). If the distribution has a log-transformed scale parameter, then the initial value for the first parameter of the distribution is used as an initial value for \( \log(\theta_0) \).

  You can use only the INEST= data set to specify the initial values for \( \beta_j \). The INEST= data set must contain nonmissing initial values for all the regressors that you specify in the SCALEMODEL statement. The only missing value allowed is the special missing value .R, which indicates that the regressor is linearly dependent on other regressors. If you specify .R for a regressor for one distribution in a BY group, you must specify it so for all the distributions in that BY group.
• If you do not specify valid initial values for \( \theta_0 \) or \( \beta_j \) parameters for all \( j \), then PROC SEVERITY initializes those parameters by using the following method:

Let a random variable \( Y \) be distributed as \( F(\theta, \Omega) \), where \( \theta \) is the scale parameter. By definition of the scale parameter, a random variable \( W = Y/\theta \) is distributed as \( G(\Omega) \) such that \( G(\Omega) = F(1, \Omega) \). Given a random error term \( e \) that is generated from a distribution \( G(\Omega) \), a value \( y \) from the distribution of \( Y \) can be generated as

\[
y = \theta \cdot e
\]

Taking the logarithm of both sides and using the relationship of \( \theta \) with the regressors yields:

\[
\log(y) = \log(\theta_0) + \sum_{j=1}^{k} \beta_j x_j + \log(e)
\]

PROC SEVERITY makes use of the preceding relationship to initialize parameters of a regression model with distribution \( \text{dist} \) as follows:

1. The following linear regression problem is solved to obtain initial estimates of \( \beta_0 \) and \( \beta_j \):

\[
\log(y) = \beta_0 + \sum_{j=1}^{k} \beta_j x_j
\]

The estimates of \( \beta_j \) \((j = 1, \ldots, k)\) in the solution of this regression problem are used to initialize the respective regression parameters of the model. The estimate of \( \beta_0 \) is later used to initialize the value of \( \theta_0 \).

The results of this regression are also used to detect whether any regressors are linearly dependent on the other regressors. If any such regressors are found, then a warning is written to the SAS log and the corresponding regressor is eliminated from further analysis. The estimates for linearly dependent regressors are denoted by a special missing value of \( .R \) in the OUTEST= data set and in any displayed output.

2. Let \( s_0 \) denote the initial value of the scale parameter.

If the distribution model of \( \text{dist} \) does not contain the \( \text{dist\_PARMINIT} \) subroutine, then \( s_0 \) and all the nonscale distribution parameters are initialized to the default value of 0.001.

However, it is strongly recommended that each distribution’s model contain the \( \text{dist\_PARMINIT} \) subroutine. See the section “Defining a Distribution Model with the FCMP Procedure” on page 1679 for more information. If that subroutine is defined, then \( s_0 \) is initialized as follows:

Each input value \( y_i \) of the response variable is transformed to its scale-normalized version \( w_i \) as

\[
w_i = \frac{y_i}{\exp(\beta_0 + \sum_{j=1}^{k} \beta_j x_{ij})}
\]

where \( x_{ij} \) denotes the value of \( j \)th regressor in the \( i \)th input observation. These \( w_i \) values are used to compute the input arguments for the \( \text{dist\_PARMINIT} \) subroutine. The values that are computed by the subroutine for nonscale parameters are used as their respective initial values. If the distribution has an untransformed scale parameter, then \( s_0 \) is set to the value of the scale parameter that is computed by the subroutine. If the distribution has a log-transformed scale parameter \( P \), then \( s_0 \) is computed as \( s_0 = \exp(l_0) \), where \( l_0 \) is the value of \( P \) computed by the subroutine.
3. The value of $\theta_0$ is initialized as

$$\theta_0 = s_0 \cdot \exp(\hat{\beta}_0)$$

**Reporting Estimates of Regression Parameters**

When you request estimates to be written to the output (either ODS displayed output or in the OUTEST= data set), the estimate of the base value of the first distribution parameter is reported. If the first parameter is the log-transformed scale parameter, then the estimate of $\log(\theta_0)$ is reported; otherwise, the estimate of $\theta_0$ is reported. The transform of the first parameter of a distribution $\text{dist}$ is controlled by the $\text{dist}_\_\text{SCALETRANSFORM}$ function that is defined for it.

**CDF and PDF Estimates with Regression Effects**

When regression effects are estimated, the estimate of the scale parameter depends on the values of the regressors and the estimates of the regression parameters. This dependency results in a potentially different distribution for each observation. To make estimates of the cumulative distribution function (CDF) and probability density function (PDF) comparable across distributions and comparable to the empirical distribution function (EDF), PROC SEVERITY reports the CDF and PDF estimates from a representative distribution. The representative distribution is a mixture of a certain number of distributions, where each distribution differs only in the value of the scale parameter. You can specify the number of distributions in the mixture and how their scale values are chosen by using the DFMIXTURE= option in the SCALEMODEL statement.

Let $N$ denote the number of observations used for estimation, $K$ denote the number of components in the mixture distribution, $s_k$ denote the scale parameter of the $k$th mixture component, and $d_k$ denote the weight associated with $k$th mixture component.

Let $f(y; s_k, \hat{\Omega})$ and $F(y; s_k, \hat{\Omega})$ denote the PDF and CDF, respectively, of the $k$th component distribution, where $\hat{\Omega}$ denotes the set of estimates of all parameters of the distribution other than the scale parameter. Then, the PDF and CDF estimates, $f^*(y)$ and $F^*(y)$, respectively, of the mixture distribution at $y$ are computed as follows:

$$f^*(y) = \frac{1}{D} \sum_{k=1}^{K} d_k f(y; s_k, \hat{\Omega})$$

$$F^*(y) = \frac{1}{D} \sum_{k=1}^{K} d_k F(y; s_k, \hat{\Omega})$$

where $D$ is the normalization factor ($D = \sum_{k=1}^{K} d_k$).

The CDF estimates reported in OUTCDF= data set, plotted in CDF plots, and used for computing the EDF-based statistics of fit are the $F^*(y)$ values. The PDF estimates plotted in PDF plots are the $f^*(y)$ values.
The scale values $s_k$ for the $K$ mixture components are derived from the set $\{\hat{\theta}_i\}_{i=1}^N$ of $N$ scale values, where $\hat{\theta}_i$ denotes the estimate of the scale parameter due to observation $i$. It is computed as

$$\hat{\theta}_i = \hat{\theta}_0 \cdot \exp\left(\sum_{j=1}^k \hat{\beta}_j x_{ij}\right)$$

where $\hat{\theta}_0$ is an estimate of the base value of the scale parameter, $\hat{\beta}_j$ are the estimates of regression coefficients, and $x_{ij}$ is the value of regressor $j$ in observation $i$.

Let $w_i$ denote the weight of observation $i$. If you specify the WEIGHT statement, then the weight is equal to the value of the specified weight variable for the corresponding observation in the DATA= data set; otherwise, the weight is set to 1.

You can specify one of the following method-names in the DFMIXTURE= option in the SCALEMODEL statement to specify the method of choosing $K$ and the corresponding $s_k$ and $d_k$ values:

- **FULL**
  In this method, there are as many mixture components as the number of observations that are used for estimation. In other words, $K = N$, $s_k = \hat{\theta}_k$, and $d_k = w_k$ ($k = 1 \ldots N$). This is the slowest method, because it requires $O(N)$ computations to compute the mixture CDF $F^*(y_i)$ or the mixture PDF $f^*(y_i)$ of one observation. For $N$ observations, the computational complexity in terms of number of PDF or CDF evaluations is $O(N^2)$. Even for moderately large values of $N$, the time taken to compute the mixture CDF and PDF can significantly exceed the time taken to estimate the model parameters. So, it is recommended that you use this method only for small data sets.

- **MEAN**
  In this method, the mixture contains only one distribution, whose scale value is the mean of the scale values that are implied by all the observations. In other words, $s_1$ is computed as

$$s_1 = \frac{1}{W} \sum_{i=1}^N w_i \hat{\theta}_i$$

where $W$ is the total weight ($W = \sum_{i=1}^N w_i$).

This method is the fastest because it requires only one CDF or PDF evaluation per observation. The computational complexity is $O(N)$ for $N$ observations.

If you do not specify the DFMIXTURE= option in the SCALEMODEL statement, then this is the default method.

- **QUANTILE**
  In this method, a certain number of quantiles are chosen from the set of all scale values. If you specify a value of $q$ for the K= option when specifying this method, then $K = q - 1$ and $s_k$ are set to be the $(q-1)$-quantiles from the set $\{\hat{\theta}_i\}_{i=1}^N$. The weight of each of the components ($d_k$) is assumed to be 1 for this method.

The default value of $q$ is 2, which implies a one-point mixture with a distribution whose scale value is equal to the median scale value.

For this method, PROC SEVERITY needs to sort the $N$ scale values in the set $\{\hat{\theta}_i\}$, which requires $O(N \log(N))$ computations. Then, computing mixture estimate of one observation requires $(q-1)$ CDF or PDF evaluations. Hence, the computational complexity of this method is $O(qN) + O(N \log(N))$ for computing a mixture PDF or CDF of $N$ observations. For $q << N$, it is significantly faster than the FULL method.
In this method, a uniform random sample of observations is chosen and the mixture contains the distributions that are implied by those observations. If you specify a value of $r$ for the $K$= option when specifying this method, then the size of the sample is $r$. Hence, $K = r$. If $l_j$ denotes the index of $j$th observation in the sample ($j = 1 \ldots r$), such that $1 \leq l_j \leq N$, then the scale of $k$th component distribution in the mixture is $s_k = \hat{\theta}_{lk}$ and the weight associated with it is $d_k = w_{lk}$.

You can also specify the seed to be used for generating the random sample by using the `SEED=` option for this method. The same sample of observations is used for all models. Computing a mixture estimate of one observation requires $r$ CDF or PDF evaluations. Hence, the computational complexity of this method is $O(rN)$ for computing a mixture PDF or CDF of $N$ observations. For $r \ll N$, it is significantly faster than the FULL method.

**Empirical Distribution Function Estimation Methods**

The empirical distribution function (EDF) is a nonparametric estimate of the cumulative distribution function (CDF) of the distribution. PROC SEVERITY uses EDF estimates for computing the EDF-based statistics of fit.

If you specify both right-censoring and left-censoring, then the EDF is estimated using Turnbull’s method as described in the section “EDF Estimation for Right-Censored and Left-Censored Data” on page 1672. If all the observations are uncensored or there is only one type of censoring, then a choice of methods is available as described in the section “EDF Estimation for No Censoring or Single Type of Censoring” on page 1669.

**Notation**

Let there be a set of $N$ observations, each containing a quintuplet of values $(y_i, t_i^L, t_i^R, c_i^R, c_i^L)$, $i = 1, \ldots, N$, where $y_i$ is the value of the response variable, $t_i^L$ is the value of the left-truncation threshold, $t_i^R$ is the value of the right-truncation threshold, $c_i^R$ is the value of the right-censoring limit, and $c_i^L$ is the value of the left-censoring limit.

If an observation is not left-truncated, then $t_i^L = \tau^L$, where $\tau^L$ is the smallest value in the support of the distribution; so $F(t_i^L) = 0$. If an observation is not right-truncated, then $t_i^R = \tau_h$, where $\tau_h$ is the largest value in the support of the distribution; so $F(t_i^R) = 1$. If an observation is not right-censored, then $c_i^R = \tau^L$; so $F(c_i^R) = 0$. If an observation is not left-censored, then $c_i^L = \tau_h$; so $F(c_i^L) = 1$.

Let $w_i$ denote the weight associated with $i$th observation. If you specify the `WEIGHT` statement, then $w_i$ is the normalized value of the weight variable; otherwise, it is set to 1. The weights are normalized such that they sum up to $N$.

An indicator function $I[e]$ takes a value of 1 or 0 if the expression $e$ is true or false, respectively.

**EDF Estimation for No Censoring or Single Type of Censoring**

The method descriptions assume that all observations are either uncensored or right-censored; that is, each observation is of the form $(y_i, t_i^L, t_i^R, c_i^R, \tau_h)$.

If all observations are either uncensored or left-censored, then each observation is of the form $(y_i, t_i^L, t_i^R, \tau_l, c_i^L)$. It is converted to an observation $(-y_i, -t_i^L, -t_i^R, -c_i^L, \tau_h)$; that is, the signs of all the
response variable values are reversed, the new left-truncation threshold is equal to the negative of the original right-truncation threshold, the new right-truncation threshold is equal to the negative of the original left-truncation threshold, and the negative of the original left-censoring limit becomes the new right-censoring limit. With this transformation, each observation is either uncensored or right-censored. The methods described for handling uncensored or right-censored data are now applicable. After the EDF estimates are computed, the observations are transformed back to the original form and EDF estimates are adjusted such that

$$F_n(y_i) = 1 - F_n(-y_i^-)$$

where $F_n(-y_i^-)$ denotes the EDF estimate of the value slightly less than the transformed value $-y_i$.

A set of uncensored or right-censored observations can be converted to a set of observations of the form $(y_i, t_i^l, t_i^r, \delta_i)$, where $\delta_i$ is the indicator of right-censoring. $\delta_i = 0$ indicates a right-censored observation, in which case $y_i$ is assumed to record the right-censoring limit $c_i^r$. $\delta_i = 1$ indicates an uncensored observation, and $y_i$ records the exact observed value. In other words, $\delta_i = I[Y \leq C^r]$ and $y_i = \min(y_i, c_i^r)$.

Given this notation, the EDF is estimated as

$$F_n(y) = \begin{cases} 
0 & \text{if } y < y^{(1)} \\
\hat{F}_n(y^{(k)}) & \text{if } y^{(k)} \leq y < y^{(k+1)}, k = 1, \ldots, N - 1 \\
\hat{F}_n(y^{(N)}) & \text{if } y^{(N)} \leq y
\end{cases}$$

where $y^{(k)}$ denotes the $k$th order statistic of the set $\{y_i\}$ and $\hat{F}_n(y^{(k)})$ is the estimate computed at that value. The definition of $\hat{F}_n$ depends on the estimation method. You can specify a particular method or let PROC SEVERITY choose an appropriate method by using the `EMPIRICALCDF=` option in the PROC SEVERITY statement. Each method computes $\hat{F}_n$ as follows:

**STANDARD** This method is the standard way of computing EDF. The EDF estimate at observation $i$ is computed as follows:

$$\hat{F}_n(y_i) = \frac{1}{N} \sum_{j=1}^{N} w_j \cdot I[y_j \leq y_i]$$

If you do not specify any censoring or truncation information, this is the default method chosen. If you specify this method, then PROC SEVERITY ignores any censoring and truncation information that you specify in the LOSS statement.

The standard error of $\hat{F}_n(y_i)$ is computed by using the normal approximation method:

$$\hat{\sigma}_n(y_i) = \sqrt{\hat{F}_n(y_i)(1 - \hat{F}_n(y_i)) / N}$$

**KAPLANMEIER** The Kaplan-Meier (KM) estimator, also known as the product-limit estimator, was first introduced by Kaplan and Meier (1958) for censored data. Lynden-Bell (1971) derived a similar estimator for left-truncated data. PROC SEVERITY uses the definition that combines both censoring and truncation information (Klein and Moeschberger 1997; Lai and Ying 1991).

The EDF estimate at observation $i$ is computed as

$$\hat{F}_n(y_i) = 1 - \prod_{\tau \leq y_i} \left(1 - \frac{n(\tau)}{R_n(\tau)}\right)$$

where $n(\tau)$ and $R_n(\tau)$ are defined as follows:
Empirical Distribution Function Estimation Methods

- \( n(\tau) = \sum_{k=1}^{N} w_k \cdot I[y_k = \tau \text{ and } \tau \leq t'_k \text{ and } \delta_k = 1] \), which is the number of uncensored observations (\( \delta_k = 1 \)) for which the response variable value is equal to \( \tau \) and \( \tau \) is observable according to the right-truncation threshold of that observation (\( \tau \leq t'_k \)).

- \( R_n(\tau) = \sum_{k=1}^{N} w_k \cdot I[y_k \geq \tau > t'_k] \), which is the size (cardinality) of the risk set at \( \tau \). The term risk set has its origins in survival analysis; it contains the events that are at risk of failure at a given time, \( \tau \). In other words, it contains the events that have survived up to time \( \tau \) and might fail at or after \( \tau \). For PROC SEVERITY, time is equivalent to the magnitude of the event and failure is equivalent to an uncensored and observable event, where observable means it satisfies the truncation thresholds.

If you do not explicitly specify a method of computing EDF, then this is the default method used if you specify either right-censoring or left-censoring, but not both. This is also the default method when you specify truncation without any censoring.

The standard error of \( \hat{F}_n(y_i) \) is computed by using Greenwood’s formula (Greenwood 1926):

\[
\hat{\sigma}_n(y_i) = \left(1 - \hat{F}_n(y_i)\right)^2 \cdot \frac{n(\tau)}{R_n(\tau)(R_n(\tau) - n(\tau))}
\]

MODIFIEDKM

The product-limit estimator used by the KAPLANMEIER method does not work well if the risk set size becomes very small. For right-censored data, the size can become small towards the right tail. For left-truncated data, the size can become small at the left tail and can remain so for the entire range of data. This was demonstrated by Lai and Ying (1991). They proposed a modification to the estimator that ignores the effects due to small risk set sizes.

The EDF estimate at observation \( i \) is computed as

\[
\hat{F}_n(y_i) = 1 - \prod_{\tau \leq y_i} \left(1 - \frac{n(\tau)}{R_n(\tau)} \cdot I[R_n(\tau) \geq c N^\alpha]\right)
\]

where the definitions of \( n(\tau) \) and \( R_n(\tau) \) are identical to those used for the KAPLANMEIER method described previously.

You can specify the values of \( c \) and \( \alpha \) by using the C= and ALPHA= options. If you do not specify a value for \( c \), the default value used is \( c = 1 \). If you do not specify a value for \( \alpha \), the default value used is \( \alpha = 0.5 \).

As an alternative, you can also specify an absolute lower bound, say \( L \), on the risk set size by using the RSLB= option, in which case \( I[R_n(\tau) \geq c N^\alpha] \) is replaced by \( I[R_n(\tau) \geq L] \) in the definition.

The standard error of \( \hat{F}_n(y_i) \) is computed by using Greenwood’s formula (Greenwood 1926):

\[
\hat{\sigma}_n(y_i) = \left(1 - \hat{F}_n(y_i)\right)^2 \cdot \frac{n(\tau)}{R_n(\tau)(R_n(\tau) - n(\tau)) \cdot I[R_n(\tau) \geq c N^\alpha]}
\]
EDF Estimation for Right-Censored and Left-Censored Data

If the response variable is subject to both left-censoring and right-censoring effects, then the SEVERITY procedure uses a method proposed by Turnbull (1976) to compute the nonparametric estimates of the cumulative distribution function. The original Turnbull’s method is modified using the suggestions made by Frydman (1994) when truncation effects are present.

Let the input data consist of \(N\) observations in the form of quintuplets of values \((y_i, t_i^l, t_i^r, c_i^l, c_i^r), i = 1, \ldots, N\) with notation described in the section “Notation” on page 1669. For each observation, let \(A_i = (c_i^l, c_i^r)\) be the censoring interval; that is, the response variable value is known to lie in the interval \(A_i\), but the exact value is not known. If an observation is uncensored, then \(A_i = (y_i - \epsilon, y_i]\) for any arbitrarily small value of \(\epsilon > 0\). If an observation is censored, then the value \(y_i\) is ignored. Similarly, for each observation, let \(B_i = (t_i^l, t_i^r]\) be the truncation interval; that is, the observation is drawn from a truncated (conditional) distribution \(F(y, B_i) = P(Y \leq y | Y \in B_i)\).

Two sets, \(L\) and \(R\), are formed using \(A_i\) and \(B_i\) as follows:

\[
L = \{c_i^r, 1 \leq i \leq N\} \cup \{t_i^r, 1 \leq i \leq N\} \\
R = \{c_i^l, 1 \leq i \leq N\} \cup \{t_i^l, 1 \leq i \leq N\}
\]

The sets \(L\) and \(R\) represent the left endpoints and right endpoints, respectively. A set of disjoint intervals \(C_j = [q_j, p_j], 1 \leq j \leq M\) is formed such that \(q_j \in L\) and \(p_j \in R\) and \(q_j \leq p_j\) and \(p_j < q_{j+1}\). The value of \(M\) is dependent on the nature of censoring and truncation intervals in the input data. Turnbull (1976) showed that the maximum likelihood estimate (MLE) of the EDF can increase only inside intervals \(C_j\). In other words, the MLE estimate is constant in the interval \((p_j, q_{j+1})\). The likelihood is independent of the behavior of \(F_n\) inside any of the intervals \(C_j\). Let \(s_j\) denote the increase in \(F_n\) inside an interval \(C_j\). Then, the EDF estimate is as follows:

\[
F_n(y) = \begin{cases} 
0 & \text{if } y < q_1 \\
\sum_{k=1}^j s_k & \text{if } p_j < y < q_{j+1}, 1 \leq j \leq M - 1 \\
\text{if } y > p_M &
\end{cases}
\]

PROC SEVERITY reports the estimates \(F_n(p_j +) = F_n(q_{j+1} -) = \sum_{k=1}^j s_k\) at points \(p_j\) and \(q_{j+1}\) and reports \(F_n(q_1 -) = 0\) at point \(q_1\), where \(F_n(x+)\) denotes the limiting estimate at a point that is infinitesimally larger than \(x\) when approaching \(x\) from values larger than \(x\) and where \(F_n(x-)\) denotes the limiting estimate at a point that is infinitesimally smaller than \(x\) when approaching \(x\) from values smaller than \(x\).

PROC SEVERITY uses the expectation-maximization (EM) algorithm proposed by Turnbull (1976), who referred to the algorithm as the self-consistency algorithm. By default, the algorithm runs until one of the following criteria is met:

- Relative-error criterion: The maximum relative error between the two consecutive estimates of \(s_j\) falls below a threshold \(\epsilon\). If \(l\) indicates an index of the current iteration, then this can be formally stated as

\[
\arg \max_{1 \leq j \leq M} \left\{ \frac{|s_j^l - s_j^{l-1}|}{s_j^{l-1}} \right\} \leq \epsilon
\]

You can control the value of \(\epsilon\) by specifying the EPS= suboption of the EDF=TURNBULL option in the PROC SEVERITY statement. The default value is 1.0E–8.
Empirical Distribution Function Estimation Methods

- Maximum-iteration criterion: The number of iterations exceeds an upper limit that you specify for the MAXITER= suboption of the EDF=TURNBULL option in the PROC SEVERITY statement. The default number of maximum iterations is 500.

The self-consistent estimates obtained in this manner might not be maximum likelihood estimates. Gentleman and Geyer (1994) suggested the use of the Kuhn-Tucker conditions for the maximum likelihood problem to ensure that the estimates are MLE. If you specify the ENSUREMLE suboption of the EDF=TURNBULL option in the PROC SEVERITY statement, then PROC SEVERITY computes the Kuhn-Tucker conditions at the end of each iteration to determine whether the estimates \{s_j\} are MLE. If you do not specify any truncation effects, then the Kuhn-Tucker conditions derived by Gentleman and Geyer (1994) are used. If you specify any truncation effects, then PROC SEVERITY uses modified Kuhn-Tucker conditions that account for the truncation effects. An integral part of checking the conditions is to determine whether an estimate \(s_j\) is zero or whether an estimate of the Lagrange multiplier or the reduced gradient associated with the estimate \(s_j\) is zero. PROC SEVERITY declares these values to be zero if they are less than or equal to a threshold \(\delta\). You can control the value of \(\delta\) by specifying the ZEROPROB= suboption of the EDF=TURNBULL option in the PROC SEVERITY statement. The default value is 1.0E–8. The algorithm continues until the Kuhn-Tucker conditions are satisfied or the number of iterations exceeds the upper limit. The relative-error criterion stated previously is not used when you specify the ENSUREMLE option.

The standard errors for Turnbull’s EDF estimates are computed by using the asymptotic theory of the maximum likelihood estimators (MLE), even though the final estimates might not be MLE. Turnbull’s estimator essentially attempts to maximize the likelihood \(L\), which depends on the parameters \(s_j\) \((j = 1 \ldots M)\). Let \(s = \{s_j\}\) denote the set of these parameters. If \(G(s) = \nabla^2(-\log(L(s)))\) denotes the Hessian matrix of the negative of log likelihood, then the variance-covariance matrix of \(s\) is estimated as \(\hat{C}(s) = G^{-1}(s)\). Given this matrix, the standard error of \(F_n(y)\) is computed as

\[
\sigma_n(y) = \sqrt{\sum_{k=1}^{j} \left( \hat{C}_{kk} + \frac{k-1}{j} \sum_{l=1}^{k-1} \hat{C}_{kl} \right)}, \text{ if } p_j < y < q_{j+1}, 1 \leq j \leq M - 1
\]

The standard error is undefined outside of these intervals.

**EDF Estimates and Truncation**

If you specify truncation, then the estimate \(\hat{F}_n(y)\) that is computed by any method other than the STANDARD method is a conditional estimate. In other words, \(\hat{F}_n(y) = \Pr(Y \leq y | \tau_G < Y \leq \tau_H)\), where \(G\) and \(H\) denote the (unknown) distribution functions of the left-truncation threshold variable \(T_l\) and the right-truncation threshold variable \(T_r\), respectively, \(\tau_G\) denotes the smallest left-truncation threshold with a nonzero cumulative probability, and \(\tau_H\) denotes the largest right-truncation threshold with a nonzero cumulative probability. Formally, \(\tau_G = \inf \{s : G(s) > 0\}\) and \(\tau_H = \sup \{s : H(s) > 0\}\). For computational purposes, PROC SEVERITY estimates \(\tau_G\) and \(\tau_H\) by \(t_{\min}\) and \(t_{\max}\), respectively, defined as

\[
t_{\min} = \min \{ t_k^l : 1 \leq k \leq N \}
\]
\[
t_{\max} = \max \{ t_k^r : 1 \leq k \leq N \}
\]

These estimates are used to compute conditional estimates of the CDF as described in the section “Truncation and Conditional CDF Estimates” on page 1660.

If you specify left-truncation with the probability of observability \(p\), then PROC SEVERITY uses the additional information provided by \(p\) to compute an estimate of the EDF that is not conditional on the
Chapter 23: The SEVERITY Procedure

left-truncation information. In particular, for each left-truncated observation \( i \) with response variable value \( y_i \) and truncation threshold \( t^L_i \), an observation \( j \) is added with weight \( w_j = (1 - p)/p \) and \( y_j = t^L_i \). Each added observation is assumed to be uncensored and untruncated. Then, your specified EDF method is used by assuming no left-truncation. The EDF estimate that is obtained using this method is not conditional on the left-truncation information. For the KAPLANMEIER and MODIFIEDKM methods with uncensored or right-censored data, definitions of \( n(\tau) \) and \( R_n(\tau) \) are modified to account for the added observations. If \( N^a \) denotes the total number of observations including the added observations, then \( n(\tau) \) is defined as 
\[
  n(\tau) = \sum_{k=1}^{N^a} w_k I[y_k = \tau \text{ and } \tau \leq t^L_k \text{ and } \delta_k = 1],
\]
and \( R_n(\tau) \) is defined as 
\[
  R_n(\tau) = \sum_{k=1}^{N^a} w_k I[y_k \geq \tau].
\]
In the definition of \( R_n(\tau) \), the left-truncation information is not used, because it was used along with \( p \) to add the observations.

If the original data are a combination of left- and right-censored data, then Turnbull’s method is applied to the appended set that contains no left-truncated observations.

**Supplying EDF Estimates to Functions and Subroutines**

The parameter initialization subroutines in distribution models and some predefined utility functions require EDF estimates. See the sections “Defining a Distribution Model with the FCMP Procedure” on page 1679 and “Predefined Utility Functions” on page 1691 for more information.

PROC SEVERITY supplies the EDF estimates to these subroutines and functions by using two arrays, \( x \) and \( F \), the dimension of each array, and a type of the EDF estimates. The type identifies how the EDF estimates are computed and stored. They are as follows:

- **Type 1** specifies that EDF estimates are computed using the STANDARD method; that is, the data used for estimation are neither censored nor truncated.
- **Type 2** specifies that EDF estimates are computed using either the KAPLANMEIER or the MODIFIEDKM method; that is, the data used for estimation are subject to truncation and one type of censoring (left or right, but not both).
- **Type 3** specifies that EDF estimates are computed using the TURNBULL method; that is, the data used for estimation are subject to both left- and right-censoring. The data might or might not be truncated.

For Types 1 and 2, the EDF estimates are stored in arrays \( x \) and \( F \) of dimension \( N \) such that the following holds:
\[
  F_n(y) = \begin{cases} 
    0 & \text{if } y < x[1] \\ 
    F[k] & \text{if } x[k] \leq y < x[k + 1], k = 1, \ldots, N - 1 \\ 
    F[N] & \text{if } x[N] \leq y 
  \end{cases}
\]
where \([k]\) denotes \( k \)th element of the array (\([1]\) denotes the first element of the array).

For Type 3, the EDF estimates are stored in arrays \( x \) and \( F \) of dimension \( N \) such that the following holds:
\[
  F_n(y) = \begin{cases} 
    0 & \text{if } y < x[1] \\ 
    \text{undefined} & \text{if } x[2k - 1] \leq y < x[2k], k = 1, \ldots, (N - 1)/2 \\ 
    F[2k] = F[2k + 1] & \text{if } x[2k] \leq y < x[2k + 1], k = 1, \ldots, (N - 1)/2 \\ 
    F[N] & \text{if } x[N] \leq y 
  \end{cases}
\]
Although the behavior of EDF is theoretically undefined for the interval \([x[2k - 1], x[2k]]\), for computational purposes, all predefined functions and subroutines assume that the EDF increases linearly from \( F[2k - 1] \)
to \( F[2k] \) in that interval if \( x[2k - 1] < x[2k] \). If \( x[2k - 1] = x[2k] \), which can happen when the EDF is estimated from a combination of uncensored and interval-censored data, the predefined functions and subroutines assume that \( F_n(x[2k - 1]) = F_n(x[2k]) = F[2k] \).

### Statistics of Fit

PROC SEVERITY computes and reports various statistics of fit to indicate how well the estimated model fits the data. The statistics belong to two categories: likelihood-based statistics and EDF-based statistics. Statistics Neg2LogLike, AIC, AICC, and BIC are likelihood-based statistics, and statistics KS, AD, and CvM are EDF-based statistics. The following subsections provide definitions of each.

#### Likelihood-Based Statistics

Let \( y_i, i = 1, \ldots, N \) denote the response variable values. Let \( L \) be the likelihood as defined in the section “Likelihood Function” on page 1661. Let \( p \) denote the number of model parameters estimated. Note that \( p = p_d + (k - k_r) \), where \( p_d \) is the number of distribution parameters, \( k \) is the number of regressors, if any, that you specify in the SCALEMODEL statement, and \( k_r \) is the number of regressors found to be linearly dependent (redundant) on other regressors. Given this notation, the likelihood-based statistics are defined as follows:

**Neg2LogLike** The log likelihood is reported as

\[
\text{Neg2LogLike} = -2 \log(L)
\]

The multiplying factor \(-2\) makes it easy to compare it to the other likelihood-based statistics. A model with a smaller value of Neg2LogLike is deemed better.

**AIC** The Akaike’s information criterion (AIC) is defined as

\[
\text{AIC} = -2 \log(L) + 2p
\]

A model with a smaller value of AIC is deemed better.

**AICC** The corrected Akaike’s information criterion (AICC) is defined as

\[
\text{AICC} = -2 \log(L) + \frac{2Np}{N - p - 1}
\]

A model with a smaller value of AICC is deemed better. It corrects the finite-sample bias that AIC has when \( N \) is small compared to \( p \). AICC is related to AIC as

\[
\text{AICC} = \text{AIC} + \frac{2p(p + 1)}{N - p - 1}
\]

As \( N \) becomes large compared to \( p \), AICC converges to AIC. AICC is usually recommended over AIC as a model selection criterion.

**BIC** The Schwarz Bayesian information criterion (BIC) is defined as

\[
\text{BIC} = -2 \log(L) + p \log(N)
\]

A model with a smaller value of BIC is deemed better.
Chapter 23: The SEVERITY Procedure

EDF-Based Statistics

This class of statistics is based on the difference between the estimate of the cumulative distribution function (CDF) and the estimate of the empirical distribution function (EDF). Let \( y_i, i = 1, \ldots, N \) denote the sample of \( N \) values of the response variable. Let \( r_i = \sum_{j=1}^{N} I[y_j \leq y_i] \) denote the number of observations with a value less than or equal to \( y_i \), where \( I \) is an indicator function. Let \( F_n(y_i) \) denote the EDF estimate that is computed by using the method that you specify in the \texttt{EMPIRICALCDF=} option. Let \( Z_i = \hat{F}(y_i) \) denote the estimate of the CDF. Let \( F_n(Z_i) \) denote the EDF estimate of \( Z_i \) values that are computed using the same method that is used to compute the EDF of \( y_i \) values. Using the probability integral transformation, if \( F(y) \) is the true distribution of the random variable \( Y \), then the random variable \( Z = F(y) \) is uniformly distributed between 0 and 1 (D’Agostino and Stephens 1986, Ch. 4). Thus, comparing \( F_n(y_i) \) with \( \hat{F}(y_i) \) is equivalent to comparing \( F_n(Z_i) \) with \( \hat{F}(Z_i) = Z_i \) (uniform distribution).

Note the following two points regarding which CDF estimates are used for computing the test statistics:

- If you specify regressor variables, then the CDF estimates \( Z_i \) that are used for computing the EDF test statistics are from a mixture distribution. See the section “CDF and PDF Estimates with Regression Effects” on page 1667 for more information.
- If the EDF estimates are conditional because of the truncation information, then each unconditional estimate \( Z_i \) is converted to a conditional estimate using the method described in the section “Truncation and Conditional CDF Estimates” on page 1660.

In the following, it is assumed that \( Z_i \) denotes an appropriate estimate of the CDF if you specify any truncation or regression effects. Given this, the EDF-based statistics of fit are defined as follows:

KS

The Kolmogorov-Smirnov (KS) statistic computes the largest vertical distance between the CDF and the EDF. It is formally defined as follows:

\[
KS = \sup_y |F_n(y) - F(y)|
\]

If the STANDARD method is used to compute the EDF, then the following formula is used:

\[
D^+ = \max_i \left( \frac{r_i}{N} - Z_i \right) \\
D^- = \max_i \left( Z_i - \frac{r_{i-1}}{N} \right) \\
KS = \sqrt{\frac{N}{N}} \max(D^+, D^-) + 0.19 \frac{1}{\sqrt{N}}
\]

Note that \( r_0 \) is assumed to be 0.

If the method used to compute the EDF is any method other than the STANDARD method, then the following formula is used:

\[
D^+ = \max_i (F_n(Z_i) - Z_i), \text{ if } F_n(Z_i) \geq Z_i \\
D^- = \max_i (Z_i - F_n(Z_i)), \text{ if } F_n(Z_i) < Z_i \\
KS = \sqrt{\frac{N}{N}} \max(D^+, D^-) + 0.19 \frac{1}{\sqrt{N}}
\]
The Anderson-Darling (AD) statistic is a quadratic EDF statistic that is proportional to the expected value of the weighted squared difference between the EDF and CDF. It is formally defined as follows:

$$AD = N \int_{-\infty}^{\infty} \frac{(F_n(y) - F(y))^2}{F(y)(1 - F(y))} dF(y)$$

If the STANDARD method is used to compute the EDF, then the following formula is used:

$$AD = -N - \frac{1}{N} \sum_{i=1}^{N} [(2r_i - 1) \log(Z_i) + (2N + 1 - 2r_i) \log(1 - Z_i)]$$

If the method used to compute the EDF is any method other than the STANDARD method, then the statistic can be computed by using the following two pieces of information:

- If the EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM methods, then EDF is a step function such that the estimate $F_n(z)$ is a constant equal to $F_n(Z_{i-1})$ in interval $[Z_{i-1}, Z_i]$. If the EDF estimates are computed using the TURNBULL method, then there are two types of intervals: one in which the EDF curve is constant and the other in which the EDF curve is theoretically undefined. For computational purposes, it is assumed that the EDF curve is linear for the latter type of the interval. For each method, the EDF estimate $F_n(y)$ at $y$ can be written as

$$F_n(z) = F_n(Z_{i-1}) + S_i(z - Z_{i-1}), \text{ for } z \in [Z_{i-1}, Z_i]$$

where $S_i$ is the slope of the line defined as

$$S_i = \frac{F_n(Z_i) - F_n(Z_{i-1})}{Z_i - Z_{i-1}}$$

For the KAPLANMEIER or MODIFIEDKM method, $S_i = 0$ in each interval.

- Using the probability integral transform $z = F(y)$, the formula simplifies to

$$AD = N \int_{-\infty}^{\infty} \frac{(F_n(z) - z)^2}{z(1 - z)} dz$$

The computation formula can then be derived from the following approximation:

$$AD = N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(F_n(z) - z)^2}{z(1 - z)} dz$$

$$= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(F_n(Z_{i-1}) + S_i(z - Z_{i-1}) - z)^2}{z(1 - z)} dz$$

$$= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(P_i - Q_i z)^2}{z(1 - z)} dz$$

where $P_i = F_n(Z_{i-1}) - S_i Z_{i-1}$, $Q_i = 1 - S_i$, and $K$ is the number of points at which the EDF estimate are computed. For the TURNBULL method, $K = 2k$ for some $k$. 
Assuming \( Z_0 = 0, Z_{K+1} = 1, F_n(0) = 0, \) and \( F_n(Z_K) = 1 \) yields the following computation formula:

\[
AD = -N(Z_1 + \log(1 - Z_1) + \log(Z_K) + (1 - Z_K)) \\
+ N \sum_{i=2}^{K} \left[ P_i^2 A_i - (Q_i - P_i)^2 B_i - Q_i^2 C_i \right]
\]

where \( A_i = \log(Z_i) - \log(Z_{i-1}), B_i = \log(1 - Z_i) - \log(1 - Z_{i-1}), \) and \( C_i = Z_i - Z_{i-1}. \)

If EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM method, then \( P_i = F_n(Z_{i-1}) \) and \( Q_i = 1, \) which simplifies the formula as

\[
AD = -N(1 + \log(1 - Z_1) + \log(Z_K)) \\
+ N \sum_{i=2}^{K} \left[ F_n(Z_{i-1})^2 A_i - (1 - F_n(Z_{i-1}))^2 B_i \right]
\]

The Cramér-von Mises (CvM) statistic is a quadratic EDF statistic that is proportional to the expected value of the squared difference between the EDF and CDF. It is formally defined as follows:

\[
\text{CvM} = N \int_{-\infty}^{\infty} (F_n(y) - F(y))^2 dF(y)
\]

If the STANDARD method is used to compute the EDF, then the following formula is used:

\[
\text{CvM} = \frac{1}{12N} + \sum_{i=1}^{N} \left( Z_i - \frac{(2r_i - 1)}{2N} \right)^2
\]

If the method used to compute the EDF is any method other than the STANDARD method, then the statistic can be computed by using the following two pieces of information:

- As described previously for the AD statistic, the EDF estimates are assumed to be piecewise linear such that the estimate \( F_n(y) \) at \( y \) is

\[
F_n(z) = F_n(Z_{i-1}) + S_i(z - Z_{i-1}), \quad \text{for } z \in [Z_{i-1}, Z_i]
\]

where \( S_i \) is the slope of the line defined as

\[
S_i = \frac{F_n(Z_i) - F_n(Z_{i-1})}{Z_i - Z_{i-1}}
\]

For the KAPLANMEIER or MODIFIEDKM method, \( S_i = 0 \) in each interval.

- Using the probability integral transform \( z = F(y) \), the formula simplifies to:

\[
\text{CvM} = N \int_{-\infty}^{\infty} (F_n(z) - z)^2 dz
\]
The computation formula can then be derived from the following approximation:

\[ \text{CvM} = N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_{i}} (F_n(z) - z)^2 dz \]

\[ = N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_{i}} (F_n(Z_{i-1}) + S_i(z - Z_{i-1}) - z)^2 dz \]

\[ = N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_{i}} (P_i - Q_i z)^2 dz \]

where \( P_i = F_n(Z_{i-1}) - S_i Z_{i-1} \), \( Q_i = 1 - S_i \), and \( K \) is the number of points at which the EDF estimate are computed. For the TURNBULL method, \( K = 2k \) for some \( k \).

Assuming \( Z_0 = 0 \), \( Z_{K+1} = 1 \), and \( F_n(0) = 0 \) yields the following computation formula:

\[ \text{CvM} = N \sum_{i=2}^{K+1} \left[ P_i^2 A_i - P_i Q_i B_i - \frac{Q_i^2}{3} C_i \right] \]

where \( A_i = Z_i - Z_{i-1} \), \( B_i = Z_i^2 - Z_{i-1}^2 \), and \( C_i = Z_i^3 - Z_{i-1}^3 \).

If EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM method, then \( P_i = F_n(Z_{i-1}) \) and \( Q_i = 1 \), which simplifies the formula as

\[ \text{CvM} = N \sum_{i=2}^{K+1} \left[ F_n(Z_{i-1})^2 (Z_i - Z_{i-1}) - F_n(Z_{i-1})(Z_i^2 - Z_{i-1}^2) \right] \]

which is similar to the formula proposed by Koziol and Green (1976).

---

**Defining a Distribution Model with the FCMP Procedure**

A severity distribution model consists of a set of functions and subroutines that are defined using the FCMP procedure. The FCMP procedure is part of Base SAS software. Each function or subroutine must be named as `<distribution-name>_<keyword>`, where `distribution-name` is the identifying short name of the distribution and `keyword` identifies one of the functions or subroutines. The total length of the name should not exceed 32. Each function or subroutine must have a specific signature, which consists of the number of arguments, sequence and types of arguments, and return value type. The summary of all the recognized function and subroutine names and their expected behavior is given in Table 23.4.

Consider following points when you define a distribution model:

- When you define a function or subroutine requiring parameter arguments, the names and order of those arguments must be the same. Arguments other than the parameter arguments can have any name, but they must satisfy the requirements on their type and order.

- When the SEVERITY procedure invokes any function or subroutine, it provides the necessary input values according to the specified signature, and expects the function or subroutine to prepare the output and return it according to the specification of the return values in the signature.
• You can typically use most of the SAS programming statements and SAS functions that you can use in a DATA step for defining the FCMP functions and subroutines. However, there are a few differences in the capabilities of the DATA step and the FCMP procedure. Refer to the documentation of the FCMP procedure to learn more.

• You must specify either the PDF or the LOGPDF function. Similarly, you must specify either the CDF or the LOGCDF function. All other functions are optional, except when necessary for correct definition of the distribution. It is strongly recommended that you define the PARMINIT subroutine to provide a good set of initial values for the parameters. The information provided by PROC SEVERITY to the PARMINIT subroutine enables you to use popular initialization approaches based on the method of moments and the method of percentile matching, but you can implement any algorithm to initialize the parameters by using the values of the response variable and the estimate of its empirical distribution function.

• The LOWERBOUNDS subroutines should be defined if the lower bound on at least one distribution parameter is different from the default lower bound of 0. If you define a LOWERBOUNDS subroutine but do not set a lower bound for some parameter inside the subroutine, then that parameter is assumed to have no lower bound (or a lower bound of \(-\infty\)). Hence, it is recommended that you explicitly return the lower bound for each parameter when you define the LOWERBOUNDS subroutine.

• The UPPERBOUNDS subroutines should be defined if the upper bound on at least one distribution parameter is different from the default upper bound of \(\infty\). If you define an UPPERBOUNDS subroutine but do not set an upper bound for some parameter inside the subroutine, then that parameter is assumed to have no upper bound (or a upper bound of \(\infty\)). Hence, it is recommended that you explicitly return the upper bound for each parameter when you define the UPPERBOUNDS subroutine.

• If you want to use the distribution in a model with regression effects, then make sure that the first parameter of the distribution is the scale parameter itself or a log-transformed scale parameter. If the first parameter is a log-transformed scale parameter, then you must define the SCALETRANSFORM function.

• In general, it is not necessary to define the gradient and Hessian functions, because PROC SEVERITY uses an internal system to evaluate the required derivatives. The internal system typically computes the derivatives analytically. But it might not be able to do so if your function definitions use other functions that it cannot differentiate analytically. In such cases, derivatives are approximated using a finite difference method and a note is written to the SAS log to indicate the components that are differentiated using such approximations. PROC SEVERITY does reasonably well with these finite difference approximations. But, if you know of a way to compute the derivatives of such components analytically, then you should define the gradient and Hessian functions.

In order to use your distribution with PROC SEVERITY, you need to record the FCMP library that contains the functions and subroutines for your distribution and other FCMP libraries that contain FCMP functions or subroutines used within your distribution’s functions and subroutines. Specify all those libraries in the CMPLIB= system option by using the OPTIONS global statement. For more information about the OPTIONS statement, see the SAS Statements: Reference. For more information about the CMPLIB= system option, see the SAS System Options: Reference.

Each predefined distribution mentioned in the section “Predefined Distributions” on page 1649 has a distribution model associated with it. The functions and subroutines of all those models are available in the Sashelp.Svrtdist library. The order of the parameters in the signatures of the functions and subroutines is
Defining a Distribution Model with the FCMP Procedure

You do not need to use the CMPLIB= option in order to use the predefined distributions with PROC SEVERITY. However, if you need to use the functions or subroutines of the predefined distributions in SAS statements other than the PROC SEVERITY step (such as in a DATA step), then specify the Sashelp.Svrtdist library in the CMPLIB= system option by using the OPTIONS global statement prior to using them.

Table 23.4 shows functions and subroutines that define a distribution model, and subsections after the table provide more detail. The functions are listed in alphabetical order of the keyword suffix.

</tbody>
</table>

Notes:
1. Either the `dist_CDF` or the `dist_LOGCDF` function must be defined.
2. Either the `dist_PDF` or the `dist_LOGPDF` function must be defined.
The signature syntax and semantics of each function or subroutine are as follows:

**dist\_CDF**

defines a function that returns the value of the cumulative distribution function (CDF) of the distribution at the specified values of the random variable and distribution parameters.

- **Type**: Function
- **Required**: YES
- **Number of arguments**: \( m + 1 \), where \( m \) is the number of distribution parameters
- **Sequence and type of arguments**:
  - \( x \) Numeric value of the random variable at which the CDF value should be evaluated
  - \( p_1 \) Numeric value of the first parameter
  - \( p_2 \) Numeric value of the second parameter
  - \ldots
  - \( p_m \) Numeric value of the \( m \)th parameter
- **Return value**: Numeric value that contains the CDF value \( F(x; p_1, p_2, \ldots, p_m) \)

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

\[
F(x; p_1, p_2, \ldots, p_m) = F\left(\frac{x}{p_1}; 1, p_2, \ldots, p_m\right)
\]

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

\[
F(x; p_1, p_2, \ldots, p_m) = F\left(\frac{x}{\exp(p_1)}; 0, p_2, \ldots, p_m\right)
\]

Here is a sample structure of the function for a distribution named ‘FOO’:

```c
function FOO_CDF(x, P1, P2);
    /* Code to compute CDF by using x, P1, and P2 */
    F = <computed CDF>;
    return (F);
endsub;
```

**dist\_CONSTANTPARM**
defines a subroutine that specifies constant parameters. A parameter is *constant* if it is required for defining a distribution but is not subject to optimization in PROC SEVERITY. Constant parameters are required to be part of the model in order to compute the PDF or the CDF of the distribution. Typically, values of these parameters are known a priori or estimated using some means other than the maximum likelihood method used by PROC SEVERITY. You can estimate them inside the dist\_PARMINIT subroutine. Once initialized, the parameters remain constant in the context of PROC SEVERITY; that is, they retain their initial value. PROC SEVERITY estimates only the nonconstant parameters.
• **Type**: Subroutine
• **Required**: NO
• **Number of arguments**: $k$, where $k$ is the number of constant parameters
• **Sequence and type of arguments**:
  
  constant parameter 1 Name of the first constant parameter
  
  . . .
  
  constant parameter $k$ Name of the $k$th constant parameter
• **Return value**: None

Here is a sample structure of the subroutine for a distribution named ‘FOO’ that has P3 and P5 as its constant parameters, assuming that distribution has at least three parameters:

```plaintext
subroutine FOO_CONSTANTPARM(p5, p3);
endsub;
```

The following points should be noted while specifying the constant parameters:

• At least one distribution parameter must be free to be optimized; that is, if a distribution has total $m$ parameters, then $k$ must be strictly less than $m$.
• If you want to use this distribution for modeling regression effects, then the first parameter must not be a constant parameter.
• The order of arguments in the signature of this subroutine does not matter as long as each argument’s name matches the name of one of the parameters that are defined in the signature of the `dist_PDF` function.
• The constant parameters must be specified in signatures of all the functions and subroutines that accept distribution parameters as their arguments.
• You must provide a nonmissing initial value for each constant parameter by using one of the supported parameter initialization methods.

`dist_DESCRIPTION` defines a function that returns a description of the distribution.

• **Type**: Function
• **Required**: NO
• **Number of arguments**: None
• **Sequence and type of arguments**: Not applicable
• **Return value**: Character value containing a description of the distribution

Here is a sample structure of the function for a distribution named ‘FOO’:

```plaintext
function FOO_DESCRIPTION() $48;
  length desc $48;
  desc = "A model for a continuous distribution named foo";
  return (desc);
endsub;
```
There is no restriction on the length of the description (the length of 48 used in the previous example is for illustration purposes only). However, if the length is greater than 256, then only the first 256 characters appear in the displayed output and in the _DESCRIPTION_ variable of the OUTMODELINFO= data set. Hence, the recommended length of the description is less than or equal to 256.

**dist_LOG**

defines a function that returns natural logarithm of the specified core function of the distribution at the specified values of the random variable and distribution parameters. The core keyword can be PDF, CDF, or SDF.

- **Type:** Function
- **Required:** YES only if core is PDF or CDF and you have not defined that core function; otherwise, NO
- **Number of arguments:** \( m + 1 \), where \( m \) is the number of distribution parameters
- **Sequence and type of arguments:**
  
  \( x \quad \text{Numeric value of the random variable at which the natural logarithm of the core function should be evaluated} \)
  
  \( p_1 \quad \text{Numeric value of the first parameter} \)
  
  \( p_2 \quad \text{Numeric value of the second parameter} \)
  
  \( \ldots \)
  
  \( p_m \quad \text{Numeric value of the } m\text{th parameter} \)

- **Return value:** Numeric value that contains the natural logarithm of the core function

Here is a sample structure of the function for the core function PDF of a distribution named ‘FOO’:

```plaintext
function FOO_LOGPDF(x, P1, P2);
  /* Code to compute LOGPDF by using x, P1, and P2 */
  l = <computed LOGPDF>;
  return (l);
endsub;
```

**dist_LOWERBOUNDS**

defines a subroutine that returns lower bounds for the parameters of the distribution. If this subroutine is not defined for a given distribution, then the SEVERITY procedure assumes a lower bound of 0 for each parameter. If a lower bound of \( l_i \) is returned for a parameter \( p_i \), then the SEVERITY procedure assumes that \( l_i < p_i \) (strict inequality). If a missing value is returned for some parameter, then the SEVERITY procedure assumes that there is no lower bound for that parameter (equivalent to a lower bound of \(-\infty\)).

- **Type:** Subroutine
- **Required:** NO
- **Number of arguments:** \( m \), where \( m \) is the number of distribution parameters
• **Sequence and type of arguments:**

  p1 → Output argument that returns the lower bound on the first parameter. You must specify this in the OUTARGS statement inside the subroutine’s definition.

  p2 → Output argument that returns the lower bound on the second parameter. You must specify this in the OUTARGS statement inside the subroutine’s definition.

  ... ...

  pm → Output argument that returns the lower bound on the mth parameter. You must specify this in the OUTARGS statement inside the subroutine’s definition.

• **Return value:** The results, lower bounds on parameter values, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named ‘FOO’:

```plaintext
subroutine FOO_LOWERBOUNDS(p1, p2);
  outargs p1, p2;
  p1 = <lower bound for P1>;
  p2 = <lower bound for P2>;
endsub;
```

**dist_PARMINIT**

defines a subroutine that returns the initial values for the distribution’s parameters given an empirical distribution function (EDF) estimate.

• **Type:** Subroutine

• **Required:** NO

• **Number of arguments:** m + 4, where m is the number of distribution parameters

• **Sequence and type of arguments:**

  dim → Input numeric value that contains the dimension of the x, nx, and F array arguments.

  x{*} → Input numeric array of dimension dim that contains values of the random variables at which the EDF estimate is available. It can be assumed that x contains values in an increasing order. In other words, if \( i < j \), then \( x[i] < x[j] \).

  nx{*} → Input numeric array of dimension dim. Each nx[i] contains the number of observations in the original data that have the value x[i].

  F{*} → Input numeric array of dimension dim. Each F[i] contains the EDF estimate for x[i]. This estimate is computed by the SEVERITY procedure based on the EMPIRICAL-CDF= option.

  Ftype → Input numeric value that contains the type of the EDF estimate that is stored in x and F. See the section “Supplying EDF Estimates to Functions and Subroutines” on page 1674 for definition of types.

  p1 → Output argument that returns the initial value of the first parameter. You must specify this in the OUTARGS statement inside the subroutine’s definition.
Chapter 23: The SEVERITY Procedure

p2 Output argument that returns the initial value of the second parameter. You must specify this in the OUTARGS statement inside the subroutine’s definition.

pm Output argument that returns the initial value of the mth parameter. You must specify this in the OUTARGS statement inside the subroutine’s definition.

- Return value: The results, initial values of the parameters, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named ‘FOO’:

```plaintext
subroutine FOO_PARMINIT(dim, x(*), nx(*), F(*), Ftype, p1, p2);
  outargs p1, p2;
  /* Code to initialize values of P1 and P2 by using
dim, x, nx, and F */
  p1 = <initial value for p1>;
  p2 = <initial value for p2>;
endsub;
```

**dist_PDF**

defines a function that returns the value of the probability density function (PDF) of the distribution at the specified values of the random variable and distribution parameters.

- Type: Function
- Required: YES
- Number of arguments: \( m + 1 \), where \( m \) is the number of distribution parameters
- Sequence and type of arguments:
  x Numeric value of the random variable at which the PDF value should be evaluated
  p1 Numeric value of the first parameter
  p2 Numeric value of the second parameter
  ....
  pm Numeric value of the mth parameter

- Return value: Numeric value that contains the PDF value \( f(x; p_1, p_2, \ldots, p_m) \)

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

\[
f(x; p_1, p_2, \ldots, p_m) = \frac{1}{p_1} f\left(\frac{x}{p_1}; 1, p_2, \ldots, p_m\right)
\]

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

\[
f(x; p_1, p_2, \ldots, p_m) = \frac{1}{\exp(p_1)} f\left(\frac{x}{\exp(p_1)}; 0, p_2, \ldots, p_m\right)
\]
Here is a sample structure of the function for a distribution named ‘FOO’:

```plaintext
function FOO_PDF(x, P1, P2);
    /* Code to compute PDF by using x, P1, and P2 */
    f = <computed PDF>;
    return (f);
endsub;
```

`dist_QUANTILE` defines a function that returns the quantile of the distribution at the specified value of the CDF for the specified values of distribution parameters.

- **Type**: Function
- **Required**: NO
- **Number of arguments**: \( m + 1 \), where \( m \) is the number of distribution parameters
- **Sequence and type of arguments**:
  - `cdf` Numeric value of the cumulative distribution function (CDF) for which the quantile should be evaluated
  - `p1` Numeric value of the first parameter
  - `p2` Numeric value of the second parameter
  - ... ...
  - `pm` Numeric value of the \( m \)th parameter
- **Return value**: Numeric value that contains the quantile \( F^{-1}(c; p_1, p_2, \ldots, p_m) \)

Here is a sample structure of the function for a distribution named ‘FOO’:

```plaintext
function FOO_QUANTILE(c, P1, P2);
    /* Code to compute Quantile by using c, P1, and P2 */
    Q = <computed quantile>;
    return (Q);
endsub;
```

`dist_SCALETRANSFORM` defines a function that returns a keyword to identify the transform that needs to be applied to the scale parameter to convert it to the first parameter of the distribution.

If you want to use this distribution for modeling regression effects, then the first parameter of this distribution must be a scale parameter. However, for some distributions, a typical or convenient parameterization might not have a scale parameter, but one of the parameters can be a simple transform of the scale parameter. As an example, consider a typical parameterization of the lognormal distribution with two parameters, location \( \mu \) and shape \( \sigma \), for which the PDF is defined as follows:

\[
f(x; \mu, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2} \left( \frac{\log(x) - \mu}{\sigma} \right)^2}
\]
You can reparameterize this distribution to contain a parameter \( \theta \) instead of the parameter \( \mu \) such that \( \mu = \log(\theta) \). The parameter \( \theta \) would then be a scale parameter. However, if you want to specify the distribution in terms of \( \mu \) and \( \sigma \) (which is a more recognized form of the lognormal distribution) and still allow it as a candidate distribution for estimating regression effects, then instead of writing another distribution with parameters \( \theta \) and \( \sigma \), you can simply define the distribution with \( \mu \) as the first parameter and specify that it is the logarithm of the scale parameter.

- **Type**: Function
- **Required**: NO
- **Number of arguments**: None
- **Sequence and type of arguments**: Not applicable
- **Return value**: Character value that contains one of the following keywords:
  - LOG specifies that the first parameter is the logarithm of the scale parameter.
  - IDENTITY specifies that the first parameter is a scale parameter without any transformation.

If you do not specify this function, then the IDENTITY transform is assumed.

Here is a sample structure of the function for a distribution named ‘FOO’:

```plaintext
function FOO_SCALETRANSFORM() $8;
length xform $8;
xform = "IDENTITY";
return (xform);
endsub;
```

**dist_SDF**

defines a function that returns the value of the survival distribution function (SDF) of the distribution at the specified values of the random variable and distribution parameters.

- **Type**: Function
- **Required**: NO
- **Number of arguments**: \( m + 1 \), where \( m \) is the number of distribution parameters
- **Sequence and type of arguments**:
  - \( x \) Numeric value of the random variable at which the SDF value should be evaluated
  - \( p1 \) Numeric value of the first parameter
  - \( p2 \) Numeric value of the second parameter
  - \ldots
  - \( pm \) Numeric value of the \( m \)th parameter

- **Return value**: Numeric value that contains the SDF value \( S(x; p1, p2, \ldots, pm) \)

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter.
or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

\[
S(x; p_1, p_2, \ldots, p_m) = S\left(\frac{x}{p_1}; 1, p_2, \ldots, p_m\right)
\]

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

\[
S(x; p_1, p_2, \ldots, p_m) = S\left(\frac{x}{\exp(p_1)}; 0, p_2, \ldots, p_m\right)
\]

Here is a sample structure of the function for a distribution named ‘FOO’:

```plaintext
function FOO_SDF(x, P1, P2);
    /* Code to compute SDF by using x, P1, and P2 */
    S = <computed SDF>;
    return (S);
endsub;
```

`dist_UPPERBOUNDS` defines a subroutine that returns upper bounds for the parameters of the distribution. If this subroutine is not defined for a given distribution, then the SEVERITY procedure assumes that there is no upper bound for any of the parameters. If an upper bound of \(u_i\) is returned for a parameter \(p_i\), then the SEVERITY procedure assumes that \(p_i < u_i\) (strict inequality). If a missing value is returned for some parameter, then the SEVERITY procedure assumes that there is no upper bound for that parameter (equivalent to an upper bound of \(\infty\)).

- **Type**: Subroutine
- **Required**: NO
- **Number of arguments**: \(m\), where \(m\) is the number of distribution parameters
- **Sequence and type of arguments**:
  - \(p_1\) Output argument that returns the upper bound on the first parameter. You must specify this in the OUTARGS statement inside the subroutine’s definition.
  - \(p_2\) Output argument that returns the upper bound on the second parameter. You must specify this in the OUTARGS statement inside the subroutine’s definition.
  - \(\ldots\)
  - \(p_m\) Output argument that returns the upper bound on the \(m\)th parameter. You must specify this in the OUTARGS statement inside the subroutine’s definition.

- **Return value**: The results, upper bounds on parameter values, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named ‘FOO’:

```plaintext
subroutine FOO_UPPERBOUNDS(p1, p2);
    outargs p1, p2;
    p1 = <upper bound for P1>;
    p2 = <upper bound for P2>;
endsub;
```
**dist_coreGRADIENT**

defines a subroutine that returns the gradient vector of the specified core function of the distribution at the specified values of the random variable and distribution parameters. The core keyword can be PDF, CDF, SDF, LOGPDF, LOGCDF, or LOGSDF.

- **Type**: Subroutine
- **Required**: NO
- **Number of arguments**: \( m + 2 \), where \( m \) is the number of distribution parameters
- **Sequence and type of arguments**:
  
<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>( x )</td>
<td>Numeric value of the random variable at which the gradient should be evaluated</td>
</tr>
<tr>
<td>( p_1 )</td>
<td>Numeric value of the first parameter</td>
</tr>
<tr>
<td>( p_2 )</td>
<td>Numeric value of the second parameter</td>
</tr>
<tr>
<td>...</td>
<td>...</td>
</tr>
<tr>
<td>( p_m )</td>
<td>Numeric value of the ( m )th parameter</td>
</tr>
</tbody>
</table>
  | grad{*}  | Output numeric array of size \( m \) that contains the gradient vector evaluated at the specified values. If \( h \) denotes the value of the core function, then the expected order of the values in the array is as follows: \( \frac{\partial h}{\partial p_1}, \frac{\partial h}{\partial p_2}, \ldots, \frac{\partial h}{\partial p_m} \)

- **Return value**: Numeric array that contains the gradient evaluated at \( x \) for the parameter values \((p_1, p_2, \ldots, p_m)\)

Here is a sample structure of the function for the core function CDF of a distribution named ‘FOO’:

```plaintext
subroutine FOO_CDFGRADIENT(x, p1, p2, grad{*});
  outargs grad;
  /* Code to compute gradient by using x, P1, and P2 */
  grad[1] = <partial derivative of CDF w.r.t. P1 evaluated at x, P1, P2>;
  grad[2] = <partial derivative of CDF w.r.t. P2 evaluated at x, P1, P2>;
endsub;
```

**dist_coreHESSIAN**

defines a subroutine that returns the Hessian matrix of the specified core function of the distribution at the specified values of the random variable and distribution parameters. The core keyword can be PDF, CDF, SDF, LOGPDF, LOGCDF, or LOGSDF.

- **Type**: Subroutine
- **Required**: NO
- **Number of arguments**: \( m + 2 \), where \( m \) is the number of distribution parameters
- **Sequence and type of arguments**:
  
<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>( x )</td>
<td>Numeric value of the random variable at which the Hessian matrix should be evaluated</td>
</tr>
<tr>
<td>( p_1 )</td>
<td>Numeric value of the first parameter</td>
</tr>
<tr>
<td>...</td>
<td>...</td>
</tr>
<tr>
<td>( p_m )</td>
<td>Numeric value of the ( m )th parameter</td>
</tr>
</tbody>
</table>
  | grad{*}  | Output numeric array of size \( m \times m \) that contains the Hessian matrix evaluated at the specified values. If \( h \) denotes the value of the core function, then the expected order of the values in the array is as follows: \( \frac{\partial^2 h}{\partial p_1^2}, \frac{\partial^2 h}{\partial p_1 \partial p_2}, \ldots, \frac{\partial^2 h}{\partial p_m^2} \)

- **Return value**: Numeric array that contains the Hessian matrix evaluated at \( x \) for the parameter values \((p_1, p_2, \ldots, p_m)\)
Predefined Utility Functions

p2 Numeric value of the second parameter

......

pm Numeric value of the mth parameter

hess{*} Output numeric array of size \( m(m + 1)/2 \) that contains the lower triangular portion of the Hessian matrix in a packed vector form, evaluated at the specified values. If \( h \) denotes the value of the core function, then the expected order of the values in the array is as follows:

\[
\frac{\partial^2 h}{\partial p_1^2} \quad \frac{\partial^2 h}{\partial p_1 \partial p_2} \quad \frac{\partial^2 h}{\partial p_2^2} \quad \cdots \quad \frac{\partial^2 h}{\partial p_1 \partial p_m} \quad \frac{\partial^2 h}{\partial p_2 \partial p_m} \quad \cdots \quad \frac{\partial^2 h}{\partial p_m^2}
\]

- Return value: Numeric array that contains the lower triangular portion of the Hessian matrix evaluated at \( x \) for the parameter values \((p_1, p_2, \ldots, p_m)\)

Here is a sample structure of the subroutine for the core function LOGSDF of a distribution named ‘FOO’:

```plaintext
subroutine FOO_LOGSDFHESSIAN(x, P1, P2, hess{*});
outargs hess;

/* Code to compute Hessian by using x, P1, and P2 */
hess[1] = <second order partial derivative of LOGSDF w.r.t. P1 evaluated at x, P1, P2>;

hess[2] = <second order partial derivative of LOGSDF w.r.t. P1 and P2 evaluated at x, P1, P2>;

hess[3] = <second order partial derivative of LOGSDF w.r.t. P2 evaluated at x, P1, P2>;

endsub;
```

Predefined Utility Functions

The following predefined utility functions are provided with the SEVERITY procedure and are available in the Sashelp.Svtldist library:

SVRTUTIL_EDF:
This function computes the empirical distribution function (EDF) estimate at the specified value of the random variable given the EDF estimate for a sample.

- **Type**: Function
- **Signature**: SVRTUTIL_EDF(y, n, x{*}, F{*}, Ftype)
- **Argument Description**:
  - \( y \) Value of the random variable at which the EDF estimate is desired.
  - \( n \) Dimension of the \( x \) and \( F \) input arrays.
  - \( x{*} \) Input numeric array of dimension \( n \) that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.
  - \( F{*} \) Input numeric array of dimension \( n \) in which each \( F[i] \) contains the EDF estimate for \( x[i] \). These values must be sorted in nondecreasing order.
Ftype Type of the empirical estimate that is stored in the $x$ and $F$ arrays. See the section “Supplying EDF Estimates to Functions and Subroutines” on page 1674 for definition of types.

- **Return value**: The EDF estimate at $y$.

The type of the sample EDF estimate determines how the EDF estimate at $y$ is computed. See the section “Supplying EDF Estimates to Functions and Subroutines” on page 1674 for more information.

**SVRTUTIL_EMPLIMMOMENT**:
This function computes the empirical estimate of the limited moment of specified order for the specified upper limit, given the EDF estimate for a sample.

- **Type**: Function
- **Signature**: `SVRTUTIL_EMPLIMMOMENT(k, u, n, x[*], F[*], Ftype)`
- **Argument Description**:
  
  - $k$ Order of the desired empirical limited moment.
  - $u$ Upper limit on the value of the random variable to be used in the computation of the desired empirical limited moment.
  - $n$ Dimension of the $x$ and $F$ input arrays.
  - $x[*]$ Input numeric array of dimension $n$ that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.
  - $F[*]$ Input numeric array of dimension $n$ in which each $F[i]$ contains the EDF estimate for $x[i]$. These values must be sorted in nondecreasing order.
  - $Ftype$ Type of the empirical estimate that is stored in the $x$ and $F$ arrays. See the section “Supplying EDF Estimates to Functions and Subroutines” on page 1674 for definition of types.

- **Return value**: The desired empirical limited moment.

The empirical limited moment is computed by using the empirical estimate of the CDF. If $F_n(x)$ denotes the EDF at $x$, then the empirical limited moment of order $k$ with upper limit $u$ is defined as

$$E_n[(X \wedge u)^k] = k \int_0^u (1 - F_n(x))x^{k-1}dx$$

The SVRTUTIL_EMPLIMMOMENT function uses the piecewise linear nature of $F_n(x)$ as described in the section “Supplying EDF Estimates to Functions and Subroutines” on page 1674 to compute the integration.

**SVRTUTIL_HILLCUTOFF**:
This function computes an estimate of the value where the right tail of a distribution is expected to begin. The function implements the algorithm described in Danielsson et al. 2001. The description of the algorithm uses the following notation:

- $n$ number of observations in the original sample
- $B$ number of bootstrap samples to draw
- $m_1$ size of the bootstrap sample in the first step of the algorithm ($m_1 < n$)
Given the input sample \( x \) and values of \( B \) and \( m_1 \), the steps of the algorithm are as follows:

1. Take \( B \) bootstrap samples of size \( m_1 \) from the original sample.
2. Find the integer \( k_1 \) that minimizes the bootstrap estimate of the mean squared error:
   \[
   k_1 = \arg\min_{1 \leq k < m_1} Q(m_1, k)
   \]
3. Take \( B \) bootstrap samples of size \( m_2 = m_1^2/n \) from the original sample.
4. Find the integer \( k_2 \) that minimizes the bootstrap estimate of the mean squared error:
   \[
   k_2 = \arg\min_{1 \leq k < m_2} Q(m_2, k)
   \]
5. Compute the integer \( k_{\text{opt}} \), which is used for computing the cutoff point:
   \[
   k_{\text{opt}} = \frac{k_2}{k_1} \left( \frac{\log(k_1)}{2 \log(m_1) - \log(k_1)} \right)^{2-2 \log(k_1)/\log(m_1)}
   \]
6. Set the cutoff point equal to \( x(k_{\text{opt}}+1) \).

The bootstrap estimate of the mean squared error is computed as
\[
Q(m, k) = \frac{1}{B} \sum_{j=1}^{B} \text{MSE}_j(m, k)
\]
The mean squared error of \( j \)th bootstrap sample is computed as
\[
\text{MSE}_j(m, k) = (M_j(m, k) - 2\gamma_j(m, k))^2
\]
where \( M_j(m, k) \) is a control variate proposed by Danielsson et al. 2001,
\[
M_j(m, k) = \frac{1}{k} \sum_{i=1}^{k} \left( \log(x_{(m-i+1)}^{j,m}) - \log(x_{(m-k)}^{j,m}) \right)^2
\]
and \( \gamma_j(m, k) \) is the Hill’s estimator of the tail index (Hill 1975),
\[
\gamma_j(m, k) = \frac{1}{k} \sum_{i=1}^{k} \log(x_{(m-i+1)}^{j,m}) - \log(x_{(m-k)}^{j,m})
\]
This algorithm has two tuning parameters, \( B \) and \( m_1 \). The number of bootstrap samples \( B \) is chosen based on the availability of computational resources. The optimal value of \( m_1 \) is chosen such that the following ratio, \( R(m_1) \), is minimized:
\[
R(m_1) = \frac{(Q(m_1, k_1))^2}{Q(m_2, k_2)}
\]
The SVRTUTIL_HILLCUTOFF utility function implements the preceding algorithm. It uses the grid search method to compute the optimal value of \( m_1 \).

- **Type**: Function
- **Signature**: SVRTUTIL_HILLCUTOFF(n, x{*}, b, s, status)
• **Argument Description:**

  n  Dimension of the array \( x \).

  \( x^* \)  Input numeric array of dimension \( n \) that contains the sample.

  b  Number of bootstrap samples used to estimate the mean squared error. If \( b \) is less than 10, then a default value of 50 is used.

  s  Approximate number of steps used to search the optimal value of \( m_1 \) in the range \([n^{0.75}, n - 1]\). If \( s \) is less than or equal to 1, then a default value of 10 is used.

  status  Output argument that contains the status of the algorithm. If the algorithm succeeds in computing a valid cutoff point, then \( status \) is set to 0. If the algorithm fails, then \( status \) is set to 1.

• **Return value:** The cutoff value where the right tail is estimated to start. If the size of the input sample is inadequate (\( n \leq 5 \)), then a missing value is returned and \( status \) is set to a missing value. If the algorithm fails to estimate a valid cutoff value (\( status = 1 \)), then the fifth largest value in the input sample is returned.

**SVRTUTIL_PERCENTILE:**

This function computes the specified empirical percentile given the EDF estimates.

• **Type:** Function

• **Signature:** SVRTUTIL_PERCENTILE(p, n, x\{\*\}, F\{\*\}, Ftype)

• **Argument Description:**

  p  Desired percentile. The value must be in the interval (0,1). The function returns the 100\( p \)th percentile.

  n  Dimension of the \( x \) and \( F \) input arrays.

  x\{\*\}  Input numeric array of dimension \( n \) that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.

  F\{\*\}  Input numeric array of dimension \( n \) in which each \( F[i] \) contains the EDF estimate for \( x[i] \). These values must be sorted in nondecreasing order.

  Ftype  Type of the empirical estimate that is stored in the \( x \) and \( F \) arrays. See the section “Supplying EDF Estimates to Functions and Subroutines” on page 1674 for definition of types.

• **Return value:** The 100\( p \)th percentile of the input sample.

The method used to compute the percentile depends on the type of the EDF estimate (Ftype argument).

Ftype = 1  Smoothed empirical estimates are computed using the method described in Klugman, Panjer, and Willmot (1998). Let \( \lceil x \rceil \) denote the greatest integer less than or equal to \( x \). Define \( g = \lfloor p(n + 1) \rfloor \) and \( h = p(n + 1) - g \). Then the empirical percentile \( \hat{\pi}_p \) is defined as

\[
\hat{\pi}_p = (1 - h)x[g] + hx[g + 1]
\]

This method does not work if \( p < 1/(n + 1) \) or \( p > n/(n + 1) \). If \( p < 1/(n + 1) \), then the function returns \( \hat{\pi}_p = x[1]/2 \), which assumes that the EDF is 0 in the interval \([0, x[1]]\). If \( p > n/(n + 1) \), then \( \hat{\pi}_p = x[n] \).
Predefined Utility Functions

SVRTUTIL_RAWMOMENTS:
This subroutine computes the raw moments of a sample.

- **Type**: Subroutine
- **Signature**: SVRTUTIL_RAWMOMENTS(n, x{*}, nx{*}, nRaw, raw{*})
- **Argument Description**:
  - n: Dimension of the x and nx input arrays.
  - x{*}: Input numeric array of dimension n that contains distinct values of the random variable that are observed in the sample.
  - nx{*}: Input numeric array of dimension n in which each nx[i] contains the number of observations in the sample that have the value x[i].
  - nRaw: Desired number of raw moments. The output array raw contains the first nRaw raw moments.
  - raw{*}: Output array of raw moments. The kth element in the array (raw{k}) contains the kth raw moment, where 1 ≤ k ≤ nRaw.
- **Return value**: Numeric array raw that contains the first nRaw raw moments. The array contains missing values if the sample has no observations (that is, if all the values in the nx array add up to zero).

SVRTUTIL_SORT:
This function sorts the given array of numeric values in an ascending or descending order.

- **Type**: Subroutine
- **Signature**: SVRTUTIL_SORT(n, x{*}, flag)
• Argument Description:
  
  n  Dimension of the input array x.
  
  x{*}  Numeric array that contains the values to be sorted at input. The subroutine uses the same array to return the sorted values.
  
  flag  A numeric value that controls the sort order. If flag is 0, then the values are sorted in an ascending order. If flag has any value other than 0, then the values are sorted in descending order.
  
• Return value: Numeric array x, which is sorted in place (that is, the sorted array is stored in the same storage area occupied by the input array x).

You can use the following predefined functions when you define functions and subroutines using the FCMP procedure. They are summarized here for your information. See the FCMP procedure documentation in Base SAS Procedures Guide for more information.

INVCDF:
This function computes the quantile from any continuous probability distribution by numerically inverting the CDF of that distribution. You need to specify the CDF function of the distribution, the values of its parameters, and the cumulative probability to compute the quantile.

LIMMOMENT:
This function computes the limited moment of order k with upper limit u for any continuous probability distribution. The limited moment is defined as

\[
E[(X \wedge u)^k] = \int_0^u x^k f(x)dx + \int_u^\infty u^k f(x)dx
\]

\[
= \int_0^u x^k f(x)dx + u^k (1 - F(u))
\]

where \(f(x)\) and \(F(x)\) denote the PDF and the CDF of the distribution, respectively. The LIMMOMENT function uses the following alternate definition, which can be derived using integration-by-parts:

\[
E[(X \wedge u)^k] = k \int_0^u (1 - F(x))x^{k-1}dx
\]

You need to specify the CDF function of the distribution, the values of its parameters, and the values of \(k\) and \(u\) to compute the limited moment.

Scoring Functions (Experimental)

Scoring refers to the act of evaluating a distribution function, such as LOGPDF, SDF, or QUANTILE, on an observation by using the fitted parameter estimates of that distribution. You can do scoring in a DATA step by using the OUTEST= data set that you create with PROC SEVERITY. However, that approach requires some cumbersome programming. In order to simplify the scoring process, you can specify that PROC SEVERITY create scoring functions for each fitted distribution.

As an example, assume that you have fitted the Pareto distribution by using PROC SEVERITY and that it converges. Further assume that you want to use the fitted distribution to evaluate the probability of observing
a loss value greater than some set of regulatory limits \( \{L\} \) that are encoded in a data set. You can simplify this scoring process as follows. First, in the PROC SEVERITY step that fits your distributions, you create the scoring functions library by specifying the OUTSCORELIB statement as illustrated in the following steps:

```sas
proc severity data=input;
  loss lossclaim;
  dist pareto;
  outscorelib outlib=sasuser.fitdist;
run;
```

Upon successful completion, if the Pareto distribution model has converged, then the \texttt{Sasuser.Fitdist} library contains the \textit{SEV_SDF} scoring function in addition to other scoring functions, such as \textit{SEV_PDF}, \textit{SEV_LOGPDF}, and so on. Further, PROC SEVERITY also sets the CMPLIB system option to include the \texttt{Sasuser.Fitdist} library. If the set of limits \( \{L\} \) is recorded in the variable \texttt{Limit} in the scoring data set \texttt{Work.Limits}, then you can submit the following DATA step to compute the probability of seeing a loss greater than each limit:

```sas
data prob;
  set work.limits;
  exceedance_probability = sev_sdf(limit);
run;
```

Without the use of scoring functions, you can still perform this scoring task, but the DATA step that you need to write to accomplish it becomes more complicated and less flexible. For example, you would need to read the parameter estimates from some output created by PROC SEVERITY. To do that, you would need to know the parameter names, which are different for different distributions; this in turn would require you to write a specific DATA step for each distribution or to write a SAS macro. With the use of scoring functions, you can accomplish that task much more easily.

If you fit multiple distributions, then you can specify the COMMONPACKAGE option in the OUTSCORELIB statement as follows:

```sas
proc severity data=input;
  loss lossclaim;
  dist exp pareto weibull;
  outscorelib outlib=sasuser.fitdist commonpackage;
run;
```

The preceding step creates scoring functions such as \textit{SEV_SDF_Exp}, \textit{SEV_SDF_Pareto}, and \textit{SEV_SDF_Weibull}. You can use them to compare the probabilities of exceeding the limit for different distributions by using the following DATA step:

```sas
data prob;
  set work.limits;
  exceedance_exp = sev_sdf_exp(limit);
  exceedance_pareto = sev_sdf_pareto(limit);
  exceedance_weibull = sev_sdf_weibull(limit);
run;
```

**Formal Description**

PROC SEVERITY creates a scoring function for each distribution function. A distribution function is defined as any function named \textit{dist_suffix}, where \textit{dist} is the name of a distribution that you specify in the \texttt{DIST}
statement and the function’s signature is identical to the signature of the required distribution function such as dist_CDF or dist_LOGCDF. For example, for the function ‘FOO_BAR’ to be a distribution function, you must specify the distribution ‘FOO’ in the DIST statement and you must define ‘FOO_BAR’ in the following manner if the distribution ‘FOO’ has parameters named ‘P1’ and ‘P2’:

```cpp
function FOO_BAR(y, P1, P2);
    /* Code to compute BAR by using y, P1, and P2 */
    R = <computed BAR>;
    return (R);
endfunc;
```

For more information about the signature that defines a distribution function, see the description of the dist_CDF function in the section “Defining a Distribution Model with the FCMP Procedure” on page 1679.

The name and package of the scoring function of a distribution function depend on whether you specify the COMMONPACKAGE option in the OUTSCORELIB statement.

When you do not specify the COMMONPACKAGE option, the scoring function that corresponds to the distribution function dist_suffix is named SEV_suffix, where SEV_ is the standard prefix of all scoring functions. The scoring function is created in a package named dist. Each scoring function accepts only one argument, the value of the loss variable, and returns the same value as the value returned by the corresponding distribution function for the final estimates of the distribution’s parameters. For example, for the preceding ‘FOO_BAR’ distribution function, the scoring function named ‘SEV_BAR’ is created in the package named ‘FOO’ and ‘SEV_BAR’ has the following signature:

```cpp
function SEV_BAR(y);
    /* returns value of FOO_BAR for the supplied value of y and fitted values of P1, P2 */
endfunc;
```

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, then the scoring function that corresponds to the distribution function dist_suffix is named SEV_suffix_dist, where SEV_ is the standard prefix of all scoring functions. The scoring function is created in a package named sevfit. For example, for the preceding ‘FOO_BAR’ distribution function, if you specify the COMMONPACKAGE option, the scoring function named ‘SEV_BAR_FOO’ is created in the sevfit package and ‘SEV_BAR_FOO’ has the following signature:

```cpp
function SEV_BAR_FOO(y);
    /* returns value of FOO_BAR for the supplied value of y and fitted values of P1, P2 */
endfunc;
```

**Scoring Functions for the Scale Regression Model**

If you use the SCALEMODEL statement to specify a scale regression model, then the estimate of the scale parameter or the log-transformed scale parameter of the distribution depends on the values of the regressors. So PROC SEVERITY creates a scoring function that has the following signature, where x(*) represents the array of regressors:

```cpp
function SEV_BAR(y, x(*));
    /* returns value of FOO_BAR for the supplied value of x and fitted values of P1, P2 */
endfunc;
```
As an illustration of using this form, assume that you submit the following PROC SEVERITY step to create
the scoring library Sasuser.Scalescore:

```plaintext
class proc severity data=input;
  loss lossclaim;
  scalemodel x1-x3;
  dist pareto;
  outscorelib outlib=sasuser.scalescore;
run;
```

Your scoring data set must contain all the regressors that you specify in the SCALEMODEL statement. You
can submit the following DATA step to score observations by using the scale regression model:

```plaintext
data prob;
  array regvals{*} x1-x3;
  set work.limits;
  exceedance_probability = sev_sdf(limit, regvals);
run;
```

PROC SEVERITY creates two utility functions, SEV_NUMREG and SEV_REGNAME, in the OUTLIB=
library that return the number of regressors and name of a given regressor, respectively. They are described in
detail in the next section. These utility functions are useful when you do not have easy access to the regressor
names in the SCALEMODEL statement. You can use the utility functions as follows:

```plaintext
data prob;
  array regvals{10} _temporary_;
  set work.limits;
  do i = 1 to sev_numreg();
    regvals(i) = input(vvaluex(sev_regname(i)), best12.);
  end;
  exceedance_probability = sev_sdf(limit, regvals);
run;
```

The dimension of the regressor values array that you supply to the scoring function must be equal to $K + L$,
where $K$ is the number of regressors that you specify in the SCALEMODEL statement irrespective of
whether PROC SEVERITY deems any of those regressors to be redundant. $L$ is 1 if you specify an OFFSET=
variable in the SCALEMODEL statement, and 0 otherwise.

Utility Functions and Subroutines in the OUTLIB= Library

In addition to creating the scoring functions for all distribution functions, PROC SEVERITY creates the
following utility functions and subroutines in the OUTLIB= library.

**SEV_NUMPARAM | SEV_NUMPARAM_dist**

is a function that returns the number of distribution parameters and has the following signature:

- **Type**: Function
- **Number of arguments**: 0
- **Sequence and type of arguments**: Not applicable
- **Return value**: Numeric value that contains the number of distribution parameters
If you do not specify the COMMONPACKAGE option in the OUTSCORELIB statement, then a function named SEV_NUMPARM is created in the package of each distribution. Here is a sample structure of the code that PROC SEVERITY uses to define the function:

```plaintext
function SEV_NUMPARM();
    n = <number of distribution parameters>;
    return (n);
endsub;
```

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, then for each distribution dist, the function named SEV_NUMPARM_dist is created in the sevfit package. SEV_NUMPARM_dist has the same structure as the SEV_NUMPARM function that is described previously.

SEV_PARMEST | SEV_PARMEST_dist
is a subroutine that returns the estimate and standard error of a specified distribution parameter and has the following signature:

- **Type**: Subroutine
- **Number of arguments**: 3
- **Sequence and type of arguments**:
  - `index` specifies the numeric value of the index of the distribution parameter for which you want the information. The value of `index` must be in the interval [1,m], where m is the number of parameters in the distribution to which this subroutine belongs.
  - `est` specifies the output argument that returns the estimate of the requested parameter.
  - `stderr` specifies the output argument that returns the standard error of the requested parameter.
- **Return value**: Estimate and standard error of the requested distribution parameter that are returned in the output arguments `est` and `stderr`, respectively

If you do not specify the COMMONPACKAGE option in the OUTSCORELIB statement, then a subroutine named SEV_PARMEST is created in the package of each distribution. Here is a sample structure of the code that PROC SEVERITY uses to define the subroutine:

```plaintext
subroutine SEV_PARMEST(index, est, stderr);
    outargs est, stderr;
    est = <value of the estimate for the distribution parameter at position 'index'>;
    stderr = <value of the standard error for distribution parameter at position 'index'>;
endsub;
```

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, then for each distribution dist, the subroutine named SEV_PARMEST_dist is created in the sevfit package. SEV_PARMEST_dist has the same structure as the SEV_PARMEST subroutine that is described previously.

If you use the SCALEMODEL statement to specify a scale regression model, then for `index`=1, the returned estimates are of $\theta_0$, the base value of the scale parameter, or $\log(\theta_0)$ if the distribution has a log-scale parameter. For more information about $\theta_0$, see the section “Estimating Regression Effects” on page 1664.
SEV_PARMNAME | SEV_PARMNAME_dist

is a function that returns the name of a specified distribution parameter and has the following signature:

- **Type**: Function
- **Number of arguments**: 1
- **Sequence and type of arguments**:
  - `index` specifies the numeric value of the index of the distribution parameter for which you want the information. The value of `index` must be in the interval \([1, m]\), where \(m\) is the number of parameters in the distribution to which this function belongs.
- **Return value**: Character value that contains the name of the distribution parameter that appears at the position `index` in the distribution’s definition

If you do not specify the COMMONPACKAGE option in the OUTSCORELIB statement, then a function named SEV_PARMNAME is created in the package of each distribution. Here is a sample structure of the code that PROC SEVERITY uses to define the function:

```plaintext
function SEV_PARMNAME(index) $32;
  name = <name of the distribution parameter at position 'index'>;
  return (name);
endsub;
```

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, then for each distribution `dist`, a function named SEV_PARMNAME_dist is created in the sevfit package. SEV_PARMNAME_dist has the same structure as the SEV_PARMNAME function that is described previously.

If you use the SCALEMODEL statement to specify a scale regression model, then the following helper functions and subroutines are also created in the OUTLIB= library.

**SEV_NUMREG**

is a function that returns the number of regressors and has the following signature:

- **Type**: Function
- **Number of arguments**: 0
- **Sequence and type of arguments**: Not applicable
- **Return value**: Numeric value that contains the number of regressors that you specify in the SCALEMODEL statement. If you specify an OFFSET= variable in the SCALEMODEL statement, then the returned value is equal to 1 plus the number of regressors that you specify in the SCALEMODEL statement.

Here is a sample structure of the code that PROC SEVERITY uses to define the function:

```plaintext
function SEV_NUMREG();
  m = <number of regressors>;
  if (<offset variable is specified>) then m = m + 1;
  return (m);
endsub;
```

This function does not depend on any distribution, so it is always created in the sevfit package.
SEV_REGEST | SEV_REGEST_dist

is a subroutine that returns the estimate and standard error of a specified regression parameter and has the following signature:

- **Type**: Subroutine
- **Number of arguments**: 3
- **Sequence and type of arguments**:
  - `index` specifies the numeric value of the index of the regression parameter for which you want the information. The value of `index` must be in the interval [1, K], where K is the number of regressors as returned by the SEV_NUMREG function. If you specify an OFFSET= variable in the SCALEMODEL statement, then an `index` value of K corresponds to the offset variable.
  - `est` specifies the output argument that returns the estimate of the requested regression parameter.
  - `stderr` specifies the output argument that returns the standard error of the requested regression parameter.
- **Return value**: Estimate and standard error of the requested regression parameter that are returned in the output arguments `est` and `stderr`, respectively.

If you do not specify the COMMONPACKAGE option in the OUTSCORELIB statement, then a subroutine named SEV_REGEST is created in the package of each distribution. Here is a sample structure of the code that PROC SEVERITY uses to define the subroutine:

```
subroutine SEV_REGEST(index, est, stderr);
  outargs est, stderr;
  est = <value of the estimate for the regression parameter at position 'index'>;
  stderr = <value of the standard error for regression parameter at position 'index'>;
endsub;
```

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, then for each distribution `dist`, the subroutine named SEV_REGEST_dist is created in the `sevfit` package. SEV_REGEST_dist has the same structure as the SEV_REGEST subroutine that is described previously.

If the regressor that corresponds to the specified `index` value is a redundant regressor, the returned values of both `est` and `stderr` are equal to the special missing value of .R. If you specify an OFFSET= variable in the SCALEMODEL statement and if the `index` value corresponds to the offset variable — that is, it is equal to the value that the SEV_NUMREG function returns — then the returned value of `est` is equal to 1 and the returned value of `stderr` is equal to the special missing value of .F.

**SEV_REGNAME**

is a function that returns the name of a specified regressor and has the following signature:

- **Type**: Function
- **Number of arguments**: 1
Custom Objective Functions

You can use a series of programming statements that use variables in the DATA= data set to assign a value to an objective function symbol. You must specify the objective function symbol by using the OBJECTIVE= option in the PROC SEVERITY statement.

The objective function can be programmed such that it is applicable to any distribution that is used in the model. For that purpose, PROC SEVERITY recognizes the following keyword functions in the programming statements:

- `_PDF_(x)` returns the probability density function (PDF) of a distribution evaluated at the current value of a data set variable `x`.
- `_CDF_(x)` returns the cumulative distribution function (CDF) of a distribution evaluated at the current value of a data set variable `x`.
- `_SDF_(x)` returns the survival distribution function (SDF) of a distribution evaluated at the current value of a data set variable `x`.
- `_LOGPDF_(x)` returns the natural logarithm of the PDF of a distribution evaluated at the current value of a data set variable `x`.
- `_LOGCDF_(x)` returns the natural logarithm of the CDF of a distribution evaluated at the current value of a data set variable `x`.
- `_LOGSDF_(x)` returns the natural logarithm of the SDF of a distribution evaluated at the current value of a data set variable `x`.
- `_EDF_(x)` returns the empirical distribution function (EDF) estimate evaluated at the current value of a data set variable `x`. Internally, PROC SEVERITY computes the estimate using the `SVRTUTIL_EDF` function as described in the section “Predefined Utility Functions”.

---

Custom Objective Functions

• **Sequence and type of arguments:**

  - `index` specifies the numeric value of the index of the regressor for which you want the name. The value of `index` must be in the interval `[1, K]`, where `K` is the number of regressors as returned by the SEV_NUMREG function. If you specify an OFFSET= variable in the SCALEMODEL statement, then an `index` value of `K` corresponds to the offset variable.

  - **Return value:** Character value that contains the name of the regressor that appears at the position `index` in the SCALEMODEL statement. If you specify an OFFSET= variable in the SCALEMODEL statement, then for an `index` value of `K`, the returned value contains the name of the offset variable.

Here is a sample structure of the code that PROC SEVERITY uses to define the function:

```plaintext
function SEV_REGNAME(index) $32;
    name = <name of regressor at position 'index'>;
    return (name);
endsub;
```

This function does not depend on any distribution, so it is always created in the `sevfit` package.
The EDF estimate that is required by the SVRTUTIL_EDF function is computed by using the response variable values in the current BY group or in the entire input data set if you do not specify the BY statement.

_EMPLIMMOMENT_(k, u)
returns the empirical limited moment of order k evaluated at the current value of a data set variable u that represents the upper limit of the limited moment. The order k can also be a data set variable. Internally, PROC SEVERITY computes the moment using the SVRTUTIL_EMPLIMMOMENT function as described in the section “Predefined Utility Functions” on page 1691. The EDF estimate that is required by the SVRTUTIL_EMPLIMMOMENT function is computed by using the response variable values in the current BY group or in the entire input data set if you do not specify the BY statement.

_LIMMOMENT_(k, u)
returns the limited moment of order k evaluated at the current value of a data set variable u that represents the upper limit of the limited moment. The order k can be a data set variable or a constant. Internally, for each candidate distribution, PROC SEVERITY computes the moment using the LIMMOMENT function as described in the section “Predefined Utility Functions” on page 1691.

All the preceding functions are right-hand side functions. They act as placeholders for distribution-specific functions, with the exception of _EDF_ and _EMPLIMMOMENT_ functions. As an example, let the data set Work.Test contain a response variable Y and a left-truncation threshold variable T. The following statements use the values in this data set to fit a model with distribution D such that the parameters of the model minimize the value of the objective function symbol MYOBJ:

```plaintext
options cmplib=(work.mydist);
proc severity data=work.test objective=myobj;
  loss y / lt=t;
    myobj = -_LOGPDF_(y);
    if (not(missing(t))) then
      myobj = myobj + log(1-_CDF_(t));
  dist d;
run;
```

The symbol MYOBJ is designated as an objective function symbol by using the OBJECTIVE= option in the PROC SEVERITY statement. The response variable Y and left-truncation variable T are specified in the LOSS statement. The distribution D is specified in the DIST statement. The remaining statements constitute a program that computes the value of the MYOBJ symbol.

Let the distribution D have parameters P1 and P2. In order to estimate the model for this distribution, PROC SEVERITY internally converts the generic program to the following program specific to distribution D:

```plaintext
myobj = -D_LOGPDF(y, p1, p2);
if (not(missing(t))) then
  myobj = myobj + log(1-D_CDF(t, p1, p2));
```

Note that the generic keyword functions _LOGPDF_ and _CDF_ have been replaced with distribution-specific functions D_LOGPDF and D_CDF, respectively, with appropriate distribution parameters. The D_LOGPDF
and D_CDF functions must have been defined previously and are assumed to be available in the Work.Mydist library that you specify in the CMPLIB= option.

The program is executed for each observation in Work.Test to compute the value of MYOBJ by using the values of variables Y and T in that observation and internally computed values of the model parameters P1 and P2. The values of MYOBJ are then added over all the observations of the data set or over all the observations of the current BY group if you specify the BY statement. The resulting aggregate value is the value of the objective function, and it is supplied to the optimizer. If the optimizer requires derivatives of the objective function, then PROC SEVERITY automatically differentiates MYOBJ with respect to the parameters P1 and P2. The optimizer iterates over various combinations of the values of parameters P1 and P2, each time computing a new value of the objective function and the needed derivatives of it, until it finds a combination that minimizes the objective function.

Note the following points when you define your own program to compute the custom objective function:

• The value of the objective function is always minimized by PROC SEVERITY. If you want to maximize the value of a certain objective, then add a statement that assigns the negated value of the maximization objective to the objective function symbol that you specify in the OBJECTIVE= option. Minimization of the negated objective is equivalent to the maximization of the original objective.

• The contributions of individual observations are always added to compute the overall objective function in a given iteration of the optimizer. If you specify the WEIGHT statement, then the contribution of each observation is weighted by multiplying it with the normalized value of the weight variable for that observation.

• If you are fitting multiple distributions in one PROC SEVERITY step and use any of the keyword functions in your program, then it is recommended that you do not explicitly use the parameters of any of the specified distributions in your programming statements.

• If you use a specific keyword function in your programming statements, then the corresponding distribution functions must be defined in a library that you specify in the CMPLIB= system option or in Sashelp.Svrtdist, the predefined functions library. In the preceding example, it is assumed that the functions D_LOGPDF and D_CDF are defined in the Work.Mydist library that is specified in the CMPLIB= option.

• You can use most DATA step statements and functions in your program. The DATA step file and the data set I/O statements (for example, INPUT, FILE, SET, and MERGE) are not available. However, some functionality of the PUT statement is supported. See the section “PROC FCMP and DATA Step Differences” in Base SAS Procedures Guide for more information. In addition to the differences listed in that section, the following differences exist:
  - Only numeric-valued variables can be used in PROC SEVERITY programming statements. This restriction also implies that you cannot use SAS functions or call routines that require character-valued arguments, unless you pass those arguments as constant (literal) strings or characters.
  - You cannot use functions that create lagged versions of a variable in PROC SEVERITY programming statements. If you need lagged versions, then you can use a DATA step prior to the PROC SEVERITY step to add those versions to the input data set.

• When coding your programming statements, avoid defining variables that begin with an underscore (_), because they might conflict with internal variables created by PROC SEVERITY.
Custom Objective Functions and Regression Effects

If you specify regressors by using the SCALEMODEL statement, then PROC SEVERITY automatically adds a statement prior to your programming statements to compute the value of the scale parameter or the log-transformed scale parameter of the distribution using the values of the regression variables and internally created regression parameters. For example, if you specify three regressors \(x_1, x_2, \) and \(x_3\) in the SCALEMODEL statement, then for a model that contains the distribution \(D\) with scale parameter \(S\), PROC SEVERITY prepends your program with a statement that is equivalent to the following statement:

\[
S = \_SEVTHETA0 \times \exp(\_SEVBETA1 \times x_1 + \_SEVBETA2 \times x_2 + \_SEVBETA3 \times x_3);
\]

If a model contains a distribution \(D_1\) with a log-transformed scale parameter \(M\), PROC SEVERITY prepends your program with a statement that is equivalent to the following statement:

\[
M = \_SEVTHETA0 + \_SEVBETA1 \times x_1 + \_SEVBETA2 \times x_2 + \_SEVBETA3 \times x_3;
\]

The \(\_SEVTHETA0, \_SEVBETA1, \_SEVBETA2,\) and \(\_SEVBETA3\) are the internal regression parameters associated with the intercept and the regressors \(x_1, x_2,\) and \(x_3,\) respectively.

Since the names of the internal regression parameters start with a prefix \(\_SEV\), if you use a variable in your program with a name that begins with \(\_SEV,\) then PROC SEVERITY writes an error message to the SAS log and stops processing.

Multithreaded Computation

PROC SEVERITY attempts to use all the computational resources of the machine where SAS is running in order to complete the estimation tasks as fast as possible. This section describes the options that control the use of multithreading by PROC SEVERITY.

Threading refers to the organization of computational work into multiple tasks (processing units that can be scheduled by the operating system). A task is associated with a thread. Multithreading refers to the concurrent execution of threads. When multithreading is possible, substantial performance gains can be realized compared to sequential (single-threaded) execution.

The number of threads spawned by the SEVERITY procedure is determined by the number of CPUs on a machine. You can control the number of threads by specifying either the CPUCOUNT= or the NOTHREADS SAS system option.

- You can specify the CPU count with the CPUCOUNT= SAS system option. For example, if you specify the following statement, then PROC SEVERITY schedules threads as if it executed on a system with four CPUs, regardless of the actual CPU count:

  \[
  \text{options cpucount=4;}
  \]

  On most systems, the default value of the CPUCOUNT= system option is set to the number of actual CPU cores available for processing.
• If you do not want PROC SEVERITY to use multithreading, then you can turn off the THREADS SAS system option by specifying the following statement:

   options nothreads;

   On most systems, the THREADS option is turned on by default.

You can examine the current settings of these system options in the SAS log by submitting the following PROC OPTIONS step:

   proc options option=(threads cpucount);
   run;

---

**Input Data Sets**

PROC SEVERITY accepts DATA= and INEST= data sets as input data sets. This section details the information they are expected to contain.

**DATA= Data Set**

The DATA= data set is expected to contain the values of the analysis variables that you specify in the LOSS statement and the SCALING statement.

If you specify the BY statement, then the DATA= data set must contain all the BY variables that you specify in the BY statement and the data set must be sorted by the BY variables unless you specify the NOTSORTED option in the BY statement.

**INEST= Data Set**

The INEST= data set is expected to contain the initial values of the parameters for the parameter estimation process.

If you specify the BY statement, then the INEST= data set must contain all the BY variables that you specify in the BY statement. If you do not specify the NOTSORTED option in the BY statement, then the INEST= data set must be sorted by the BY variables. However, it is not required to contain all the BY groups present in the DATA= data set. For the BY groups that are not present in the INEST= data set, the default parameter initialization method is used. If you specify the NOTSORTED option in the BY statement, then the INEST= data set must contain all the BY groups that are present in the DATA= data set and they must appear in the same order as they appear in the DATA= data set.

In addition to any variables that you specify in the BY statement, the data set must contain the following variables:

   _MODEL_     identifying name of the distribution for which the estimates are provided.
   _TYPE_      type of the estimate. The value of this variable must be EST for an observation to be valid.
   <Parameter 1> . . . <Parameter M>

   $M$ variables, named after the parameters of all candidate distributions, that contain initial values of the respective parameters. $M$ is the cardinality of the union of parameter
name sets from all candidate distributions. In an observation, estimates are read only from variables for parameters that correspond to the distribution that is indicated by the _MODEL_ variable.

If you specify a missing value for some parameters, then default initial values are used unless the parameter is initialized by using the INIT= option in the DIST statement. If you want to use the dist_PARMINIT subroutine for initializing the parameters of a model, then you should either not specify the model in the INEST= data set or specify missing values for all the distribution parameters in the INEST= data set and not use the INIT= option in the DIST statement.

If you specify regressors, then the initial value that you provide for the first parameter of each distribution must be the base value of the scale or log-transformed scale parameter. See the section “Estimating Regression Effects” on page 1664 for more information.

<Regressor 1> . . . <Regressor K>
If you specify $K$ regressors in the SCALEMODEL statement, then the INEST= data set must contain $K$ variables that are named for each regressor. The variables contain initial values of the respective regression coefficients. If a regressor is linearly dependent on other regressors for a given BY group, then you can indicate this by providing a special missing value of .R for the respective variable. In a given BY group, if you mark a variable as linearly dependent for one model, then you must mark that variable as linearly dependent for all the models. Similarly, in a given BY group, if you do not mark a variable as linearly dependent for one model, then you must not mark that variable as linearly dependent for all the models.

Output Data Sets

PROC SEVERITY writes OUTCDF=, OUTEST=, OUTMODELINFO=, and OUTSTAT= data sets when requested with respective options. The data sets and their contents are described in the following sections.

OUTCDF= Data Set

The OUTCDF= data set records the estimates of the cumulative distribution function (CDF) of each of the specified model distributions and an estimate of the empirical distribution function (EDF).

If you specify BY variables, then the data are organized in BY groups and the data set contains variables that you specify in the BY statement. In addition, it contains the following variables:

<response variable>
value of the response variable. The values are sorted. If there are multiple BY groups, the values are sorted within each BY group.

_OBSNUM_
observation number in the DATA= data set.

_EDF_
estimate of the empirical distribution function (EDF). This estimate is computed by using the EMPIRICALCDF= option that you specify in the PROC SEVERITY statement.

_EDF_STD_estimate of the standard error of EDF. This estimate is computed by using a method that is appropriate for the EMPIRICALCDF= option that you specify in the PROC SEVERITY statement.
**_EDF_LOWER_**

Estimate of the lower confidence limit of EDF for a pointwise 100(1 − α)% confidence interval, where α is the value of the **EDFALPHA=** option that you specify in the PROC SEVERITY statement (default is α = 0.05). For an EDF estimate $F_n$ with standard error $\sigma_n$, it is computed as $\text{MAX}(0, F_n - z_{(1-\alpha/2)}\sigma_n)$, where $z_p$ is the $p$th quantile from the standard normal distribution.

**_EDF_UPPER_**

Estimate of the upper confidence limit of EDF for a pointwise 100(1 − α)% confidence interval, where α is the value of the **EDFALPHA=** option that you specify in the PROC SEVERITY statement (default is α = 0.05). For an EDF estimate $F_n$ with standard error $\sigma_n$, it is computed as $\text{MIN}(1, F_n + z_{(1-\alpha/2)}\sigma_n)$, where $z_p$ is the $p$th quantile from the standard normal distribution.

**<distribution1>_CDF ... <distributionD>_CDF**

Estimate of the cumulative distribution function (CDF) for each of the $D$ candidate distributions, computed by using the final parameter estimates for that distribution. This value is missing if parameter estimation process does not converge for the given distribution.

If you specify regressor variables, then the reported estimates are from a mixture distribution. See the section “CDF and PDF Estimates with Regression Effects” on page 1667 for more information.

If you specify truncation, then the data set contains the following additional variables:

**<distribution1>_COND_CDF ... <distributionD>_COND_CDF**

Estimate of the conditional CDF for each of the $D$ candidate distributions, computed by using the final parameter estimates for that distribution. This value is missing if parameter estimation process does not converge for the distribution. The conditional estimates are computed using the method described in the section “Truncation and Conditional CDF Estimates” on page 1660.

---

**OUTTEST= Data Set**

The OUTTEST= data set records the estimates of the model parameters. It also contains estimates of their standard errors and optionally, their covariance structure. If you specify BY variables, then the data are organized in BY groups and the data set contains variables that you specify in the BY statement.

If you do not specify the COVOUT option, then the data set contains the following variables:

**_MODEL_**

Identifying name of the distribution model. The observation contains information about this distribution.

**_TYPE_**

Type of the estimates reported in this observation. It can take one of the following two values:

- **EST**—point estimates of model parameters
- **STDERR**—standard error estimates of model parameters

**_STATUS_**

Status of the reported estimates. The possible values are listed in the section “_STATUS_ Variable Values” on page 1712.
Chapter 23: The SEVERITY Procedure

<Parameter 1> . . . <Parameter M>

\( M \) variables, named after the parameters of all candidate distributions, containing estimates of the respective parameters. \( M \) is the cardinality of the union of parameter name sets from all candidate distributions. In an observation, estimates are populated only for parameters that correspond to the distribution that is indicated by the _MODEL_ variable. If _TYPE_ is EST, then the estimates are missing if the model does not converge. If _TYPE_ is STDERR, then the estimates are missing if covariance estimates cannot be obtained.

If you specify regressors, then the estimate that is reported for the first parameter of each distribution is the estimate of the base value of the scale or log-transformed scale parameter. See the section “Estimating Regression Effects” on page 1664 for more information.

<Regressor 1> . . . <Regressor K>

If you specify \( K \) regressors in the SCALEMODEL statement, then the OUTEST= data set contains \( K \) variables that are named for each regressor. The variables contain estimates for their respective regression coefficients. If a regressor is deemed to be linearly dependent on other regressors for a given BY group, then a warning is written to the SAS log and a special missing value of .R is written in the respective variable. If _TYPE_ is EST, then the estimates are missing if the model does not converge. If _TYPE_ is STDERR, then the estimates are missing if covariance estimates cannot be obtained.

<Offset Variable>

If you specify an OFFSET= variable in the SCALEMODEL statement, then the OUTEST= data set contains a variable that is named after the offset variable. If _TYPE_ is EST, then the value of this variable is 1. If _TYPE_ is STDERR, then the value of this variable is a special missing value of .F.

If you specify the COVOUT option in the PROC SEVERITY statement, then the OUTEST= data set contains additional observations that contain the estimates of the covariance structure. Given the symmetric nature of the covariance structure, only the lower triangular portion is reported. In addition to the variables listed and described previously, the data set contains the following variables that are either new or have a modified description:

_TYPE_  type of the estimates reported in this observation. For observations that contain rows of the covariance structure, the value is COV.

_STATUS_  status of the reported estimates. For observations that contain rows of the covariance structure, the status is 0 if covariance estimation was successful. If estimation fails, the status is 1 and a single observation is reported with _TYPE_=COV and missing values for all the parameter variables.

_NAME_  Name of the parameter for the row of covariance matrix reported in the current observation.

OUTMODELINFO= Data Set

The OUTMODELINFO= data set records the information about each candidate distribution that you specify in the DIST statement. It contains the following variables:
Output Data Sets

_OUTSTAT_

The OUTSTAT= data set records statistics of fit and model selection information. If you specify BY variables, then the data are organized in BY groups and the data set contains variables that you specify in the BY statement. The data set contains the following variables:

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_OUTSTAT_ Data Set

The OUTSTAT= data set records statistics of fit and model selection information. If you specify BY variables, then the data are organized in BY groups and the data set contains variables that you specify in the BY statement. The data set contains the following variables:

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_

two parameters that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models.

_FPARMNAME1 ... _FPARMNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.

_IDENTIFIER__ identifying name of the distribution model. The observation contains information about this distribution.

_NMODEL_..._MEQNAMEM

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables _PARMNAMEj (j > m) are missing.
KS value of the Kolmogorov-Smirnov (KS) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.

AD value of the Anderson-Darling (AD) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.

CVM value of the Cramér-von Mises (CvM) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.

_STATUS_ Variable Values

The _STATUS_ variable in the OUTEST= and OUTSTAT= data sets contains a value that indicates the status of the parameter estimation process for the respective distribution model. The variable can take the following values in the OUTEST= data set for _TYPE_=EST observations and in the OUTSTAT= data set:

- **0**: The parameter estimation process converged for this model.
- **301**: The parameter estimation process might not have converged for this model because there is no improvement in the objective function value. This might indicate that the initial values of the parameters are optimal, or you can try different convergence criteria in the NLOPT_OPTIONS statement.
- **302**: The parameter estimation process might not have converged for this model because the number of iterations exceeded the maximum allowed value. You can try setting a larger value for the MAXITER= options in the NLOPT_OPTIONS statement.
- **303**: The parameter estimation process might not have converged for this model because the number of objective function evaluations exceeded the maximum allowed value. You can try setting a larger value for the MAXFUNC= options in the NLOPT_OPTIONS statement.
- **304**: The parameter estimation process might not have converged for this model because the time taken by the process exceeded the maximum allowed value. You can try setting a larger value for the MAXTIME= option in the NLOPT_OPTIONS statement.
- **400**: The parameter estimation process did not converge for this model.

The _STATUS_ variable can take the following values in the OUTEST= data set for _TYPE_=STDERR and _TYPE_=COV observations:

- **0**: The covariance and standard error estimates are available and valid.
- **1**: The covariance and standard error estimates are not available, because the process of computing covariance estimates failed.

Displayed Output

The SEVERITY procedure optionally produces displayed output by using the Output Delivery System (ODS). All output is controlled by the PRINT= option in the PROC SEVERITY statement. Table 23.5 relates the PRINT= options to ODS tables.
Table 23.5  ODS Tables Produced in PROC SEVERITY

<table>
<thead>

<td>PRINT=ALL</td>
</tr>
</tbody>
</table>

If you do not specify the PRINT= option, then by default PROC SEVERITY produces ModelSelection, ConvergenceStatus, OptimizationSummary, StatisticsOfFit, and ParameterEstimates ODS tables.

The TurnbullSummary table is produced only if you specify PRINT=ALL and Turnbull’s method is used for computing EDF estimates.

**AllFitStatistics (PRINT=ALLFITSTATS)**

displays the comparison of all the statistics of fit for all the models in one table. The table does not include the models whose parameter estimation process does not converge. If all the models fail to converge, then this table is not produced. If the table contains more than one model, then the best model according to each statistic is indicated with an asterisk (*) in that statistic’s column.

**ConvergenceStatus (PRINT=CONVSTATUS)**

displays the convergence status of the parameter estimation process.

**DescStats (PRINT=DESCSTATS)**

displays the descriptive statistics for the response variable.

**DistributionInfo (PRINT=DISTINFO)**

displays the information about all the candidate distribution. It includes the name, the description, the number of distribution parameters, and whether the distribution is valid for the specified modeling task.
InitialValues (PRINT=INITIALVALUES)

displays the initial values and bounds used for estimating each model.

IterationHistory (PRINT=NLOHISTORY)

displays the iteration history of the nonlinear optimization process used for estimating the parameters.

ModelSelection (PRINT=SELECTION)

displays the model selection table. The table shows the convergence status of each candidate model, and the value of the selection criterion along with an indication of the selected model.

OptimizationSummary (PRINT=NLOSUMMARY)

displays the summary of the nonlinear optimization process used for estimating the parameters.

ParameterEstimates (PRINT=ESTIMATES)

displays the final estimates of parameters. The estimates are not displayed for models whose parameter estimation process does not converge.

RegDescStats (PRINT=DESCSTATS)

displays the descriptive statistics for the regressor variables, if you specify the SCALEMODEL statement.

StatisticsOfFit (PRINT=STATISTICS)

displays the statistics of fit for each model. The statistics of fit are not displayed for models whose parameter estimation process does not converge.

TurnbullSummary (PRINT=ALL)

displays the summary of Turnbull’s estimation process if Turnbull’s method is used for computing EDF estimates. The summary includes whether the nonlinear optimization converged, the number of iterations, the maximum absolute relative error, the maximum absolute reduced gradient, and whether the final estimates are maximum likelihood estimates.

---

**ODS Graphics**

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the SEVERITY procedure.
ODS Graphics 

1715

ODS Graph Names

PROC SEVERITY assigns a name to each graph it creates by using ODS. You can use these names to selectively reference the graphs. The names are listed in Table 23.6.

Table 23.6  ODS Graphics Produced by PROC SEVERITY

Comparative CDF Plot

The comparative CDF plot helps you visually compare the cumulative distribution function (CDF) estimates of all the candidate distribution models and the empirical distribution function (EDF) estimate. The plot does not contain CDF estimates for models whose parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the CDF or EDF estimates.

If you specify truncation, then conditional CDF estimates are plotted. Otherwise, unconditional CDF estimates are plotted. The conditional estimates are computed using the method described in the section “Truncation and Conditional CDF Estimates” on page 1660.

If you specify regressor variables, then the plotted CDF estimates are from a mixture distribution. See the section “CDF and PDF Estimates with Regression Effects” on page 1667 for more information.

CDF Plot per Distribution

The CDF plot per distribution shows the CDF estimates of each candidate distribution model unless that model’s parameter estimation process does not converge. The plot also contains estimates of the EDF. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the CDF or EDF estimates.

This plot shows the lower and upper pointwise confidence limits for the EDF estimates. For an EDF estimate $F_n$ with standard error $\sigma_n$, they are computed as $\text{MAX}(0, F_n - z_{(1-\alpha/2)}\sigma_n)$ and $\text{MIN}(1, F_n + z_{(1-\alpha/2)}\sigma_n)$ respectively, where $z_p$ is the $p$th quantile from the standard normal distribution and $\alpha$ denotes the confidence level that you specify in the EDFALPHA= option (the default is $\alpha = 0.05$).

If you specify truncation, then conditional CDF estimates are plotted. Otherwise unconditional CDF estimates are plotted. The conditional estimates are computed using the method described in the section “Truncation and Conditional CDF Estimates” on page 1660.

If you specify regressor variables, then the plotted CDF estimates are from a mixture distribution. See the section “CDF and PDF Estimates with Regression Effects” on page 1667 for more information.
Comparative PDF Plot

The comparative PDF plot helps you visually compare the probability density function (PDF) estimates of all the candidate distribution models. The plot does not contain PDF estimates for models whose parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the PDF estimates.

If you specify the HISTOGRAM option, then the plot also contains the histogram of response variable values. If you specify the KERNEL option, then the plot also contains the kernel density estimate for the response variable values.

If you specify regressor variables, then the plotted PDF estimates are from a mixture distribution. See the section “CDF and PDF Estimates with Regression Effects” on page 1667 for more information.

PDF Plot per Distribution

The PDF plot per distribution shows the PDF estimates of each candidate distribution model unless that model’s parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the PDF estimates.

If you specify the HISTOGRAM option, then the plot also contains the histogram of response variable values. If you specify the KERNEL option, then the plot also contains the kernel density estimate for the response variable values.

If you specify regressor variables, then the plotted PDF estimates are from a mixture distribution. See the section “CDF and PDF Estimates with Regression Effects” on page 1667 for more information.

P-P Plot of CDF and EDF

The P-P plot of CDF and EDF is the probability-probability plot that compares the CDF estimates of a distribution with the EDF estimates. A plot is not prepared for models whose parameter estimation process does not converge. The horizontal axis represents the CDF estimates of a candidate distribution and the vertical axis represents the EDF estimates.

This plot can be interpreted as displaying the data that are used for computing the EDF-based statistics of fit for the given candidate distribution. As described in the section “EDF-Based Statistics” on page 1676, these statistics are computed by comparing the EDF, denoted by \( F_n(y) \), and the CDF, denoted by \( \hat{F}(y) \), at each of the response variable values \( y \). Using the probability inverse transform \( z = F(y) \), this is equivalent to comparing the EDF of the \( z \), denoted by \( F_n(z) \), and the CDF of \( z \), denoted by \( \hat{F}(z) \) (D’Agostino and Stephens 1986, Ch. 4). Given that the CDF of \( z \) is a uniform distribution (\( F(z) = z \)), the EDF-based statistics can be computed by comparing the EDF estimate of \( z \) with the estimate of \( z \). The horizontal axis of the plot represents the estimated CDF \( \hat{z} = \hat{F}(y) \). The vertical axis represents the estimated EDF of \( z \), \( \hat{F}_n(z) \). The plot contains a scatter plot of \( (\hat{z}, \hat{F}_n(z)) \) points and a reference line \( F_n(z) = z \) that represents the expected uniform distribution of \( z \). Points scattered closer to the reference line indicate a better fit than the points scattered away from the reference line.

If you specify truncation, then the EDF estimates are conditional as described in the section “EDF Estimates and Truncation” on page 1673. So, conditional estimates of CDF are displayed, which are computed using the method described in the section “Truncation and Conditional CDF Estimates” on page 1660.

If you specify regressor variables, then the displayed CDF estimates, both unconditional and conditional, are from a mixture distribution. See the section “CDF and PDF Estimates with Regression Effects” on page 1667 for more information.
Q-Q Plot

The Q-Q plot is a quantile-quantile scatter plot that compares the empirical quantiles with the quantiles from a candidate distribution. A plot is not prepared for models whose parameter estimation process does not converge. The horizontal axis represents the quantiles from a candidate distribution, and the vertical axis represents the empirical quantiles.

Each point in the plot corresponds to a specific value of EDF estimate, \( F_n \). The Y coordinate is the value of the response variable for which \( F_n \) is computed. The X coordinate is computed by using one of two following methods for a candidate distribution named \( \text{dist} \):

- If you have defined the \( \text{dist}_\text{QUANTILE} \) function that satisfies the requirements listed in the section “\( \text{dist}_\text{QUANTILE} \)” on page 1687, then that function is invoked with \( F_n \) and estimated distribution parameters as arguments. The QUANTILE function is defined in the Sashelp.Svrtdist library for all the predefined distributions except for the Burr distribution.

- If the \( \text{dist}_\text{QUANTILE} \) function is not defined, then PROC SEVERITY numerically inverts the \( \text{dist}_\text{CDF} \) function at the CDF value of \( F_n \) for the estimated distribution parameters. If the \( \text{dist}_\text{CDF} \) function is not defined, then the \( \exp(\text{dist}_\text{LOGCDF}) \) function is inverted. If the inversion fails, the corresponding point is not plotted in the Q-Q plot.

If you specify truncation, then the EDF estimates are conditional as described in the section “EDF Estimates and Truncation” on page 1673. The CDF inversion process, whether done numerically or by evaluating the \( \text{dist}_\text{QUANTILE} \) function, needs to accept an unconditional CDF value. So, the \( F_n \) value is first transformed to an unconditional estimate \( F_n^u \) as

\[
F_n^u = F_n \cdot (\hat{F}(t_{\text{max}}^\text{r}) - \hat{F}(t_{\text{min}}^\text{l})) + \hat{F}(t_{\text{min}}^\text{l})
\]

where \( \hat{F}(t_{\text{max}}^\text{r}) \) and \( \hat{F}(t_{\text{min}}^\text{l}) \) are as defined in the section “Truncation and Conditional CDF Estimates” on page 1660.

If you specify regressor variables, then the value of the first distribution parameter is the mean of the scale values that are implied by all the observations in the current BY group (or in the entire DATA= data set if you do not specify the BY statement).

Examples: SEVERITY Procedure

Example 23.1: Defining a Model for Gaussian Distribution

Suppose you want to fit a distribution model other than one of the predefined ones available to you. Suppose you want to define a model for the Gaussian distribution with the following typical parameterization of the PDF \( f \) and CDF \( F \):

\[
f(x; \mu, \sigma) = \frac{1}{\sigma \sqrt{2\pi}} \exp\left(-\frac{(x - \mu)^2}{2\sigma^2}\right)
\]

\[
F(x; \mu, \sigma) = \frac{1}{2} \left(1 + \text{erf}\left(\frac{x - \mu}{\sigma \sqrt{2}}\right)\right)
\]
For PROC SEVERITY, a distribution model consists of a set of functions and subroutines that are defined with the FCMP procedure. Each function and subroutine should be written following certain rules. For more information, see the section “Defining a Distribution Model with the FCMP Procedure” on page 1679.

**NOTE:** The Gaussian distribution is not a commonly used severity distribution. It is used in this example primarily to illustrate the process of defining your own distribution models. Although the distribution has a support over the entire real line, you can fit the distribution with PROC SEVERITY only if the input sample contains nonnegative values.

The following SAS statements define a distribution model named NORMAL for the Gaussian distribution. The OUTLIB= option in the PROC FCMP statement stores the compiled versions of the functions and subroutines in the ‘models’ package of the Work.Sevexmpl library. The LIBRARY= option in the PROC FCMP statement enables this PROC FCMP step to use the SVRTUTIL_RAWMOMENTS utility subroutine that is available in the Sashelp.Svrdist library. The subroutine is described in the section “Predefined Utility Functions” on page 1691.

```sas
/*-------- Define Normal Distribution with PROC FCMP ---------- */
proc fcmp library=sashelp.svrtdist outlib=work.sevexmpl.models;
    function normal_pdf(x,Mu,Sigma);
        /* Mu : Location */
        /* Sigma : Standard Deviation */
        return ( exp(-(x-Mu)**2/(2 * Sigma**2)) / (Sigma * sqrt(2*constant('PI'))) );
    endsub;

    function normal_cdf(x,Mu,Sigma);
        /* Mu : Location */
        /* Sigma : Standard Deviation */
        z = (x-Mu)/Sigma;
        return (0.5 + 0.5*erf(z/sqrt(2)));
    endsub;

    subroutine normal_parminit(dim, x[*], nx[*], F[*], Ftype, Mu, Sigma);
        outargs Mu, Sigma;
        array m[2] / nosymbols;
        /* Compute estimates by using method of moments */
        call svrtutil_rawmoments(dim, x, nx, 2, m);
        Mu = m[1];
        Sigma = sqrt(m[2] - m[1]**2);
    endsub;

    subroutine normal_lowerbounds(Mu, Sigma);
        outargs Mu, Sigma;
        Mu = .; /* Mu has no lower bound */
        Sigma = 0; /* Sigma > 0 */
    endsub;
quit;
```

The statements define the two functions required of any distribution model (NORMAL_PDF and NORMAL_CDF) and two optional subroutines (NORMAL_PARMINIT and NORMAL_LOWERBOUNDS). The name of each function or subroutine must follow a specific structure. It should start with the model’s
Example 23.1: Defining a Model for Gaussian Distribution

short or identifying name, which is ‘NORMAL’ in this case, followed by an underscore ‘_’, followed by a keyword suffix such as ‘PDF’. Each function or subroutine has a specific purpose. For more information about all the functions and subroutines that you can define for a distribution model, see the section “Defining a Distribution Model with the FCMP Procedure” on page 1679. Following is the description of each function and subroutine defined in this example:

- The PDF and CDF suffixes define functions that return the probability density function and cumulative distribution function values, respectively, given the values of the random variable and the distribution parameters.

- The PARMINIT suffix defines a subroutine that returns the initial values for the parameters by using the sample data or the empirical distribution function (EDF) estimate computed from it. In this example, the parameters are initialized by using the method of moments. Hence, you do not need to use the EDF estimates, which are available in the F array. The first two raw moments of the Gaussian distribution are as follows:

\[
E[x] = \mu, \quad E[x^2] = \mu^2 + \sigma^2
\]

Given the sample estimates, \(m_1\) and \(m_2\), of these two raw moments, you can solve the equations \(E[x] = m_1\) and \(E[x^2] = m_2\) to get the following estimates for the parameters: \(\hat{\mu} = m_1\) and \(\hat{\sigma} = \sqrt{m_2 - m_1^2}\). The NORMAL_PARMINIT subroutine implements this solution. It uses the SVRTUTIL_RAWMOMENTS utility subroutine to compute the first two raw moments.

- The LOWERBOUNDS suffix defines a subroutine that returns the lower bounds on the parameters. PROC SEVERITY assumes a default lower bound of 0 for all the parameters when a LOWERBOUNDS subroutine is not defined. For the parameter \(\mu\) (\(\text{Mu}\)), there is no lower bound, so you need to define the NORMAL_LOWERBOUNDS subroutine. It is recommended that you assign bounds for all the parameters when you define the LOWERBOUNDS subroutine or its counterpart, the UPPERBOUNDS subroutine. Any unassigned value is returned as a missing value, which is interpreted by PROC SEVERITY to mean that the parameter is unbounded, and that might not be what you want.

You can now use this distribution model with PROC SEVERITY. Let the following DATA step statements simulate a normal sample with \(\mu = 10\) and \(\sigma = 2.5\).

```sas
/*-------- Simulate a Normal sample ----------*/
data testnorm(keep=y);
call streaminit(12345);
do i=1 to 100;
   y = rand('NORMAL', 10, 2.5);
   output;
end;
run;
```
Prior to using your distribution with PROC SEVERITY, you must communicate the location of the library that contains the definition of the distribution and the locations of libraries that contain any functions and subroutines used by your distribution model. The following OPTIONS statement sets the CMPLIB= system option to include the FCMP library Work.Sevexmpl in the search path used by PROC SEVERITY to find FCMP functions and subroutines.

```plaintext
/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);
```

Now, you are ready to fit the NORMAL distribution model with PROC SEVERITY. The following statements fit the model to the values of \( Y \) in the Work.Testnorm data set:

```plaintext
/*--- Fit models with PROC SEVERITY ---*/
proc severity data=testnorm print=all;
   loss y;
   dist Normal;
run;
```

The DIST statement specifies the identifying name of the distribution model, which is ‘NORMAL’. Neither is the INEST= option specified in the PROC SEVERITY statement nor is the INIT= option specified in the DIST statement. So, PROC SEVERITY initializes the parameters by invoking the NORMAL_PARMINIT subroutine.

Some of the results prepared by the preceding PROC SEVERITY step are shown in Output 23.1.1 and Output 23.1.2. The descriptive statistics of variable \( Y \) and the “Model Selection Table”, which includes just the normal distribution, are shown in Output 23.1.1.

The initial values for the parameters, the optimization summary, and the final parameter estimates are shown in Output 23.1.2. No iterations are required to arrive at the final parameter estimates, which are identical to the initial values. This confirms the fact that the maximum likelihood estimates for the Gaussian distribution are identical to the estimates obtained by the method of moments that was used to initialize the parameters in the NORMAL_PARMINIT subroutine.

| Parameter | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----------|----------------|---------|-------|
| Mu        | 10.02059 | 0.23894        | 41.94   | <.0001|
| Sigma     | 2.36538  | 0.16896        | 14.00   | <.0001|

The NORMAL distribution defined and illustrated here has no scale parameter, because all the following inequalities are true:

\[
f(x; \mu, \sigma) \neq \frac{1}{\mu} f(\frac{x}{\mu}; 1, \sigma)\]

\[
f(x; \mu, \sigma) \neq \frac{1}{\sigma} f(\frac{x}{\sigma}; \mu, 1)\]

\[
F(x; \mu, \sigma) \neq F(\frac{x}{\mu}; 1, \sigma)\]

\[
F(x; \mu, \sigma) \neq F(\frac{x}{\sigma}; \mu, 1)\]

This implies that you cannot estimate the effect of regressors on a model for the response variable based on this distribution.
Example 23.2: Defining a Model for Gaussian Distribution with a Scale Parameter

If you want to estimate the effects of regressors, then the model needs to be parameterized to have a scale parameter. While this might not be always possible, for the case of the Gaussian distribution it is possible by replacing the location parameter \( \mu \) with another parameter, \( \alpha = \mu / \sigma \), and defining the PDF \( f \) and the CDF \( F \) as follows:

\[
\begin{align*}
    f(x; \sigma, \alpha) &= \frac{1}{\sigma \sqrt{2\pi}} \exp \left( -\frac{1}{2} \left( \frac{x - \alpha}{\sigma} \right)^2 \right) \\
    F(x; \sigma, \alpha) &= \frac{1}{2} \left( 1 + \text{erf} \left( \frac{x}{\sigma \sqrt{2}} - \alpha \right) \right)
\end{align*}
\]

It can be verified that \( \sigma \) is the scale parameter, because both of the following equalities are true:

\[
\begin{align*}
    f(x; \sigma, \alpha) &= \frac{1}{\sigma} f\left( \frac{x}{\sigma}; 1, \alpha \right) \\
    F(x; \sigma, \alpha) &= F\left( \frac{x}{\sigma}; 1, \alpha \right)
\end{align*}
\]

**NOTE:** The Gaussian distribution is not a commonly used severity distribution. It is used in this example primarily to illustrate the concept of parameterizing a distribution such that it has a scale parameter. Although the distribution has a support over the entire real line, you can fit the distribution with PROC SEVERITY only if the input sample contains nonnegative values.

The following statements use the alternate parameterization to define a new model named NORMAL_S. The definition is stored in the Work.Sevexmpl library.

```css
/****** Define Normal Distribution With Scale Parameter ********/ proc fcmp library=sashelp.svrtdist outlib=work.sevexmpl.models;
    function normal_s_pdf(x, Sigma, Alpha);
        /* Sigma : Scale & Standard Deviation */
        /* Alpha : Scaled mean */
        return ( exp(-x/Sigma - Alpha)**2/2 ) /
            (Sigma * sqrt(2*constant('PI'))) ;
    endsub;

    function normal_s_cdf(x, Sigma, Alpha);
        /* Sigma : Scale & Standard Deviation */
        /* Alpha : Scaled mean */
        z = x/Sigma - Alpha;
        return (0.5 + 0.5*erf(z/sqrt(2))) ;
    endsub;

    subroutine normal_s_parminit(dim, x[*], nx[*], F[*], Ftype, Sigma, Alpha);
        outargs Sigma, Alpha;
        array m[2] / nosymbols;
        /* Compute estimates by using method of moments */
```
Example 23.2: Defining a Model for Gaussian Distribution with a Scale Parameter

```plaintext
call svtutil_rawmoments(dim, x, nx, 2, m);
Sigma = sqrt(m[2] - m[1]**2);
Alpha = m[1]/Sigma;
endsub;

subroutine normal_s_lowerbounds(Sigma, Alpha);
  outargs Sigma, Alpha;
  Alpha = .; /* Alpha has no lower bound */
  Sigma = 0; /* Sigma > 0 */
endsub;
quit;

An important point to note is that the scale parameter Sigma is the first distribution parameter (after the 'x' argument) listed in the signatures of NORMAL_S_PDF and NORMAL_S_CDF functions. Sigma is also the first distribution parameter listed in the signatures of other subroutines. This is required by PROC SEVERITY, so that it can identify which is the scale parameter. When you specify regressor variables, PROC SEVERITY checks whether the first parameter of each candidate distribution is a scale parameter (or a log-transformed scale parameter if dist_SCALETRANSFORM subroutine is defined for the distribution with LOG as the transform). If it is not, then an appropriate message is written the SAS log and that distribution is not fitted.

Let the following DATA step statements simulate a sample from the normal distribution where the parameter $\sigma$ is affected by the regressors as follows:

$$\sigma = \exp(1 + 0.5 \times 1 + 0.75 \times 3 - 2 \times 4 + 5)$$

The sample is simulated such that the regressor $X_2$ is linearly dependent on regressors $X_1$ and $X_3$.

```
The following statements use PROC SEVERITY to fit the NORMAL_S distribution model along with some of the predefined distributions to the simulated sample:

```sql
/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);
/*-------- Fit models with PROC SEVERITY --------*/
proc severity data=testnorm_reg print=all plots=none;
   loss y;
   scalemodel x1-x5;
   dist Normal_s burr logn pareto weibull;
run;
```

The “Model Selection Table” in Output 23.2.1 indicates that all the models, except the Burr distribution model, have converged. Also, only three models, Normal_s, Burr, and Weibull, seem to have a good fit for the data. The table that compares all the fit statistics indicates that Normal_s model is the best according to the likelihood-based statistics; however, the Burr model is the best according to the EDF-based statistics.

This prompts for further evaluation of why the model with Burr distribution has not converged. The initial values, convergence status, and the optimization summary for the Burr distribution are shown in Output 23.2.2. The initial values table indicates that the regressor $X_2$ is redundant, which is expected. More importantly, the convergence status indicates that it requires more than 50 iterations. PROC SEVERITY enables you to change several settings of the optimizer by using the NLOPTIONS statement. In this case, you can increase the limit of 50 on the iterations, change the convergence criterion, or change the technique to something other than the default trust-region technique.

Output 23.2.2 Details of the Fitted Burr Distribution Model

<table>

<td>4</td>
</tr>
</tbody>
</table>
The following PROC SEVERITY step uses the NLOPTIONS statement to change the convergence criterion and the limits on the iterations and function evaluations, exclude the lognormal and Pareto distributions that have been confirmed previously to fit the data poorly, and exclude the redundant regressor \(X_2\) from the model:

```latex
/*--- Refit and compare models with higher limit on iterations ---*/
proc severity data=testnorm_reg print=all plots=pp;
  loss y;
  scalemodel x1 x3-x5;
  dist Normal_s burr weibull;
  nloptions absfconv=2.0e-5 maxiter=100 maxfunc=500;
run;
```

The results shown in Output 23.2.3 indicate that the Burr distribution has now converged and that the Burr and Weibull distributions have an almost identical fit for the data. The NORMAL_S distribution is still the best distribution according to the likelihood-based criteria.

Note: The asterisk (*) marks the best model according to each column's criterion.

The comparison of the PDF estimates of all the candidates is shown in Output 23.2.4. Each plotted PDF estimate is an average computed over the \( N \) PDF estimates that are obtained with the scale parameter determined by each of the \( N \) observations in the input data set. The PDF plot shows that the Burr and Weibull models result in almost identical estimates. All the estimates have a slight left skew with the mode closer to \( Y=25 \), which is the mean of the simulated sample.
The P-P plots for the Normal_s and Burr distributions are shown in Output 23.2.5. These plots show how the EDF estimates compare against the CDF estimates. Each plotted CDF estimate is an average computed over the $N$ CDF estimates that are obtained with the scale parameter determined by each of the $N$ observations in the input data set. Comparing the P-P plots of Normal_s and Burr distributions indicates that both fit the data almost similarly, but the Burr distribution fits the right tail slightly better, which explains why the EDF-based statistics prefer it over the Normal_s distribution.
Example 23.3: Defining a Model for Mixed-Tail Distributions

In some applications, a few severity values tend to be extreme as compared to the typical values. The extreme values represent the worst case scenarios and cannot be discarded as outliers. Instead, their distribution must be modeled to prepare for their occurrences. In such cases, it is often useful to fit one distribution to the non-extreme values and another distribution to the extreme values. The mixed-tail distribution mixes two distributions: one for the body region, which contains the non-extreme values, and another for the tail region, which contains the extreme values. The tail distribution is typically a generalized Pareto distribution (GPD), because it is usually good for modeling the conditional excess severity above a threshold. The body distribution can be any distribution. The following definitions are used in describing a generic formulation of a mixed-tail distribution:

\[ g(x) \quad \text{PDF of the body distribution} \]
\[ G(x) \quad \text{CDF of the body distribution} \]
\[ h(x) \quad \text{PDF of the tail distribution} \]
\[ H(x) \quad \text{CDF of the tail distribution} \]
\[ \theta \quad \text{scale parameter for the body distribution} \]
\[ \Omega \quad \text{set of nonscale parameters for the body distribution} \]
\[ \xi \quad \text{shape parameter for the GPD tail distribution} \]
\[ x_r \quad \text{normalized value of the response variable at which the tail starts} \]
\[ p_n \quad \text{mixing probability} \]
Given these notations, the PDF $f(x)$ and the CDF $F(x)$ of the mixed-tail distribution are defined as

$$f(x) = \begin{cases} \frac{p_n}{\sigma(x_b)} g(x) & \text{if } x \leq x_b \\ (1 - p_n) h(x - x_b) & \text{if } x > x_b \end{cases}$$

$$F(x) = \begin{cases} \frac{p_n}{\sigma(x_b)} G(x) & \text{if } x \leq x_b \\ p_n + (1 - p_n) H(x - x_b) & \text{if } x > x_b \end{cases}$$

where $x_b = \theta x_r$ is the value of the response variable at which the tail starts.

These definitions indicate the following:

- The body distribution is conditional on $X \leq x_b$, where $X$ denotes the random response variable.
- The tail distribution is the generalized Pareto distribution of the $(X - x_b)$ values.
- The probability that a response variable value belongs to the body is $p_n$. Consequently the probability that the value belongs to the tail is $(1 - p_n)$.

The parameters of this distribution are $\theta$, $\Omega$, $\xi$, $x_r$, and $p_n$. The scale of the GPD tail distribution $\theta_t$ is computed as

$$\theta_t = \frac{G(x_b; \theta, \Omega)}{g(x_b; \theta, \Omega)} \frac{(1 - p_n)}{p_n} = \theta \frac{G(x_r; \theta = 1, \Omega)}{g(x_r; \theta = 1, \Omega)} \frac{(1 - p_n)}{p_n}$$

The parameter $x_r$ is typically estimated using a tail index estimation algorithm. One such algorithm is the Hill’s algorithm (Danielsson et al. 2001), which is implemented by the predefined utility function SVRTUTIL_HILLCUTOFF available to you in the Sashelp.Svrdist library. The algorithm and the utility function are described in detail in the section “Predefined Utility Functions” on page 1691. The function computes an estimate of $x_b$, which can be used to compute an estimate of $x_r$ because $x_r = x_b / \hat{\theta}$, where $\hat{\theta}$ is the estimate of the scale parameter of the body distribution.

The parameter $p_n$ is typically determined by the domain expert based on the fraction of losses that are expected to belong to the tail.

The following SAS statements define the LOGNGPD distribution model for a mixed-tail distribution with the lognormal distribution as the body distribution and GPD as the tail distribution:

```
/*------- Define Lognormal Body-GPD Tail Mixed Distribution -------*/
proc fcmp library=sashelp.svrdist outlib=work.sevexmpl.models;
  function LOGNGPD_DESCRIPTION() $256;
    length desc $256;
    desc1 = "Lognormal Body-GPD Tail Distribution.";
    desc2 = " Mu, Sigma, and Xi are free parameters.";
    desc3 = " Xr and Pn are constant parameters.";
    desc = desc1 || desc2 || desc3;
    return(desc);
  endsub;

  function LOGNGPD_SCALETRANSFORM() $3;
    length xform $3;
    xform = "LOG";
    return (xform);
```
Example 23.3: Defining a Model for Mixed-Tail Distributions

endsub;

subroutine LOGNGPD_CONSTANTPARM(Xr,Pn);
endsub;

function LOGNGPD_PDF(x, Mu,Sigma,Xi,Xr,Pn);
cutoff = exp(Mu) * Xr;
p = CDF('LOGN',cutoff, Mu, Sigma);
if (x < cutoff + constant('MACEPS')) then do;
   return ((Pn/p)*PDF('LOGN', x, Mu, Sigma));
end;
else do;
gpd_scale = p*((1-Pn)/Pn)/PDF('LOGN', cutoff, Mu, Sigma);
h = (1+Xi*(x-cutoff)/gpd_scale)**(-1/(1/Xi))/gpd_scale;
return ((1-Pn)*h);
end;
endsub;

function LOGNGPD_CDF(x, Mu,Sigma,Xi,Xr,Pn);
cutoff = exp(Mu) * Xr;
p = CDF('LOGN',cutoff, Mu, Sigma);
if (x < cutoff + constant('MACEPS')) then do;

   Mu = .; /* Mu has no lower bound */
   Sigma = 0; /* Sigma > 0 */
   Xi = 0; /* Xi > 0 */
endsub;
quit;

The following points should be noted regarding the LOGNGPD definition:

- The parameters \( x_r \) and \( p_n \) are not estimated with the maximum likelihood method used by PROC SEVERITY, so you need to specify them as constant parameters by defining the dist_CONSTANTPARM subroutine. The signature of LOGNGPD_CONSTANTPARM subroutine lists only the constant parameters \( X_r \) and \( P_n \).

- The parameter \( x_r \) is estimated by first using the SVRTUTIL_HILLCUTOFF utility function to compute an estimate of the cutoff point \( \hat{x}_b \) and then computing \( x_r = \hat{x}_b/e^\beta \). If SVRTUTIL_HILLCUTOFF fails to compute a valid estimate, then the SVRTUTIL_PERCENTILE utility function is used to set \( \hat{x}_b \) to the \( p_n \)th percentile of the data. The parameter \( p_n \) is fixed to 0.8.

- The Sashelp.Svrtdist library is specified with the LIBRARY= option in the PROC FCMP statement to enable the LOGNGPD_PARMINIT subroutine to use the predefined utility functions (SVRTUTIL_HILLCUTOFF and SVRTUTIL_PERCENTILE) and parameter initialization subroutines (LOGN_PARMINIT and GPD_PARMINIT).

- The LOGNGPDLOWERBOUNDS subroutine defines the lower bounds for all parameters. This subroutine is required because the parameter \( Mu \) has a non-default lower bound. The bounds for \( Sigma \) and \( Xi \) must be specified. If they are not specified, they are returned as missing values, which get interpreted as having no lower bound by PROC SEVERITY. You need not specify any bounds for the constant parameters \( X_r \) and \( P_n \), because they are not subject to optimization.
The following DATA step statements simulate a sample from a mixed-tail distribution with a lognormal body and GPD tail. The parameter $p_n$ is fixed to 0.8, the same value used in the LOGNGPD_PARMINIT subroutine defined previously:

```sas
/*----- Simulate a sample for the mixed-tail distribution -----*/
data testmixdist(keep=y label='Lognormal Body-GPD Tail Sample');
call streaminit(45678);
label y='Response Variable';
N = 100;
Mu = 1.5;
Sigma = 0.25;
Xi = 1.5;
Pn = 0.8;

/* Generate data comprising the lognormal body */
Nbody = N*Pn;
do i=1 to Nbody;
y = exp(Mu) * rand('LOGNORMAL')**Sigma;
output;
end;

/* Generate data comprising the GPD tail */
cutoff = quantile('LOGNORMAL', Pn, Mu, Sigma);
gpd_scale = (1-Pn) / pdf('LOGNORMAL', cutoff, Mu, Sigma);
do i=Nbody+1 to N;
y = cutoff + ((1-rand('UNIFORM'))**(-Xi) - 1)*gpd_scale/Xi;
output;
end;
run;
```

The following statements use PROC SEVERITY to fit the LOGNGPD distribution model to the simulated sample. They also fit three other predefined distributions (Burr, LogN, and GPD). The final parameter estimates are written to the Work.Parmest data set.

```sas
/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);

/*-------- Fit LOGNGPD model with PROC SEVERITY --------*/
proc severity data=testmixdist print=all plots(histogram kernel)=all
    outest=parmest;
    loss y;
    dist logngpd burr logn gpd;
run;
```

Some of the results prepared by PROC SEVERITY are shown in Output 23.3.1 through Output 23.3.4. The “Model Selection Table” in Output 23.3.1 indicates that all models converged. The last table in Output 23.3.1 shows that the model with LOGNGPD distribution has the best fit according to almost all the statistics of fit. The Burr distribution model is the closest contender to the LOGNGPD model, but the GPD distribution model fits the data very poorly.
The plots in Output 23.3.2 show that both the lognormal and GPD distributions fit the data poorly, GPD being the worst. The Burr distribution fits the data as well as the LOGNGPD distribution in the body region, but has a poorer fit in the tail region than the LOGNGPD distribution.
Output 23.3.2  Comparison of the CDF and PDF Estimates of the Fitted Models
The P-P plots of Output 23.3.3 provide a better visual confirmation that the LOGNGPD distribution fits the tail region better than the Burr distribution.
Example 23.3: Defining a Model for Mixed-Tail Distributions

Output 23.3.3 P-P Plots for the LOGNGPD and BURR Distribution Models

The detailed results for the LOGNGPD distribution are shown in Output 23.3.4. The initial values table indicates the values computed by LOGNGPD_PARMINIT subroutine for the \( X_r \) and \( P_n \) parameters. It also uses the bounds columns to indicate the constant parameters. The last table in the figure shows the final parameter estimates. The estimates of all free parameters are significantly different from 0. As expected, the final estimates of the constant parameters \( X_r \) and \( P_n \) have not changed from their initial values.

**Parameter Estimates**

| Parameter | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----------|----------------|---------|-------|
| Mu        | 1.57921  | 0.06426        | 24.57   | <.0001|
| Sigma     | 0.31868  | 0.04459        | 7.15    | <.0001|
| Xi        | 1.03771  | 0.38205        | 2.72    | 0.0078|
| Xr        | 1.27395  | Constant        | .       |       |
| Pn        | 0.80000  | Constant        | .       |       |

The following SAS statements use the parameter estimates to compute the value where the tail region is estimated to start ($x_b = e^{\hat{\mu} \cdot X_r}$) and the scale of the GPD tail distribution ($\theta_t = \frac{g(x_b)}{G(x_b)} \frac{(1-Pn)}{Pn}$):

```sas
/*-------- Compute tail cutoff and tail distribution's scale --------*/
data xb_thetat(keep=x_b theta_t);
  set parmest(where=(_MODEL_='logngpd' and _TYPE_='EST'));
  x_b = exp(Mu) * Xr;
  theta_t = (CDF('LOGN',x_b,Mu,Sigma)/PDF('LOGN',x_b,Mu,Sigma)) * ((1-Pn)/Pn);
run;

proc print data=xb_thetat noobs;
run;
```

**Output 23.3.5** Start of the Tail and Scale of the GPD Tail Distribution

<table>
<thead>
<tr>
<th>x_b</th>
<th>theta_t</th>
</tr>
</thead>
<tbody>
<tr>
<td>6.18005</td>
<td>1.27865</td>
</tr>
</tbody>
</table>
The computed values of \( x_b \) and \( \theta_t \) are shown as \( x_{b} \) and \( \theta_t \) in Output 23.3.5. Equipped with this additional derived information, you can now interpret the results of fitting the mixed-tail distribution as follows:

- The tail starts at \( y \approx 6.18 \). The primary benefit of using the scale-normalized cutoff (\( x_r \)) as the constant parameter instead of using the actual cutoff (\( x_b \)) is that the absolute cutoff gets optimized by virtue of optimizing the scale of the body region (\( \theta = e^{\mu} \)).
- The values \( y \leq 6.18 \) follow the lognormal distribution with parameters \( \mu \approx 1.58 \) and \( \sigma \approx 0.32 \). These parameter estimates are reasonably close to the parameters used for simulating the sample.
- The values \( y_t = y - 6.18 \) (\( y_t > 0 \)) follow the GPD distribution with scale \( \theta_t \approx 1.28 \) and shape \( \xi \approx 1.04 \).

---

**Example 23.4: Estimating Parameters Using Cramér-von Mises Estimator**

PROC SEVERITY enables you to estimate model parameters by minimizing your own objective function. This example illustrates how you can use PROC SEVERITY to implement the Cramér-von Mises estimator. Let \( F(y_i; \Theta) \) denote the estimate of CDF at \( y_i \) for a distribution with parameters \( \Theta \), and let \( F_n(y_i) \) denote the empirical estimate of CDF (EDF) at \( y_i \) that is computed from a sample \( y_i \), \( 1 \leq i \leq N \). Then, the Cramér-von Mises estimator of the parameters is defined as

\[
\hat{\Theta} = \arg\min_{\Theta} \sum_{i=1}^{N} (F(y_i; \Theta) - F_n(y_i))^2
\]

This estimator belongs to the class of minimum distance estimators. It attempts to estimate the parameters such that the squared distance between the CDF and EDF estimates is minimized.

The following PROC SEVERITY step uses the Cramér-von Mises estimator to fit four candidate distribution models, including the LOGNGPD mixed-tail distribution model that was defined in “Example 23.3: Defining a Model for Mixed-Tail Distributions” on page 1729. The input sample is the same as is used in that example.

```plaintext
/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);

/******* Fit LOGNGPD model with PROC HPSEVERITY by using *******
******** the Cramer-von Mises minimum distance estimator ***********/
proc severity data=testmixdist obj=cvmobj print=all plots=pp;
  loss y;
  dist logngpd burr logn gpd;

  * Cramer-von Mises estimator (minimizes the distance *
  * between parametric and nonparametric estimates) *
  cvmobj = _cdf_(y);
  cvmobj = (cvmobj -_edf_(y))**2;
run;
```
The OBJ= option in the PROC SEVERITY statement specifies that the objective function \( c_{v}\text{mobj} \) should be minimized. The programming statements compute the contribution of each observation in the input data set to the objective function \( c_{v}\text{mobj} \). The use of keyword functions _CDF_ and _EDF_ makes the program applicable to all the distributions.

Some of the key results prepared by PROC SEVERITY are shown in Output 23.4.1. The “Model Selection Table” indicates that all models converged. When you specify a custom objective function, the default selection criterion is the value of the custom objective function. The “All Fit Statistics Table” indicates that LOGNGPD is the best distribution according to all the statistics of fit. Comparing the fit statistics of Output 23.4.1 with those of Output 23.3.1 indicates that the use of the Cramér-von Mises estimator has resulted in smaller values for all the EDF-based statistics of fit for all the models, which is expected from a minimum distance estimator.

Example 23.5: Fitting a Scaled Tweedie Model with Regressors

The Tweedie distribution is often used in the insurance industry to explain the effect of independent variables (regressors) on the distribution of losses. PROC SEVERITY provides a predefined scaled Tweedie distribution (STWEEDIE) that enables you to model the regression effects on the scale parameter. The scale regression model has its own advantages such as the ability to easily account for inflation effects. This example illustrates how that model can be used to evaluate the effect of regressors on the mean of the Tweedie distribution, which is useful in problems such rate-making and pure premium modeling.

Assume a Tweedie process, whose mean $\mu$ is affected by $k$ regressors $x_j$, $j = 1, \ldots, k$ as follows:

$$
\mu = \mu_0 \exp \left( \sum_{j=1}^{k} \beta_j x_j \right)
$$

where $\mu_0$ represents the base value of the mean (you can think of $\mu_0$ as $\exp(\beta_0)$, where $\beta_0$ is the intercept). This model for the mean is identical to the popular generalized linear model for the mean with a logarithmic link function. More interestingly, it parallels the model used by PROC SEVERITY for the scale parameter $\theta$, which is as follows

$$
\theta = \theta_0 \exp \left( \sum_{j=1}^{k} \beta_j x_j \right)
$$

where $\theta_0$ represents the base value of the scale parameter. As described in the section “Tweedie Distributions” on page 1651, for the parameter range $p \in (1, 2)$, the mean of the Tweedie distribution is given by

$$
\mu = \theta \lambda^2 - p
$$

where $\lambda$ is the Poisson mean parameter of the scaled Tweedie distribution. This relationship enables you to use the scale regression model to infer the effect of regressors on the mean of the distribution.

Let the data set Work.Test_Sevtw contain a sample generated from a Tweedie distribution with dispersion parameter $\phi = 0.5$, index parameter $p = 1.75$, and the mean parameter that is affected by three regression variables x1, x2, and x3 as follows:

$$
\mu = 5 \exp(0.25 x1 - x2 + 3 x3)
$$

Thus, the population values of regression parameters are $\mu_0 = 5$, $\beta_1 = 0.25$, $\beta_2 = -1$, and $\beta_3 = 3$. You can find the code used to generate the sample in the PROC SEVERITY sample program sevex05.sas.

The following PROC SEVERITY step uses the sample in Work.Test_Sevtw data set to estimate the parameters of the scale regression model for the predefined scaled Tweedie distribution (STWEEDIE) with the dual quasi-Newton (QUANEW) optimization technique:

```sas
/*--- Fit the scale parameter version of the Tweedie distribution ---*/
proc severity data=test_sevtw outest=estw covout print=all plots=none;
  loss y;
  scalemodel x1-x3;
  dist stweedie;
  nloptions tech=quanew;
run;
```
The dual quasi-Newton technique is used because it requires only the first-order derivatives of the objective function, and it is harder to compute reasonably accurate estimates of the second-order derivatives of Tweedie distribution’s PDF with respect to the parameters.

Some of the key results prepared by PROC SEVERITY are shown in Output 23.5.1 and Output 23.5.2. The distribution information and the convergence results are shown in Output 23.5.1.

The final parameter estimates of the STWEEDIE regression model are shown in Output 23.5.2. The estimate that is reported for the parameter \( \Theta \) is the estimate of the base value \( \theta_0 \). The estimates of regression coefficients \( \beta_1, \beta_2, \) and \( \beta_3 \) are indicated by the rows of \( x_1, x_2, \) and \( x_3 \), respectively.

</tbody>
</table>

If your goal is to explain the effect of regressors on the scale parameter, then the output displayed in Output 23.5.2 is sufficient. But, if you want to compute the effect of regressors on the mean of the distribution,
Chapter 23: The SEVERITY Procedure

then some postprocessing needs to be done. Using the relationship between \( \mu \) and \( \theta \), \( \mu \) can be written in terms of the parameters of the STWEEDIE model as

\[
\mu = \theta_0 \exp \left( \sum_{j=1}^{k} \beta_j x_j \right) \frac{2 - p}{p - 1} \lambda \frac{\lambda}{p - 1}
\]

This shows that the parameters \( \beta_j \) are identical for the mean and the scale model, and the base value \( \mu_0 \) of the mean model is

\[
\mu_0 = \theta_0 \lambda \frac{2 - p}{p - 1}
\]

The estimate of \( \mu_0 \) and the standard error associated with it can be computed by using the property of the functions of maximum likelihood estimators (MLE). If \( g(\Omega) \) represents a totally differentiable function of parameters \( \Omega \), then the MLE of \( g \) has an asymptotic normal distribution with mean \( g(\hat{\Omega}) \) and covariance \( C = (\partial g/\partial \Omega) (\hat{\Omega}) (\partial g/\partial \Omega) \), where \( \hat{\Omega} \) is the MLE of \( \Omega \), \( \hat{\Sigma} \) is the estimate of covariance matrix of \( \Omega \), and \( \partial g \) is the gradient vector of \( g \) with respect to \( \Omega \) evaluated at \( \hat{\Omega} \). For \( \mu_0 \), the function is \( g(\Omega) = \theta_0 \lambda (2 - p)/(p - 1) \). The gradient vector is

\[
\partial g = \begin{pmatrix}
\frac{\partial g}{\partial \theta_0} & \frac{\partial g}{\partial \lambda} & \frac{\partial g}{\partial p} & \frac{\partial g}{\partial \beta_1} & \cdots & \frac{\partial g}{\partial \beta_k}
\end{pmatrix}
\]

\[
= \begin{pmatrix}
\mu_0 & \mu_0 & \mu_0 & \mu_0 & \cdots & \mu_0 \\
\theta_0 & \lambda & (p - 1)(2 - p) & 0 & \cdots & 0
\end{pmatrix}
\]

You can write a DATA step that implements these computations by using the parameter and covariance estimates prepared by PROC SEVERITY step. The DATA step program is available in the sample program `sevex05.sas`. The estimates of \( \mu_0 \) prepared by that program are shown in Output 23.5.3. These estimates and the estimates of \( \beta_j \) as shown in Output 23.5.2 are reasonably close (that is, within one or two standard errors) to the parameters of the population from which the sample in `Work.Test_Sevtw` data set was drawn.

**Output 23.5.3** Estimate of the Base Value Mu0 of the Mean Parameter

| Parameter | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----------|----------------|---------|------|-----|
| Mu0       | 4.47472  | 0.42271        | 10.5858 | 0    |     |

Another effect of using the scaled Tweedie distribution to model the regression effects is that the regressors also affect the variance \( V \) of the Tweedie distribution. The variance is related to the mean as \( V = \phi \mu^p \), where \( \phi \) is the dispersion parameter. Using the relationship between the parameters `TWEEDIE` and `STWEEDIE` distributions as described in the section “Tweedie Distributions” on page 1651, the regression model for the dispersion parameter is

\[
\log(\phi) = (2 - p) \log(\mu) - \log(\lambda(2 - p))
\]

\[
= ((2 - p) \log(\mu_0) - \log(\lambda(2 - p))) + (2 - p) \sum_{j=1}^{k} \beta_j x_j
\]
Subsequently, the regression model for the variance is
\[
\log(V) = 2 \log(\mu) - \log(\lambda(2 - p))
\]
\[
= (2 \log(\mu_0) - \log(\lambda(2 - p))) + 2 \sum_{j=1}^{k} \beta_j x_j
\]

In summary, PROC SEVERITY enables you to estimate regression effects on various parameters and statistics of the Tweedie model.

---

### Example 23.6: Fitting Distributions to Interval-Censored Data

In some applications, the data available for modeling might not be exact. A commonly encountered scenario is the use of grouped data from an external agency, which for several reasons, including privacy, does not provide information about individual loss events. The losses are grouped into disjoint bins, and you know only the range and number of values in each bin. Each group is essentially interval-censored, because you know that a loss magnitude is in certain interval, but you do not know the exact magnitude. This example illustrates how you can use PROC SEVERITY to model such data.

The following DATA step generates sample grouped data for dental insurance claims, which is taken from Klugman, Panjer, and Willmot (1998).

```sas
/* Grouped dental insurance claims data 
   (Klugman, Panjer, and Willmot, 1998) */
data gdental;
  input lowerbd upperbd count @@;
datalines;
  0 25 30 25 50 31 50 100 57 100 150 42 150 250 65 250 500 84
  500 1000 45 1000 1500 10 1500 2500 11 2500 4000 3
; run;
```

Often, when you do not know the nature of the data, it is recommended that you first explore the nature of the sample distribution by examining the nonparametric estimates of PDF and CDF. The following PROC SEVERITY step prepares the nonparametric estimates, but it does not fit any distribution because there is no DIST statement specified:

```sas
/* Prepare nonparametric estimates */
proc severity data=gdental print=all plots(histogram kernel)=all;
  loss / rc=lowerbd lc=upperbd;
  weight count;
run;
```

The LOSS statement specifies the left and right boundary of each group as the right-censoring and left-censoring limits, respectively. The variable count records the number of losses in each group and is specified in the WEIGHT statement. Note that there is no response or loss variable specified in the LOSS statement, which is allowed as long as each observation in the input data set is censored. The nonparametric estimates prepared by this step are shown in Output 23.6.1. The histogram, kernel density, and EDF plots all indicate
that the data is heavy-tailed. For interval-censored data, PROC SEVERITY uses Turnbull’s algorithm to compute the EDF estimates. The plot of Turnbull’s EDF estimates is shown to be linear between the endpoints of a censored group. The linear relationship is chosen for convenient visualization and ease of computation of EDF-based statistics, but you should note that theoretically the behavior of Turnbull’s EDF estimates is undefined within a group.

**Output 23.6.1** Nonparametric Distribution Estimates for Interval-Censored Data

With the PRINT=ALL option, PROC SEVERITY prints the summary of the Turnbull EDF estimation process as shown in **Output 23.6.2**. It indicates that the final EDF estimates have converged and are in fact maximum likelihood (ML) estimates. If they were not ML estimates, then you could have used the ENSUREMLE option to force the algorithm to search for ML estimates.

**Output 23.6.2** Turnbull EDF Estimation Summary for Interval-Censored Data

<table>

After exploring the nature of the data, you can now fit a set of heavy-tailed distributions to this data. The following PROC SEVERITY step fits all the predefined distributions to the data in Work.Gdental data set:

```latex
/* Fit all predefined distributions */
proc severity data=gdental print=all plots(histogram kernel)=all
   criterion=ad;
   loss / rc=lowerbd lc=upperbd;
   weight count;
   dist _predef_;
run;
```

Some of the key results prepared by PROC SEVERITY are shown in Output 23.6.3 through Output 23.6.4. According to the “Model Selection Table” in Output 23.6.3, all distribution models have converged. The “All Fit Statistics Table” in Output 23.6.3 indicates that the generalized Pareto distribution (GPD) has the best fit for data according to a majority of the likelihood-based statistics and that the Burr distribution (BURR) has the best fit according to all the EDF-based statistics.

**Output 23.6.3** Statistics of Fit for Interval-Censored Data

</tbody>
</table>
The P-P plots of Output 23.6.4 show that both GPD and BURR have a close fit between EDF and CDF estimates, although BURR has slightly better fit, which is also indicated by the EDF-based statistics. Given that BURR is a generalization of the GPD and that the plots do not offer strong evidence in support of the more complex distribution, GPD seems like a good choice for this data.
A finite mixture model is a stochastic model that postulates that the probability distribution of the data generation process is a mixture of a finite number of probability distributions. For example, when an insurance company analyzes loss data from multiple policies that are underwritten in different geographic regions, some regions might behave similarly, but the distribution that governs some regions might be different from the distribution that governs other regions. Further, it might not be known which regions behave similarly. Also, the larger amounts of losses might follow a different stochastic process from the stochastic process that governs the smaller amounts of losses. It helps to model all policies together in order to pool the data together and exploit any commonalities among the regions, and the use of a finite mixture model can help capture the differences in distributions across regions and ranges of loss amounts.

Formally, if \( f_i \) and \( F_i \) denote the PDF and CDF, respectively, of component distribution \( i \) and \( p_i \) represents the mixing probability that is associated with component \( i \), then the PDF and CDF of the finite mixture of \( K \) distribution components are

\[
\begin{align*}
    f(x; \Theta, p) &= \sum_{i=1}^{K} p_i f_i(x; \Theta_i) \\
    F(x; \Theta, p) &= \sum_{i=1}^{K} p_i F_i(x; \Theta_i)
\end{align*}
\]

where \( \Theta_i \) denotes the parameters of component distribution \( i \) and \( \Theta \) denotes the parameters of the mixture distribution, which is a union of all the \( \Theta_i \) parameters. \( p \) denotes the set of mixing probabilities. All mixing probabilities must add up to 1 (\( \sum_{i=1}^{K} p_i = 1 \)).

You can define the finite mixture of a specific number of components and specific distributions for each of the components by defining the FCMP functions for the PDF and CDF. However, in general, it is not possible to fit a scale regression model by using any finite mixture distribution unless you take special care to ensure...
that the mixture distribution has a scale parameter. This example provides a formulation of a two-component finite mixture model that has a scale parameter.

To start with, each component distribution must have either a scale parameter or a log-transformed scale parameter. Let \( \theta_1 \) and \( \theta_2 \) denote the scale parameters of the first and second components, respectively. Let \( p_1 = p \) be the mixing probability, which makes \( p_2 = 1 - p \) by using the constraint on \( p \). The PDF of the mixture of these two distributions can be written as

\[
f(x; \theta_1, \theta_2, p) = \frac{p}{\theta_1} f_1\left(\frac{x}{\theta_1}; \Phi_1\right) + \frac{1 - p}{\theta_2} f_2\left(\frac{x}{\theta_2}; \Phi_2\right)
\]

where \( \Phi_1 \) and \( \Phi_2 \) denote the sets of nonscale parameters of the first and second components, respectively, and \( \Phi \) denotes a union of \( \Phi_1 \) and \( \Phi_2 \). For the mixture to have the scale parameter \( \theta \), the PDF must be of the form

\[
f(x; \theta, \Phi', p) = \frac{1}{\theta} \left( p f_1\left(\frac{x}{\theta}; \Phi'_1\right) + (1 - p) f_2\left(\frac{x}{\theta}; \Phi'_2\right) \right)
\]

where \( \Phi', \Phi'_1, \) and \( \Phi'_2 \) denote the modified sets of nonscale parameters. One simple way to achieve this is to make \( \theta_1 = \theta_2 = \theta \) and \( \Phi' = \Phi \); that is, you simply equate the scale parameters of both components and keep the set of nonscale parameters unchanged. However, forcing the scale parameters to be equal in both components is restrictive, because the mixture cannot model potential differences in the scales of the two components. A better approach is to tie the scale parameters of the two components by a ratio such that \( \theta_1 = \theta \) and \( \theta_2 = \rho \theta \). If the ratio parameter \( \rho \) is estimated along with the other parameters, then the mixture distribution becomes flexible enough to model the variations across the scale parameters of individual components.

To summarize, the PDF and CDF are of the following form for the two-component mixture that has a scale parameter:

\[
f(x; \theta, p, \Phi, p) = \frac{1}{\theta} \left( p f_1\left(\frac{x}{\theta}; \Phi'_1\right) + (1 - p) f_2\left(\frac{x}{\theta}; \Phi'_2\right) \right)
\]

\[
F(x; \theta, p, \Phi, p) = p F_1\left(\frac{x}{\theta}; \Phi'_1\right) + (1 - p) F_2\left(\frac{x}{\theta}; \Phi'_2\right)
\]

This can be generalized to a mixture of \( K \) components by introducing the \( K - 1 \) ratio parameters \( \rho_i \) that relate the scale parameters of each of the \( K \) components to the scale parameter \( \theta \) of the mixture distribution as follows:

\[
\theta_1 = \theta \\
\theta_i = \rho_i \theta; \ i \in [2, K]
\]

In order to illustrate this approach, define a mixture of two lognormal distributions by using the following PDF function:

\[
f(x; \mu, \sigma_1, p_2, \rho_2, \sigma_2) = \frac{(1 - p_2)}{\sigma_1 \sqrt{2\pi}} \exp \left( \frac{-\left(\log(x) - \mu\right)^2}{2\sigma_1^2} \right) + \frac{p_2}{\sigma_2 \sqrt{2\pi}} \exp \left( \frac{-\left(\log(x) - \mu - \log(\rho_2)\right)^2}{2\sigma_2^2} \right)
\]

You can verify that \( \mu \) serves as the log of the scale parameter \( \theta (\mu = \log(\theta)) \). The following PROC FCMP steps encode this formulation in a distribution named SLOGNMIX2 for use with PROC SEVERITY:
Example 23.7: Defining a Finite Mixture Model That Has a Scale Parameter

```plaintext
/*- Define Mixture of 2 Lognormal Distributions with a Log-Scale Parameter -*/
proc fcmp library=sashelp.svrtdist outlib=work.sevexmpl.models;
function slognmix2_description() $128;
    return ("Mixture of two lognormals with a log-scale parameter Mu");
endsub;

function slognmix2_scaletransform() $8;
    return ("LOG");
endsub;

function slognmix2_pdf(x, Mu, Sigma1, p2, Rho2, Sigma2);
    Mu1 = Mu;
    Mu2 = Mu + log(Rho2);
    pdf1 = logn_pdf(x, Mu1, Sigma1);
    pdf2 = logn_pdf(x, Mu2, Sigma2);
    return ((1-p2)*pdf1 + p2*pdf2);
endsub;

function slognmix2_cdf(x, Mu, Sigma1, p2, Rho2, Sigma2);
    Mu1 = Mu;
    Mu2 = Mu + log(Rho2);
    cdf1 = logn_cdf(x, Mu1, Sigma1);
    cdf2 = logn_cdf(x, Mu2, Sigma2);
    return ((1-p2)*cdf1 + p2*cdf2);
endsub;

subroutine slognmix2_parminit(dim, x[*], nx[*], F[*], Ftype, Mu, Sigma1, p2, Rho2, Sigma2);
    outargs Mu, Sigma1, p2, Rho2, Sigma2;
    array m[1] / nosymbols;
    p2 = 0.5;
    Rho2 = 0.5;
    median = svrtutil_percentile(0.5, dim, x, F, Ftype);
    Mu = log(2*median/1.5);
    call svrtutil_rawmoments(dim, x, nx, 1, m);
    lm1 = log(m[1]);
    /* Search Rho2 that makes log(sample mean) > Mu */
do while (lm1 <= Mu and Rho2 < 1);
    Rho2 = Rho2 + 0.01;
    Mu = log(2*median/(1+Rho2));
end;
if (Rho2 >= 1) then
    /* If Mu cannot be decreased enough to make it less
    than log(sample mean), then revert to Rho2=0.5.
    That will set Sigma1 and possibly Sigma2 to missing.
    PROC SEVERITY replaces missing initial values with 0.001. */
    Mu = log(2*median/1.5);
    Sigma1 = sqrt(2.0*(log(m[1])-Mu));
    Sigma2 = sqrt(2.0*(log(m[1])-Mu*log(Rho2)));
endsub;
```
As shown in previous examples, an important aspect of defining a distribution for use with PROC SEVERITY is the definition of the PARMINIT subroutine that initializes the parameters. For mixture distributions, in general, the parameter initialization is a nontrivial task. For a two-component mixture, some simplifying assumptions make the problem easier to handle. For the initialization of SLOGNMIX2, the initial values of \( p_2 \) and \( \rho_2 \) are fixed at 0.5, and the following two simplifying assumptions are made:

- The median of the mixture is the average of the medians of the two components:

\[
F^{-1}(0.5) = \left( \exp(\mu_1) + \exp(\mu_2) \right) / 2 = \exp(\mu)(1 + \rho_2)/2
\]

Solution of this equation yields the value of \( \mu \) in terms of \( \rho_2 \) and the sample median.

- Each component has the same mean, which implies the following:

\[
\exp(\mu + \sigma_2^2/2) = \exp(\mu + \log(\rho_2) + \sigma_2^2/2)
\]

If \( X_i \) represents the random variable of component distribution \( i \) and \( X \) represents the random variable of the mixture distribution, then the following equation holds for the raw moment of any order \( k \):

\[
E[X^k] = \sum_{i=1}^{K} p_i E[X_i^k]
\]

This, in conjunction with the assumption on component means, leads to the equations

\[
\log(m_1) = \mu + \frac{\sigma_1^2}{2} \quad \quad \log(m_1) = \mu + \log(\rho_2) + \frac{\sigma_2^2}{2}
\]
where \( m_1 \) denotes the first raw moment of the sample. Solving these equations leads to the following values of \( \sigma_1 \) and \( \sigma_2 \):

\[
\sigma_1^2 = 2(\log(m_1) - \mu) \quad \quad \sigma_2^2 = 2(\log(m_1) - \mu - \log(\rho_2))
\]

Note that \( \sigma_1 \) has a valid value only if \( \log(m_1) > \mu \). Among the many possible methods of ensuring this condition, the SLOGNMIX2_PARMINIT subroutine uses the method of doing a linear search over \( \rho_2 \).

Even when the preceding assumptions are not true for a given problem, they produce reasonable initial values to help guide the nonlinear optimizer to an acceptable optimum if the mixture of two lognormal distributions is indeed a good fit for your input data. This is illustrated by the results of the following steps that fit the SLOGNMIX2 distribution to simulated data, which have different means for the two components (12.18 and 22.76, respectively), and the median of the sample (15.94) is not equal to the average of the medians of the two components (7.39 and 20.09, respectively):

```plaintext
/*-------- Simulate a lognormal mixture sample ----------*/
data testlognmix(keep=y);
  call streaminit(12345);
  Mu1 = 2;
  Sigma1 = 1;
  i = 0;
  do j=1 to 2000;
    y = exp(Mu1) * rand('LOGNORMAL')**Sigma1;
    output;
  end;
  Mu2 = 3;
  Sigma2 = 0.5;
  do j=1 to 3000;
    y = exp(Mu2) * rand('LOGNORMAL')**Sigma2;
    output;
  end;
run;

/*-- Fit and compare scale regression models with 2-component --*/
/*-- lognormal mixture and the standard lognormal distribution --*/
options cmplib=(work.sevexmpl);
proc severity data=testlognmix print=all plots(histogram kernel)=all;
  loss y;
  dist slognmix2 logn;
run;
```

The comparison of the fit statistics of SLOGNMIX2 and LOGN, as shown in Output 23.7.1, confirms that the two-component mixture is certainly a better fit to these data than the single lognormal distribution.
Output 23.7.1 Comparison of Fitting One versus Two Lognormal Components to Mixture Data

**Parameter Estimates**

| Parameter | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----------|----------------|---------|-------|
| Mu        | 3.00922  | 0.01554        | 193.68  | <.0001|
| Sigma1    | 0.49516  | 0.01451        | 34.13   | <.0001|
| P2        | 0.40619  | 0.02600        | 15.62   | <.0001|
| Rho2      | 0.37212  | 0.02038        | 18.26   | <.0001|
| Sigma2    | 1.00019  | 0.02124        | 47.09   | <.0001|

By using the relationship that $\mu_2 = \mu + \log(\rho_2)$, you can see that the final parameter estimates are indeed close to the true parameter values that were used to simulate the input sample.

**Example 23.8: Predicting Mean and Value-at-Risk by Using Scoring Functions**

If you work in the risk management department of an insurance company or a bank, then one of your primary applications of severity loss distribution models is to predict the value-at-risk (VaR), such that the probability of experiencing a loss value greater than the VaR is very low. The probability level at which VaR is measured is prescribed by industry regulations such as Basel III and Solvency II. The VaR level is usually specified in terms of $(1 - \alpha)$, where $\alpha \in (0, 1)$ is the probability that a loss value exceeds the VaR. Typical VaR levels are 0.95, 0.975, and 0.995.

In addition to predicting VaR, which is regarded as an estimate of the worst-case loss, businesses are often interested in predicting the average loss by estimating either the mean or median of the distribution.

The estimation of the mean and VaR combined with the scale regression model is very potent tool for analyzing worst-case and average losses for various scenarios. For example, if the regressors that are used in a scale regression model represent some key macroeconomic and operational indicators, which are widely referred to as key risk indicators (KRIs), then you can analyze the VaR and mean loss estimates over various values for the KRIs to get a more comprehensive picture of the risk profile of your organization across various market and internal conditions.

This example illustrates the use of scoring functions to simplify the process of predicting the mean and VaR of scale regression models.
First, the following PROC FCMP steps define the functions to compute the mean for each of the 10 predefined distributions that are available in the Sashelp.Svrtdist library:

```plaintext
/*--------- Define distribution functions that compute the mean ----------*/
proc fcmp library=sashelp.svrtdist outlib=work.means.scalemod;
  function BURR_MEAN(x, Theta, Alpha, Gamma);
    if not(Alpha * Gamma > 1) then
      return (.); /* first moment does not exist */
    return (Theta*gamma(1 + 1/Gamma)*gamma(Alpha - 1/Gamma)/gamma(Alpha));
  endsub;
  function EXP_MEAN(x, Theta);
    return (Theta);
  endsub;
  function GAMMA_MEAN(x, Theta, Alpha);
    return (Theta*Alpha);
  endsub;
  function GPD_MEAN(x, Theta, Xi);
    if not(Xi < 1) then
      return (.); /* first moment does not exist */
    return (Theta/(1 - Xi));
  endsub;
  function IGAUSS_MEAN(x, Theta, Alpha);
    return (Theta);
  endsub;
  function LOGN_MEAN(x, Mu, Sigma);
    return (exp(Mu + Sigma*Sigma/2.0));
  endsub;
  function PARETO_MEAN(x, Theta, Alpha);
    if not(Alpha > 1) then
      return (.); /* first moment does not exist */
    return (Theta/(Alpha - 1));
  endsub;
  function STWEEDIE_MEAN(x, Theta, Lambda, P);
    return (Theta* Lambda * (2 - P) / (P - 1));
  endsub;
  function TWEEDIE_MEAN(x, P, Mu, Phi);
    return (Mu);
  endsub;
  function WEIBULL_MEAN(x, Theta, Tau);
    return (Theta*gamma(1 + 1/Tau));
  endsub;
quit;
```

The following statements include the Work.Means library in the CMPLIB= system option and submit a PROC SEVERITY step to estimate the scale regression models for various distributions by using a lognormal sample in the Work.Test_sev8 data set:

```plaintext
/*----- Fit all distributions and generate scoring functions ------*/
options cmplib=work.means;
proc severity data=test_sev8 outest=est print=all plots=none;
  loss y;
  scalemodel x1-x5;
  dist _predefined_ stweedie;
  outscorelib outlib=scorefuncs commonpackage;
run;
```
The SAS statements that simulate the sample in the Work.Test_sev8 data set are available in the PROC SEVERITY sample program sevex08.sas. The OUTLIB= option in the OUTSCORELIB statement requests that the scoring functions be written to the Work.Scorefuncs library, and the COMMONPACKAGE option in the OUTSCORELIB statement requests that all the functions be written to the same package. Upon completion, PROC SEVERITY sets the CMPLIB system option to the following value:

(work.means sashelp.svrtdist work.scorefuncs)

The “All Fit Statistics” table in Output 23.8.1 shows that the lognormal distribution’s scale model is the best and the inverse Gaussian’s scale model is a close second according to the likelihood-based statistics.

Output 23.8.1  Comparison of Fitted Scale Models for Mean and VaR Illustration

Note: The asterisk (*) marks the best model according to each column’s criterion.
You can examine the scoring functions that are written to the Work.Scorefuncs library by using the FCMP Function Editor that is available in the Display Manager session of Base SAS when you select Solutions→Analysis from the main menu. For example, PROC SEVERITY automatically generates and submits the following PROC FCMP statements to define the scoring functions ‘SEV_MEAN_LOGN’ and ‘SEV_QUANTILE_IGAUSS’:

```sas
proc fcmp library=(work.means sashelp.svrtdist) outlib=work.scorefuncs.sevfit;
function SEV_MEAN_LOGN(y, x{*});
  _logscale_=0;
  _logscale_ = _logscale_ + ( 7.6472278930350E-01 * x{1});
  _logscale_ = _logscale_ + ( 2.99209540369860E+00 * x{2});
  _logscale_ = _logscale_ + (-1.0078916253430E+00 * x{3});
  _logscale_ = _logscale_ + ( 2.5883602184890E-01 * x{4});
  _logscale_ = _logscale_ + ( 5.00927479793970E+00 * x{5});
  _logscale_ = _logscale_ + ( 9.95078833050690E-01);
  return (LOGN_MEAN(y, _logscale_, 2.31592981635590E-01));
endsub;
function SEV_QUANTILE_IGAUSS(y, x{*});
  _logscale_=0;
  _logscale_ = _logscale_ + ( 7.64581738373520E-01 * x{1});
  _logscale_ = _logscale_ + ( 2.99159055015310E+00 * x{2});
  _logscale_ = _logscale_ + (-1.00793496641510E+00 * x{3});
  _logscale_ = _logscale_ + ( 2.58870460543840E-01 * x{4});
  _logscale_ = _logscale_ + ( 5.00996884646730E+00 * x{5});
  _scale_ = 2.77854870591020E+00 * exp(_logscale_);
  return (IGAUSS_QUANTILE(y, _scale_, 1.81511227238720E+01));
endsub;
quit;
```

An important point to note is that the dist_MEAN distribution functions are not available in the original definition of any of the distributions in the Sashelp.Svrtdist library. PROC SEVERITY detects the availability of those functions in the Work.Means library that is included in the value of the CMPLIB= system option just before submitting the PROC SEVERITY step. Each dist_MEAN distribution function has a signature that matches the signature of a distribution function of the respective distribution, so PROC SEVERITY creates the corresponding scoring functions. Specifying the COMMONPACKAGE option in the OUTSCORELIB statement causes the name of the scoring function to take the form SEV_MEAN_dist. You can define any distribution function that has the desired signature to compute an estimate of your choice, include its library in the CMPLIB= system option, and then specify the OUTSCORELIB statement to generate the corresponding scoring functions.

To illustrate the use of scoring functions, let Work.Reginput contain the scoring data, where the values of regressors in each observation define one scenario. Scoring functions make it very easy to compute the mean and VaR of each distribution’s scale model for each of the scenarios, as the following steps illustrate for the lognormal and inverse Gaussian distributions:

```sas
/*--- Set VaR level ---*/
%let varLevel=0.975;

/*--- Compute scores (mean and var) for the ---
--- scoring data by using the scoring functions ---*/
data scores;
  array x{*} x1-x5;
  set reginput;
```
igauss_mean = sev_mean_igauss(., x);
igauss_var = sev_quantile_igauss(&varLevel, x);
logn_mean = sev_mean_logn(., x);
logn_var = sev_quantile_logn(&varLevel, x);
run;

The preceding steps use a VaR level of 97.5%.

The following DATA step accomplishes the same task by reading the parameter estimates that were written to the Work.Est data set by the previous PROC SEVERITY step:

```sas
/*--- Compute scores (mean and var) for the ---
   --- scoring data by using the OUTEST= data set ---*/
data scoresWithOutest(keep=x1-x5 igauss_mean igauss_var logn_mean logn_var);
  array _x_{*} x1-x5;
  array _xparmIgauss_{5} _temporary_;
  array _xparmLogn_{5} _temporary_;  
  retain _Theta0_ Alpha0;
  retain _Mu0_ Sigma0;
  *--- read parameter estimates for igauss and logn models ---*;
  if (_n_ = 1) then do;
    set est(where=(upcase(_MODEL_)= IgAuss' and _TYPE_='EST'));
    _Theta0_ = Theta; Alpha0 = Alpha;
    do _i_=1 to dim(_x_);
      if (_x_(_i_) = .R) then _xparmIgauss_(_i_) = 0;
      else _xparmIgauss_(_i_) = _x_(_i_);
    end;
    set est(where=(upcase(_MODEL_)= LOGN' and _TYPE_='EST'));
    _Mu0_ = Mu; Sigma0 = Sigma;
    do _i_=1 to dim(_x_);
      if (_x_(_i_) = .R) then _xparmLogn_(_i_) = 0;
      else _xparmLogn_(_i_) = _x_(_i_);
    end;
  end;
  set reginput;
  *--- predict mean and VaR for inverse Gaussian ---*;
  * first compute X'*beta for inverse Gaussian *;
  _xbeta_ = 0.0;
  do _i_ = 1 to dim(_x_);
    _xbeta_ = _xbeta_ + _xparmIgauss_(_i_) * _x_(_i_);
  end;
  * now compute scale for inverse Gaussian *;
  _SCALE_ = _Theta0_ * exp(_xbeta_);
  igauss_mean = igauss_mean(., _SCALE_, Alpha0);
  igauss_var = igauss_quantile(&varLevel, _SCALE_, Alpha0);
  *--- predict mean and VaR for lognormal ---*;
  * first compute X'*beta for lognormal*;
  _xbeta_ = 0.0;
  do _i_ = 1 to dim(_x_);
    _xbeta_ = _xbeta_ + _xparmLogn_(_i_) * _x_(_i_);
  end;
  * now compute Mu=log(scale) for lognormal *;
  _MU_ = _Mu0_ + _xbeta_;  
  logn_mean = logn_mean(., _MU_, Sigma0);
  logn_var = logn_quantile(&varLevel, _MU_, Sigma0);
run;
```
The “Values Comparison Summary” table in Output 23.8.2 shows that the difference between the estimates that are produced by both methods is within the acceptable machine precision. However, the comparison of the DATA step complexity of each method clearly shows that the method that uses the scoring functions is much easier because it saves a lot of programming effort. Further, new distribution functions, such as the dist_MEAN functions that are illustrated here, are automatically discovered and converted to scoring functions by PROC SEVERITY. That enables you to focus your efforts on writing the distribution function that computes your desired score, which needs to be done only once. Then, you can create and use the corresponding scoring functions multiple times with much less effort.

Overview: SIMILARITY Procedure

The SIMILARITY procedure computes similarity measures associated with time-stamped data, time series, and other sequentially ordered numeric data. PROC SIMILARITY computes similarity measures for time-stamped transactional data (transactions) with respect to time by accumulating the data into a time series format, and it computes similarity measures for sequentially ordered numeric data (sequences) by respecting the ordering of the data.

Given two ordered numeric sequences (input and target), a similarity measure is a metric that measures the distance between the input and target sequences while taking into account the ordering of the data. The SIMILARITY procedure computes similarity measures between an input sequence and a target sequence, in addition to similarity measures that “slide” the target sequence with respect to the input sequence. The “slides” can be by observation index (sliding-sequence similarity measures) or by seasonal index (seasonal-sliding-sequence similarity measures).

In order to compare the raw input and the raw target time-stamped data, the raw data must be accumulated to a time series format. After the input and target time series are formed, the two accumulated time series can be compared as two ordered numeric sequences.

For raw time-stamped data, after the transactional data are accumulated to form time series and any missing values are interpreted, each accumulated time series can be functionally transformed, if desired. Transformations are useful when you want to stabilize the time series before computing the similarity measures. Transformations performed by the SIMILARITY procedure include the following:

- log (LOG)
- square-root (SQRT)
- logistic (LOGISTIC)
- Box-Cox (BOXCOX)
- user-defined transformations

Each time series can be transformed further by using simple differencing or seasonal differencing or both. Additional time series transformations can be performed by using various time series transformation and analysis techniques provided by this procedure or other SAS/ETS procedures.

After optionally transforming each time series, the accumulated and transformed time series can be stored in an output data set (OUT= data set).
After optional accumulation and transformation, each of these time series are the “working series,” which can now be analyzed as sequences of numeric data. Each of these sequences can be a target sequence, an input sequence, or both a target and an input sequence. Throughout the remainder of this chapter, the term “original sequence” applies to both the original input and target sequence. The term “working sequence” applies to a version of both the original input and target sequence under investigation.

Each original sequence can be normalized prior to similarity analysis. Normalizations are useful when you want to compare the “shape” or “profile” of the time series. Normalizations performed by the SIMILARITY procedure include the following:

- standard (STANDARD)
- absolute (ABSOLUTE)
- user-defined normalizations

After each original sequence is optionally normalized, each working input sequence can be scaled to the target sequence prior to similarity analysis. Scaling is useful when you want to compare the input sequence to the target sequence while discounting the variation of the target sequence. Input sequence scaling performed by the SIMILARITY procedure include the following:

- standard (STANDARD)
- absolute (ABSOLUTE)
- user-defined scaling

After the working input sequence is optionally scaled to the target sequence, similarity measures can be computed. Similarity measures computed by the SIMILARITY procedure include:

- squared deviation (SQRDEV)
- absolute deviation (ABSDEV)
- mean square deviation (MSQRDEV)
- mean absolute deviation (MABSDEV)
- user-defined similarity measures

In computing the similarity measure between two time series, tasks are needed for transforming time series, normalizing sequences, scaling sequences, and computing metrics or measures. The SIMILARITY procedure provides built-in routines to perform these tasks. The SIMILARITY procedure also enables you to extend the procedure with user-defined routines.

All results of the similarity analysis can be stored in output data sets, printed, or graphed using the Output Delivery System (ODS).

The SIMILARITY procedure can process large amounts of time-stamped transactional data, time series, or sequential data. Therefore, the analysis results are useful for large-scale time series analysis, analogous time series forecasting, new product forecasting, or time series (temporal) data mining.
The SAS/ETS EXPAND procedure can be used for frequency conversion and transformations of time series. The TIMESERIES procedure can be used for large-scale time series analysis. The SAS/STAT DISTANCE procedure can be used to compute various measures of distance, dissimilarity, or similarity between observations (rows) of a SAS data set.

---

### Getting Started: SIMILARITY Procedure

This section outlines the use of the SIMILARITY procedure and gives a cursory description of some of the analysis techniques that can be performed on time-stamped transactional data, time series, or sequentially ordered numeric data.

Given an input data set that contains numerous transaction variables recorded over time at no specific frequency, the SIMILARITY procedure can form equally spaced input and target time series as follows:

```sas
PROC SIMILARITY DATA=<input-data-set>
   OUT=<output-data-set>
   OUTSUM=<summary-data-set>
   ID <time-ID-variable> INTERVAL=<frequency>
      ACCUMULATE=<statistic>
   INPUT <input-time-stamp-variables>;
   TARGET <target-time-stamp-variables>;
RUN;
```

The SIMILARITY procedure forms time series from the input time-stamped transactional data. It can provide results in output data sets or in other output formats using the Output Delivery System (ODS). The examples in this section are more fully illustrated in the section “Examples: SIMILARITY Procedure” on page 1807.

Time-stamped transactional data are often recorded at no fixed interval. Analysts often want to use time series analysis techniques that require fixed-time intervals. Therefore, the transactional data must be accumulated to form a fixed-interval time series.

Suppose that a bank wants to analyze the transactions that are associated with each of its customers over time. Further, suppose that the data set WORK.TRANSACTIONS contains three variables that are related to the customer transactions (CUSTOMER, DATE, and WITHDRAWAL) and one variable that contains an example fraudulent behavior (FRAUD).

The following statements illustrate how to use the SIMILARITY procedure to accumulate time-stamped transactional data to form a daily time series based on the accumulated daily totals of each type of transaction (WITHDRAWALS and FRAUD):

```sas
proc similarity data=transactions out=timedata;
   by customer;
   id date interval=day accumulate=total;
   input withdrawals;
   target fraud;
run;
```

The OUT=TIMEDATA option specifies that the resulting time series data for each customer are to be stored in the data set WORK.TIMEDATA. The INTERVAL=DAY option specifies that the transactions are to be
accumulated on a daily basis. The ACCUMULATE=TOTAL option specifies that the sum of the transactions are to be accumulated. After the transactional data are accumulated into a time series format, the time series data can be normalized so that the “shape” or “profile” is analyzed.

For example, the following statements build on the previous statements and demonstrate normalization of the accumulated time series:

```plaintext
proc similarity data=transactions out=timedata;
   by customer;
   id date interval=day accumulate=total;
   input withdrawals / NORMALIZE=STANDARD;
   target fraud / NORMALIZE=STANDARD;
run;
```

The NORMALIZE=STANDARD option specifies that each accumulated time series observation is normalized by subtracting the mean and then dividing by the standard deviation of the accumulated time series. The WORK.TIMEDATA data set now contains the accumulated and normalized time series data for each customer.

After the transactional data are accumulated into a time series format and normalized to a mean of zero and standard deviation of one, similarity analysis can be performed on the accumulated and normalized time series.

For example, the following statements build on the previous statements and demonstrate similarity analysis of the accumulated and normalized time series:

```plaintext
proc similarity data=transactions out=timedata OUTSUM=SUMMARY;
   by customer;
   id date interval=day accumulate=total;
   input withdrawals / normalize=standard;
   target fraud / normalize=standard MEASURE=MABSDEV;
run;
```

The MEASURE=MABSDEV option specifies the accumulated and normalized time series data that are associated with the variables WITHDRAWALS and FRAUD are to be compared by using mean absolute deviation. The OUTSUM=SUMMARY option specifies that the similarity analysis summary for each customer is to be stored in the data set WORK.SUMMARY.
## Syntax: SIMILARITY Procedure

The following statements are used with the SIMILARITY procedure.

```
PROC SIMILARITY options;
    BY variables;
    ID variable INTERVAL= interval options;
    FCMPOPT options;
    INPUT variable-list / options;
    TARGET variable-list / options;
```

## Functional Summary

The statements and options that control the SIMILARITY procedure are summarized in the following table.

PROC SIMILARITY Statement

PROC SIMILARITY options ;

The following options can be used in the PROC SIMILARITY statement.

**DATA=SAS-data-set**

names the SAS data set that contains the time series, transactional, or sequence input data for the procedure. If the DATA= option is not specified, the most recently created SAS data set is used.

**ORDER=order-option**

specifies the order in which the variables listed in the INPUT and TARGET statements are to be processed. This ordering affects the OUTSEQUENCE=, OUTPATH=, OUTMEASURE=, and OUTSUM= data sets, in addition to the printed and graphical output. The SORTNAMES option also affects the ordering of the analysis. You must specify one of the following order-options:

- **INPUT** specifies that each INPUT variable be processed and then the TARGET variables be processed. The results are stored and printed based only on the INPUT variables.
- **INPUTTARGET** specifies that each INPUT variable be processed and then the TARGET variables be processed. The results are stored and printed based on both the INPUT and TARGET variables. This is the default.
- **TARGET** specifies that each TARGET variable be processed and then the INPUT variables be processed. The results are stored and printed based only on the TARGET variables.
- **TARGETINPUT** specifies that each TARGET variable be processed and then the INPUT variables be processed. The results are stored and printed based on both the TARGET and INPUT variables.

**OUT=SAS-data-set**

names the output data set to contain the time series variables specified in the subsequent INPUT and TARGET statements. If an ID variable is specified in the ID statement, it is also included in the OUT= data set. The values are accumulated based on the ID statement INTERVAL= option or the ACCUMULATE= options or both. The values are transformed based on the INPUT or TARGET statement TRANSFORM=, DIF=, and SDIF= options in this order. The OUT= data set is particularly useful when you want to further analyze, model, or forecast the resulting time series with other SAS/ETS procedures.

**OUTMEASURE=SAS-data-set**

names the output data set to contain the detailed similarity measures by time ID value. The form of the OUTMEASURE= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

**OUTPATH=SAS-data-set**

names the output data set to contain the path used to compute the similarity measures for each slide and warp. The form of the OUTPATH= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options. If a user-defined similarity measure is specified, the path cannot be determined; therefore, the OUTPATH= data set does not contain information related to this measure.
OUTSEQUENCE=SAS-data-set
names the output data set to contain the sequences used to compute the similarity measures for each slide and warp. The form of the OUTSEQUENCE= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

OUTSUM=SAS-data-set
names the output data set to contain the similarity measure summary. The OUTSUM= data set is particularly useful when analyzing large numbers of series and only the summary of the results are needed. The form of the OUTSUM= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

PLOTS=option
PLOTS=( options ... )
specifies the graphical output desired. To specify multiple options, separate them by spaces and enclose the group in parentheses. By default, the SIMILARITY procedure produces no graphical output. The following graphical options are available:

- COSTS plots graphics for time warp costs.
- DISTANCES plots graphics for similarity absolute and relative distances (OUTPATH= data set).
- INPUTS plots graphics for input variable time series (OUT= data set).
- MAPS plots graphics for time warp maps (OUTPATH= data set).
- MEASURES plots graphics for similarity measures (OUTMEASURE= data set).
- NORMALIZED plots graphics for both the input and target variable normalized sequence. These plots are displayed only when the INPUT or TARGET statement NORMALIZE= option is specified.
- PATHS plots time warp paths graphics (OUTPATH= data set).
- SCALED plots graphics for both the input variable scaled sequence. These plots are displayed only when the INPUT statement SCALE= option is specified.
- SEQUENCES plots graphics for both the input and target variable sequence (OUTSEQUENCE= data set).
- TARGETS plots graphics for the target variable time series (OUT= data set).
- WARPS plots graphics for time warps (OUTPATH= data set).
- ALL is the same as PLOTS=(INPUTS TARGETS SEQUENCES NORMALIZED SCALED DISTANCES PATHS MAPS WARPS COST MEASURES).

PRINT=option
PRINT=(options ... )
specifies the printed output desired. To specify multiple options, separate them by spaces and enclose the group in parentheses. By default, the SIMILARITY procedure produces no printed output. The following printing options are available:

- DESCSTATS prints the descriptive statistics for the working time series.
- PATHS prints the path statistics table. If a user-defined similarity measure is specified, the path cannot be determined; therefore, the PRINT=PATHS table is not printed for this measure.
Chapter 24: The SIMILARITY Procedure

COSTS prints the cost statistics table.
WARPS prints the warp summary table.
SLIDES prints the slides summary table.
SUMMARY prints the similarity measure summary table.
ALL is the same as PRINT=(DESCSTATS PATHS COSTS WARPS SLIDES SUMMARY).

PRINTDETAILS
specifies that the output requested with the PRINT= option be printed in greater detail.

SEASONALITY=integer
specifies the length of the seasonal cycle where integer ranges from one to 10,000. For example, SEASONALITY=3 means that every group of three time periods forms a seasonal cycle. By default, the length of the seasonal cycle is 1 (no seasonality) or the length implied by the INTERVAL= option specified in the ID statement. For example, INTERVAL=MONTH implies that the length of the seasonal cycle is 12.

SORTNAMES
specifies that the variables specified in the INPUT and TARGET statements be processed in alphabetical order of the variable names. By default, the SIMILARITY procedure processes the variables in the order in which they are listed. The ORDER= option also affects the ordering in which the analysis is performed.

BY Statement

A BY statement can be used with PROC SIMILARITY to obtain separate dummy variable definitions for groups of observations defined by the BY variables.

When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the option NOTSORTED or DESCENDING in the BY statement for the SIMILARITY procedure. The NOTSORTED option does not mean that the data are unsorted, but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY-group processing, see SAS Language Reference: Concepts. For more information about the DATASETS procedure, see the discussion in the Base SAS Procedures Guide.
FCMPOPT Statement

FCMPOPT options ;

The FCMPOPT statement specifies the following *options* that are related to user-defined functions and subroutines:

QUICK=ON | OFF
specifies whether the nonfatal errors and warnings that are generated by the user-defined SAS language functions and subroutines are printed to the log. Nonfatal errors are usually associated with operations with missing values. The default is QUIET=ON.

TRACE=ON | OFF
specifies whether the user-defined SAS language functions and subroutines tracings are printed to the log. Tracings are the results of every operation executed. This option is generally used for debugging. The default is TRACE=OFF.

ID Statement

ID variable INTERVAL= interval options ;

The ID statement names a numeric variable that identifies observations in the input and output data sets. The ID variable’s values are assumed to be SAS date, time, or datetime values. In addition, the ID statement specifies the (desired) frequency associated with the time series. The ID statement options also specify how the observations are accumulated and how the time ID values are aligned to form the time series. The options specified affect all variables listed in subsequent INPUT and TARGET statements. If an ID statement is specified, the INTERVAL= option must also be specified. The other ID statement options are optional. If an ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID.

The following options can be used with the ID statement:

ACCUMULATE=option
specifies how the data set observations are accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option. The ID variable contains the time ID values. Each time ID variable value corresponds to a specific time period. The accumulated values form the time series, which is used in subsequent analysis.

The ACCUMULATE= option is particularly useful when there are zero or more than one input observations that coincide with a particular time period (for example, time-stamped transactional data). The EXPAND procedure offers additional frequency conversions and transformations that can also be useful in creating a time series.

The following options determine how the observations are accumulated within each time period based on the ID variable and the frequency specified by the INTERVAL= option:

NONE No accumulation occurs; the ID variable values must be equally spaced with respect to the frequency. This is the default option.

TOTAL Observations are accumulated based on the total sum of their values.
### Chapter 24: The SIMILARITY Procedure

#### ACCUMULATE= Option

The ACCUMULATE= option specifies how observations are accumulated. The available options are:

- **AVERAGE | AVG** Observations are accumulated based on the average of their values.
- **MINIMUM | MIN** Observations are accumulated based on the minimum of their values.
- **MEDIAN | MED** Observations are accumulated based on the median of their values.
- **MAXIMUM | MAX** Observations are accumulated based on the maximum of their values.
- **N** Observations are accumulated based on the number of nonmissing observations.
- **NMISS** Observations are accumulated based on the number of missing observations.
- **NOBS** Observations are accumulated based on the number of observations.
- **FIRST** Observations are accumulated based on the first of their values.
- **LAST** Observations are accumulated based on the last of their values.
- **STDDEV | STD** Observations are accumulated based on the standard deviation of their values.
- **CSS** Observations are accumulated based on the corrected sum of squares of their values.
- **USS** Observations are accumulated based on the uncorrected sum of squares of their values.

If the ACCUMULATE= option is specified, the SETMISSING= option is useful for specifying how accumulated missing values are treated. If missing values should be interpreted as zero, then SETMISSING=0 should be used. The section “Details: SIMILARITY Procedure” on page 1785 describes accumulation in greater detail.

#### ALIGN= Option

The ALIGN= option controls the alignment of SAS dates that are used to identify output observations. The ALIGN= option accepts the following values: **BEGINNING | BEG | B, MIDDLE | MID | M, and ENDING | END | E. ALIGN=BEGINNING is the default.**

#### END= Option

The END= option specifies a SAS date, datetime, or time value that represents the end of the data. If the last time ID variable value is less than the END= value, the series is extended with missing values. If the last time ID variable value is greater than the END= value, the series is truncated. For example, END="&sysdate"D uses the automatic macro variable SYSDATE to extend or truncate the series to the current date. The START= and END= options can be used to ensure that data that are associated within each BY group contain the same number of observations.

#### FORMAT= Option

The FORMAT= option specifies the SAS format for the time ID values. If the FORMAT= option is not specified, the default format is implied by the INTERVAL= option. For example, FORMAT=DATE9. specifies that the DATE9. SAS format be used. Notice that the terminating “.” is required when specifying a SAS format.
**INTERVAL**= *interval*

specifies the frequency of the accumulated time series. For example, if the input data set consists of quarterly observations, then **INTERVAL=QTR** should be used. If the **SEASONALITY**= option is not specified, the length of the seasonal cycle is implied from the **INTERVAL**= option. For example, **INTERVAL=QTR** implies a seasonal cycle of length 4. If the **ACCUMULATE**= option is also specified, the **INTERVAL**= option determines the time periods for the accumulation of observations.

**NOTSORTED**

specifies that the time ID values are not in sorted order. The SIMILARITY procedure sorts the data with respect to the time ID prior to analysis if the **NOTSORTED** option is specified.

**SETMISSING**=option | number

specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series. If a number is specified, missing values are set to that number. If a missing value indicates an unknown value, the **SETMISSING**= option should not be used. If a missing value indicates no value, then **SETMISSING=0** should be used. You typically use **SETMISSING=0** for transactional data, because no recorded data usually implies no activity. The following options can also be used to determine how missing values are assigned:

- **MISSING**: Missing values are set to missing. This is the default option.
- **AVERAGE | AVG**: Missing values are set to the accumulated average value.
- **MINIMUM | MIN**: Missing values are set to the accumulated minimum value.
- **MEDIAN | MED**: Missing values are set to the accumulated median value.
- **MAXIMUM | MAX**: Missing values are set to the accumulated maximum value.
- **FIRST**: Missing values are set to the accumulated first nonmissing value.
- **LAST**: Missing values are set to the accumulated last nonmissing value.
- **PREVIOUS | PREV**: Missing values are set to the previous period’s accumulated nonmissing value. Missing values at the beginning of the accumulated series remain missing.
- **NEXT**: Missing values are set to the next period’s accumulated nonmissing value. Missing values at the end of the accumulated series remain missing.

**START**=option

specifies a SAS date, datetime, or time value that represents the beginning of the data. If the first time ID variable value is greater than the **START**= value, the series is prepended with missing values. If the first time ID variable value is less than the **START**= value, the series is truncated. The **START**= and **END**= options can be used to ensure that data that are associated with each BY group contain the same number of observations.

**ZEROMISS**=option

specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series. The following options can also be used to determine how beginning and ending zero values are assigned:
INPUT Statement  

**INPUT** variable-list < / options> ;

The INPUT statement lists the input numeric variables in the DATA= data set whose values are to be accumulated to form the time series or represent ordered numeric sequences (when no ID statement is specified).

An input data set variable can be specified in only one INPUT or TARGET statement. Any number of INPUT statements can be used. The following **options** can be used with an INPUT statement:

**ACCUMULATE=option**  
specifies how the data set observations are accumulated within each time period for the variables listed in the INPUT statement. If the ACCUMULATE= option is not specified in the INPUT statement, accumulation is determined by the ACCUMULATE= option of the ID statement. If the ACCUMULATE= option is not specified in the ID statement or the INPUT statement, no accumulation is performed. See the ID statement ACCUMULATE= option for more details.

**DIF=(numlist)**  
specifies the differencing to be applied to the accumulated time series. The list of differencing orders must be separated by spaces or commas. For example, DIF=(1,3) specifies first, then third order, differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the DIF= option. Simple differencing is useful when you want to detrend the time series before computing the similarity measures.

**NORMALIZE=option**  
specifies the sequence normalization to be applied to the working input sequence. The following normalization **options** are provided:

- NONE No normalization is applied. This option is the default.
- ABSOLUTE Absolute normalization is applied.
- STANDARD Standard normalization is applied.
- **User-Defined** Normalization is computed by a user-defined subroutine that is created using the FCMP procedure, where **User-Defined** is the subroutine name.

Normalization is applied to the working input sequence, which can be a subset of the working input time series if the SLIDE=INDEX or SLIDE=SEASON option is specified.
**SCALE=** *option*

specifies the scaling of the working input sequence with respect to the working target sequence. Scaling is performed after normalization. The following scaling *options* are provided:

- **NONE**  
  No scaling is applied. This option is the default.
- **ABSOLUTE**  
  Absolute scaling is applied.
- **STANDARD**  
  Standard scaling is applied.
- **User-Defined**  
  Scaling is computed by a user-defined subroutine that is created using the FCMP procedure, where *User-Defined* is the subroutine name.

Scaling is applied to the working input sequence, which can be a subset of the working input time series if the SLIDE=INDEX or SLIDE=SEASON option is specified.

**SDIF=(numlist)**

specifies the seasonal differencing to be applied to the accumulated time series. The list of seasonal differencing orders must be separated by spaces or commas. For example, SDIF=(1,3) specifies first, then third, order seasonal differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the SDIF= option. Seasonal differencing is useful when you want to deseasonalize the time series before computing the similarity measures.

**SETMISSING=** *option | number*

**SETMISS=** *option | number*

specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the INPUT statement. If the SETMISSING= option is not specified in the INPUT statement, missing values are set based on the SETMISSING= option in the ID statement. If the SETMISSING= option is not specified in the ID statement or the INPUT statement, no missing value interpretation is performed. See the ID statement SETMISSING= option for more details.

**TRANSFORM=** *option*

specifies the time series transformation to be applied to the accumulated time series. The following transformations are provided:

- **NONE**  
  No transformation is applied. This option is the default.
- **LOG**  
  Logarithmic transformation is applied.
- **SQRT**  
  Square-root transformation is applied.
- **LOGISTIC**  
  Logistic transformation is applied.
- **BOXCOX(\textit{number})**  
  Box-Cox transformation with parameter is applied, where the real \textit{number} is between –5 and 5.
- **User-Defined**  
  Transformation is computed by a user-defined subroutine that is created using the FCMP procedure, where *User-Defined* is the subroutine name.

When the TRANSFORM= option is specified, the time series must be strictly positive unless a user-defined function is used.
**TRIMMISSING=** option

specifies how missing values (either actual or accumulated) are trimmed from the accumulated time series or ordered sequence for variables that are listed in the INPUT statement. The following trimming options are provided:

- **NONE** No missing value trimming is applied.
- **LEFT** Beginning missing values are trimmed.
- **RIGHT** Ending missing values are trimmed.
- **BOTH** Both beginning and ending missing value are trimmed. This is the default.

**ZEROMISS=** option

specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the INPUT statement. If the ZEROMISS= option is not specified in the INPUT statement, beginning and ending zero values are set based on the ZEROMISS= option of the ID statement. If the ZERO= option is not specified in the ID statement or the INPUT statement, no zero value interpretation is performed. See the ID statement ZEROMISS= option for more details.

---

**TARGET Statement**

**TARGET** variable-list < / options> ;

The TARGET statement lists the numeric target variables in the DATA= data set whose values are to be accumulated to form the time series or represent ordered numeric sequences (when no ID statement is specified).

An input data set variable can be specified in only one INPUT or TARGET statement. Any number of TARGET statements can be used. The following **options** can be used with a TARGET statement:

- **ACCUMULATE=** option
  specifies how the data set observations are accumulated within each time period for the variables listed in the TARGET statement. If the ACCUMULATE= option is not specified in the TARGET statement, accumulation is determined by the ACCUMULATE= option in the ID statement. If the ACCUMULATE= option is not specified in the ID statement or the TARGET statement, no accumulation is performed. See the ID statement ACCUMULATE= option for more details.

- **COMPRESS=** option | (options)
  specifies the sliding sequence (global) and warping (local) compression range of the target sequence with respect to the input sequence. Compression of the target sequence is the same as expansion of the input sequence and vice versa. The compression limits are defined based on the length of the target sequence and are imposed on the target sequence. The following compression options are provided:

  - **GLOBALABS=** integer specifies the absolute global compression, where integer ranges from zero to 10,000. GLOBALABS=0 implies no global compression, which is the default unless the GLOBALPCT= option is specified.
GLOBALPCT=number specifies global compression as a percentage of the length of the target sequence, where number ranges from zero to 100. GLOBALPCT=0 implies no global compression, which is the default. GLOBALPCT=100 implies maximum allowable compression.

LOCALABS=integer specifies the absolute local compression, where integer ranges from zero to 10,000. The default is maximum allowable absolute local compression unless the LOCALPCT= option is specified.

LOCALPCT=number specifies local compression as a percentage of the length of the target sequence, where number ranges from zero to 100. The percentage specified by the LOCALPCT= option must be less than the GLOBALPCT= option. LOCALPCT=0 implies no local compression. LOCALPCT=100 implies maximum allowable local compression. The default is LOCALPCT=100.

If the SLIDE=NONE or the SLIDE=SEASON option is specified in the TARGET statement, the global compression options are ignored. To disallow local compression, use the option COMPRESS=(LOCALPCT=0 LOCALABS=0).

If the SLIDE=INDEX option is specified, the global compression options are not ignored. To completely disallow both global and local compression, use the option COMPRESS=(GLOBALPCT=0 LOCALPCT=0) or COMPRESS=(GLOBALABS=0 LOCALABS=0). To allow only local compression, use the option COMPRESS=(GLOBALPCT=0 LOCALABS=0). These are the default compression options.

The preceding options can be used in combination to specify the desired amount of global and local compression as the following examples illustrate, where \( L_c \) denotes the global compression limit and \( l_c \) denotes the local compression limit:

- COMPRESS=(GLOBALPCT=20) allows the global and local compression to range from zero to \( L_c = \min \left( \left\lfloor 0.2N_y \right\rfloor, (N_y - 1) \right) \).
- COMPRESS=(GLOBALPCT=20 GLOBALABS=10) allows the global and local compression to range from zero to \( L_c = \min \left( \left\lfloor 0.2N_y \right\rfloor, \min \left( (N_y - 1), 10 \right) \right) \).
- COMPRESS=(LOCALPCT=10) allows the local compression to range from zero to \( l_c = \min \left( \left\lfloor 0.1N_y \right\rfloor, (N_y - 1) \right) \).
- COMPRESS=(LOCALPCT=20 LOCALABS=5) allows the local compression to range from zero to \( l_c = \min \left( \left\lfloor 0.2N_y \right\rfloor, \min \left( (N_y - 1), 5 \right) \right) \).
- COMPRESS=(GLOBALPCT=20 LOCALPCT=20) allows the global compression to range from zero to \( L_c = \min \left( \left\lfloor 0.2N_y \right\rfloor, (N_y - 1) \right) \) and allows the local compression to range from zero to \( l_c = \min \left( \left\lfloor 0.2N_y \right\rfloor, (N_y - 1) \right) \).
- COMPRESS=(GLOBALPCT=20 GLOBALABS=10 LOCALPCT=10 LOCALABS=5) allows the global compression to range from zero to \( L_c = \min \left( \left\lfloor 0.2N_y \right\rfloor, \min \left( (N_y - 1), 10 \right) \right) \) and allows the local compression to range from zero to \( l_c = \min \left( \left\lfloor 0.1N_y \right\rfloor, \min \left( (N_y - 1), 5 \right) \right) \).

Suppose \( T_z \) is the length of the input time series and \( N_y \) is the length of the target sequence. The valid global compression limit, \( L_c \), is always limited by the length of the target sequence: \( 0 \leq L_c < N_y \).

Suppose \( N_x \) is the length of the input sequence and \( N_y \) is the length of the target sequence. The valid local compression limit, \( l_c \), is always limited by the lengths of the input and target sequence: \( \max(0, (N_y - N_x)) \leq l_c < N_y \).
**DIF=(numlist)**
specifies the differencing to be applied to the accumulated time series. The list of differencing orders must be separated by spaces or commas. For example, DIF=(1,3) specifies first, then third, order differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the DIF= option. Simple differencing is useful when you want to detrend the time series before computing the similarity measures.

**EXPAND=option | (options)**
specifies the sliding sequence (global) and warping (local) expansion range of the target sequence with respect to the input sequence. Expansion of the target sequence is the same as compression of the input sequence and vice versa. The expansion limits are defined based on the length of the input sequence, but are imposed on the target sequence. The following expansion options are provided:

- **GLOBALABS=integer** specifies the absolute global expansion, where integer ranges from zero to 10,000. GLOBALABS=0 implies no global expansion, which is the default unless the GLOBALPCT= option is specified.
- **GLOBALPCT=number** specifies global expansion as a percentage of the length of the target sequence, where number ranges from zero to 100. GLOBALPCT=0 implies no global expansion, which is the default unless the GLOBALABS= option is specified. GLOBALPCT=100 implies maximum allowable global expansion.
- **LOCALABS=integer** specifies the absolute local expansion, where integer ranges from zero to 10,000. The default is the maximum allowable absolute local expansion unless the LOCALPCT= option is specified.
- **LOCALPCT=number** specifies local expansion as a percentage of the length of the target sequence, where number ranges from zero to 100. LOCALPCT=0 implies no local expansion. LOCALPCT=100 implies maximum allowable local expansion. The default is LOCALPCT=100.

If the SLIDE=NONE or the SLIDE=SEASON option is specified in the TARGET statement, the global expansion options are ignored. To disallow local expansion, use the option EXPAND=(LOCALPCT=0 LOCALABS=0).

If the SLIDE=INDEX option is specified, the global expansion options are not ignored. To completely disallow both global and local expansion, use the option EXPAND=(GLOBALPCT=0 LOCALPCT=0) or EXPAND=(GLOBALABS=0 LOCALABS=0). To allow only local expansion, use the option EXPAND=(GLOBALPCT=0 GLOBALABS=0). These are the default expansion options.

The preceding options can be used in combination to specify the desired amount of global and local expansion as the following examples illustrate, where \( L_e \) denotes the global expansion limit and \( l_e \) denotes the local expansion limit:

- **EXPAND=(GLOBALPCT=20)** allows the global and local expansion to range from zero to \( L_e = \min \left( \left\lfloor 0.2N_y \right\rfloor, (N_y - 1) \right) \).
- **EXPAND=(GLOBALPCT=20 GLOBALABS=10)** allows the global and local expansion to range from zero to \( L_e = \min \left( \left\lfloor 0.2N_y \right\rfloor, \min \left( (N_y - 1), 10 \right) \right) \).
- **EXPAND=(LOCALPCT=10)** allows the local expansion to range from zero to \( l_e = \min \left( \left\lfloor 0.1N_y \right\rfloor, (N_y - 1) \right) \).
- EXPAND=(LOCALPCT=10 LOCALABS=5) allows the local expansion to range from zero to \( l_e = \min \left( \left[ 0.1 N_y \right], \min \left( (N_y - 1), 5 \right) \right) \).
- EXPAND=(GLOBALPCT=20 LOCALPCT=10) allows the global expansion to range from zero to \( L_e = \min \left( \left[ 0.2 N_y \right], \min \left( (N_y - 1), 10 \right) \right) \) and allows the local expansion to range from zero to \( l_e = \min \left( \left[ 0.1 N_y \right], (N_y - 1) \right) \).
- EXPAND=(GLOBALPCT=20 GLOBALABS=10 LOCALPCT=10 LOCALABS=5) allows the global expansion to range from zero to \( L_e = \min \left( \left[ 0.2 N_y \right], \min \left( (N_y - 1), 10 \right) \right) \) and allows the local expansion to range from zero to \( l_e = \min \left( \left[ 0.1 N_y \right], (N_y - 1) \right) \).

Suppose \( T_z \) is the length of the input time series and \( N_y \) is the length of the target sequence. The valid global expansion limit, \( L_e \), is always limited by the length of the input time series: \( 0 \leq L_e < T_z \).

Suppose \( N_x \) is the length of the input sequence and \( N_y \) is the length of the target sequence. The valid local expansion limit, \( l_e \), is always limited by the lengths of the input and target sequence: \( \max \left( 0, (N_x - N_y) \right) \leq l_e < N_x \).

**MEASURE=** option

specifies the similarity measure to be computed by using the working input and target sequences. The following similarity measures are provided:

- SQRDEV squared deviation. This option is the default.
- ABSDEV absolute deviation
- MSQRDEV mean squared deviation
- MSQRDEVINP mean squared deviation relative to the length of the input sequence
- MSQRDEV TAR mean squared deviation relative to the length of the target sequence
- MSQRDEVMIN mean squared deviation relative to the minimum valid path length
- MSQRDEVMAX mean squared deviation relative to the maximum valid path length
- MABSDEV mean absolute deviation
- MABSDEVINP mean absolute deviation relative to the length of the input sequence
- MABSDEVTAR mean absolute deviation relative to the length of the target sequence
- MABSDEVMIN mean absolute deviation relative to the minimum valid path length
- MABSDEVMAX mean absolute deviation relative to the maximum valid path length
- User-Defined The measure is computed by a user-defined function created by using the FCMP procedure, where User-Defined is the function name.

**NORMALIZE=** option

specifies the sequence normalization to be applied to the working target sequence. The following normalization options are provided:

- NONE No normalization is applied. This option is the default.
- ABSOLUTE Absolute normalization is applied.
- STANDARD Standard normalization is applied.
- User-Defined Normalization is computed by a user-defined subroutine that is created by using the FCMP procedure, where User-Defined is the subroutine name.
**PATH=**\_\_\_\_\_\_option

specifies the similarity measure and warping path information to be computed using the working input and target sequences. The following similarity measures and warping path are provided:

*User-Defined* The measure and path are computed by a user-defined subroutine that is created by using the FCMP procedure, where *User-Defined* is the subroutine name.

For computational efficiency, the **PATH=** option should be only used when you want to compute both the similarity measure and the warping path information. If only the similarity measure is needed, use the **MEASURE=** option. If you specify both the **MEASURE=** and **PATH=** option in the TARGET statement, the **PATH=** option takes precedence.

**SDIF=(numlist)**

specifies the seasonal differencing to be applied to the accumulated time series. The list of seasonal differencing orders must be separated by spaces or commas. For example, **SDIF=(1,3)** specifies first, then third, order seasonal differencing. Differencing is applied after time series transformation. The **TRANSFORM=** option is applied before the **SDIF=** option. Seasonal differencing is useful when you want to deseasonalize the time series before computing the similarity measures.

**SETMISSING=**\_\_\_\_\_\_option \_\_\_\_\_\_| \_\_\_\_\_\_number

**SETMISS=**\_\_\_\_\_\_option \_\_\_\_\_\_| \_\_\_\_\_\_number

option specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series for variables that are listed in the TARGET statement. If the **SETMISSING=** option is not specified in the TARGET statement, missing values are set based on the **SETMISSING=** option in the ID statement. If the **SETMISSING=** option is not specified in the ID statement or the TARGET statement, no missing value interpretation is performed. See the ID statement **SETMISSING=** option for more details.

**SLIDE=**\_\_\_\_\_\_option

specifies the sliding of the target sequence with respect to the input sequence. The following slides are provided:

- **NONE** No sequence sliding. The input time series is compared with the target sequence directly with no sliding. This option is the default.
- **INDEX** Slide by time index. The input time series is compared with the target sequence by observation index.
- **SEASON** Slide by seasonal index. The input time series is compared with the target sequence by seasonal index.

The **SLIDE=** option takes precedence over the **COMPRESS=** and **EXPAND=** options.

**TRANSFORM=**\_\_\_\_\_\_option

specifies the time series transformation to be applied to the accumulated time series. The following transformations are provided:

- **NONE** No transformation is applied. This option is the default.
- **LOG** Logarithmic transformation is applied.
- **SQRT** Square-root transformation is applied.
LOGISTIC  Logistic transformation is applied.

BOXCOX(\textit{number})  Box-Cox transformation with parameter is applied, where the real \textit{number} is between –5 and 5

\textit{User-Defined}  Transformation is computed by a user-defined subroutine that is created by using the FCMP procedure, where \textit{User-Defined} is the subroutine name.

When the TRANSFORM= option is specified, the time series must be strictly positive unless a user-defined function is used.

\textbf{TRIMMISSING=\textit{option}}

\textbf{TRIMMISS= \textit{option}} specifies how missing values (either actual or accumulated) are trimmed from the accumulated time series or ordered sequence for variables that are listed in the TARGET statement. The following trimming options are provided:

\begin{itemize}
  \item \textbf{NONE}  No missing value trimming is applied.
  \item \textbf{LEFT}  Beginning missing values are trimmed.
  \item \textbf{RIGHT}  Ending missing values are trimmed.
  \item \textbf{BOTH}  Both beginning and ending missing values are trimmed. This is the default.
\end{itemize}

\textbf{ZEROMISS=\textit{option}} specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the TARGET statement. If the ZEROMISS= option is not specified in the TARGET statement, beginning and ending values are set based on the ZEROMISS= option in the ID statement. See the ID statement ZEROMISS= option for more details.

---

\textbf{Details: SIMILARITY Procedure}

You can use the SIMILARITY procedure to do the following functions, which are done in the order shown. First, you can form time series data from transactional data with the options shown:

1. accumulation       ACCUMULATE= \textit{option}
2. missing value interpretation  SETMISSING= \textit{option}
3. zero value interpretation  ZEROMISS= \textit{option}

Next, you can transform the accumulated time series to form the working time series with the following options. Transformations are useful when you want to stabilize the time series before computing the similarity measures. Simple and seasonal differencing are useful when you want to detrend or deseasonalize the time series before computing the similarity measures. Often, but not always, the TRANSFORM=, DIF=, and SDIF= options should be specified in the same way for both the target and input variables.
4. time series transformation  TRANSFORM= option
5. time series differencing  DIF= and SDIF= option
6. time series missing value trimming  TRIMMISSING= option
7. time series descriptive statistics  PRINT=DESCSTATS option

After the working series is formed, you can treat it as an ordered sequence that can be normalized or scaled. Normalizations are useful when you want to compare the “shape” or “profile” of the time series. Scaling is useful when you want to compare the input sequence to the target sequence while discounting the variation of the target sequence.

8. normalization  NORMALIZE= option
9. scaling  SCALE= option

After the working sequences are formed, you can compute similarity measures between input and target sequences:

10. sliding  SLIDE= option
11. warping  COMPRESS= and EXPAND= option
12. similarity measure  MEASURE= and PATH= option

The SLIDE= option specifies observation-index sliding, seasonal-index sliding, or no sliding. The COMPRESS= and EXPAND= options specify the warping limits. The MEASURE= and PATH= options specify how the similarity measures are computed.

Accumulation

If the ACCUMULATE= option is specified in the ID, INPUT, or TARGET statement, data set observations are accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option in the ID statement. The ID variable contains the time ID values. Each time ID value corresponds to a specific time period. Accumulation is particularly useful when the input data set contains transactional data, whose observations are not spaced with respect to any particular time interval. The accumulated values form the time series, which is used in subsequent analyses.

For example, suppose a data set contains the following observations:

<table>
<thead>
<tr>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>19MAR1999</td>
<td>10</td>

<tr>
<td>23MAY1999</td>
<td>20</td>
</tr>
</tbody>
</table>
If the INTERVAL=MONTH is specified, all of the preceding observations fall within three time periods of March 1999, April 1999, and May 1999. The observations are accumulated within each time period as follows:

If the ACCUMULATE=NONE option is specified, an error is generated because the ID variable values are not equally spaced with respect to the specified frequency (MONTH).

If the ACCUMULATE=TOTAL option is specified, the data are accumulated as follows:

<table>
<thead>
<tr>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>01MAR1999</td>
<td>40</td>
</tr>
<tr>
<td>01APR1999</td>
<td></td>
</tr>
<tr>
<td>01MAY1999</td>
<td>90</td>
</tr>
</tbody>
</table>

If the ACCUMULATE=AVERAGE option is specified, the data are accumulated as follows:

<table>
<thead>
<tr>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>01MAR1999</td>
<td>20</td>
</tr>
<tr>
<td>01APR1999</td>
<td></td>
</tr>
<tr>
<td>01MAY1999</td>
<td>30</td>
</tr>
</tbody>
</table>

If the ACCUMULATE=MINIMUM option is specified, the data are accumulated as follows:

<table>
<thead>
<tr>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>01MAR1999</td>
<td>10</td>
</tr>
<tr>
<td>01APR1999</td>
<td></td>
</tr>
<tr>
<td>01MAY1999</td>
<td>20</td>
</tr>
</tbody>
</table>

If the ACCUMULATE=median option is specified, the data are accumulated as follows:

<table>
<thead>
<tr>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>01MAR1999</td>
<td>20</td>
</tr>
<tr>
<td>01APR1999</td>
<td></td>
</tr>
<tr>
<td>01MAY1999</td>
<td>20</td>
</tr>
</tbody>
</table>

If the ACCUMULATE=MAXIMUM option is specified, the data are accumulated as follows:

<table>
<thead>
<tr>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>01MAR1999</td>
<td>30</td>
</tr>
<tr>
<td>01APR1999</td>
<td></td>
</tr>
<tr>
<td>01MAY1999</td>
<td>50</td>
</tr>
</tbody>
</table>

If the ACCUMULATE=FIRST option is specified, the data are accumulated as follows:

<table>
<thead>
<tr>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>01MAR1999</td>
<td>10</td>
</tr>
<tr>
<td>01APR1999</td>
<td></td>
</tr>
<tr>
<td>01MAY1999</td>
<td>50</td>
</tr>
</tbody>
</table>

If the ACCUMULATE=LAST option is specified, the data are accumulated as follows:

<table>
<thead>
<tr>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>01MAR1999</td>
<td>30</td>
</tr>
<tr>
<td>01APR1999</td>
<td></td>
</tr>
<tr>
<td>01MAY1999</td>
<td>20</td>
</tr>
</tbody>
</table>
If the ACCUMULATE=STDDEV option is specified, the data are accumulated as follows:

<table>
<thead>
<tr>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>O1MAR1999</td>
<td>14.14</td>
</tr>
<tr>
<td>O1APR1999</td>
<td>.</td>
</tr>
<tr>
<td>O1MAY1999</td>
<td>17.32</td>
</tr>
</tbody>
</table>

As can be seen from the preceding examples, even though the data set observations contain no missing values, the accumulated time series can have missing values.

### Missing Value Interpretation

Sometimes missing values should be interpreted as unknown values. But sometimes missing values are known, such as when missing values are created from accumulation and no observations should be interpreted as no (zero) value. In the former case, the SETMISSING= option in the ID, INPUT, or TARGET statement can be used to interpret how missing values are treated. The SETMISSING=0 option should be used when missing observations are to be treated as no (zero) values. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and interpreted time series is used in subsequent analyses.

The SETMISSING=0 option should be used with missing observations are to be treated as a zero value. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and interpreted time series is then used in subsequent analyses.

### Zero Value Interpretation

When querying certain databases for time-stamped data based on a particular time range, time periods that contain no data are sometimes assigned zero values. For certain analyses, it is more desirable to assign these values to missing. Often, these beginning or ending zero values need to be interpreted as missing values. The ZEROMISS= option in the ID, INPUT, or TARGET statement specifies that the beginning, ending, or both the beginning and ending values are to be interpreted as zero values.

### Time Series Transformation

Transformations are useful when you want to stabilize the time series before computing the similarity measures. There are four transformations available, for strictly positive series only. Let $y_t > 0$ be the original time series, and let $w_t$ be the transformed series. The transformations are defined as follows:

- **Log** is the logarithmic transformation,
  \[ w_t = \ln(y_t) \]
- **Logistic** is the logistic transformation,
  \[ w_t = \ln(c y_t/(1 - c y_t)) \]
where the scaling factor \( c \) is

\[
c = (1 - e^{-6}) 10^{-\text{ceil}(\log_{10}(\text{max}(y_t))))
\]

and \( \text{ceil}(x) \) is the smallest integer greater than or equal to \( x \).

Square root is the square root transformation,

\[
w_t = \sqrt{y_t}
\]

Box-Cox is the Box-Cox transformation,

\[
w_t = \begin{cases} 
\frac{y_t^{\lambda} - 1}{\lambda} & \lambda \neq 0 \\
\ln(y_t) & \lambda = 0
\end{cases}
\]

User-Defined is the transformation computed by a user-defined subroutine that is created by using the FCMP procedure, where User-Defined is the subroutine name.

Other time series transformations can be performed prior to invoking the SIMILARITY procedure by using the SAS/ETS EXPAND procedure or the DATA step.

---

**Time Series Differencing**

After optionally transforming the series, the accumulated series can be simply or seasonally differenced using the INPUT or TARGET statement DIF= and SDIF= options. Simple and seasonal differencing are useful when you want to detrend or deseasonalize the time series before computing the similarity measures.

For example, suppose \( y_t \) is a monthly time series. The following examples of the DIF= and SDIF= options demonstrate how to simply and seasonally difference the time series: DIF=(1,3) specifies first, then third, order differencing; SDIF=(1,3) specifies first, then third, order seasonal differencing.

Additionally, assuming that \( y_t \) is strictly positive, the INPUT or TARGET statement TRANSFORM= option and the DIF= and SDIF= options can be combined.

---

**Time Series Missing Value Trimming**

In some instances, missing values should be interpreted as an unknown observation, but other times, missing values are known and should be interpreted as a zero value. This is the case when missing values are created from accumulation, and a missing observation should be interpreted as having no value (meaning a value of zero). In the former case, the SETMISSING= option in the ID, INPUT, or TARGET, statement can be used to interpret how missing observations should be treated. By default, missing values, at the beginning and ending of the data set, are trimmed from the data set prior to analysis. This can be performed using TRIMMISS= both.
Time Series Descriptive Statistics

After a series has been optionally accumulated and transformed with missing values interpreted, descriptive statistics can be computed for the resulting working series by specifying the PRINT=DESCSTATS option. This option produces an ODS table that contains the sum, mean, minimum, maximum, and standard deviation of the working series.

Input and Target Sequences

After the input and target working series are formed, they can be treated as two ordered sequences. Given an input time sequence, \( x_i \), for \( i = 1 \) to \( N_x \), where \( i \) is the input sequence index, and a target time sequence, \( y_j \), for \( j = 1 \) to \( N_y \), where \( j \) is the target sequence index, these sequences are analyzed for similarity.

Sliding Sequences

Similarity measures can be computed between the target sequence and any contiguous subsequences of the input time series.

There are three types of sequence sliding:

- no sliding
- slide by time index
- slide by season index

For more information, see Leonard, Elsheimer, and Sloan (2008).

Time Warping

Time warping allows for the comparison between target and input sequences of differing lengths by compressing or expanding the input sequence with respect the target sequence while respecting the order of the sequence elements.

For more information, see Leonard, Elsheimer, and Sloan (2008).

Sequence Normalization

The working (input or target) sequence can be normalized prior to further analysis. Let \( q_i \) be the original sequence with mean \( \mu_q \) and standard deviation \( \sigma_q \), and let \( r_i \) be the normalized sequence. The normalizations are defined as follows:
• Standard is the standard normalization

\[ r_i = (q_i - \mu_q)/\sigma_q \]

• Absolute is the absolute normalization

\[ r_i = (q_i - min(q_i))/(max(q_i) - min(q_i)) \]

• User-defined is a user-defined normalization created by the FCMP procedure.

**Sequence Scaling**

The working input sequence can be scaled to the working target sequence. Sequence scaling is applied after normalization. Let \( y_j \) be the working target sequence with mean \( \mu_y \) and standard deviation \( \sigma_y \). Let \( x_i \) be the working input sequence and let \( q_i \) be the scaled sequence. The scaling is defined as follows:

• Standard is the standard normalization

\[ q_i = (x_i - \mu_y)/\sigma_y \]

• Absolute is the absolute scaling

\[ q_i = (x_i - min(y_j))/(max(y_j) - min(y_j)) \]

• User-defined is a user-defined scaling created by the FCMP procedure.

**Similarity Measures**

The working input sequence can be compared to the working target sequence to create a similarity.

For more information, see Leonard, Elsheimer, and Sloan (2008).

**User-Defined Functions and Subroutines**

A user-defined routine can be written in the SAS language by using the FCMP procedure or in the C language by using both the FCMP procedure and the PROTO procedure, respectively. The SIMILARITY procedure cannot use C language routines directly. The procedure can use only SAS language routines that might or might not call C language routines. Creating user-defined routines is more completely described in the FCMP procedure and the PROTO procedure documentation. The FCMP and PROTO procedures are part of Base SAS software.

The SAS language provides integrated memory management and exception handling such as operations on missing values. The C language provides flexibility and allows the integration of existing C language libraries. However, proper memory management and exception handling are solely the responsibility of
the user. Additionally, the support for standard C libraries is restricted. If you have a choice, it is highly recommended that you write user-defined functions and subroutines in the SAS language using the FCMP procedure.

For each of the tasks previously described, the following sections describe the required subroutine or function signature and provide examples of using a user-defined routine with the SIMILARITY procedure.

**Time Series Transformations**

A user-defined transformation subroutine has the following subroutine signature:

```
SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*] );
```

where the array-name is the time series to be transformed.

For example, to duplicate the functionality of the built-in TRANSFORM=LOG option in the INPUT and TARGET statement, the following SAS statements create a user-defined version of this transformation called MYTRANSFORM and store this subroutine in the catalog SASUSER.MYSIMILAR.

```
proc fcmp outlib=sasuser.mysimilar.package;
    subroutine mytransform( series[*] );
        outargs series;
        length = DIM(series);
        do i = 1 to length;
            value = series[i];
            if value > 0 then do;
                series[i] = log( value );
            end;
            else do;
                series[i] = .;
            end;
        end;
    endsub;
run;
```

This user-defined subroutine can be specified in the TRANSFORM= option in the INPUT or TARGET statement as follows:

```
  options cmplib = sasuser.mysimilar;
  proc similarity ...;
  ...
  input myinput / transform=mytransform;
  target mytarget / transform=mytransform;
  ...
  run;
```
Sequence Normalizations

A user-defined normalization subroutine has the following signature:

    SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*] );

where the array-name is the sequence to be normalized.

For example, to duplicate the functionality of the built-in NORMALIZE=ABSOLUTE option in the INPUT and TARGET statement, the following SAS statements create a user-defined version of this normalization called MYNORMALIZE and store this subroutine in the catalog SASUSER.MYSIMILAR.

```
proc fcmp outlib=sasuser.mysimilar.package;
    subroutine mynormalize( sequence[*] );
        outargs sequence;
        length = DIM(sequence);
        minimum = .; maximum = .;
        do i = 1 to length;
            value = sequence[i];
            if nmiss(minimum) | nmiss(maximum) then do;
                minimum = value;
                maximum = value;
            end;
            if nmiss(value) = 0 then do;
                if value < minimum then minimum = value;
                if value > maximum then maximum = value;
            end;
        end;
        do i = 1 to length;
            value = sequence[i];
            if nmiss(value) | minimum > maximum then do;
                sequence[i] = .;
            end;
            else do;
                sequence[i] = (value - minimum) / (maximum - minimum);
            end;
        end;
    endsib;
run;
```

This user-defined subroutine can be specified in the NORMALIZE= option in the INPUT or TARGET statement as follows:

```
options cmplib = sasuser.mysimilar;
proc similarity ...;
    ...;
    input myinput / normalize=mynormalize;
```
target mytarget / normalize=mynormalize;
...
run;

**Sequence Scaling**

A user-defined scaling subroutine has the following signature:

```
SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*], <ARRAY-NAME>[*] );
```

where the first array-name is the target sequence and the second array-name is the input sequence to be scaled.

For example, to duplicate the functionality of the built-in SCALE=ABSOLUTE option in the INPUT statement, the following SAS statements create a user-defined version of this scaling called MYSCALE and store this subroutine in the catalog SASUSER.MYSIMILAR.

```sas
proc fcmp outlib=sasuser.mysimilar.package;
    subroutine myscale( target[*], input[*] );
        outargs input;
        length = DIM(target);
        minimum = .; maximum = .;
        do i = 1 to length;
            value = target[i];
            if nmiss(minimum) | nmiss(maximum) then do;
                minimum = value;
                maximum = value;
            end;
            if nmiss(value) = 0 then do;
                if value < minimum then minimum = value;
                if value > maximum then maximum = value;
            end;
        end;
        do i = 1 to length;
            value = input[i];
            if nmiss( value ) | minimum > maximum then do;
                input[i] = .;
            end;
            else do;
                input[i] = (value - minimum) / (maximum - minimum);
            end;
        endsub;
    run;
```

This user-defined subroutine can be specified in the SCALE= option in the INPUT statement as follows:
options cmplib=sasuser.mysimilar;

proc similarity ...;
   ... input myinput / scale=myscale;
   ... run;

Similarity Measures

A user-defined similarity measure function has the following signature:

\[
\text{FUNCTION } \text{<FUNCTION-NAME>}(\text{<ARRAY-NAME>}[*], \text{<ARRAY-NAME>}[*])
\]

where the first array-name is the target sequence and the second array-name is the input sequence. The return value of the function is the similarity measure associated with the target sequence and the input sequence.

For example, to duplicate the functionality of the built-in MEASURE=ABSDEV option in the TARGET statement with no warping, the following SAS statements create a user-defined version of this measure called MYMEASURE and store this subroutine in the catalog SASUSER.MYSIMILAR.

proc fcmp outlib=sasuser.mysimilar.package;
   function mymeasure( target[*], input[*] );
      length = min(DIM(target), DIM(input));
      sum = 0; num = 0;
      do i = 1 to length;
         x = input[i];
         w = target[i];
         if nmiss(x) = 0 & nmiss(w) = 0 then do;
            d = x - w;
            sum = sum + abs(d);
            num = num + 1;
         end;
      end;
      if num <= 0 then return(.);
      return(sum);
   endsub;
run;

This user-defined function can be specified in the MEASURE= option in the TARGET statement as follows:

options cmplib=sasuser.mysimilar;

proc similarity ...;
   ... target mytarget / measure=mymeasure;
   ... run;
For another example, to duplicate the functionality of the built-in MEASURE=SQRDEV and MEASURE=ABSDEV options by using the C language, the following SAS statements create a user-defined C language version of these measures called DTW_SQRDEV_C and DTW_ABSDEV_C and store these functions in the catalog SASUSER.CSIMIL.CFUNCS. DTW refers to dynamic time warping. These C language functions can be then called by SAS language functions and subroutines.

```sas
proc proto package=sasuser.csimil.cfuncs;
mapmiss double = 9999999999;

double dtw_sqrdev_c( double * target / iotype=input,  
                     int targetLength,  
                     double * input / iotype=input,  
                     int inputLength );

externc dtw_sqrdev_c;

double dtw_sqrdev_c( double * target,  
                     int targetLength,  
                     double * input,  
                     int inputLength )
{
    int i,j;
    double x,w,d;
    double * prev = (double *)malloc( sizeof(double)*targetLength);
    double * curr = (double *)malloc( sizeof(double)*inputLength);
    if ( prev == 0 || curr == 0 ) return 9999999999;
    x = input[0];
    for ( j=0; j<targetLength; j++ ) {
        w = target[j];
        d = x - w;
        d = d*d;
        if ( j == 0 ) prev[j] = d;
        else prev[j] = d + prev[j-1];
    }
    for (i=1; i<inputLength; i++ ) {
        x = input[i];
        j = 0;
        w = target[j];
        d = x - w;
        d = d*d;
        curr[j] = d + prev[j];
        for (j=1; j<targetLength; j++ ) {
            w = target[j];
            d = x - w;
            d = d*d;
            curr[j] = d + fmin( prev[j],
                                fmin( prev[j-1], curr[j]) );
        }
        if ( i < targetLength ) {
            for( j=0; j<inputLength; j++ )
                prev[j] = curr[j];
        }
    }
}
```
User-Defined Functions and Subroutines

```c
double dtw_absdev_c( double * target / iotype=input, int targetLength, double * input / iotype=input, int inputLength );

double dtw_absdev_c( double * target, int targetLength, double * input, int inputLength )
{
    int i, j;
    double x, w, d;
    double * prev = (double *)malloc( sizeof(double)*targetLength);
    double * curr = (double *)malloc( sizeof(double)*inputLength);
    if ( prev == 0 || curr == 0 ) return 999999999;
    x = input[0];
    for ( j=0; j<targetLength; j++ ) {
        w = target[j];
        d = x - w;
        d = fabs(d);
        if ( j == 0 ) prev[j] = d;
        else prev[j] = d + prev[j-1];
    }
    for (i=1; i<inputLength; i++ ) {
        x = input[i];
        j = 0;
        w = target[j];
        d = x - w;
        d = fabs(d);
        curr[j] = d + prev[j];
        for (j=1; j<targetLength; j++) {
            w = target[j];
            d = x - w;
            d = fabs(d);
            curr[j] = d + fmin( prev[j],
                                fmin( prev[j-1], curr[j] ));
        }
        if ( i < inputLength ) {
            for ( j=0; j<targetLength; j++ )
                prev[j] = curr[j];
        }
    }
    d = curr[inputLength-1];
}
```
The preceding SAS statements create two C language functions which can then be used in SAS language functions or subroutines or both. However, these functions cannot be directly used by the SIMILARITY procedure. In order to use these C language functions in the SIMILARITY procedure, two SAS language functions must be created that call these two C language functions. The following SAS statements create two user-defined SAS language versions of these measures called DTW_SQRDEV and DTW_ABSDEV and stores these functions in the catalog SASUSER.MYSIMILAR.FUNCS. These SAS language functions use the previously created C language function; the SAS language functions can then be used by the SIMILARITY procedure.

```
proc fcmp outlib=sasuser.mysimilar.funcs
   inlib=sasuser.cfuncs;
   function dtw_sqrdev( target[*], input[*] );
      dev = dtw_sqrdev_c(target,DIM(target),input,DIM(input));
      return( dev );
   endsub;

   function dtw_absdev( target[*], input[*] );
      dev = dtw_absdev_c(target,DIM(target),input,DIM(input));
      return( dev );
   endsub;
run;
```

This user-defined function can be specified in the MEASURE= option in the TARGET statement as follows:

```
options cmplib=sasuser.mysimilar;

proc similarity ...;
   ... 
   target mytarget / measure=dtw_sqrdev;
   target yourtarget / measure=dtw_absdev;
   ... 
run;
```

**Similarity Measures and Warping Path**

A user-defined similarity measure and warping path information function has the following signature:

```
FUNCTION <FUNCTION-NAME> ( <ARRAY-NAME>[*], <ARRAY-NAME>[*], 
   <ARRAY-NAME>[*], <ARRAY-NAME>[*], 
   <ARRAY-NAME>[*] );
```
where the first array-name is the target sequence, the second array-name is the input sequence, the third array-name is the returned target sequence indices, the fourth array-name is the returned input sequence indices, the fifth array-name is the returned path distances. The returned value of the function is the similarity measure. The last three returned arrays are used to compute the path and cost statistics.

The returned sequence indices must represent a valid warping path; that is, integers greater than zero and less than or equal to the sequence length and recorded in ascending order. The returned path distances must be nonnegative numbers.

---

**Output Data Sets**

The SIMILARITY procedure can create the OUT=, OUTMEASURE=, OUTPATH=, OUTSEQUENCE=, and OUTSUM= data sets. In general, these data sets contain the variables listed in the BY statement. The ID statement time ID variable is also included in the data sets when the time dimension is important. If an analysis step related to an output data step fails, then the values of this step are not recorded or are set to missing in the related output data set, and appropriate error and warning messages are recorded in the SAS log.

---

**OUT= Data Set**

The OUT= data set contains the variables that are specified in the BY, ID, INPUT, and TARGET statements. If the ID statement is specified, the ID variable values are aligned and extended based on the ALIGN=, INTERVAL=, START=, and END= options. The values of the variables specified in the INPUT and TARGET statements are accumulated based on the ACCUMULATE= option, missing values are interpreted based on the SETMISSING= option, and zero values are interpreted using the ZEROMISS= option. The accumulated time series is transformed based on the TRANSFORM=, DIF=, and SDIF= options.

---

**OUTMEASURE= Data Set**

The OUTMEASURE= data set records the similarity measures between each INPUT and TARGET statement variable with respect to each time ID value. The form of the OUTMEASURE= data set depends on the SORTNAMES and ORDER= options. The OUTMEASURE= data set contains the variables specified in the BY statement in addition to the variables listed below.

For ORDER=INPUTTARGET and ORDER=TARGETINPUT, the OUTMEASURE= data set has the following form:

- _INPUT_ input variable name
- _TARGET_ target variable name
- _TIMEID_ time ID values
- _INPSEQ_ input sequence values
- _TARSEQ_ target sequence values
- _SIM_ similarity measures
Chapter 24: The SIMILARITY Procedure

The OUTMEASURE= data set is ordered by the variables _INPUT_, then _TARGET_, then _TIMEID_ when ORDER=INPUTTARGET. The OUTMEASURE= data set is ordered by the variables _TARGET_, then _INPUT_, then _TIMEID_ when ORDER=TARGETINPUT.

For ORDER=INPUT, the OUTMEASURE= data set has the following form:

* _INPUT_ input variable name
  _TIMEID_ time ID values
  _INPSEQ_ input sequence values
  *target-names* similarity measures that are associated with each TARGET statement variable name

The OUTMEASURE= data set is ordered by the variables _INPUT_, then _TIMEID_.

For ORDER=TARGET, the OUTMEASURE= data set has the following form:

* _TARGET_ target variable name
  _TIMEID_ time ID values
  _TARSEQ_ target sequence values
  *input-names* similarity measures that are associated with each INPUT statement variable name

The OUTMEASURE= data set is ordered by the variables _TARGET_, then _TIMEID_.

---

OUTPATH= Data Set

The OUTPATH= data set records the path analysis between each INPUT and TARGET statement variable. This data set records the path sequences for each slide index and for each warp index associated with the slide index. The sequence values recorded are normalized and scaled based on the NORMALIZE= and SCALE= options.

The OUTPATH= data set contains the variables specified in the BY statement and the following variables:

* _INPUT_ input variable name
  _TARGET_ target variable name
  _TIMEID_ time ID values
  _SLIDE_ slide index
  _WARP_ warp index
  _INPSEQ_ input sequence values
  _TARSEQ_ target sequence values
  _INPPTH_ input path index
  _TARPTH_ target path index
  _METRIC_ distance metric values
The Warp Index indicates the total amount of warping for each slide. A negative number represents compression of the target sequence. A positive number represents expansion of the target sequence. The Warp Index is always zero for SLIDE=NONE and SLIDE=SEASON.

The sorting of the OUTPATH= data set depends on the SORTNAMES and the ORDER= option.

The OUTPATH= data set is ordered by the variables _INPUT_, then _TARGET_, then _TIMEID_ when ORDER=INPUTTARGET or ORDER=INPUT. The OUTPATH= data set is ordered by the variables _TARGET_, then _INPUT_, then _TIMEID_ when ORDER=TARGETINPUT or ORDER=TARGET.

If there are a large number of slides or warps or both, this data set might be large.

---

### OUTSEQUENCE= Data Set

The OUTSEQUENCE= data set records the input and target sequences that are associated with each INPUT and TARGET statement variable. This data set records the input and target sequence values for each slide index and for each warp index that is associated with the slide index. The sequence values that are recorded are normalized and scaled based on the NORMALIZE= and SCALE= options. This data set also contains the similarity measure associated with the two sequences.

The OUTSEQUENCE= data set contains the variables specified in the BY statement in addition to the following variables:

- _INPUT_  
  input variable name
- _TARGET_  
  target variable name
- _TIMEID_  
  time ID values
- _SLIDE_  
  slide index
- _WARP_  
  warp index
- _INPSEQ_  
  input sequence values
- _TARSEQ_  
  target sequence values
- _SIM_  
  similarity measure
- _STATUS_  
  sequence status

The sorting of the OUTSEQUENCE= data set depends on the SORTNAMES and the ORDER= option.

The OUTSEQUENCE= data set is ordered by the variables _INPUT_, then _TARGET_, then _TIMEID_ when ORDER=INPUTTARGET or ORDER=INPUT. The OUTSEQUENCE= data set is ordered by the variables _TARGET_, then _INPUT_, then _TIMEID_ when ORDER=TARGETINPUT or ORDER=TARGET.

If there are a large number of slides or warps or both, this data set might be large.

---

### OUTSUM= Data Set

The OUTSUM= data set summarizes the similarity measures between each INPUT and TARGET statement variable. The form of the OUTSUM= data set depends on the SORTNAMES and ORDER= option. If the SORTNAMES option is specified, each variable (INPUT or TARGET) is analyzed in ascending order. The
OUTSUM= data set contains the variables specified in the BY statement in addition to the variables listed below.

For ORDER=INPUTTARGET and ORDER=TARGETINPUT, the OUTSUM= data set has the following form:

_greater_ _INPUT_   input variable name
_greater_ _TARGET_  target variable name
_greater_ _STATUS_   status flag that indicates whether the requested analyses were successful
_greater_ _TIMEID_   time ID values
_greater_ _SIM_      similarity measure summary

The OUTSUM= data set is ordered by the variables _INPUT_, then _TARGET_ when ORDER=INPUTTARGET. The OUTSUM= data set is ordered by the variables _TARGET_, then _INPUT_ when ORDER=TARGETINPUT.

For ORDER=INPUT, the OUTSUM= data set has the following form:

_greater_ _INPUT_   input variable name
_greater_ _STATUS_   status flag that indicates whether the requested analyses were successful
_greater_ target-names similarity measure summary that is associated with each TARGET statement variable name

The OUTSUM= data set is ordered by the variable _INPUT_.

For ORDER=TARGET, the OUTSUM= data set has the following form:

_greater_ _TARGET_  target variable name
_greater_ _STATUS_   status flag that indicates whether the requested analyses were successful
_greater_ input-names similarity measure summary that is associated with each INPUT statement variable name

The OUTSUM= data set is ordered by the variable _TARGET_.

_STATUS_ Variable Values

The _STATUS_ variable contains a code that specifies whether the similarity analysis has been successful or not. The _STATUS_ variable can take the following values:

0               Success
3000            Accumulation failure
4000            Missing value interpretation failure
6000            Series is all missing
7000            Transformation failure
8000            Differencing failure
Printed Output

The SIMILARITY procedure optionally produces printed output by using the Output Delivery System (ODS). By default, the procedure produces no printed output. All output is controlled by the PRINT= and PRINTDETAILS options in the PROC SIMILARITY statement.

The sort, order, and form of the printed output depends on both the SORTNAMES option and the ORDER= option. If the SORTNAMES option is specified, each variable (INPUT or TARGET) is analyzed in ascending order. For ORDER=INPUTTARGET, the printed output is ordered by the INPUT statement variables (row) and then by the TARGET statement variables (row). For ORDER=TARGETINPUT, the printed output is ordered by the TARGET statement variables (row) and then by the INPUT statement variables (row). For ORDER=INPUT, the printed output is ordered by the INPUT statement variables (row) and then by the TARGET statement variables (column). For ORDER=TARGET, the printed output is ordered by the TARGET statement variables (row) and then by the INPUT statement variables (column).

In general, if an analysis step related to printed output fails, the values of that step are not printed and appropriate error and warning messages are recorded in the SAS log. The printed output is similar to the output data set; these similarities are described as follows:

**PRINT=COSTS**

prints the costs statistics.

**PRINT=DESCSTATS**

prints the descriptive statistics.

**PRINT=PATHS**

prints the path statistics.

**PRINT=SLIDES**

prints the sliding sequence summary.
PRINT=SUMMARY

prints the summary of similarity measures similar to the OUTSUM= data set.

PRINT=WARPS

prints the warp summary.

PRINTDETAILS

prints each table with greater detail.

---

**ODS Table Names**

The following table relates the PRINT= options to ODS tables.

<table>
<thead>
<tr>
<th>ODS Table Name</th>
<th>Description</th>
<th>Option</th>
</tr>
</thead>
<tbody>
<tr>

The tables are related to a single series within a BY group.

---

**ODS Graphics**

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the SIMILARITY procedure.
ODS Graph Names

PROC SIMILARITY assigns a name to each graph it creates by using ODS. You can use these names to selectively reference the graphs. The names are listed in Table 24.3.

Time Series Plots

The time series plots (SeriesPlot) illustrate the input time series to be compared. The horizontal axis represents the input series time ID values, and the vertical axis represents the input series values.

Sequence Plots

The sequence plots (SequencePlot) illustrate the target and input sequences to be compared. The horizontal axis represents the (target or input) sequence index, and the vertical axis represents the (target or input) sequence values.

Path Plots

The path plot (PathPlot) and path limits plot (PathLimitsPlot) illustrate the path through the distance matrix. The horizontal axis represents the input sequence index, and the vertical axis represents the target sequence index. The dots represent the path coordinates. The upper parallel line represents the compression limit, and the lower parallel line represents the expansion limit. These plots visualize the path through the distance matrix. Vertical movements indicate compression, and horizontal movements represent expansion of the
target sequence with respect to the input sequence. These plots are useful for visualizing the amount of expansion and compression along the path.

**Time Warp Plots**

The time warp plot (WarpPlot) and scaled time warp plot (WarpScaledPlot) illustrate the time warping. The horizontal axis represents the (input and target) sequence index. The upper line plot represents the target sequence. The lower line plot represents the input sequence. The lines that connect the input and target sequence values represent the mapping between the input and target sequence indices along the optimal path. These plots visualize the warping of the time index with respect to the input and target sequence values. Expansion of a single target sequence value occurs when it is mapped to more than one input sequence value. Expansion of a single input sequence value occurs when it is mapped to more than one target sequence value. The plots are useful for visualizing the mapping between the input and target sequence values along the path. The plots are useful for comparing the path sequences or input and target sequence after time warping.

**Path Sequence Plots**

The path sequence plot (PathSequencesPlot) and scaled path sequence plot (PathSequencesScaledPlot) illustrate the sequence mapping along the optimal path. The horizontal axis represents the path index. The dashed line represents the time warped input sequence. The solid line represents the time warped target sequence. These plots visualize the mapping between the input and target sequence values with respect to the path index. The scaled plot with the input and target sequence values are scaled and evenly separated for visual convenience.

**Path Distance Plots**

The path distance plots (PathDistancePlot) and path relative distance plots (PathRelativeDistancePlot) illustrate the path (relative) distances. The horizontal axis represents the path index. The vertical needles represent the (relative) distances. The horizontal reference lines indicate one and two standard deviations.

The path distance histogram (PathDistanceHistogram) and path relative distance histogram (PathDistanceRelativeHistogram) illustrate the distribution of the path (relative) distances. The bars represent the histogram, and the solid line represents a normal distribution with the same mean and variance.

**Cost Plots**

The cost plot (CostPlot) and cost limits plot (CostPlot) illustrate the cost of traversing the distance matrix. The horizontal axis represents the input sequence index, and the vertical axis represents the target sequence index. The colors and shading within the plot illustrate the incremental cost of traversing the distance matrix. The upper parallel line represents the compression limit, and the lower parallel line represents the expansion limit.
Example 24.1: Accumulating Transactional Data into Time Series Data

This example uses the SIMILARITY procedure to illustrate the accumulation of time-stamped transactional data that has been recorded at no particular frequency into time series data at a specific frequency. After the time series is created, the various SAS/ETS procedures related to time series analysis, similarity analysis, seasonal adjustment and decomposition, modeling, and forecasting can be used to further analyze the time series data.

Suppose that the input data set WORK.RETAIL contains variables STORE and TIMESTAMP and numerous other numeric transaction variables. The BY variable STORE contains values that break up the transactions into groups (BY groups). The time ID variable TIMESTAMP contains SAS date values recorded at no particular frequency. The other data set variables contain the numeric transaction values to be analyzed. It is further assumed that the input data set is sorted by the variables STORE and TIMESTAMP.

The following statements form monthly time series from the transactional data based on the median value (ACCUMULATE=MEDIAN) of the transactions recorded with each time period. The accumulated time series values for time periods with no transactions are set to zero instead of missing (SETMISS=0). Only transactions recorded between the first day of 1998 (START='01JAN1998'D) and last day of 2000 (END='31JAN2000'D) are considered and if needed are extended to include this range.

```
proc similarity data=work.retail out=mseries;
  by store;
  id timestamp interval=month
      accumulate=median
      setmiss=0
      start='01jan1998'd
      end   = '31dec2000'd;
  target _NUMERIC_;
run;
```

The monthly time series data are stored in the data WORK.MSERIES. Each BY group associated with the BY variable STORE contains an observation for each of the 36 months associated with the years 1998, 1999, and 2000. Each observation contains the variable STORE, TIMESTAMP, and each of the analysis variables in the input DATA= data set.

After each set of transactions has been accumulated to form the corresponding time series, the accumulated time series can be analyzed by using various time series analysis techniques. For example, exponentially weighted moving averages can be used to smooth each series. The following statements use the EXPAND procedure to smooth the analysis variable named STOREITEM.

```
proc expand data=mseries
   out=smoothed
   from=month;
  by store;
  id timestamp;
  convert storeitem=smooth / transform=(ewma 0.1);
run;
```
The smoothed series is stored in the data set WORK.SMOOTHED. The variable SMOOTH contains the smoothed series.

If the time ID variable TIMESTAMP contains SAS datetime values instead of SAS date values, the INTERVAL=, START=, and END= options in the SIMILARITY procedure must be changed accordingly, and the following statements could be used to accumulate the datetime transactions to a monthly interval:

```sas
proc similarity data=work.retail
   out=tseries;
   by store;
   id timestamp interval=dtmonth
       accumulate=median
       setmiss=0
       start='01jan1998:00:00:00'dt
       end   ='31dec2000:00:00:00'dt;
   target _NUMERIC_;
run;
```

The monthly time series data are stored in the data WORK.TSERIES, and the time ID values use a SAS datetime representation.

---

**Example 24.2: Similarity Analysis**

This simple example illustrates how to use similarity analysis to compare two time sequences. The following statements create an example data set that contains two time sequences of differing lengths:

```sas
data test;
   input i y x;
datalines;
1   2   3
2   4   5
3   6   3
4   7   3
5   3   3
6   8   6
7   9   3
8   3   8
9   10  .
10  11  .;
run;
```

The following statements perform similarity analysis on the example data set:

```sas
proc similarity data=test out=_null_
   print=all plot=all;
   input x;
   target y / measure=absdev;
run;
```

The DATA=TEST option specifies that the input data set WORK.TEST is to be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The PRINT=ALL and
PLOTS=ALL options specify that all ODS tables and graphs are to be produced. The INPUT statement specifies that the input variable is \( X \). The TARGET statement specifies that the target variable is \( Y \) and that the similarity measure is computed using absolute deviation (MEASURE=ABSDEV).

<td>9</td>
<td>2</td>
</tr>
<tr>
<td>Expansion</td>
<td>2</td>
<td>None</td>
<td>0</td>
<td>7</td>
<td>2</td>
</tr>
</tbody>
</table>
The following statements repeat the preceding similarity analysis on the example data set but store the results in output data sets:

``` SAS 
proc similarity data=test out=series 
   outsequence=sequences outpath=path outsum=summary; 
   input x; 
   target y / measure=absdev 
      compress=(localabs=2) 
      expand=(localabs=2); 
run;
```

The OUT=SERIES, OUTSEQUENCE=SEQUENCES, OUTPATH=PATH, and OUTSUM=SUMMARY options specify that the output time series, time sequences, path analysis, and summary data sets be created, respectively.
Example 24.3: Sliding Similarity Analysis

This example illustrates how to use sliding similarity analysis to compare two time sequences. The SASHELP.WORKERS data set contains two similar time series variables (ELECTRIC and MASONRY), which represent employment over time. The following statements create an example data set that contains two time series of differing lengths, where the variable MASONRY has the first 12 and last 7 observations set to missing to simulate the lack of data associated with the target series:

```sas
data workers; set sashelp.workers;
    if '01JAN1978'D <= date < '01JAN1982'D then masonry = masonry;
    else masonry = .;
run;
```

The goal of sliding similarity measures analysis is find the slide index that corresponds to the most similar subsequence of the input series when compared to the target sequence. The following statements perform sliding similarity analysis on the example data set:

```sas
proc similarity data=workers out=_NULL_ print=(slides summary);
    id date interval=month;
    input electric;
    target masonry / slide=index measure=msqrdev
        expand=(localabs=3 globalabs=3)
        compress=(localabs=3 globalabs=3);
run;
```

The DATA=WORKERS option specifies that the input data set WORK.WORKERS is to be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The PRINT=(SLIDES SUMMARY) option specifies that the ODS tables related to the sliding similarity measures and their summary be produced. The INPUT statement specifies that the input variable is ELECTRIC. The TARGET statement specifies that the target variable is MASONRY and that the similarity measure be computed using mean squared deviation (MEASURE=MSQRDEV). The SLIDE=INDEX option specifies observation index sliding. The COMPRESS=(LOCALABS=3 GLOBALABS=3) option limits local and global absolute compression to 3. The EXPAND=(LOCALABS=3 GLOBALABS=3) option limits local and global absolute expansion to 3.
Output 24.3.1 Summary of the Slide Measures

<tbody>
<tr>
<td>Input Variable</td>
</tr>
<tr>
<td>MASONRY</td>
</tr>
<tr>
<td>ELECTRIC</td>
</tr>
<tr>
<td>322.5460</td>
</tr>
</tbody>
</table>

This analysis results in 23 slides based on the observation index. The minimum measure (322.5460) occurs at slide index 13 which corresponds to the time value FEB1978. Note that the original data set SASHELP.WORKERS was modified beginning at the time value JAN1978. This similarity analysis justifies the belief the ELECTRIC lags MASONRY by one month based on the time series cross-correlation analysis despite the lack of target data (MASONRY).
The goal of seasonal sliding similarity measures is to find the seasonal slide index that corresponds to the most similar seasonal subsequence of the input series when compared to the target sequence. The following statements repeat the preceding similarity analysis on the example data set with seasonal sliding:

```sas
proc similarity data=workers out=_NULL_ print=(slides summary);
  id date interval=month;
  input electric;
  target masonry / slide=season measure=msqrdev;
run;
```

Output 24.3.3 Summary of the Seasonal Slide Measures

<table>
<thead>
<tr>
<th>Slide Index</th>
<th>Slide Sequence</th>
<th>Target Sequence</th>
<th>Slide Input Length</th>
<th>Slide Warping Amount</th>
<th>Minimum Measure</th>
</tr>
</thead>
<tbody>
<tr>

<tbody>
<tr>
<td>Input Variable</td>
</tr>
<tr>
<td>MASONRY</td>
</tr>
<tr>
<td>ELECTRIC</td>
</tr>
<tr>
<td>641.9273</td>
</tr>
</tbody>
</table>

The analysis differs from the previous analysis in that the slides are performed based on the seasonal index (SLIDE=SEASON) with no warping. With a seasonality of 12, two seasonal slides are considered at slide indices 0 and 12 with the minimum measure (641.9273) occurring at slide index 12 which corresponds to the time value JAN1978. Note that the original data set SASHELP.WORKERS was modified beginning at the time value JAN1978. This similarity analysis justifies the belief that ELECTRIC and MASONRY have similar seasonal properties based on seasonal decomposition analysis despite the lack of target data (MASONRY).
Example 24.4: Searching for Historical Analogies

This example illustrates how to search for historical analogies by using seasonal sliding similarity analysis of transactional time-stamped data. The SASHELP.TIMEDATA data set contains the variable (VOLUME), which represents activity over time. The following statements create an example data set that contains two time series of differing lengths, where the variable HISTORY represents the historical activity and RECENT represents the more recent activity:

```sas
data timedata; set sashelp.timedata;
  drop volume;
  recent = .;
  history = volume;
  if datetime >= '20AUG2000:00:00:00'DT then do;
    recent = volume;
    history = .;
  end;
run;
```

The goal of seasonal sliding similarity measures is to find the seasonal slide index that corresponds to the most similar seasonal subsequence of the input series when compared to the target sequence. The following statements perform similarity analysis on the example data set with seasonal sliding:

```sas
proc similarity data=timedata out=_NULL_ outsequence=sequences
  outsum=summary;
  id datetime interval=dtday accumulate=total
    start='27JUL1997:00:00:00'dt
    end='21OCT2000:11:59:59'DT;
  input history / normalize=absolute;
  target recent / slide=season normalize=absolute measure=mabsdev;
run;
```

The DATA=TIMEDATA option specifies that the input data set WORK.TIMEDATA be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The OUTSEQUENCE=SEQUENCES and OUTSUM=SUMMARY options specify the output sequences and summary data sets, respectively. The ID statement specifies that the time ID variable is DATETIME, which is to be accumulated on a daily basis (INTERVAL=DTDAY) by summing the transactions (ACCUMULATE=TOTAL). The ID statement also specifies that the data is accumulated on the weekly boundaries starting on the week of 27JUL1997 and ending on the week of 15OCT2000 (START='27JUL1997:00:00:00'DT END='21OCT2000:11:59:59'DT). The INPUT statement specifies that the input variable is HISTORY, which is to be normalized using absolute normalization (NORMALIZE=ABSOLUTE). The TARGET statement specifies that the target variable is RECENT, which is to be normalized by using absolute normalization (NORMALIZE=ABSOLUTE) and that the similarity measure be computed by using mean absolute deviation (MEASURE=MABSDEV). The SLIDE=SEASON options specifies season index sliding.

To illustrate the results of the similarity analysis, the output sequence data set must be subset by using the output summary data set.

```sas
data _NULL_; set summary;
  call symput('MEASURE', left(trim(putn(recent,'BEST20.'))));
run;

data result; set sequences;
```
Example 24.4: Searching for Historical Analogies

by _SLIDE_;  
retain flag 0;  
if first._SLIDE_ then do;  
  if (&measure - 0.00001 < _SIM_ < &measure + 0.00001)  
    then flag = 1;  
end;  
if flag then output;  
if last._SLIDE_ then flag = 0;  
run;

The following statements generate a cross series plot of the results:

```plaintext
proc timeseries data=result out=_NULL_ crossplot=series;  
id datetime interval=dtday;  
var _TARSEQ_;  
crossvar _INPSEQ_;  
run;
```

The cross series plot illustrates that the historical time series analogy most similar to the most recent time series data that started on 20AUG2000 occurred on 02AUG1998.

**Output 24.4.1** Cross Series Plot of the Historical Time Series
Example 24.5: Clustering Time Series

This example illustrates how to cluster time series using a similarity matrix. The WORK.APPLIANCE data set contains 24 variables that record sales histories. The following statements create a similarity matrix and store the matrix in the WORK.SIMMATRIX data set:

```sas
proc similarity data=sashelp.applianc out=_null_ outsum=simmatrix;
  target units_1--units_24 / measure=mabsdev normalize=absolute;
run;
```

The following statements cluster the rows of the similarity matrix.

```sas
proc cluster data=simmatrix(drop=_status_) outtree=tree method=ward noprint;
  id _input_;
run;
```

The following statements plot the dendrogram:

```sas
proc tree data=tree horizontal;
run;
```

References

Overview: SIMLIN Procedure

The SIMLIN procedure reads the coefficients for a set of linear structural equations, which are usually produced by the SYSLIN procedure. PROC SIMLIN then computes the reduced form and, if input data are given, uses the reduced form equations to generate predicted values. PROC SIMLIN is especially useful
The SIMLIN procedure can perform simulation or forecasting of the endogenous variables.

The SIMLIN procedure can be applied only to models that are:

- linear with respect to the parameters
- linear with respect to the variables
- square (as many equations as endogenous variables)
- nonsingular (the coefficients of the endogenous variables form an invertible matrix)

### Getting Started: SIMLIN Procedure

The SIMLIN procedure processes the coefficients in a data set created by the SYSLIN procedure using the OUTEST= option or by another regression procedure such as PROC REG. To use PROC SIMLIN you must first produce the coefficient data set and then specify this data set on the EST= option of the PROC SIMLIN statement. You must also tell PROC SIMLIN which variables are endogenous and which variables are exogenous. List the endogenous variables in an ENDOGENOUS statement, and list the exogenous variables in an EXOGENOUS statement.

The following example illustrates the creation of an OUTEST= data set with PROC SYSLIN and the computation and printing of the reduced form coefficients for the model with PROC SIMLIN.

```plaintext
proc syslin data=in outest=e;
  model y1 = y2 x1;
  model y2 = y1 x2;
run;

proc simlin est=e;
  endogenous y1 y2;
  exogenous x1 x2;
run;
```

If the model contains lagged endogenous variables you must also use a LAGGED statement to tell PROC SIMLIN which variables contain lagged values, which endogenous variables they are lags of, and the number of periods of lagging. For dynamic models, the TOTAL and INTERIM= options can be used on the PROC SIMLIN statement to compute and print total and impact multipliers. (See "Dynamic Multipliers" later in this section for an explanation of multipliers.)

In the following example the variables Y1LAG1, Y2LAG1, and Y2LAG2 contain lagged values of the endogenous variables Y1 and Y2. Y1LAG1 and Y2LAG1 contain values of Y1 and Y2 for the previous observation, while Y2LAG2 contains 2 period lags of Y2. The LAGGED statement specifies the lagged relationships, and the TOTAL and INTERIM= options request multiplier analysis. The INTERIM=2 option prints matrices showing the impact that changes to the exogenous variables have on the endogenous variables after 1 and 2 periods.
data in; set in;
y1lag1 = lag(y1);
y2lag1 = lag(y2);
y2lag2 = lag2(y2);
run;

proc syslin data=in outest=e;
    model y1 = y2 y1lag1 y2lag2 x1;
    model y2 = y1 y2lag1 x2;
run;

proc simlin est=e total interim=2;
    endogenous y1 y2;
    exogenous x1 x2;
    lagged y1lag1 y1 1 y2lag1 y2 1 y2lag2 y2 2;
run;

After the reduced form of the model is computed, the model can be simulated by specifying an input data set on the PROC SIMLIN statement and using an OUTPUT statement to write the simulation results to an output data set. The following example modifies the PROC SIMLIN step from the preceding example to simulate the model and stores the results in an output data set.

proc simlin est=e total interim=2 data=in;
    endogenous y1 y2;
    exogenous x1 x2;
    lagged y1lag1 y1 1 y2lag1 y2 1 y2lag2 y2 2;
    output out=sim predicted=y1hat y2hat residual=y1resid y2resid;
run;

Prediction and Simulation

If an input data set is specified with the DATA= option in the PROC SIMLIN statement, the procedure reads the data and uses the reduced form equations to compute predicted and residual values for each of the endogenous variables. (If no data set is specified with the DATA= option, no simulation of the system is performed, and only the reduced form and multipliers are computed.)

The character of the prediction is based on the START= value. Until PROC SIMLIN encounters the START= observation, actual endogenous values are found and fed into the lagged endogenous terms. Once the START= observation is reached, dynamic simulation begins, where predicted values are fed into lagged endogenous terms until the end of the data set is reached.

The predicted and residual values generated here are different from those produced by the SYSLIN procedure since PROC SYSLIN uses the structural form with actual endogenous values. The predicted values computed by the SIMLIN procedure solve the simultaneous equation system. These reduced-form predicted values are functions only of the exogenous and lagged endogenous variables and do not depend on actual values of current period endogenous variables.
Syntax: SIMLIN Procedure

The following statements can be used with PROC SIMLIN:

```
PROC SIMLIN options ;
    BY variables ;
    ENDOGENOUS variables ;
    EXOGENOUS variables ;
    ID variables ;
    LAGGED lag-var endogenous-var number ellipsis ;
    OUTPUT OUT=SAS-data-set options ;
```

Functional Summary

The statements and options controlling the SIMLIN procedure are summarized in the following table.

PROC SIMLIN Statement

PROC SIMLIN options;

The following options can be used in the PROC SIMLIN statement:

**DATA= SAS-data-set**
specifies the SAS data set containing input data for the simulation. If the DATA= option is used, the data set specified must supply values for all exogenous variables throughout the simulation. If the DATA= option is not specified, no simulation of the system is performed, and only the reduced form and multipliers are computed.

**EST= SAS-data-set**
specifies the input data set containing the structural coefficients of the system. If EST= is omitted the most recently created SAS data set is used. The EST= data set is normally a "TYPE=EST" data set produced by the OUTEST= option of PROC SYSLIN. However, you can also build the EST= data set with a SAS DATA step. See "The EST= Data Set" later in this chapter for details.

**ESTPRINT**
prints the structural coefficients read from the EST= data set.

**INTERIM= n**
requests that interim multipliers be computed for interims 1 through n. If not specified, no interim multipliers are computed. This feature is available only if there are no lags greater than 1.

**NOPRINT**
suppresses all printed output.

**NORED**
suppresses the printing of the reduced form coefficients.

**OUTEST= SAS-data-set**
specifies an output SAS data set to contain the reduced form coefficients and multipliers, in addition to the structural coefficients read from the EST= data set. The OUTEST= data set has the same form as the EST= data set. If the OUTEST= option is not specified, the reduced form coefficients and multipliers are not written to a data set.

**START= n**
specifies the observation number in the DATA= data set where the dynamic simulation is to be started. By default, the dynamic simulation starts with the first observation in the DATA= data set for which all variables (including lags) are not missing.

---

Controlling the Simulation

specify the starting observation for dynamic simulation

<table>
<thead>
<tr>
<th>Description</th>
<th>Statement</th>
<th>Option</th>
</tr>
</thead>
<tbody>
<tr>
<td>PROC SIMLIN</td>
<td></td>
<td>START=</td>
</tr>
</tbody>
</table>

---
requests that the total multipliers be computed. This feature is available only if there are no lags greater than 1.

**TYPE= value**
specifies the type of estimates to be read from the EST= data set. The TYPE= value must match the value of the _TYPE_ variable for the observations that you want to select from the EST= data set (TYPE=2SLS, for example).

**BY Statement**

```
BY variables ;
```

A BY statement can be used with PROC SIMLIN to obtain separate analyses for groups of observations defined by the BY variables.

The BY statement can be applied to one or both of the EST= and the DATA= input data set. When a BY statement is used and both an EST= and a DATA= input data set are specified, PROC SIMLIN checks to see if one or both of the data sets contain the BY variables.

Thus, there are three ways of using the BY statement with PROC SIMLIN:

1. If the BY variables are found in the EST= data set only, PROC SIMLIN simulates over the entire DATA= data set once for each set of coefficients read from the BY groups in the EST= data set.
2. If the BY variables are found in the DATA= data set only, PROC SIMLIN performs separate simulations over each BY group in the DATA= data set, using the single set of coefficients in the EST= data set.
3. If the BY variables are found in both the EST= and the DATA= data sets, PROC SIMLIN performs separate simulations over each BY group in the DATA= data set using the coefficients from the corresponding BY group in the EST= data set.

**ENDOGENOUS Statement**

```
ENDOGENOUS variables ;
```

List the names of the endogenous (jointly dependent) variables in the ENDOGENOUS statement. The ENDOGENOUS statement can be abbreviated as ENDOG or ENDO.

**EXOGENOUS Statement**

```
EXOGENOUS variables ;
```

List the names of the exogenous (independent) variables in the EXOGENOUS statement. The EXOGENOUS statement can be abbreviated as EXOG or EXO.
**ID Statement**

\[
\text{ID variables ;}
\]

The ID statement can be used to restrict the variables copied from the DATA= data set to the OUT= data set. Use the ID statement to list the variables you want copied to the OUT= data set besides the exogenous, endogenous, lagged endogenous, and BY variables. If the ID statement is omitted, all the variables in the DATA= data set are copied to the OUT= data set.

**LAGGED Statement**

\[
\text{LAGGED lag-var endogenous-var number ellipsis ;}
\]

For each lagged endogenous variable, specify the name of the lagged variable, the name of the endogenous variable that was lagged, and the degree of the lag. Only one LAGGED statement is allowed.

The following is an example of the use of the LAGGED statement:

```plaintext
proc simlin est=e;
   endog y1 y2;
   lagged y1lag1 y1 1 y2lag1 y2 1 y2lag3 y2 3;
run;
```

This statement specifies that the variable Y1LAG1 contains the values of the endogenous variable Y1 lagged one period; the variable Y2LAG1 refers to the values of Y2 lagged one period; and the variable Y2LAG3 refers to the values of Y2 lagged three periods.

**OUTPUT Statement**

\[
\text{OUTPUT OUT= SAS-data-set options ;}
\]

The OUTPUT statement specifies that predicted and residual values be put in an output data set. A DATA= input data set must be supplied if the OUTPUT statement is used, and only one OUTPUT statement is allowed. The following options can be used in the OUTPUT statement:

**OUT= SAS-data-set**

names the output SAS data set to contain the predicted values and residuals. If OUT= is not specified, the output data set is named using the DATAn convention.

**PREDICTED= names**

names the variables in the output data set that contain the predicted values of the simulation. These variables correspond to the endogenous variables in the order in which they are specified in the ENDOGENOUS statement. Specify up to as many names as there are endogenous variables. If you specify names on the PREDICTED= option for only some of the endogenous variables, predicted values for the remaining variables are not output. The names must not match any variable name in the input data set.
**RESIDUAL= names**

**R= names**

names the variables in the output data set that contain the residual values from the simulation. The residuals are the differences between the actual values of the endogenous variables from the DATA= data set and the predicted values from the simulation. These variables correspond to the endogenous variables in the order in which they are specified in the ENDOGENOUS statement. Specify up to as many names as there are endogenous variables. The names must not match any variable name in the input data set.

The following is an example of the use of the OUTPUT statement. This example outputs predicted values for Y1 and Y2 and outputs residuals for Y1.

```sas
proc simlin est=e;
endog y1 y2;
   output out=b predicted=y1hat y2hat
        residual=y1resid;
run;
```

---

**Details: SIMLIN Procedure**

The following sections explain the structural and reduced forms, dynamic multipliers, input data sets, and the model simulation process in more detail.

---

**Defining the Structural Form**

An EST= input data set supplies the coefficients of the equation system. The data set containing the coefficients is normally a "TYPE=EST" data set created by the OUTEST= option of PROC SYSLIN or another regression procedure. The data set contains the special variables _TYPE_, _DEPVAR_, and INTERCEPT. You can also supply the structural coefficients of the system to PROC SIMLIN in a data set produced by a SAS DATA step as long as the data set is of the form TYPE=EST. Refer to SAS/STAT software documentation for a discussion of the special TYPE=EST type of SAS data set.

Suppose that there is a \( g \times 1 \) vector of endogenous variables \( y_t \), an \( l \times 1 \) vector of lagged endogenous variables \( y_L^t \), and a \( k \times 1 \) vector of exogenous variables \( x_t \), including the intercept. Then, there are \( g \) structural equations in the simultaneous system that can be written

\[
Gy_t = Cy_L^t + Bx_t
\]

where \( G \) is the matrix of coefficients of current period endogenous variables, \( C \) is the matrix of coefficients of lagged endogenous variables, and \( B \) is the matrix of coefficients of exogenous variables. \( G \) is assumed to be nonsingular.
Computing the Reduced Form

First, the SIMLIN procedure computes reduced form coefficients by premultiplying by $G^{-1}$:

$$y_t = G^{-1} C y_t^L + G^{-1} B x_t$$

This can be written as

$$y_t = \Pi_1 y_t^L + \Pi_2 x_t$$

where $\Pi_1 = G^{-1} C$ and $\Pi_2 = G^{-1} B$ are the reduced form coefficient matrices.

The reduced form matrices $\Pi_1 = G^{-1} C$ and $\Pi_2 = G^{-1} B$ are printed unless the NORED option is specified in the PROC SIMLIN statement. The structural coefficient matrices $G$, $C$, and $B$ are printed when the ESTPRINT option is specified.

Dynamic Multipliers

For models that have only first-order lags, the equation of the reduced form of the system can be rewritten

$$y_t = D y_{t-1} + \Pi_2 x_t$$

$D$ is a matrix formed from the columns of $\Pi_1$ plus some columns of zeros, arranged in the order in which the variables meet the lags. The elements of $\Pi_2$ are called impact multipliers because they show the immediate effect of changes in each exogenous variable on the values of the endogenous variables. This equation can be rewritten as

$$y_t = D^2 y_{t-2} + D \Pi_2 x_{t-1} + \Pi_2 x_t$$

The matrix formed by the product $D \Pi_2$ shows the effect of the exogenous variables one lag back; the elements in this matrix are called interim multipliers and are computed and printed when the INTERIM= option is specified in the PROC SIMLIN statement. The $i$th period interim multipliers are formed by $D^i \Pi_2$.

The series can be expanded as

$$y_t = D^\infty y_{t-\infty} + \sum_{i=0}^{\infty} D^i \Pi_2 x_{t-i}$$

A permanent and constant setting of a value for $x$ has the following cumulative effect:

$$\left( \sum_{i=0}^{\infty} D^i \right) \Pi_2 x = (I - D)^{-1} \Pi_2 x$$

The elements of $(I - D)^{-1} \Pi_2$ are called the total multipliers. Assuming that the sum converges and that $(I - D)$ is invertible, PROC SIMLIN computes the total multipliers when the TOTAL option is specified in the PROC SIMLIN statement.
Chapter 25: The SIMLIN Procedure

Multipliers for Higher Order Lags

The dynamic multiplier options require the system to have no lags of order greater than one. This limitation can be circumvented, since any system with lags greater than one can be rewritten as a system where no lag is greater than one by forming new endogenous variables that are single-period lags.

For example, suppose you have the third-order single equation

\[ y_t = ay_{t-3} + bx_t \]

This can be converted to a first-order three-equation system by introducing two additional endogenous variables, \( y_{1,t} \) and \( y_{2,t} \), and computing corresponding first-order lagged variables for each endogenous variable: \( y_{t-1}, y_{1,t-1}, \) and \( y_{2,t-1} \). The higher order lag relations are then produced by adding identities to link the endogenous and identical lagged endogenous variables:

\[
\begin{align*}
  y_{1,t} & = y_{t-1} \\
  y_{2,t} & = y_{1,t-1} \\
  y_t & = ay_{2,t-1} + bx_t
\end{align*}
\]

This conversion using the SYSLIN and SIMLIN procedures requires three steps:

1. Add the extra endogenous and lagged endogenous variables to the input data set using a DATA step. Note that two copies of each lagged endogenous variable are needed for each lag reduced, one to serve as an endogenous variable and one to serve as a lagged endogenous variable in the reduced system.

2. Add IDENTITY statements to the PROC SYSLIN step to equate each added endogenous variable to its lagged endogenous variable copy.

3. In the PROC SIMLIN step, declare the added endogenous variables in the ENDOGENOUS statement and define the lag relations in the LAGGED statement.

See Example 25.2 for an illustration of how to convert an equation system with higher-order lags into a larger system with only first-order lags.

EST= Data Set

Normally, PROC SIMLIN uses an EST= data set produced by PROC SYSLIN with the OUTEST= option. This data set is in the form expected by PROC SIMLIN. If there is more than one set of estimates produced by PROC SYSLIN, you must use the TYPE= option in the PROC SIMLIN statement to select the set to be simulated. Then PROC SIMLIN reads from the EST= data set only those observations with a _TYPE_ value corresponding to the TYPE= option (for example, TYPE=2SLS) or with a _TYPE_ value of IDENTITY.

The SIMLIN procedure can only solve square, nonsingular systems. If you have fewer equations than endogenous variables, you must specify IDENTITY statements in the PROC SYSLIN step to bring the system up to full rank. If there are \( g \) endogenous variables and \( m < g \) stochastic equations with unknown
parameters, then you use $m$ MODEL statements to specify the equations with parameters to be estimated and you must use $g-m$ IDENTITY statements to complete the system.

You can build your own EST= data set rather than use PROC SYSLIN. The EST= data set must contain the endogenous variables, the lagged endogenous variables (if any), and the exogenous variables in the system (if any). If any of the equations have intercept terms, the variable INTERCEPT must supply these coefficients. The EST= data set should also contain the special character variable comp _DEPVAR_ to label the equations.

The EST= data set must contain one observation for each equation in the system. The values of the lagged endogenous variables must contain the $C$ coefficients. The values of the exogenous variables and the INTERCEPT variable must contain the $B$ coefficients. The values of the endogenous variables, however, must contain the negatives of the $G$ coefficients. This is because the SYSLIN procedure writes the coefficients to the OUTEST= data set in the form

$$0 = H_y t + C_y^L t + B x_t$$

where $H = -G$.

See "Multipliers for Higher Order Lags" and Example 25.2 later in this chapter for more information on building the EST= data set.

---

**DATA= Data Set**

The DATA= data set must contain all of the exogenous variables. Values for all of the exogenous variables are required for each observation for which predicted endogenous values are desired. To forecast past the end of the historical data, the DATA= data set should contain nonmissing values for all of the exogenous variables and missing values for the endogenous variables for the forecast periods, in addition to the historical data. (See Example 25.1 for an illustration.)

In order for PROC SIMLIN to output residuals and compute statistics of fit, the DATA= data set must also contain the endogenous variables with nonmissing actual values for each observation for which residuals and statistics are to be computed.

If the system contains lags, initial values must be supplied for the lagged variables. This can be done by including either the lagged variables or the endogenous variables, or both, in the DATA= data set. If the lagged variables are not in the DATA= data set or if they have missing values in the early observations, PROC SIMLIN prints a warning and uses the endogenous variable values from the early observations to initialize the lags.

---

**OUTEST= Data Set**

The OUTEST= data set contains all the variables read from the EST= data set. The variables in the OUTEST= data set are as follows.

- the BY statement variables, if any
- _TYPE_, a character variable that identifies the type of observation
• _DEPVAR_, a character variable containing the name of the dependent variable for the observation
• the endogenous variables
• the lagged endogenous variables
• the exogenous variables
• INTERCEPT, a numeric variable containing the intercept values
• _MODEL_, a character variable containing the name of the equation
• _SIGMA_, a numeric variable containing the estimated error variance of the equation (output only if present in the EST= data set)

The observations read from the EST= data set that supply the structural coefficients are copied to the OUTEST= data set, except that the signs of endogenous coefficients are reversed. For these observations, the _TYPE_ variable values are the same as in the EST= data set.

In addition, the OUTEST= data set contains observations with the following _TYPE_ values:

REDUCED the reduced form coefficients. The endogenous variables for this group of observations contain the inverse of the endogenous coefficient matrix G. The lagged endogenous variables contain the matrix \( \Pi_1 = G^{-1}C \). The exogenous variables contain the matrix \( \Pi_2 = G^{-1}B \).

IMULTi the interim multipliers, if the INTERIM= option is specified. There are \( gn \) observations for the interim multipliers, where \( g \) is the number of endogenous variables and \( n \) is the value of the INTERIM=\( n \) option. For these observations the _TYPE_ variable has the value IMULTi, where the interim number \( i \) ranges from 1 to \( n \).

The exogenous variables in groups of \( g \) observations that have a _TYPE_ value of IMULTi contain the matrix \( D_i \Pi_2 \) of multipliers at interim \( i \). The endogenous and lagged endogenous variables for this group of observations are set to missing.

TOTAL the total multipliers, if the TOTAL option is specified. The exogenous variables in this group of observations contain the matrix \( (I - D)^{-1} \Pi_2 \). The endogenous and lagged endogenous variables for this group of observations are set to missing.

---

### OUT= Data Set

The OUT= data set normally contains all of the variables in the input DATA= data set, plus the variables named in the PREDICTED= and RESIDUAL= options in the OUTPUT statement.

You can use an ID statement to restrict the variables that are copied from the input data set. If an ID statement is used, the OUT= data set contains only the BY variables (if any), the ID variables, the endogenous and lagged endogenous variables (if any), the exogenous variables, plus the PREDICTED= and RESIDUAL= variables.

The OUT= data set contains an observation for each observation in the DATA= data set. When the actual value of an endogenous variable is missing in the DATA= data set, or when the DATA= data set does not contain the endogenous variable, the corresponding residual is missing.
### Printed Output

#### Structural Form

The following items are printed as they are read from the EST= input data set. Structural zeros are printed as dots in the listing of these matrices.

1. Structural Coefficients for Endogenous Variables. This is the $G$ matrix, with $g$ rows and $g$ columns.

2. Structural Coefficients for Lagged Endogenous Variables. These coefficients make up the $C$ matrix, with $g$ rows and $l$ columns.

3. Structural Coefficients for Exogenous Variables. These coefficients make up the $B$ matrix, with $g$ rows and $k$ columns.

#### Reduced Form

1. The reduced form coefficients are obtained by inverting $G$ so that the endogenous variables can be directly expressed as functions of only lagged endogenous and exogenous variables.

2. Inverse Coefficient Matrix for Endogenous Variables. This is the inverse of the $G$ matrix.

3. Reduced Form for Lagged Endogenous Variables. This is $\Pi_1 = G^{-1}C$, with $g$ rows and $l$ columns. Each value is a dynamic multiplier that shows how past values of lagged endogenous variables affect values of each of the endogenous variables.

4. Reduced Form for Exogenous Variables. This is $\Pi_2 = G^{-1}B$, with $g$ rows and $k$ columns. Its values are called *impact multipliers* because they show the immediate effect of each exogenous variable on the value of the endogenous variables.

#### Multipliers

Interim and total multipliers show the effect of a change in an exogenous variable over time.

1. Interim Multipliers. These are the interim multiplier matrices. They are formed by multiplying $\Pi_2$ by powers of $D$. The $d$th interim multiplier is $D^d \Pi_2$. The interim multiplier of order $d$ shows the effects of a change in the exogenous variables after $d$ periods. Interim multipliers are only available if the maximum lag of the endogenous variables is 1.

2. Total Multipliers. This is the matrix of total multipliers, $T = (I - D)^{-1} \Pi_2$. This matrix shows the cumulative effect of changes in the exogenous variables. Total multipliers are only available if the maximum lag is one.
Statistics of Fit

If the DATA= option is used and the DATA= data set contains endogenous variables, PROC SIMLIN prints a statistics-of-fit report for the simulation. The statistics printed include the following. (Summations are over the observations for which both $y_t$ and $\hat{y}_t$ are nonmissing.)

1. the number of nonmissing errors. (Number of observations for which both $y_t$ and $\hat{y}_t$ are nonmissing.)

2. the mean error: \[ \frac{1}{n} \sum (y_t - \hat{y}_t) \]

3. the mean percent error: \[ \frac{100}{n} \sum \frac{(y_t - \hat{y}_t)}{y_t} \]

4. the mean absolute error: \[ \frac{1}{n} \sum |y_t - \hat{y}_t| \]

5. the mean absolute percent error \[ \frac{100}{n} \sum \frac{|y_t - \hat{y}_t|}{y_t} \]

6. the root mean square error: \[ \sqrt{\frac{1}{n} \sum (y_t - \hat{y}_t)^2} \]

7. the root mean square percent error: \[ \sqrt{\frac{100}{n} \sum \left( \frac{(y_t - \hat{y}_t)}{y_t} \right)^2} \]

ODS Table Names

PROC SIMLIN assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

<table>

Example 25.1: Simulating Klein’s Model I

In this example, the SIMLIN procedure simulates a model of the U.S. economy called Klein’s Model I. The SAS data set KLEIN is used as input to the SYSLIN and SIMLIN procedures.

```sas
data klein;
  input year c p i x wp t g t wsum;
  date=mdy(1,1,year);
  format date year.;
  y = c + i + g - t;
  yr = year - 1931;
  klag = lag( k );
  plag = lag( p );
  xlag = lag( x );
  if year >= 1921;
label c ='consumption'
  p = 'profits'
  w = 'private wage bill'
  i = 'investment'
  k = 'capital stock'
  y = 'national income'
  x = 'private production'
  wsum = 'total wage bill'
  wp = 'govt wage bill'
  g = 'govt demand'
  t = 'taxes'
  klag = 'capital stock lagged'
  plag = 'profits lagged'
  xlag = 'private product lagged'
  yr = 'year-1931';
datalines;
1920 . 12.7 . . 44.9 . . . 182.8 .
1921 41.9 12.4 25.5 -0.2 45.6 2.7 3.9 7.7 182.6 28.2
... more lines ...
```

First, the model is specified and estimated using the SYSLIN procedure, and the parameter estimates are written to an OUTEST= data set. The printed output produced by the SYSLIN procedure is not shown here; see Example 29.1 in Chapter 29 for the printed output of the PROC SYSLIN step.
title1 'Simulation of Klein''s Model I using SIMLIN';
proc syslin 3sls data=klein outest=a;

   instruments klag plag xlag wp g t yr;
   endogenous c p w i x wsum k y;

   consume: model   c = p plag wsum;
   invest:  model   i = p plag klag;
   labor:   model   w = x xlag yr;

   product: identity x = c + i + g;
   income:  identity y = c + i + g - t;
   profit:  identity p = x - w - t;
   stock:   identity k = klag + i;
   wage:    identity wsum = w + wp;
run;

The OUTEST= data set A created by the SYSLIN procedure contains parameter estimates to be used by the SIMLIN procedure. The OUTEST= data set is shown in Output 25.1.1.

</table>
Using the OUTEST= data set A produced by the SYSLIN procedure, the SIMLIN procedure can now compute the reduced form and simulate the model. The following statements perform the simulation.

```plaintext
title1 'Simulation of Klein''s Model I using SIMLIN';
proc simlin data=klein
   est=a type=3sls
   estprint
   total interim=2
   outest=b;
endogenous c p w i x wsum k y;
exogenous wp g t yr;
lagged klag k 1 plag p 1 xlag x 1;
id year;
output out=c p=chat phat what ihat xhat wsumhat khat yhat
   r=cres pres wres ires xres wsumres kres yres;
run;
```

The reduced form coefficients and multipliers are added to the information read from EST= data set A and written to the OUTEST= data set B. The predicted and residual values from the simulation are written to the OUT= data set C specified in the OUTPUT statement.

The SIMLIN procedure first prints the structural coefficient matrices read from the EST= data set, as shown in Output 25.1.2 through Output 25.1.4.

The OUTEST= output data set contains all the observations read from the EST= data set, and in addition contains observations for the reduced form and multiplier matrices. The following statements produce a partial listing of the OUTEST= data set, as shown in Output 25.1.10.

```plaintext
proc print data=b;
   where _type_ = 'REDUCED' | _type_ = 'IMULT1';
run;
```

**Example 25.2: Multipliers for a Third-Order System**

This example shows how to fit and simulate a single equation dynamic model with third-order lags. It then shows how to convert the third-order equation into a three equation system with only first-order lags, so that the SIMLIN procedure can compute multipliers. (See the section "Multipliers for Higher Order Lags" earlier in this chapter for more information.)

The input data set TEST is created from simulated data. A partial listing of the data set TEST produced by PROC PRINT is shown in Output 25.2.1.
Example 25.2: Multipliers for a Third-Order System

Overview: SPECTRA Procedure

The SPECTRA procedure performs spectral and cross-spectral analysis of time series. You can use spectral analysis techniques to look for periodicities or cyclical patterns in data.

The SPECTRA procedure produces estimates of the spectral and cross-spectral densities of a multivariate time series. Estimates of the spectral and cross-spectral densities of a multivariate time series are produced using a finite Fourier transform to obtain periodograms and cross-periodograms. The periodogram ordinates are smoothed by a moving average to produce estimated spectral and cross-spectral densities. PROC SPECTRA can also test whether or not the data are white noise.
PROC SPECTRA uses the finite Fourier transform to decompose data series into a sum of sine and cosine waves of different amplitudes and wavelengths. The finite Fourier transform decomposition of the series \( x_t \) is

\[
x_t = \frac{a_0}{2} + \sum_{k=1}^{m-1} f_k \left( a_k \cos \omega_k t + b_k \sin \omega_k t \right)
\]

\[
f_k = \begin{cases} 
1/2 & \text{if } n \text{ is even and } k = m - 1 \\
1 & \text{otherwise}
\end{cases}
\]

where

- \( t \) is the time subscript, \( t = 0, 1, 2, \ldots, n - 1 \)
- \( x_t \) are the equally spaced time series data
- \( n \) is the number of observations in the time series
- \( m \) is the number of frequencies in the Fourier decomposition: \( m = \frac{n+2}{2} \) if \( n \) is even, \( m = \frac{n+1}{2} \) if \( n \) is odd
- \( k \) is the frequency subscript, \( k = 0, 1, 2, \ldots, m - 1 \)
- \( a_0 \) is the mean term: \( a_0 = 2\bar{x} \)
- \( a_k \) are the cosine coefficients
- \( b_k \) are the sine coefficients
- \( \omega_k \) are the Fourier frequencies: \( \omega_k = \frac{2\pi k}{n} \)

Functions of the Fourier coefficients \( a_k \) and \( b_k \) can be plotted against frequency or against wave length to form periodograms. The amplitude periodogram \( J_k \) is defined as follows:

\[
J_k = \frac{n}{2} \left( a_k^2 + b_k^2 \right)
\]

Several definitions of the term periodogram are used in the spectral analysis literature. The following discussion refers to the \( J_k \) sequence as the periodogram.

The periodogram can be interpreted as the contribution of the \( k \)th harmonic \( \omega_k \) to the total sum of squares (in an analysis of variance sense) in the decomposition of the process into two-degree-of-freedom components for each of the \( m \) frequencies. When \( n \) is even, \( \sin(\omega_n^2) \) is zero, and thus the last periodogram value is a one-degree-of-freedom component.

The periodogram is a volatile and inconsistent estimator of the spectrum. The spectral density estimate is produced by smoothing the periodogram. Smoothing reduces the variance of the estimator but introduces a bias. The weight function used for the smoothing process, \( W() \), often called the kernel or spectral window, is specified with the WEIGHTS statement. It is related to another weight function, \( w() \), the lag window, that is used in other methods to taper the correlogram rather than to smooth the periodogram. Many specific weighting functions have been suggested in the literature (Fuller 1976; Jenkins and Watts 1968; Priestley 1981). Table 26.3 later in this chapter gives the relevant formulas when the WEIGHTS statement is used.

Letting \( i \) represent the imaginary unit \( \sqrt{-1} \), the cross-periodogram is defined as follows:

\[
J_{xy}^k = \frac{n}{2} \left( a_k^x a_k^y + b_k^x b_k^y \right) + i \frac{n}{2} \left( a_k^x b_k^y - b_k^x a_k^y \right)
\]
The cross-spectral density estimate is produced by smoothing the cross-periodogram in the same way as the periodograms are smoothed using the spectral window specified by the WEIGHTS statement.

The SPECTRA procedure creates an output SAS data set whose variables contain values of the periodograms, cross-periodograms, estimates of spectral densities, and estimates of cross-spectral densities. The form of the output data set is described in the section “OUT= Data Set” on page 1871.

---

**Getting Started: SPECTRA Procedure**

To use the SPECTRA procedure, specify the input and output data sets and options for the analysis you want in the PROC SPECTRA statement, and list the variables to analyze in the VAR statement. The procedure produces no printed output unless the WHITETEST option is specified in the PROC SPECTRA statement. The periodogram, spectral density, and other results are written to the OUT= data set, depending on the options used.

For example, to compute the Fourier transform of a variable \( X \) in a data set \( A \), use the following statements:

```plaintext
proc spectra data=a out=b coef;
  var x;
run;
```

This PROC SPECTRA step writes the Fourier coefficients \( a_k \) and \( b_k \) to the variables COS_01 and SIN_01 in the output data set \( B \).

When a WEIGHTS statement is specified, the periodogram is smoothed by a weighted moving average to produce an estimate of the spectral density of the series. The following statements write a spectral density estimate for \( X \) to the variable \( S_01 \) in the output data set \( B \).

```plaintext
proc spectra data=a out=b s;
  var x;
  weights 1 2 3 4 3 2 1;
run;
```

When the VAR statement specifies more than one variable, you can perform cross-spectral analysis by specifying the CROSS option in the PROC SPECTRA statement. The CROSS option by itself produces the cross-periodograms for all two-way combinations of the variables listed in the VAR statement. For example, the following statements write the real and imaginary parts of the cross-periodogram of \( X \) and \( Y \) to the variables RP_01_02 and IP_01_02 in the output data set \( B \).

```plaintext
proc spectra data=a out=b cross;
  var x y;
run;
```

To produce cross-spectral density estimates, specify both the CROSS option and the S option. The cross-periodogram is smoothed using the weights specified by the WEIGHTS statement in the same way as the spectral density. The squared coherency and phase estimates of the cross-spectrum are computed when the K and PH options are used.

The following example computes cross-spectral density estimates for the variables \( X \) and \( Y \).
proc spectra data=a out=b cross s;
   var x y;
   weights 1 2 3 4 3 2 1;
run;

The real part and imaginary part of the cross-spectral density estimates are written to the variables CS_01_02 and QS_01_02, respectively.

Syntax: SPECTRA Procedure

The following statements are used with the SPECTRA procedure:

```
PROC SPECTRA options ;
   BY variables ;
   VAR variables ;
   WEIGHTS <weights> <kernel> ;
```

Functional Summary

Table 26.1 summarizes the statements and options that control the SPECTRA procedure.

**PROC SPECTRA Statement**

PROC SPECTRA statement can be used in the PROC SPECTRA statement:

**A**
outputs the amplitude variables (Aₙₙ, Aₘₘ) of the cross-spectrum.

**ADJMEAN**
subtracts the series mean before performing the Fourier decomposition. This sets the first periodogram ordinate to 0 rather than 2\(n\) times the squared mean. This option is commonly used when the periodograms are to be plotted to prevent a large first periodogram ordinate from distorting the scale of the plot.

**ALTW**
specifies that the quadrature spectrum estimate is computed at the boundaries in the same way as the spectral density estimate and the cospectrum estimate are computed.

**COEF**
outputs the Fourier cosine and sine coefficients of each series.

**CROSS**
is used with the P and S options to output cross-periodograms and cross-spectral densities when more than one variable is listed in the VAR statement.

**DATA=SAS-data-set**
names the SAS data set that contains the input data. If the DATA= option is omitted, the most recently created SAS data set is used.
K outputs the squared coherency variables ($K_{nn \_mm}$) of the cross-spectrum. The $K_{nn \_mm}$ variables are identically 1 unless weights are given in the WEIGHTS statement and the S option is specified.

**OUT=SAS-data-set**

names the output data set created by PROC SPECTRA to store the results. If the OUT= option is omitted, the output data set is named by using the DATAn convention.

P outputs the periodogram variables. The variables are named $P_{nn}$, where $nn$ is an index of the original variable with which the periodogram variable is associated. When both the P and CROSS options are specified, the cross-periodogram variables $RP_{nn \_mm}$ and $IP_{nn \_mm}$ are also output.

PH outputs the phase variables ($PH_{nn \_mm}$) of the cross-spectrum.

S outputs the spectral density estimates. The variables are named $S_{nn}$, where $nn$ is an index of the original variable with which the estimate variable is associated. When both the S and CROSS options are specified, the cross-spectral variables $CS_{nn \_mm}$ and $QS_{nn \_mm}$ are also output.

**WHITETEST**

prints two tests of the hypothesis that the data are white noise. See the section “White Noise Test” on page 1871 for details.

Note that the CROSS, A, K, and PH options are meaningful only if more than one variable is listed in the VAR statement.

---

### BY Statement

**BY variables ;**

A BY statement can be used with PROC SPECTRA to obtain separate analyses for groups of observations defined by the BY variables.

---

### VAR Statement

**VAR variables ;**

The VAR statement specifies one or more numeric variables that contain the time series to analyze. The order of the variables in the VAR statement list determines the index, $nn$, used to name the output variables. The VAR statement is required.

---

### WEIGHTS Statement

**WEIGHTS weight-constants | kernel-specification ;**
The WEIGHTS statement specifies the relative weights used in the moving average applied to the periodogram ordinates to form the spectral density estimates. A WEIGHTS statement must be used to produce smoothed spectral density estimates. You can specify the relative weights in two ways: you can specify them explicitly as explained in the section “Using Weight Constants Specification” on page 1867, or you can specify them implicitly by using the kernel specification as explained in the section “Using Kernel Specifications” on page 1867. If the WEIGHTS statement is not used, only the periodogram is produced.

**Using Weight Constants Specification**

Any number of weighting constants can be specified. The constants should be positive and symmetric about the middle weight. The middle constant (or the constant to the right of the middle if an even number of weight constants are specified) is the relative weight of the current periodogram ordinate. The constant immediately following the middle one is the relative weight of the next periodogram ordinate, and so on. The actual weights used in the smoothing process are the weights specified in the WEIGHTS statement scaled so that they sum to $\frac{1}{4\pi}$.

The moving average reflects at each end of the periodogram. The first periodogram ordinate is not used; the second periodogram ordinate is used in its place.

For example, a simple triangular weighting can be specified using the following WEIGHTS statement:

```plaintext
weights 1 2 3 2 1;
```

**Using Kernel Specifications**

You can specify five different kernels in the WEIGHTS statement. The syntax for the statement is

```plaintext
WEIGHTS [PARZEN][BART][TUKEY][TRUNCAT][QS] [c e] ;
```

where $c \geq 0$ and $e \geq 0$ are used to compute the bandwidth parameter as

$$l(q) = cq^e$$

and $q$ is the number of periodogram ordinates +1:

$$q = \text{floor}(n/2) + 1$$

To specify the bandwidth explicitly, set $c =$ to the desired bandwidth and $e =$ 0.

For example, a Parzen kernel can be specified using the following WEIGHTS statement:

```plaintext
weights parzen 0.5 0;
```

For details, see the section “Kernels” on page 1868.
Details: SPECTRA Procedure

Input Data

Observations in the data set analyzed by the SPECTRA procedure should form ordered, equally spaced time series. No more than 99 variables can be included in the analysis.

Data are often detrended before analysis by the SPECTRA procedure. This can be done by using the residuals output by a SAS regression procedure. Optionally, the data can be centered using the ADJMEAN option in the PROC SPECTRA statement, since the zero periodogram ordinate corresponding to the mean is of little interest from the point of view of spectral analysis.

Missing Values

Missing values are excluded from the analysis by the SPECTRA procedure. If the SPECTRA procedure encounters missing values for any variable listed in the VAR statement, the procedure determines the longest contiguous span of data that has no missing values for the variables listed in the VAR statement and uses that span for the analysis.

Computational Method

If the number of observations \( n \) factors into prime integers that are less than or equal to 23, and the product of the square-free factors of \( n \) is less than 210, then PROC SPECTRA uses the fast Fourier transform developed by Cooley and Tukey and implemented by Singleton (1969). If \( n \) cannot be factored in this way, then PROC SPECTRA uses a Chirp-Z algorithm similar to that proposed by Monro and Branch (1977). To reduce memory requirements, when \( n \) is small, the Fourier coefficients are computed directly using the defining formulas.

Kernels

Kernels are used to smooth the periodogram by using a weighted moving average of nearby points. A smoothed periodogram is defined by the following equation.

\[
\tilde{J}_i(l(q)) = \sum_{\tau=-l(q)}^{l(q)} w\left(\frac{\tau}{l(q)}\right) \tilde{J}_{i+\tau}
\]
where \( w(x) \) is the kernel or weight function. At the endpoints, the moving average is computed cyclically; that is,

\[
\tilde{J}_{i+\tau} = \begin{cases} 
J_{i+\tau} & 0 \leq i + \tau \leq q \\
J_{-(i+\tau)} & i + \tau < 0 \\
J_{q-(i+\tau)} & i + \tau > q 
\end{cases}
\]

The SPECTRA procedure supports the following kernels. They are listed with their default bandwidth functions.

**Bartlett: KERNEL BART**

\[
w(x) = \begin{cases} 
1 - |x| & |x| \leq 1 \\
0 & \text{otherwise}
\end{cases}
\]

\[
l(q) = \frac{1}{2} q^{1/3}
\]

**Parzen: KERNEL PARZEN**

\[
w(x) = \begin{cases} 
1 - 6|x|^2 + 6|x|^3 & 0 \leq |x| \leq \frac{1}{2} \\
2(1 - |x|)^3 & \frac{1}{2} \leq |x| \leq 1 \\
0 & \text{otherwise}
\end{cases}
\]

\[
l(q) = q^{1/5}
\]

**Quadratic spectral: KERNEL QS**

\[
w(x) = \frac{25}{12\pi^2 x^2} \left( \frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right)
\]

\[
l(q) = \frac{1}{2} q^{1/5}
\]

**Tukey-Hanning: KERNEL TUKEY**

\[
w(x) = \begin{cases} 
(1 + \cos(\pi x))/2 & |x| \leq 1 \\
0 & \text{otherwise}
\end{cases}
\]

\[
l(q) = \frac{2}{3} q^{1/5}
\]

**Truncated: KERNEL TRUNCAT**

\[
w(x) = \begin{cases} 
1 & |x| \leq 1 \\
0 & \text{otherwise}
\end{cases}
\]

\[
l(q) = \frac{1}{4} q^{1/5}
\]
A summary of the default values of the bandwidth parameters, $c$ and $e$, associated with the kernel smoothers in PROC SPECTRA are listed below in Table 26.2:

See Andrews (1991) for details about the properties of these kernels.
**White Noise Test**

PROC SPECTRA prints two test statistics for white noise when the WHITETEST option is specified: Fisher’s Kappa (Davis 1941; Fuller 1976) and Bartlett’s Kolmogorov-Smirnov statistic (Bartlett 1966; Fuller 1976; Durbin 1967).

If the time series is a sequence of independent random variables with mean 0 and variance $\sigma^2$, then the periodogram, $J_k$, will have the same expected value for all $k$. For a time series with nonzero autocorrelation, each ordinate of the periodogram, $J_k$, will have different expected values. The Fisher’s Kappa statistic tests whether the largest $J_k$ can be considered different from the mean of the $J_k$. Critical values for the Fisher’s Kappa test can be found in Fuller 1976.

The Kolmogorov-Smirnov statistic reported by PROC SPECTRA has the same asymptotic distribution as Bartlett’s test (Durbin 1967). The Kolmogorov-Smirnov statistic compares the normalized cumulative periodogram with the cumulative distribution function of a uniform(0,1) random variable. The normalized cumulative periodogram, $F_j$, of the series is

$$F_j = \frac{\sum_{k=1}^{j} J_k}{\sum_{k=1}^{m} J_k}, \quad j = 1, 2, \ldots, m - 1$$

where $m = \frac{n}{2}$ if $n$ is even or $m = \frac{n-1}{2}$ if $n$ is odd. The test statistic is the maximum absolute difference of the normalized cumulative periodogram and the uniform cumulative distribution function. Approximate $p$-values for Bartlett’s Kolmogorov-Smirnov test statistics are provided with the test statistics. Small $p$-values cause you to reject the null-hypothesis that the series is white noise.

**Transforming Frequencies**

The variable FREQ in the data set created by the SPECTRA procedure ranges from 0 to $\pi$. Sometimes it is preferable to express frequencies in cycles per observation period, which is equal to $\frac{1}{2\pi} FREQ$.

To express frequencies in cycles per unit time (for example, in cycles per year), multiply FREQ by $\frac{d}{2\pi}$, where $d$ is the number of observations per unit of time. For example, for monthly data, if the desired time unit is years then $d$ is 12. The period of the cycle is $\frac{2\pi}{d \times FREQ}$, which ranges from $\frac{2}{d}$ to infinity.

**OUT= Data Set**

The OUT= data set contains $\frac{n}{2} + 1$ observations, if $n$ is even, or $\frac{n+1}{2}$ observations, if $n$ is odd, where $n$ is the number of observations in the time series or the span of data being analyzed if missing values are present in the data. See the section “Missing Values” on page 1868 for details.

The variables in the new data set are named according to the following conventions. Each variable to be analyzed is associated with an index. The first variable listed in the VAR statement is indexed as 01, the second variable as 02, and so on. Output variables are named by combining indexes with prefixes. The prefix always identifies the nature of the new variable, and the indices identify the original variables from which the statistics were obtained.

Variables that contain spectral analysis results have names that consist of a prefix, an underscore, and the index of the variable analyzed. For example, the variable S_01 contains spectral density estimates for the
first variable in the VAR statement. Variables that contain cross-spectral analysis results have names that consist of a prefix, an underscore, the index of the first variable, another underscore, and the index of the second variable. For example, the variable A_01_02 contains the amplitude of the cross-spectral density estimate for the first and second variables in the VAR statement.

Table 26.3 shows the formulas and naming conventions used for the variables in the OUT= data set. Let X be variable number nn in the VAR statement list and let Y be variable number mm in the VAR statement list. Table 26.3 shows the output variables that contain the results of the spectral and cross-spectral analysis of X and Y.

In Table 26.3 the following notation is used. Let $W_j$ be the vector of $2p + 1$ smoothing weights given by the WEIGHTS statement, normalized to sum to $\frac{1}{4\pi}$. Note that the weights are either explicitly provided using the constant specification or are implicitly determined by the kernel specification in the WEIGHTS statement.

The subscript of $W_j$ runs from $W_{-p}$ to $W_p$, so that $W_0$ is the middle weight in the list. Let $\omega_k = \frac{2\pi k}{n}$, where $k = 0, 1, \ldots, \text{floor}(\frac{n}{2})$.

**K\_nn\_mm** coherency squared of X and Y:

\[
K_k^{xy} = \frac{(A_k^{xy})^2}{(F_x^k F_y^k)}
\]

**PH\_nn\_mm** phase spectrum in radians of X and Y:

\[
\Phi_k^{xy} = \arctan\left(\frac{Q_k^{xy}}{C_k^{xy}}\right)
\]

### Printed Output

By default PROC SPECTRA produces no printed output.

When the WHITETEST option is specified, the SPECTRA procedure prints the following statistics for each variable in the VAR statement:

1. the name of the variable
2. M–1, the number of two-degree-of-freedom periodogram ordinates used in the test
3. MAX(P(*)), the maximum periodogram ordinate
4. SUM(P(*)), the sum of the periodogram ordinates
5. Fisher’s Kappa statistic
6. Bartlett’s Kolmogorov-Smirnov test statistic
7. Approximate \(p\)-value for Bartlett’s Kolmogorov-Smirnov test statistic

See the section “White Noise Test” on page 1871 for details.

### ODS Table Names: SPECTRA procedure

PROC SPECTRA assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.
### Examples: SPECTRA Procedure

#### Example 26.1: Spectral Analysis of Sunspot Activity

This example analyzes Wolfer’s sunspot data (Anderson 1971). The following statements read and plot the data.

```plaintext
title "Wolfer's Sunspot Data";
data sunspot;
  input year wolfer @@;
datalines;
1749 809 1750 834 1751 477 1752 478 1753 307 1754 122 1755 96 ...
... more lines ...
proc sgplot data=sunspot;
  series x=year y=wolfer / markers markerattrs=(symbol=circlefilled);
  xaxis values=(1740 to 1930 by 10);
  yaxis values=(0 to 1600 by 200);
run;
```

The plot of the sunspot series is shown in Output 26.1.1.

---

### Table 26.4  ODS Tables Produced in PROC SPECTRA

</tbody>
</table>
Example 26.1: Spectral Analysis of Sunspot Activity

Output 26.1.1 Plot of Original Sunspot Data

The spectral analysis of the sunspot series is performed by the following statements:

```sas
proc spectra data=sunspot out=b p s adjmean whitetest;
  var wolfer;
  weights 1 2 3 4 3 2 1;
run;

proc print data=b(obs=12);
run;
```

The PROC SPECTRA statement specifies the P and S options to write the periodogram and spectral density estimates to the OUT= data set B. The WEIGHTS statement specifies a triangular spectral window for smoothing the periodogram to produce the spectral density estimate. The ADJMEAN option zeros the frequency 0 value and avoids the need to exclude that observation from the plots. The WHITETEST option prints tests for white noise.

The Fisher’s Kappa test statistic of 16.070 is larger than the 5% critical value of 7.2, so the null hypothesis that the sunspot series is white noise is rejected (see the table of critical values in Fuller (1976)).

The Bartlett’s Kolmogorov-Smirnov statistic is 0.6501, and its approximate p-value is < 0.0001. The small p-value associated with this test leads to the rejection of the null hypothesis that the spectrum represents white noise.
The printed output produced by PROC SPECTRA is shown in Output 26.1.2. The output data set B created by PROC SPECTRA is shown in part in Output 26.1.3.

**Output 26.1.2**  White Noise Test Results

</tbody>
</table>

The following statements plot the periodogram and spectral density estimate by the frequency and period.
Example 26.1: Spectral Analysis of Sunspot Activity

The periodogram is plotted against the frequency in Output 26.1.4 and plotted against the period in Output 26.1.5. The spectral density estimate is plotted against the frequency in Output 26.1.6 and plotted against the period in Output 26.1.7.

**Output 26.1.4** Plot of Periodogram by Frequency

```
proc sgplot data=b;
    series x=freq y=p_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
    series x=period y=p_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
    series x=freq y=s_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
    series x=period y=s_01 / markers markerattrs=(symbol=circlefilled);
run;
```
Output 26.1.5 Plot of Periodogram by Period
Example 26.1: Spectral Analysis of Sunspot Activity

Output 26.1.6  Plot of Spectral Density Estimate by Frequency

Wolfer's Sunspot Data

Spectral Density of Wolfer

Frequency from 0 to PI
Since PERIOD is the reciprocal of frequency, the plot axis for PERIOD is stretched for low frequencies and compressed at high frequencies. One way to correct for this is to use a WHERE statement to restrict the plots and exclude the low frequency components. The following statements plot the spectral density for periods less than 50.

```plaintext
proc sgplot data=b;
  where period < 50;
  series x=period y=s_01 / markers markerattrs=(symbol=circlefilled);
  refline 11 / axis=x;
run;
title;
```

The spectral analysis of the sunspot series confirms a strong 11-year cycle of sunspot activity. The plot makes this clear by drawing a reference line at the 11 year period, which highlights the position of the main peak in the spectral density.

**Output 26.1.8** shows the plot. Contrast **Output 26.1.8** with **Output 26.1.7**.
Example 26.2: Cross-Spectral Analysis

This example uses simulated data to show cross-spectral analysis for two variables X and Y. X is generated by an AR(1) process; Y is generated as white noise plus an input from X lagged 2 periods. All output options are specified in the PROC SPECTRA statement. PROC CONTENTS shows the contents of the OUT= data set.

```sas
data a;
  x1 = 0; xll = 0;
  do i = -10 to 100;
    x = .4 * x1 + rannor(123);
    y = .5 * xll + rannor(123);
    if i > 0 then output;
    xll = x1; x1 = x;
  end;
run;

proc spectra data=a out=b cross coef a k p ph s;
  var x y;
  weights 1 1.5 2 4 8 9 8 4 2 1.5 1;
```

Output 26.1.8  Plot of Spectral Density Estimate by Period to 50 Years
run;

proc contents data=b position;
run;

The PROC CONTENTS report for the output data set \( B \) is shown in Output 26.2.1.

**Output 26.2.1** Contents of PROC SPECTRA OUT= Data Set

Overview: SSM Procedure

State space models (SSMs) are used for analyzing continuous response variables that are recorded sequentially according to a numeric indexing variable. In many cases, the indexing variable is time and the observations are collected at regular time intervals—for example, hourly, weekly, or monthly. In such cases, the resulting data are called time series data. In other cases, the indexing variable might not be time or the observations might not be equally spaced according to the indexing variable. These more general types of sequential data are called longitudinal data. Because of their sequential nature, these types of data exhibit some characteristic features. For example, chronologically closer measurements tend to be highly correlated while measurements
farther apart are essentially uncorrelated. Data can be trending in a particular direction and can have seasonal or other periodic patterns. SSMs are specially designed to model such sequential data. They apply to both univariate and multivariate response situations and can easily incorporate predictor (independent variable) information when it is available.

The SSM procedure performs state space modeling of univariate and multivariate time series and longitudinal data. You can do the following with the SSM procedure:

- analyze quite general linear state space models.
- use an expressive language to specify an SSM. An SSM specification consists of specifying a variety of matrices—for example, the state transition matrix and the covariance matrices of the state and observation disturbances. The SSM procedure provides language similar to a DATA step for specifying the elements of these matrices. The matrix elements can be user-defined functions of data variables and unknown parameters.
- easily specify several commonly needed univariate and multivariate SSMs by using only a few keywords. These SSMs include the principal univariate and multivariate structural models for regularly spaced data and a variety of trend and cycle models for the longitudinal data.
- estimate unknown model parameters by (restricted) maximum likelihood. The likelihood function is computed by using the (diffuse) Kalman filter algorithm.
- print, or output to a data set, the series forecasts, residuals, and the full-sample estimates of any linear combination of the underlying state variables. These estimates are obtained by using the (diffuse) Kalman filter and smoother algorithm.
- generate residual diagnostic plots and plots useful for detecting structural breaks.

**Background**

State space models are widely used in a variety of fields such as engineering, statistics, econometrics, and agriculture. There are numerous references that deal with state space modeling, particularly with the state space modeling of time series data. State space modeling of longitudinal data has received a little less attention. The primary reference for the modeling techniques implemented in the SSM procedure is Harvey (1989). It contains treatment of both the time series and longitudinal data. Other useful books about this subject are: Durbin and Koopman (2001); Jones (1993); Anderson and Moore (1979). In addition, informative articles about state space modeling of longitudinal data include Wecker and Ansley (1983); Kohn and Ansley (1991); de Jong and Mazzi (2001); Eubank, Huang, and Wang (2003). For the implementation details of the diffuse Kalman filter and smoother (the main computational tool used by the SSM procedure), the main references are a series of articles (de Jong 1989, 1991; de Jong and Chu-Chun-Lin 2003) and the references therein.

**Getting Started: SSM Procedure**

This example illustrates how you can use the SSM procedure to analyze a panel of time series. The following data set, Cigar, contains information about yearly per capita cigarette sales for 46 geographic regions in
Chapter 27: The SSM Procedure

the United States over the period 1963–1992. The variables lsa, lprice, lndi, and lpimin denote the per capita cigarette sales, price per pack of cigarettes, per capita disposable income, and minimum price in adjoining regions per pack of cigarettes, respectively (all in the natural log scale). The variable year contains the observation year, and the variable region contains an integer between 1 to 46 that serves as the unique identifier for the region. For additional data description see Baltagi and Levin (1992); Baltagi (1995). The data are sorted by year.

data cigar;
  input year region lsa lprice lndi lpimin;
  label lsa = 'Log cigarette sales in packs per capita';
  label lprice = 'Log price per pack of cigarettes';
  label lndi = 'Log per capita disposable income';
  label lpimin = 'Log minimum price in adjoining regions per pack of cigarettes';
  year = intnx( 'year', '1jan63'd, year-63 );
  format year year.1;
datalines;
63 1 4.54223 3.35341 7.3514 3.26194
63 2 4.82831 3.17388 7.5729 3.21487
63 3 4.63860 3.29584 7.3000 3.25037
63 4 4.95583 3.23080 7.9288 3.17388
63 5 5.05114 3.28840 7.9772 3.26576
... more lines ...

The goal of the analysis is to study the impact of the regressors on the smoking behavior and to understand the changes in the smoking patterns in different regions over the years. Consider the following model for lsa:

\[
\text{lsales}_{i,t} = \mu_{i,t} + \text{lprice}_{t} \beta_{1} + \text{lndi}_{t} \beta_{2} + \text{lpimin}_{t} \beta_{3} + \epsilon_{i,t}
\]

This model represents lsa in a region \(i\) and in a year \(t\) as a sum of region-specific trend components \(\mu_{i,t}\), the regression effects due to lprice, lndi, and lpimin, and the observation noise \(\epsilon_{i,t}\). Different variations of this model are obtained by considering different models for the trend component \(\mu_{i,t}\). Proper modeling of the trend component is important because it captures differences between the regions because of unrecorded factors such as demographic changes over time, results of anti-smoking campaigns, and so on. The following statements specify and fit one such model:

proc ssm data=Cigar plots=residual;
  id year interval=year;
  array RegionArray{46} region1-region46;
  do i=1 to 46;
    RegionArray[i] = (region=i);
  end;
  trend IrwTrend(ll) cross(matchparm)=(RegionArray) levelvar=0;
  irregular wn;
  model lsa = lprice lndi lpimin IrwTrend wn;
  eval TrendPlusReg = IrwTrend + lprice + lndi + lpimin;
  output out=forCigar pdv press;
run;
The PROC SSM statement specifies the input data set, Cigar, which contains analysis variables such as the response variable, lsales, and the predictor variables, lprice, lndi, and lpimin. The PLOTS=RESIDUAL option in the PROC SSM statement produces residual diagnostic plots. The optional ID statement specifies a numeric index variable (often a SAS date or datetime variable), which is year in this case. The INTERVAL=YEAR option in the ID statement indicates that the measurements are collected on a yearly basis. The next few statements define a 46-dimensional array of dummy variables, RegionArray, such that RegionArray[i] is 1 if region is i and is 0 otherwise. The next three statements, TREND, IRREGULAR, and MODEL, constitute the model specification part of the program:

• trend IrwTrend(ll) cross(matchparm)=(RegionArray) levelvar=0; defines a trend, named IrwTrend, of local linear type (which is signified by the keyword ll used within the parenthesis after the name). A local linear trend—a trend with time-varying level and time-varying slope—depends on two parameters: the disturbance variance of the level equation and the disturbance variance of the slope equation (see the section “Local Linear Trend” on page 1934 for more information). The LEVELVAR=0 specification fixes the disturbance variance of the level equation to 0, which results in a trend model called an integrated random walk (IRW). An IRW model tends to produce a smoother trend than a general local linear trend. In the limiting case, if the disturbance variance of the slope equation is also 0, the IRW trend reduces to a straight line (with a fixed intercept and slope). In addition, because of the use of the 46-dimensional array, RegionArray, in the CROSS= option (cross(matchparm)=(RegionArray)), this trend specification amounts to fitting a separate IRW trend for each region. This is because, as a result of the CROSS= option, IrwTrend is treated as a linear combination of 46 (the number of variables in RegionArray) stochastically independent, integrated random walks,

\[ \text{IrwTrend}_t = \sum_{i=1}^{46} \text{RegionArray}[i] \mu_{i,t} \]

where each \( \mu_{i,t} \) is an integrated random walk. Note that since RegionArray[i] is a binary variable, IrwTrend equals \( \mu_{i,t} \) when region is i. Lastly, the use of MATCHPARM option specifies that the different IRW trends \( \mu_{i,t} \) use the same disturbance variance parameter for their slope equation. This is done mainly for parsimony. Based on the model diagnostics shown later, this appears to be a reasonable model simplification.

• irregular wn; defines the observation noise \( \epsilon_{i,t} \), named wn, as a sequence of independent, identically distributed, zero-mean, Gaussian variables—a white noise sequence.

• model lsales = lprice lndi lpimin IrwTrend wn; defines the model for lsales as a sum of regression effects that involve lprice, lndi, and lpimin, a trend term, IrwTrend, and the observation noise wn.

The last two statements, EVAL and OUTPUT, control certain aspects of the procedure output. The following EVAL statement defines a linear combination, named TrendPlusReg, of selected terms in the MODEL statement.

\[ \text{eval TrendPlusReg} = \text{IrwTrend} + \text{lprice} + \text{lndi} + \text{lpimin}; \]

This EVAL statement causes the SSM procedure to produce an estimate of TrendPlusReg (and its standard error), which can then be printed or output to a data set. TrendPlusReg contains all the terms in the model
except for the observation noise and thus can be regarded as the explanatory part of the model. In the
OUTPUT statement, you can specify an output data set that stores all the component estimates that are
produced by the procedure. The following OUTPUT statement specifies forCigar as the output data set:

```plaintext
output out=forCigar pdv press;
```

The PDV option causes variables such as region1–region46, which are defined by the DATA step statements
within the SSM procedure, also to be included in the output data set. The PRESS option causes the printing
of fit measures that are based on the delete-one cross validation errors (see the section “Delete-One Cross
Validation and Structural Breaks” on page 1930 for more information).

All the models that are specified in the SSM procedure possess a state space representation. See the section
“State Space Model and Notation” on page 1919 for more information. The SSM procedure output begins
with a table (not shown here) of the input data set that provides the name and other information. Next, the
“Model Summary” table, shown in Figure 27.1, provides basic model information, such as the following:

- the dimension of the underlying state equation, 92 (because each of the 46 IRW trends \( \mu_{i,t} \) contributes
two elements to the state)
- the diffuse dimension of the model, 95 (which is equal to the three regressors plus the 92 diffuse initial
states of \( \mu_{i,t} \))
- the number of model parameters, 2 (which is the common disturbance variance of the slope equation
in IrWTrend and the variance of the noise term \( w_n \))

This information is very useful in determining the computational complexity of the model (the larger state
size, 92, explains the relatively long computing time—as much as two minutes on some desktops—for this
example).

**Figure 27.1** Summary of the Underlying State Space Model

The index variable information is shown in Figure 27.2. Among other things, it categorizes the data to be of
the type Regular with Replication, which implies that the data are regularly spaced with respect to the ID
variable and at least some observations have the same ID value. This is clearly true in this example: the data
are yearly without any gaps, and there are 46 observations in each year—one per region.

**Figure 27.3** provides simple summary information about the response variable. It shows that \( l\)sales has no missing values and no induced missing values because the predictors in the model, \( l\)price, \( l\)ndi, and \( l\)pimin, do not have any missing values either.

</tr>
</tbody>
</table>

The regression coefficients of \( l\)price, \( l\)ndi, and \( l\)pimin are shown in **Figure 27.4**. As expected, the coefficient of \( l\)price is negative and the coefficients of \( l\)ndi and \( l\)pimin are positive, all being statistically significant. This is consistent with the expectation that the cigarette sales are adversely affected by the price and are positively correlated with the disposable income. The estimated effect of \( l\)pimin, called bootlegging effect by Baltagi and Levin (1992), is statistically significant but much smaller than the effects of \( l\)price and \( l\)ndi.

*Figure 27.5* shows the estimates of the disturbance variance of the slope equation in IrwTrend and the variance of the noise term wn. The estimate of the disturbance variance of the slope equation in IrwTrend, 0.00017, is statistically significant (being several times larger than its standard error, 0.000022). This implies that the estimated trends $\mu_{i,t}$ are not simple lines with fixed intercept and slope.

*Figure 27.6* shows a panel of residual normality diagnostic plots. These plots show that the residuals are symmetrically distributed but contain slightly larger than expected number of extreme residuals. *Figure 27.7* shows the plot of residuals versus time. There the residuals do not exhibit any obvious pattern; however, the plot does show that more extreme residuals appear before 1970 and after 1989. On the whole, however, these plots do not exhibit serious violations of model assumptions.

**Figure 27.6** Residual Normality Check
Figure 27.7 Standardized Residuals Plotted against Time

Figure 27.8 shows the details of the likelihood computations such as the number of nonmissing response values used and the likelihood of the fitted model. See the section “Likelihood Computation and Model Fitting Phase” on page 1928 for more information. Figure 27.8 shows the likelihood-based information criteria in lower-is-better format, which are useful for model comparison.

In addition to the regression estimates, it is useful to analyze the estimates of different model components such as the trend component IrwTrend and the linear combination TrendPlusReg. These estimates can be printed by using the PRINT= option provided in the TREND and EVAL statements, or they can be output to a data set (as it is done in this illustration). This latter option is particularly useful for graphical exploration of these components by standard graphical procedures such as SGPLOT and SGPANEL procedures. The following statements produce a panel of plots that shows how well the proposed model fits the observed cigarette sales in the first three regions, which correspond to Alabama, Arizona, and Arkansas. The output data set, forCigar, contains all the needed information: Smoothed_TrendPlusReg contains the smoothed (full-sample) estimate of TrendPlusReg, and Smoothed_Lower_TrendPlusReg and Smoothed_Upper_TrendPlusReg contain its 95% lower and upper confidence limits. In addition, for easy readability, a user-defined format (RegionFormat), which is created by using the FORMAT procedure (not shown), is used to associate the region names to region values.

```plaintext
proc sgpanel data=forCigar noautolegend;  
  where region <= 3;  
  format region RegionFormat.;  
  title 'Region-Specific Sales Patterns with 95% Confidence Band';  
  panelby region / columns=3;  
  band x=year lower=Smoothed_Lower_TrendPlusReg upper=Smoothed_Upper_TrendPlusReg;  
  scatter x=year y=lsales;  
  series x=year y=Smoothed_TrendPlusReg;  
run;
```
Figure 27.10 seems to indicate that the model fits the data reasonably well. It also shows that Arizona differs markedly from Alabama and Arkansas in its cigarette sales pattern over the years. The following statements produce a similar panel of plots that show the estimate of trend without the regression effects:

```plaintext
proc sgpanel data=forCigar noautolegend;
    where region <= 3;
    format region RegionFormat.;
    title 'Region-Specific Trend Estimates';
    panelby region / columns=3;
    series x=year y=smoothed_IrwTrend;
run;
```
The trend patterns, shown in Figure 27.11, seem to suggest that after accounting for the regression effects, per capita cigarette sales were on the rise in Alabama and Arkansas while they were declining in Arizona.

### Syntax: SSM Procedure

The following statements are available in the SSM procedure:
PROC SSM <options>;
   BY variables;
   COMPONENT name = (variables) * state </options>;
   EVAL name = expression </options>;
   ID variable <option>;
   IRREGULAR name <options>;
   MODEL response = variables </options>;
   OUTPUT <options>;
   PARMS variables </options>;
   Programming statements;
   STATE name(dim) <options>;
   TREND name(type) <options>;

You can specify all statements except the BY, ID, and the OUTPUT statements multiple times. The PROC SSM statement and at least one MODEL statement are required. In addition to these statements, you can use most DATA step programming statements to define new variables that are needed for specifying different parts of the state space model.

NOTE: In the statement options described throughout this section, whenever you use a list to specify the elements of the system matrices, the list elements must all be of the same type: either all of them must be variables or all of them must be numbers. In addition, if the list contains more than one variable, then they cannot be of the array type. These are not serious restrictions. When the list contains mix of variables and numbers, you can redefine the numbers as constant variables. Similarly, you can reformulate a list that contains a mix of variables of array and non-array types as just one array by combining all its elements in a new array.

### Functional Summary

Table 27.1 summarizes the statements and options that control the SSM procedure. Most commonly needed scenarios are listed; see the individual statements for additional details.

**Likelihood Optimization Process Control Options**

- Specifies the optimization technique: PROC SSM OPTIMIZER(TECH=)
- Limits the number of iterations: PROC SSM OPTIMIZER(MAXITER=)

**Outlier and Structural Break Detection Options**

- Turns on the search for additive outliers (AO): Default
- Turns on the search for structural breaks in a state subsection: STATE CHECKBREAK
- Turns on the search for structural breaks in a state subsection associated with a trend: TREND CHECKBREAK
- Specifies the significance level for additive outlier tests: OUTPUT AO(ALPHA=)
- Limits the reported number of additive outliers: OUTPUT AO(MAXNUM=)
- Limits the reported number of additive outliers to a percentage of the series length: OUTPUT AO(MAXPCT=)
- Specifies the significance level for structural break tests: OUTPUT BREAK(ALPHA=)
- Limits the reported number of structural breaks: OUTPUT BREAK(MAXNUM=)
- Limits the reported number of structural breaks to a percentage of the series length: OUTPUT BREAK(MAXPCT=)
- Turns on the search for maximal state shock: OUTPUT MAXSHOCK

**Graphical Residual and Outlier Analysis Options**

- Creates a panel of plots that consists of residual normality plots: PROC SSM PLOTS=RESIDUAL(NORMAL)
- Creates the standardized residual plot against time: PROC SSM PLOTS=RESIDUAL(STD)
- Creates a panel of plots that consists of prediction error normality plots: PROC SSM PLOTS=AO(NORMAL)
- Creates the standardized prediction error plot against time: PROC SSM PLOTS=AO(STD)

PROC SSM Statement

```
PROC SSM < options > ;
```

The PROC SSM statement is required. You can specify the following `options` in the PROC SSM statement:

- **DATA=SAS-data-set**
  specifies the name of the SAS data set that contains the variables needed for the analysis. If you do not specify this option, PROC SSM uses the most recently created SAS data set.

- **NOPRINT**
  turns off all the printing and plotting for the procedure. Any subsequent print options are ignored.

- **PLOTS < (global-plot-options) > = plot-request < (options) >**
- **PLOTS< (global-plot-options) > = ( plot-request < (options) > < ... plot-request < (options) > )**
  controls the plots produced with ODS Graphics. When you specify only one `plot-request`, you can omit the parentheses around it. Here are some examples:

  ```
  plots=none
  plots=all
  plots=residual
  plots=residual(normal)
  plots=(maxshock residual(normal))
  plots(unpack)=residual
  ```

If you do not specify any specific `plot-request`, then by default PROC SSM produces the plot of standardized residuals against time. For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” *(SAS/STAT User’s Guide)*.

**Global Plot Options:**
The `global-plot-options` apply to all relevant plots generated by the SSM procedure. The following `global-plot-option` is supported:

- **UNPACK**
  displays each graph separately. (By default, some graphs can appear together in a single panel.)

**Specific Plot Options:**
The following list describes the specific `plot-requests` and their `options`:

- **ALL**
  produces all plots appropriate for the particular analysis.

- **AO < (prediction-error-plot-options) >**
  produces the prediction error plots—one for each response variable. You can specify the following `prediction-error-plot-options`:
PROC SSM Statement

NORMAL
produces a summary panel of the prediction error diagnostics, which consist of the following:
- histogram of prediction errors
- normal quantile plot of prediction errors

STD
produces a scatter plot of standardized prediction errors against time.

MAXSHOCK
produces a scatter plot of maximal state shock statistics against time.

NONE
suppresses all plots.

RESIDUAL < (residual-plot-options) >
produces the residuals plots—one for each response variable. You can specify the following residual-plot-options:

NORMAL
produces a summary panel of the residual diagnostics, which consist of the following:
- histogram of residuals
- normal quantile plot of residuals

STD
produces a scatter plot of standardized residuals against time.

See the section “Delete-One Cross Validation and Structural Breaks” on page 1930 for more information about the precise meaning of the terms maximal state shock statistics and prediction errors.

PRINTALL
turns on all the printing options for the procedure. All subsequent NOPRINT options in the procedure are ignored.

STATEINFO
prints two tables that provide information about the composition of the state vector in terms of the components specified in the model. One table describes the composition of state $\mathbf{a}_t$, and the other table describes the diffuse vector $\mathbf{d}$ and the regressors, which are part of the initial condition specification $\mathbf{a}_1$.

See the section “State Space Model and Notation” on page 1919 for more information about the state space model notation.

OPTIMIZER( < TECHNIQUE=technique > < MAXITER=integer >)
specifies options that are associated with the optimizer used in the maximum likelihood parameter estimation. The default settings of the optimization process are adequate in most problems. However, in some cases it might be useful to change the optimization technique or to change the maximum number of iterations. You can specify one of the following techniques:
ACTIVESET corresponds to the active-set method.

DBLDOG corresponds to the double-dogleg method.

INTERIORPOINT corresponds to the primal-dual interior point method.

NEWRAP corresponds to the Newton-Raphson method.

QUANEW corresponds to the (dual) quasi-Newton method.

TRUREG corresponds to the trust region method.

The default technique is TRUREG. The INTERIORPOINT and ACTIVESET techniques are documented in Chapter 9, “The Nonlinear Programming Solver” (SAS/OR User’s Guide: Mathematical Programming) and the remaining techniques are documented in Chapter 6, “Nonlinear Optimization Methods.” You can alter the maximum number of iterations setting in the nonlinear optimization search by specifying a nonnegative integer as the MAXITER= value.

**BY Statement**

```plaintext
BY variables;
```

A BY statement can be used in the SSM procedure to process a data set in groups of observations that are defined by the BY variables. The model specified by using the MODEL and other statements is applied to all the groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The BY variables are one or more variables in the input data set. The BY variables cannot be used in the model specification; in particular, they cannot be used as response variables or regressors in a MODEL statement.

**COMPONENT Statement**

```plaintext
COMPONENT name = (var1 var2 ...) * state < / options >;
COMPONENT name = state[ integer ] < / options >;
COMPONENT name = ( Variable | Number ) * state[ integer ] < / options >;
```

The COMPONENT statement specifies a component (a linear combination of state elements), named name. You can use name later as a term in the right-hand side of the MODEL statement, which defines the observation equation. The estimate of name is output to the OUT= data set that is specified in the OUTPUT statement. In addition, you can print the component estimate by using the PRINT= option.

The first form of the COMPONENT statement defines a component as a dot product of a state subsection state and a row vector (var1 var2 ...). The value of state can be the name of a state subsection that is defined by using a STATE statement elsewhere in the program, or it can be the name of the state that is associated with a trend component defined by using a TREND statement elsewhere in the program (see the section “TREND Statement” on page 1914 for more information about the naming of the state that is associated with a trend component). The row vector (var1 var2 ...), which can be either a list of numbers or a list of variables, must be of the same dimension as the actual dimension of the state subsection. The dot product form—also called the explicit dot product form—of the component specification is unambiguous; however, it requires detailed knowledge of the state vector underlying the state specification. Suppose that mystate is a two-dimensional
state defined by a STATE statement elsewhere in the program and that \(X1\) and \(X2\) are (numeric) predictor variables. The following are valid examples of the dot product form of the COMPONENT statement:

\[
\text{component c1 = (x1 x2) } \ast \text{ mystate;}
\]
\[
\text{component c2 = (1 1) } \ast \text{ mystate;}
\]

The second and the third forms of the COMPONENT statement are a shortened version of the first form. The second form defines the component as a particular element of state—for example, state[3] defines the component as the third element of state. The specified integer must lie between 1 and \(dim\), the nominal dimension of state. The second form of component specification has another important use when the STATE statement that defines state uses the TYPE= option to set its type or when state is associated with a trend component. In these cases, the second form of the component specification assumes additional meaning when the nominal state dimension and the actual state dimensions differ (specifically the state types LL, SEASON, CYCLE, and VARMA and the states associated with all the trend types). For example, if state is a three-dimensional seasonal component, state[2] signifies an appropriate linear combination of state that results in the second of the three seasonals that constitute the three-dimensional seasonal. Similar interpretation holds for the CYCLE type. See the sections “Multivariate Season” on page 1940 and “Predefined Structural Models” on page 1936 for more information. The third form extends the second form by permitting multiplication by a variable or a number.

**NOTE:** A component that is based on a state associated with a trend component cannot be used as a right-hand side term in any MODEL statement. That is, it is defined purely for output purposes (either printed or output to a data set). However, it can be used as a term in the expression that is specified in an EVAL statement to build more complex linear combinations for output.

You can specify the following **options** to print the filtered or smoothed estimate of the component:

- **PRINT=FILTER** | **SMOOTH**
- **PRINT=(<FILTER> <SMOOTH>)**
  
  requests printing of the filtered or smoothed estimate of the specified component.

---

**EVAL Statement**

\[
\text{EVAL name = number1}\ast\text{variable1 + number2}\ast\text{variable2 + \ldots</options> ;}
\]

The EVAL statement defines a linear combination, named *name*, of the terms used in the right-hand side of a MODEL statement. You can specify any variables (for example, predictor variables and names of components) in the expression of the EVAL statement; however, you cannot specify in this expression any observation disturbances that are specified by the IRREGULAR statement. Suppose C1 and C2 are two components (defined by COMPONENT statements elsewhere in the program), T1 is a trend component, and X1 is a regression variable used in a model. The following are valid examples of the EVAL statement:

\[
\text{eval e1 = c1 - c2;}
\]
\[
\text{eval e2 = t1 + c1 + x1;}
\]
\[
\text{eval e2 = t1 + 2*c1 - 1.5*x1;}
\]

The estimates of linear combinations defined by the EVAL statement (for example, E1, E2, and E3) are output to the OUT= data set that is specified in the OUTPUT statement.

The components used in a given EVAL expression must correspond to distinct state subsections. This requirement is imposed only to simplify the overall readability of the program and does not limit the type of
linear combinations that can be specified; if two components in the right hand side of an EVAL expression share the same state subsection, a new component that combines the effect of these two components can always be defined.

In addition, you can print these estimates by using the following PRINT= options:

\[
\text{PRINT=FILTER | SMOOTH}
\]

\[
\text{PRINT=(FILTER SMOOTH)}
\]

requests printing of the filtered or smoothed estimate of the specified linear combination.

**ID Statement**

\[
\text{ID variable < option> ;}
\]

The ID statement names a numeric variable to associate a sequence value—usually related to a time stamp—to the observations in the input data set. The observations within a BY group must be ordered in ascending order by the ID variable. Often the ID variable’s values are SAS date, time, or datetime values, and each observation within a BY group has a unique ID value. Generally, however, the ID variable can be any numeric variable, and there can be multiple observations with the same ID value. If the ID values are SAS date, time, or datetime values, you can specify the associated unit of time—for example, day, week or month—by using the INTERVAL= option. If an ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID. Whenever an ID variable is specified, a variable, _ID_DELTA_, is automatically created that can be used as any input data set variable in the programming statements. _ID_DELTA_ contains the distance between two successive ID values. The first _ID_DELTA_ value is arbitrarily taken as one. If the INTERVAL= option is specified, the distance between the ID values is measured in terms of the number of intervals; therefore, for regularly spaced data, _ID_DELTA_ is identically equal to one. You can specify the following option in the ID statement:

\[
\text{INTERVAL=value}
\]

specifies the unit of time interval that is used for measuring the ID values. INTERVAL=VALUE is used in conjunction with the ID variable to check that the input data are in the proper order. For a complete discussion of the supported intervals, see Chapter 4, “Date Intervals, Formats, and Functions.”

**IRREGULAR Statement**

\[
\text{IRREGULAR name < options> ;}
\]

The IRREGULAR statement specifies a one-dimensional white noise component, which can be used to specify the observation error in a MODEL statement. You can specify the following options in the IRREGULAR statement:

\[
\text{PRINT=SMOOTH}
\]

requests printing of the smoothed estimate of the specified irregular component.

\[
\text{VARIANCE=variable | number}
\]

specifies the variance of the white noise. Any nonnegative value, including 0, is permissible. If the variable contains unknown parameters, they are estimated from the data. Similarly, if the VARIANCE option is not specified, the variance is estimated from the data.
MODEL Statement

MODEL response = variables < / options > ;

A MODEL statement specifies an observation equation that describes a response variable as a sum of regression effects and components that are defined in the program. The response variable must be a numeric variable from the input data set. The variables used in the right-hand side of the model expression can be numeric variables from the input data set, numeric variables defined by using programming statements, or names of components that are specified in the COMPONENT, TREND, or IRREGULAR statements.

For a multivariate model, a separate MODEL statement is needed for each of the response variables. In this case, the observation errors, which are specified in an IRREGULAR statement, must be different in each MODEL statement.

The components that are specified in a given MODEL statement must correspond to distinct state subsections. This requirement is imposed only to simplify the overall readability of the program and does not limit the type of models that can be specified; if two components on the right-hand side of a MODEL statement share the same state subsection, a new component that combines the effect of these two components can always be defined.

You can specify the following options to print the filtered or smoothed estimate of the response variable:

PRINT=FILTER | SMOOTH
PRINT=(< FILTER > < SMOOTH >)
requests printing of the filtered or smoothed estimate of the specified response variable. The filtered estimate is produced during the filtering phase, and the smoothed estimate is produced by the smoothing phase of the Kalman filter and smoother algorithm. The filtered estimate is also called the one-step-ahead forecast of the response variable. The smoothed estimate corresponds to the full-sample prediction of the response variable. Since the full-sample prediction of a nonmissing response value is that value itself, full-sample predictions are printed only for the missing response values.

OUTPUT Statement

OUTPUT < options > ;

The OUTPUT statement specifies an output data set to store the estimates of the model components and series forecasts. In addition, it provides options to control certain aspects of the procedure output—for example, you can control the searching of additive outliers and structural breaks by using the suboptions of the AO and BREAK options, respectively.

AO(< ALPHA=number > < MAXNUM=number > < MAXPCT=number >)
controls the additive outlier search (see the section “Delete-One Cross Validation and the Additive Outlier Detection” on page 1930 for more information). The ALPHA= suboption specifies the significance level for reporting the outliers. The default is ALPHA=0.05. The MAXNUM= suboption limits the number of outliers to search. The default is MAXNUM=5. The MAXPCT= suboption is similar to the MAXNUM= suboption. In the MAXPCT= option you can limit the number of outliers to search for according to a percentage of the series length. The default is MAXPCT=1. When you specify both of these options, the lesser of the two search numbers is used.
**ALPHA=number**
specifies the significance level of the forecast confidence intervals. For example, ALPHA=0.05, which is the default, results in a 95% confidence interval.

**BREAK(< ALPHA=number > < MAXNUM=number > < MAXPCT=number >)**
controls the structural break search (for more information, see the section “Structural Breaks in the State Evolution” on page 1931). In order for this option to have any effect, the CHECKBREAK option in one of the STATE or TREND statements, or the MAXSHOCK option in the OUTPUT statement, must be turned on. The ALPHA= suboption specifies the significance level for reporting the breaks. The default is ALPHA=0.05. The MAXNUM= suboption limits the number of breaks to search. The default is MAXNUM=5. The MAXPCT= suboption is similar to the MAXNUM= suboption. In the MAXPCT= option, you can limit the number of breaks to search for according to a percentage of the number of distinct time points in the data. The default is MAXPCT=1. When you specify both of these options, the lesser of the two search numbers is used.

**MAXSHOCK**
causes the computation of the maximal state shock chi-square statistic at each distinct time point in the input data set. These statistics are output to the data set that is specified in the OUT= option. A time series plot of these statistics is produced if the PLOTS=MAXSHOCK option is specified in the PROC SSM statement. These statistics are useful for detecting structural breaks in the state evolution process. This option can be computationally expensive for a model with large state size. See the section “Structural Breaks in the State Evolution” on page 1931 for more information.

**OUT=SAS-data-set**
specifies an output data set for the forecasts. The output data set contains the ID variable (if specified), the response variables, the one-step-ahead and out-of-sample response variable forecasts, the forecast confidence intervals, the smoothed values of the response series, and the one-step-ahead and smoothed estimates of the model components—including expressions that are defined by using the EVAL statement. See the section “OUT= Data Set” on page 1948 for more information.

**PDV**
causes the inclusion of the variables (variables in the program data vector) that are defined by using the programming statements in the SSM procedure in the OUT= data set. The parameters defined by the PARMS statement are also included. The output data set contains the values of these variables evaluated for all the rows in the input data set that is specified in the DATA= option. The parameters in the PARMS statement contain their estimated values.

**PRESS**
prints the prediction error sum of squares (PRESS) and the generalized cross validation error sum of squares (GCV). The PRESS table also reports the number of summands that are used in these sums of squares. See the section “Delete-One Cross Validation and the Additive Outlier Detection” on page 1930 for more information.

---

### PARMS Statement

```
PARMS variable=number variable=number / options;
```

The PARMS statement declares the parameters of a model and optionally sets their initial values. You can also specify the lower and upper limits of their validity range. The parameters declared by using the PARMS
statement are called named parameters throughout this chapter. A model can have additional parameters: any unspecified quantity in the model specification becomes part of the parameter vector. You can specify the following options:

\[ \text{LOWER}=(\text{number1 number2 \ldots}) \]

\[ \text{LOWER}=(\text{number}) \]

specifies the lower bounds for the specified parameters. The list can contain exactly one number, which is taken to be the lower bound for all the listed parameters in the statement, or it must contain as many values as the number of parameters specified. A missing value, denoted by \( . \), is a permissible value, which signifies that the parameter has no lower bound.

\[ \text{UPPER}=(\text{number1 number2 \ldots}) \]

\[ \text{UPPER}=(\text{number}) \]

specifies the upper bounds for the specified parameters. The list can contain exactly one number, which is taken to be the upper bound for all the listed parameters in the statement, or it must contain as many values as the number of parameters specified. A missing value, denoted by \( . \), is a permissible value, which signifies that the parameter has no upper bound.

---

**Programming Statements**

To define the model, you can use most of the programming statements that are allowed in the SAS DATA step. See the *SAS Language Reference: Dictionary* for more information. For the most part, the syntax of programming statements used in PROC SSM is identical to that used in the MODEL procedure (see Chapter 19, “The MODEL Procedure”) and the NLMIXED procedure (see Chapter 68, “The NLMIXED Procedure” (*SAS/STAT User’s Guide*)). However, there are some restrictions: the DATA step lagging and differencing functions are not allowed, and the use of character variables in the DATA step expressions is not permitted. These are not serious restrictions; usually you can overcome them by adding the variables that are created by such operations to the input data set before its use in the SSM procedure.

---

**STATE Statement**

\[ \text{STATE} \quad \text{name (dim) <options> ;} \]

The STATE statement specifies a subsection of \( \alpha_t \), the overall state vector at time \( t \) (for more information, see the section “State Space Model and Notation” on page 1919). Consider the state equations that define the state space model:

\[
\begin{align*}
\alpha_{t+1} &= T_t \alpha_t + W_{t+1} \gamma + c_{t+1} + \eta_{t+1} \\
\alpha_1 &= c_1 + A_1 \delta + W_1 \gamma + \eta_1
\end{align*}
\]

You can specify multiple STATE statements, each specifying a separate subsection. It is assumed that the subsections that are specified by using different STATE statements are mutually independent. This independence assumption implies a block-diagonal structure for the transition matrices \( T_t \) and the disturbance covariances \( Q_t \) for all \( t \geq 1 \). An appropriate block structure also applies to \( W_t \) and \( A_1 \). The options in the STATE statement provide complete control over the description of the relevant blocks of \( T_t, Q_t, W_t, \) and
Chapter 27: The SSM Procedure

A1. The argument `dim` (a positive integer in `name(dim)`) specifies the nominal dimension of this subsection. In most situations, the nominal dimension and the actual dimension of the state subsection are the same. However, when you specify the `TYPE=` option, the actual dimension of the state subsection can be different from the nominal dimension. The `TYPE=` option simplifies the state specification task for some commonly needed models.

**Note:** The `T`, `COV`, `W`, and `COV1` options, described later in this section, specify the relevant blocks of $T_t$, $Q_t$, $W_t$, and $Q_1$, respectively. The structure of these matrix blocks is described in a similar way in the option descriptions. For example, the specification `COV(I)` corresponds to the identity form, `COV(D)` corresponds to the diagonal form, and `COV(G)` corresponds to the general form of the $Q_t$ block.

You can use the following options in the `STATE` statement to specify the system matrices $T_t$, $Q_t$, $W_t$, and $A_1$ and to request printing of their estimates when they contain unknown parameters. You can also request the checking of unexpected changes—structural breaks—in the evolution of this state subsection by using the `CHECKBREAK` option.

`A1(nd)` specifies that the last `nd` elements of the state subsection be treated as diffuse. This becomes the dimension of the relevant subsection of the diffuse vector $\delta$. The $A_1$ block is created by using appropriate columns of the identity matrix. The value of `nd` must lie between 1 and the nominal dimension, `dim`. The absence of this option signifies that this subsection of $a_t$ is nondiffuse. If both the `COV1` and `A1` options are specified, the last `nd` rows and columns of the matrix specified in the `COV1` option are taken to be 0. This option cannot be used together with the `RANK=` option of the `COV1` option.

`CHECKBREAK< (ELEMENTWISE | OVERALL) >` turns on the checking of breaks for this state subsection. The `ELEMENTWISE` suboption requests the elementwise checking of any unexpected change in the state subsection as it evolves from one time point to the next. The `OVERALL` suboption requests a similar check for the entire state subsection—that is, in this case the change is measured as a multidimensional change. The `ELEMENTWISE` suboption is the default. Unless the `PRINT=BREAKDETAIL` option is specified, only a summary of the most significant breaks is produced. If the `PRINT=BREAKDETAIL` is specified, tables that contain the break significance statistics at every distinct time point are produced—one for the `ELEMENTWISE` suboption and one for the `OVERALL` suboption. For more information about the structural break detection process, see the section “Structural Breaks in the State Evolution” on page 1931. For an example of the use of the `CHECKBREAK` option, see Example 27.8.

`COV( D ) <= (var1 var2 ...) | (number1 number2 ...) >`

`COV( G ) <= (var1 var2 ...) | (number1 number2 ...) >`

`COV( I ) <= (variable) | (number) >`

`COV( RANK=integer )`
specifies the relevant block of the disturbance covariance $Q_t$ (for $t \geq 2$) in the transition equation. As with the `T` option, the absence of this option signifies that this Q-block consists of only zeros. The structure of the $Q$-block is also similarly specified. However, the following differences exist:

- The list that is specified to form the covariance must result in a symmetric, positive semidefinite matrix. For an example, see Example 27.5.
- You can specify a rank constraint on the $Q$-block by specifying `COV(RANK=integer)`, where the specified integer must lie between 1 and `dim`. A rank constraint is permissible only for the general form and only when its elements are not specified by using a list.
• The convention of treating unset variables as structural zeros, which is used in specifying sparsity of the T-block, is not used in the Q-block specification. Whenever you explicitly specify the entries of the Q-block by specifying a list of variables in parentheses, all variables in the list must evaluate to nonmissing values.

The following examples illustrate different ways of specifying a Q-block. It is assumed that \( \text{dim} = 2 \).

- \( \text{COV}(G) \) specifies a general-form Q-block, which contributes \( (2 \times (2 + 1))/2 = 3 \) unspecified elements to the parameter vector \( \theta \).
- \( \text{COV}(\text{RANK}=1) \) specifies a rank-one Q-block.

\[
\text{COV1( D ) <= (var1 var2 ...) | (number1 number2 ...)}> \\
\text{COV1( G ) <= (var1 var2 ...) | (number1 number2 ...)}> \\
\text{COV1( I ) <= (variable) | (number)}> \\
\text{COV1( RANK=integer )}
\]

specifies the relevant block of the initial state covariance \( Q_1 \). The different options in this case have the same meaning as the options of the \( \text{COV} \) option. However, the following differences exist:

- If the elements of \( Q_1 \) are specified by a list of variables in parentheses, then these variables must evaluate to constant values. In particular, they can depend on parameters that are specified by the \( \text{PARMS} \) statements; however, they cannot depend on any of the input data columns.
- If the initial condition is partially diffuse (that is, the diffuse dimension \( nd \) specified in the A1 option is nonzero), the last \( nd \) rows and columns of the matrix specified in COV1 are taken to be zero. Moreover, if the elements of \( Q_1 \) are specified by a list, its number of elements must correspond to a matrix of dimension \( (\text{dim} – nd) \).

\[
\text{PRINT=AR | BREAKDETAIL | COV | COV1 | MA | T}
\]

\( \text{PRINT=(< AR > < BREAKDETAIL > < COV > < COV1 > < MA > < T > )} \)

requests printing of the respective system matrices and the printing of the break statistics at each distinct time point. You can specify \( \text{PRINT=AR} \) or \( \text{PRINT=MA} \) only if you specify the \( \text{TYPE=VARMA} \) option. If any of these matrices are time-varying, the matrix that corresponds to the first time instance is printed. For the BREAKDETAIL suboption to have any effect, the \( \text{CHECKBREAK} \) option must be turned on.

\[
\text{SINPUT = (var1 var2 ...) | (number1 number2 ...)}
\]

specifies the relevant \( \text{dim} \)-dimensional block of the state input vector \( c_t \). The absence of this option signifies that this block of the \( c_t \) vector consists of only zeros. If the elements of \( c_t \) are specified by a list of variables in parentheses, then these variables must be independent of unknown parameters. In particular, they cannot be functions of parameters that are defined by the \( \text{PARMS} \) statements.

\[
\text{T( D ) <= (var1 var2 ...) | (number1 number2 ...)}> \\
\text{T( G ) <= (var1 var2 ...) | (number1 number2 ...)}> \\
\text{T( I ) <= (variable) | (number)}> \\
\]

specifies the relevant block of the transition matrix \( T_t \). The absence of this option signifies that this block consists of only zeros. You can specify the structure of the T-block by specifying \( \text{T(I)} \) for the identity form, \( \text{T(D)} \) for the diagonal form, and \( \text{T(G)} \) for a general unstructured form. In addition, you can explicitly specify the entries of the T-block by specifying a list of numbers in parentheses, or by
Chapter 27: The SSM Procedure

specifying in parentheses a list of variables that are defined by using the programming statements. The unspecified elements of the T-block are included in the list of parameters to be estimated from the data. If the elements of the T-block are supplied by a list in parentheses, the number of elements in the list depends on its structure. For the diagonal form, the list must contain exactly $dim$ elements. In the case of the identity form—$T(I)$—the block is already fully specified; however, a specification $T(I)=(variable)$ is understood to mean that the identity block is scaled by the specified variable (or a number). In the general case—$T(G)$—the list must consist of $dim \times dim$ elements, specified in a rowwise fashion. An inappropriate number of elements in the list results in a syntax error.

The following examples illustrate different ways of specifying the transition matrix. It is assumed that $dim = 2$.

- $T(I)$ specifies that the T-block is a two-dimensional identity matrix.
- $T(D)$ specifies that the T-block is a two-dimensional diagonal matrix. The two unspecified diagonal entries become part of the parameter vector $\theta$.
- $T(D)=(1.1 \ 2)$ fully specifies the two-dimensional diagonal T-block.
- $T(D)=(X_1 \ X_2)$ specifies a two-dimensional diagonal T-block where the diagonal elements are dynamically calculated based on the values of the variables $X_1$ and $X_2$. In this case the T-block can change with time if $X_1$ or $X_2$ changes with time.
- $T(G)$ specifies a general form T-block (with $2^2 = 4$ unspecified elements).
- $T(G)=(X_1 \ X_2 \ X_3 \ X_4)$ specifies a general form T-block where the first row is formed by $X_1$ and $X_2$, and the second row is formed by $X_3$ and $X_4$.

In practice the transition matrix is often sparse—that is, many of its elements are 0. The algorithms in the SSM procedure exploit this sparsity structure for computational efficiency. Whenever you explicitly specify the entries of the T-block by specifying a list of variables in parentheses, you can leave the variables that correspond to the zero elements unset. These unset variables are treated as structural zeros by the SSM procedure. The section “Sparse Transition Matrix Specification” on page 1924 further explains how to use this sparsity convention.

TYPE=WN

TYPE=RW

TYPE=LL (SLOPECOV(I | D | G) <= (var1, var2, ...) | (number1, number2, ...)>)

TYPE=LL (SLOPECOV( RANK=integer ) )

TYPE=SEASON (LENGTH=integer < DROPH=number-list > < KEEPH=number-list >)

TYPE=CYCLE < ( < CT > < RHO=variable | number > < PERIOD=variable | number > ) >

TYPE=VARMA ( < p < (I | D) >= integer > < q < (D) >= integer > )

specifies a state subsection that corresponds to the specified type. You can specify either a number or a variable for the RHO= and PERIOD= suboptions. When TYPE=VARMA, the autoregressive and moving average orders can be at most 1 ($0 \leq p \leq 1$ and $0 \leq q \leq 1$). Moreover, by using the D and I flags with the order specification, you can impose additional structure on the autoregressive and moving average coefficient matrices—for example, specifying TYPE=VARMA(P=1) implies a VAR(1) model with general autoregressive coefficient matrix, whereas specifying TYPE=VARMA(P(D)=1) implies a VAR(1) model with diagonal autoregressive coefficient matrix. If you specify the TYPE= option, the T, COV1, SINPUT, and A1 options are not needed. In fact they are ignored, since the transition matrix $T_t$ and the matrices in the initial condition ($Q_1$ and $A_1$) are implicitly defined by the
choice of the type. However, the COV and W options can be useful. In fact, the specification of the
COV option does play a key role in the eventual form of $Q_t$ — the covariance of the disturbance term
in the transition equation. For the types LL, CYCLE, SEASON, and VARMA, the dimension of the
resulting state subsection is a certain multiple of $\dim$, the nominal dimension in the STATE statement.
For example, the following specification results in a state subsection, named cycleState, of dimension
$2^\dim$:

```
state cycleState(dim) cov(g) type=cycle;
```

The name cycleState corresponds to the state underlying a $\dim$-dimensional cycle component. All of
these special state types require that the data be regular (replication is permissible); the only exception
is TYPE=CYCLE(CT), which defines a continuous-time cycle and is applicable to any data type.
Table 27.2 summarizes some of this information for easy reference. For more information about these
state types, see the section “Predefined Structural Models” on page 1936.

The TYPE=LL specification results in a state that corresponds to a multivariate local linear trend. It is
governed by two covariance matrices: the COV option specifies the covariance that corresponds to the
level equation, and the SLOPECOV suboption specifies the covariance used in the slope equation. The
form of the SLOPECOV suboption is exactly the same as that of the COV option.

The TYPE=CYCLE option results in a state that corresponds to a (stochastic) cycle. By default, this
cycle is assumed to be for the regular data type. If TYPE=CYCLE(CT), the resulting cycle is applicable
to any data type. The CT option is available only for $\dim = 1$; that is, only a univariate cycle is available
for the irregular data type. The cycle specification depends on a covariance matrix and two numbers:
the damping factor RHO and the cycle period PERIOD. The covariance can be specified by the COV
option. The damping factor is specified by the RHO= suboption; its value must lie between 0.0 and 1.0.
The cycle period can be specified by the PERIOD= suboption. If the CT suboption is not included, the
period value must be larger than 2.0. On the other hand, if the CT suboption is included, its value must
be strictly positive. If these parameters are not specified, they are estimated from the data.

The TYPE=SEASON(LENGTH=integer) specifies a multivariate trigonometric season that contains
the full set of harmonics (for more information, see “Multivariate Season” on page 1940). In some cases,
you might want to drop some of the harmonics from this complete set to obtain a more parsimonious
trigonometric season specification. You can use the DROPH= (to drop) or KEEPH= (to keep) suboption
to control the harmonics that are included in the season specification as follows:

```
TYPE=SEASON(
  LENGTH=integer
  |< DROPH=number-list | n TO m BY p > |
  |< KEEPH=number-list | n TO m BY p > |
)
```

The DROPH= and KEEPH= lists can include any integer between 1 and $LENGTH/2$ if the season
length is even and any integer between 1 and $(LENGTH - 1)/2$ if the season length is odd. For example,
the following specification results in a specification of a trigonometric season with a season length 12
that consists of only the first four harmonics $\xi_j, j = 1, 2, 3, 4$:

```
type=season(length=12  DROPH=5 6) ...;
```
The last two high-frequency harmonics, $\zeta_5$ and $\zeta_6$, are dropped. The DROPH= suboption cannot be used with the KEEPH= suboption.

### Table 27.2 Summary of Predefined State Types

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
<th>Parameters</th>
<th>State Dimension</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
</tbody>
</table>

$W(D) = (\text{var1 var2 ...})$

$W(G) = (\text{var1 var2 ...})$

$W(I) = (\text{variable})$

specifies the relevant block of the design matrix $W_t$ in the transition equation. The W-block is of dimension $sdim \times sg$, where $sdim$ denotes the actual dimension of the state subsection (which can be the same as $dim$, the nominal dimension, or different if the TYPE= option is used) and $sg$ denotes the desired size of the subsection of the overall state regression vector $\gamma$. As with the T option, the absence of this option signifies that this W-block consists of only zeros. The structure of the W-block is also similarly specified. The number of variables supplied in the W(G)= list option must be a multiple of $sdim$. For example, if $sdim = 4$ and the W(G)= list contains 8 variables, then the implied size of $\gamma$ subsection is 2. If the W(D)= or W(I)= option is used, then the W-block is assumed to be an $sdim$-dimensional diagonal matrix and the W(D)= list must contain exactly $sdim$ variables. For examples of the use of this option, see Example 27.8, Example 27.10, and Example 27.11.

**TREND Statement**

```
TREND name (type) <options>; 
```

The TREND statement defines a term in the model that follows a stochastic pattern of a certain predefined type. The options in the TREND statement enable you to specify a wide variety of commonly used stochastic patterns. Each TREND statement in effect stands for a special pair of STATE and COMPONENT statements. You can specify more than one TREND statement. Each separate TREND statement defines a component that is assumed to be independent of all other component specifications in the model. Very often the TREND statement is used to specify a component that captures the time-varying level of the data. However, in many cases it is also used to define components of a more general nature; for example, it can be used to define a noise component that follows a stationary ARMA model.

You can refer to the state that is associated with a TREND statement by appending the string “_state_” to the end of its name. For example, name_state_ is the state that is associated with a trend named name. You can use name_state_ in a COMPONENT statement to define a linear combination of its elements. The estimate of this linear combination can then be printed or output to a data set. The nominal dimension of name_state_ is taken to be 1, or the number of variables in the list that is specified in the CROSS= option in the TREND
TREND Statement

Some of these trend specifications are applicable to all the data types—that is, they can be used for both regular data types and irregular data types, whereas the others require that the data be regular or regular with replication. Of course, the trend specification is only part of the overall model specification. Therefore, the other parts of the model can imply additional constraints on the data type.

Table 27.3 lists the available trend models and their data requirements. The type column shows the admissible keywords that signify the particular trend type. For brevity, the Data Type column groups the data types regular and regular with replication into one category: regular. For more information about these trend models, see the section “Predefined Trend Models” on page 1933.

</tbody>
</table>

The keyword specification of different trend types, except possibly the ARIMA trend, is quite simple. For example, the following statement specifies polySpline as a trend of the type second-order polynomial spline:

```
trend polySpline(ps(2));
```

Similarly, the following statement defines dampedTrend as a damped local linear trend:

```
trend dampedTrend(dll) slopevar=x;
```

The variance parameter that governs the slope equation of this trend type is given by a variable \( x \), which must be defined elsewhere in the program. The other parameters that define dampedTrend are left unspecified (and are estimated by using the data).

The ARIMA trend specification permits specification of trends that follow an \( ARIMA(p,d,q) \times (P,D,Q)_s \) model. The specification of ARIMA models requires some notation, which is explained first.

Let \( B \) denote the backshift operator—that is, for any sequence \( \zeta_t \), \( B \zeta_t = \zeta_{t-1} \). The higher powers of \( B \) represent larger shifts (for example, \( B^3 \zeta_t = \zeta_{t-3} \)). A random sequence \( \zeta_t \) follows an \( ARIMA(p,d,q) \times (P,D,Q)_s \) model with nonseasonal autoregressive order \( p \), seasonal autoregressive order \( P \), nonseasonal differencing order \( d \), seasonal differencing order \( D \), nonseasonal moving average order \( q \), and seasonal moving average
order $Q$ if it satisfies the following difference equation, which is specified in terms of the polynomials in the backshift operator, where $a_t$ is a white noise sequence and $s$ is the season length:

$$
\phi(B)\Phi(B^s)(1 - B)^d (1 - B^s)^D \zeta_t = \theta(B)\Theta(B^s)a_t
$$

The polynomials $\phi$, $\Phi$, $\theta$, and $\Theta$ are of orders $p$, $P$, $q$, and $Q$, respectively, which can be any nonnegative integers. The season length $s$ must be a positive integer. For example, $\zeta_t$ satisfies an ARIMA(1,0,1) model (that is, $p = 1$, $d = 0$, $q = 1$, $P = 0$, $D = 0$, and $Q = 0$) if

$$
\zeta_t = \phi_1 \zeta_{t-1} + a_t - \theta_1 a_{t-1}
$$

for some coefficients $\phi_1$ and $\theta_1$ and a white noise sequence $a_t$. Similarly, $\zeta_t$ satisfies an ARIMA(0,1,1) model if

$$
\zeta_t = \zeta_{t-1} + \zeta_{t-2} - \zeta_{t-13} + a_t - \theta_1 a_{t-1} - \Theta_1 a_{t-12} + \theta_1 \Theta_1 a_{t-13}
$$

for some coefficients $\theta_1$ and $\Theta_1$ and a white noise sequence $a_t$. An ARIMA process is zero-mean, stationary, and invertible if $d = 0$, $D = 0$, and the defining polynomials $\phi$, $\Phi$, $\theta$, and $\Theta$ have all their roots outside the unit circle—that is, their absolute values are strictly larger than 1.0. It is assumed that the coefficients of the polynomials $\phi$, $\Phi$, $\theta$, and $\Theta$ are constrained so that the stationarity and invertibility conditions are satisfied. The unknown coefficients of these polynomials become part of the model parameter vector that is estimated by using the data. The general form of the ARIMA trend specification is as follows:

ARIMA(\text{\texttt{P=integer}} \text{,} \text{\texttt{D=integer}} \text{,} \text{\texttt{Q=integer}} \text{,} \text{\texttt{SP=integer}} \text{,} \text{\texttt{SD=integer}} \text{,} \text{\texttt{SQ=integer}} \text{,} \text{\texttt{S=integer}})

By default, the different orders are equal to 0 and the season length is equal to 1. The following examples illustrate a few different ARIMA trend specifications. The following statement defines ima as an integrated moving average trend:

```plaintext
trend ima(arima(d=1 q=1));
```

The following statement defines airTrend as a trend that satisfies the well-known airline model (ARIMA(0,1,1)(0,1,1)12 model) for monthly seasonal data:

```plaintext
trend airTrend(arima(d=1 q=1 sd=1 sq=1 s=12));
```

The following statement defines arma11 as a zero-mean ARMA(1,1) trend with autoregressive parameter fixed to 0.1:

```plaintext
trend arma11(arima(p=1 q=1) ar=0.1);
```

For an example of the use of the ARIMA trend specification, see Example 27.6.

You can use the following `options` in the TREND statement to specify the trend parameters and to request printing of the trend estimates. In addition, you can create a custom combination of a given trend type by specifying the CROSS= option to create a more general trend. For an example of using the CROSS= option, see the section “Getting Started: SSM Procedure” on page 1889 and the discussion of the second model in Example 27.4. You can also check for the unexpected changes in the trend component by using the CHECKBREAK option.
AR=\phi_1 \phi_2 \ldots \phi_p

lists the values of the coefficients of the nonseasonal autoregressive polynomial

\phi(B) = 1 - \phi_1 B - \ldots - \phi_p B^p

where the order \( p \) is specified in the ARIMA trend specification. The coefficients \( \phi_i \) must define a stationary autoregressive polynomial.

CHECKBREAK<( ELEMENTWISE | OVERALL )>

turns on the checking of breaks for this trend component. The ELEMENTWISE suboption requests the elementwise checking of any unexpected change in the state subsection that is associated with the trend component. The OVERALL suboption requests a similar check for the entire state subsection—that is, in this case the change is measured as a multidimensional change. The ELEMENTWISE suboption is the default. Unless the PRINT=BREAKDETAIL option is specified, only a summary of the most significant breaks is produced. If the PRINT=BREAKDETAIL is specified, tables that contain the break significance statistics at every distinct time point are produced—one for the ELEMENTWISE suboption and one for the OVERALL suboption. If the CROSS= option is specified and the CROSS= list contains more than one variable, the OVERALL suboption considers subsections that are associated with each CROSS= variable separately. For more information about the structural break detection process, see the section “Structural Breaks in the State Evolution” on page 1931.

CROSS=(var1, var2, ...)

CROSS(MATCHPARM)=(var1, var2, ...)

creates a linear combination of one or more independent trend components that is based on the variables in the list. If the parameters of the trend are specified by options such as the LEVELVAR= option or the PHI= option, these parameters are shared by these constituent trends. For example, suppose that the CROSS= list contains two variables \( X_1 \) and \( X_2 \) and the trend specification is of the type RW, the effect of \( \text{CROSS}=(X_1, X_2) \) is to create a component \( \mu_t = X_1 \mu_{1,t} + X_2 \mu_{2,t} \), where \( \mu_{1,t} \) and \( \mu_{2,t} \) are two independent random walk trends. Moreover, if the random walk trend specification uses the LEVELVAR= option to specify the variance parameter, \( \mu_{1,t} \) and \( \mu_{2,t} \) share the same variance parameter; otherwise, two separate variance parameters are assigned to these random walks. If the second form of the CROSS option, \( \text{CROSS(MATCHPARM)}= \), is used, then the constituent trends share all the relevant parameters no matter how they are specified. The CROSS= option is useful for a variety of situations. For example, suppose \( X \) is an indicator variable that is 1 before a certain time point \( t_0 \) and 0 thereafter. Then \( \text{CROSS}=(X) \) has the effect of turning off the trend component after time \( t_0 \). Similarly, suppose \( G_1 \) and \( G_2 \) are indicators for gender—for example, \( G_1 = (\text{GENDER}=1) \) and \( G_2 = (\text{GENDER}=0) \) for male and female cases, respectively. Then \( \text{CROSS}=(G_1, G_2) \) results in separate trends according to the gender. The variables in the CROSS= list must be free of unknown parameters.

The CROSS= option can be computationally expensive; computationally it is equivalent to specifying as many separate trends as the number of variables in the specified list.

LEVELVAR=variable | number

specifies the disturbance variance parameter for all the trend types. For trend types LL and DLL, this option specifies \( \sigma_1^2 \). Any nonnegative value, including 0, is permissible. If \( \text{variable} \) contains unknown parameters, they are estimated from the data. Similarly, if the LEVELVAR= option is not specified, \( \sigma^2 \) is estimated from the data.
Chapter 27: The SSM Procedure

\[
MA=\theta_1 \theta_2 \ldots \theta_q
\]
lists the values of the coefficients of the nonseasonal moving average polynomial,

\[
\theta(B) = 1 - \theta_1 B - \ldots - \theta_q B^q
\]

where the order \( q \) is specified in the ARIMA trend specification. The coefficients \( \theta_i \) must define an invertible moving average polynomial.

\section*{NODIFFUSE}
causes the diffuse elements in the initial state of the state subsection underlying the trend component to be treated as nondiffuse. This option is applicable to all trend types except ARIMA. For the ARIMA trend type, this option is ignored even if the nonseasonal or seasonal differencing orders are nonzero. The diffuse elements are assumed to be independent, zero-mean, Gaussian variables. Their variances become part of the parameter vector and are estimated by using the data. This option is useful for creating a trend component that can be interpreted as a deviation from an overall trend component (with diffuse initialization), which is defined separately.

\section*{PHI=variable | number}
specifies the value of \( \phi \) for trend types DLL, DECAY, DECAY(OU), GROWTH, and GROWTH(OU). For the type DLL, the specified value must be between 0.0 and 1.0. For types DECAY and DECAY(OU), \( \phi \) must be strictly negative. For types GROWTH and GROWTH(OU), \( \phi \) must be strictly positive. If \( \text{variable} \) contains unknown parameters, they are estimated from the data. Similarly, if the PHI= option is not specified, \( \phi \) is estimated from the data.

\section*{PRINT=breakdetail | cov | cov1 | filter | smooth | t}

\text{PRINT= (breakdetail > cov > cov1 > filter > smooth > t )}
requests printing of the respective system matrices of the state equation that underlies the specified trend, the printing of its filtered and smoothed estimates, and the printing of the break statistics at each distinct time point. For the BREAKDETAIL suboption to have any effect, the CHECKBREAK option must be turned on. If any of these matrices are time-varying, the matrix that corresponds to the first time instance is printed.

\section*{SAR=\Phi_1 \Phi_2 \ldots \Phi_P}
lists the values of the coefficients of the seasonal autoregressive polynomial

\[
\Phi(B^s) = 1 - \Phi_1 B^s - \ldots - \Phi_P B^{sp}
\]

where the order \( P \) is specified by using the SP= option in the ARIMA trend specification and the season length \( s \) is specified in the S= option. The coefficients \( \Phi_i \) must define a stationary autoregressive polynomial.

\section*{SMA=\Theta_1 \Theta_2 \ldots \Theta_Q}
lists the values of the coefficients of the seasonal moving average polynomial

\[
\Theta(B^s) = 1 - \Theta_1 B^s - \ldots - \Theta_Q B^{sQ}
\]

where the order \( Q \) is specified by using the SQ= option in the ARIMA trend specification and the season length \( s \) is specified in the S= option. The coefficients \( \Theta_i \) must define an invertible moving average polynomial.
SLOPEVAR=variable | number

specifies the second disturbance variance parameter, $\sigma^2_2$, for trend types LL and DLL. Any nonnegative value, including 0, is permissible. If variable contains unknown parameters, they are estimated from the data. Similarly, if the SLOPEVAR= option is not specified, $\sigma^2_2$ is estimated from the data.

Details

Throughout this section, vectors and matrices are denoted by boldface letters. Generally, Greek letters (such as $\alpha$, $\beta$, and $\epsilon$) denote unobserved or latent quantities—often estimated from the data—that represent model parameters, latent states, or noise variables. Capital letters such as $X$, $Y$, and $Z$ are used to denote the observed data variables. Whenever there is no ambiguity, it is assumed that the matrices have appropriate dimensions when they are being multiplied—in particular, the vectors behave as column vectors or row vectors as the need arises. On many occasions, matrices are described inline—that is, they are described as parenthesized lists, in a rowwise fashion, with the rows separated by a comma. The term “dot product” is used to describe the scalar that results from the product of a row vector with a (conforming) column vector.

State Space Model and Notation

The (linear) state space model is described in the literature in a few different ways and with varying degree of generality. The description given in this section loosely follows the description given in Durbin and Koopman (2001, chap. 6, sec. 4). This formulation of SSM is quite general; in particular, it includes nonstationary SSMs with time-varying system matrices and state equations with a diffuse initial condition (these terms are defined later in this subsection).

Suppose that observations are collected in a sequential fashion (indexed by a numeric variable $\tau$) on some variables: the vector $y = (y_1, y_2, \ldots, y_q)$, which denotes the $q$-variate response values, and the $k$-dimensional vector $x$, which denotes the predictors. Suppose that the observation instances are $\tau_1 < \tau_2 < \ldots < \tau_n$. The possibility that multiple observations are taken at a particular instance $\tau_i$ is not ruled out, and the successive observation instances do not need to be regularly spaced—that is, $(\tau_2 - \tau_1)$ does not need to equal $(\tau_3 - \tau_2)$. For $t = 1, 2, \ldots, n$, suppose $p_t \geq 1$ denotes the number of observations recorded at instance $\tau_t$. For notational simplicity, an integer-valued secondary index $t$ is used to index the data so that $t = 1$ corresponds to $\tau = \tau_1$, $t = 2$ corresponds to $\tau = \tau_2$, and so on. Consider the following model:

\[
Y_t = Z_t \alpha_t + X_t \beta + \epsilon_t \\
\alpha_{t+1} = T_t \alpha_t + W_{t+1} \gamma + c_{t+1} + \eta_{t+1} \\
\alpha_1 = c_1 + A_1 \delta + W_1 \gamma + \eta_1
\]

The following list describes these equations:

- The observation equation describes the relationship between the $(p_t \times q)$-dimensional response vector $Y_t$ and the unobserved vectors $\alpha_t$, $\beta$, and $\epsilon_t$. The $q$-variate responses are vertically stacked in a column to form this $(p_t \times q)$-dimensional response vector $Y_t$. The $m$-dimensional vectors $\alpha_t$ are called states, the $k$-dimensional vector $\beta$ is the regression coefficient vector associated with predictors $x$, and the $(p_t \times q)$-dimensional vectors $\epsilon_t$ are called the observation disturbances. The matrices $Z_t$ (of dimension...
Although this description of the state space model might appear involved, it conveniently covers many variants of the covariance matrix. However, for simplicity, the former notation is used throughout this chapter. The same comment applies to the covariance of the observation disturbances that are diagonal. In most practical situations, the model under consideration can be easily reformulated to a statistically equivalent form that conforms to this restriction.

- The state sequence \( \mathbf{a}_t \) is assumed to follow a Markovian structure described by the state transition equation and the associated initial condition.

- The state transition equation postulates that a new instance of the state, \( \mathbf{a}_{t+1} \), is obtained by multiplying its previous instance, \( \mathbf{a}_t \), by an \( m \)-dimensional square matrix \( \mathbf{T}_t \) (called the state transition matrix) and by adding three more terms: a known nonrandom vector \( \mathbf{c}_{t+1} \) (called the state input); a regression term \( \mathbf{W}_{t+1} \mathbf{y} \), where \( \mathbf{W}_{t+1} \) is an \( m \times g \)-dimensional design matrix with fully known elements and \( \mathbf{y} \) is the \( g \)-dimensional regression vector; and a random disturbance vector \( \mathbf{\eta}_{t+1} \). The \( m \)-dimensional state disturbance vectors \( \mathbf{\eta}_t \) are assumed to be independent, zero-mean, Gaussian random vectors with covariances \( \mathbf{Q}_t \) (not necessarily diagonal).

- The initial condition describes the starting condition of the state evolution equation. The starting state vector \( \mathbf{a}_1 \) is assumed to be partially diffuse: it is the sum of a known nonrandom vector \( \mathbf{c}_1 \), a mean-zero Gaussian vector \( \mathbf{\eta}_1 \), and the terms \( \mathbf{A}_1 \mathbf{\delta} \) and \( \mathbf{W}_1 \mathbf{y} \). \( \mathbf{A}_1 \mathbf{\delta} \) represents the contribution from a \( d \)-dimensional diffuse vector \( \mathbf{\delta} \) (a diffuse vector is a Gaussian vector with infinite covariance). The observation and state regression vectors \( \mathbf{\beta} \) and \( \mathbf{y} \) are also assumed to be diffuse. The \( m \times d \) matrix \( \mathbf{A}_1 \) is assumed to be completely known.

- The observation disturbances \( \mathbf{e}_t \) and the state disturbances \( \mathbf{\eta}_t \) (for \( t \geq 1 \)) are assumed to be mutually independent. Either the elements of the matrices \( \mathbf{Z}_t \), \( \mathbf{T}_t \), and \( \mathbf{Q}_t \) and the diagonal elements of the observation disturbance covariances \( \sigma^2_{t,ij} \) are assumed to be completely known, or some of them can be functions of a small set of unknown parameters (to be estimated from the data). Suppose that this unknown set of parameters is denoted by \( \mathbf{\theta} \).

- The \( d \)-dimensional diffuse vector \( \mathbf{\delta} \) from the state initial condition together with the observation and state regression vectors \( \mathbf{\beta} \) and \( \mathbf{y} \) constitute the overall \( (d+k+g) \)-dimensional diffuse initial condition of the model. See the section “Filtering, Smoothing, Likelihood, and Structural Break Detection” on page 1926 for more information.

Although this description of the state space model might appear involved, it conveniently covers many variants of the SSMs that are encountered in practice and precisely describes the most general case that can be handled by the SSM procedure. An important restriction about the preceding description of the model formulation is that it assumes that the matrices \( \mathbf{X}_t \) and \( \mathbf{W}_t \) that appear in the observation equation and the state equation respectively are free of unknown parameters and that the covariances of the observation disturbances \( \mathbf{e}_t \) are diagonal. In most practical situations, the model under consideration can be easily reformulated to a statistically equivalent form that conforms to this restriction.

**NOTE:** The transition matrix \( \mathbf{T}_t \) in the state equation relates the state \( \mathbf{a}_t \) at time \( t \) with the state \( \mathbf{a}_{t+1} \) at time \( t+1 \). In many situations, such as when the observations are taken at irregular time intervals, \( \mathbf{T}_t \) depends on information at both \( t \) and \( t+1 \). Therefore, it is more appropriate to denote the transition matrix as \( \mathbf{T}_{t;1}^{t+1} \). However, for simplicity, the former notation is used throughout this chapter. The same comment applies to the covariance matrix \( \mathbf{Q}_t \) of the disturbance term \( \mathbf{\eta}_t \).

For easy reference, Table 27.4 summarizes the information contained in the SSM equations.
Types of Sequence Data

The state space model specification in the SSM procedure requires proper understanding of both the data organization and the form of the model. The SSMs that are appropriate for time series data might not be appropriate for irregularly spaced longitudinal data. The SSM procedure distinguishes three types of data organization based on the way the observations are sequenced by the index variable. If an index variable is not specified, it is assumed that the observations are sequenced according to the observation number.

**Regular:** The observations are recorded at regularly spaced intervals; that is, \( \tau_1, \tau_2, \ldots, \tau_n \) are regularly spaced. Moreover, at each observation instance \( \tau_t \) a single observation is recorded; that is, \( p_t = 1 \) for all \( t \). The standard time series data (both univariate and multivariate) fall in this category.

**Regular with Replication:** The observations are recorded at regularly spaced intervals, but \( p_t > 1 \) for at least one \( t \). Here the word replication is used loosely—it does not mean that the multiple observations at \( \tau_t \) are replications in the precise statistical sense. The panel or cross-sectional data types fall into this category. In the panel data case with \( p \) cross-sections, \( p_t = p \) for all \( t \).

**Irregular:** The observations are not recorded at regular intervals, and the number of observations \( p_t \) at each index instance can be different. The longitudinal data fall into this category.

</table>
It is not always easy to decide whether the specified model is appropriate for the given data type. Whenever possible, the SSM procedure issues a note regarding the possible mismatch between the specified model and the data type being analyzed.

Overview of Model Specification Syntax

An SSM specification involves the description of the terms in the observation equation, the state transition equation, and the initial condition. For example, the response variables, the predictor variables, and the elements of the state transition matrix $T_t$ must somehow be specified. The SSM procedure syntax is designed so that little effort is needed to specify the more commonly needed models, while a highly flexible language is available for specifying more complex models. Two syntax features help achieve this goal: the ability to build a complex specification by combining simpler subspecifications, and a programming language for creating lists of variables to be used later in the model specification.

The SSM procedure statements can be divided into two classes:

- **programming statements**, which are used to create lists of variables that can be used for a variety purposes (for example, as the elements of the model system matrices)
- statements specific to the SSM procedure that formulate the state space model and control its other aspects such as the input data specification and the resulting output

Since the matrices involved in the model specification can be specified as lists of variables, which you separately create by using the programming statements, you can finely control all aspects of the model specification. These programming statements permit the use of most DATA step language features such as the conditional logic (IF-THEN-ELSE), array type variables, and all the mathematical functions available in the DATA step. You can also use programming statements to define predictor variables on the fly.

Building a Complex Model Specification

In addition to being able to specify the system matrices in a flexible way, you can also build a complex model specification in a modular way by combining simpler subspecifications. Suppose that the state vector for the model to be specified is composed of subsections that are statistically independent, which is a common scenario in practical modeling situations. For example, suppose that $\alpha_t$ can be divided into two disjoint subsections $\alpha^a_t$ and $\alpha^b_t$, which are statistically independent. This entails a corresponding block-diagonal structure to the system matrices $T_t$, $W_t$, and $Q_t$ that govern the state equations. In this case the term $Z_t\alpha_t$ that appears in the observation equation also splits into the sum $Z^a_t\alpha^a_t + Z^b_t\alpha^b_t$ for appropriately partitioned matrices $Z^a_t$ and $Z^b_t$. The model specification syntax of the SSM procedure makes building an SSM from such smaller pieces easy. Throughout this chapter, the linear combinations of the state subsections (such as $Z^a_t\alpha^a_t$) that appear in the observation equation are called **components**. An SSM specification in the SSM procedure is created by combining separate component specifications. In general, you specify a component in two steps: first you define a state subsection $\alpha^a_t$, and then you define a matching linear combination $Z^a_t\alpha^a_t$. For some special components, such as some commonly needed trend components, you can combine these two steps into one keyword specification.

The following list summarizes the (nonprogramming) SSM procedure syntax statements used for model specification:
• The **ID** statement specifies the index variable ($\tau$). It is assumed that the data within each BY group are ordered (in ascending order) according to the ID variable. The SSM procedure automatically creates a variable, _ID_DELTA_, which contains the difference between the successive ID values. This variable is available for use by the programming statements to define time-varying system matrices. For example, in the case of SSMs used for modeling the longitudinal data, the $T_\tau$ and $Q_\tau$ matrices often depend on _ID_DELTA_ (see Example 27.5).

• The **PARMS** statement specifies variables that serve as the parameters of the model. That is, it partially defines the model parameter vector $\mathbf{\theta}$. Other elements of $\mathbf{\theta}$ are implicitly defined if your specification of the system matrices is not fully complete.

• The **STATE** statement specifies a subsection of the model state vector. Multiple STATE statements can be used in the model specification; each one defines a statistically independent subsection of the model state vector. For full customization, $T_\tau$, $W_\tau$, and $Q_\tau$ blocks that govern this subsection can be specified as lists of variables that are created by programming statements. However, you can obtain many commonly needed state subsection types simply by using the TYPE= option in this statement. For example, the use of TYPE=SEASON(LENGTH=12) results in a state subsection that can be used to define a monthly seasonal component.

• The **COMPONENT** statement specifies a linear combination that matches a state subsection that is previously defined in a STATE statement. Thus, a matching pair of STATE and COMPONENT statements define a component.

• The **TREND** statement is used for easy specification of some commonly needed components that follow stochastic patterns of certain predefined types.

• The **IRREGULAR** statement specifies the observation disturbance for a particular response variable.

• The **MODEL** statement specifies the observation equation for one of the response variables. A separate MODEL statement is needed for each response variable in the multivariate case. The MODEL statement specifies an equation in which the left-hand side is the response variable and the right-hand side is a list that contains components and regression variables.

**Model Specification Steps**

To illustrate the model specification steps, suppose $y$ is a response variable and variables $x_1$ and $x_2$ are predictors. The following statements specify a model for $y$ that includes two components named cycle and randomWalk, predictors $x_1$ and $x_2$, and an observation disturbance named whiteNoise:

```plaintext
parms lambda / lower=(1.e-6) upper=(3.14);  
parms cycleVar / lower=(1.e-6);  
array cycleT{4} c1-c4;  
c1 = cos(lambda);  
c2 = sin(lambda);  
c3 = -c2;  
c4 = c1;  
state s_cycle(2) T(g)=(cycleT) cov(I)=(cycleVar) a1(2);  
component cycle=(1 0)*s_cycle;  
trend randomWalk(rw);  
irregular whiteNoise;  
model y = x1 x2 randomWalk cycle whiteNoise;
```
The specification begins with a PARMS statement that defines two parameters, \( \lambda \) and \( \text{cycleVar} \), along with their lower and upper bounds (essentially 0 and \( \pi \) for \( \lambda \), and 0 and infinity for \( \text{cycleVar} \)). Next, programming statements define an array of variables, \( \text{cycleT} \), which contains four variables, \( c_1-c_4 \); these variables are used later for defining the elements of the transition matrix of a state subsection. The STATE statement specifies the two-dimensional subsection \( s_{\text{cycle}} \); the dimension appears within the parentheses after the name (\( s_{\text{cycle}}(2) \)). The \( T= \) option specifies the transition matrix for the \( s_{\text{cycle}} \) (\( T(g) = (\text{cycleT}) \)); the \( g \) in \( T(g) \) signifies that the form of the \( T \) matrix is general. The \( \text{COV=} \) option (\( \text{COV} = (\text{cycleVar}) \)) specifies the covariance of the state disturbance (\( Q_t \) for \( t \geq 2 \)); because of the use of \( I \) in \( \text{COV} = (I) \), the covariance is of the form scaled identity, essentially a two-dimensional diagonal matrix with both diagonal elements equal to \( \text{cycleVar} \). The initial condition for \( s_{\text{cycle}} \) is completely diffuse because the \( A1= \) option, which specifies \( A_1 \), specifies that the dimension of the diffuse vector \( \delta \) is 2: \( a_1(2) \). In this case there is no need to specify the covariance \( Q_1 \) in the initial condition. The COMPONENT statement specifies the component cycle. It specifies cycle as a dot product of two vectors—\((1 0)\) and \( s_{\text{cycle}} \), which merely selects the first element of \( s_{\text{cycle}} \): \text{component cycle} = (1 0) * s_{\text{cycle}}. The TREND statement defines a component named randomWalk; its type is \( \text{rw} \), which signifies random walk. The IRREGULAR statement defines an observation disturbance named whiteNoise. Both the randomWalk and whiteNoise specifications are only partially complete—for example, the disturbance variance of whiteNoise is not specified. These unspecified variances, trendVar, which corresponds to randomWalk, and \( \text{wnVar} \), which corresponds to whiteNoise, are automatically included in the list of unknown parameters, \( \theta \), along with the parameters that are defined by the PARMS statements. Thus, the parameter vector for this model is \( \theta = (\lambda \ \text{cycleVar} \ \text{trendVar} \ \text{wnVar}) \). Finally, the model specification is completed by the MODEL statement, which specifies the components of the observation equation: the response variable \( y \), the predictors \( x_1 \) and \( x_2 \), the components randomWalk and cycle, and the irregular term whiteNoise.

The preceding statements result in an SSM with a three-dimensional state vector, which is the result of combining the two-dimensional state subsection, \( s_{\text{cycle}} \), and a one-dimensional subsection underlying the trend, randomWalk. In this specification, the initial state is completely diffuse with \( Q_1 \) a null matrix, and \( A_1 \) equal to the three-dimensional identity. The other state system matrices \( T_g \) and \( Q_t \) are time-invariant:

\[
T = \begin{bmatrix}
\cos(\lambda) & \sin(\lambda) & 0 \\
-\sin(\lambda) & \cos(\lambda) & 0 \\
0 & 0 & 1
\end{bmatrix}
\quad Q = \begin{bmatrix}
\text{cycleVar} & 0 & 0 \\
0 & \text{cycleVar} & 0 \\
0 & 0 & \text{trendVar}
\end{bmatrix}
\]

The observation equation is obvious with \( Z = [1 \ 0 \ 1] \).

**Sparse Transition Matrix Specification**

It often happens that the transition matrix \( T \) (or \( T_t \) in the time-varying case) specified in a STATE statement is sparse—that is, many of its elements are zero. The algorithms in the SSM procedure exploit this sparsity for computational efficiency. In most cases the sparsity of a T-block can be inferred from the context. However, if the elements of the T-block are supplied by a list of variables in parentheses, it can be difficult to recognize elements that are structurally zero (this is because of the generality of the DATA step language used for defining the variables). To simplify the specification of such sparse transition matrix, SSM procedure has adopted a convention: the variables that correspond to structural zeros can (and should) be left unset—that is, these variables are declared, but no value is assigned to them. As an example, suppose that a three-dimensional state subsection has the following form of transition matrix for some variables \( X_1, X_2, \) and \( X_3 \) defined elsewhere in the program:

\[
T = \begin{bmatrix}
X_1 & 0 & 0 \\
X_2 & X_1 & 0 \\
X_3 & 0 & X_1
\end{bmatrix}
\]
The following (incomplete) statements show how to specify such a T-block:

```plaintext
array tMat{3,3};
do i=1 to 3;
    tMat[i, i] = x1;
end;
tMat[2,1] = x2;
tMat[3,1] = x3;
state foo(3) T(g)=(tMat) ...;
```

In this specification only the nonzero elements of the `tMat` array, which contains $3 \times 3 = 9$ elements, are assigned a value. On the other hand, the following statements show an alternate way of specifying the same T-block. This specification explicitly sets the zeros in the T-block (the elements above the diagonal and `tMat[3,2]`) to 0.

```plaintext
array tMat{3,3};
do i=1 to 3;
    do j=1 to 3;
        if i=j then tMat[i, j] = x1;
        else if j > i then tMat[i, j] = 0;
    end;
end;
tMat[2,1] = x2;
tMat[3,1] = x3;
tMat[3,2] = 0;
state foo(3) T(g)=(tMat) ...;
```

The first specification is simpler, and is preferred. The second specification is mathematically equivalent (and generates the same output) but is computationally less efficient since its sparsity structure cannot always be reliably inferred due to the generality of the DATA step language. In the first specification, the unset elements are recognized to be structural zeros while the set elements are treated as nonzero for sparsity purposes. See Example 27.5 for a simple illustration. Proper sparsity specification can lead to significant computational savings for larger matrices.

### Regression Variable Specification in Multivariate Models

Suppose that a regression variable in a multivariate model affects two or more response variables. For example, suppose that response variables $y_1$ and $y_2$ depend on a regression variable $x$. This dependence can be categorized as one of two types:

- In the more common case, the regression coefficient of $x$ for $y_1$ and the regression coefficient of $x$ for $y_2$ are different. The relationship can be described as follows:

  $$
  y_1 = \beta_1 x + \text{other terms}
  $$
  $$
  y_2 = \beta_2 x + \text{other terms}
  $$

  In the SSM procedure you can specify this type of relationship in two equivalent ways:

  - You can specify the variable $x$ in the MODEL statement for $y_1$ and specify the variable $x_copy$ (a copy of $x$) in the MODEL statement for $y_2$ as follows:
x_copy = x; /* create a copy of x */
model y1 = x ...;
model y2 = x_copy ...;

You can specify the variable x in MODEL statements for both y1 and y2 as follows:
model y1 = x ...;
model y2 = x ...;

This specification avoids creating x_copy.

Of these two alternate ways, the first is preferred because x and x_copy can then be unambiguously used in an EVAL statement to refer to the terms β_1 x and β_2 x, respectively.

• In the less common case, y1 and y2 share a common regression coefficient. The relationship can be described as follows:

  y1 = β x + other terms
  y2 = β x + other terms

You can specify this type of relationship by placing the regression coefficient in the model state vector as follows:

| state beta(1) T(I) A1(1); /* beta is a constant state */ |
| comp xeffect = beta*(x); |
| model y1 = xeffect ...; |
| model y2 = xeffect ...; |

Here the STATE statement defines beta as a one-dimensional, time-invariant constant (because the transition matrix is identity, the disturbance covariance is 0 and the initial state is diffuse). Next, the COMP statement defines xeffect as the product between beta and the variable x. Subsequently, both y1 and y2 use xeffect in their respective MODEL statements.

Filtering, Smoothing, Likelihood, and Structural Break Detection

The Kalman filter and smoother (KFS) algorithm is the main computational tool for using SSM for data analysis. This subsection briefly describes the basic quantities generated by this algorithm and their relationship to the output generated by the SSM procedure. For proper treatment of SSMs with a diffuse initial condition or when regression variables are present, a modified version of the traditional KFS, called diffuse Kalman filter and smoother (DKFS), is needed. A good discussion of the different variants of the traditional and diffuse KFS can be found in Durbin and Koopman (2001). The DKFS implemented in the SSM procedure closely follows the treatment in de Jong and Chu-Chun-Lin (2003). Additional details can be found in these references.

The state space model equations (see the section “State Space Model and Notation” on page 1919) imply that the combined response data vector \( \mathbf{Y} = (Y_1, Y_2, \ldots, Y_n) \) has a Gaussian probability distribution. This probability distribution is proper if \( d \), the dimension of the diffuse vector \( \mathbf{b} \) in the initial condition, is 0 and if \( (k + g) \), the total number of regression variables in the observation and state equations, is also 0 (the regression vectors \( \mathbf{B} \) and \( \mathbf{y} \) are also treated as a diffuse vectors). Otherwise, this probability distribution is improper. The KFS algorithm is a combination of two iterative phases: a forward pass through the data, called filtering, and a backward pass through the data, called smoothing, that uses the quantities generated
Filtering Pass

The filtering pass sequentially computes the quantities shown in Table 27.5 for \( t = 1, 2, \ldots, n \) and \( i = 1, 2, \ldots, q \star p_t \).

**Table 27.5** KFS: Filtering Phase

<table>

</tbody>
</table>

Here the notation \( \text{E}(y_{t,i} | y_{t,i-1}, \ldots, y_{t,1}, Y_{t-1}, \ldots, Y_1) \) denotes the *conditional expectation* of \( y_{t,i} \) given the history up to the index \((t, i - 1): (y_{t,i-1}, \ldots, y_{t,1}, Y_{t-1}, \ldots, Y_1)\). Similarly \( \text{Var}(y_{t,i} | y_{t,i-1}, \ldots, y_{t,1}, Y_{t-1}, \ldots, Y_1) \) denotes the corresponding conditional variance. The quantity \( v_{t,i} = y_{t,i} - \hat{y}_{t,i} \) is set to missing whenever \( y_{t,i} \) is missing. Note that \( \hat{y}_{t,i} \) are *one-step-ahead* forecasts only when the model has only one response variable and the data are a time series; in all other cases it is more appropriate to call them *one-measurement-ahead* forecasts (since the next measurement might be at the same time point). Despite this, \( \hat{y}_{t,i} \) are called one-step-ahead predictions (and \( v_{t,i} \) are called one-step-ahead residuals) throughout this document. In the diffuse case, the conditional expectations must be appropriately interpreted. The vector \( b_{t,i} \) and the matrix \( S_{t,i} \) contain some accumulated quantities that are needed for the estimation of \( \delta, \beta, \gamma \). Of course, when \((d + k + g) = 0\) (the nondiffuse case), these quantities are not needed. In the diffuse case, because the matrix \( S_{t,i} \) is sequentially accumulated (starting at \( t = 1, i = 1 \)), it might not be invertible until some \( t = t_*, i = i_* \). The filtering process is called *initialized* after \( t = t_*, i = i_* \). In some situations, this initialization might not happen even after the entire sample is processed—that is, the filtering process remains *uninitialized*. This can happen if the regression variables are collinear or if the data are not sufficient to estimate the initial condition \( \delta \) for some other reason.

The filtering process is used for a variety of purposes. One important use of filtering is to compute the likelihood of the data. In the model-fitting phase, the unknown model parameters \( \theta \) are estimated by maximum likelihood. This requires repeated evaluation of the likelihood at different trial values of \( \theta \). After \( \theta \) is estimated, it is treated as a known vector. The filtering process is used again with the fitted model in the forecasting phase, when the one-step-ahead forecasts and residuals based on the fitted model are provided. In addition, this filtering output is needed by the smoothing phase to produce the full-sample component estimates and for the structural break analysis.
Likelihood Computation and Model Fitting Phase

In view of the Gaussian nature of the response vector, the likelihood of $Y$ can be computed by using the prediction-error decomposition. In the diffuse case the definition of the likelihood depends on the treatment of the diffuse quantities—$\delta$, $\beta$, and $y$. In the SSM procedure a likelihood called the diffuse-likelihood, $L_d(Y, \theta)$, is used for parameter estimation. In the literature the diffuse likelihood is also called the restricted-likelihood. The diffuse likelihood is computed by treating the diffuse quantities as zero-mean, Gaussian, random variables with infinite variance (that is, they have diffuse distribution). In terms of the quantities described in Table 27.5 the diffuse likelihood is defined as follows:

$$-2 \log L_d(Y, \theta) = N_0 \log 2\pi + \sum_{t=1}^{n} \sum_{i=1}^{q} \left( \log F_{t,i} + \frac{y_{t,i}^2}{F_{t,i}} \right) - \log(|S_{n,p_n}^{-1}|) - b_{n,p_n}^t S_{n,p_n}^{-1} b_{n,p_n}$$

where $N_0 = (N - k - g - d)$, $|S_{n,p_n}^{-1}|$ denotes the determinant of $S_{n,p_n}^{-1}$, and $b_{n,p_n}^t$ denotes the transpose of the column vector $b_{n,p_n}$. In the preceding formula, the terms that are associated with the missing response values $y_{t,i}$ are excluded and $N$ denotes the total number of nonmissing response values in the sample. If $S_{n,p_n}$ is not invertible, then a generalized inverse is used in place of $S_{n,p_n}^{-1}$, and $|S_{n,p_n}^{-1}|$ is computed based on the nonzero eigenvalues of $S_{n,p_n}$. Moreover, in this case $N_0 = N - \text{Rank}(S_{n,p_n})$. When $(d + k + g) = 0$, the terms that involve $S_{n,p_n}$ and $b_{n,p_n}$ are absent.

In addition to reporting the diffuse likelihood, the SSM procedure reports a variant of the likelihood called the profile likelihood. The profile likelihood is computed by treating the diffuse quantities—$\delta$, $\beta$, and $y$—as unknown parameters (similar to $\theta$). Interestingly, the quantities that are described in Table 27.5 play a key role in the computation of this variant of the likelihood also. It turns out that the filtering process yields the maximum likelihood (ML) estimates of $\delta$, $\beta$, and $y$ conditional on the remaining parameters of the model—$\theta$. Moreover, the likelihood that is evaluated at the ML estimates of $\delta$, $\beta$, and $y$—that is, the likelihood from which these parameters are profiled out—has the following expression:

$$-2 \log L_p(Y, \theta) = N \log 2\pi + \sum_{t=1}^{n} \sum_{i=1}^{q} \left( \log F_{t,i} + \frac{y_{t,i}^2}{F_{t,i}} \right) - b_{n,p_n}^t S_{n,p_n}^{-1} b_{n,p_n}$$

Note that, computationally, the profile likelihood differs from the diffuse likelihood in only two respects: the constant term involves $N$—the total number of nonmissing response values—rather than $N_0$, and the log-determinant term $\log(|S_{n,p_n}^{-1}|)$ is absent. However, in terms of theoretical considerations, the diffuse likelihood and the profile likelihood differ in an important way. It can be shown that the diffuse likelihood corresponds to the (nondiffuse) likelihood of a suitable transformation of $Y$. The transformation is chosen in such a way that the distribution of the transformed data no longer depends on the initial condition $\delta$ and the regression vectors $\beta$ and $y$. In this sense, the diffuse likelihood is a pseudo-likelihood of the original data $Y$. The profile likelihood, on the other hand, does not involve any data transformation and can be considered as the likelihood of the original data $Y$. Of course, if the state space model for $Y$ does not involve any diffuse quantities, then the two likelihoods are the same.

As noted earlier, the SSM procedure does not use the profile likelihood for parameter estimation. When the model specification contains any unknown parameters $\theta$, they are estimated by maximizing the diffuse likelihood function. This is done by using a nonlinear optimization process that involves repeated evaluations of $L_d(Y, \theta)$ at different values of $\theta$. The maximum likelihood (ML) estimate of $\theta$ is denoted by $\hat{\theta}$. Because the diffuse likelihood is also called the restricted likelihood, $\hat{\theta}$ is sometimes called the restricted maximum likelihood (REML) estimate. Approximate standard errors of $\hat{\theta}$ are computed by taking the square root of the diagonal elements of its (approximate) covariance matrix. This covariance is computed as $-H^{-1}$, where $H$ is the Hessian (the matrix of the second-order partials) of $\log L_d(Y, \theta)$ evaluated at the optimum $\theta$. It is known
that the ML (or REML) estimate of \( \theta \) based on the diffuse likelihood as well as the profile likelihood is consistent and efficient under mild regularity assumptions (as the number of distinct time points tend toward infinity). In addition, it is known that the estimate based on the diffuse likelihood is better in terms of having smaller bias.

Let \( \text{dim}(\theta) \) denote the dimension of the parameter vector \( \theta \). After the parameter estimation is completed, PROC SSM prints the “Likelihood Computation Summary” table, which summarizes the likelihood calculations at \( \hat{\theta} \), as shown in Table 27.6.

In addition, the information criteria based on the diffuse likelihood and the profile likelihood are also reported. A variety of information criteria are reported. All these criteria are functions of twice the negative likelihood, \(-2 \log L\) (the likelihood can be either diffuse or profile); \( N_* \), the effective sample size; and \( n_{parm} \), the effective number of model parameters. For the information criteria based on the diffuse likelihood, the effective sample size \( N_* = N_0 \) and the effective number of model parameters \( n_{parm} = \text{dim}(\theta) \). For the information criteria based on the profile likelihood, the effective sample size \( N_* = N \) and the effective number of model parameters \( n_{parm} = \text{dim}(\theta) + d + k + g \). Table 27.7 summarizes the reported information criteria in smaller-is-better form.

### Forecasting Phase

After the model-fitting phase, the filtering process is repeated again to produce the model-based one-step-ahead response variable forecasts \( \hat{y}_{t,i} \), residuals \( \hat{\nu}_{t,i} \), and their standard errors \( \sqrt{F_{t,i}} \). In addition, one-step-ahead forecasts of the components that are specified in the MODEL statements, and any other user-defined linear combinations of \( \alpha_t \), are also produced. These forecasts are set to missing as long as the index \( t < t_* \) (that is, until the filtering process is initialized). If the filtering process remains uninitialized, then all the quantities that are related to the one-step-ahead forecast (such as \( \hat{y}_{t,i} \) and \( \hat{\nu}_{t,i} \)) are reported
as missing. When the fitted model is appropriate, the one-step-ahead residuals $v_{t,i}$ form a sequence of uncorrelated normal variates. This fact can be used during model diagnostic process.

**Smoothing Phase**

After the filtering phase of KFS produces the one-step-ahead predictions of the response variables and the underlying state vectors, the smoothing phase of KFS produces the full-sample versions of these quantities—that is, rather than using the history up to $(t,i-1)$, the entire sample $Y$ is used. The smoothing phase of KFS is a backward algorithm, which begins at $t = n$ and $i = q * p_n$ and goes back toward $t = 1$ and $i = 1$.

It produces the following quantities:

<table>
<thead>
<tr>
<th>Quantity</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>$\tilde{y}_{t,i}$</td>
<td>E($y_{t,i}</td>
</tr>
<tr>
<td>$\tilde{F}_{t,i}$</td>
<td>Var($y_{t,i}</td>
</tr>
<tr>
<td>$\tilde{\alpha}_t$</td>
<td>E($\alpha_t</td>
</tr>
<tr>
<td>$\tilde{P}_t$</td>
<td>Cov($\alpha_t</td>
</tr>
<tr>
<td>$(\hat{\delta}, \hat{\beta}, \hat{\gamma})$</td>
<td>$S_{n,p_n}^{-1} b_{n,p_n}$ Full-sample estimates of $\delta, \beta$, and $\gamma$</td>
</tr>
<tr>
<td>$S_{n,p_n}^{-1}$</td>
<td>Covariance of $(\hat{\delta}, \hat{\beta}, \hat{\gamma})$</td>
</tr>
</tbody>
</table>

Note that if $y_{t,i}$ is not missing, then $\tilde{y}_{t,i} = E(y_{t,i}|Y) = y_{t,i}$ and $\tilde{F}_{t,i} = \text{Var}(y_{t,i}|Y) = 0$ because $y_{t,i}$ is completely known, given $Y$. Therefore, $\tilde{y}_{t,i}$ provides nontrivial information only when $y_{t,i}$ is missing—in which case $\tilde{y}_{t,i}$ represents the best estimate of $y_{t,i}$ based on the available data. The full-sample estimates of components that are specified in the model equations are based on the corresponding linear combinations of $\tilde{\alpha}_t$. Similarly, their standard errors are computed by using appropriate functions of $\tilde{P}_t$.

If the filtering process remains uninitialized until the end of the sample (that is, if $S_{n,p_n}$ is not invertible), some linear combinations of $\tilde{\alpha}_t$ are also inestimable. These inestimable quantities are reported as missing. For more information about the estimability of the state effects, see Selukar (2010).

**Delete-One Cross Validation and Structural Breaks**

In addition to the interpolation of missing response values and the full-sample estimation of components in the model, the smoothing phase can also produce several useful diagnostic measures that can indicate outlying observations and breaks in the state evolution process. The treatment of additive outliers and structural breaks that is described in this section is based on de Jong and Penzer (1998).

**Delete-One Cross Validation and the Additive Outlier Detection**

Let $AO_{t,i} = y_{t,i} - E(y_{t,i}|Y^{t,i})$ denote the difference between the observed response value $y_{t,i}$ and its estimate or prediction by using all the data except $y_{t,i}$, which is denoted by $Y^{t,i}$. The smoothing phase of DKFS can generate $AO_{t,i}$ (and its variance) at all $(t,i)$. A large value of $AO_{t,i}$ signifies that the observed response value ($y_{t,i}$) is unusual relative to the rest of the sample (according to the postulated model). Such values are called additive outliers. In the literature, $AO_{t,i}$ are referred by a few different names. Sometimes they are called delete-one cross validation errors or simply prediction errors. In this chapter, these names are
Filtering, Smoothing, Likelihood, and Structural Break Detection

Like the one-step-ahead residuals, $v_{t,i}$, the prediction errors can be used in checking the adequacy of the model. The prediction errors are normally distributed; however, unlike $v_{t,i}$, they are not serially uncorrelated. $AO_{t,i}$ is set to missing when $y_{t,i}$ is missing. The SSM procedure prints a summary table of extreme additive outliers by default. In addition, you can request the plotting of the standardized prediction errors, and they can be output to a data set.

The prediction error sum of squares (PRESS)

$$\sum_{t,i} AO_{t,i}^2$$

can be a useful measure of fit to compare different models. It is also called the cross validation error sum of squares. An additional measure of fit based on the prediction errors is called the generalized cross validation error sum of squares (GCV). Denoting the variance of $AO_{t,i}$ by $VAR_{AO_{t,i}}$, it is defined as

$$\frac{\sum_{t,i}(AO_{t,i}^2/VAR_{AO_{t,i}})}{[\sum_{t,i}(1/VAR_{AO_{t,i}})]^2}$$

You can request the printing of PRESS and GCV by specifying the PRESS option in the OUTPUT statement.

After inspecting the reported additive outliers, you can adjust the model to account for the effects of some of the extreme outlying observations. This can be done by including appropriate dummy variables in the observation equation.

**Structural Breaks in the State Evolution**

The additive outliers that are discussed in the preceding section are diagnostic measures associated with the measurement equation. The smoothing phase of DKFS can generate diagnostic measures that are also associated with the state equation.

For simplicity of notation and exposition, initially assume that the state equation has the following form:

$$\alpha_{t+1} = T_{t}\alpha_t + c_{t+1} + \eta_{t+1}$$

That is, the state regression term $W_{t+1}y$ is absent in the postulated model. Suppose that an unanticipated change of unknown size takes place in the $i$th element of the state at time $(t_0 + 1)$. The model can then be adjusted to account for this change by including a suitable dummy regressor in the state equation as follows:

$$\alpha_{t+1} = T_{t}\alpha_t + W_{t+1}y + c_{t+1} + \eta_{t+1}$$

Here $W_t$ is a sequence of $m$-dimensional column vectors such that $W_{t_0+1}[i_0] = 1$ and $W_{t}[i] = 0$ for all other $t$ and $i$. The estimate of the regression coefficient $y$ provides information about the size of the unanticipated change in the $i$th element of $\alpha_t$ at time $t = t_0 + 1$. Similarly, an unanticipated change in a subsection of $\alpha_t$ at a time $t = t_0 + 1$ can be estimated by using a set of appropriate dummies (the number of dummies equals the number of elements in the state subsection) in the state equation. The algorithm of de Jong and Penzer (1998) efficiently generates the estimates of such one-time changes in the state at all distinct time points in the sample in one smoothing pass. A statistically significant value of $y$ at a time point $t_0$ indicates an unanticipated change in the relevant element (or the subsection) of $\alpha_{t_0}$. Note that the change associated with an additive outlier is temporary: the previous or the subsequent measurements are not affected. On the other hand, because of the evolutionary nature of the state equation, a one-time change in the state affects all the subsequent states, which in turn affect the subsequent observations. In this sense, a significant unanticipated change in the state is a structural break.
In the preceding discussion, the absence of the state regression variables in the postulated model was assumed only for notational simplicity. If the postulated model does contain some state regression variables, the dummy variable that is associated with the one-time state change is simply added to the existing set of state regression variables, and the interpretation of its regression coefficient as the measure of unanticipated change in the state remains unaffected.

In the SSM procedure, you can request the computation of significance statistics that are associated with one-time changes in the state subsections specified by using the STATE statement in addition to the state subsections that are associated with the components specified by using the TREND statements. This is done by using the CHECKBREAK option in these statements. In addition, you can request the computation of such statistics for the entire state $\alpha_t$ by using the MAXSHOCK option in the OUTPUT statement. The significance statistics can be computed for both elementwise change and subsectionwise change. The computation of subsectionwise change statistics can be computationally expensive for large subsections (an inversion of a $p \times p$-dimensional matrix at each distinct time point in the sample is needed for the computation of significance statistics for a state subsection of size $p$). For an example of structural break analysis, see Example 27.8.

Estimation of User-Specified Linear Combination of State Elements

By default, the SSM procedure computes the estimates of all the components that are specified in the MODEL statements (you can print these estimates by using the PRINT= option in the respective TREND and COMPONENT statements, or you can output these estimates to a data set by specifying it in the OUT= option in the OUTPUT statement). However, in many cases it is desirable to obtain the estimates of additional linear combinations of the state elements and the regression effects. The SSM procedure provides two statements, the COMPONENT statement and the EVAL statement, that are useful for specifying virtually any desired linear combination of the elements of the state vector and the regression effects in the observation equation. After a desired linear combination is specified, you can print or output its estimate as you would for a component that is used in the MODEL statement. This feature of the SSM procedure is illustrated in many examples in the section “Examples: SSM Procedure” on page 1949. For example, in the second part of Example 27.4, the COMPONENT and EVAL statements are used to define the contrasts between the growth profiles of cows that are receiving different treatments. Similarly, in Example 27.7, the EVAL statement is used to define the yield curve as a sum of the components that are used in the MODEL statement.

Contrasting PROC SSM with Other SAS Procedures

The SSM procedure complements several SAS/ETS procedures and the MIXED procedure in SAS/STAT software (see Chapter 63, “The MIXED Procedure” (SAS/STAT User’s Guide)). The statistical models underlying all these procedures can be formulated as state space models; however, in many cases this formulation effort can be considerable. Generally speaking, when a problem can be formulated and satisfactorily solved either by using the SSM procedure or by using one of these other procedures, the other procedures are likely to be more efficient. However, in many instances, the SSM procedure can solve more general problems or offer more detailed analysis, or both. Throughout this discussion, it is assumed that the problem being solved can be modeled as a linear statistical model with Gaussian response variables. In particular, situations that require models such as autoregressive conditional heteroscedasticity (ARCH) models, and models with categorical response variables are not considered. The following list provides a more specific comparison of the SSM procedure with different procedures:
Predefined Trend Models

The statistical models that govern the predefined trend components available in the SSM procedure are divided into two groups: models that are applicable to equally spaced data (possibly with replication), and models that are applicable more generally (the irregular data type). Each trend component can be described as a dot product $Z\alpha_t$ for some (time-invariant) vector $Z$ and a state vector $\alpha_t$. The component specification is complete after the vector $Z$ is specified and the system matrices that govern the equations of $\alpha_t$ are specified. For trend models for regular data, all the system matrices are time-invariant. For irregular data, $T_t$ and $Q_t$ depend on the spacing between the distinct time points: $(\tau_{t+1} - \tau_t)$.

Trend Models for Regular Data

These models are applicable when the data type is either regular or regular with replication. A good reference for these models is Harvey (1989).

Random Walk Trend

This model provides a trend pattern in which the level of the curve changes with time. The rapidity of this change is inversely proportional to the disturbance variance $\sigma^2$ that governs the underlying state. It can be
described as $Z\alpha_t$, where $Z = (1)$ and the (one-dimensional) state $\alpha_t$ follows a random walk:

$$\alpha_{t+1} = \alpha_t + \eta_{t+1}, \quad \eta_t \sim N(0, \sigma^2)$$

Here $T = 1$ and $Q = \sigma^2$. The initial condition is fully diffuse. Note that if $\sigma^2 = 0$, the resulting trend is a fixed constant.

**Local Linear Trend**

This model provides a trend pattern in which both the level and the slope of the curve change with time. This variation in the level and the slope is controlled by two parameters: $\sigma_1^2$ controls the level variation, and $\sigma_2^2$ controls the slope variation. If $\sigma_1^2 = 0$, the resulting trend is called an integrated random walk. If both $\sigma_1^2 = 0$ and $\sigma_2^2 = 0$, then the resulting model is the deterministic linear time trend. Here $Z = (1\ 0)$, $T = (1\ 1\ 0\ 1)$, and $Q = \text{Diag}(\sigma_1^2, \sigma_2^2)$. The initial condition is fully diffuse.

**Damped Local Linear Trend**

This trend pattern is similar to the local linear trend pattern. However, in the DLL trend the slope follows a first-order autoregressive model, whereas in the LL trend the slope follows a random walk. The autoregressive parameter or the damping factor, $\phi$, must lie between 0.0 and 1.0, which implies that the long-run forecast according to this pattern has a slope that tends to 0. Here $Z = (1\ 0)$, $T = (1\ 1\ 0\ \phi)$, and $Q = \text{Diag}(\sigma_1^2, \sigma_2^2)$. The initial condition is partially diffuse with $Q_1 = \text{Diag}(0, \sigma_2^2/(1 - \phi \times \phi))$.

**ARIMA Trend**

This section describes the state space form for a component that follows an ARIMA($p,d,q$)$\times$(P,D,Q)$_s$ model. The notation for ARIMA models is explained in the TREND statement.

First the state space form for the stationary case—that is, when $d = 0$ and $D = 0$, is explained. A number of alternate state space forms are possible in this case; the one described here is based on Jones (1980). With slight abuse of notation, let $p = p + s \times P$ denote the effective autoregressive order, and let $q = q + s Q$ denote the effective moving average order of the model. Similarly, let $\phi$ be the effective autoregressive polynomial, and let $\theta$ be the effective moving average polynomial in the backshift operator with coefficients $\phi_1, \ldots, \phi_p$ and $\theta_1, \ldots, \theta_q$, obtained by multiplying the respective nonseasonal and seasonal factors. Then, a random sequence $\xi_t$ that follows an ARMA($p,q$)$\times$(P,Q)$_s$ model with a white noise sequence $a_t$ has a state space form with state vector of size $m = \max(p, q + 1)$. The system matrices are as follows: $Z = [1\ 0\ \ldots\ 0]$, and the transition matrix $T$, in a blocked form, is given by

$$T = \begin{bmatrix} 0 & I_{m-1} \\ \phi_m & \ldots & \phi_1 \end{bmatrix}$$

where $\phi_i = 0$ if $i > p$ and $I_{m-1}$ is an $(m - 1)$ dimensional identity matrix. The covariance of the state disturbance matrix $Q = \sigma^2 \psi \psi'$, where $\sigma^2$ is the variance of the white noise sequence $a_t$ and the vector $\psi = [\psi_0 \ldots \psi_{m-1}]$ contains the first $m$ values of the impulse response function—that is, the first $m$ coefficients in the expansion of the ratio $\theta/\phi$. The covariance matrix of the initial state, $Q_1$, is computed as

$$\text{vec}(Q_1) = (I - T \otimes T)^{-1} \text{vec}(Q)$$

where $\otimes$ denotes the Kronecker product and the $\text{vec}$ operation on a matrix creates a vector formed by vertically stacking the rows of that matrix.

A number of alternate state space forms are possible in the nonstationary case also. The form used by the SSM procedure utilizes the state space form for the stationary case as a building block. Suppose that a random
sequence $\xi_t$ follows an ARIMA($p,d,q$)$\times$(P,D,Q), model with a white noise sequence $a_t$. As in the notation for the stationary case, with slight abuse of notation, let $d = d + s \ast D$ denote the effective differencing order, and let $\Delta$ be the effective differencing polynomial in the backshift operator with coefficients $\Delta_1, \ldots, \Delta_d$. It can be shown that $\xi_t$ has a state space form with state vector size $m^\dagger = m + d$. In what follows, the system matrices and related quantities in the nonstationary case are described in terms of similar entities in the stationary case. A superscript dagger ($\dagger$) has been added to distinguish the entities from the nonstationary case.

$Z^\dagger = [0 \ 0 \ \ldots \ 1 \ \ldots \ 0]$ where the only nonzero value, 1, is at the index $m + 1$, and the transition matrix, $T^\dagger$, in a blocked form, is given by

$$T^\dagger = \begin{bmatrix} T & 0 & 0 \\ ZT & \Delta_1 \ldots & \Delta_d \\ 0 & I_{d-1} & 0 \end{bmatrix}$$

The state disturbance matrix $Q^\dagger$ is given by

$$Q^\dagger = \begin{bmatrix} Q & QZ' & 0 \\ ZQ & ZQZ' & 0 \\ 0 & 0 & 0 \end{bmatrix}$$

Finally, the initial state is partially diffuse: the first $m$ elements are nondiffuse and the last $d$ elements are diffuse. The covariance matrix of the first $m$ elements is $Q_1$.

**Trend Models for Irregular Data**

A good reference for these models is de Jong and Mazzi (2001). Throughout this section $h_t = (t_{r+1} - t_t)$ denotes the difference between the successive time points. The system matrices $T_t$ and $Q_t$ that govern these models depend on $h_t$. However, whenever the notation is unambiguous, the subscript $t$ is omitted.

**Polynomial Spline Trend**

This model is a general-purpose tool for extracting a smooth trend from the noisy data. The order of the spline governs the order of the local polynomial that defines the spline. The order-1 spline corresponds to Brownian motion (continuous-time random walk), the order-2 spline corresponds to integrated Brownian motion (continuous-time integrated random walk), and the order-3 spline provides a locally quadratic trend; the default order is 1. The dimension of the state underlying this component is the same as the order of the spline. The system matrices for the orders up to 3 are described as follows (in all the cases the initial condition is fully diffuse):

- order-1 spline: $Z = (1), T = (1), \text{ and } Q = \sigma^2(h)$
- order-2 spline: $Z = (1 0), T = (1 \ h, \ 0 \ 1), \text{ and } Q = \sigma^2\left(\frac{h^3}{3}, \frac{h^2}{2}, \frac{h^2}{2}, \ h\right)$
- order-3 spline: $Z = (1 0 0), T = \begin{pmatrix} 1 & h \ h^2/2 & 0 & 1 & h, 0 & 0 & 1 \end{pmatrix}$, and

$$Q[i, j] = \sigma^2 \ast \frac{h^{6-i-j+1}}{(6-i-j+1)(3-i)!(3-j)!} \ \text{ for } 1 \leq i, j \leq 3$$

The system matrices for higher orders are similarly defined (for more information, see de Jong and Mazzi (2001)).
Note that, in addition to providing an estimate of the trend, this methodology can provide estimates of the higher-order derivatives of the trend. If \( \alpha \) denotes the \( k \)-dimensional subsection that is associated with a polynomial spline of order \( k \), then its \( j \)th element (\( 1 \leq j \leq k \)), \( \alpha[j] \), corresponds to the derivative of order \( (j - 1) \) of this polynomial spline. For an example of the estimation of the first derivative of a trend component, see Example 27.12. For additional information about using these types of trend patterns in data analysis, see Eubank, Huang, and Wang (2003) and Kohn, Ansley, and Tharm (1991).

**Decay and Growth Trends**

There are two choices for the decay trend: DECAY and DECAY(OU). Similarly, there are two choices for the growth trend: GROWTH and GROWTH(OU). The “OU” stands for the Ornstein-Uhlenbeck form of these models. The decay trend is a sum of two correlated components: one component is a random walk, and the other component is a stationary autoregression. In its Ornstein-Uhlenbeck form, the random walk component is replaced by a constant. The growth trend (and its Ornstein-Uhlenbeck variant) has the same form as the decay trend except that the autoregression is nonstationary (in fact, it is explosive). For growth trend models, floating-point errors can result for even moderately long forecast horizons because of the explosive growth in the trend values.

The system matrices for the decay and the growth types in their respective cases are identical, except for the sign of the rate parameter \( \phi \): \( \phi < 0.0 \) for the decay type, and \( \phi > 0.0 \) for the growth type. In addition, the initial conditions for the growth models are fully diffuse; they are only partially diffuse for the decay models. The underlying state vector for all these models is two-dimensional.

The system matrices for the DECAY type are:

\[
\begin{align*}
Z &= (1 1) \\
T &= \text{Diag}(1, \exp(h\phi)) \\
Q &= \frac{\sigma^2}{\phi^3} (h\phi - \exp(h\phi), 1 - \exp(h\phi), 1 - \exp(h\phi) (\exp(2h\phi) - 1)/2)
\end{align*}
\]

The initial condition is partially diffuse with \( Q_1 = \text{Diag}(0, -\frac{\sigma^2}{2\phi}) \). The system matrices for the GROWTH type are the same (with \( \phi > 0.0 \)), except that the initial condition is fully diffuse; so \( Q_1 = 0 \).

For the DECAY(OU) type, \( Z \) and \( T \) are the same as DECAY, whereas

\[
Q = \text{Diag} \left( 0, \frac{\sigma^2 (\exp(2h\phi) - 1)}{2\phi} \right) \quad \text{and} \quad Q_1 = \text{Diag} \left( 0, -\frac{\sigma^2}{2\phi} \right)
\]

The system matrices for the GROWTH(OU) type are the same (with \( \phi > 0.0 \)), except that the initial condition is fully diffuse; so \( Q_1 = 0 \).

**Predefined Structural Models**

A set of predefined models is available in the SSM procedure for models called structural models in the time series literature. These predefined models can be used to model trend, seasonal, and cyclical patterns in the univariate and multivariate time series. For the most part, the multivariate models are straightforward generalizations of the corresponding univariate models—for example, the multivariate random walk trend described later in this section generalizes the univariate random walk trend that is described in the section “Random Walk Trend” on page 1933. All of these models, with the exception of the continuous-time cycle
To specify these models, you must first use the STATE statement with the correct TYPE= option. When you specify the TYPE= option, you do not need to specify other options of the STATE statement (for example, the T option, the COV1 option, and the A1 option). However, you must specify the COV option, which describes the covariance of the disturbance term that drives the state equation. Throughout this section, the symmetric matrix specified by using the COV option is denoted by $\Sigma$. For TYPE= LL, an additional matrix, specified by using the SLOPECOV suboption, also plays a role; it is denoted by $\Sigma_{slope}$. Subsequently you must specify one or more COMPONENT statements to define the (univariate) components that are based on this state subsection for their inclusion in the MODEL statement. These univariate components exhibit interesting behavior based on the structure of $\Sigma$ (and $\Sigma_{slope}$, whenever applicable)—for example, imposing rank restrictions on $\Sigma$ in the multivariate random walk results in these univariate trends moving together. For additional information about these models, see Harvey (1989).

The following example summarizes the steps needed to define a multivariate structural model by using a sequence of STATE and COMPONENT statements. For a full example, see Example 27.1. Suppose that a three-dimensional time series is being studied with response variables $y_1$, $y_2$, and $y_3$. Suppose you want to specify the trivariate structural model

$$y_t = \mu_t + \psi_t + \epsilon_t$$

where $y_t = (y_{1,t}, y_{2,t}, y_{3,t})$ denotes the response series, and $\mu_t$, $\psi_t$, and $\epsilon_t$ denote the trivariate components, trend, cycle, and white noise, respectively. The three components of $\epsilon_t$, the observation noise in the model, are not assumed to be independent. Therefore, you cannot specify them by using three IRREGULAR statements; you must include them in the state specification. The following (incomplete) statements show how to specify this model:

```plaintext
state whiteNoise(3) type=wn ...;
component wn1 = whiteNoise[1];
component wn2 = whiteNoise[2];
component wn3 = whiteNoise[3];
state randomWalk(3) type=rw ...;
component rw1 = randomWalk[1];
component rw2 = randomWalk[2];
component rw3 = randomWalk[3];
state cycleState(3) type=cycle ...;
component c1 = cycleState[1];
component c2 = cycleState[2];
component c3 = cycleState[3];
model y1 = rw1 c1 wn1;
model y2 = rw2 c2 wn2;
model y3 = rw3 c3 wn3;
```

The first STATE statement defines whiteNoise, a state subsection that is needed for defining a three-dimensional white noise component. In turn, whiteNoise is used to define the three univariate white noise components: wn1, wn2, and wn3. The components wn1, wn2, and wn3 are correlated—their correlation structure is controlled by the covariance specification of whiteNoise. The second set of STATE and COMPONENT statements result in three correlated random walk trend components: rw1, rw2, and rw3. Finally, the last set of STATE and COMPONENT statements result in three correlated cycle components: c1,
Chapter 27: The SSM Procedure

In the end, the desired multivariate model is defined by including these (univariate) components in the appropriate MODEL statements.

In the preceding example, it is important to note the relationship between the nominal dimension (denoted by \( dim \) throughout this section) that is specified in the STATE statement and the actual dimension of the resulting state subsection. Note that the three state subsections, whiteNoise, randomWalk, and cycleState, are defined by using the same \( dim \) specification: 3. However, the actual dimensions of these state subsections depend on their type; they do not need to equal this specified dimension. Here, whiteNoise and randomWalk do have the same size, 3, as the specified \( dim \). However, the size of cycleState, which is of TYPE=CYCLE, is \( 2 \times dim = 6 \). Another important point to note: no matter what the underlying size of the state subsection, the desired univariate components were obtained by using an identical specification scheme in the COMPONENT statement. This happens because the component specification style that is based on the element operator—[]—in the COMPONENT statement behaves differently when the TYPE= option is used to define the state subsection (see the section “Multivariate Season” on page 1940 for an illustration).

The system matrices for all these models are time-invariant, with the exception of the continuous-time cycle model. In this section, \( \mathbf{a}_t \) denotes the subsection of the overall model state \( \mathbf{a}_t \), and \( T, Q, \) and \( A_1 \) denote the corresponding blocks of the larger system matrices.

For the multivariate cycle system matrices described in the section “Multivariate Cycle” on page 1939, the Kronecker product notation is useful: if \( A \) is an \( m \times n \) matrix and \( B \) is a \( p \times q \) matrix, then the Kronecker product \( A \otimes B \) is an \( mp \times nq \) block matrix:

\[
A \otimes B = \begin{bmatrix}
a_{11}B & \cdots & a_{1n}B \\
\vdots & \ddots & \vdots \\
a_{m1}B & \cdots & a_{mn}B
\end{bmatrix}
\]

**Multivariate White Noise**

The STATE statement option TYPE=WN specifies white noise of dimension \( dim \)—that is, a sequence of zero mean, independent, Gaussian vectors with covariance \( \Sigma \). The specification of the associated system matrices is trivial: \( T \) is zero, \( Q = \Sigma \), and the initial condition is nondiffuse (\( Q_1 = \Sigma \) and \( A_1 = 0 \)).

Multivariate white noise is needed to specify the observation equation noise term for the multivariate models for the time series data. Since the state space formulation for the SSM procedure requires the observation equation noise vector to have the diagonal form, you need to include the noise vector in the state. The noise term for the \( i \)th response variable is defined by a component that simply picks the \( i \)th element of this multivariate white noise. For example, the component \( \text{wn}_i \) defined as follows can be used as a noise term in the MODEL statement of the \( i \)th response variable:

```plaintext
state white(dim) type=wn . . . ;
component wn_3 = white[3];
```

**Multivariate Random Walk Trend**

The STATE statement option TYPE=RW specifies a \( dim \)-dimensional random walk

\[
\mathbf{a}_{t+1} = \mathbf{a}_t + \eta_{t+1}
\]
where $\eta_t$ is a sequence of zero mean, independent, Gaussian vectors with covariance $\Sigma$. The specification of the associated system matrices is trivial: $T$ is a $dim$-dimensional identity matrix, $I_{dim}$, $Q = \Sigma$, and the initial condition is fully diffuse ($Q_1 = 0$ and $A_1 = I_{dim}$).

The multivariate random walk is a useful trend model for multivariate time series data. The trend term for the $i$th response variable is defined by a component that simply picks the $i$th ($1 \leq i \leq dim$) element of $\alpha_t$. For example, the component $rw_i$ defined as follows can be used as a trend term in the MODEL statement of the $i$th response variable:

```plaintext
state randomWalk(3) type=rw ...;
component rw_2 = randomWalk[2];
```

### Multivariate Local Linear Trend

The STATE statement option TYPE=LL specifies a $(2*dim)$-dimensional $\alpha_t$, needed for defining a $dim$-dimensional local linear trend. The first $dim$ elements of $\alpha_t$ correspond to the needed multivariate trend, and the subsequent $dim$ elements are needed to capture the slope vector of this trend. $\alpha_t$ can be defined as

$$\alpha_{t+1} = T\alpha_t + \eta_{t+1}$$

where $\eta_t$ is a sequence of zero mean, independent, Gaussian vectors with covariance $\text{Diag}(\Sigma, \Sigma_{slope})$ and $T$ is a $2*dim$-dimensional block matrix $T = (I_{dim} \ 0_{dim}, \ 0_{dim} \ I_{dim})$. The initial condition is fully diffuse ($Q_1 = 0$ and $A_1 = I_{2*dim}$). This is a multivariate generalization of the univariate local linear trend.

The multivariate local linear trend is a useful trend model for multivariate time series data. The trend term for the $i$th response variable is defined by a component that simply picks the $i$th element ($1 \leq i \leq dim$) of $\alpha_t$. For example, the component $ll_i$ defined as follows can be used as a trend term in the MODEL statement of the $i$th response variable:

```plaintext
state localLin(dim) type=ll(slopecov..) ...;
component ll_3 = localLin[3];
```

### Multivariate Cycle

The STATE statement option TYPE=CYCLE specifies a $(2*dim)$-dimensional $\alpha_t$, needed for defining a $dim$-dimensional cycle. As in the LL case, the first $dim$ elements of $\alpha_t$ correspond to the needed $dim$-dimensional cycle, and the remaining $dim$ elements contain some auxiliary quantities. The cycle model defined in this subsection requires a regular data type—that is, the CT option is not included. Let $\rho$ denote the damping factor, and let $\lambda = 2\pi/\text{period}$ be the frequency associated with the cycle. The admissible parameter ranges are $0 < \rho < 1$ and $\text{period} > 2$, which implies that $0 < \lambda < \pi$. Let $C = \rho (\cos(\lambda) \ -\sin(\lambda), \ -\sin(\lambda) \ \cos(\lambda))$, a $2 \times 2$ matrix, and let $T = C \otimes I_{dim}$, a $2 \times dim \times 2 \times dim$ matrix. With this notation, the transition equation associated with $\alpha_t$ is

$$\alpha_{t+1} = T\alpha_t + \eta_{t+1}$$

where $\eta_t$ is a sequence of zero mean, independent, $(2 \times dim)$-dimensional Gaussian vectors with covariance $\text{Diag}(\Sigma, \Sigma)$. If $\rho = 1$, the initial condition is fully diffuse ($Q_1 = 0$ and $A_1 = I_{2*dim}$). Otherwise, it is nondiffuse: $Q_1 = \frac{1}{(1-\rho^2)} \text{Diag}(\Sigma, \Sigma)$ and $A_1 = 0$.

The multivariate cycle is useful for capturing periodic behavior for multivariate time series data. The cycle term for the $i$th response variable is defined by a component that simply picks the $i$th element of $\alpha_t$. For
example, the component cycle_i defined as follows can be used as a cycle term in the MODEL statement of the i-th response variable:

```plaintext
state cycleState(dim) type=cycle ...;
component cycle_2 = cycleState[2];
```

### Multivariate Season

The STATE statement option TYPE=SEASON(LENGTH=s) specifies a \((s-1)\times dim\)-dimensional \(\alpha_t\), needed for defining a \(dim\)-dimensional trigonometric season component with season length \(s\). A (multivariate) trigonometric season component, \(\zeta\), is a sum of (multivariate) cycles of different frequencies,

\[
\zeta = \sum_{j=1}^{[s/2]} \zeta_j
\]

where the constituent cycles \(\zeta_j\), called harmonics, have frequencies \(\lambda_j = 2\pi j/s\). All the harmonics are assumed to be statistically independent, have the same damping factor \(\rho = 1\), and are governed by the disturbances with the same covariance matrix \(\Sigma\). The number of harmonics, \([s/2]\), equals \(s/2\) if \(s\) is even and \((s-1)/2\) if it is odd. This means that specifying TYPE=SEASON(LENGTH=s) is equivalent to specifying \([s/2]\) cycle specifications with correct frequencies, damping factor \(\rho = 1\), and the COV option restricted to the same covariance \(\Sigma\). The resulting \(\alpha_t\) is necessarily \((s-1)\times dim\)-dimensional. When the season length \(s\) is even, the last harmonic cycle, \(\zeta_{s/2}\), has frequency \(\pi\) and requires special attention. It is of dimension \(dim\) rather than \(2\times dim\) because its underlying state equation simplifies to a \(dim\)-variate autoregression with autoregression coefficient \(-I_{dim}\). As a result of this discussion, it is clear that the system matrices \(T\) and \(Q\) associated with the \((s-1)\times dim\)-dimensional \(\alpha_t\) are block-diagonal with the blocks corresponding to the harmonics. The initial condition is fully diffuse.

For all the models discussed so far, the first \(dim\) elements of \(\alpha_t\) provided the needed (multivariate) component. This is not the case for the (multivariate) season component. Extracting the \(i\)th seasonal component from \(\alpha_t\) requires accumulating the contributions from the \([s/2]\) harmonics that are associated with this \(i\)th seasonal, which are not organized contiguously in \(\alpha_t\). For example, suppose that \(\dim\) is 2 and the season length \(s\) is 4. In this case \([s/2]\) is 2, and the bivariate seasonal component is a sum of two independent bivariate cycles, \(\zeta_1\) and \(\zeta_2\). The cycle \(\zeta_1\) has frequency \(\pi/2\) and its underlying state, say \(\alpha_{t}^{a}\), has dimension 2 * \(dim\) = 4. The last harmonic, \(\zeta_2\), has frequency \(\pi\), and therefore its underlying state, say \(\alpha_{t}^{b}\), has dimension 2. The combined state \(\alpha_{t} = (\alpha_{t}^{a}, \alpha_{t}^{b})\) has dimension 6 = 4 + 2. In order to extract the first bivariate seasonal component, you must extract the first components of bivariate cycles \(\zeta_1\) and \(\zeta_2\), which in turn implies the first elements of \(\alpha_{t}^{a}\) and \(\alpha_{t}^{b}\), respectively. Thus, obtaining the first bivariate seasonal component requires extracting the first and the fifth elements of the combined state \(\alpha_{t}\). Similarly, obtaining the second bivariate seasonal component requires extracting the second and the sixth elements of the combined state \(\alpha_{t}\). All this can be summarized by the dot product expressions

\[
\begin{align*}
  s_{1t} &= (1 0 0 0 1 0) \alpha_{t} \\
  s_{2t} &= (0 1 0 0 0 1) \alpha_{t}
\end{align*}
\]

where \(s_{1t}\) and \(s_{2t}\) denote the first and second components, respectively, of the bivariate seasonal component. Note that \(s_{1t}\) and \(s_{2t}\) are univariate seasonal components, each of season length 4, in their own right. They are correlated components; their correlation structure depends on \(\Sigma\).
Obtaining the desired components of the multivariate seasonal component is made easy by a special syntax convention of the COMPONENT statement. Continuing with the previous example, the following examples illustrate two equivalent ways of obtaining \( s_{1t} \) and \( s_{2t} \). The first set of statements explicitly specify the linear combinations needed for defining \( s_{1t} \) and \( s_{2t} \):

\[
\text{state seasonState(2) type=season(length=4)} \ldots;
\text{component s_1 } = ( 1 \ 0 \ 0 \ 0 \ 1 \ 0 ) * \text{seasonState;}
\text{component s_2 } = ( 0 \ 1 \ 0 \ 0 \ 0 \ 1 ) * \text{seasonState;}
\]

The following simpler specification achieves the same result:

\[
\text{state seasonState(2) type=season(length=4)} \ldots;
\text{component s_1 } = \text{seasonState}[1];
\text{component s_2 } = \text{seasonState}[2];
\]

In the latter specification, the meaning of the element operator [] changes if the state in question is defined by using the TYPE= option.

### Multivariate ARMA

You can specify a state vector that follows a multivariate autoregressive, moving average (VARMA) model by using the STATE statement option TYPE=VARMA. The autoregressive and moving average orders can be either 0 or 1 (0 \( \leq p \leq 1 \) and 0 \( \leq q \leq 1 \)—that is, only VAR(1), MA(1), and VARMA(1,1) models can be specified. The notation and the state space form of the VARMA model described here is taken from Reinsel (1997), which is a good reference for VARMA modeling.

A \( \text{dim} \)-dimensional vector process \( \xi_t \) follows a zero-mean, autoregressive order \( p \), moving average order \( q \) (VARMA\((p, q)\)) model if it satisfies the following matrix difference equation:

\[
\xi_t = \sum_{i=1}^{p} \Phi_i \xi_{t-i} + \epsilon_t - \sum_{j=1}^{q} \Theta_j \epsilon_{t-i}
\]

Here \( \Phi_i \) and \( \Theta_j \) are \( \text{dim} \)-dimensional square matrices and \( \epsilon_t \) is a \( \text{dim} \)-dimensional, Gaussian, white noise sequence with covariance matrix \( \Sigma \). If autoregressive order \( p \) is 0, the term that involves \( \Phi_i \) is absent; similarly, if the moving average order \( q \) is 0, the term that involves \( \Theta_j \) is absent. Since AR and MA orders can be at most 1, the subscripts of \( \Phi_i \) and \( \Theta_j \) can be ignored in this discussion—when applicable, an AR coefficient matrix is denoted by \( \Phi \) and an MA coefficient matrix is denoted by \( \Theta \). The unknown elements of \( \Phi, \Theta, \) and \( \Sigma \) constitute the parameter vector that is associated with a VARMA state. The process \( \xi_t \) defined by the VARMA difference equation is stationary and invertible (Reinsel 1997) if and only if the eigenvalues of \( \Phi \) and \( \Theta \) are strictly less than 1 in magnitude. By default, the SSM procedure imposes these stationarity and invertibility restrictions on \( \Phi \) and \( \Theta \). However, you can specify \( \Phi \) to be an identity matrix, in which case the resulting process is nonstationary.

A VARMA model can be cast into a state space form. The state space form used by the SSM procedure is described in Reinsel (1997, pp 52–53). The system matrices for the supported VARMA models are as follows:

- The VAR(1) form is the simplest. In this case, the underlying state \( \alpha_t \) is the same as the VAR(1) process \( \xi_t \). Therefore, \( T = \Phi \) and \( Q_t = \Sigma \).
• Taking $\Phi$ equal to the zero matrix if $p = 0$, the VARMA(1,1) and MA(1) cases can be treated together. In this case, the underlying state $\alpha_t$ is $2 \times \text{dim}$ dimensional and the desired VARMA process $\zeta_t$ corresponds to its first $\text{dim}$ elements. Let $\Psi = \Phi - \Theta$. Then, in the blocked form,

$$T = \begin{bmatrix} 0 & \text{Idim} \\ 0 & \Phi \end{bmatrix} \quad \text{and} \quad Q_t = Q = \begin{bmatrix} \Sigma & \Sigma \Psi' \\ \Psi \Sigma & \Psi \Sigma \Psi' \end{bmatrix}$$

Unless $\Phi$ is restricted to be identity, the underlying state $\alpha_t$ is stationary and the covariance of the initial condition is computed by

$$\text{vec}(Q_1) = (I - T \otimes T)^{-1} \text{vec}(Q)$$

where $\otimes$ denotes the Kronecker product and the $\text{vec}$ operation on a matrix creates a vector formed by vertically stacking the rows of that matrix. If $\Phi$ is restricted to be identity, the initial condition is fully diffuse.

**Continuous-Time Cycle**

The STATE statement option TYPE=CYCLE(CT) specifies a two-dimensional $\alpha_t$, needed for defining a univariate continuous time cycle. In this case the nominal dimension, $\text{dim}$, must be 1. In particular, $\Sigma$ becomes one-dimensional, which is denoted by $\sigma^2$. This cycle can be used for any data type. As before, the parameters of the cycle are a damping factor $\rho$, $0 < \rho \leq 1$, and $\text{period} > 0$. Unlike in the discrete-time cycle described in the section “Multivariate Cycle” on page 1939, the $\text{period}$ is not required to be larger than 2. Let $\lambda = 2\pi/\text{period}$, and let $h_t = (t_{t+1} - t_t)$ denote the difference between successive time points. In this case, the system matrices $T$ and $Q$ that govern $\alpha_t$ depend on $h_t$. They are:

$$T = \rho^h \begin{bmatrix} \cos(\lambda h) & \sin(\lambda h) \\ -\sin(\lambda h) & \cos(\lambda h) \end{bmatrix}$$

$$Q = \begin{cases} \frac{\sigma^2 (1 - \rho^{2h})}{-2 \ln(\rho)} \cdot I_2 & \text{if } \rho < 1 \\ \sigma^2 h I_2 & \text{if } \rho = 1 \end{cases}$$

If $\rho < 1$, the initial condition is nondiffuse: $Q_1 = \frac{\sigma^2}{-2 \ln(\rho)} I_2$. For $\rho = 1$, the initial condition is fully diffuse. The first element of $\alpha_t$ corresponds to the needed cycle, and the second element is an auxiliary quantity. You can define a cycle term based on this state as follows:

```plaintext
state cycleState(1) type=cycle(CT) ...;
component cycle = cycleState[1];
```

The CT option must be included in the use of TYPE=CYCLE.

**Covariance Parameterization**

The covariance matrices specified by the COV and COV1 options in the STATE statement must be positive semidefinite. When these matrices are of general form and are not user-specified, they are internally parameterized by their Cholesky root. Suppose that $\Sigma$, an $m \times m$ positive semidefinite matrix of rank $r$, is such a covariance matrix. Then, $\Sigma$ can always be written as

$$\Sigma = RR'$$
where the (generalized) Cholesky root, $R$, is an $m \times r$ lower triangular matrix with nonnegative diagonal elements (that is, $R[i, j] = 0$ if $j > i$ and $R[i, i] \geq 0$, $1 \leq i \leq r$). The SSM procedure parameterizes $\Sigma$ by the elements of its Cholesky root, which adds $r \times (r + 1)/2 + r \times (m - r)$ elements to the parameter vector $\theta$.

**Missing Values**

For a variety of reasons the data might contain missing response and predictor values. Before starting the analysis of a particular BY group, SSM procedure makes an internal copy of the data. The actual analysis is done by using this copy. The data in the copy are first examined for missing values in the response, predictor, and the ID variables. No missing values are permitted in the ID variable (if it is specified). If all the missing values are associated with only the response variables, then the internal copy of the data is not altered. However, if any of the predictors in the observation equation—the elements of $X$ matrix—are found to contain missing values, the internal copy of the data is altered as follows: any missing predictor value is replaced by 0, and the response values that are dependent on that predictor in the corresponding row are set to missing. These missing response values are called the *induced missing values*. The reported analysis is based on the (possibly altered) internal copy of the BY group.

Missing values are not permitted in any of the other system matrices that define the state space model. In particular, missing values are not permitted in $Z$, $T$, $W$, and $Q$ matrices. In some cases the elements of these matrices depend on the data values. In such cases, care must be taken to ensure that these data values are not missing.

**Computational Issues**

**A Well-Behaved Model**

The model defined by the state space model equations (see the section “State Space Model and Notation” on page 1919) is very general. This generality is quite useful because it encompasses a wide variety of data generation processes. On the other hand, it also makes it easy to specify overly complex and numerically unstable models. If a suitable model is not already known and you are in the early phases of modeling, it is important to start with models that are relatively simple and well-behaved from the numerical standpoint. From the numerical and statistical considerations, two aspects of model formulation are particularly important: identifiability and numerical stability. A model is identifiable if the observed data has a distinct probability distribution for each admissible parameter vector. Unless proper care is taken, it is easy to specify an unidentifiable state space model. Similarly, predictions according to some types of state space models can display explosive growth or wild oscillations. This behavior is primarily governed by the transition matrix $T$ (or $T_t$ in the time-varying case). Unidentifiable models can run into difficulties during parameter estimation, and explosive growth (and wild oscillation) causes numerical problems associated with finite-precision arithmetic. Unfortunately, no simple identifiability check is available for a general state space model, and it is difficult to decide at the outset whether a specified model might suffer from numerical instability. See Harvey (1989, chap. 4, sec. 4) for a discussion of identifiability issues, and see Harvey (1989, chap. 3, sec. 3) for a discussion of the stability properties of time-invariant state space models. The following guidelines are likely to result in models that are identifiable and numerically stable:

- Build models by composing submodels that are known to be well-behaved. The predefined models provided by the SSM procedure are good submodel candidates (see the sections “Predefined Trend Models” on page 1933 and “Predefined Structural Models” on page 1936).
• Pay careful attention to the way the variety of system matrices are defined. The behavior of their elements, as functions of model parameters and other variables, must be well-understood. If these elements are defined by using DATA steps, you can validate their behavior by running these DATA steps outside of the SSM procedure. In particular, note the following:

  – The transition matrix $T$ (or $T_t$ in the time-varying case) determines the explosiveness characteristics of the model; it must be well-behaved for all parameters.
  – The disturbance covariances $Q_t$ must be positive semidefinite for all parameters.
  – If the system matrices in the state equation, such as the transition matrix $T_t$ or the disturbance covariance $Q_t$, are time-varying and the data contain replicate observations (observations with the same ID value), check that the elements of these matrices do not vary during replicate observations. This follows from the fact that the underlying state does not vary during replications (see the state equation in the section “State Space Model and Notation” on page 1919 and the section “Types of Sequence Data” on page 1921).

**Convergence Problems**

As explained in the section “Likelihood Computation and Model Fitting Phase” on page 1928, the model parameters are estimated by nonlinear optimization of the likelihood. This process is not guaranteed to succeed. For some data sets, the optimization algorithm can fail to converge. Nonconvergence can result from a number of causes, including flat or ridged likelihood surfaces and ill-conditioned data. It is also possible for the algorithm to converge to a point that is not the global optimum of the likelihood.

If you experience convergence problems, consider the following:

• Data that are extremely large or extremely small can adversely affect results because of the internal tolerances used during the filtering steps of the likelihood calculation. Rescaling the data can improve stability.

• Examine your model for redundancies in the included components and regressors. The components or regressors that are nearly collinear to each other can cause the optimization process to become unstable.

• Lack of convergence can indicate model misspecification such as unidentifiable model or a violation of the normality assumption.

**Computer Resource Requirements**

The computing resources required for the SSM procedure depend on several factors. The memory requirement for the procedure is largely dependent on the number of observations to be processed and the size of the state vector underlying the specified model. If $n$ denotes the sample size and $m$ denotes the size of the state vector, the memory requirement for the smoothing phase of the Kalman filter is of the order of $6 \times 8 \times n \times m^2$ bytes, ignoring the lower-order terms. If the smoothed component estimates are not needed, then the memory requirement is of the order of $6 \times 8 \times (m^2 + n)$ bytes. Besides $m$ and $n$, the computing time for the parameter estimation depends on the size of the parameter vector $\theta$ and how many likelihood evaluations are needed to reach the optimum.
Displayed Output

The default printed output produced by the SSM procedure contains the following information:

- brief information about the input data set, including the data set name and label
- summary statistics for the response variables in the model, including the names of the variables, the total number of observations and the number of missing observations, the smallest and largest measurements, and the mean and standard deviation
- information about the index variable, including the index value of the first and the last observation, the maximum difference between the successive index values, and the categorization of the data into regular, regular with replication, or irregular types
- estimates of the regression parameters if the model contains any predictors, including their standard errors, \( t \) statistics, and \( p \)-values
- convergence status of the likelihood optimization process if any parameters are estimated
- estimates of the free parameters at the end of the model-fitting phase, including the parameter estimates and their approximate standard errors
- the likelihood-based goodness-of-fit statistics, including the full likelihood, the sum of squares of residuals normalized by their standard errors, and the information criteria: AIC, AICC, HQIC, BIC, and CAIC
- summary of most significant additive outliers

ODS Table Names

The SSM procedure assigns a name to each table it creates. You can use these names to refer to the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 27.9.

OUT= Data Set

You can use the OUT= option in the OUTPUT statement to store the series and component forecasts that are produced by PROC SSM. Which columns are included in the data set depends on the model specification. The model can have one or more response variables, a variety of components that appear in the MODEL statement, and components specified by the EVAL statement. The OUT= data set contains the one-step-ahead and full-sample estimates of the response variables, and all these components.

The following list describes the columns of the data set:

- the BY variables
- the ID variable, if specified by the ID statement
- Obs, a variable that contains the observation number
- the response series (more than one in the multivariate case)
- the following columns associated with the response series (the wildcard * is substituted by the name of one of the response variables):
  - FORECAST_* contains the one-step-ahead predicted values, and the multistep forecasts of the response series.
  - RESIDUAL_* contains the difference between the actual and forecast values.
  - StdErr_* contains the standard error of prediction.
  - Lower_* and Upper_* contain the lower and upper forecast confidence limits.
  - Smoothed_* contains the smoothed values of the response variable.
  - StdErr_Smoothed_* contains standard errors of the smoothed values of the response variable.
  - AO_* contains the additive outlier estimate.
  - StdErr_AO_* contains the standard error of the additive outlier estimate.
- the following columns associated with the components (the wildcard * is substituted by the name of one of the components):
  - FORECAST_* contains the one-step-ahead predicted values and the multistep forecasts of the component.
  - StdErr_* contains the standard error of prediction.
  - Smoothed_* contains the smoothed values of the component.
  - StdErr_Smoothed_* contains standard errors of the smoothed values of the component.
  - Smoothed_Lower_* and Smoothed_Upper_* contain the lower and upper confidence limits of the smoothed component.
- the maximal state shock chi-square statistics at distinct time points (this column is present only if the MAXSHOCK option is used in the OUTPUT statement)
Confidence limits are not produced for the smoothed series values or for the component forecasts; they are produced for the smoothed components.

---

**Examples: SSM Procedure**

### Example 27.1: Bivariate Basic Structural Model

This example illustrates how you can use the SSM procedure to analyze a bivariate time series. The following data set contains two variables, $f_{KSI}$ and $r_{KSI}$, which are measured quarterly, starting the first quarter of 1969. The variable $f_{KSI}$ represents the quarterly average of the log of the monthly totals of the front-seat passengers killed or seriously injured during the car accidents, and $r_{KSI}$ represents a similar number for the rear-seat passengers. The data set has been extended at the end with eight missing values, which represent four quarters, to cause the SSM procedure to produce model forecasts for this span.

```sas
data seatBelt;
  input f_KSI r_KSI @@;
  label f_KSI = "Front Seat Passengers Injured--log scale";
  label r_KSI = "Rear Seat Passengers Injured--log scale";
  date = intnx( 'quarter', '1jan1969'd, _n_-1 );
  format date YYQS.;
datalines;
  7.00942  6.30167  7.09329  6.14476  6.78554  5.78212
  7.02016  6.40524  6.87849  6.06308  6.55966  5.66084
  6.52075  5.76028  6.59860  5.91208  6.70597  6.08029
  6.75110  5.98833  6.53117  5.67676  6.52718  5.90572
  6.65963  6.01003  6.76869  5.93226  6.44483  5.55616
  6.62063  5.82533  6.72938  6.04531  6.82182  5.98277
  6.64134  5.76540  6.66762  5.91378  6.83524  5.13387
  6.81594  5.97907  6.60761  5.66838  6.62985  5.88151
  6.60666  5.92841  6.72242  6.03111  6.76228  5.93898
  6.54290  5.72538  6.62469  5.92028  6.73415  6.11880
  6.74094  5.98009  6.46418  5.63517  6.61537  5.96040
  6.27565  5.92508  6.40771  6.13903  6.37293  5.96883
  6.53678  6.13404
run;
```

These data have been analyzed in Durbin and Koopman (2001, chap. 9, sec. 3). The analysis presented here is similar. To simplify the illustration, the monthly data have been converted to quarterly data and two predictors (the number of kilometers traveled and the real price of petrol) are excluded from the analysis. You can also use PROC SSM to carry out the more elaborate analysis in Durbin and Koopman (2001).
One of the original reasons for studying these data was to assess the effect on \( f_{\text{KSI}} \) of the enactment of a seat-belt law in February 1983 that compelled the front seat passengers to wear seat belts. A simple graphical inspection of the data (not shown here) reveals that \( f_{\text{KSI}} \) and \( r_{\text{KSI}} \) do not show a pronounced upward or downward trend but do show seasonal variation, and that these two series seem to move together. Additional inspection also shows that the seasonal effect is relatively stable throughout the data span. These considerations suggest the following model for \( y = (f_{\text{KSI}}, r_{\text{KSI}}) \):

\[
y_t = \begin{pmatrix} X_t \\ 0 \end{pmatrix} \beta + \mu_t + \xi_t + \xi_t.
\]

All the terms on the right-hand side of this equation are assumed to be statistically independent. These terms are as follows:

- The predictor \( X_t \) (defined as \( Q1\_83\_Shift \) later in the program) denotes a variable that is 0 before the first quarter of 1983, and 1 thereafter. \( X_t \) is supposed to affect only \( f_{\text{KSI}} \) (the first element of \( y \)); it represents the enactment of the seat-belt law of 1983.

- \( \mu_t \) denotes a bivariate random walk. It is supposed to capture the slowly changing level of the vector \( y_t \). To capture the fact that \( f_{\text{KSI}} \) and \( r_{\text{KSI}} \) move together (that is, they are co-integrated), the covariance of the disturbance term of this random walk is assumed to be of lower than full rank.

- \( \xi_t \) denotes a bivariate trigonometric seasonal term. In this model, it is taken to be fixed (that is, the seasonal effects do not change over time).

- \( \xi_t \) denotes a bivariate white noise term, which captures the residual variation that is unexplained by the other terms in the model.

The preceding model is an example of a (bivariate) basic structural model (BSM). The following statements specify and fit this model to \( f_{\text{KSI}} \) and \( r_{\text{KSI}} \):

```sas
proc ssm data=seatBelt stateinfo;
id date interval=quarter;
Q1_83_Shift = (date >= '1jan1983'd);
state error(2) type=WN cov(g) print=cov;
component wn1 = error[1];
component wn2 = error[2];
state level(2) type=RW cov(rank=1) print=cov;
component rw1 = level[1];
component rw2 = level[2];
state season(2) type=season(length=4);
component s1 = season[1];
component s2 = season[2];
model f_KSI = Q1_83_Shift rw1 s1 wn1 / print=(smooth);
model r_KSI = rw2 s2 wn2;
eval f_KSI_sa = rw1 + Q1_83_Shift;
output out=For1;
run;
```

The PROC SSM statement specifies the input data set, seatBelt. The use of the STATEINFO option in the PROC SSM statement produces additional information about the model state vector and its diffuse initial state. The optional ID statement specifies an index variable, date. The INTERVAL=QUARTER option in the ID statement indicates that the measurements were collected on a quarterly basis. Next, a programming
Example 27.1: Bivariate Basic Structural Model

Statement defines Q1_83_Shift, the predictor that represents the enactment of the seat-belt law of 1983. It is used later in the MODEL statement for f_KSI. Separate STATE statements specify the terms \( \mu_t \), \( \xi_t \), and \( \zeta_t \) because they are statistically independent. Each model that governs them (white noise for \( \xi_t \), random walk for \( \mu_t \), and trigonometric seasonal for \( \zeta_t \)) can be specified by using the TYPE= option of the STATE statement. When you use the TYPE= option, you can use the COV option to specify the information about the disturbance covariance in the state transition equation. The other details, such as the transition matrix specification and the specification of \( A_1 \) in the initial condition, are inferred from the TYPE= option. The use of PRINT=COV in the STATE statement causes the estimated disturbance covariance to be printed. For \( \xi_t \) (a white noise), \( A_1 \) is zero and \( Q_t = Q \) for all \( t \geq 1 \), where \( Q \) is specified by the COV option. For \( \mu_t \) and \( \zeta_t \) the initial condition is fully diffuse—that is, \( A_1 \) is an identity matrix of appropriate order and \( Q_1 = 0 \). The total diffuse dimension of this model, \((d + k)\), is \( 9 = 8 + 1 \) as a result of one predictor, Q1_83_Shift, and two fully diffuse state subsections, \( \mu_t \) and \( \zeta_t \). The components in the model are defined by suitable linear combinations of these different state subsections. The program statements define the model as follows:

1. **STATE** error(2) type=WN cov(g); defines \( \xi_t \) as a two-dimensional white noise, named error, with the covariance of general form. Then two COMPONENT statements define wn1 and wn2 as the first and second elements of error, respectively.

2. **STATE** level(2) type=RW cov(rank=1); defines \( \mu_t \) as a two-dimensional random walk, named level, with covariance of general form whose rank is restricted to 1. Then two COMPONENT statements define rw1 and rw2 as the first and second elements of level, respectively.

3. **STATE** season(2) type=season(length=4); defines \( \zeta_t \) as a two-dimensional trigonometric seasonal of season length 4, named season, with zero covariance—signified by the absence of the COV option. Then two COMPONENT statements define s1 and s2 as appropriate linear combinations of season so that s1 represents the seasonal for f_KSI and s2 represents the seasonal for r_KSI. Because TYPE=SEASON in the STATE statement, the COMPONENT statement appropriately interprets component s1 = season[1]; as s1 being a dot product: \((1 0 0 1 0) \ast \text{season}\). See the section “Multivariate Season” on page 1940 for more information.

4. **MODEL** f_KSI = Q1_83_Shift rw1 s1 wn1; defines the model for f_KSI, and model r_KSI = rw2 s2 wn2; defines the model for r_KSI.

The SSM procedure fits the model and reports the parameter estimates, their approximate standard errors, and the likelihood-based goodness-of-fit measures by default. In order to output the one-step-ahead and full-sample estimates of the components in the model, you can either use the PRINT= options in the MODEL statement and the respective COMPONENT statements or you can specify an output data set in the OUTPUT statement. In addition, you can use the EVAL statement to define specific linear combinations of the underlying state that should also be estimated. The statement eval f_KSI_sa = rw1 + Q1_83_Shift; is an example of one such linear combination. It defines f_KSI_sa, a linear combination that represents the seasonal adjustment of f_KSI. The output data set, For1 (named in the OUTPUT statement) contains estimates of all the model components in addition to the estimate of f_KSI_sa.

The model summary table, shown in Output 27.1.1, provides basic model information, such as the dimension of the underlying state equation \((m = 10)\), the diffuse dimension of the model \((d + k) = 9\), and the number of parameters \((5)\) in the model parameter vector \(\theta\).

</tbody>
</table>

Additional details about the role of different components in forming the model state and its diffuse initial condition are shown in Output 27.1.2 and Output 27.1.3. They show that the 10-dimensional model state vector is made up of subsections that are associated with error and level (each of dimension 2) and season (of dimension 6). Similarly, the nine-dimensional diffuse vector in the initial condition is made up of subsections that correspond to level, season, and the regression variable, Q1_83_Shift. Note that error does not contribute to the diffuse initial vector because it has a fully nondiffuse initial state.

The regression coefficient of \( Q1_{\text{83_Shift}} \), shown in *Output 27.1.6*, is negative and is statistically significant. This is consistent with the expected drop in \( f_{\text{KSI}} \) after the enactment of the seat-belt law.

**Output 27.1.6** Regression Coefficient of \( Q1_{\text{83_Shift}} \)

| Response Variable | Regression Variable | Estimate | Standard Error | t Value | Pr > |t| |
|-------------------|---------------------|----------|----------------|---------|------|---|
| \( f_{\text{KSI}} \) | \( Q1_{\text{83_Shift}} \) | -0.408   | 0.0259          | -15.74  | <.0001 |

*Output 27.1.7* shows the estimates of the elements of \( \theta \). The five parameters in \( \theta \) correspond to unknown elements that are associated with the covariance matrices in the specifications of \( \text{error} \) and \( \text{level} \). Whenever a covariance specification is of a general form and is not defined by a user-specified variable list, it is internally parameterized as a product of its Cholesky root: \( \text{Cov} = \text{Root} \text{Root}^\top \). This ensures that the resulting covariance is positive semidefinite. The Cholesky root is constrained to be lower triangular, with positive diagonal elements. If rank constraints (such as the rank-one constraint on the covariance in the specification of \( \text{level} \)) are imposed, the number of free parameters in the Cholesky factor is reduced appropriately. See the section “Covariance Parameterization” on page 1942 for more information. In view of these considerations, the five parameters in \( \theta \) are a result of three parameters from the Cholesky root of \( \text{error} \) and two parameters that are associated with the Cholesky root of \( \text{level} \).
Output 27.1.7 Parameter Estimates

The output data set, For1, specified in the OUTPUT statement contains one-step-ahead and full-sample estimates of all the model components and the user-specified components (defined by the EVAL statement). Their standard errors and the upper and lower confidence limits (by default, 95%) are also produced.

The following statements use the For1 data set to produce a time series plot of the seasonally adjusted f_KSI:

```
proc sgplot data=For1;
   title "Seasonally Adjusted f_KSI with 95% Confidence Band";
   band x=date lower=smoothed_lower_f_KSI_sa
      upper=smoothed_upper_f_KSI_sa;
   series x=date y=smoothed_f_KSI_sa;
   reline '1jan1985’d / axis=x lineattrs=(pattern=shortdash)
      LEGENDLABEL= "Start of Multistep Forecasts"
      name="Forecast Reference Line";
   scatter x=date y=f_KSI ;
run;
```

The generated plot is shown in Output 27.1.11.
Example 27.2: Panel Data: Two-Way Random-Effects and Autoregressive Models

This example shows how you can use the SSM procedure to specify and fit the two-way random-effects model and the autoregressive model to analyze a panel of time series. The fitting of dynamic panel model for such data is is illustrated in Example 27.11. These (and a few other) model types can also be fitted by the PANEL procedure, a SAS/ETS procedure that is specially designed to efficiently handle the cross-sectional time series data. However, because of the differences in their model fitting algorithms, generally the parameter estimates and other fit statistics produced by the SSM and PANEL procedures do not match. The SSM procedure always uses the (restricted) maximum likelihood for parameter estimation. The estimation method used by the PANEL procedure depends on the model type and the particular estimation options.

The cross-sectional data, Cigar, that are used in the section “Getting Started: SSM Procedure” on page 1889 are reused in this example. The output shown here is less extensive than the output shown in that section. The main emphasis of this example is how you can specify the two-way random effects model and the autoregressive model in the SSM procedure.
Example 27.2: Panel Data: Two-Way Random-Effects and Autoregressive Models

According to the two-way random effects model, the cigarette sales, \( l_{sales} \), can be described by the following equation:

\[
l_{sales} \_{i;t} = \mu + l_{price} \beta_1 + l_{ndi} \beta_2 + l_{pimin} \beta_3 + \xi_i + \eta_t + \epsilon_{i,t}
\]

This model represents \( l_{sales} \) in region \( i \) and in year \( t \) as a sum of an overall intercept \( \mu \), the regression effects due to \( l_{price}, l_{ndi}, \) and \( l_{pimin} \), a zero-mean, random effect \( \xi_i \) associated with region \( i \), a zero-mean, random effect \( \eta_t \) associated with year \( t \), and the observation noise \( \epsilon_{i,t} \). The region-specific random effects \( \xi_i \) and the year-specific random effects \( \eta_t \) are assumed to be independent, Gaussian sequences with variances \( \sigma_\xi^2 \) and \( \sigma_\eta^2 \), respectively. In addition, they are assumed to be independent of the observation noise, which is also assumed to be a sequence of independent, zero-mean, Gaussian variables with variance \( \sigma_\epsilon^2 \).

You can specify and fit this model by using the following statements:

```plaintext
proc ssm data=Cigar;
   id year interval=year;
   parms s2g/ lower=(1.e-6);
   array RegionArray{46} region1-region46;
   do i=1 to 46;
      RegionArray[i] = (region=i);
   end;
   /* region-specific random effects */
   state zeta(46) T(I) cov1(I)=(s2g);
   component regionEffect = zeta * (RegionArray);
   /* year-specific random effect */
   state eta(1) type=wn cov(D);
   component timeEffect = eta[1];
   irregular wn;
   intercept = 1.0;
   model lsales = intercept lprice lndi lpimin
                 timeEffect regionEffect wn;
run;
```

The PARMS statement defines \( s2g \), a parameter that is restricted to be positive and is used later as the variance parameter for the region effect. Similarly, the 46-dimensional array, `RegionArray`, of region-specific dummy variables is defined to be used later. The state subsection `zeta` corresponds to \( \xi \), which is the 46-dimensional vector of region-specific, zero-mean, random effects. The component `regionEffect` extracts the proper element of \( \xi \) by using the array `RegionArray`. A constant column, `intercept`, is defined to be used later as an intercept term. The component `timeEffect` corresponds to \( \eta_t \), and `wn` specifies the observation noise \( \epsilon_{i,t} \). Finally, the MODEL statement defines the model. Some of the tables that are produced by running these statements are shown in Output 27.2.1 through Output 27.2.5.

The model summary, shown in Output 27.2.1, shows that the model is defined by one MODEL statement, the dimension of the underlying state vector is 47 (because \( \xi \) is 46-dimensional and \( \eta_t \) is one-dimensional), the diffuse dimension is 4 (because of the four predictors in the model), and there are three parameters to be estimated.

</tbody>
</table>

The ML estimate of $s_{2g}$, a parameter specified in the PARMS statement, is shown in Output 27.2.4. It corresponds to $\sigma_2^2$, the variance of the region effect.
The estimates of the other unknown parameters in the model are shown in Output 27.2.5. It shows the estimate of the variance of the irregular component \( w_n \) and the estimate of the variance of the time effect \( \eta_t \).

The remainder of this example describes how you can specify and fit the following first-order vector autoregressive model to the cigarette data:

\[
\begin{align*}
lsales_{i,t} & = \mu + \text{lprice} \beta_1 + \text{lndi} \beta_2 + \text{lpimin} \beta_3 + \zeta_t[i] \\
\zeta_t & = \Phi \zeta_{t-1} + \eta_t
\end{align*}
\]

This model represents \( lsales \) in region \( i \) and in year \( t \) as a sum of an overall intercept \( \mu \), the regression effects due to \( l\text{price}, l\text{ndi}, \) and \( l\text{pimin} \), and the \( i \)th element of a vector error term \( \zeta_t[i] \). The multidimensional error sequence \( \zeta_t \) is assumed to follow a first-order autoregression with a diagonal autoregressive coefficient matrix \( \Phi \) and with a multivariate, white noise sequence \( \eta_t \) as its disturbance sequence. The covariance matrix of \( \eta_t \), \( \Sigma_t \), is assumed to be dense. Note that the dimension of the vectors \( \zeta_t \) is the same as the number of cross-sections in the study (the number of regions in this example). Therefore, even for a relatively modest panel study, the total number of parameters to be estimated can get quite large. Therefore, in this example only the first three regions are considered in the analysis. The following statements specify and fit this model to the Cigar data set:

```plaintext
proc ssm data=Cigar;
   where region <= 3;
   id year interval=year;
   array RegionArray{3} region1-region3;
   do i=1 to 3;
      RegionArray[i] = (region=i);
   end;
   state zeta(3) type=varma(p(d)=1) cov(g) print=(ar cov);
   component eta = zeta*(RegionArray);
   intercept = 1.0;
   model lsales = intercept lprice lndi lpimin eta;
run;
```
The vectors $\xi_t$ are specified in the STATE statement. The TYPE= specification signifies that the three-dimensional state subsection, $\zeta$, follows a vector AR(1) model with a diagonal transition matrix and a disturbance covariance of a general form. The PRINT=(AR COV) option causes the SSM procedure to print the estimated AR coefficient matrix, $\hat{\Phi}$, and the disturbance error covariance $\hat{\Sigma}$, respectively. The COMPONENT statement defines the appropriate error contribution (named $\eta_t$), $\xi_t[i]$. Output 27.2.6 shows the estimated regression coefficients, Output 27.2.7 shows the estimate of $\hat{\Phi}$, and Output 27.2.8 shows the estimate of $\hat{\Sigma}$:

**Output 27.2.6** Autoregressive Model: Regression Estimates

| Response Variable | Regression Variable | Estimate | Standard Error | $t$ Value | Pr > $|t|$ |
|------------------|---------------------|----------|----------------|-----------|-----------|

Example 27.3: Backcasting, Forecasting, and Interpolation

This example illustrates how you can do model-based extrapolation—backcasting, forecasting, or interpolation—of a response variable. All you need is to appropriately augment the input data set with the relevant ID and predictor information and assign missing values to the response variable in these places. The following DATA step creates one such augmented data set by using a well-known data set that contains recordings of the Nile River water level measured between the years 1871 and 1970. Suppose you want to backcast the Nile water level for two years before 1871, forecast it for two years after 1970, and interpolate its value for the year 1921—for illustration purposes, this value is assumed to be missing in the available data set.

```sas
data Nile;
  input level @@;
  year = intnx( 'year', '1jan1869'd, _n_-1 );
  format year year4.;
  if year = '1jan1921'd then level=.;
datalines;
. .
1120 1160 963 1210 1160 1160 813 1230 1370 1140
995 935 1110 994 1020 960 1180 799 958 1140
1100 1210 1150 1250 1260 1220 1030 1100 774 840
874 694 940 833 701 916 692 1020 1050 969
831 726 456 824 702 1120 1100 832 764 821
768 845 864 862 698 845 744 796 1040 759
781 865 845 944 984 897 822 1010 771 676
649 846 812 742 801 1040 860 874 848 890
744 749 838 1050 918 986 797 923 975 815
1020 906 901 1170 912 746 919 718 714 740
. .
;
```

It is also known that for this time span the Nile water level can be reasonably modeled as a sum of a random walk trend, a level shift in the year 1899, and the observation error. The following statements fit this model to the data:

```sas
proc ssm data=Nile;
  id year interval=year;
  shift1899 = ( year >= '1jan1899'd );
  trend rw(rw);
  irregular wn;
  model level = shift1899 RW wn / print=smooth;
  output out=nileOut;
quit;
```

The model-based interpolated and extrapolated values of the Nile water level are shown in Output 27.3.1, which is produced by using the PRINT=SMOOTH option in the MODEL statement.
Output 27.3.1 Interpolated and Extrapolated Nile Water Level

Example 27.4: Longitudinal Data: Smoothing of Repeated Measures

This example of a repeated measures study is taken from Diggle, Liang, and Zeger (1994, p. 100). The data consist of body weights of 27 cows, measured at 23 unequally spaced time points over a period of approximately 22 months. Following Diggle, Liang, and Zeger (1994), one animal is removed from the analysis, one observation is removed according to their Figure 5.7, and the time is shifted to start at 0 and is measured in 10-day increments. The design is a $2 \times 2$ factorial, and the factors are the infection of an animal with M. paratuberculosis and whether the animal is receiving iron dosing. The data set contains five variables: cow assigns a unique identification number—from 1 to 26—to each cow in the study, tpoint denotes the time of the growth measurement, weight denotes the growth measurement, iron is a dummy variable that indicates whether the animal is receiving iron or not, and infection is a dummy variable that indicates whether the animal is infected or not. The goal of the study is to assess the effect of iron and infection—and their possible interaction—on weight. The following DATA steps create this data set:

```plaintext
data times;
  input time1-time23;

... more lines ...
```

The following DATA step adds ironInf, a grouping variable that is used later during the plotting of the results. In the next step, the data are sorted by the index variable, tpoint.

```
data Cows;
  set Cows;
  ironInf = "No Iron and No Infection";
  if iron=1 and infection=1 then ironInf = "Iron and Infection";
  else if iron=1 and infection=0 then ironInf = "Iron and No Infection";
  else if iron=0 and infection=1 then ironInf = "No Iron and Infection";
  else ironInf = "No Iron and No Infection";
run;
```

```
proc sort data=Cows;
  by tpoint;
run;
```

To assess the effect of iron and infection on weight, the natural growth profile of the animals must also be accounted for. Here two alternate models for this problem are considered. The first model assumes that the observed weight of an animal is the sum of a common growth profile, which is modeled by a polynomial spline trend of order 2, the regression effects of iron and infection, and the observation error—modeled as white noise. An interaction term, for interaction between iron and infection, was found to be insignificant and is not included. In the second model, the common growth profile and the regression variables of the first model are replaced by four environment specific growth profiles.

The following statements fit the first model:

```
proc ssm data=Cows;
  id tpoint;
  trend growth(ps(2));
  irregular wn;
  model weight = iron infection growth wn;
  eval pattern = iron + infection + growth;
  output out=For;
quit;
```

Output 27.4.1 shows that the state dimension of this model is 2 (corresponding to the polynomial trend specification of order 2), the number of diffuse elements in the initial condition is 4 (corresponding to the trend and the two regressors iron and infection), and the number of unknown parameters is 2 (corresponding to the variance parameters of trend and irregular).

After examining the model fit, it is useful to study how well the patterns implied by the model follow the data. The pattern, defined by the EVAL statement, is a sum of the trend component and the regression effects. A graphical examination of the smoothed estimate of pattern is done next. The following DATA step merges the output data set specified in the OUTPUT statement, For, with the input data set, Cows. In particular, this adds ironInf (a grouping variable from Cows) to For.

```plaintext
data For;
  merge for Cows;
  by tpoint;
run;
```

The following statements produce the graphs of smoothed_pattern, grouped according to the environment condition (see Output 27.4.5). The plot clearly shows that the control group “No Iron and No Infection” has the best growth profile, while the worst growth profile is for the group “Iron and Infection.”

```plaintext
proc sgplot data=For noautolegend;
  title 'Common Growth Profile Adjusted by Iron and Infection Status';
  band x=tpoint lower=smoothed_lower_pattern
    upper=smoothed_upper_pattern / group=ironInf name="band";
  series x=tpoint y=smoothed_pattern / group=ironInf name="series";
  keylegend "series";
run;
```
Output 27.4.5 Model 1: Growth Profile Comparison with 95% Confidence Bands

The following statements produce a panel of plots that show how well smoothed_pattern follows the observed data:

```
proc sgpanel data=For noautolegend;
  title 'Growth Plots Grouped by Iron and Infection';
  label tpoint='Time';
  panelby iron infection / columns=2;
  band x=tpoint lower=smoothed_lower_pattern upper=smoothed_upper_pattern;
  scatter x=tpoint y=weight;
  series x=tpoint y=smoothed_pattern;
run;
```
Output 27.4.6 shows that the model fits the data reasonably well.

**Output 27.4.6 Model 1: Smoothed Model Fit Lines**

The following statements fit the second model. In this model separate polynomial trends are fit according to different settings of iron and infection by specifying an appropriate list of (dummy) variables in the CROSS= option of the trend specification.

```sas
proc ssm data=Cows;
   id tpoint;
   a1 = (iron=1 and infection=1);
   a2 = (iron=1 and infection=0);
```
\[
\begin{aligned}
a3 &= (\text{iron}=0 \text{ and } \text{infection}=1); \\
a4 &= (\text{iron}=0 \text{ and } \text{infection}=0); \\
trend \text{ growth}(\text{ps}(2)) \text{ cross}=(a1-a4); \\
\text{irregular wn}; \\
\text{model weight} = \text{growth wn}; \\
\end{aligned}
\]

As a result of the \texttt{CROSS=} option, the trend component \texttt{growth} is actually a sum of four separate trends that correspond to the different iron-infection settings. Denoting \texttt{growth} by \( \mu_t \) and the four independent trends by \( \mu_{1,t}, \mu_{2,t}, \mu_{3,t}, \text{ and } \mu_{4,t} \),

\[ \mu_t = a1 \cdot \mu_{1,t} + a2 \cdot \mu_{2,t} + a3 \cdot \mu_{3,t} + a4 \cdot \mu_{4,t} \]

where \( a1, a2, a3, \text{ and } a4 \) are the dummy variables specified in the \texttt{CROSS=} option. This shows that, for any given setting (say, the one for \( a4 \)) \( \mu_t \) is simply the corresponding trend \( \mu_{4,t} \). In addition, note the form of the \texttt{COMPONENT} statements that define the components \texttt{a1Curve}, \texttt{a2Curve}, \texttt{a3Curve}, and \texttt{a4Curve}. This form of the \texttt{COMPONENT} statement treats the state that is associated with \texttt{growth}, named \texttt{growth\_state\_} by convention, as a state of nominal dimension 4—the number of variables in the \texttt{CROSS=} list. This, in turn, implies that \texttt{a1Curve}, which is defined as \texttt{growth\_state\_[1]}, refers to \( \mu_{1,t} \). These components are subsequently used in the \texttt{EVAL} statements to define contrasts between the trends—for example, \texttt{contrast21} corresponds to the difference between the trends \( \mu_{2,t} \) and \( \mu_{1,t} \). The estimates of these components (\texttt{a1Curve}, \texttt{a2Curve}, . . . , \texttt{contrast41}) are output to the data set \texttt{For1} named in the \texttt{OUT=} option of the \texttt{OUTPUT} data set.

The model summary, shown in \textbf{Output 27.4.7}, reflects the increased state dimension and the increased number of parameters.

\textbf{Output 27.4.7} Model2: Model Summary Information

<table>
<thead>
<tr>

</tr>
<tr>
<td>wn</td>
<td>Variance</td>
<td>8.39E-03</td>
<td>4.98E-04</td>
</tr>
</tbody>
</table>

Next, the smoothed estimate of trend (growth) is graphically studied. The following DATA step prepares the data for the grouped plots of \( \text{smoothed\_growth} \) by merging For1 with the input data set Cows. As before, the reason is merely to include ironInf (the grouping variable).

```sas
data For1;
merge For1 Cows;
by tpoint;
run;
```

The following statements produce the graphs of smoothed \( \mu_t \) for the desired settings (since the grouping variable ironInf exactly corresponds to these settings). Once again, the plot in Output 27.4.9 clearly shows that the control group “No Iron and No Infection” has the best growth profile, while the worst growth profile is for the group “Iron and Infection.” However, unlike the first model, the profile curves are not merely shifted versions of a common profile.

```sas
proc sgplot data=For1 noautolegend;
title 'Iron and Infection Status-Specific Growth Profiles';
band x=tpoint lower=smoothed_lower_growth
  upper=smoothed_upper_growth / group=ironInf name="band";
series x=tpoint y=smoothed_growth / group=ironInf name="series";
keylegend "series";
run;
```
The following statements produce the plot of smoothed \((\mu_{4,t} - \mu_{1,t})\)—contrast between the best and the worst growth profiles.

```
proc sgplot data=For1;
    title "Estimated Contrast Between the Treatments 4 and 1 ";
    band x=tpoint lower=smoothed_lower_contrast41
        upper=smoothed_upper_contrast41;
    series x=tpoint y=smoothed_contrast41;
run;
```

Output 27.4.10 shows that the growth pattern of the control group “No Iron and No Infection” consistently remains above the growth pattern of the treatment group “Iron and Infection.”
Example 27.5: A User-Defined Trend Model

This example shows how to specify a continuous-time trend model discussed in Harvey (1989, chap. 9, sec. 9.2.1). This model is not one of the predefined trend models in the SSM procedure. The system matrices that govern the two-dimensional state of this model are

\[
T = \begin{bmatrix} 1 & h \\ 0 & 1 \end{bmatrix}
\]

\[
Q = \begin{bmatrix} h\sigma_1^2 + \frac{h^3\sigma_2^2}{3} & \frac{h^2\sigma_2^2}{2} \\ \frac{h^2\sigma_2^2}{2} & h\sigma_2^2 \end{bmatrix}
\]

where \( h = h_t = (\tau_{t+1} - \tau_t) \) denotes the difference between the successive time points, and the parameters \( \sigma_1^2 \) and \( \sigma_2^2 \) are called the level variance and the slope variance, respectively. The initial condition is fully diffuse. The trend component corresponds to the first element of this state vector. The second element of the state vector corresponds to the slope of this trend component. This model reduces to the polynomial spline model of order 2 if the level variance \( \sigma_1^2 = 0 \). See the section “Polynomial Spline Trend” on page 1935.
The following statements specify a trend-plus-noise model to model the growth of cows in the previous example (Example 27.4). The only cows that are considered are the ones that received iron and are infected.

```plaintext
proc ssm data=Cows;
    where iron=1 and infection=1;
    id tpoint;
    parms var1 var2 / lower=(1.e-8 1.e-8);
    array tMat{2,2};
    tMat[1,1] = 1;
    tMat[2,2] = 1;
    tMat[1,2] = _ID_DELTA_; 
    array covMat{2,2};
    covMat[1,1] = var1_*_ID_DELTA_ + var2_*_ID_DELTA_**3/3;
    covMat[1,2] = var2_*_ID_DELTA_**2/2;
    covMat[2,1] = covMat[1,2];
    covMat[2,2] = var2_*_ID_DELTA_; 
    state harveyLL(2) T(g)=(tMat) cov(g)=(covMat) a1(2);
    component trend = harveyLL[1];
    component slope = harveyLL[2];
    irregular wn;
    model weight = trend wn;
    output out=for;
run;
```

The program is easy to follow. The PARMS statement declares var1 and var2 as positive parameters, which correspond to \( \sigma_1^2 \) and \( \sigma_2^2 \), respectively. The programming statements define arrays tMat and covMat, which later become the matrices \( T \) and \( Q \), respectively. Note that the element tMat[2,1] is left unassigned, since it is a structural zero of \( T \) (see the section “Sparse Transition Matrix Specification” on page 1924 for more information). Recall that the predefined variable _ID_DELTA_ contains the value of \( h_t \), which is needed for defining the elements of \( T \) and \( Q \) (see the section “ID Statement” on page 1906). The STATE statement defines the trend state vector, harveyLL, and the COMPONENT statement defines the trend component, trend, by selecting the first element of harveyLL. An additional COMPONENT statement defines the slope component, slope, as the second element of harveyLL. The slope component (which represents the cow’s growth rate) is not part of the observation equation; it is specified so that its estimate is output to For (the OUT= data set specified in the OUTPUT statement). The IRREGULAR statement defines the observation noise, and the MODEL statement defines the trend-plus-noise model.

The estimates of var1 and var2 are shown in Output 27.5.1. It shows that the estimate of the level variance is nearly 0, implying that the fitted trend model is identical to the polynomial spline trend of order 2.

**Output 27.5.1** Estimates of the Named Parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Estimate</th>
<th>Standard Error</th>

The following statements produce the plot of the fit of this trend model (shown in Output 27.5.3).

```sas
proc sgplot data=For;
  title "Model Fit: Two-Parameter Polynomial Spline of Order 2";
  series x=tpoint y=smoothed_trend;
  scatter x=tpoint y=weight;
run;
```

Output 27.5.3 A User-Defined Trend Model
The following statements produce the plot of the estimate of the slope component (shown in Output 27.5.4). This plot complements the preceding plot of trend; it shows the pattern of decline in the growth rate as the animals age.

```sas
proc sgplot data=For;
    title "Smoothed Estimate of Growth-Rate";
    series x=tpoint y=smoothed_slope;
run;
```

**Output 27.5.4**  Estimate of the slope Component

---

**Example 27.6: Model with Multiple ARIMA Components**

This example shows how you can fit the REGCOMPONENT models in Bell (2011) by using the SSM procedure. The following DATA step generates the data used in the last example of this article (Example 6: “Modeling a time series with a sampling error component”). The variable y in this data set contains monthly values of the VIP series (value of construction put in place), a U.S. Census Bureau publication that measures the value of construction installed or erected at construction sites during a given month. The values of y are known to be contaminated with heterogeneous sampling errors; the variable hwt in the data set is a proxy for this sampling error in the log scale. The variable hwt is treated as a weight variable for the noise component in the model.
data Test;
  input y hwt;
  date = intnx('month', '01jan1997'd, _n_-1 );
  format date date.;
  logy = log(y);
  label logy = 'Log value of construction put in place';
  datalines;
  115.2 0.042
  110.4 0.042
  111.5 0.067
  127.9 0.122
  150.0 0.129
  149.5 0.135
  139.5 0.152
  144.6 0.168
  176.0 0.173

... more lines ...

The article proposes the following model for the log VIP series:

$$\log(y) = \mu_t + hwt \cdot \eta_t$$

where $\mu_t$ follows an ARIMA$(0,1,1) \times (0,1,1)_{12}$ model and $\eta_t$ is a zero-mean, AR(2) error process. The following statements specify this model for logy:

proc ssm data=Test;
  id date interval=month;
  trend airlineTrend(arma(d=1 sd=1 q=1 sq=1 s=12));
  trend ar2Noise(arma(p=2)) cross=(hwt);
  model logy = airlineTrend ar2Noise;
  output outfor=For;
run;

Output 27.6.1 Estimates of the ARIMA Components Model

<table>
<thead>
<tr>
<th>Component</th>
<th>Type</th>
<th>Parameter</th>
<th>Estimate</th>
<th>Standard Error</th>
</tr>
</thead>
<tbody>
<tr>
<td>airlineTrend</td>
<td>ARMA</td>
<td>Error Variance</td>
<td>0.000642</td>
<td>0.00906</td>
</tr>
<tr>
<td>airlineTrend</td>
<td>ARMA</td>
<td>MA_1</td>
<td>0.251125</td>
<td>0.57239</td>
</tr>
<tr>

<td>0.08027</td>
</tr>
<tr>
<td>ar2Noise</td>
<td>ARMA</td>
<td>AR_2</td>
<td>0.399923</td>
<td>0.21560</td>
</tr>
</tbody>
</table>

The ARIMA$(0,1,1) \times (0,1,1)_{12}$ trend $\mu_t$ is named airlineTrend and the zero-mean, AR(2) error process $\eta_t$ is named ar2Noise. See the TREND statement for more information about the ARIMA notation. The estimates
of model parameters are shown in Output 27.6.1. These estimates are different from the estimates given in the article; however, the estimated trend and noise series are qualitatively similar. The article uses an estimation procedure that consists of a sequence of alternating steps in which one subset of parameters is held fixed and the remaining parameters are estimated by MLE in each step. This process continues until all the estimates stabilize. The SSM procedure estimates all the parameters simultaneously by MLE.

The following statements produce the plot of the estimate of the airlineTrend component (shown in Output 27.6.2). This plot is very similar to the trend plot shown in the article (the article plots are in the antilog scale).

```plaintext
proc sgplot data=For;
    title "Smoothed Estimate of the ARIMA(0,1,1)(0,1,1)12 Trend";
    series x= date y=smoothed_airlineTrend;
    scatter x= date y=logy;
run;
```

**Output 27.6.2** Estimate of the airlineTrend Component

The following statements produce the plot of the estimate of the ar2Noise component (shown in Output 27.6.3). This plot is also very similar to the noise plot shown in the article (once again, the article plots are in the antilog scale).
Example 27.7: Dynamic Factor Modeling

This example shows how you can fit the dynamic Nelson-Siegel (DNS) factor model discussed in Koopman, Mallee, and van der Wel (2010). The following DATA step creates the yield-curve data set, Dns, that is used in this article. The data are monthly bond yields that were recorded between the start of 1970 to the end of 2000 for 17 bonds of different maturities; the maturities range from three months to 10 years (120 months). The variable date contains the observation date, yield contains the bond yield, maturity contains the associated bond maturity, and mtype contains an index (ranging from 1 to 17) that sequentially labels bonds of increasing maturity. The data have been extended for two more years by adding missing yields for the years 2001 and 2002, which causes the SSM procedure to produce model forecasts for this span.
data Dns;
input date date. yield maturity mtype;
format date date.;
datalines;
