Writes the residual values to the OUT= data set	FIT	OUTRESID
Writes the covariance matrix of the equation errors to a data set	FIT	OUTS=
Writes the S matrix used in the objective function definition to a data set	FIT	OUTSUSED=
Writes the estimate of the variance matrix of the moment generating function	FIT	OUTV=
Reads the covariance matrix of the equation errors	FIT, SOLVE	SDATA=
Reads the covariance matrix for GMM and IT-GMM	FIT	VDATA=
Specifies the name of the time variable	FIT, SOLVE, MODEL	TIME=
Selects the estimation type to read	FIT, SOLVE	TYPE=
General ESTIMATE Statement Options		
Specifies the name of the data set in which the estimate of the functions of the parameters are to be written	ESTIMATE	OUTEST=

Description	Statement	Option
Writes the covariance matrix of the functions of the parameters to the OUTEST= data set	ESTIMATE	OUTCOV
Prints the covariance matrix of the functions of the parameters	ESTIMATE	COVB
Prints the correlation matrix of the functions of the parameters	ESTIMATE	CORRB
Printing Options for FIT Tasks		
Prints the modified Breusch-Pagan test for heteroscedasticity	FIT	BREUSCH
Prints the Chow test for structural breaks	FIT	CHOW=
Prints collinearity diagnostics	FIT	COLLIN
Prints the correlation matrices	FIT	CORR
Prints the correlation matrix of the parameters	FIT	CORRB
Prints the correlation matrix of the residuals	FIT	CORRS
Prints the covariance matrices	FIT	COV
Prints the covariance matrix of the parameters	FIT	COVB
Prints the covariance matrix of the residuals	FIT	COVS
Prints Durbin-Watson d statistics	FIT	DW
Prints first-stage R^2 statistics	FIT	FSRSQ
Prints Godfrey's tests for autocorrelated residuals for each equation	FIT	GODFREY
Prints Hausman's specification test	FIT	HAUSMAN
Prints tests of normality of the model residuals	FIT	NORMAL
Prints the predictive Chow test for structural breaks	FIT	PCHOW=
Specifies all the printing options	FIT	PRINTALL
Prints White's test for heteroscedasticity	FIT	WHITE
Options to Control FIT Iteration Output		
Prints the inverse of the crossproducts Jacobian matrix	FIT	I
Prints a summary iteration listing	FIT	ITPRINT
Prints a detailed iteration listing	FIT	ITDETAILS
Prints the crossproduct Jacobian matrix	FIT	XPX
Specifies all the iteration printing-control options	FIT	ITALL
Options to Control the Minimization Process		
Specifies the convergence criteria	FIT	CONVERGE=
Selects the Hessian approximation used for FIML	FIT	HESSIAN=

Description	Statement	Option
Specifies the local truncation error bound for the integration	FIT, SOLVE, MODEL	LTEBOUND=
Specifies the maximum number of iterations allowed	FIT	MAXITER=
Specifies the maximum number of subiterations allowed	FIT	MAXSUBITER=
Selects the iterative minimization method to use	FIT	METHOD=
Specifies the smallest allowed time step to be used in the integration	FIT, SOLVE, MODEL	MINTIMESTEP=
Modify the iterations for estimation methods that iterate the S matrix or the V matrix	FIT	NESTIT
Specifies the smallest pivot value	MODEL, FIT, SOLVE	SINGULAR
Specifies the number of minimization iterations to perform at each grid point	FIT	STARTITER=
Specifies a weight variable	WEIGHT	
Options to Read and Write Model Files		
Deletes a model from a model file	DELETEMODEL	MODNAME=
Reads a model from one or more input model files	INCLUDE	MODEL=
Suppresses the default output of the model file	MODEL, RESET	NOSTORE
Specifies the name of an output model file	MODEL, RESET	OUTMODEL=
Deletes the current model	RESET	PURGE
Options to List or Analyze the Structure of the Model		
Identifies equations in a dependency analysis	EQGROUP	
Identifies variables in a dependency analysis	VARGROUP	
Prints a dependency analysis of a simulation model	SOLVE	ANALYZEDEP=
Prints a dependency structure of a normal form model	MODEL	BLOCK
Prints a graph of the dependency structure of a normal form model	MODEL	GRAPH
Prints the model program and variable lists	MODEL	LIST
Prints the derivative tables and compiled model program code	MODEL	LISTCODE
Prints a dependency list	MODEL	LISTDEP
Prints a table of derivatives	MODEL	LISTDER
Prints a cross-reference of the variables	MODEL	XREF
General Printing Control Options		
Expands parts of the printed output	FIT, SOLVE	DETAILS

Description	Statement	Option
Prints a message for each statement as it is executed	FIT, SOLVE	FLOW
Selects the maximum number of execution errors that can be printed	FIT, SOLVE	MAXERRORS=
Requests a comprehensive memory usage summary	FIT, SOLVE, MODEL, RESET	MEMORYUSE
Selects the number of decimal places shown in the printed output	FIT, SOLVE	NDEC=
Suppresses the normal printed output	FIT, SOLVE	NOPRINT
Turns off the NOPRINT option	RESET	PRINT
Specifies all the noniteration printing options	FIT, SOLVE	PRINTALL
Prints tables which summarize missing value calculations	FIT, SOLVE, MODEL	REPORTMISSINGS
Prints the result of each operation as it is executed	FIT, SOLVE	TRACE
Statements that Declare Variables		
Associates a name with a list of variables and constants	ARRAY	
Declares a variable to have a fixed value	CONTROL	
Declares a variable to be a dependent or endogenous variable	ENDOGENOUS	
Declares a variable to be an independent or exogenous variable	EXOGENOUS	
Specifies identifying variables	ID	
Assigns a label to a variable	LABEL	
Selects additional variables to be output	OUTVARS	
Declares a variable to be a parameter	PARAMETERS	
Forces a variable to hold its value from a previous observation	RETAIN	
Declares a model variable	VAR	
Declares an instrumental variable	INSTRUMENTS	
Omits the default intercept term in the instruments list	INSTRUMENTS	NOINT
General FIT Statement Options		
Omits parameters from the estimation	FIT	DROP=
Associates a variable with an initial value as a parameter or a constant	FIT	INITIAL=
Bypasses OLS to get initial parameter estimates for GMM, ITGMM, or FIML	FIT	NOOLS
Bypasses 2SLS to get initial parameter estimates for GMM, ITGMM, or FIML	FIT	NO2SLS
Specifies the parameters to estimate	FIT	PARMS=

Description	Statement	Option
Requests confidence intervals on estimated parameters	FIT	PRL=
Selects a grid search	FIT	START=
Options to Control the Estimation Method Used		
Specifies nonlinear ordinary least squares	FIT	OLS
Specifies iterated nonlinear ordinary least squares	FIT	ITOLS
Specifies seemingly unrelated regression	FIT	SUR
Specifies iterated seemingly unrelated regression	FIT	ITSUR
Specifies two-stage least squares	FIT	2SLS
Specifies iterated two-stage least squares	FIT	IT2SLS
Specifies three-stage least squares	FIT	3SLS
Specifies iterated three-stage least squares	FIT	IT3SLS
Specifies full information maximum likelihood	FIT	FIML
Specifies simulated method of moments	FIT	NDRAW
Specifies number of draws for the V matrix	FIT	NDRAWV
Specifies number of initial observations for SMM	FIT	NPREOBS
Selects the variance-covariance estimator used for FIML	FIT	COVBEST=
Specifies generalized method of moments	FIT	GMM
Specifies the kernel for GMM and ITGMM	FIT	KERNEL=
Specifies iterated generalized method of moments	FIT	ITGMM
Specifies the type of generalized inverse used for the covariance matrix	FIT	GINV=
Specifies the denominator for computing variances and covariances	FIT	VARDEF=
Specifies adding the variance adjustment for SMM	FIT	ADJSMMV
Specifies variance correction for heteroscedasticity	FIT	HCCME=
Specifies GMM variance under arbitrary weighting matrix	FIT	GENGMMV
Specifies GMM variance under optimal weighting matrix	FIT	NOGENGMMV
Solution Mode Options		
Selects a subset of the model equations	SOLVE	SATISFY=
Solves only for missing variables	SOLVE	FORECAST
Solves for all solution variables	SOLVE	SIMULATE

Description	Statement	Option
Solution Mode Options: Lag Processing		
Uses solved values in the lag functions	SOLVE	DYNAMIC
Uses actual values in the lag functions	SOLVE	STATIC
Produces successive forecasts to a fixed forecast horizon	SOLVE	NAHEAD=
Selects the observation to start dynamic solutions	SOLVE	START=
Solution Mode Options: Numerical Methods		
Specifies the maximum number of iterations allowed	SOLVE	MAXITER=
Specifies the maximum number of subiterations allowed	SOLVE	MAXSUBITER=
Specifies the convergence criteria	SOLVE	CONVERGE=
Computes a simultaneous solution using a Jacobi-like iteration	SOLVE	JACOBI
Computes a simultaneous solution using a Gauss-Seidel-like iteration	SOLVE	SEIDEL
Computes a simultaneous solution using Newton's method	SOLVE	NEWTON
Computes a nonsimultaneous solution	SOLVE	SINGLE
Monte Carlo Simulation Options		
Specifies quasi-random number generator	SOLVE	QUASI=
Specifies pseudo-random number generator	SOLVE	PSUEDO=
Repeats the solution multiple times	SOLVE	RANDOM=
Initializes the pseudo-random number generator	SOLVE	SEED=
Specifies copula options	SOLVE	COPULA=
Solution Mode Printing Options		
Prints between data points integration values for the DERT. variables and the auxiliary variables	FIT, SOLVE, MODEL	INTGPRINT
Prints the solution approximation and equation errors	SOLVE	ITPRINT
Prints the solution values and residuals at each observation	SOLVE	SOLVEPRINT
Prints various summary statistics	SOLVE	STATS
Prints tables of Theil inequality coefficients	SOLVE	THEIL
Specifies all printing control options	SOLVE	PRINTALL

Description	Statement	Option
General TEST Statement Options		
Specifies that a Wald test be computed	TEST	WALD
Specifies that a Lagrange multiplier test be computed	TEST	LM
Specifies that a likelihood ratio test be computed	TEST	LR
Request all three types of tests	TEST	ALL
Specifies the name of an output SAS data set that contains the test results	TEST	OUT=
Miscellaneous Statements		
Specifies the range of observations to be used	RANGE	
Subsets the data set with BY variables	BY	

PROC MODEL Statement

PROC MODEL *options* ;

The following options can be specified in the PROC MODEL statement. All of the nonassignment options (the options that do not accept a value after an equal sign) can have NO prefixed to the option name in the RESET statement to turn the option off. The default case is not explicitly indicated in the discussion that follows. Thus, for example, the option DETAILS is documented in the following, but NODETAILS is not documented since it is the default. Also, the NOSTORE option is documented because STORE is the default.

Data Set Options

DATA=SAS-data-set

names the input data set. Variables in the model program are looked up in the DATA= data set and, if found, their attributes (type, length, label, format) are set to be the same as those in the input data set (if not previously defined otherwise). The values for the variables in the program are read from the input data set when the model is estimated or simulated by FIT and SOLVE statements.

OUTPARMS=SAS-data-set

writes the parameter estimates to a SAS data set. See the section “[Output Data Sets](#)” on page 1217 for details.

PARMSDATA=SAS-data-set

names the SAS data set that contains the parameter estimates. In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used. See the section “[Input Data Sets](#)” on page 1211 for details.

PLOTS< (*global-plot-options*) > < =(*plot-request* ...) >

selects plots that the MODEL procedure produces via the Output Delivery System. For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*). The *global-plot-options* apply to all relevant plots generated by the MODEL procedure. The *global-plot-options* and specific *plot-request* options supported by the MODEL procedure follow.

Global Plot Options

ONLY suppresses the default plots. Only the plots specifically requested are produced.

UNPACKPANEL displays each graph separately. (By default, some graphs can appear together in a single panel.)

Specific Plot Options

ALL requests that all plots appropriate for the particular analysis be produced.

ACF produces the autocorrelation function plot.

DEPENDENCY< (OUTLINE=ON | OFF) > produces the dependency analysis plots. Specifying the OUTLINE= option displays, or suppresses outlines around the dependency cells.

IACF produces the inverse autocorrelation function plot of residuals.

PACF produces the partial autocorrelation function plot of residuals.

FITPLOT plots the predicted and actual values.

COOKSD produces the Cook’s D plot.

QQ produces a QQ plot of residuals.

RESIDUAL | **RES** plots the residuals.

STUDENTRESIDUAL plots the studentized residuals.

RESIDUALHISTOGRAM | **RESIDHISTOGRAM** plots the histogram of residuals.

NONE suppresses all plots.

Options to Read and Write Model Files

MODEL=*model-name*

MODEL=(*model-list*)

reads the model from one or more input model files created by previous PROC MODEL executions. Model files are written by the OUTMODEL= option.

NOSTORE

suppresses the default output of the model file. This option is applicable only when FIT or SOLVE statements are not used, the MODEL= option is not used, and when a model is specified.

OUTCAT=(*outcat-name* **MODNAME**=*model-key* < *outcat-options* >)

SLIST=(*outcat-name* **MODNAME**=*model-key* < *outcat-options* >)

specifies the name and *model-key* for writing fitted model files. The *model-key* is a SAS name. Files written using the OUTCAT= option are used by SAS Risk Dimensions. The OUTCAT= option only applies to FIT statements. You can specify the following *outcat-options*:

DIM=*n* specifies the dimensionality of the model.

GROUPIMODGROUP=*group* specifies a SAS name which is the group for the model.

INTERVAL=*interval* specifies the time interval between observations.

MODLABEL=*label* specifies a label for the model.

STARTDATE=*date* specifies the starting date of the model.

OUTMODEL=*model-name*

specifies the name of an output model file to which the model is to be written. Starting with SAS 9.2, model files are being stored as XML-based SAS data sets instead of being stored as members of a SAS catalog as in earlier releases. This makes MODEL files more readily extendable in the future and enables Java-based applications to read the MODEL files directly. To change this behavior, use the SAS *global-CMPMODEL-options*. You can choose the format in which the output model file is stored and read by using the **CMPMODEL=*global-CMPMODEL-options*** in an **OPTIONS** statement as follows.

OPTIONS CMPMODEL=*global-CMPMODEL-options*;

You can specify the following *global-CMPMODEL-options*:

CATALOG specifies that model files be written and read from SAS catalogs only.

XML specifies that model files be written and read from XML data sets only.

BOTH specifies that model files be written to both XML and CATALOG formats. When BOTH is specified, model files are read from the data set first and read from the SAS catalog only if the data set is not found. This is the default.

Options to List or Analyze the Structure of the Model

These options produce reports on the structure of the model or list the programming statements that define the models. These options are automatically reset (turned off) after the reports are printed. To turn these options back on after a RUN statement has been entered, use the RESET statement or specify the options in a FIT or SOLVE statement.

ANALYZEDEP=(*dependency-plot1* < *dependency-plot2* ... >)

plots analyses of the dependencies among equations and solve variables. Each *dependency-plot* is one of the following:

BLOCK specifies a block dependency matrix of the entire system.

BLOCK(*eq-list*,*var-list*) specifies a block dependency matrix for a subset of equations and solve variables.

DETAILS specifies a dependency matrix of all equations and solve variables.

DETAILS(*eq-list*,*var-list*) specifies a dependency matrix for a subset of equations and solve variables.

NOLISTBLOCK suppresses the listing of dependency blocks.

You can specify which equations and solve variables are included in the dependency analysis by qualifying both the BLOCK and DETAILS *dependency-plot* options with a pair of lists. The first list in the pair is the *eq-list*. It specifies which equations to include in the dependency analysis. You can specify a mix of equation names and equation group labels in the *eq-list*. The MODEL procedure replaces each equation group label in the *eq-list* with the list of equations that are specified in the corresponding EQGROUP statement. The second list in the pair is the *var-list*. It specifies which solve variables to include in the dependency analysis. You can specify a mix of variable names and variable group labels in the *var-list*. The MODEL procedure replaces each variable group label in the *var-list* with the list of variables that are specified in the corresponding VARGROUP statement. By default, when you specify a BLOCK option, a listing of the equations and solve variables that form each dependency block is generated. The NOLISTBLOCK option suppresses this listing. The ANALYZE= option applies only to SOLVE steps. For more information about the analyses that are performed by the ANALYZE= option, see the section “[Diagnostics and Debugging](#)” on page 1276.

BLOCK

prints an analysis of the structure of the model given by the assignments to model variables that appear in the model program. This analysis includes a classification of model variables into endogenous (dependent) and exogenous (independent) groups based on the presence of the variable on the left side of an assignment statement. The endogenous variables are grouped into simultaneously determined blocks. The dependency structure of the simultaneous blocks and exogenous variables is also printed. The BLOCK option cannot analyze dependencies implied by general form equations.

GRAPH

prints the graph of the dependency structure of the model. The GRAPH option also invokes the BLOCK option and produces a graphical display of the information listed by the BLOCK option.

LIST

prints the model program and variable lists, including the statements added by PROC MODEL and macros.

LISTALL

selects the LIST, LISTDEP, LISTDER, and LISTCODE options.

LISTCODE

prints the derivative tables and compiled model program code. LISTCODE is a debugging feature and is not normally needed.

LISTDEP

prints a report that lists for each variable in the model program the variables that depend on it and that it depends on. These lists are given separately for current-period values and for lagged values of the variables.

The information displayed is the same as that used to construct the BLOCK report but differs in that the information is listed for all variables (including parameters, control variables, and program variables), not just for the model variables. Classification into endogenous and exogenous groups and analysis of simultaneous structure is not done by the LISTDEP report.

LISTDER

prints a table of derivatives for FIT and SOLVE tasks. (The LISTDER option is applicable only for the default NEWTON method for SOLVE tasks.) The derivatives table shows each nonzero derivative computed for the problem. The derivative listed can be a constant, a variable in the model program, or a special derivative variable created to hold the result of the derivative expression. This option is turned on by the LISTCODE and PRINTALL options.

XREF

prints a cross-reference of the variables in the model program that shows where each variable was referenced or given a value. The XREF option is normally used in conjunction with the LIST option. A more detailed description is given in the section “[Diagnostics and Debugging](#)” on page 1276.

General Printing Control Options**DETAILS**

specifies the detailed printout. Parts of the printed output are expanded when the DETAILS option is specified. The following additional graphs of the residuals are produced when graphics output is enabled: ACF, PACF, IACF, white noise, and QQ plot versus the normal.

FLOW

prints a message for each statement in the model program as it is executed. This debugging option is needed very rarely and produces voluminous output.

MAXERRORS=*n*

specifies the maximum number of execution errors that can be printed. The default is MAXERRORS=50.

MEMORYUSE

prints a report of the memory required for the various parts of the analysis.

NDEC=*n*

specifies the precision of the format that PROC MODEL uses when printing various numbers. The default is NDEC=3, which means that PROC MODEL attempts to print values by using the D format but ensures that at least three significant digits are shown. If the NDEC= value is greater than nine, the BEST. format is used. The smallest value allowed is NDEC=2.

The NDEC= option affects the format of most, but not all, of the floating point numbers that PROC MODEL can print. For some values (such as parameter estimates), a precision limit one or two digits greater than the NDEC= value is used. This option does not apply to the precision of the variables in the output data set.

NOPRINT

suppresses the normal printed output but does not suppress error listings. Using any other print option turns the NOPRINT option off. The PRINT option can be used with the RESET statement to turn off NOPRINT.

PRINTALL

turns on all the printing-control options. The options set by PRINTALL are DETAILS; the model information options LIST, LISTDEP, LISTDER, XREF, BLOCK, and GRAPH; the FIT task printing options FSRSQ, COVB, CORRB, COVS, CORRS, DW, and COLLIN; and the SOLVE task printing options STATS, THEIL, SOLVEPRINT, and ITPRINT.

REPORTMISSINGS

prints tables that summarize missing values that are encountered during a SOLVE or FIT task. The missing values that are summarized in these tabular reports can be produced by missing values in the DATA= data set or by calculations in the model program that generate missing values. The number of missing values that are reported can be limited by using the MAXERRORS= option.

TRACE

prints the result of each operation in each statement in the model program as it is executed, in addition to the information printed by the FLOW option. This debugging option is needed very rarely and produces voluminous output.

FIT Task Options

The following options are used in the FIT statement (parameter estimation) and can also be used in the PROC MODEL statement: COLLIN, CONVERGE=, CORR, CORRB, CORRS, COVB, COVBEST=, COVS, DW, FIML, FSRSQ, GMM, HESSIAN=, I, INTGPRINT, ITALL, ITDETAILS, ITGMM, ITPRINT, ITOLS, ITSUR, IT2SLS, IT3SLS, KERNEL=, LTEBOUND=, MAXITER=, MAXSUBITER=, METHOD=, MINTIMESTEP=, NESTIT, N2SLS, N3SLS, OLS, OUTPREDICT, OUTRESID, OUTACTUAL, OUTLAGS, OUTALL, OUTCOV, SINGULAR=, STARTITER=, SUR, TIME=, VARDEF, and XPX. See the section “FIT Statement” on page 1095 for a description of these options.

When used in the PROC MODEL or RESET statement, these are default options for subsequent FIT statements. For example, the statement

```
proc model n2sls ... ;
```

makes two-stage least squares the default parameter estimation method for FIT statements that do not specify an estimation method.

SOLVE Task Options

The following options for the SOLVE statement can also be used in the PROC MODEL statement: CONVERGE=, DYNAMIC, FORECAST, INTGPRINT, ITPRINT, JACOBI, LTEBOUND=, MAXITER=, MAXSUBITER=, MINTIMESTEP=, NAHEAD=, NEWTON, OUTPREDICT, OUTRESID, OUTACTUAL, OUTLAGS, OUTERERRORS, OUTALL, SEED=, SEIDEL, SIMULATE, SINGLE, SINGULAR=, SOLVEPRINT, START=, STATIC, STATS, THEIL, TIME=, and TYPE=. For more information about these options, see section “SOLVE Statement” on page 1111.

When used in the PROC MODEL or RESET statement, these options provide default values for subsequent SOLVE statements.

BOUNDS Statement

BOUNDS *bound1* < , *bound2* ... > ;

The BOUNDS statement imposes simple boundary constraints either on the parameters in an estimation or on the solution variables specified in a solve operation. A BOUNDS statement that applies to parameters constrains the parameters estimated in the preceding FIT statement or, in the absence of a preceding FIT

statement, in the following FIT statement. A BOUNDS statement that is applied to solution variables constrains the solution of the preceding SOLVE statement or, in the absence of a preceding SOLVE statement, of the following SOLVE statement. You can specify any number of BOUNDS statements.

Each *bound* is composed of either parameters or solution variables, constants, and inequality operators:

item operator item < operator item < operator item ... > >

For BOUNDS statements that apply to FIT statements, each *item* is a constant, the name of an estimated parameter, or a list of parameter names. For BOUNDS statements that apply to SOLVE statements, each *item* is a constant, the name of a solution variable, or a list of solution variables. Each *operator* is <, >, <=, or >=.

You can use either the BOUNDS statement or the RESTRICT statement to impose boundary constraints when estimating parameters or solving for solution variables.

The BOUNDS statement provides a simpler syntax for specifying boundary constraints than the RESTRICT statement. For more information about the computational details of estimation and solutions with inequality restrictions, see the section “[RESTRICT Statement](#)” on page 1109.

Parameter Estimates

Each active boundary constraint on estimated parameters is associated with a Lagrange multiplier. In the printed output and in the OUTEST= data set, the Lagrange multiplier estimates are identified with the names BOUND0, BOUND1, and so forth. The probabilities of the Lagrange multipliers are computed by using a beta distribution (LaMotte 1994). To give the constraints more descriptive names, use the RESTRICT statement instead of the BOUNDS statement.

The following BOUNDS statement constrains the estimates of the parameters A and B and the ten parameters P1 through P10 to be between 0 and 1. This example illustrates the use of parameter lists to specify boundary constraints.

```
bounds 0 < a b p1-p10 < 1;
```

The following statements show how to use the BOUNDS statement, and they produce the output shown in [Figure 19.13](#):

```
title 'Holzman Function (1969), Himmelblau No. 21, N=3';
data zero;
  do i = 1 to 99;
    output;
  end;
run;

proc model data=zero;
  parms x1= 100 x2= 12.5 x3= 3;
  bounds .1 <= x1 <= 100,
         0 <= x2 <= 25.6,
         0 <= x3 <= 5;

  t = 2 / 3;
  u = 25 + (-50 * log(0.01 * i )) ** t;
  v = (u - x2) ** x3;
  w = exp(-v / x1);
  eq.foo = -.01 * i + w;
```

```
fit foo / method=marquardt;
run;
```

Figure 19.13 Output from Bounded Estimation

Holzman Function (1969), Himmelblau No. 21, N=3				
The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
x1	49.99999	0	.	.
x2	25	0	.	.
x3	1.5	0	.	.

Solution Variables

Boundary constraints on solution variables can be used to specify which solution is reported when an equation has multiple solutions. The BOUNDS statement in the following example causes its associated SOLVE statement to compute only the negative value of the solution variable shown in Figure 19.14:

```
data d;
  date = 0;
run;

proc model data=d;
  endo x;
  bounds x < 0;

  eq.sqrt = x**2 - 4;

  solve / optimize out=o;
run;

proc print data = o; run;
```

Figure 19.14 Listing of OUT= Data Set Created by a Bounded SOLVE Statement

Obs	_TYPE_	_MODE_	_ERRORS_	x
1	PREDICT	SIMULATE	0	-2

BY Statement

BY variables ;

A BY statement is used with the FIT statement to obtain separate estimates for observations in groups defined by the BY variables. If an output model file is written using the OUTMODEL= option, the parameter values that are stored are those from the last BY group processed. To save parameter estimates for each BY group, use the OUTEST= option in the FIT statement.

A BY statement is used with the SOLVE statement to obtain solutions for observations in groups defined by the BY variables. If the BY variables in the DATA= data set and the ESTDATA= data set are identical, then the two data sets are synchronized and the calculations are performed by using the data and parameters for each BY group. This holds for BY variables in the SDATA= data set as well. If the BY variables do not match, BY-group processing is abandoned in either the ESTDATA= data set or the SDATA= data set, whichever has the missing BY value. If the DATA= data set does not contain BY variables and the ESTDATA= data set or the SDATA= data set does, then BY-group processing is performed for the ESTDATA= data set and the SDATA= data set by reusing the data in the DATA= data set for each BY group.

If both FIT and SOLVE tasks require BY-group processing, then two separate BY statements are needed. If parameters for each BY group in the OUTEST = data set that is obtained from the FIT task are to be used for the corresponding BY group for the SOLVE task, then one of the two BY statements must appear after the SOLVE statement.

The following linear regression example illustrates the use of BY-group processing. Both the data sets A and D to be used for fitting and solving, respectively, have three groups.

```
/*----- data set for fit task----- */
data a ;
  do group = 1 to 3 ;
    do i = 1 to 100 ;
      x = normal(1);
      y = 2 + 3*x + rannor(1) ;
      output ;
    end ;
  end ;
run ;

/*----- data set for solve task----- */
data d ;
  do group = 1 to 3 ;
    x = normal(1) ;
    output ;
  end ;
run ;

/* ----- 2 BY statements, one of them appear after SOLVE statement ----- */
proc model data = a ;
  by group ;
  y = a0 + a1*x ;
  fit y / outest = b1 ;
  solve y / data = d estdata = b1 out = c1 ;
  by group ;
```

```
run;

proc print data = b1 ;run;
proc print data = c1 ; run;
```

Each of the parameter estimates obtained from the BY group processing in the FIT statement shown in Figure 19.15 is used in the corresponding BY group variables in the SOLVE statement. The output dataset is shown in Figure 19.16.

Figure 19.15 Listing of OUTEST= Data Set Created in the FIT Statement with Two BY Statements

Obs	group	_NAME_	_TYPE_	_STATUS_	_NUSED_	a0	a1
1	1		OLS	0 Converged	100	2.00338	3.00298
2	2		OLS	0 Converged	100	2.05091	3.08808
3	3		OLS	0 Converged	100	2.15528	3.04290

Figure 19.16 Listing of OUT= Data Set Created in the SOLVE Statement with Two BY Statements

Obs	group	_TYPE_	_MODE_	_ERRORS_	y	x
1	1	PREDICT	SIMULATE	0	7.42322	1.80482
2	2	PREDICT	SIMULATE	0	1.80413	-0.07992
3	3	PREDICT	SIMULATE	0	3.36202	0.39658

If only one BY statement is used and it appears before the SOLVE statement, then parameters for the last BY group in the OUTEST = data set are used for all BY groups for the SOLVE task.

```
/*----- 1 BY statement that appears before SOLVE statement----- */
proc model data = a ;
  by group ;
  y = a0 + a1*x ;
  fit y / outest = b2 ;
  solve y / data = d estdata = b2 out = c2 ;
run;

proc print data = b2 ; run;
proc print data = c2 ; run;
```

The estimates of the parameters are shown in Figure 19.17, and the output data set of the SOLVE statement is shown in Figure 19.18. Hence, the estimates and the predicted values obtained in the last BY group variable of both DATA C1 and C2 are the same while the others do not match.

Figure 19.17 Listing of OUTEST= Data Set Created in the FIT Statement with One BY Statement That Appears before the SOLVE Statement

Obs	group	_NAME_	_TYPE_	_STATUS_	_NUSED_	a0	a1
1	1		OLS	0 Converged	100	2.00338	3.00298
2	2		OLS	0 Converged	100	2.05091	3.08808
3	3		OLS	0 Converged	100	2.15528	3.04290

Figure 19.18 Listing of OUT= Data Set Created in the SOLVE Statement with One BY Statement That Appears before the SOLVE Statement

Obs	_TYPE_	_MODE_	_ERRORS_	y	x
1	PREDICT	SIMULATE	0	7.64717	1.80482
2	PREDICT	SIMULATE	0	1.91211	-0.07992
3	PREDICT	SIMULATE	0	3.36202	0.39658

If only one BY statement is used and it appears after the SOLVE statement, then BY group processing does not apply to the FIT task. In this case, the OUTEST=data set does not contain the BY variable, and the single set of parameter estimates obtained from the FIT task are used for all BY groups during the SOLVE task.

```

/*----- 1 BY statement that appears after SOLVE statement-----*/
proc model data = a ;
  y = a0 + a1*x ;
  fit y / outest = b3 ;
  solve y / data = d estdata = b3 out = c3 ;
  by group ;
run;

proc print data = b3 ; run;
proc print data = c3 ; run;

```

The output data B3 and C3 are listed in [Figure 19.19](#) and [Figure 19.20](#), respectively.

Figure 19.19 Listing of OUTEST= Data Set Created in the FIT Statement with One BY Statement That Appears after the SOLVE Statement

Obs	_NAME_	_TYPE_	_STATUS_	_NUSED_	a0	a1

1	1	PREDICT	SIMULATE	0	7.55686	1.80482
2	2	PREDICT	SIMULATE	0	1.82312	-0.07992
3	3	PREDICT	SIMULATE	0	3.27270	0.39658

CONTROL Statement

CONTROL *variable* < *value* > ... ;

The CONTROL statement declares control variables and specifies their values. A control variable is like a parameter except that it has a fixed value and is not estimated from the data. You can use control variables for constants in model equations that you might want to change in different solution cases. You can use control variables to vary the program logic. Unlike the retained variables, these values are fixed across iterations.

DELETEMODEL Statement

DELETEMODEL *model* < MODNAME=*model-name* > ;

The DELETEMODEL statement deletes a model created using the OUTMODEL= option in a previous PROC MODEL execution. The *model* argument specifies the catalog or XML-based data set containing the model to be deleted, and the *model-name* argument specifies which model is to be deleted.

ENDOGENOUS Statement

ENDOGENOUS *variable* < *initial-values* > ... ;

The ENDOGENOUS statement declares model variables and identifies them as endogenous. You can declare model variables with an ENDOGENOUS statement instead of with a VAR statement to help document the model or to indicate the default solution variables. The variables declared endogenous are solved when a SOLVE statement does not indicate which variables to solve. Valid abbreviations for the ENDOGENOUS statement are ENDOG and ENDO.

The DEPENDENT statement is equivalent to the ENDOGENOUS statement and is provided for the convenience of noneconometric practitioners.

The ENDOGENOUS statement optionally provides initial values for lagged dependent variables. See the section “Lag Logic” on page 1269 for more information.

EQGROUP Statement

EQGROUP *label=equation*... ;

The EQGROUP statement applies a group label to the specified list of equations in the model program. Equation groups identify sets of related equations. The equation groups can be used by the ANALYZE= option in a subsequent SOLVE statement to help specify and understand the role of groups of equations in a SOLVE step. If an equation appears in more than one EQGROUP statement, the label that is specified in the last EQGROUP statement is applied to that equation.

ERRORMODEL Statement

ERRORMODEL *equation-name* ~ *distribution* < CDF= *CDF(options)* > ;

The ERRORMODEL statement is the mechanism for specifying the distribution of the residuals. You must specify the dependent/endogenous variables or general form model name, a tilde (~), and then a *distribution* with its parameters. You can specify the following options:

Options to Specify the Distribution

CAUCHY(*< location, scale >*)

specifies the Cauchy distribution. This option is supported only for simulation. The arguments correspond to the arguments of the SAS CDF function that computes the cumulative distribution function (ignoring the random variable argument).

CHISQUARED (*df <, nc>*)

specifies the χ^2 distribution. This option is supported only for simulation. The arguments correspond to the arguments of the SAS CDF function (ignoring the random variable argument).

GENERAL(*Likelihood <, parm1, parm2, ... parmn >*)

specifies the negative of a general log-likelihood function that you construct by using SAS programming statements. The procedure minimizes the negative log-likelihood function specified. *parm1, parm2, ... parmn* are optional parameters for this distribution and are used for documentation purposes only.

F(*ndf, ddf <, nc>*)

specifies the F distribution. This option is supported only for simulation. The arguments correspond to the arguments of the SAS CDF function (ignoring the random variable argument).

NORMAL(*v₁ v₂ ... v_n*)

specifies a multivariate normal (Gaussian) distribution with mean 0 and variances v_1 through v_n .

POISSON(*mean*)

specifies the Poisson distribution. This option is supported only for simulation. The arguments correspond to the arguments of the SAS CDF function (ignoring the random variable argument).

T(*v₁ v₂ ... v_n, df*)

specifies a multivariate t distribution with noncentrality 0, variance v_1 through v_n , and common degrees of freedom df .

UNIFORM(*< left, right >*)

specifies the uniform distribution. This option is supported only for simulation. The arguments correspond to the arguments of the SAS CDF function (ignoring the random variable argument).

Options to Specify the CDF for Simulation

CDF=(*CDF(options)*)

specifies the univariate distribution that is used for simulation so that the estimation can be done for one set of distributional assumptions and the simulation for another. The *CDF* can be any of the distributions from the previous section with the exception of the general likelihood. In addition, you can specify the empirical distribution of the residuals.

EMPIRICAL= (*< TAILS=(options)>*)

uses the sorted residual data to create an empirical CDF.

TAILS=(*tail-options*)

specifies how to handle the tails in computing the inverse CDF from an empirical distribution, where *tail-options* are:

NORMAL	specifies the normal distribution to extrapolate the tails.
T(<i>df</i>)	specifies the <i>t</i> distribution to extrapolate the tails.
PERCENT= <i>p</i>	specifies the percentage of the observations to use in constructing each tail. The default for the PERCENT= option is 10. A normal distribution or a <i>t</i> distribution is used to extrapolate the tails to infinity. The variance for the tail distribution is obtained from the data so that the empirical CDF is continuous.

ESTIMATE Statement

ESTIMATE *item* < , *item* ... > < ,/ *options* > ;

The ESTIMATE statement computes estimates of functions of the parameters.

The ESTIMATE statement refers to the parameters estimated by the associated FIT statement (that is, to either the preceding FIT statement or, in the absence of a preceding FIT statement, to the following FIT statement). You can use any number of ESTIMATE statements.

Let $\mathbf{h}(\theta)$ denote the function of parameters that needs to be estimated. Let $\hat{\theta}$ denote the unconstrained estimate of the parameter of interest, θ . Let $\hat{\mathbf{V}}$ be the estimate of the covariance matrix of θ . Denote

$$\mathbf{A}(\theta) = \partial \mathbf{h}(\theta) / \partial \theta \big|_{\hat{\theta}}$$

Then the standard error of the parameter function estimate is computed by obtaining the square root of $\mathbf{A}(\hat{\theta})\hat{\mathbf{V}}\mathbf{A}'(\hat{\theta})$. This is the same as the variance needed for a Wald type test statistic with null hypothesis $\mathbf{h}(\theta) = 0$.

If the expression of the function in the ESTIMATE statement includes a variable, then the value used in computing the function estimate is the last observation of the variable in the DATA= data set.

If you specify options on the ESTIMATE statement, a comma is required before the “/” character that separates the test expressions from the options, since the “/” character can also be used within test expressions to indicate division. Each *item* is written as an optional name followed by an expression,

< "name" > expression

where "name" is a string used to identify the estimate in the printed output and in the OUTEST= data set.

Expressions can be composed of parameter names, arithmetic operators, functions, and constants. Comparison operators (such as = or <) and logical operators (such as &) cannot be used in ESTIMATE statement expressions. Parameters named in ESTIMATE expressions must be among the parameters estimated by the associated FIT statement.

You can use the following options in the ESTIMATE statement:

OUTEST=

specifies the name of the data set in which the estimate of the functions of the parameters are to be written. The format for this data set is identical to the OUTEST= data set for the FIT statement.

If you specify a *name* in the ESTIMATE statement, that name is used as the parameter name for the estimate in the OUTEST= data set. If no *name* is provided and the expression is just a symbol, the symbol name is used; otherwise, the string “_Estimate #” is used, where “#” is the variable number in the OUTEST= data set.

OUTCOV

writes the covariance matrix of the functions of the parameters to the OUTEST= data set in addition to the parameter estimates.

COVB

prints the covariance matrix of the functions of the parameters.

CORRB

prints the correlation matrix of the functions of the parameters.

The following statements are an example of the use of the ESTIMATE statement in a segmented model and produce the output shown in [Figure 19.21](#):

```
data a;
  input y x @@;
datalines;
  .46 1  .47 2 .57 3 .61 4 .62 5 .68 6 .69 7
  .78 8  .70 9 .74 10 .77 11 .78 12 .74 13 .80 13
  .80 15 .78 16
;

title 'Segmented Model -- Quadratic with Plateau';
proc model data=a;

  x0 = -.5 * b / c;

  if x < x0 then y = a + b*x + c*x*x;
  else          y = a + b*x0 + c*x0*x0;

  fit y start=( a .45 b .5 c -.0025 );

  estimate 'Join point' x0 ,
           'plateau' a + b*x0 + c*x0**2 ;
run;
```

Figure 19.21 ESTIMATE Statement Output

Segmented Model -- Quadratic with Plateau					
The MODEL Procedure					
Nonlinear OLS Estimates					
Term	Estimate	Approx Std Err	t Value	Approx Pr > t	Label
Join point	12.7504	1.2785	9.97	<.0001	x0
plateau	0.777516	0.0123	63.10	<.0001	a + b*x0 + c*x0**2

EXOGENOUS Statement

EXOGENOUS *variable* < *initial-values* > ... ;

The EXOGENOUS statement declares model variables and identifies them as exogenous. You can declare model variables with an EXOGENOUS statement instead of with a VAR statement to help document the model or to indicate the default instrumental variables. The variables declared exogenous are used as instruments when an instrumental variables estimation method is requested (such as N2SLS or N3SLS) and an INSTRUMENTS statement is not used. Valid abbreviations for the EXOGENOUS statement are EXOG and EXO.

The INDEPENDENT statement is equivalent to the EXOGENOUS statement and is provided for the convenience of non-econometric practitioners.

The EXOGENOUS statement optionally provides initial values for lagged exogenous variables. See the section “[Lag Logic](#)” on page 1269 for more information.

FIT Statement

FIT < *equations* > < *PARMS*=(*parameter* < *values* > ...) > < *START*=(*parameter values* ...) > < *DROP*=(*parameter* ...) > < *INITIAL*=(*variable* = < *parameter* | *constant* > ...) > < / *options* > ;

The FIT statement estimates model parameters by fitting the model equations to input data and optionally selects the equations to be fit. If the list of equations is omitted, all model equations that contain parameters are fitted.

The following options can be used in the FIT statement.

DROP= (*parameters* ...)

specifies that the named parameters not be estimated. All the parameters in the equations fit are estimated except those listed in the DROP= option. The dropped parameters retain their previous values and are not changed by the estimation.

INITIAL= (*variable* = < *parameter* | *constant* > ...)

associates a *variable* with an initial value as a *parameter* or a *constant*. This option applies only to ordinary differential equations. See the section “[Ordinary Differential Equations](#)” on page 1174 for more information.

PARMS= (*parameters* [*values*] ...)

selects a subset of the parameters for estimation. When the PARMS= option is used, only the named parameters are estimated. Any parameters not specified in the PARMS= list retain their previous values and are not changed by the estimation.

In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used.

PRL= WALD | LR | BOTH

requests confidence intervals on estimated parameters. By default, the PRL option produces 95% likelihood ratio confidence limits. The coverage of the confidence interval is controlled by the ALPHA= option in the FIT statement.

START= (parameter values ...)

supplies starting values for the parameter estimates. In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used. If the START= option specifies more than one starting value for one or more parameters, a grid search is performed over all combinations of the values, and the best combination is used to start the iterations. For more information, see the STARTITER= option.

Options to Control the Estimation Method Used**ADJSMMV**

specifies adding the variance adjustment from simulating the moments to the variance-covariance matrix of the parameter estimators. By default, no adjustment is made.

COVBEST=GLS | CROSS | FDA

specifies the variance-covariance estimator used for FIML. COVBEST=GLS selects the generalized least squares estimator. COVBEST=CROSS selects the crossproducts estimator. COVBEST=FDA selects the inverse of the finite difference approximation to the Hessian. The default is COVBEST=CROSS.

DYNAMIC

specifies dynamic estimation of ordinary differential equations. See the section “[Ordinary Differential Equations](#)” on page 1174 for more details.

FIML

specifies full information maximum likelihood estimation.

GINV=G2 | G4

specifies the type of generalized inverse to be used when computing the covariance matrix. G4 selects the Moore-Penrose generalized inverse. The default is GINV=G2.

Rather than deleting linearly related rows and columns of the covariance matrix, the Moore-Penrose generalized inverse averages the variance effects between collinear rows. When the option GINV=G4 is used, the Moore-Penrose generalized inverse is used to calculate standard errors and the covariance matrix of the parameters as well as the change vector for the optimization problem. For singular systems, a normal G2 inverse is used to determine the singular rows so that the parameters can be marked in the parameter estimates table. A G2 inverse is calculated by satisfying the first two properties of the Moore-Penrose generalized inverse; that is, $\mathbf{A}\mathbf{A}^+\mathbf{A} = \mathbf{A}$ and $\mathbf{A}^+\mathbf{A}\mathbf{A}^+ = \mathbf{A}^+$. Whether or not you use a G4 inverse, if the covariance matrix is singular, the parameter estimates are not unique. Refer to Noble and Daniel (1977, pp. 337–340) for more details about generalized inverses.

GENGMMV

specify GMM variance under arbitrary weighting matrix. See the section “[Estimation Methods](#)” on page 1119 for more details.

This is the default method for GMM estimation.

GMM

specifies generalized method of moments estimation.

HCCME= 0 | 1 | 2 | 3 | NO

specifies the type of heteroscedasticity-consistent covariance matrix estimator to use for OLS, 2SLS, 3SLS, SUR, and the iterated versions of these estimation methods. The number corresponds to the type of covariance matrix estimator to use as

$$\begin{aligned} HC_0 &: \hat{\epsilon}_t^2 \\ HC_1 &: \frac{n}{n-df} \hat{\epsilon}_t^2 \\ HC_2 &: \hat{\epsilon}_t^2 / (1 - \hat{h}_t) \\ HC_3 &: \hat{\epsilon}_t^2 / (1 - \hat{h}_t)^2 \end{aligned}$$

The default is NO.

ITGMM

specifies iterated generalized method of moments estimation.

ITOLS

specifies iterated ordinary least squares estimation. This is the same as OLS unless there are cross-equation parameter restrictions.

ITSUR

specifies iterated seemingly unrelated regression estimation

IT2SLS

specifies iterated two-stage least squares estimation. This is the same as 2SLS unless there are cross-equation parameter restrictions.

IT3SLS

specifies iterated three-stage least squares estimation.

KERNEL=(PARZEN | BART | QS, <c> , <e>)**KERNEL=PARZEN | BART | QS**

specifies the kernel to be used for GMM and ITGMM. PARZEN selects the Parzen kernel, BART selects the Bartlett kernel, and QS selects the quadratic spectral kernel. $e \geq 0$ and $c \geq 0$ are used to compute the bandwidth parameter. The default is **KERNEL=(PARZEN, 1, 0.2)**. See the section “[Estimation Methods](#)” on page 1119 for more details.

N2SLS | 2SLS

specifies nonlinear two-stage least squares estimation. This is the default when an **INSTRUMENTS** statement is used.

N3SLS | 3SLS

specifies nonlinear three-stage least squares estimation.

NDRAW <=*number of draws*>

requests the simulation method for parameter estimation where the contribution of each observation to the estimation is approximated by using *number of draws* evaluations of the model program. If *number of draws* is not specified, the default value of 10 is used.

NOOLS**NO2SLS**

specifies bypassing OLS or 2SLS to get initial parameter estimates for GMM, ITGMM, or FIML. This is important for certain models that are poorly defined in OLS or 2SLS, or if good initial parameter values are already provided. Note that for GMM, the **V** matrix is created by using the initial values specified and this might not be consistently estimated.

NO3SLS

specifies not to use 3SLS automatically for FIML initial parameter starting values.

NOGENGMMV

specifies not to use GMM variance under arbitrary weighting matrix. Use GMM variance under optimal weighting matrix instead. See the section “[Estimation Methods](#)” on page 1119 for more details.

NPREOBS =*number of obs to initialize*

specifies the initial number of observations to run the simulation before the simulated values are compared to observed variables. This option is most useful in cases where the program statements involve lag operations. Use this option to avoid the effect of the starting point on the simulation.

NVDRAW =*number of draws for V matrix*

specifies H' , the number of draws for **V** matrix. If this option is not specified, the default H' is set to 20.

OLS

specifies ordinary least squares estimation. This is the default.

SUR

specifies seemingly unrelated regression estimation.

VARDEF=N | WGT | DF | WDF

specifies the denominator to be used in computing variances and covariances, MSE, root MSE measures, and so on. VARDEF=N specifies that the number of nonmissing observations be used. VARDEF=WGT specifies that the sum of the weights be used. VARDEF=DF specifies that the number of nonmissing observations minus the model degrees of freedom (number of parameters) be used. VARDEF=WDF specifies that the sum of the weights minus the model degrees of freedom be used. The default is VARDEF=DF. For FIML estimation the VARDEF= option does not affect the calculation of the parameter covariance matrix, which is determined by the COVBEST= option.

Data Set Options

DATA=SAS-data-set

specifies the input data set. Values for the variables in the program are read from this data set. If the DATA= option is not specified on the FIT statement, the data set specified by the DATA= option on the PROC MODEL statement is used.

ESTDATA=SAS-data-set

specifies a data set whose first observation provides initial values for some or all of the parameters.

MISSING=PAIRWISE | DELETE

specifies how missing values are handled. MISSING=PAIRWISE specifies that missing values are tracked on an equation-by-equation basis. MISSING=DELETE specifies that the entire observation is omitted from the analysis when any equation has a missing predicted or actual value for the equation. The default is MISSING=DELETE.

OUT=SAS-data-set

names the SAS data set to contain the residuals, predicted values, or actual values from each estimation. The residual values written to the OUT= data set are defined as the *actual – predicted*, which is the negative of RESID.variable as defined in the section “Equation Translations” on page 1264. Only the residuals are output by default.

OUTACTUAL

writes the actual values of the endogenous variables of the estimation to the OUT= data set. This option is applicable only if the OUT= option is specified.

OUTALL

selects the OUTACTUAL, OUTERRORS, OUTLAGS, OUTPREDICT, and OUTRESID options.

OUTCOV

COVOUT

writes the covariance matrix of the estimates to the OUTEST= data set in addition to the parameter estimates. The OUTCOV option is applicable only if the OUTEST= option is also specified.

OUTEST=SAS-data-set

names the SAS data set to contain the parameter estimates and optionally the covariance of the estimates.

OUTLAGS

writes the observations used to start the lags to the OUT= data set. This option is applicable only if the OUT= option is specified.

OUTPREDICT

writes the predicted values to the OUT= data set. This option is applicable only if OUT= is specified.

OUTRESID

writes the residual values computed from the parameter estimates to the OUT= data set. The OUTRESID option is the default if neither OUTPREDICT nor OUTACTUAL is specified. This option is applicable only if the OUT= option is specified. If the h.var equation is specified, the residual values written to the OUT= data set are the normalized residuals, defined as *actual – predicted*, divided by the square root of the h.var value. If the WEIGHT statement is used, the residual values are calculated as *actual – predicted* multiplied by the square root of the WEIGHT variable.

OUTS=SAS-data-set

names the SAS data set to contain the estimated covariance matrix of the equation errors. This is the covariance of the residuals computed from the parameter estimates.

OUTSN=SAS-data-set

names the SAS data set to contain the estimated normalized covariance matrix of the equation errors. This is valid for multivariate t distribution estimation.

OUTSUSED=SAS-data-set

names the SAS data set to contain the **S** matrix used in the objective function definition. The OUTSUSED= data set is the same as the OUTS= data set for the methods that iterate the **S** matrix.

OUTUNWGTRESID

writes the unweighted residual values computed from the parameter estimates to the OUT= data set. These are residuals computed as *actual – predicted* with no accounting for the WEIGHT statement, the `_WEIGHT_` variable, or any variance expressions. This option is applicable only if the OUT= option is specified.

OUTV=SAS-data-set

names the SAS data set to contain the estimate of the variance matrix for GMM and ITGMM.

SDATA=SAS-data-set

specifies a data set that provides the covariance matrix of the equation errors. The matrix read from the SDATA= data set is used for the equation covariance matrix (**S** matrix) in the estimation. (The SDATA= **S** matrix is used to provide only the initial estimate of **S** for the methods that iterate the **S** matrix.)

TIME=name

specifies the name of the time variable. This variable must be in the data set.

TYPE=name

specifies the estimation type to read from the SDATA= and ESTDATA= data sets. The name specified in the TYPE= option is compared to the `_TYPE_` variable in the ESTDATA= and SDATA= data sets to select observations to use in constructing the covariance matrices. When the TYPE= option is omitted, the last estimation type in the data set is used. Valid values are the estimation methods used in PROC MODEL.

VDATA=SAS-data-set

specifies a data set that contains a variance matrix for GMM and ITGMM estimation. See the section “[Output Data Sets](#)” on page 1217 for details.

Printing Options for FIT Tasks

BREUSCH=(variable-list)

specifies the modified Breusch-Pagan test, where *variable-list* is a list of variables used to model the error variance.

CHOW=obs**CHOW=(obs1 obs2 ... obsn)**

prints the Chow test for break points or structural changes in a model. The argument is the number of observations in the first sample or a parenthesized list of first sample sizes. If the size of the one of the two groups in which the sample is partitioned is less than the number of parameters, then a [predictive Chow](#) test is automatically used. See the section “[Chow Tests](#)” on page 1189 for details.

COLLIN

prints collinearity diagnostics for the Jacobian crossproducts matrix (**XPX**) after the parameters have converged. Collinearity diagnostics are also automatically printed if the estimation fails to converge.

CORR

prints the correlation matrices of the residuals and parameters. Using CORR is the same as using both CORRB and CORRS.

CORRB

prints the correlation matrix of the parameter estimates.

CORRS

prints the correlation matrix of the residuals.

COV

prints the covariance matrices of the residuals and parameters. Specifying COV is the same as specifying both COVB and COVS.

COVB

prints the covariance matrix of the parameter estimates.

COVS

prints the covariance matrix of the residuals.

DW <=>

prints Durbin-Watson d statistics, which measure autocorrelation of the residuals. When the residual series is interrupted by missing observations, the Durbin-Watson statistic calculated is d' as suggested by Savin and White (1978). This is the usual Durbin-Watson computed by ignoring the gaps. Savin and White show that it has the same null distribution as the DW with no gaps in the series and can be used to test for autocorrelation using the standard tables. The Durbin-Watson statistic is not valid for models that contain lagged endogenous variables.

You can use the DW= option to request higher-order Durbin-Watson statistics. Since the ordinary Durbin-Watson statistic tests only for first-order autocorrelation, the Durbin-Watson statistics for higher-order autocorrelation are called *generalized Durbin-Watson* statistics.

DWPROB

prints the significance level (p -values) for the Durbin-Watson tests. Since the Durbin-Watson p -values are computationally expensive, they are not reported by default. In the Durbin-Watson test, the null hypothesis is that there is autocorrelation at a specific lag.

See the section “Generalized Durbin-Watson Tests” for limitations of the statistic in the Chapter 8, “[The AUTOREG Procedure](#).”

FSRSQ

prints the first-stage R^2 statistics for instrumental estimation methods. These R^2 statistics measure the proportion of the variance retained when the Jacobian columns associated with the parameters are projected through the instruments space.

GODFREY**GODFREY=*n***

performs Godfrey's tests for autocorrelated residuals for each equation, where n is the maximum autoregressive order, and specifies that Godfrey's tests be computed for lags 1 through n . The default number of lags is one.

HAUSMAN

performs Hausman's specification test, or m -statistics.

NORMAL

performs tests of normality of the model residuals.

PCHOW=*obs***PCHOW=(*obs1 obs2 ... obsn*)**

prints the predictive Chow test for break points or structural changes in a model. The argument is the number of observations in the first sample or a parenthesized list of first sample sizes. See the section "[Chow Tests](#)" on page 1189 for details.

PRINTALL

specifies the printing options COLLIN, CORRB, CORRS, COVB, COVS, DETAILS, DW, and FSRSQ.

WHITE

specifies White's test.

Options to Control Iteration Output

Details of the output produced are discussed in the section "[Iteration History](#)" on page 1151.

I

prints the inverse of the crossproducts Jacobian matrix at each iteration.

ITALL

specifies all iteration printing-control options (I, ITDETAILS, ITPRINT, and XPX). ITALL also prints the crossproducts matrix (labeled CROSS), the parameter change vector, and the estimate of the cross-equation covariance of residuals matrix at each iteration.

ITDETAILS

prints a detailed iteration listing. This includes the ITPRINT information and additional statistics.

ITPRINT

prints the parameter estimates, objective function value, and convergence criteria at each iteration.

XPX

prints the crossproducts Jacobian matrix at each iteration.

Options to Control the Minimization Process

The following options can be helpful when you experience a convergence problem:

CONVERGE=*value1*

CONVERGE=(*value1*, *value2*)

specifies the convergence criteria. The convergence measure must be less than *value1* before convergence is assumed. *value2* is the convergence criterion for the **S** and **V** matrices for **S** and **V** iterated methods. *value2* defaults to *value1*. See the section “[Convergence Criteria](#)” on page 1139 for details. The default value is CONVERGE=0.001.

HESSIAN=CROSS | GLS | FDA

specifies the Hessian approximation used for FIML. HESSIAN=CROSS selects the crossproducts approximation to the Hessian, HESSIAN=GLS selects the generalized least squares approximation to the Hessian, and HESSIAN=FDA selects the finite difference approximation to the Hessian. HESSIAN=GLS is the default.

LTEBOUND=*n*

specifies the local truncation error bound for the integration. This option is ignored if no ordinary differential equations (ODEs) are specified.

EPSILON =*value*

specifies the tolerance value used to transform strict inequalities into inequalities when restrictions on parameters are imposed. By default, EPSILON=1E-8. See the section “[Restrictions and Bounds on Parameters](#)” on page 1184 for details.

MAXITER=*n*

specifies the maximum number of iterations allowed. The default is MAXITER=100.

MAXSUBITER=*n*

specifies the maximum number of subiterations allowed for an iteration. For the GAUSS method, the MAXSUBITER= option limits the number of step halvings. For the MARQUARDT method, the MAXSUBITER= option limits the number of times λ can be increased. The default is MAXSUBITER=30. See the section “[Minimization Methods](#)” on page 1138 for details.

METHOD=GAUSS | MARQUARDT

specifies the iterative minimization method to use. METHOD=GAUSS specifies the Gauss-Newton method, and METHOD=MARQUARDT specifies the Marquardt-Levenberg method. The default is METHOD=GAUSS. If the default GAUSS method fails to converge, the procedure switches to the MARQUARDT method. See the section “[Minimization Methods](#)” on page 1138 for details.

MINTIMESTEP=*n*

specifies the smallest allowed time step to be used in the integration. This option is ignored if no ODEs are specified.

NESTIT

changes the way the iterations are performed for estimation methods that iterate the estimate of the equation covariance (**S** matrix). The NESTIT option is relevant only for the methods that iterate the estimate of the covariance matrix (ITGMM, ITOLS, ITSUR, IT2SLS, and IT3SLS). See the section “[Details on the Covariance of Equation Errors](#)” on page 1136 for an explanation of NESTIT.

SINGULAR=value

specifies the smallest pivot value allowed. The default 1.0E-12.

STARTITER=n

specifies the number of minimization iterations to perform at each grid point. The default is STARTITER=0, which implies that no minimization is performed at the grid points. See the section “[Using the STARTITER Option](#)” on page 1145 for more details.

Other Options

Other options that can be used on the FIT statement include the following that list and analyze the model: BLOCK, GRAPH, LIST, LISTCODE, LISTDEP, LISTDER, and XREF. The following printing control options are also available: DETAILS, FLOW, INTGPRINT, MAXERRORS=, NOPRINT, PRINTALL, and TRACE. For complete descriptions of these options, see the discussion of the PROC MODEL statement options earlier in this chapter.

ID Statement

ID *variables* ;

The ID statement specifies variables to identify observations in error messages or other listings and in the OUT= data set. The ID variables are normally SAS date or datetime variables. If more than one ID variable is used, the first variable is used to identify the observations; the remaining variables are added to the OUT= data set.

INCLUDE Statement

INCLUDE *model-names* ... ;

The INCLUDE statement reads model files and inserts their contents into the current model. However, instead of replacing the current model as the RESET MODEL= option does, the contents of included model files are inserted into the model program at the position that the INCLUDE statement appears.

INSTRUMENTS Statement

INSTRUMENTS *variables* < _EXOG_ > ;

INSTRUMENTS < *variables-list* > < _EXOG_ > < EXCLUDE =(*parameters*) > < / *options* > ;

INSTRUMENTS (*equation, variables*) (*equation, variables*) ... ;

The INSTRUMENTS statement specifies the instrumental variables to be used in the N2SLS, N3SLS, IT2SLS, IT3SLS, GMM, and ITGMM estimation methods.

There are three ways of specifying the INSTRUMENTS statement. The first form of the INSTRUMENTS statement is declared before a FIT statement and defines the default instruments list. The items specified as instruments can be variables or the special keyword _EXOG_. The keyword _EXOG_ indicates that all the

model variables declared EXOGENOUS are to be added to the instruments list. If a single INSTRUMENTS statement of the first form is declared before multiple FIT statements, then it serves as the default instruments list for each of the FIT statements. However, if any of these FIT statements are followed by separate INSTRUMENTS statement, then the latter take precedence over the default list. Hence, in the case of multiple FIT statements, the INSTRUMENTS statement for a particular FIT statement is written below the FIT statement if instruments other than the default are required. For a single FIT statement, you can declare the INSTRUMENTS statement of the first form either preceding or following the FIT statement.

The second form of the INSTRUMENTS statement is used only after the FIT statement and before the next RUN statement. The items specified as instruments for the second form can be variables, names of parameters to be estimated, or the special keyword `_EXOG_`. If you specify the name of a parameter in the instruments list, the partial derivatives of the equations with respect to the parameter (that is, the columns of the Jacobian matrix associated with the parameter) are used as instruments. The parameter itself is not used as an instrument. These partial derivatives should not depend on any of the parameters to be estimated. Only the names of parameters to be estimated can be specified.

Note that an INSTRUMENTS statement of only the first form declared before multiple FIT statements serves as the default instruments list. Hence, in the cases of multiple as well as single FIT statements, you can declare the second form of INSTRUMENTS statements only following the FIT statements.

In the case where a FIT statement is preceded by an INSTRUMENTS statement of the second form in error and not followed by any INSTRUMENTS statement, then the default list is used. This default list is given by the INSTRUMENTS statement of the first form as explained above. If such a list is not declared, all the model variables declared EXOGENOUS comprise the default.

A third form of the INSTRUMENTS statement is used to specify instruments for each equation. No explicit intercept is added, parameters cannot be specified to represent instruments, and the `_EXOG_` keyword is not allowed. Equations not explicitly assigned instruments use all the instruments specified for the other equations as well as instruments not assigned specific equations. In the following statements, `z1`, `z2`, and `z3` are instruments used with equation `y1`, and `z2`, `z3`, and `z4` are instruments used with equation `y2`.

```
proc model data=data_sim;
  exogenous x1 x2;
  parms a b c d e f;

  y1 =a*x1**2 + b*x2**2 + c*x1*x2    ;
  y2 =d*x1**2 + e*x2**2 + f*x1*x2**2;

  fit y1 y2 / 3s1s ;
  instruments (y1, z1 z2 z3) (y2,z2 z3 z4);
run;
```

EXCLUDE=(parameters)

specifies that the derivatives of the equations with respect to all of the parameters to be estimated (except the parameters listed in the EXCLUDE list) be used as instruments, in addition to the other instruments specified. If you use the EXCLUDE= option, you should be sure that the derivatives with respect to the nonexcluded parameters in the estimation are independent of the endogenous variables and not functions of the parameters estimated.

The following options can be specified on the INSTRUMENTS statement following a slash (/):

NOINTERCEPT**NOINT**

excludes the constant of 1.0 (intercept) from the instruments list. An intercept is included as an instrument while using the first or second form of the INSTRUMENTS statement unless NOINTERCEPT is specified.

When a FIT statement specifies an instrumental variables estimation method and no INSTRUMENTS statement accompanies the FIT statement, the default instruments are used. If no default instruments list has been specified, all the model variables declared EXOGENOUS are used as instruments. See the section “[Choice of Instruments](#)” on page 1192 for more details.

INTONLY

specifies that only the intercept be used as an instrument. This option is used for GMM estimation where the moments have been specified explicitly.

LABEL Statement

LABEL *variable*='label' ... ;

The LABEL statement specifies a label of up to 255 characters for parameters and other variables used in the model program. Labels are used to identify parts of the printout of FIT and SOLVE tasks. The labels are displayed in the output if the LINESIZE= option is large enough.

MOMENT Statement

MOMENT *variables* = *moment specification* ;

In many scenarios, endogenous variables are observed from data. From the models, you can simulate these endogenous variables based on a fixed set of parameters. The goal of simulated method of moments (SMM) is to find a set of parameters such that the moments of the simulated data match the moments of the observed variables. If there are many moments to match, the code might be tedious. The following MOMENT statement provides a way to generate some commonly used moments automatically. Multiple MOMENT statements can be used.

variables can be one or more endogenous variables.

moment specification can have the following four types:

- (*number list*) specifies that the endogenous variable is raised to the power specified by each number in *number list*. For example,

```
moment y = (2 3);
```

adds the following two equations to be estimated:

```
eq._moment_1 = y**2 - pred.y**2;
eq._moment_2 = y**3 - pred.y**3;
```

- `ABS(number list)` specifies that the absolute value of the endogenous variable is raised to the power specified by each number in *number list*. For example,

```
moment y = ABS(3);
```

adds the following equation to be estimated:

```
eq._moment_2 = abs(y)**3 - abs(pred.y)**3;
```

- `LAGnum (number list)` specifies that the endogenous variable is multiplied by the *num* th lag of the endogenous variable, and this product is raised to the power specified by each number in *number list*. For example,

```
moment y = LAG4(3);
```

adds the following equation to be estimated:

```
eq._moment_3 = (y*lag4(y))**3 - (pred.y*lag4(pred.y))**3;
```

- `ABS_LAGnum (number list)` specifies that the endogenous variable is multiplied by the *num* th lag of the endogenous variable, and the absolute value of this product is raised to the power specified by each number in *number list*. For example,

```
moment y = ABS_LAG4(3);
```

adds the following equation to be estimated:

```
eq._moment_4 = abs(y*lag4(y))**3 - abs(pred.y*lag4(pred.y))**3;
```

The following PROC MODEL statements use the MOMENT statement to generate 24 moments and fit these moments using SMM.

```
proc model data=tmpdata list;
  parms a b .5 s 1;
  instrument _exog_ / intonly;

  u = rannor( 10091 );
  z = rannor( 97631 );

  lsigmasq = xlag(sigmasq,exp(a));

  lnsigmasq = a + b * log(lsigmasq) + s * u;
  sigmasq = exp( lnsigmasq );

  y = sqrt(sigmasq) * z;

  moment y = (2 4) abs(1 3) abs_lag1(1 2) abs_lag2(1 2);
  moment y = abs_lag3(1 2) abs_lag4(1 2)
              abs_lag5(1 2) abs_lag6(1 2)
              abs_lag7(1 2) abs_lag8(1 2)
              abs_lag9(1 2) abs_lag10(1 2);

  fit y / gmm npreobs=20 ndraw=10;
  bound s > 0, 1>b>0;

run;
```

OUTVARS Statement

OUTVARS *variables* ;

The OUTVARS statement specifies additional variables defined in the model program to be output to the OUT= data sets. The OUTVARS statement is not needed unless the variables to be added to the output data set are not referred to by the model, or unless you want to include parameters or other special variables in the OUT= data set. The OUTVARS statement includes additional variables, whereas the KEEP statement excludes variables.

PARAMETERS Statement

PARAMETERS *variable* < *value* > < *variable* < *value* > > ... ;

The PARAMETERS statement declares the parameters of a model and optionally sets their initial values. Valid abbreviations are PARMS and PARM.

Each parameter has a single value associated with it, which is the same for all observations. Lagging is not relevant for parameters. If a value is not specified in the PARMS statement (or by the PARMS= option of a FIT statement), the value defaults to 0.0001 for FIT tasks and to a missing value for SOLVE tasks.

Programming Statements

To define the model, you can use most of the programming statements that are allowed in the SAS DATA step. See the *SAS Language Reference: Dictionary* for more information.

RANGE Statement

RANGE *variable* < = *first* > < *TO last* > ;

The RANGE statement specifies the range of observations to be read from the DATA= data set. For FIT tasks, the RANGE statement controls the period of fit for the estimation. For SOLVE tasks, the RANGE statement controls the simulation period or forecast horizon.

The RANGE variable must be a numeric variable in the DATA= data set that identifies the observations, and the data set must be sorted by the RANGE variable. The first observation in the range is identified by *first*, and the last observation is identified by *last*.

PROC MODEL uses the first *l* observations prior to *first* to initialize the lags, where *l* is the maximum number of lags needed to evaluate any of the equations to be fit or solved, or the maximum number of lags needed to compute any of the instruments when an instrumental variables estimation method is used. There should be at least *l* observations in the data set before *first*. If *last* is not specified, all the nonmissing observations starting with *first* are used.

If *first* is omitted, the first *l* observations are used to initialize the lags, and the rest of the data, until *last*, is used. If a RANGE statement is used but both *first* and *last* are omitted, the RANGE statement variable is used to report the range of observations processed.

The RANGE variable should be nonmissing for all observations. Observations that contain missing RANGE values are deleted.

The following are examples of RANGE statements:

```
range year = 1971 to 1988;           /* yearly data */
range date = '1feb73'd to '1nov82'd; /* monthly data */
range time = 60.5;                  /* time in years */
range year to 1977;                 /* use all years through 1977 */
range date; /* use values of date to report period-of-fit */
```

If no RANGE statements follow multiple FIT statements and if a single RANGE statement is declared before all the FIT statements, estimation in each of the multiple FIT statements is based on the data specified in the single RANGE statement. A single RANGE statement that follows multiple FIT statements affects only the fit immediately preceding it.

If the FIT statement is both followed by and preceded by RANGE statements, the following RANGE statement takes precedence over the preceding RANGE statement.

In the case where a range of data is to be used for a particular SOLVE task, the RANGE statement should be specified following the SOLVE statement in the case of either single or multiple SOLVE statements.

RESET Statement

RESET *options* ;

All the options of the PROC MODEL statement can be reset by the RESET statement. In addition, the RESET statement supports one additional option:

PURGE

deletes the current model so that a new model can be defined.

When the MODEL= option is used in the RESET statement, the current model is deleted before the new model is read.

RESTRICT Statement

RESTRICT *restriction1* < , *restriction2* ... > ;

The RESTRICT statement is used to impose linear and nonlinear restrictions either on the parameters in an estimation or on the solution variables that are specified in a solve operation.

Each *restriction* is written as an optional name, followed by an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

< "name" > *expression operator expression*

The optional "name" is a string used to identify the restriction. The *operator* can be =, <, >, <=, or >=. The *operator* and second *expression* are optional. When they are omitted, the default *operator* is > and the default second *expression* is 0.

Each RESTRICT statement is associated with the preceding FIT statement or SOLVE statement. When there is no preceding FIT or SOLVE statement, the RESTRICT statement is associated with the following FIT or SOLVE statement. You can specify any number of RESTRICT statements.

Parameter Estimates

Expressions in RESTRICT statements that apply to the parameters estimated by a FIT statement can be composed of parameter names, arithmetic operators, functions, and constants. Comparison operators (such as = or <) and logical operators (such as &) cannot be used in RESTRICT statement expressions. Parameters that are named in restriction expressions must be among the parameters estimated by the associated FIT statement. Expressions can refer to variables defined in the program.

The restriction expressions can be linear or nonlinear functions of the parameters.

The optional *"name"* is a string used to identify the restriction in the printed output and in the OUTEST= data set.

The following example shows how to use the RESTRICT statement:

```
proc model data=one;
  endogenous y1 y2;
  exogenous x1 x2;
  parms a b c;
  restrict b*(b+c) <= a;

  eq.one = -y1/c + a/x2 + b * x1**2 + c * x2**2;
  eq.two = -y2 * y1 + b * x2**2 - c/(2 * x1);

  fit one two / fiml;
run;
```

Solution Variables

Expressions in RESTRICT statements that apply to the solution variables in a SOLVE statement can be composed of any variables in the model. Unlike restriction expressions that are used in parameter estimation, exogenous model variables can be used in restriction expressions that involve solution variables because each observation is solved independently in a SOLVE statement. To include constraints that are imposed by RESTRICT inequalities in a solution, you must specify the OPTIMIZE option in the SOLVE statement.

The following example illustrates how multiple solutions to a nonlinear system of equations can be found by using a RESTRICT expression that depends on exogenous variables. Two of the four possible solutions are presented in [Figure 19.22](#).

```
data d;
  do i = 0 to 1;
    date=i;
    if i = 0 then r = -1;
    else          r = +1;
    output;
  end;
run;
```

```

proc model data=d ;
  endo x y;

  eq.a = x*x - 4;
  eq.b = y*y - 9;

  restrict x*y*r > 1;

  solve / optimize out=o outall;
quit;

proc print data = o; run;

```

Figure 19.22 Listing of OUT= Data Set Created by a Nonlinear Restriction

SOLVE Statement

SOLVE *variables* < *SATISFY= equations* > < /*options* > ;

The SOLVE statement specifies that the model be simulated or forecast for input data values and, optionally, selects the variables to be solved. If the list of variables is omitted, all of the model variables declared ENDOGENOUS are solved. If no model variables are declared ENDOGENOUS, then all model variables are solved.

The following specification can be used in the SOLVE statement:

SATISFY=*equation*

SATISFY=(*equations*)

specifies a subset of the model equations that the solution values are to satisfy. If the SATISFY= option is not used, the solution is computed to satisfy all the model equations. Note that the number of equations must equal the number of variables solved.

Data Set Options

DATA=SAS-data-set

names the input data set. The model is solved for each observation read from the DATA= data set. If the DATA= option is not specified on the SOLVE statement, the data set specified by the DATA= option in the PROC MODEL statement is used.

ESTDATA=SAS-data-set

names a data set whose first observation provides values for some or all of the parameters and whose additional observations (if any) give the covariance matrix of the parameter estimates. The covariance matrix read from the ESTDATA= data set is used to generate multivariate normal pseudo-random shocks to the model parameters when the RANDOM= option requests Monte Carlo simulation.

OUT=SAS-data-set

outputs the predicted (solution) values, residual values, actual values, or equation errors from the solution to a data set. The residual values are the *actual – predicted* values, which is the negative of RESID.*variable* as defined in the section “Equation Translations” on page 1264. Only the solution values are output by default.

OUTACTUAL

outputs the actual values of the solved variables read from the input data set to the OUT= data set. This option is applicable only if the OUT= option is specified.

OUTALL

specifies the OUTACTUAL, OUTERRORS, OUTLAGS, OUTPREDICT, and OUTRESID options.

OUTERRORS

writes the equation errors to the OUT= data set. These values are normally very close to 0 when a simultaneous solution is computed; they can be used to double-check the accuracy of the solution process. This option applies only if the OUT= option is specified.

OUTLAGS

writes the observations that are used to start the lags to the OUT= data set. This option applies only if the OUT= option is specified.

OUTOBJVALS

writes the objective function value to the OBJVALS variable in the OUT= data set. The objective function value is computed only when the OPTIMIZE solution method is specified. This value is close to 0 when an unbounded simultaneous solution is computed and can be greater than 0 when bounds are active in the solution. This option applies only if the OUT= option is specified.

OUTPREDICT

writes the solution values to the OUT= data set. This option applies only if the OUT= option is specified.

The OUTPREDICT option is the default unless one of the other output options is specified.

OUTRESID

writes the residual values that are computed as the *actual – predicted* values and is not the same as the RESID.*variable* values. This option applies only if the OUT= option is specified.

OUTVIOLATIONS

writes the equation violations to the OUT= data set. The equation violations are computed only when the OPTIMIZE solution method is specified. The violations provide information about how much each equation contributes to the objective function value when bounds are active in the solution. This option applies only if the OUT= option is specified.

PARMSDATA=SAS-data-set

specifies a data set that contains the parameter estimates. See the section “[Input Data Sets](#)” on page 1211 for more details.

RESIDDATA=SAS-data-set

specifies a data set that contains the residuals to be used in the empirical distribution. This data set can be created using the OUT= option in the FIT statement.

SDATA=SAS-data-set

specifies a data set that provides the covariance matrix of the equation errors. The covariance matrix that is read from the SDATA= data set is used to generate multivariate normal pseudo-random shocks to the equations when the RANDOM= option requests Monte Carlo simulation.

TIME=name

specifies the name of the time variable. This variable must be in the data set.

TYPE=name

specifies the estimation type. The name that is specified in the TYPE= option is compared to the _TYPE_ variable in the ESTDATA= and SDATA= data sets to select observations to use in constructing the covariance matrices. When TYPE= is omitted, the last estimation type in the data set is used.

Solution Mode Options: Lag Processing**DYNAMIC**

specifies a dynamic solution. In the dynamic solution mode, solved values are used by the lagging functions. DYNAMIC is the default.

NAHEAD=*n*

specifies a simulation of *n*-period-ahead dynamic forecasting. The NAHEAD= option is used to simulate the process of using the model to produce successive forecasts to a fixed forecast horizon, in which each forecast uses the historical data available at the time the forecast is made.

Note that NAHEAD=1 produces a static (one-step-ahead) solution. NAHEAD=2 produces a solution that uses one-step-ahead solutions for the first lag (LAG1 functions return static predicted values) and actual values for longer lags. NAHEAD=3 produces a solution that uses NAHEAD=2 solutions for the first lags, NAHEAD=1 solutions for the second lags, and actual values for longer lags. In general, NAHEAD=*n* solutions use NAHEAD=*n*−1 solutions for LAG1, NAHEAD=*n*−2 solutions for LAG2, and so forth.

START=*s*

specifies static solutions until the *s*th observation and then changes to dynamic solutions. If the START=*s* option is specified, the first observation in the range in which LAG*n* delivers solved predicted values is *s*+*n*, while LAG*n* returns actual values for earlier observations.

STATIC

specifies a static solution. In static solution mode, actual values of the solved variables from the input data set are used by the lagging functions.

Solution Mode Options: Use of Available Data**FORECAST**

specifies that the actual value of a solved variable is used as the solution value (instead of the predicted value from the model equations) whenever nonmissing data are available in the input data set. That is, in FORECAST mode, PROC MODEL solves only for those variables that are missing in the input data set.

SIMULATE

specifies that PROC MODEL always solves for all solution variables as a function of the input values of the other variables, even when actual data for some of the solution variables are available in the input data set. SIMULATE is the default.

Solution Mode Options: Numerical Solution Method**JACOBI**

computes a simultaneous solution using a Jacobi iteration.

NEWTON

computes a simultaneous solution by using Newton's method. When the NEWTON option is selected, the analytic derivatives of the equation errors with respect to the solution variables are computed, and memory-efficient sparse matrix techniques are used for factoring the Jacobian matrix.

The NEWTON option can be used to solve both normalized-form and general-form equations and can compute goal-seeking solutions. NEWTON is the default.

OPTIMIZE

computes a simultaneous solution by minimizing a norm of the equation errors with respect to the solution variables. The OPTIMIZE method obeys constraints on the solution variables that are imposed by the BOUNDS and RESTRICT statements.

SEIDEL

computes a simultaneous solution by using a Gauss-Seidel method.

SINGLE**ONEPASS**

specifies a single-equation (nonsimultaneous) solution. The model is executed once to compute predicted values for the variables from the actual values of the other endogenous variables. The SINGLE option can be used only for normalized-form equations and cannot be used for goal-seeking solutions.

For more information about these options, see the section “[Solution Modes](#)” on page 1223.

Monte Carlo Simulation Options

COPULA=(*copula-options*)

specifies the copula to be used in the simulation. You can specify the following *copula-options*:

- CLAYTON(θ), where θ is the Clayton copula parameter
- FRANK(θ), where θ is the Frank copula parameter
- GUMBEL(θ), where θ is the Gumbel copula parameter
- NORMAL
- NORMALMIX($n, p_1 \dots p_n, v_1 \dots v_n$), where p_i are the probabilities and v_i are the variances
- T(df) < ASYM >, where df is the degrees-of-freedom parameter

The normal (Gaussian) copula is the default. The copula applies to covariance of equation errors.

PSEUDO=DEFAULT | TWISTER

specifies which pseudo-number generator to use in generating draws for Monte Carlo simulation. The two pseudo-random number generators that are supported by the MODEL procedure are a default congruential generator that has period $2^{31} - 1$ and a Mersenne-Twister pseudo-random number generator that has an extraordinarily long period $2^{19937} - 1$.

QUASI=NONE|SOBOL|FAURE

specifies a pseudo- or quasi-random number generator. Two quasi-random number generators are supported by the MODEL procedure: the Sobol sequence (QUASI=SOBOL) and the Faure sequence (QUASI=FAURE). The default is QUASI=NONE, which is the pseudo-random number generator.

RANDOM= n

repeats the solution n times for each BY group, with different random perturbations of the equation errors if the SDATA= option is specified; with different random perturbations of the parameters if the ESTDATA= option is specified and the ESTDATA= data set contains a parameter covariance matrix; and with different values returned from the random number generator functions, if any are used in the model program. If RANDOM=0, the random number generator functions always return zero. See the section “[Monte Carlo Simulation](#)” on page 1226 for details. The default is RANDOM=0.

SEED= n

specifies an integer to use as the seed in generating pseudo-random numbers to shock the parameters and equations when the ESTDATA= or SDATA= option is specified. If n is negative or 0, the time of day from the computer’s clock is used as the seed. The SEED= option is relevant only if the RANDOM= option is specified. The default is SEED=0.

WISHART= df

specifies that a Wishart distribution with degrees of freedom df be used in place of the normal error covariance matrix. This option is used to model the variance of the error covariance matrix when Monte Carlo simulation is selected.

Options for Controlling the Numerical Solution Process

The following options are useful when you have difficulty converging to the simultaneous solution.

CONVERGE=*value*

specifies the convergence criterion for the simultaneous solution. Convergence of the solution is judged by comparing the CONVERGE= value to the maximum over the equations of

$$\frac{|\epsilon_i|}{|y_i| + 1E-6}$$

if they are computable, otherwise

$$|\epsilon_i|$$

where ϵ_i represents the equation error and y_i represents the solution variable that corresponds to the i th equation for normalized-form equations. The default is CONVERGE=1E-8.

MAXITER=*n*

specifies the maximum number of iterations allowed for computing the simultaneous solution for any observation. The default is MAXITER=50.

MAXSUBITER=*n*

specifies the maximum number of damping subiterations that are performed in solving a nonlinear system when using the NEWTON solution method. Damping is disabled by setting MAXSUBITER=0. The default is MAXSUBITER=10.

Printing Options

INTGPRINT

prints between data points integration values for the DERT. variables and the auxiliary variables. If you specify the DETAILS option, the integrated derivative variables are printed as well.

ITPRINT

prints the solution approximation and equation errors at each iteration for each observation. This option can produce voluminous output.

PRINTALL

specifies the printing control options DETAILS, ITPRINT, SOLVEPRINT, STATS, and THEIL.

SOLVEPRINT

prints the solution values and residuals at each observation.

STATS

prints various summary statistics for the solution values.

THEIL

prints tables of Theil inequality coefficients and Theil relative change forecast error measures for the solution values. See the section “[Summary Statistics](#)” on page 1242 for more information.

Other Options

Other options that can be used on the SOLVE statement include the following that list and analyze the model: BLOCK, GRAPH, LIST, LISTCODE, LISTDEP, LISTDER, and XREF. The LTEBOUND= and MINTIMESTEP= options can be used to control the integration process. The following printing-control options are also available: DETAILS, FLOW, MAXERRORS=, NOPRINT, and TRACE. For complete descriptions of these options, see the PROC MODEL and FIT statement options described earlier in this chapter.

TEST Statement

TEST < "name"> test1 <, test2 ... > <, / options > ;

The TEST statement performs tests of nonlinear hypotheses on the model parameters.

Each TEST statement applies to the parameters estimated by one FIT statement. TEST statements that appear before or after the first FIT statement are associated with the first FIT statement. Subsequent TEST statements are associated with the FIT statement that precedes them. TEST statements that are separated from a FIT statement by an intervening RUN, SOLVE, or RESET statement are ignored. You can specify any number of TEST statements.

If you specify options on the TEST statement, a comma is required before the “/” character that separates the test expressions from the options, because the “/” character can also be used within test expressions to indicate division.

The label lengths for tests and estimate statements are 256 characters. If the labels exceed this length, the label is truncated to 256 characters with a note printed to the log.

Each test is written as an expression optionally followed by an equal sign (=) and a second expression:

< expression > <= expression >

Test expressions can be composed of parameter names, arithmetic operators, functions, and constants. Comparison operators (such as =) and logical operators (such as &) cannot be used in TEST statement expressions. Parameters named in test expressions must be among the parameters estimated by the associated FIT statement.

If you specify only one expression in a test, that expression is tested against zero. For example, the following two TEST statements are equivalent:

```
test a + b;
```

```
test a + b = 0;
```

When you specify multiple tests in the same TEST statement, a joint test is performed. For example, the following TEST statement tests the joint hypothesis that both A and B are equal to zero.

```
test a, b;
```

To perform separate tests rather than a joint test, use separate TEST statements. For example, the following TEST statements test the two separate hypotheses that A is equal to zero and that B is equal to zero.

```
test a;
```

```
test b;
```

You can use the following options in the TEST statement.

WALD

specifies that a Wald test be computed. By default, the Wald test is computed.

LM**RAO****LAGRANGE**

specifies that a Lagrange multiplier test be computed.

LR**LIKE**

specifies that a likelihood ratio test be computed.

ALL

requests all three types of tests.

OUT=SAS-data-set

specifies the name of an output *SAS data set* that contains the test results. The format of the OUT= data set that is produced by the TEST statement is similar to that of the OUTEST= data set produced by the FIT statement.

VAR Statement

VAR *variables* < *initial-values* > ... ;

The VAR statement declares model variables and optionally provides initial values for the lags of the variables. See the section “[Lag Logic](#)” on page 1269 for more information.

VARGROUP Statement

VARGROUP *label=variable*... ;

The VARGROUP statement applies a group label to the specified list of variables in the model program. Variable groups are used to identify sets of related solve variables. The variable groups can be used by the ANALYZESEP= option in a subsequent SOLVE statement to help specify and understand the role of groups of solve variables in a SOLVE step. If a variable appears in more than one VARGROUP statement, the label that is specified in the last VARGROUP statement is applied to that variable.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters.

If the weight of an observation is nonpositive, that observation is not used for the estimation. *variable* must be a numeric variable in the input data set.

An alternative weighting method is to use an assignment statement to give values to the special variable `_WEIGHT_`. The `_WEIGHT_` variable must not depend on the parameters being estimated. If both weighting specifications are given, the weights are multiplied together.

Details: Estimation by the MODEL Procedure

Estimation Methods

Consider the general nonlinear model:

$$\begin{aligned}\epsilon_t &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \\ \mathbf{z}_t &= \mathbf{Z}(\mathbf{x}_t)\end{aligned}$$

where $\mathbf{q} \in R^g$ is a real vector valued function of $\mathbf{y}_t \in R^g$, $\mathbf{x}_t \in R^l$, $\boldsymbol{\theta} \in R^p$, where g is the number of equations, l is the number of exogenous variables (lagged endogenous variables are considered exogenous here), p is the number of parameters, and t ranges from 1 to n . $\mathbf{z}_t \in R^k$ is a vector of instruments. ϵ_t is an unobservable disturbance vector with the following properties:

$$\begin{aligned}E(\epsilon_t) &= 0 \\ E(\epsilon_t \epsilon_t') &= \Sigma\end{aligned}$$

All of the methods implemented in PROC MODEL aim to minimize an *objective function*. The following table summarizes the objective functions that define the estimators and the corresponding estimator of the covariance of the parameter estimates for each method.

Table 19.2 Summary of PROC MODEL Estimation Methods

Method	Instruments	Objective Function	Covariance of θ
OLS	no	$\mathbf{r}'\mathbf{r}/n$	$(\mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{X})^{-1}$
ITOLS	no	$\mathbf{r}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{r}/n$	$(\mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{X})^{-1}$
SUR	no	$\mathbf{r}'(\mathbf{S}_{\text{OLS}}^{-1} \otimes \mathbf{I})\mathbf{r}/n$	$(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{I})\mathbf{X})^{-1}$
ITSUR	no	$\mathbf{r}'(\mathbf{S}^{-1} \otimes \mathbf{I})\mathbf{r}/n$	$(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{I})\mathbf{X})^{-1}$
N2SLS	yes	$\mathbf{r}'(\mathbf{I} \otimes \mathbf{W})\mathbf{r}/n$	$(\mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}$
IT2SLS	yes	$\mathbf{r}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{W})\mathbf{r}/n$	$(\mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}$
N3SLS	yes	$\mathbf{r}'(\mathbf{S}_{\text{N2SLS}}^{-1} \otimes \mathbf{W})\mathbf{r}/n$	$(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}$
IT3SLS	yes	$\mathbf{r}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{r}/n$	$(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}$
GMM	yes	$[\mathbf{nm}_n(\theta)]'\hat{\mathbf{V}}_{\text{N2SLS}}^{-1}[\mathbf{nm}_n(\theta)]/n$	$[(\mathbf{YX})'\hat{\mathbf{V}}^{-1}(\mathbf{YX})]^{-1}$
ITGMM	yes	$[\mathbf{nm}_n(\theta)]'\hat{\mathbf{V}}^{-1}[\mathbf{nm}_n(\theta)]/n$	$[(\mathbf{YX})'\hat{\mathbf{V}}^{-1}(\mathbf{YX})]^{-1}$
FIML	no	$\text{constant} + \frac{n}{2}\ln(\det(\mathbf{S})) - \sum_1^n \ln (\mathbf{J}_t) $	$[\hat{\mathbf{Z}}'(\mathbf{S}^{-1} \otimes \mathbf{I})\hat{\mathbf{Z}}]^{-1}$

The column labeled “Instruments” identifies the estimation methods that require instruments. The variables used in this table and the remainder of this chapter are defined as follows:

n = is the number of nonmissing observations.

g = is the number of equations.

k = is the number of instrumental variables.

$\mathbf{r} = \begin{bmatrix} r_1 \\ r_2 \\ \vdots \\ r_g \end{bmatrix}$ is the $ng \times 1$ vector of residuals for the g equations stacked together.

$\mathbf{r}_i = \begin{bmatrix} q_i(\mathbf{y}_1, \mathbf{x}_1, \boldsymbol{\theta}) \\ q_i(\mathbf{y}_2, \mathbf{x}_2, \boldsymbol{\theta}) \\ \vdots \\ q_i(\mathbf{y}_n, \mathbf{x}_n, \boldsymbol{\theta}) \end{bmatrix}$ is the $n \times 1$ column vector of residuals for the i th equation.

\mathbf{S} is a $g \times g$ matrix that estimates $\boldsymbol{\Sigma}$, the covariances of the errors across equations (referred to as the \mathbf{S} matrix).

\mathbf{X} is an $ng \times p$ matrix of partial derivatives of the residual with respect to the parameters.

\mathbf{W} is an $n \times n$ matrix, $\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$.

\mathbf{Z} is an $n \times k$ matrix of instruments.

\mathbf{Y} is a $gk \times ng$ matrix of instruments. $\mathbf{Y} = \mathbf{I}_g \otimes \mathbf{Z}'$.

$\hat{\mathbf{Z}}$ $\hat{\mathbf{Z}} = (\hat{\mathbf{Z}}_1, \hat{\mathbf{Z}}_2, \dots, \hat{\mathbf{Z}}_p)$ is an $ng \times p$ matrix. $\hat{\mathbf{Z}}_i$ is a $ng \times 1$ column vector obtained from stacking the columns of

$$\mathbf{U} \frac{1}{n} \sum_{t=1}^n \left(\frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \mathbf{y}_t} \right)^{-1} \frac{\partial^2 \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \mathbf{y}_t \partial \theta_i} - \mathbf{Q}_i$$

\mathbf{U} is an $n \times g$ matrix of residual errors. $\mathbf{U} = \boldsymbol{\epsilon}_1, \boldsymbol{\epsilon}_2, \dots, \boldsymbol{\epsilon}_n'$.

\mathbf{Q} is the $n \times g$ matrix $\mathbf{q}(\mathbf{y}_1, \mathbf{x}_1, \boldsymbol{\theta}), \mathbf{q}(\mathbf{y}_2, \mathbf{x}_2, \boldsymbol{\theta}), \dots, \mathbf{q}(\mathbf{y}_n, \mathbf{x}_n, \boldsymbol{\theta})$.

\mathbf{Q}_i is an $n \times g$ matrix $\frac{\partial \mathbf{Q}}{\partial \theta_i}$.

\mathbf{I} is an $n \times n$ identity matrix.

\mathbf{J}_t is $\frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{\partial \mathbf{y}_t}$, which is a $g \times g$ Jacobian matrix.

\mathbf{m}_n is first moment of the crossproduct $\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \otimes \mathbf{z}_t$,

$$\mathbf{m}_n = \frac{1}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \otimes \mathbf{z}_t$$

\mathbf{z}_t is a k column vector of instruments for observation t . \mathbf{z}_t' is also the t th row of \mathbf{Z} .

$\hat{\mathbf{V}}$ is the $gk \times gk$ matrix that represents the variance of the moment functions.

k is the number of instrumental variables used.

constant is the constant $\frac{ng}{2}(1 + \ln(2\pi))$.

\otimes is the notation for a Kronecker product.

All vectors are column vectors unless otherwise noted. Other estimates of the covariance matrix for FIML are also available.

Dependent Regressors and Two-Stage Least Squares

Ordinary regression analysis is based on several assumptions. A key assumption is that the independent variables are in fact statistically independent of the unobserved error component of the model. If this assumption is not true (if the regressor varies systematically with the error), then ordinary regression produces inconsistent results. The parameter estimates are *biased*.

Regressors might fail to be independent variables because they are dependent variables in a larger simultaneous system. For this reason, the problem of dependent regressors is often called *simultaneous equation bias*. For example, consider the following two-equation system:

$$y_1 = a_1 + b_1 y_2 + c_1 x_1 + \epsilon_1$$

$$y_2 = a_2 + b_2 y_1 + c_2 x_2 + \epsilon_2$$

In the first equation, y_2 is a dependent, or *endogenous*, variable. As shown by the second equation, y_2 is a function of y_1 , which by the first equation is a function of ϵ_1 , and therefore y_2 depends on ϵ_1 . Likewise, y_1 depends on ϵ_2 and is a dependent regressor in the second equation. This is an example of a *simultaneous equation* system; y_1 and y_2 are a function of all the variables in the system.

Using the ordinary least squares (OLS) estimation method to estimate these equations produces biased estimates. One solution to this problem is to replace y_1 and y_2 on the right-hand side of the equations with predicted values, thus changing the regression problem to the following:

$$y_1 = a_1 + b_1 \hat{y}_2 + c_1 x_1 + \epsilon_1$$

$$y_2 = a_2 + b_2 \hat{y}_1 + c_2 x_2 + \epsilon_2$$

This method requires estimating the predicted values \hat{y}_1 and \hat{y}_2 through a preliminary, or “first stage,” *instrumental regression*. An instrumental regression is a regression of the dependent regressors on a set of *instrumental variables*, which can be any independent variables useful for predicting the dependent regressors. In this example, the equations are linear and the exogenous variables for the whole system are known. Thus, the best choice for instruments (of the variables in the model) are the variables x_1 and x_2 .

This method is known as *two-stage least squares* or 2SLS, or more generally as the *instrumental variables method*. The 2SLS method for linear models is discussed in Pindyck and Rubinfeld (1981, pp. 191–192). For nonlinear models this situation is more complex, but the idea is the same. In nonlinear 2SLS, the derivatives of the model with respect to the parameters are replaced with predicted values. See the section “[Choice of Instruments](#)” on page 1192 for further discussion of the use of instrumental variables in nonlinear regression.

To perform nonlinear 2SLS estimation with PROC MODEL, specify the instrumental variables with an INSTRUMENTS statement and specify the 2SLS or N2SLS option in the FIT statement. The following statements show how to estimate the first equation in the preceding example with PROC MODEL:

```
proc model data=in;
  y1 = a1 + b1 * y2 + c1 * x1;
  fit y1 / 2sls;
  instruments x1 x2;
run;
```

The 2SLS or instrumental variables estimator can be computed by using a first-stage regression on the instrumental variables as described previously. However, PROC MODEL actually uses the equivalent but

computationally more appropriate technique of projecting the regression problem into the linear space defined by the instruments. Thus, PROC MODEL does not produce any “first stage” results when you use 2SLS. If you specify the FSRSQ option in the FIT statement, PROC MODEL prints “First-Stage R²” statistic for each parameter estimate.

Formally, the $\hat{\theta}$ that minimizes

$$\hat{S}_n = \frac{1}{n} \left(\sum_{t=1}^n (\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \otimes \mathbf{z}_t) \right)' \left(\sum_{t=1}^n I \otimes \mathbf{z}_t \mathbf{z}_t' \right)^{-1} \left(\sum_{t=1}^n (\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \otimes \mathbf{z}_t) \right)$$

is the N2SLS estimator of the parameters. The estimate of Σ at the final iteration is used in the covariance of the parameters given in Table 19.2. See Amemiya (1985, p. 250) for details on the properties of nonlinear two-stage least squares.

Seemingly Unrelated Regression

If the regression equations are not simultaneous (so there are no dependent regressors), *seemingly unrelated regression* (SUR) can be used to estimate systems of equations with correlated random errors. The large-sample efficiency of an estimation can be improved if these cross-equation correlations are taken into account. SUR is also known as *joint generalized least squares* or *Zellner regression*. Formally, the $\hat{\theta}$ that minimizes

$$\hat{S}_n = \frac{1}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)' \hat{\Sigma}^{-1} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)$$

is the SUR estimator of the parameters.

The SUR method requires an estimate of the cross-equation covariance matrix, Σ . PROC MODEL first performs an OLS estimation, computes an estimate, $\hat{\Sigma}$, from the OLS residuals, and then performs the SUR estimation based on $\hat{\Sigma}$. The OLS results are not printed unless you specify the OLS option in addition to the SUR option.

You can specify the $\hat{\Sigma}$ to use for SUR by storing the matrix in a SAS data set and naming that data set in the SDATA= option. You can also feed the $\hat{\Sigma}$ computed from the SUR residuals back into the SUR estimation process by specifying the ITSUR option. You can print the estimated covariance matrix $\hat{\Sigma}$ by using the COVS option in the FIT statement.

The SUR method requires estimation of the Σ matrix, and this increases the sampling variability of the estimator for small sample sizes. The efficiency gain that SUR has over OLS is a large sample property, and you must have a reasonable amount of data to realize this gain. For a more detailed discussion of SUR, see Pindyck and Rubinfeld (1981, pp. 331–333).

Three-Stage Least Squares Estimation

If the equation system is simultaneous, you can combine the 2SLS and SUR methods to take into account both dependent regressors and cross-equation correlation of the errors. This is called *three-stage least squares* (3SLS).

Formally, the $\hat{\theta}$ that minimizes

$$\hat{S}_n = \frac{1}{n} \left(\sum_{t=1}^n (\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \otimes \mathbf{z}_t) \right)' \left(\sum_{t=1}^n (\hat{\Sigma} \otimes \mathbf{z}_t \mathbf{z}_t') \right)^{-1} \left(\sum_{t=1}^n (\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \otimes \mathbf{z}_t) \right)$$

is the 3SLS estimator of the parameters. For more details on 3SLS, see Gallant (1987, p. 435).

Residuals from the 2SLS method are used to estimate the Σ matrix required for 3SLS. The results of the preliminary 2SLS step are not printed unless the 2SLS option is also specified.

To use the three-stage least squares method, specify an INSTRUMENTS statement and use the 3SLS or N3SLS option in either the PROC MODEL statement or a FIT statement.

Generalized Method of Moments (GMM)

For systems of equations with heteroscedastic errors, generalized method of moments (GMM) can be used to obtain efficient estimates of the parameters. See the section “[Heteroscedasticity](#)” on page 1160 for alternatives to GMM.

Consider the nonlinear model

$$\begin{aligned}\epsilon_t &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \\ \mathbf{z}_t &= \mathbf{Z}(\mathbf{x}_t)\end{aligned}$$

where \mathbf{z}_t is a vector of instruments and ϵ_t is an unobservable disturbance vector that can be serially correlated and nonstationary.

In general, the following orthogonality condition is desired:

$$E(\epsilon_t \otimes \mathbf{z}_t) = 0$$

This condition states that the expected crossproducts of the unobservable disturbances, ϵ_t , and functions of the observable variables are set to 0. The first moment of the crossproducts is

$$\begin{aligned}\mathbf{m}_n &= \frac{1}{n} \sum_{t=1}^n \mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \\ \mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \otimes \mathbf{z}_t\end{aligned}$$

where $\mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \in R^{gk}$.

The case where $gk > p$ is considered here, where p is the number of parameters.

Estimate the true parameter vector θ^0 by the value of $\hat{\theta}$ that minimizes

$$S(\theta, \mathbf{V}) = [n\mathbf{m}_n(\theta)]' \mathbf{V}^{-1} [n\mathbf{m}_n(\theta)] / n$$

where

$$\mathbf{V} = \text{Cov}([n\mathbf{m}_n(\theta^0)], [n\mathbf{m}_n(\theta^0)]')$$

The parameter vector that minimizes this objective function is the GMM estimator. GMM estimation is requested in the FIT statement with the GMM option.

The variance of the moment functions, \mathbf{V} , can be expressed as

$$\begin{aligned}\mathbf{V} &= E \left(\sum_{t=1}^n \boldsymbol{\epsilon}_t \otimes \mathbf{z}_t \right) \left(\sum_{s=1}^n \boldsymbol{\epsilon}_s \otimes \mathbf{z}_s \right)' \\ &= \sum_{t=1}^n \sum_{s=1}^n E [(\boldsymbol{\epsilon}_t \otimes \mathbf{z}_t)(\boldsymbol{\epsilon}_s \otimes \mathbf{z}_s)'] \\ &= n\mathbf{S}_n^0\end{aligned}$$

where \mathbf{S}_n^0 is estimated as

$$\hat{\mathbf{S}}_n = \frac{1}{n} \sum_{t=1}^n \sum_{s=1}^n (\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \otimes \mathbf{z}_t)(\mathbf{q}(\mathbf{y}_s, \mathbf{x}_s, \boldsymbol{\theta}) \otimes \mathbf{z}_s)'$$

Note that $\hat{\mathbf{S}}_n$ is a $gk \times gk$ matrix. Because $\text{Var}(\hat{\mathbf{S}}_n)$ does not decrease with increasing n , you consider estimators of \mathbf{S}_n^0 of the form:

$$\begin{aligned}\hat{\mathbf{S}}_n(l(n)) &= \sum_{\tau=-n+1}^{n-1} \hat{w}\left(\frac{\tau}{l(n)}\right) \mathbf{D} \hat{\mathbf{S}}_{n,\tau} \mathbf{D} \\ \hat{\mathbf{S}}_{n,\tau} &= \begin{cases} \sum_{t=1+\tau}^n [\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}^\#) \otimes \mathbf{z}_t][\mathbf{q}(\mathbf{y}_{t-\tau}, \mathbf{x}_{t-\tau}, \boldsymbol{\theta}^\#) \otimes \mathbf{z}_{t-\tau}]' & \tau \geq 0 \\ (\hat{\mathbf{S}}_{n,-\tau})' & \tau < 0 \end{cases} \\ \hat{w}\left(\frac{\tau}{l(n)}\right) &= \begin{cases} w\left(\frac{\tau}{l(n)}\right) & l(n) > 0 \\ \delta_{\tau,0} & l(n) = 0 \end{cases}\end{aligned}$$

where $l(n)$ is a scalar function that computes the bandwidth parameter, $w(\cdot)$ is a scalar valued kernel, and the Kronecker delta function, $\delta_{i,j}$, is 1 if $i = j$ and 0 otherwise. The diagonal matrix \mathbf{D} is used for a small sample degrees of freedom correction (Gallant 1987). The initial $\boldsymbol{\theta}^\#$ used for the estimation of $\hat{\mathbf{S}}_n$ is obtained from a 2SLS estimation of the system. The degrees of freedom correction is handled by the VARDEF= option as it is for the \mathbf{S} matrix estimation.

The following kernels are supported by PROC MODEL. They are listed with their default bandwidth functions.

Bartlett: KERNEL=BART

$$\begin{aligned}w(x) &= \begin{cases} 1 - |x| & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(n) &= \frac{1}{2} n^{1/3}\end{aligned}$$

Parzen: KERNEL=PARZEN

$$w(x) = \begin{cases} 1 - 6|x|^2 + 6|x|^3 & 0 \leq |x| \leq \frac{1}{2} \\ 2(1 - |x|)^3 & \frac{1}{2} \leq |x| \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

$$l(n) = n^{1/5}$$

Quadratic spectral: KERNEL=QS

$$w(x) = \frac{25}{12\pi^2 x^2} \left(\frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right)$$

$$l(n) = \frac{1}{2}n^{1/5}$$

Figure 19.23 Kernels for Smoothing

Details of the properties of these and other kernels are given in Andrews (1991). Kernels are selected with the KERNEL= option; KERNEL=PARZEN is the default. The general form of the KERNEL= option is

KERNEL= (PARZEN | QS | BART, c, e)

where the $e \geq 0$ and $c \geq 0$ are used to compute the bandwidth parameter as

$$l(n) = cn^e$$

The bias of the standard error estimates increases for large bandwidth parameters. A warning message is produced for bandwidth parameters greater than $n^{\frac{1}{3}}$. For a discussion of the computation of the optimal $l(n)$, refer to Andrews (1991).

The “Newey-West” kernel (Newey and West 1987) corresponds to the Bartlett kernel with bandwidth parameter $l(n) = L + 1$. That is, if the “lag length” for the Newey-West kernel is L , then the corresponding MODEL procedure syntax is `KERNEL=(bart, L+1, 0)`.

Andrews and Monahan (1992) show that using prewhitening in combination with GMM can improve confidence interval coverage and reduce over rejection of t statistics at the cost of inflating the variance and MSE of the estimator. Prewhitening can be performed by using the `%AR` macros.

For the special case that the errors are not serially correlated—that is,

$$E(e_t \otimes z_t)(e_s \otimes z_s) = 0 \quad t \neq s$$

the estimate for S_n^0 reduces to

$$\hat{S}_n = \frac{1}{n} \sum_{t=1}^n [q(y_t, x_t, \theta) \otimes z_t][q(y_t, x_t, \theta) \otimes z_t]'$$

The option `KERNEL=(kernel,0,)` is used to select this type of estimation when using GMM.

Covariance of GMM estimators

The covariance of GMM estimators, given a general weighting matrix V_G^{-1} , is

$$[(YX)'V_G^{-1}(YX)]^{-1}(YX)'V_G^{-1}\hat{V}V_G^{-1}(YX)[(YX)'V_G^{-1}(YX)]^{-1}$$

By default or when `GENGMMV` is specified, this is the covariance of GMM estimators.

If the weighting matrix is the same as \hat{V} , then the covariance of GMM estimators becomes

$$[(YX)'\hat{V}^{-1}(YX)]^{-1}$$

If `NOGENGMMV` is specified, this is used as the covariance estimators.

Testing Overidentifying Restrictions

Let r be the number of unique instruments times the number of equations. The value r represents the number of orthogonality conditions imposed by the GMM method. Under the assumptions of the GMM method, $r - p$ linearly independent combinations of the orthogonality should be close to zero. The GMM estimates are computed by setting these combinations to zero. When r exceeds the number of parameters to be estimated, the `OBJECTIVE*N`, reported at the end of the estimation, is an asymptotically valid statistic to test the null hypothesis that the overidentifying restrictions of the model are valid. The `OBJECTIVE*N` is distributed as a chi-square with $r - p$ degrees of freedom (Hansen 1982, p. 1049). When the GMM method is selected, the value of the overidentifying restrictions test statistic, also known as Hansen’s J test statistic, and its associated number of degrees of freedom are reported together with the probability under the null hypothesis.

Iterated Generalized Method of Moments (ITGMM)

Iterated generalized method of moments is similar to the iterated versions of 2SLS, SUR, and 3SLS. The variance matrix for GMM estimation is reestimated at each iteration with the parameters determined by the GMM estimation. The iteration terminates when the variance matrix for the equation errors change less than the CONVERGE= value. Iterated generalized method of moments is selected by the ITGMM option on the FIT statement. For some indication of the small sample properties of ITGMM, see Ferson and Foerster (1993).

Simulated Method of Moments (SMM)

The SMM method uses simulation techniques in model inference and estimation. It is appropriate for estimating models in which integrals appear in the objective function, and these integrals can be approximated by simulation. There might be various reasons for integrals to appear in an objective function (for example, transformation of a latent model into an observable model, missing data, random coefficients, heterogeneity, and so on).

This simulation method can be used with all the estimation methods except full information maximum likelihood (FIML) in PROC MODEL. SMM, also known as simulated generalized method of moments (SGMM), is the default estimation method because of its nice properties.

Estimation Details

A general nonlinear model can be described as

$$\epsilon_t = \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})$$

where $\mathbf{q} \in R^g$ is a real vector valued function of $\mathbf{y}_t \in R^g$, $\mathbf{x}_t \in R^l$, $\boldsymbol{\theta} \in R^p$; g is the number of equations; l is the number of exogenous variables (lagged endogenous variables are considered exogenous here); p is the number of parameters; and t ranges from 1 to n . ϵ_t is an unobservable disturbance vector with the following properties:

$$\begin{aligned} E(\epsilon_t) &= 0 \\ E(\epsilon_t \epsilon_t') &= \Sigma \end{aligned}$$

In many cases, it is not possible to write $\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})$ in a closed form. Instead \mathbf{q} is expressed as an integral of a function \mathbf{f} ; that is,

$$\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) = \int \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}, \mathbf{u}_t) dP(\mathbf{u})$$

where $\mathbf{f} \in R^g$ is a real vector valued function of $\mathbf{y}_t \in R^g$, $\mathbf{x}_t \in R^l$, $\boldsymbol{\theta} \in R^p$, and $\mathbf{u}_t \in R^m$, m is the number of stochastic variables with a known distribution $P(\mathbf{u})$. Since the distribution of \mathbf{u} is completely known, it is possible to simulate artificial draws from this distribution. Using such independent draws \mathbf{u}_{ht} , $h = 1, \dots, H$, and the strong law of large numbers, \mathbf{q} can be approximated by

$$\frac{1}{H} \sum_{h=1}^H \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}, \mathbf{u}_{ht}).$$

Simulated Generalized Method of Moments (SGMM)

Generalized method of moments (GMM) is widely used to obtain efficient estimates for general model systems. When the moment conditions are not readily available in closed forms but can be approximated by simulation, simulated generalized method of moments (SGMM) can be used. The SGMM estimators have the nice property of being asymptotically consistent and normally distributed even if the number of draws H is fixed (see McFadden 1989; Pakes and Pollard 1989).

Consider the nonlinear model

$$\begin{aligned}\epsilon_t &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) = \frac{1}{H} \sum_{h=1}^H \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \theta, \mathbf{u}_{ht}) \\ \mathbf{z}_t &= \mathbf{Z}(\mathbf{x}_t)\end{aligned}$$

where $\mathbf{z}_t \in R^k$ is a vector of k instruments and ϵ_t is an unobservable disturbance vector that can be serially correlated and nonstationary. In the case of no instrumental variables, \mathbf{z}_t is 1. $\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)$ is the vector of moment conditions, and it is approximated by simulation.

In general, theory suggests the following orthogonality condition

$$E(\epsilon_t \otimes \mathbf{z}_t) = 0$$

which states that the expected crossproducts of the unobservable disturbances, ϵ_t , and functions of the observable variables are set to 0. The sample means of the crossproducts are

$$\begin{aligned}\mathbf{m}_n &= \frac{1}{n} \sum_{t=1}^n \mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \theta) \\ \mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \theta) &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \otimes \mathbf{z}_t\end{aligned}$$

where $\mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \theta) \in R^{gk}$. The case where $gk > p$, where p is the number of parameters, is considered here. An estimate of the true parameter vector θ^0 is the value of $\hat{\theta}$ that minimizes

$$S(\theta, V) = [n\mathbf{m}_n(\theta)]' \mathbf{V}^{-1} [n\mathbf{m}_n(\theta)] / n$$

where

$$\mathbf{V} = \text{Cov}(\mathbf{m}(\theta^0), \mathbf{m}(\theta^0)').$$

The steps for SGMM are as follows:

1. Start with a positive definite $\hat{\mathbf{V}}$ matrix. This $\hat{\mathbf{V}}$ matrix can be estimated from a consistent estimator of θ . If $\hat{\theta}$ is a consistent estimator, then \mathbf{u}_t for $t = 1, \dots, n$ can be simulated H' number of times. A consistent estimator of \mathbf{V} is obtained as

$$\hat{\mathbf{V}} = \frac{1}{n} \sum_{t=1}^n \left[\frac{1}{H'} \sum_{h=1}^{H'} \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \hat{\theta}, \mathbf{u}_{ht}) \otimes \mathbf{z}_t \right] \left[\frac{1}{H'} \sum_{h=1}^{H'} \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \hat{\theta}, \mathbf{u}_{ht}) \otimes \mathbf{z}_t \right]'$$

H' must be large so that this is an consistent estimator of \mathbf{V} .

2. Simulate H number of \mathbf{u}_t for $t = 1, \dots, n$. As shown by Gourieroux and Monfort (1993), the number of simulations H does not need to be very large. For $H = 10$, the SGMM estimator achieves 90% of the

efficiency of the corresponding GMM estimator. Find $\hat{\theta}$ that minimizes the quadratic product of the moment conditions again with the weight matrix being $\hat{\mathbf{V}}^{-1}$.

$$\min_{\theta} [n\mathbf{m}_n(\theta)]' \hat{\mathbf{V}}^{-1} [n\mathbf{m}_n(\theta)] / n$$

3. The covariance matrix of $\sqrt{n}\theta$ is given as (Gourieroux and Monfort 1993)

$$\mathbf{\Sigma}_1^{-1} \mathbf{D} \hat{\mathbf{V}}^{-1} \mathbf{V}(\hat{\theta}) \hat{\mathbf{V}}^{-1} \mathbf{D}' \mathbf{\Sigma}_1^{-1} + \frac{1}{H} \mathbf{\Sigma}_1^{-1} \mathbf{D} \hat{\mathbf{V}}^{-1} E[\mathbf{z} \otimes \text{Var}(\mathbf{f}|\mathbf{x}) \otimes \mathbf{z}] \hat{\mathbf{V}}^{-1} \mathbf{D}' \mathbf{\Sigma}_1^{-1}$$

where $\mathbf{\Sigma}_1 = \mathbf{D} \hat{\mathbf{V}}^{-1} \mathbf{D}$, \mathbf{D} is the matrix of partial derivatives of the residuals with respect to the parameters, $\mathbf{V}(\hat{\theta})$ is the covariance of moments from estimated parameters $\hat{\theta}$, and $\text{Var}(\mathbf{f}|\mathbf{x})$ is the covariance of moments for each observation from simulation. The first term is the variance-covariance matrix of the exact GMM estimator, and the second term accounts for the variation contributed by simulating the moments.

Implementation in PROC MODEL

In PROC MODEL, if the user specifies the GMM and NDRAW options in the FIT statement, PROC MODEL first fits the model by using N2SLS and computes $\hat{\mathbf{V}}$ by using the estimates from N2SLS and H' simulation. If NO2SLS is specified in the FIT statement, $\hat{\mathbf{V}}$ is read from VDATA= data set. If the user does not provide a $\hat{\mathbf{V}}$ matrix, the initial starting value of θ is used as the estimator for computing the $\hat{\mathbf{V}}$ matrix in step 1. If ITGMM option is specified instead of GMM, then PROC MODEL iterates from step 1 to step 3 until the \mathbf{V} matrix converges.

The consistency of the parameter estimates is not affected by the variance correction shown in the second term in step 3. The correction on the variance of parameter estimates is not computed by default. To add the adjustment, use ADJSMMV option on the FIT statement. This correction is of the order of $\frac{1}{H}$ and is small even for moderate H .

The following example illustrates how to use SMM to estimate a simple regression model. Suppose the model is

$$y = a + bx + u, u \sim iid N(0, s^2).$$

First, consider the problem in a GMM context. The first two moments of y are easily derived:

$$\begin{aligned} E(y) &= a + bx \\ E(y^2) &= (a + bx)^2 + s^2 \end{aligned}$$

Rewrite the moment conditions in the form similar to the discussion above:

$$\begin{aligned} \epsilon_{1t} &= y_t - (a + bx_t) \\ \epsilon_{2t} &= y_t^2 - (a + bx_t)^2 - s^2 \end{aligned}$$

Then you can estimate this model by using GMM with following statements:

```
proc model data=a;
  parms a b s;
  instrument x;
```

```

eq.m1 = y-(a+b*x);
eq.m2 = y*y - (a+b*x)**2 - s*s;
bound s > 0;
fit m1 m2 / gmm;
run;

```

Now suppose you do not have the closed form for the moment conditions. Instead you can simulate the moment conditions by generating H number of simulated samples based on the parameters. Then the simulated moment conditions are

$$\epsilon_{1t} = \frac{1}{H} \sum_{h=1}^H \{y_t - (a + bx_t + su_{t,h})\}$$

$$\epsilon_{2t} = \frac{1}{H} \sum_{h=1}^H \{y_t^2 - (a + bx_t + su_{t,h})^2\}$$

This model can be estimated by using SGMM with the following statements:

```

proc model data=_tmpdata;
  parms a b s;
  instrument x;
  ysim = (a+b*x) + s * rannor( 98711 );
  eq.m1 = y-ysim;
  eq.m2 = y*y - ysim*ysim;
  bound s > 0;
  fit m1 m2 / gmm ndraw=10;
run;

```

You can use the following MOMENT statement instead of specifying the two moment equations above:

```
moment ysim=(1, 2);
```

In cases where you require a large number of moment equations, using the MOMENT statement to specify them is more efficient.

Note that the NDRAW= option tells PROC MODEL that this is a simulation-based estimation. Thus, the random number function RANNOR returns random numbers in estimation process. During the simulation, 10 draws of $m1$ and $m2$ are generated for each observation, and the averages enter the objective functions just as the equations specified previously.

Other Estimation Methods

The simulation method can be used not only with GMM and ITGMM, but also with OLS, ITOLS, SUR, ITSUR, N2SLS, IT2SLS, N3SLS, and IT3SLS. These simulation-based methods are similar to the corresponding methods in PROC MODEL; the only difference is that the objective functions include the average of the H simulations.

Full Information Maximum Likelihood Estimation (FIML)

A different approach to the simultaneous equation bias problem is the full information maximum likelihood (FIML) estimation method (Amemiya 1977).

Compared to the instrumental variables methods (2SLS and 3SLS), the FIML method has these advantages and disadvantages:

- FIML does not require instrumental variables.
- FIML requires that the model include the full equation system, with as many equations as there are endogenous variables. With 2SLS or 3SLS, you can estimate some of the equations without specifying the complete system.
- FIML assumes that the equations errors have a multivariate normal distribution. If the errors are not normally distributed, the FIML method might produce poor results. 2SLS and 3SLS do not assume a specific distribution for the errors.
- The FIML method is computationally expensive.

The full information maximum likelihood estimators of θ and σ are the $\hat{\theta}$ and $\hat{\sigma}$ that minimize the negative log-likelihood function:

$$\begin{aligned} l_n(\theta, \sigma) = & \frac{ng}{2} \ln(2\pi) - \sum_{t=1}^n \ln \left(\left| \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)}{\partial \mathbf{y}_t'} \right| \right) + \frac{n}{2} \ln(|\Sigma(\sigma)|) \\ & + \frac{1}{2} \text{tr} \left(\Sigma(\sigma)^{-1} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \mathbf{q}'(\mathbf{y}_t, \mathbf{x}_t, \theta) \right) \end{aligned}$$

The option FIML requests full information maximum likelihood estimation. If the errors are distributed normally, FIML produces efficient estimators of the parameters. If instrumental variables are not provided, the starting values for the estimation are obtained from a SUR estimation. If instrumental variables are provided, then the starting values are obtained from a 3SLS estimation. The log-likelihood value and the l_2 norm of the gradient of the negative log-likelihood function are shown in the estimation summary.

FIML Details

To compute the minimum of $l_n(\theta, \sigma)$, this function is *concentrated* using the relation

$$\Sigma(\theta) = \frac{1}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \mathbf{q}'(\mathbf{y}_t, \mathbf{x}_t, \theta)$$

This results in the concentrated negative log-likelihood function discussed in Davidson and MacKinnon (1993):

$$l_n(\theta) = \frac{ng}{2} (1 + \ln(2\pi)) - \sum_{t=1}^n \ln \left| \frac{\partial}{\partial \mathbf{y}_t'} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \right| + \frac{n}{2} \ln |\Sigma(\theta)|$$

The gradient of the negative log-likelihood function is

$$\begin{aligned}\frac{\partial}{\partial \theta_i} l_n(\boldsymbol{\theta}) &= \sum_{t=1}^n \nabla_i(t) \\ \nabla_i(t) &= -\text{tr} \left(\left(\frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{\partial \mathbf{y}'_t} \right)^{-1} \frac{\partial^2 \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{\partial \mathbf{y}'_t \partial \theta_i} \right) \\ &+ \frac{1}{2} \text{tr} \left(\boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \frac{\partial \boldsymbol{\Sigma}(\boldsymbol{\theta})}{\partial \theta_i} \right. \\ &\quad \left. [I - \boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'] \right) \\ &+ \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}') \boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{\partial \theta_i}\end{aligned}$$

where

$$\frac{\partial \boldsymbol{\Sigma}(\boldsymbol{\theta})}{\partial \theta_i} = \frac{2}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \theta_i}$$

The estimator of the variance-covariance of $\hat{\boldsymbol{\theta}}$ (COVB) for FIML can be selected with the COVBEST= option with the following arguments:

CROSS selects the crossproducts estimator of the covariance matrix (Gallant 1987, p. 473):

$$C = \left(\frac{1}{n} \sum_{t=1}^n \nabla(t) \nabla'(t) \right)^{-1}$$

where $\nabla(t) = [\nabla_1(t), \nabla_2(t), \dots, \nabla_p(t)]'$. This is the default.

GLS selects the generalized least squares estimator of the covariance matrix. This is computed as (Dagenais 1978)

$$C = [\hat{\mathbf{Z}}' (\boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \otimes I) \hat{\mathbf{Z}}]^{-1}$$

where $\hat{\mathbf{Z}} = (\hat{Z}_1, \hat{Z}_2, \dots, \hat{Z}_p)$ is $ng \times p$ and each \hat{Z}_i column vector is obtained from stacking the columns of

$$\mathbf{U} \frac{1}{n} \sum_{t=1}^n \left(\frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \mathbf{y}} \right)^{-1} \frac{\partial^2 \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \mathbf{y}'_n \partial \theta_i} - Q_i$$

\mathbf{U} is an $n \times g$ matrix of residuals and q_i is an $n \times g$ matrix $\frac{\partial \mathbf{Q}}{\partial \theta_i}$.

FDA selects the inverse of concentrated likelihood Hessian as an estimator of the covariance matrix. The Hessian is computed numerically, so for a large problem this is computationally expensive.

The HESSIAN= option controls which approximation to the Hessian is used in the minimization procedure. Alternate approximations are used to improve convergence and execution time. The choices are as follows:

CROSS	The crossproducts approximation is used.
GLS	The generalized least squares approximation is used (default).
FDA	The Hessian is computed numerically by finite differences.

HESSIAN=GLS has better convergence properties in general, but COVBEST=CROSS produces the most pessimistic standard error bounds. When the HESSIAN= option is used, the default estimator of the variance-covariance of $\hat{\theta}$ is the inverse of the Hessian selected.

Multivariate t Distribution Estimation

The multivariate t distribution is specified by using the ERRORMODEL statement with the T option. Other method specifications (FIML and OLS, for example) are ignored when the ERRORMODEL statement is used for a distribution other than normal.

The probability density function for the multivariate t distribution is

$$P_q = \frac{\Gamma(\frac{df+m}{2})}{(\pi * df)^{\frac{m}{2}} * \Gamma(\frac{df}{2}) |\Sigma(\sigma)|^{\frac{1}{2}}} * \left(1 + \frac{\mathbf{q}'(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \Sigma(\sigma)^{-1} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{df} \right)^{-\frac{df+m}{2}}$$

where m is the number of equations and df is the degrees of freedom.

The maximum likelihood estimators of θ and σ are the $\hat{\theta}$ and $\hat{\sigma}$ that minimize the negative log-likelihood function:

$$\begin{aligned} l_n(\boldsymbol{\theta}, \sigma) = & - \sum_{t=1}^n \ln \left(\frac{\Gamma(\frac{df+m}{2})}{(\pi * df)^{\frac{m}{2}} * \Gamma(\frac{df}{2})} * \left(1 + \frac{q_t' \Sigma^{-1} q_t}{df} \right)^{-\frac{df+m}{2}} \right) \\ & + \frac{n}{2} * \ln(|\Sigma|) - \sum_{t=1}^n \ln \left(\left| \frac{\partial q_t}{\partial y_t'} \right| \right) \end{aligned}$$

The ERRORMODEL statement is used to request the t distribution maximum likelihood estimation. An OLS estimation is done to obtain initial parameter estimates and MSE.var estimates. Use NOOLS to turn off this initial estimation. If the errors are distributed normally, t distribution estimation produces results similar to FIML.

The multivariate model has a single shared degrees-of-freedom parameter, which is estimated. The degrees-of-freedom parameter can also be set to a fixed value. The log-likelihood value and the l_2 norm of the gradient of the negative log-likelihood function are shown in the estimation summary.

t Distribution Details

Since a variance term is explicitly specified by using the ERRORMODEL statement, $\Sigma(\theta)$ is estimated as a correlation matrix and $\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})$ is normalized by the variance. The gradient of the negative log-likelihood function with respect to the degrees of freedom is

$$\begin{aligned} \frac{\partial l_n}{\partial df} = & \frac{nm}{2 df} - \frac{n}{2} \frac{\Gamma'(\frac{df+m}{2})}{\Gamma(\frac{df+m}{2})} + \frac{n}{2} \frac{\Gamma'(\frac{df}{2})}{\Gamma(\frac{df}{2})} + \\ & 0.5 \log(1 + \frac{\mathbf{q}' \Sigma^{-1} \mathbf{q}}{df}) - \frac{0.5(df+m)}{(1 + \frac{\mathbf{q}' \Sigma^{-1} \mathbf{q}}{df})} \frac{\mathbf{q}' \Sigma^{-1} \mathbf{q}}{df^2} \end{aligned}$$

The gradient of the negative log-likelihood function with respect to the parameters is

$$\frac{\partial l_n}{\partial \theta_i} = \frac{0.5(df + m)}{(1 + \mathbf{q}'\Sigma^{-1}\mathbf{q}/df)} \left[\frac{(2 \mathbf{q}'\Sigma^{-1} \frac{\partial \mathbf{q}}{\partial \theta_i})}{df} + \mathbf{q}'\Sigma^{-1} \frac{\partial \Sigma}{\partial \theta_i} \Sigma^{-1} \mathbf{q} \right] - \frac{n}{2} \text{trace}(\Sigma^{-1} \frac{\partial \Sigma}{\partial \theta_i})$$

where

$$\frac{\partial \Sigma(\theta)}{\partial \theta_i} = \frac{2}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)'}{\partial \theta_i}$$

and

$$\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) = \frac{\epsilon(\theta)}{\sqrt{h(\theta)}} \in R^{m \times n}$$

The estimator of the variance-covariance of $\hat{\theta}$ (COVB) for the t distribution is the inverse of the likelihood Hessian. The gradient is computed analytically, and the Hessian is computed numerically.

Empirical Distribution Estimation and Simulation

The following SAS statements fit a model that uses least squares as the likelihood function, but represent the distribution of the residuals with an empirical cumulative distribution function (CDF). The plot of the empirical probability distribution is shown in [Figure 19.24](#).

```
data t; /* Sum of two normals */
  format date monyy.;
  do t = 0 to 9.9 by 0.1;
    date = intnx( 'month', '1jun90'd, (t*10)-1 );
    y = 0.1 * (rannor(123)-10) +
        .5 * (rannor(123)+10);
    output;
  end;
run;

ods select Model.Likelihood.ResidSummary
           Model.Likelihood.ParameterEstimates;

proc model data=t time=t itprint;
  dependent y;
  parm a 5;

  y = a;
  obj = resid.y * resid.y;
  errormodel y ~ general( obj )
  cdf=(empirical=(tails=( normal percent=10)));

  fit y / outsn=s out=r;
  id date;

  solve y / data=t (where=(date='1aug98'd))
         residdata=r sdata=s
         random=200 seed=6789 out=monte ;
run;
```

```
proc kde data=monte;
  univar y / plots=density;
run;
```

Figure 19.24 Empirical PDF Plot

For simulation, if the CDF for the model is not built in to the procedure, you can use the `CDF=EMPIRICAL()` option. This uses the sorted residual data to create an empirical CDF. For computing the inverse CDF, the program needs to know how to handle the tails. For continuous data, the tail distribution is generally poorly determined. To counter this, the `PERCENT=` option specifies the percentage of the observations to use in constructing each tail. The default for the `PERCENT=` option is 10.

A normal distribution or a t distribution is used to extrapolate the tails to infinity. The standard errors for this extrapolation are obtained from the data so that the empirical CDF is continuous.

Properties of the Estimates

All of the methods are consistent. Small sample properties might not be good for nonlinear models. The tests and standard errors reported are based on the convergence of the distribution of the estimates to a normal distribution in large samples.

These nonlinear estimation methods reduce to the corresponding linear systems regression methods if the model is linear. If this is the case, PROC MODEL produces the same estimates as PROC SYSLIN.

Except for GMM, the estimation methods assume that the equation errors for each observation are identically and independently distributed with a 0 mean vector and positive definite covariance matrix Σ consistently estimated by S . For FIML, the errors need to be normally distributed. There are no other assumptions concerning the distribution of the errors for the other estimation methods.

The consistency of the parameter estimates relies on the assumption that the S matrix is a consistent estimate of Σ . These standard error estimates are asymptotically valid, but for nonlinear models they might not be reliable for small samples.

The S matrix used for the calculation of the covariance of the parameter estimates is the best estimate available for the estimation method selected. For S -iterated methods, this is the most recent estimation of Σ . For OLS and 2SLS, an estimate of the S matrix is computed from OLS or 2SLS residuals and used for the calculation of the covariance matrix. For a complete list of the S matrix used for the calculation of the covariance of the parameter estimates, see [Table 19.2](#).

Missing Values

An observation is excluded from the estimation if any variable used for FIT tasks is missing, if the weight for the observation is not greater than 0 when weights are used, or if a DELETE statement is executed by the model program. Variables used for FIT tasks include the equation errors for each equation, the instruments, if any, and the derivatives of the equation errors with respect to the parameters estimated. Note that variables can become missing as a result of computational errors or calculations with missing values.

The number of usable observations can change when different parameter values are used; some parameter values can be invalid and cause execution errors for some observations. PROC MODEL keeps track of the number of usable and missing observations at each pass through the data, and if the number of missing observations counted during a pass exceeds the number that was obtained using the previous parameter vector, the pass is terminated and the new parameter vector is considered infeasible. PROC MODEL never takes a step that produces more missing observations than the current estimate does.

The values used to compute the Durbin-Watson, R^2 , and other statistics of fit are from the observations used in calculating the objective function and do not include any observation for which any needed variable was missing (residuals, derivatives, and instruments).

Details on the Covariance of Equation Errors

There are several S matrices that can be involved in the various estimation methods and in forming the estimate of the covariance of parameter estimates. These S matrices are estimates of Σ , the true covariance of the equation errors. Apart from the choice of instrumental or noninstrumental methods, many of the methods provided by PROC MODEL differ in the way the various S matrices are formed and used.

All of the estimation methods result in a final estimate of Σ , which is included in the output if the COVS option is specified. The final S matrix of each method provides the initial S matrix for any subsequent estimation.

This estimate of the covariance of equation errors is defined as

$$S = D(R'R)D$$

where $\mathbf{R} = (\mathbf{r}_1, \dots, \mathbf{r}_g)$ is composed of the equation residuals computed from the current parameter estimates in an $n \times g$ matrix and \mathbf{D} is a diagonal matrix that depends on the VARDEF= option.

For VARDEF=N, the diagonal elements of \mathbf{D} are $1/\sqrt{n}$, where n is the number of nonmissing observations. For VARDEF=WGT, n is replaced with the sum of the weights. For VARDEF=WDF, n is replaced with the sum of the weights minus the model degrees of freedom. For the default VARDEF=DF, the i th diagonal element of \mathbf{D} is $1/\sqrt{n - df_i}$, where df_i is the degrees of freedom (number of parameters) for the i th equation. Binkley and Nelson (1984) show the importance of using a degrees-of-freedom correction in estimating Σ . Their results indicate that the DF method produces more accurate confidence intervals for N3SLS parameter estimates in the linear case than the alternative approach they tested. VARDEF=N is always used for the computation of the FIML estimates.

For the fixed \mathbf{S} methods, the OUTSUSED= option writes the \mathbf{S} matrix used in the estimation to a data set. This \mathbf{S} matrix is either the estimate of the covariance of equation errors matrix from the preceding estimation, or a prior Σ estimate read in from a data set when the SDATA= option is specified. For the diagonal \mathbf{S} methods, all of the off-diagonal elements of the \mathbf{S} matrix are set to 0 for the estimation of the parameters and for the OUTSUSED= data set, but the output data set produced by the OUTS= option contains the off-diagonal elements. For the OLS and N2SLS methods, there is no previous estimate of the covariance of equation errors matrix, and the option OUTSUSED= saves an identity matrix unless a prior Σ estimate is supplied by the SDATA= option. For FIML, the OUTSUSED= data set contains the \mathbf{S} matrix computed with VARDEF=N. The OUTS= data set contains the \mathbf{S} matrix computed with the selected VARDEF= option. Both versions of the \mathbf{S} matrix appear in the printed output for FIML.

If the COVS option is used, the method is not \mathbf{S} -iterated, \mathbf{S} is not an identity, and the OUTSUSED= matrix is included in the printed output.

For the methods that iterate the covariance of equation errors matrix, the \mathbf{S} matrix is iteratively re-estimated from the residuals produced by the current parameter estimates. This \mathbf{S} matrix estimate iteratively replaces the previous estimate until both the parameter estimates and the estimate of the covariance of equation errors matrix converge. The final OUTS= matrix and OUTSUSED= matrix are thus identical for the \mathbf{S} -iterated methods.

Nested Iterations

By default, for \mathbf{S} -iterated methods, the \mathbf{S} matrix is held constant until the parameters converge once. Then the \mathbf{S} matrix is reestimated. One iteration of the parameter estimation algorithm is performed, and the \mathbf{S} matrix is again reestimated. This latter process is repeated until convergence of both the parameters and the \mathbf{S} matrix. Since the objective of the minimization depends on the \mathbf{S} matrix, this has the effect of chasing a moving target.

When the NESTIT option is specified, iterations are performed to convergence for the structural parameters with a fixed \mathbf{S} matrix. The \mathbf{S} matrix is then reestimated, the parameter iterations are repeated to convergence, and so on until both the parameters and the \mathbf{S} matrix converge. This has the effect of fixing the objective function for the inner parameter iterations. It is more reliable, but usually more expensive, to nest the iterations.

R-Square Statistic

For unrestricted linear models with an intercept successfully estimated by OLS, R^2 is always between 0 and 1. However, nonlinear models do not necessarily encompass the dependent mean as a special case and can

produce negative R^2 statistics. Negative R^2 statistics can also be produced even for linear models when an estimation method other than OLS is used and no intercept term is in the model.

R^2 is defined for normalized equations as

$$R^2 = 1 - \frac{SSE}{SSA - \bar{y}^2 \times n}$$

where SSA is the sum of the squares of the actual y 's and \bar{y} are the actual means. R^2 cannot be computed for models in general form because of the need for an actual Y .

Minimization Methods

PROC MODEL currently supports two methods for minimizing the objective function. These methods are described in the following sections.

GAUSS

The Gauss-Newton parameter-change vector for a system with g equations, n nonmissing observations, and p unknown parameters is

$$\Delta = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{r}$$

where Δ is the change vector, \mathbf{X} is the stacked $ng \times p$ Jacobian matrix of partial derivatives of the residuals with respect to the parameters, and \mathbf{r} is an $ng \times 1$ vector of the stacked residuals. The components of \mathbf{X} and \mathbf{r} are weighted by the \mathbf{S}^{-1} matrix. When instrumental methods are used, \mathbf{X} and \mathbf{r} are the projections of the Jacobian matrix and residuals vector in the instruments space and not the Jacobian and residuals themselves. In the preceding formula, \mathbf{S} and \mathbf{W} are suppressed. If instrumental variables are used, then the change vector becomes:

$$\Delta = (\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{r}$$

This vector is computed at the end of each iteration. The objective function is then computed at the changed parameter values at the start of the next iteration. If the objective function is not improved by the change, the Δ vector is reduced by one-half and the objective function is reevaluated. The change vector will be halved up to MAXSUBITER= times until the objective function is improved. If the objective function cannot be improved after MAXSUBITER= times, the procedure switches to the MARQUARDT method described in the next section to further improve the objective function.

For FIML, the $\mathbf{X}'\mathbf{X}$ matrix is substituted with one of three choices for approximations to the Hessian. See the section “Full Information Maximum Likelihood Estimation (FIML)” on page 1131 in this chapter.

MARQUARDT

The Marquardt-Levenberg parameter change vector is

$$\Delta = (\mathbf{X}'\mathbf{X} + \lambda \text{diag}(\mathbf{X}'\mathbf{X}))^{-1}\mathbf{X}'\mathbf{r}$$

where Δ is the change vector, and \mathbf{X} and \mathbf{r} are the same as for the Gauss-Newton method, described in the preceding section. Before the iterations start, λ is set to a small value (1E-6). At each iteration, the objective function is evaluated at the parameters changed by Δ . If the objective function is not improved, λ is increased to 10λ and the step is tried again. λ can be increased up to MAXSUBITER= times to a maximum of 1E15 (whichever comes first) until the objective function is improved. For the start of the next iteration, λ is reduced to $\max(\lambda/10, 1E-10)$.

Convergence Criteria

There are a number of measures that could be used as convergence or stopping criteria. PROC MODEL computes five convergence measures labeled R, S, PPC, RPC, and OBJECT.

When an estimation technique that iterates estimates of Σ is used (that is, IT3SLS), two convergence criteria are used. The termination values can be specified with the CONVERGE=(p,s) option in the FIT statement. If the second value, s , is not specified, it defaults to p . The criterion labeled S (described later in the section) controls the convergence of the \mathbf{S} matrix. When S is less than s , the \mathbf{S} matrix has converged. The criterion labeled R is compared to the p -value to test convergence of the parameters.

The R convergence measure cannot be computed accurately in the special case of singular residuals (when all the residuals are close to 0) or in the case of a 0 objective value. When either the trace of the \mathbf{S} matrix computed from the current residuals (trace(S)) or the objective value is less than the value of the SINGULAR= option, convergence is assumed.

The various convergence measures are explained in the following:

R is the primary convergence measure for the parameters. It measures the degree to which the residuals are orthogonal to the Jacobian columns, and it approaches 0 as the gradient of the objective function becomes small. R is defined as the square root of

$$\frac{(r'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X}(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{r})}{(r'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{r})}$$

where \mathbf{X} is the Jacobian matrix and \mathbf{r} is the residuals vector. R is similar to the relative offset orthogonality convergence criterion proposed by Bates and Watts (1981).

In the univariate case, the R measure has several equivalent interpretations:

- the cosine of the angle between the residuals vector and the column space of the Jacobian matrix. When this cosine is 0, the residuals are orthogonal to the partial derivatives of the predicted values with respect to the parameters, and the gradient of the objective function is 0.
- the square root of the R^2 for the current linear pseudo-model in the residuals
- a norm of the gradient of the objective function, where the normalizing matrix is proportional to the current estimate of the covariance of the parameter estimates. Thus, using R, convergence is judged when the gradient becomes small in this norm.
- the prospective relative change in the objective function value expected from the next GAUSS step, assuming that the current linearization of the model is a good local approximation.

In the multivariate case, R is somewhat more complicated but is designed to go to 0 as the gradient of the objective becomes small and can still be given the previous interpretations for the aggregation of the equations weighted by \mathbf{S}^{-1} .

PPC is the prospective parameter change measure. PPC measures the maximum relative change in the parameters implied by the parameter-change vector computed for the next iteration. At the k th iteration, PPC is the maximum over the parameters

$$\frac{|\theta_i^{k+1} - \theta_i^k|}{|\theta_i^k| + 10^{-6}}$$

where θ_i^k is the current value of the i th parameter and θ_i^{k+1} is the prospective value of this parameter after adding the change vector computed for the next iteration. The parameter with the maximum prospective relative change is printed with the value of PPC, unless the PPC is nearly 0.

RPC is the retrospective parameter change measure. RPC measures the maximum relative change in the parameters from the previous iteration. At the k th iteration, RPC is the maximum over i of

$$\frac{|\theta_i^k - \theta_i^{k-1}|}{|\theta_i^{k-1}| + 10^{-6}}$$

where θ_i^k is the current value of the i th parameter and θ_i^{k-1} is the previous value of this parameter. The name of the parameter with the maximum retrospective relative change is printed with the value of RPC, unless the RPC is nearly 0.

OBJECT measures the relative change in the objective function value between iterations:

$$\frac{|O^k - O^{k-1}|}{|O^{k-1}| + 10^{-6}}$$

where O^{k-1} is the value of the objective function (O^k) from the previous iteration.

S measures the relative change in the \mathbf{S} matrix. S is computed as the maximum over i, j of

$$\frac{|S_{ij}^k - S_{ij}^{k-1}|}{|S_{ij}^{k-1}| + 10^{-6}}$$

where S^{k-1} is the previous \mathbf{S} matrix. The S measure is relevant only for estimation methods that iterate the \mathbf{S} matrix.

An example of the convergence criteria output is shown in [Figure 19.25](#).

Figure 19.25 Convergence Criteria Output

Final Convergence Criteria	
R	0.000737
PPC(b)	0.003943
RPC(b)	0.00968
Object	4.784E-6
Trace(S)	0.533325
Objective Value	0.522214

The Trace(S) is the trace (the sum of the diagonal elements) of the **S** matrix computed from the current residuals. This row is labeled MSE if there is only one equation.

Troubleshooting Convergence Problems

As with any nonlinear estimation routine, there is no guarantee that the estimation will be successful for a given model and data. If the equations are linear with respect to the parameters, the parameter estimates always converge in one iteration. The methods that iterate the **S** matrix must iterate further for the **S** matrix to converge. Nonlinear models might not necessarily converge.

Convergence can be expected only with fully identified parameters, adequate data, and starting values sufficiently close to solution estimates.

Convergence and the rate of convergence might depend primarily on the choice of starting values for the estimates. This does not mean that a great deal of effort should be invested in choosing starting values. First, try the default values. If the estimation fails with these starting values, examine the model and data and rerun the estimation using reasonable starting values. It is usually not necessary that the starting values be very good, just that they not be very bad; choose values that seem plausible for the model and data.

An Example of Requiring Starting Values

Suppose you want to regress a variable *Y* on a variable *X*, assuming that the variables are related by the following nonlinear equation:

$$y = a + bx^c + \epsilon$$

In this equation, *Y* is linearly related to a power transformation of *X*. The unknown parameters are *a*, *b*, and *c*. ϵ is an unobserved random error. The following SAS statements generate simulated data. In this simulation, $a = 10$, $b = 2$, and the use of the SQRT function corresponds to $c = .5$.

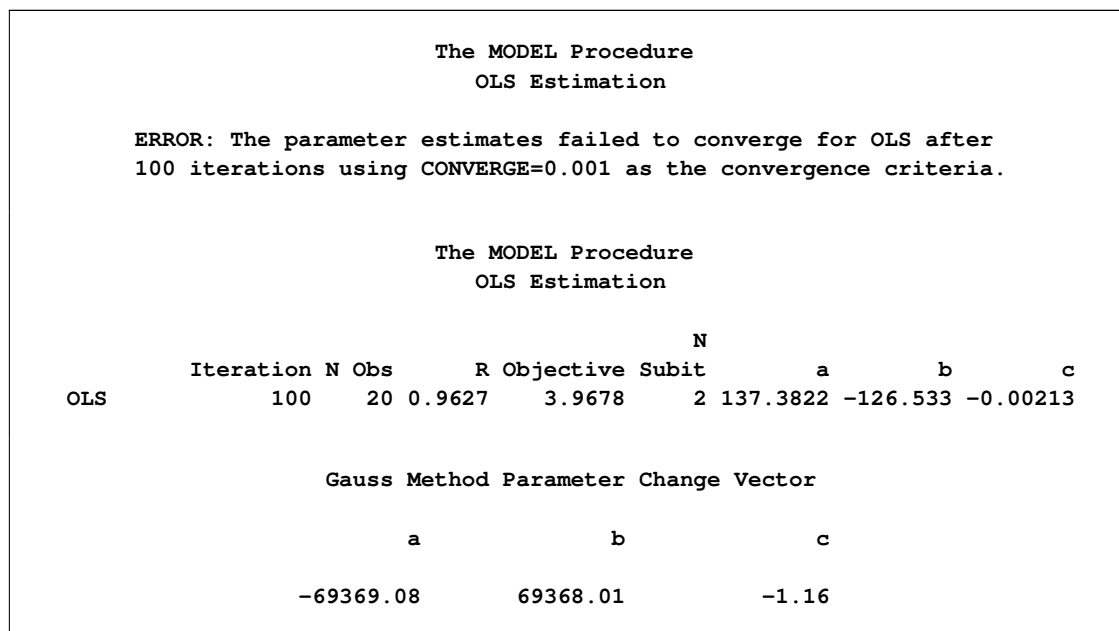

```
data test;
  do i = 1 to 20;
    x = 5 * ranuni(1234);
    y = 10 + 2 * sqrt(x) + .5 * rannor(1234);
    output;
  end;
run;
```

The following statements specify the model and give descriptive labels to the model parameters. Then the FIT statement attempts to estimate a , b , and c by using the default starting value 0.0001.

```
proc model data=test;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y;
run;
```

PROC MODEL prints model summary and estimation problem summary reports and then prints the output shown in Figure 19.26.

Figure 19.26 Diagnostics for Convergence Failure

By using the default starting values, PROC MODEL is unable to take even the first step in iterating to the solution. The change in the parameters that the Gauss-Newton method computes is very extreme and makes the objective values worse instead of better. Even when this step is shortened by a factor of a million, the objective function is still worse, and PROC MODEL is unable to estimate the model parameters.

The problem is caused by the starting value of C . Using the default starting value $C=0.0001$, the first iteration attempts to compute better values of A and B by what is, in effect, a linear regression of Y on the 10,000th root of X , which is almost the same as the constant 1. Thus the matrix that is inverted to compute the changes is nearly singular and affects the accuracy of the computed parameter changes.

This is also illustrated by the next part of the output, which displays collinearity diagnostics for the crossproducts matrix of the partial derivatives with respect to the parameters, shown in Figure 19.27.

Figure 19.27 Collinearity Diagnostics

Collinearity Diagnostics					
Number	Eigenvalue	Condition Number	-----Proportion of Variation-----		
			a	b	c
1	2.376793	1.0000	0.0000	0.0000	0.0000
2	0.623207	1.9529	0.0000	0.0000	0.0000
3	1.68475E-12	1187758	1.0000	1.0000	1.0000

This output shows that the matrix is singular and that the partials of A, B, and C with respect to the residual are collinear at the point (0.0001, 0.0001, 0.0001) in the parameter space. See the section “[Linear Dependencies](#)” on page 1150 for a full explanation of the collinearity diagnostics.

The MODEL procedure next prints the note shown in [Figure 19.28](#), which suggests that you try different starting values.

Figure 19.28 Estimation Failure Note

NOTE: The parameter estimation is abandoned. Check your model and data. If the model is correct and the input data are appropriate, try rerunning the parameter estimation using different starting values for the parameter estimates.

PROC MODEL continues as if the parameter estimates had converged.

PROC MODEL then produces the usual printout of results for the nonconverged parameter values. The estimation summary is shown in [Figure 19.29](#). The heading includes the reminder “(Not Converged)”.

The nonconverged estimation results are shown in Figure 19.30.

Figure 19.30 Nonconverged Results

The MODEL Procedure							
Nonlinear OLS Summary of Residual Errors (Not Converged)							
Equation	DF Model	DF Error	SSE	MSE	Root MSE	R-Square	Adj R-Sq
y	3	17	79.3551	4.6679	2.1605	-1.6812	-1.9966

Note that the R^2 statistic is negative. An $R^2 < 0$ results when the residual mean squared error for the model is larger than the variance of the dependent variable. Negative R^2 statistics might be produced when either the parameter estimates fail to converge correctly, as in this case, or when the correctly estimated model fits the data very poorly.

Controlling Starting Values

To fit the preceding model you must specify a better starting value for C. Avoid starting values of C that are either very large or close to 0. For starting values of A and B, you can specify values, use the default, or have PROC MODEL fit starting values for them conditional on the starting value for C.

Starting values are specified with the START= option of the FIT statement or in a PARMS statement. In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. When no starting values for the parameter estimates are specified with BY group processing, the default start value 0.0001 is used for each by group. Again, when no starting values are specified, and a model with a FIT statement is stored by the OUTMODEL=outmodel-filename option in a previous step, the outmodel-filename can be invoked in a subsequent PROC MODEL step by using the MODEL=outmodel-filename option with multiple estimation methods in the second step. In such a case,

the parameter estimates from the *outmodel-filename* are used directly as starting values for OLS, and OLS results from the second step provide starting values for the subsequent estimation method such as 2SLS or SUR, provided that NOOLS is not specified.

For example, the following statements estimate the model parameters by using the starting values A=0.0001, B=0.0001, and C=5.

```
proc model data=test;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y start=(c=5);
run;
```

Using these starting values, the estimates converge in 16 iterations. The results are shown in [Figure 19.31](#). Note that since the START= option explicitly declares parameters, the parameter C is placed first in the table.

Figure 19.31 Converged Results

The MODEL Procedure							
Nonlinear OLS Summary of Residual Errors							
Equation	DF Model	DF Error	SSE	MSE	Root MSE	R-Square	Adj R-Sq
y	3	17	5.7359	0.3374	0.5809	0.8062	0.7834
Nonlinear OLS Parameter Estimates							
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t	Label		
c	0.327079	0.2892	1.13	0.2738	Power Transformation Parameter		
a	8.384311	3.3775	2.48	0.0238	Intercept		
b	3.505391	3.4858	1.01	0.3287	Coefficient of Transformed X		

Using the STARTITER Option

PROC MODEL can compute starting values for some parameters conditional on starting values you specify for the other parameters. You supply starting values for some parameters and specify the STARTITER option on the FIT statement.

For example, the following statements set C to 1 and compute starting values for A and B by estimating these parameters conditional on the fixed value of C. With C=1, this is equivalent to computing A and B by linear regression on X. A PARMS statement is used to declare the parameters in alphabetical order. The ITPRINT option is used to print the parameter values at each iteration.

```

proc model data=test;
  parms a b c;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y start=(c=1) / starttiter itprint;
run;

```

With better starting values, the estimates converge in only eight iterations. Counting the iteration required to compute the starting values for A and B, this is seven fewer than the 16 iterations required without the STARTTITER option. The iteration history listing is shown in Figure 19.32.

Figure 19.32 ITPRINT Listing

The MODEL Procedure									
OLS Estimation									
	Iteration	N	Obs	R	Objective	Subit	a	b	c
GRID	0	20	0.9989		162.9	0	0.00010	0.00010	1.00000
GRID	1	20	0.0000		0.3464	0	10.96530	0.77007	1.00000
	Iteration	N	Obs	R	Objective	Subit	a	b	c
OLS	0	20	0.3873		0.3464	0	10.96530	0.77007	1.00000
OLS	1	20	0.3339		0.3282	2	10.75993	0.99433	0.83096
OLS	2	20	0.3244		0.3233	1	10.46894	1.31205	0.66810
OLS	3	20	0.3151		0.3197	1	10.11707	1.69149	0.54626
OLS	4	20	0.2764		0.3110	1	9.74691	2.08492	0.46615
OLS	5	20	0.2379		0.3040	0	9.06175	2.80546	0.36575
OLS	6	20	0.0612		0.2879	0	8.51825	3.36746	0.33201
OLS	7	20	0.0022		0.2868	0	8.39485	3.49449	0.32776
OLS	8	20	0.0001		0.2868	0	8.38467	3.50502	0.32711
NOTE: At OLS Iteration 8 CONVERGE=0.001 Criteria Met.									

The results produced in this case are almost the same as the results shown in Figure 19.31, except that the PARMS statement causes the parameter estimates table to be ordered A, B, C instead of C, A, B. They are not exactly the same because the different starting values caused the iterations to converge at a slightly different place. This effect is controlled by changing the convergence criterion with the CONVERGE= option.

By default, the STARTTITER option performs one iteration to find starting values for the parameters that are not given values. In this case, the model is linear in A and B, so only one iteration is needed. If A or B were nonlinear, you could specify more than one “starting values” iteration by specifying a number for the STARTTITER= option.

Finding Starting Values by Grid Search

PROC MODEL can try various combinations of parameter values and use the combination that produces the smallest objective function value as starting values. (For OLS the objective function is the residual mean square.) This is known as a preliminary *grid search*. You can combine the STARTITER option with a grid search.

For example, the following statements try five different starting values for C: 1, 0.7, 0.5, 0.3, and 0. For each value of C, values for A and B are estimated. The combination of A, B, and C values that produce the smallest residual mean square is then used to start the iterative process.

```
proc model data=test;
  parms a b c;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y start=(c=1 .7 .5 .3 0) / startiter itprint;
run;
```

The iteration history listing is shown in Figure 19.33. Using the best starting values found by the grid search, the OLS estimation only requires two iterations. However, since the grid search required nine iterations, the total iterations in this case is 11.

Figure 19.33 ITPRINT Listing

The MODEL Procedure									
OLS Estimation									
	Iteration	N	Obs	R	Objective	Subit	a	b	c

GRID	1	20	0.0000		0.2869	0	8.04397	3.85767	0.30000
GRID	0	20	0.5518		2.1277	0	8.04397	3.85767	0.00000
GRID	1	20	0.0000		1.4799	0	8.04397	4.66255	0.00000
	Iteration	N	Obs	R	Objective	Subit	a	b	c
OLS	0	20	0.0189		0.2869	0	8.04397	3.85767	0.30000
OLS	1	20	0.0158		0.2869	0	8.35023	3.54145	0.32233
OLS	2	20	0.0006		0.2868	0	8.37468	3.51540	0.32622
NOTE: At OLS Iteration 2 CONVERGE=0.001 Criteria Met.									

Because no initial values for A or B were provided in the PARAMETERS statement or were read in with a PARMSDATA= or ESTDATA= option, A and B were given the default value of 0.0001 for the first iteration.

At the second grid point, $C=5$, the values of A and B obtained from the previous iterations are used for the initial iteration. If initial values are provided for parameters, the parameters start at those initial values at each grid point.

Guessing Starting Values from the Logic of the Model

Example 19.1, which uses a logistic growth curve model of the U.S. population, illustrates the need for reasonable starting values. This model can be written

$$pop = \frac{a}{1 + \exp(b - c(t - 1790))}$$

where t is time in years. The model is estimated by using decennial census data of the U.S. population in millions. If this simple but highly nonlinear model is estimated by using the default starting values, the estimation fails to converge.

To find reasonable starting values, first consider the meaning of a and c . Taking the limit as time increases, a is the limiting or maximum possible population. So, as a starting value for a , several times the most recent population known can be used—for example, one billion (1000 million).

Dividing the time derivative by the function to find the growth rate and taking the limit as t moves into the past, you can determine that c is the initial growth rate. You can examine the data and compute an estimate of the growth rate for the first few decades, or you can pick a number that sounds like a plausible population growth rate figure, such as 2%.

To find a starting value for b , let t equal the base year used, 1790, which causes c to drop out of the formula for that year, and then solve for the value of b that is consistent with the known population in 1790 and with the starting value of a . This yields $b = \ln(a/3.9 - 1)$ or about 5.5, where a is 1000 and 3.9 is roughly the population for 1790 given in the data. The estimates converge using these starting values.

Convergence Problems

When estimating nonlinear models, you might encounter some of the following convergence problems.

Unable to Improve

The optimization algorithm might be unable to find a step that improves the objective function. If this happens in the Gauss-Newton method, the step size is halved to find a change vector for which the objective improves. In the Marquardt method, λ is increased to find a change vector for which the objective improves. If, after MAXSUBITER= step-size halvings or increases in λ , the change vector still does not produce a better objective value, the iterations are stopped and an error message is printed.

Failure of the algorithm to improve the objective value can be caused by a CONVERGE= value that is too small. Look at the convergence measures reported at the point of failure. If the estimates appear to be approximately converged, you can accept the NOT CONVERGED results reported, or you can try rerunning the FIT task with a larger CONVERGE= value.

If the procedure fails to converge because it is unable to find a change vector that improves the objective value, check your model and data to ensure that all parameters are identified and data values are reasonably scaled. Then, rerun the model with different starting values. Also, consider using the Marquardt method if the Gauss-Newton method fails; the Gauss-Newton method can get into trouble if the Jacobian matrix is nearly singular or ill-conditioned. Keep in mind that a nonlinear model may be well-identified and well-conditioned for parameter values close to the solution values but unidentified or numerically ill-conditioned for other parameter values. The choice of starting values can make a big difference.

Nonconvergence

The estimates might diverge into areas where the program overflows or the estimates might go into areas where function values are illegal or too badly scaled for accurate calculation. The estimation might also take steps that are too small or that make only marginal improvement in the objective function and thus fail to converge within the iteration limit.

When the estimates fail to converge, collinearity diagnostics for the Jacobian crossproducts matrix are printed if there are 20 or fewer parameters estimated. See the section “[Linear Dependencies](#)” on page 1150 for an explanation of these diagnostics.

Inadequate Convergence Criterion

If convergence is obtained, the resulting estimates approximate only a minimum point of the objective function. The statistical validity of the results is based on the exact minimization of the objective function, and for nonlinear models the quality of the results depends on the accuracy of the approximation of the minimum. This is controlled by the convergence criterion used.

There are many nonlinear functions for which the objective function is quite flat in a large region around the minimum point so that many quite different parameter vectors might satisfy a weak convergence criterion. By using different starting values, different convergence criteria, or different minimization methods, you can produce very different estimates for such models.

You can guard against this by running the estimation with different starting values and different convergence criteria and checking that the estimates produced are essentially the same. If they are not, use a smaller CONVERGE= value.

Local Minimum

You might have converged to a local minimum rather than a global one. This problem is difficult to detect because the procedure appears to have succeeded. You can guard against this by running the estimation with different starting values or with a different minimization technique. The START= option can be used to automatically perform a grid search to aid in the search for a global minimum.

Discontinuities

The computational methods assume that the model is a continuous and smooth function of the parameters. If this is not the case, the methods might not work.

If the model equations or their derivatives contain discontinuities, the estimation usually succeeds, provided that the final parameter estimates lie in a continuous interval and that the iterations do not produce parameter values at points of discontinuity or parameter values that try to cross asymptotes.

One common case of discontinuities causing estimation failure is that of an asymptotic discontinuity between the final estimates and the initial values. For example, consider the following model, which is basically linear but is written with one parameter in reciprocal form:

$$y = a + b * x1 + x2 / c;$$

By placing the parameter C in the denominator, a singularity is introduced into the parameter space at C=0. This is not necessarily a problem, but if the correct estimate of C is negative while the starting value is positive (or vice versa), the asymptotic discontinuity at 0 will lie between the estimate and the starting value. This means that the iterations have to pass through the singularity to get to the correct estimates. The situation is shown in [Figure 19.34](#).

Figure 19.34 Asymptotic Discontinuity

Because of the incorrect sign of the starting value, the C estimate goes off towards positive infinity in a vain effort to get past the asymptote and onto the correct arm of the hyperbola. As the computer is required to work with ever closer approximations to infinity, the numerical calculations break down and an “objective function was not improved” convergence failure message is printed. At this point, the iterations terminate with an extremely large positive value for C . When the sign of the starting value for C is changed, the estimates converge quickly to the correct values.

Linear Dependencies

In some cases, the Jacobian matrix might not be of full rank; parameters might not be fully identified for the current parameter values with the current data. When linear dependencies occur among the derivatives of the model, some parameters appear with a standard error of 0 and with the word **BIASED** printed in place of the t statistic. When this happens, collinearity diagnostics for the Jacobian crossproducts matrix are printed if the **DETAILS** option is specified and there are twenty or fewer parameters estimated. Collinearity diagnostics are also printed out automatically when a minimization method fails, or when the **COLLIN** option is specified.

For each parameter, the proportion of the variance of the estimate accounted for by each *principal component* is printed. The principal components are constructed from the eigenvalues and eigenvectors of the correlation matrix (scaled covariance matrix). When collinearity exists, a principal component is associated with proportion of the variance of more than one parameter. The numbers reported are proportions so they remain between 0 and 1. If two or more parameters have large proportion values associated with the same principal component, then two problems can occur: the computation of the parameter estimates are slow or nonconvergent; and the parameter estimates have inflated variances (Belsley, Kuh, and Welsch 1980, pp. 105–117).

For example, the following cubic model is fit to a quadratic data set:

```
proc model data=test3;
  exogenous x1;
  parms b1 a1 c1 ;
  y1 = a1 * x1 + b1 * x1 * x1 + c1 * x1 * x1 *x1;
  fit y1 / collin;
run;
```

The collinearity diagnostics are shown in [Figure 19.35](#).

Figure 19.35 Collinearity Diagnostics

The MODEL Procedure					
Collinearity Diagnostics					
Number	Eigenvalue	Condition Number	-----Proportion of Variation-----		
			b1	a1	c1
1	2.942920	1.0000	0.0001	0.0004	0.0002
2	0.056638	7.2084	0.0001	0.0357	0.0148
3	0.000442	81.5801	0.9999	0.9639	0.9850

Notice that the proportions associated with the smallest eigenvalue are almost 1. For this model, removing any of the parameters decreases the variances of the remaining parameters.

In many models, the collinearity might not be clear cut. Collinearity is not necessarily something you remove. A model might need to be reformulated to remove the redundant parameterization, or the limitations on the estimability of the model can be accepted. The GINV=G4 option can be helpful to avoid problems with convergence for models containing collinearities.

Collinearity diagnostics are also useful when an estimation does not converge. The diagnostics provide insight into the numerical problems and can suggest which parameters need better starting values. These diagnostics are based on the approach of Belsley, Kuh, and Welsch (1980).

Iteration History

The options ITPRINT, ITDETAILS, XPX, I, and ITALL specify a detailed listing of each iteration of the minimization process.

ITPRINT Option

The ITPRINT information is selected whenever any iteration information is requested.

The following information is displayed for each iteration:

N	is the number of usable observations.
Objective	is the corrected objective function value.
Trace(S)	is the trace of the S matrix.
subit	is the number of subiterations required to find a λ or a damping factor that reduces the objective function.
R	is the R convergence measure.

The estimates for the parameters at each iteration are also printed.

ITDETAILS Option

The additional values printed for the ITDETAILS option are:

Theta	is the angle in degrees between Δ , the parameter change vector, and the negative gradient of the objective function.
Phi	is the directional derivative of the objective function in the Δ direction scaled by the objective function.
Stepsize	is the value of the damping factor used to reduce Δ if the Gauss-Newton method is used.
Lambda	is the value of λ if the Marquardt method is used.
Rank(XPX)	is the rank of the $X'X$ matrix (output if the projected Jacobian crossproducts matrix is singular).

The definitions of PPC and R are explained in the section “[Convergence Criteria](#)” on page 1139. When the values of PPC are large, the parameter associated with the criteria is displayed in parentheses after the value.

XPX and I Options

The XPX and the I options select the printing of the augmented $X'X$ matrix and the augmented $X'X$ matrix after a *sweep* operation (Goodnight 1979) has been performed on it. An example of the output from the following statements is shown in [Figure 19.36](#).

```
proc model data=test2;
  y1 = a1 * x2 * x2 - exp( d1*x1);
  y2 = a2 * x1 * x1 + b2 * exp( d2*x2);
  fit y1 y2 / itall XPX I ;
run;
```

Figure 19.36 XPX and I Options Output

The MODEL Procedure						
OLS Estimation						
Cross Products for System At OLS Iteration 0						
	a1	d1	a2	b2	d2	Residual
a1	1839468	-33818.35	0.0	0.00	0.000000	3879959
d1	-33818	1276.45	0.0	0.00	0.000000	-76928
a2	0	0.00	42925.0	1275.15	0.154739	470686
b2	0	0.00	1275.2	50.01	0.003867	16055
d2	0	0.00	0.2	0.00	0.000064	2
Residual	3879959	-76928.14	470686.3	16055.07	2.329718	24576144
XPX Inverse for System At OLS Iteration 0						
	a1	d1	a2	b2	d2	Residual
a1	0.000001	0.000028	0.000000	0.0000	0.00	2
d1	0.000028	0.001527	0.000000	0.0000	0.00	-9
a2	0.000000	0.000000	0.000097	-0.0025	-0.08	6
b2	0.000000	0.000000	-0.002455	0.0825	0.95	172
d2	0.000000	0.000000	-0.084915	0.9476	15746.71	11931
Residual	1.952150	-8.546875	5.823969	171.6234	11930.89	10819902

The first matrix, labeled “Cross Products,” for OLS estimation is

$$\begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{r} \\ \mathbf{r}'\mathbf{X} & \mathbf{r}'\mathbf{r} \end{bmatrix}$$

The column labeled Residual in the output is the vector $\mathbf{X}'\mathbf{r}$, which is the gradient of the objective function. The diagonal scalar value $\mathbf{r}'\mathbf{r}$ is the objective function uncorrected for degrees of freedom. The second matrix, labeled “XPX Inverse,” is created through a sweep operation on the augmented $\mathbf{X}'\mathbf{X}$ matrix to get:

$$\begin{bmatrix} (\mathbf{X}'\mathbf{X})^{-1} & (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{r} \\ (\mathbf{X}'\mathbf{r})'(\mathbf{X}'\mathbf{X})^{-1} & \mathbf{r}'\mathbf{r} - (\mathbf{X}'\mathbf{r})'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{r} \end{bmatrix}$$

Note that the residual column is the change vector used to update the parameter estimates at each iteration. The corner scalar element is used to compute the R convergence criteria.

ITALL Option

The ITALL option, in addition to causing the output of all of the preceding options, outputs the \mathbf{S} matrix, the inverse of the \mathbf{S} matrix, the CROSS matrix, and the swept CROSS matrix. An example of a portion of the CROSS matrix for the preceding example is shown in [Figure 19.37](#).

Computer Resource Requirements

If you are estimating large systems, you need to be aware of how PROC MODEL uses computer resources (such as memory and the CPU) so they can be used most efficiently.

Saving Time with Large Data Sets

If your input data set has many observations, the FIT statement performs a large number of model program executions. A pass through the data is made at least once for each iteration and the model program is executed once for each observation in each pass. If you refine the starting estimates by using a smaller data set, the final estimation with the full data set might require fewer iterations.

For example, you could use

```
proc model;
  /* Model goes here */
  fit / data=a(obs=25);
  fit / data=a;
```

where OBS=25 selects the first 25 observations in A. The second FIT statement produces the final estimates using the full data set and starting values from the first run.

Fitting the Model in Sections to Save Space and Time

If you have a very large model (with several hundred parameters, for example), the procedure uses considerable space and time. You might be able to save resources by breaking the estimation process into several steps and estimating the parameters in subsets.

You can use the FIT statement to select for estimation only the parameters for selected equations. Do not break the estimation into too many small steps; the total computer time required is minimized by compromising between the number of FIT statements that are executed and the size of the crossproducts matrices that must be processed.

When the parameters are estimated for selected equations, the entire model program must be executed even though only a part of the model program might be needed to compute the residuals for the equations selected for estimation. If the model itself can be broken into sections for estimation (and later combined for simulation and forecasting), then more resources can be saved.

For example, to estimate the following four equation model in two steps, you could use

```
proc model data=a outmodel=part1;
  parms a0-a2 b0-b2 c0-c3 d0-d3;
  y1 = a0 + a1*y2 + a2*x1;
  y2 = b0 + b1*y1 + b2*x2;
  y3 = c0 + c1*y1 + c2*y4 + c3*x3;
  y4 = d0 + d1*y1 + d2*y3 + d3*x4;
  fit y1 y2;
  fit y3 y4;
  fit y1 y2 y3 y4;
run;
```

You should try estimating the model in pieces to save time only if there are more than 14 parameters; the preceding example takes more time, not less, and the difference in memory required is trivial.

Memory Requirements for Parameter Estimation

PROC MODEL is a large program, and it requires much memory. Memory is also required for the SAS System, various data areas, the model program and associated tables and data vectors, and a few crossproducts matrices. For most models, the memory required for PROC MODEL itself is much larger than that required for the model program, and the memory required for the model program is larger than that required for the crossproducts matrices.

The number of bytes needed for two crossproducts matrices, four **S** matrices, and three parameter covariance matrices is

$$8 \times (2 + k + m + g)^2 + 16 \times g^2 + 12 \times (p + 1)^2$$

plus lower-order terms, where m is the number of unique nonzero derivatives of each residual with respect to each parameter, g is the number of equations, k is the number of instruments, and p is the number of parameters. This formula is for the memory required for 3SLS. If you are using OLS, a reasonable estimate of the memory required for large problems (greater than 100 parameters) is to divide the value obtained from the formula in half.

Consider the following model program.

```
proc model data=test2 details;
  exogenous x1 x2;
  parms b1 100 a1 a2 b2 2.5 c2 55;
  y1 = a1 * y2 + b1 * x1 * x1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2;
  fit y1 y2 / n3sls memoryuse;
  inst b1 b2 c2 x1 ;
run;
```

The DETAILS option prints the storage requirements information shown in [Figure 19.38](#).

Figure 19.38 Storage Requirements Information

The MODEL Procedure	
Storage Requirements for this Problem	
Order of XPX Matrix	6
Order of S Matrix	2
Order of Cross Matrix	13
Total Nonzero Derivatives	5
Distinct Variable Derivatives	5
Size of Cross matrix	728

The matrix $X'X$ augmented by the residual vector is called the XPX matrix in the output, and it has the size $m + 1$. The order of the S matrix, 2 for this example, is the value of g . The CROSS matrix is made up of the k unique instruments, a constant column that represents the intercept terms, followed by the m unique Jacobian variables plus a constant column that represents the parameters with constant derivatives, followed by the g residuals.

The size of two CROSS matrices in bytes is

$$8 \times (2 + k + m + g)^2 + 2 + k + m + g$$

Note that the CROSS matrix is symmetric, so only the diagonal and the upper triangular part of the matrix is stored. For examples of the CROSS and XPX matrices see the section “[Iteration History](#)” on page 1151.

The MEMORYUSE Option

The MEMORYUSE option in the FIT, SOLVE, MODEL, or RESET statement can be used to request a comprehensive memory usage summary.

[Figure 19.39](#) shows an example of the output produced by the MEMORYUSE option.

Figure 19.39 MEMORYUSE Option Output for FIT Task

Memory Usage Summary (in bytes)	
Symbols	15652
Strings	2593
Lists	2412
Arrays	2208
Statements	2448
Opcodes	1840
Parsing	6180
Executable	12717
Block option	0
Cross reference	0
Flow analysis	336
Derivatives	28640
Data vector	368
Cross matrix	1480
X'X matrix	590
S matrix	144
GMM memory	0
Jacobian	0
Work vectors	702
Overhead	14222

Total	92532

Definitions of the memory components follow:

symbols	memory used to store information about variables in the model
strings	memory used to store the variable names and labels
lists	space used to hold lists of variables
arrays	memory used by ARRAY statements
statements	memory used for the list of programming statements in the model
opcodes	memory used to store the code compiled to evaluate the expression in the model program
parsing	memory used in parsing the SAS statements
executable	the compiled model program size
block option	memory used by the BLOCK option
cross ref.	memory used by the XREF option
flow analysis	memory used to compute the interdependencies of the variables
derivatives	memory used to compute and store the analytical derivatives
data vector	memory used for the program data vector
cross matrix	memory used for one or more copies of the CROSS matrix
X'X matrix	memory used for one or more copies of the X'X matrix
S matrix	memory used for the covariance matrix
GMM memory	additional memory used for the GMM and ITGMM methods
Jacobian	memory used for the Jacobian matrix for SOLVE and FIML
work vectors	memory used for miscellaneous work vectors
overhead	other miscellaneous memory

Testing for Normality

The NORMAL option in the FIT statement performs multivariate and univariate tests of normality.

The three multivariate tests provided are Mardia's skewness test and kurtosis test (Mardia 1970) and the Henze-Zirkler $T_{n,\beta}$ test (Henze and Zirkler 1990). The two univariate tests provided are the Shapiro-Wilk W test and the Kolmogorov-Smirnov test. (For details on the univariate tests, refer to "Goodness-of-Fit Tests" section in "The UNIVARIATE Procedure" chapter in the *Base SAS Procedures Guide*.) The null hypothesis for all these tests is that the residuals are normally distributed.

For a random sample X_1, \dots, X_n , $X_i \in \mathbb{R}^d$, where d is the dimension of X_i and n is the number of observations, a measure of multivariate skewness is

$$b_{1,d} = \frac{1}{n^2} \sum_{i=1}^n \sum_{j=1}^n [(X_i - \mu)' \mathbf{S}^{-1} (X_j - \mu)]^3$$

where \mathbf{S} is the sample covariance matrix of \mathbf{X} . For weighted regression, both \mathbf{S} and $(X_i - \mu)$ are computed by using the weights supplied by the WEIGHT statement or the _WEIGHT_ variable.

Mardia showed that under the null hypothesis $\frac{n}{6} b_{1,d}$ is asymptotically distributed as $\chi^2(d(d+1)(d+2)/6)$. For small samples, Mardia's skewness test statistic is calculated with a small sample correction formula, given by $\frac{nk}{6} b_{1,d}$ where the correction factor k is given by $k = (d+1)(n+1)(n+3)/n(((n+1)(d+1)) - 6)$. Mardia's skewness test statistic in PROC MODEL uses this small sample corrected formula.

A measure of multivariate kurtosis is given by

$$b_{2,d} = \frac{1}{n} \sum_{i=1}^n [(X_i - \mu)' \mathbf{S}^{-1} (X_i - \mu)]^2$$

Mardia showed that under the null hypothesis, $b_{2,d}$ is asymptotically normally distributed with mean $d(d+2)$ and variance $8d(d+2)/n$.

The Henze-Zirkler test is based on a nonnegative functional $D(.,.)$ that measures the distance between two distribution functions and has the property that

$$D(N_d(0, I_d), Q) = 0$$

if and only if

$$Q = N_d(0, I_d)$$

where $N_d(\mu, \Sigma_d)$ is a d -dimensional normal distribution.

The distance measure $D(.,.)$ can be written as

$$D_\beta(P, Q) = \int_{\mathbb{R}^d} |\hat{P}(t) - \hat{Q}(t)|^2 \varphi_\beta(t) dt$$

where $\hat{P}(t)$ and $\hat{Q}(t)$ are the Fourier transforms of P and Q , and $\varphi_\beta(t)$ is a weight or a kernel function. The density of the normal distribution $N_d(0, \beta^2 I_d)$ is used as $\varphi_\beta(t)$

$$\varphi_\beta(t) = (2\pi\beta^2)^{-\frac{d}{2}} \exp\left(-\frac{|t|^2}{2\beta^2}\right), t \in \mathbb{R}^d$$

where $|t| = (t' t)^{0.5}$.

The parameter β depends on n as

$$\beta_d(n) = \frac{1}{\sqrt{2}} \left(\frac{2d+1}{4} \right)^{1/(d+4)} n^{1/(d+4)}$$

The test statistic computed is called $T_\beta(d)$ and is approximately distributed as a lognormal. The lognormal distribution is used to compute the null hypothesis probability.

$$T_\beta(d) = \frac{1}{n} \sum_{j=1}^n \sum_{k=1}^n \exp\left(-\frac{\beta^2}{2} |Y_j - Y_k|^2\right) - 2(1 + \beta^2)^{-d/2} \sum_{j=1}^n \exp\left(-\frac{\beta^2}{2(1 + \beta^2)} |Y_j|^2\right) + n(1 + 2\beta^2)^{-d/2}$$

where

$$|Y_j - Y_k|^2 = (X_j - X_k)' \mathbf{S}^{-1} (X_j - X_k)$$

$$|Y_j|^2 = (X_j - \bar{X})' \mathbf{S}^{-1} (X_j - \bar{X})$$

Monte Carlo simulations suggest that $T_\beta(d)$ has good power against distributions with heavy tails.

The Shapiro-Wilk W test is computed only when the number of observations (n) is less than 2000 while computation of the Kolmogorov-Smirnov test statistic requires at least 2000 observations.

The following is an example of the output produced by the NORMAL option.

```
proc model data=test2;
  y1 = a1 * x2 * x2 - exp( d1*x1);
  y2 = a2 * x1 * x1 + b2 * exp( d2*x2);
  fit y1 y2 / normal ;
run;
```

Figure 19.40 Normality Test Output

The MODEL Procedure			
Normality Test			
Equation	Test Statistic	Value	Prob
y1	Shapiro-Wilk W	0.34	<.0001
y2	Shapiro-Wilk W	0.82	<.0001
System	Mardia Skewness	286.4	<.0001
	Mardia Kurtosis	31.28	<.0001
	Henze-Zirkler T	6.65	<.0001

Heteroscedasticity

One of the key assumptions of regression is that the variance of the errors is constant across observations. If the errors have constant variance, the errors are called *homoscedastic*. Typically, residuals are plotted to assess this assumption. Standard estimation methods are inefficient when the errors are *heteroscedastic* or have nonconstant variance.

Heteroscedasticity Tests

The MODEL procedure provides two tests for heteroscedasticity of the errors: White's test and the modified Breusch-Pagan test.

Both White's test and the Breusch-Pagan are based on the residuals of the fitted model. For systems of equations, these tests are computed separately for the residuals of each equation.

The residuals of an estimation are used to investigate the heteroscedasticity of the true disturbances.

The WHITE option tests the null hypothesis

$$H_0 : \sigma_i^2 = \sigma^2 \text{ for all } i$$

White's test is general because it makes no assumptions about the form of the heteroscedasticity (White 1980). Because of its generality, White's test might identify specification errors other than heteroscedasticity (Thursby 1982). Thus, White's test might be significant when the errors are homoscedastic but the model is misspecified in other ways.

White's test is equivalent to obtaining the error sum of squares for the regression of squared residuals on a constant and all the unique variables in $\mathbf{J} \otimes \mathbf{J}$, where the matrix \mathbf{J} is composed of the partial derivatives of the equation residual with respect to the estimated parameters. White's test statistic W is computed as follows:

$$W = nR^2$$

where R^2 is the correlation coefficient obtained from the above regression. The statistic is asymptotically distributed as chi-squared with $P-1$ degrees of freedom, where P is the number of regressors in the regression, including the constant and n is the total number of observations. In the example given below, the regressors are constant, income, income*income, income*income*income, and income*income*income*income. income*income occurs twice and one is dropped. Hence, $P=5$ with degrees of freedom, $P-1=4$.

Note that White's test in the MODEL procedure is different than White's test in the REG procedure requested by the SPEC option. The SPEC option produces the test from Theorem 2 on page 823 of White (1980). The WHITE option, on the other hand, produces the statistic discussed in Greene (1993).

The null hypothesis for the modified Breusch-Pagan test is homoscedasticity. The alternate hypothesis is that the error variance varies with a set of regressors, which are listed in the BREUSCH= option.

Define the matrix \mathbf{Z} to be composed of the values of the variables listed in the BREUSCH= option, such that $z_{i,j}$ is the value of the j th variable in the BREUSCH= option for the i th observation. The null hypothesis of the Breusch-Pagan test is

$$\sigma_i^2 = \sigma^2(\alpha_0 + \alpha' \mathbf{z}_i) \qquad H_0 : \alpha = \mathbf{0}$$

where σ_i^2 is the error variance for the i th observation and α_0 and α are regression coefficients.

The test statistic for the Breusch-Pagan test is

$$bp = \frac{1}{v} (\mathbf{u} - \bar{u}\mathbf{i})' \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \mathbf{Z}' (\mathbf{u} - \bar{u}\mathbf{i})$$

where $\mathbf{u} = (e_1^2, e_2^2, \dots, e_n^2)$, \mathbf{i} is a $n \times 1$ vector of ones, and

$$v = \frac{1}{n} \sum_{i=1}^n (e_i^2 - \frac{\mathbf{e}'\mathbf{e}}{n})^2$$

This is a modified version of the Breusch-Pagan test, which is less sensitive to the assumption of normality than the original test (Greene 1993, p. 395).

The statements in the following example produce the output in [Figure 19.41](#):

```
proc model data=schools;
    parms const inc inc2;

    exp = const + inc * income + inc2 * income * income;
    incsq = income * income;

    fit exp / white breusch=(1 income incsq);
run;
```

Figure 19.41 Output for Heteroscedasticity Tests

The MODEL Procedure					
Heteroscedasticity Test					
Equation	Test	Statistic	DF	Pr > ChiSq	Variables
exp	White's Test	21.16	4	0.0003	Cross of all vars
	Breusch-Pagan	15.83	2	0.0004	1, income, incsq

Correcting for Heteroscedasticity

There are two methods for improving the efficiency of the parameter estimation in the presence of heteroscedastic errors. If the error variance relationships are known, weighted regression can be used or an error model can be estimated. For details about error model estimation, see the section “[Error Covariance Structure Specification](#)” on page 1170. If the error variance relationship is unknown, GMM estimation can be used.

Weighted Regression

The WEIGHT statement can be used to correct for the heteroscedasticity. Consider the following model, which has a heteroscedastic error term:

$$y_t = 250(e^{-0.2t} - e^{-0.8t}) + \sqrt{(9/t)}\epsilon_t$$

The data for this model is generated with the following SAS statements.

```

data test;
  do t=1 to 25;
    y = 250 * (exp( -0.2 * t ) - exp( -0.8 * t )) +
        sqrt( 9 / t ) * rannor(1);
    output;
  end;
run;

```

If this model is estimated with OLS, as shown in the following statements, the estimates shown in Figure 19.42 are obtained for the parameters.

```

proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  fit y;
run;

```

Figure 19.42 Unweighted OLS Estimates

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
b1	0.200977	0.00101	198.60	<.0001
b2	0.826236	0.00853	96.82	<.0001

If both sides of the model equation are multiplied by \sqrt{t} , the model has a homoscedastic error term. This multiplication or weighting is done through the WEIGHT statement. The WEIGHT statement variable operates on the squared residuals as

$$\epsilon'_t \epsilon_t = \text{weight} \times \mathbf{q}'_t \mathbf{q}_t$$

so that the WEIGHT statement variable represents the square of the model multiplier. The following PROC MODEL statements corrects the heteroscedasticity with a WEIGHT statement:

```

proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  fit y;
  weight t;
run;

```

Note that the WEIGHT statement follows the FIT statement. The weighted estimates are shown in Figure 19.43.

Figure 19.43 Weighted OLS Estimates

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
b1	0.200503	0.000844	237.53	<.0001
b2	0.816701	0.0139	58.71	<.0001

The weighted OLS estimates are identical to the output produced by the following PROC MODEL example:

```
proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  _weight_ = t;
  fit y;
run;
```

If the WEIGHT statement is used in conjunction with the `_WEIGHT_` variable, the two values are multiplied together to obtain the weight used.

The WEIGHT statement and the `_WEIGHT_` variable operate on all the residuals in a system of equations. If a subset of the equations needs to be weighted, the residuals for each equation can be modified through the `RESID.` variable for each equation. The following example demonstrates the use of the `RESID.` variable to make a homoscedastic error term:

```
proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  resid.y = resid.y * sqrt(t);
  fit y;
run;
```

These statements produce estimates of the parameters and standard errors that are identical to the weighted OLS estimates. The reassignment of the `RESID.Y` variable must be done after `Y` is assigned; otherwise it would have no effect. Also, note that the residual (`RESID.Y`) is multiplied by \sqrt{t} . Here the multiplier is acting on the residual before it is squared.

GMM Estimation

If the form of the heteroscedasticity is unknown, generalized method of moments estimation (GMM) can be used. The following PROC MODEL statements use GMM to estimate the example model used in the preceding section:

```

proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  fit y / gmm;
  instruments b1 b2;
run;

```

GMM is an instrumental method, so instrument variables must be provided.

GMM estimation generates estimates for the parameters shown in Figure 19.44.

Figure 19.44 GMM Estimation for Heteroscedasticity

The MODEL Procedure				
Nonlinear GMM Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
b1	0.200487	0.000800	250.69	<.0001
b2	0.822148	0.0148	55.39	<.0001

Heteroscedasticity-Consistent Covariance Matrix Estimation

Homoscedasticity is required for ordinary least squares regression estimates to be efficient. A nonconstant error variance, heteroscedasticity, causes the OLS estimates to be inefficient, and the usual OLS covariance matrix, $\hat{\Sigma}$, is generally invalid:

$$\hat{\Sigma} = \sigma^2(\mathbf{X}'\mathbf{X})^{-1}$$

When the variance of the errors of a classical linear model

$$Y = \mathbf{X}\beta + \epsilon$$

is not constant across observations (heteroscedastic), so that $\sigma_i^2 \neq \sigma_j^2$ for some $j > 1$, the OLS estimator

$$\hat{\beta}_{OLS} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y}$$

is unbiased but it is inefficient. Models that take into account the changing variance can make more efficient use of the data. When the variances, σ_i^2 , are known, generalized least squares (GLS) can be used and the estimator

$$\hat{\beta}_{GLS} = (\mathbf{X}'\mathbf{\Omega}\mathbf{X})^{-1}\mathbf{X}'\mathbf{\Omega}^{-1}\mathbf{Y}$$

where

$$\mathbf{\Omega} = \begin{bmatrix} \sigma_1^2 & 0 & 0 & 0 \\ 0 & \sigma_2^2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \sigma_T^2 \end{bmatrix}$$

is unbiased and efficient. However, GLS is unavailable when the variances, σ_t^2 , are unknown.

To solve this problem White (1980) proposed a heteroscedastic consistent-covariance matrix estimator (HCCME)

$$\hat{\Sigma} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\hat{\Omega}\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}$$

that is consistent as well as unbiased, where

$$\hat{\Omega}_0 = \begin{bmatrix} \epsilon_1^2 & 0 & 0 & 0 \\ 0 & \epsilon_2^2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \epsilon_T^2 \end{bmatrix}$$

and $\epsilon_t = Y_t - \mathbf{X}_t\beta_{OLS}$.

This estimator is considered somewhat unreliable in finite samples. Therefore, Davidson and MacKinnon (1993) propose three different modifications to estimating $\hat{\Omega}$. The first solution is to simply multiply ϵ_t^2 by $\frac{n}{n-df}$, where n is the number of observations and df is the number of explanatory variables, so that

$$\hat{\Omega}_1 = \begin{bmatrix} \frac{n}{n-df} \epsilon_1^2 & 0 & 0 & 0 \\ 0 & \frac{n}{n-df} \epsilon_2^2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \frac{n}{n-df} \epsilon_n^2 \end{bmatrix}$$

The second solution is to define

$$\hat{\Omega}_2 = \begin{bmatrix} \frac{\epsilon_1^2}{1-\hat{h}_1} & 0 & 0 & 0 \\ 0 & \frac{\epsilon_2^2}{1-\hat{h}_2} & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \frac{\epsilon_n^2}{1-\hat{h}_n} \end{bmatrix}$$

where $\hat{h}_t = \mathbf{X}_t(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}_t'$.

The third solution, called the “jackknife,” is to define

$$\hat{\Omega}_3 = \begin{bmatrix} \frac{\epsilon_1^2}{(1-\hat{h}_1)^2} & 0 & 0 & 0 \\ 0 & \frac{\epsilon_2^2}{(1-\hat{h}_2)^2} & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \frac{\epsilon_n^2}{(1-\hat{h}_n)^2} \end{bmatrix}$$

MacKinnon and White (1985) investigated these three modified HCCMEs, including the original HCCME, based on finite-sample performance of pseudo- t statistics. The original HCCME performed the worst. The first modification performed better. The second modification performed even better than the first, and the third modification performed the best. They concluded that the original HCCME should never be used in finite sample estimation, and that the second and third modifications should be used over the first modification if the diagonals of $\hat{\Omega}$ are available.

Seemingly Unrelated Regression HCCME

Extending the discussion to systems of g equations, the HCCME for SUR estimation is

$$(\tilde{\mathbf{X}}'\tilde{\mathbf{X}})^{-1}\tilde{\mathbf{X}}'\hat{\mathbf{\Omega}}\tilde{\mathbf{X}}(\tilde{\mathbf{X}}'\tilde{\mathbf{X}})^{-1}$$

where $\tilde{\mathbf{X}}$ is a $n \times g \times k$ matrix with the first g rows representing the first observation, the next g rows representing the second observation, and so on. $\hat{\mathbf{\Omega}}$ is now a $n \times g \times n \times g$ block diagonal matrix with typical block $g \times g$

$$\hat{\mathbf{\Omega}}_i = \begin{bmatrix} \psi_{1,i} & \psi_{1,i} & \psi_{1,i} & \psi_{2,i} & \cdots & \psi_{1,i} & \psi_{g,i} \\ \psi_{2,i} & \psi_{1,i} & \psi_{2,i} & \psi_{2,i} & \cdots & \psi_{2,i} & \psi_{g,i} \\ \vdots & & \vdots & & \vdots & & \vdots \\ \psi_{g,i} & \psi_{1,i} & \psi_{g,i} & \psi_{2,i} & \cdots & \psi_{g,i} & \psi_{g,i} \end{bmatrix}$$

where

$$\psi_{j,i} = \epsilon_{j,i} \quad HC_0$$

or

$$\psi_{j,i} = \sqrt{\frac{n}{n-df}} \epsilon_{j,i} \quad HC_1$$

or

$$\psi_{j,i} = \epsilon_{j,i} / \sqrt{1 - \hat{h}_i} \quad HC_2$$

or

$$\psi_{j,i} = \epsilon_{j,i} / (1 - \hat{h}_i) \quad HC_3$$

Two- and Three-Stage Least Squares HCCME

For two- and three-stage least squares, the HCCME for a g equation system is

$$\text{Cov} F(\hat{\mathbf{\Omega}}) \text{Cov}$$

where

$$\text{Cov} = \left(\frac{1}{n} \mathbf{X}'(\mathbf{I} \otimes \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}')\mathbf{X} \right)^{-1}$$

is the normal covariance matrix without the \mathbf{S} matrix and

$$F(\mathbf{\Omega}) = \frac{1}{n} \sum_i^g \sum_j^g \mathbf{X}_i' \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \mathbf{Z}' \hat{\mathbf{\Omega}}_{ij} \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \mathbf{Z}' \mathbf{X}_j$$

where \mathbf{X}_j is a $n \times p$ matrix with the j th equations regressors in the appropriate columns and zeros everywhere else.

$$\hat{\mathbf{\Omega}}_{ij} = \begin{bmatrix} \psi_{i,1}\psi_{j,1} & 0 & 0 & 0 \\ 0 & \psi_{i,2}\psi_{j,2} & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \psi_{i,n}\psi_{j,n} \end{bmatrix}$$

For 2SLS $\hat{\Omega}_{ij} = 0$ when $i \neq j$. The ϵ_t used in $\hat{\Omega}$ is computed by using the parameter estimates obtained from the instrumental variables estimation.

The leverage value for the i th equation used in the HCCME=2 and HCCME=3 methods is computed as conditional on the first stage as

$$h_{ti} = \mathbf{Z}_t(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{X}_i(\mathbf{X}'(\mathbf{I} \otimes \mathbf{Z}(\mathbf{Z}' * \mathbf{Z})^{-1}\mathbf{Z}')\mathbf{X})^{-1}\mathbf{X}_i'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}_t'$$

for 2SLS and

$$h_{ti} = \mathbf{Z}_t(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{X}_i(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{Z}(\mathbf{Z}' * \mathbf{Z})^{-1}\mathbf{Z}')\mathbf{X})^{-1}\mathbf{X}_i'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}_t'/\mathbf{S}_{ii}$$

for 3SLS.

Testing for Autocorrelation

The GODFREY= option in the FIT statement produces the Godfrey Lagrange multiplier test for serially correlated residuals for each equation (Godfrey 1978a, b). n is the maximum autoregressive order, and specifies that Godfrey's tests be computed for lags 1 through n . The default number of lags is four.

The tests are performed separately for each equation estimated by the FIT statement. When a nonlinear model is estimated, the test is computed by using a linearized model.

The following is an example of the output produced by the GODFREY=3 option:

Figure 19.45 Autocorrelation Test Output

Godfrey Test Output			
The MODEL Procedure			
Godfrey's Serial Correlation Test			
Equation	Alternative	LM	Pr > LM
y	1	6.63	0.0100
	2	6.89	0.0319
	3	6.96	0.0732

The three variations of the test reported by the GODFREY=3 option are designed to have power against different alternative hypothesis. Thus, if the residuals in fact have only first-order autocorrelation, the lag 1 test has the most power for rejecting the null hypothesis of uncorrelated residuals. If the residuals have second- but not higher-order autocorrelation, the lag 2 test might be more likely to reject; the same is true for third-order autocorrelation and the lag 3 test.

The null hypothesis of Godfrey's tests is that the equation residuals are white noise. However, if the equation includes autoregressive error model of order p (AR(p),) then the lag i test, when considered in terms of the structural error, is for the null hypothesis that the structural errors are from an AR(p) process versus the alternative hypothesis that the errors are from an AR($p + i$) process.

The alternative $\text{ARMA}(p, i)$ process is locally equivalent to the alternative $\text{AR}(p + i)$ process with respect to the null model $\text{AR}(p)$. Thus, the GODFREY= option results are also a test of $\text{AR}(p)$ errors against the alternative hypothesis of $\text{ARMA}(p, i)$ errors. See Godfrey (1978a, b) for more detailed information.

Transformation of Error Terms

In PROC MODEL you can control the form of the error term. By default, the error term is assumed to be additive. This section demonstrates how to specify nonadditive error terms and discusses the effects of these transformations.

Models with Nonadditive Errors

The estimation methods used by PROC MODEL assume that the error terms of the equations are independently and identically distributed with zero means and finite variances. Furthermore, the methods assume that the *RESID.name* equation variable for normalized form equations or the *EQ.name* equation variable for general form equations contains an estimate of the error term of the true stochastic model whose parameters are being estimated. Details on *RESID.name* and *EQ.name* equation variables are in the section “[Equation Translations](#)” on page 1264.

To illustrate these points, consider the common loglinear model

$$y = \alpha x^\beta \quad (1)$$

$$\ln y = a + b \ln(x) \quad (2)$$

where $a = \log(\alpha)$ and $b = \beta$. Equation (2) is called the *log form* of the equation in contrast to equation (1), which is called the *level form* of the equation. Using the SYSLIN procedure, you can estimate equation (2) by specifying

```
proc syslin data=in;
  model logy=logx;
run;
```

where LOGY and LOGX are the logs of Y and X computed in a preceding DATA step. The resulting values for INTERCEPT and LOGX correspond to a and b in equation (2).

Using the MODEL procedure, you can try to estimate the parameters in the level form (and avoid the DATA step) by specifying

```
proc model data=in;
  parms alpha beta;
  y = alpha * x ** beta;
  fit y;
run;
```

where ALPHA and BETA are the parameters in equation (1).

Unfortunately, at least one of the preceding is wrong; an ambiguity results because equations (1) and (2) contain no explicit error term. The SYSLIN and MODEL procedures both deal with additive errors; the residual used (the estimate of the error term in the equation) is the difference between the predicted and actual values (of LOGY for PROC SYSLIN and of Y for PROC MODEL in this example). If you perform the regressions discussed previously, PROC SYSLIN estimates equation (3) while PROC MODEL estimates equation (4).

$$\ln y = a + b \ln(x) + \epsilon \quad (3)$$

$$y = \alpha x^\beta + \xi \quad (4)$$

These are different statistical models. Equation (3) is the log form of equation (5)

$$y = \alpha x^\beta \mu \quad (5) \quad \text{where } \mu = e^\epsilon. \text{ Equation (4), on the other hand, cannot be linearized because the error term } \xi \text{ (different from } \mu) \text{ is additive in the level form.}$$

You must decide whether your model is equation (4) or (5). If the model is equation (4), you should use PROC MODEL. If you linearize equation (1) without considering the error term and apply SYSLIN to MODEL LOGY=LOGX, the results will be wrong. On the other hand, if your model is equation (5) (in practice it usually is), and you want to use PROC MODEL to estimate the parameters in the *level* form, you must do something to account for the multiplicative error.

PROC MODEL estimates parameters by minimizing an objective function. The objective function is computed using either the RESID.-prefixed equation variable or the EQ.-prefixed equation variable. You must make sure that these prefixed equation variables are assigned an appropriate error term. If the model has additive errors that satisfy the assumptions, nothing needs to be done. In the case of equation (5), the error is nonadditive and the equation is in normalized form, so you must alter the value of RESID.Y.

The following assigns a valid estimate of μ to RESID.Y:

```
y = alpha * x ** beta;
resid.y = actual.y / pred.y;
```

However, $\mu = e^\epsilon$, and therefore μ , cannot have a mean of zero, and you cannot consistently estimate α and β by minimizing the sum of squares of an estimate of μ . Instead, you use $\epsilon = \ln \mu$.

```
proc model data=in;
  parms alpha beta;
  y = alpha * x ** beta;
  resid.y = log( actual.y / pred.y );
  fit y;
run;
```

If the model was expressed in general form, this transformation becomes

```
proc model data=in;
  parms alpha beta;
  EQ.trans = log( y / (alpha * x ** beta) );
  fit trans;
run;
```

Both examples produce estimates of α and β of the level form that match the estimates of a and b of the log form. That is, ALPHA=exp(INTERCEPT) and BETA=LOGX, where INTERCEPT and LOGX are the PROC SYSLIN parameter estimates from the MODEL LOGY=LOGX. The standard error reported for ALPHA is different from that for the INTERCEPT in the log form.

The preceding example is not intended to suggest that loglinear models should be estimated in level form but, rather, to make the following points:

- Nonlinear transformations of equations involve the error term of the equation, and this should be taken into account when transforming models.
- The RESID.-prefixed and the EQ.-prefixed equation variables for models estimated by the MODEL procedure must represent additive errors with zero means.
- You can use assignments to RESID.-prefixed and EQ.-prefixed equation variables to transform error terms.
- Some models do not have additive errors or zero means, and many such models can be estimated using the MODEL procedure. The preceding approach applies not only to multiplicative models but to any model that can be manipulated to isolate the error term.

Predicted Values of Transformed Models

Nonadditive or transformed errors affect the distribution of the predicted values, as well as the estimates. For the preceding loglinear example, the MODEL procedure produces consistent parameter estimates. However, the predicted values for Y computed by PROC MODEL are not unbiased estimates of the expected values of Y, although they do estimate the conditional median Y values.

In general, the predicted values produced for a model with nonadditive errors are not unbiased estimates of the conditional means of the endogenous value. If the model can be transformed to a model with additive errors by using a *monotonic* transformation, the predicted values estimate the conditional medians of the endogenous variable.

For transformed models in which the biasing factor is known, you can use programming statements to correct for the bias in the predicted values as estimates of the endogenous means. In the preceding log-linear case, the predicted values are biased by the factor $\exp(\sigma^2/2)$. You can produce approximately unbiased predicted values in this case by writing the model as

```
proc model data=in;
  parms alpha beta;
  y=alpha * x ** beta;
  resid.y = log( actual.y / pred.y );
  fit y;
run;
```

See Miller (1984) for a discussion of bias factors for predicted values of transformed models.

Note that models with transformed errors are not appropriate for Monte Carlo simulation that uses the SDATA= option. PROC MODEL computes the OUTS= matrix from the transformed RESID.-prefixed equation variables, while it uses the SDATA= matrix to generate multivariate normal errors, which are added to the predicted values. This method of computing errors is inconsistent when the equation variables have been transformed.

Error Covariance Structure Specification

One of the key assumptions of regression is that the variance of the errors is constant across observations. Correcting for heteroscedasticity improves the efficiency of the estimates.

Consider the following general form for models:

$$\begin{aligned} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) &= \boldsymbol{\varepsilon}_t \\ \boldsymbol{\varepsilon}_t &= H_t * \boldsymbol{\epsilon}_t \\ H_t &= \begin{bmatrix} \sqrt{h_{t,1}} & 0 & \dots & 0 \\ 0 & \sqrt{h_{t,2}} & \dots & 0 \\ & & \ddots & \\ 0 & 0 & \dots & \sqrt{h_{t,g}} \end{bmatrix} \\ \mathbf{h}_t &= \mathbf{g}(\mathbf{y}_t, \mathbf{x}_t, \phi) \end{aligned}$$

where $\boldsymbol{\epsilon}_t \sim N(0, \Sigma)$.

For models that are homoscedastic,

$$h_t = 1$$

If you have a model that is heteroscedastic with known form, you can improve the efficiency of the estimates by performing a weighted regression. The weight variable, using this notation, would be $1/\sqrt{h_t}$.

If the errors for a model are heteroscedastic and the functional form of the variance is known, the model for the variance can be estimated along with the regression function.

To specify a functional form for the variance, assign the function to an `H.var` variable where `var` is the equation variable. For example, if you want to estimate the scale parameter for the variance of a simple regression model

$$y = a * x + b$$

you can specify

```
proc model data=s;
  y = a * x + b;
  h.y = sigma**2;
fit y;
```

Consider the same model with the following functional form for the variance:

$$h_t = \sigma^2 * x^{2*\alpha}$$

This would be written as

```
proc model data=s;
  y = a * x + b;
  h.y = sigma**2 * x**(2*alpha);
fit y;
```

There are three ways to model the variance in the MODEL procedure: feasible generalized least squares, generalized method of moments, and full information maximum likelihood.

Feasible GLS

A simple approach to estimating a variance function is to estimate the mean parameters θ by using some auxiliary method, such as OLS, and then use the residuals of that estimation to estimate the parameters ϕ of the variance function. This scheme is called *feasible GLS*. It is possible to use the residuals from an auxiliary method for the purpose of estimating ϕ because in many cases the residuals consistently estimate the error terms.

For all estimation methods except GMM and FIML, using the H.var syntax specifies that feasible GLS is used in the estimation. For feasible GLS, the mean function is estimated by the usual method. The variance function is then estimated using pseudo-likelihood (PL) function of the generated residuals. The objective function for the PL estimation is

$$p_n(\sigma, \theta) = \sum_{i=1}^n \left(\frac{(y_i - f(x_i, \hat{\beta}))^2}{\sigma^2 h(z_i, \theta)} + \log[\sigma^2 h(z_i, \theta)] \right)$$

Once the variance function has been estimated, the mean function is reestimated by using the variance function as weights. If an S-iterated method is selected, this process is repeated until convergence (iterated feasible GLS).

Note that feasible GLS does not yield consistent estimates when one of the following is true:

- The variance is unbounded.
- There is too much serial dependence in the errors (the dependence does not fade with time).
- There is a combination of serial dependence and lag dependent variables.

The first two cases are unusual, but the third is much more common. Whether iterated feasible GLS avoids consistency problems with the last case is an unanswered research question. For more information see: Davidson and MacKinnon (1993, pp. 298–301); Gallant (1987, pp. 124–125); Amemiya (1985, pp. 202–203).

One limitation is that parameters cannot be shared between the mean equation and the variance equation. This implies that certain GARCH models, cross-equation restrictions of parameters, or testing of combinations of parameters in the mean and variance component are not allowed.

Generalized Method of Moments

In GMM, normally the first moment of the mean function is used in the objective function.

$$\begin{aligned} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) &= \epsilon_t \\ \mathbf{E}(\epsilon_t) &= 0 \end{aligned}$$

To add the second moment conditions to the estimation, add the equation

$$\mathbf{E}(\epsilon_t * \epsilon_t - h_t) = 0$$

to the model. For example, if you want to estimate σ for linear example above, you can write

```

proc model data=s;
  y = a * x + b;
  eq.two = resid.y**2 - sigma**2;
fit y two/ gmm;
instruments x;
run;

```

This is a popular way to estimate a continuous-time interest rate processes (see Chan et al. 1992). The H.var syntax automatically generates this system of equations.

To further take advantage of the information obtained about the variance, the moment equations can be modified to

$$\begin{aligned} E(\varepsilon_t / \sqrt{h_t}) &= 0 \\ E(\varepsilon_t * \varepsilon_t - h_t) &= 0 \end{aligned}$$

For the above example, this can be written as

```

proc model data=s;
  y = a * x + b;
  eq.two = resid.y**2 - sigma**2;
  resid.y = resid.y / sigma;
fit y two/ gmm;
instruments x;
run;

```

Note that, if the error model is misspecified in this form of the GMM model, the parameter estimates might be inconsistent.

Full Information Maximum Likelihood

For FIML estimation of variance functions, the concentrated likelihood below is used as the objective function. That is, the mean function is coupled with the variance function and the system is solved simultaneously.

$$\begin{aligned} l_n(\phi) &= \frac{ng}{2}(1 + \ln(2\pi)) - \sum_{t=1}^n \ln \left(\left| \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)}{\partial \mathbf{y}_t} \right| \right) \\ &\quad + \frac{1}{2} \sum_{t=1}^n \sum_{i=1}^g (\ln(h_{t,i}) + \mathbf{q}_i(\mathbf{y}_t, \mathbf{x}_t, \theta)^2 / h_{t,i}) \end{aligned}$$

where g is the number of equations in the system.

The HESSIAN=GLS option is not available for FIML estimation that involves variance functions. The matrix used when HESSIAN=CROSS is specified is a crossproducts matrix that has been enhanced by the dual quasi-Newton approximation.

Examples

You can specify a GARCH(1,1) model as follows:

```
proc model data=modloc.usd_jpy;

    /* Mean model -----*/
    jpyret = intercept ;

    /* Variance model -----*/
    h.jpyret = arch0
              + arch1 * xlag( resid.jpyret ** 2, mse.jpyret )
              + garch1 * xlag(h.jpyret, mse.jpyret) ;

    bounds arch0 arch1 garch1 >= 0;

    fit jpyret / method=marquardt fiml;
run;
```

Note that the BOUNDS statement is used to ensure that the parameters are positive, a requirement for GARCH models.

EGARCH models are used because there are no restrictions on the parameters. You can specify a EGARCH(1,1) model as follows:

```
proc model data=sasuser.usd_dem ;

    /* Mean model -----*/
    demret = intercept ;

    /* Variance model -----*/
    if ( _OBS_ =1 ) then
        h.demret = exp( earch0 + egarch1 * log(mse.demret) );
    else
        h.demret = exp( earch0 + earch1 * zlag( g)
                      + egarch1 * log(zlag(h.demret)));
        g = - theta * nresid.demret + abs( nresid.demret ) - sqrt(2/3.1415);

    fit demret / method=marquardt fiml maxiter=100 converge=1.0e-6;
run;
```

Ordinary Differential Equations

Ordinary differential equations (ODEs) are also called *initial value problems* because a time zero value for each first-order differential equation is needed. The following is an example of a first-order system of ODEs:

$$\begin{aligned} y' &= -0.1y + 2.5z^2 \\ z' &= -z \\ y_0 &= 0 \\ z_0 &= 1 \end{aligned}$$

Note that you must provide an initial value for each ODE.

As a reminder, any n -order differential equation can be modeled as a system of first-order differential equations. For example, consider the differential equations

$$\begin{aligned} y'' &= by' + cy \\ y_0 &= 0 \\ y'_0 &= 1 \end{aligned}$$

which can be written as the system of differential equations

$$\begin{aligned} y' &= z \\ z' &= by' + cy \\ y_0 &= 0 \\ z_0 &= 1 \end{aligned}$$

This differential system can be simulated as follows:

```
data t;
  time=0; output;
  time=1; output;
  time=2; output;
run;

proc model data=t ;
  dependent y 0 z 1;
  parm b -2 c -4;

  dert.y = z;
  dert.z = b * dert.y + c * y;

  solve y z / dynamic solveprint;
run;
```

The preceding statements produce the output shown in [Figure 19.46](#). These statements produce additional output, which is not shown.

-.0247649				-.1035929			

The differential variables are distinguished by the derivative with respect to time (DERT.) prefix. Once you define the DERT. variable, you can use it on the right-hand side of another equation. The differential equations must be expressed in normal form; implicit differential equations are not allowed, and other terms on the left-hand side are not allowed.

The TIME variable is the *implied with respect to* variable for all DERT. variables. The TIME variable is also the only variable that must be in the input data set.

You can provide initial values for the differential equations in the data set, in the declaration statement (as in the previous example), or in statements in the program. Using the previous example, you can specify the initial values as

```
proc model data=t ;
  dependent y z ;
  parm b -2 c -4;

  if ( time=0 ) then
    do;
      y=0;
      z=1;
    end;
  else
    do;
      dert.y = z;
      dert.z = b * dert.y + c * y;
    end;
  end;
```

```

    solve y z / dynamic solveprint;
run;

```

If you do not provide an initial value, 0 is used.

DYNAMIC and STATIC Simulation

Note that, in the previous example, the DYNAMIC option is specified in the SOLVE statement. The DYNAMIC and STATIC options work the same for differential equations as they do for dynamic systems. In the differential equation case, the DYNAMIC option makes the initial value needed at each observation the computed value from the previous iteration. For a static simulation, the data set must contain values for the integrated variables. For example, if DERT.Y and DERT.Z are the differential variables, you must include Y and Z in the input data set in order to do a static simulation of the model.

If the simulation is dynamic, the initial values for the differential equations are obtained from the data set, if they are available. If the variable is not in the data set, you can specify the initial value in a declaration statement. If you do not specify an initial value, the value of 0.0 is used.

A dynamic solution is obtained by solving one initial value problem for all the data. A graph of a simple dynamic simulation is shown in Figure 19.47. If the time variable for the current observation is less than the time variable for the previous observation, the integration is restarted from this point. This allows for multiple samples in one data file.

Figure 19.47 Dynamic Solution

In a static solution, $n-1$ initial value problems are solved using the first $n-1$ data values as initial values. The equations are integrated using the i th data value as an initial value to the $i+1$ data value. Figure 19.48 displays a static simulation of noisy data from a simple differential equation. The static solution does not propagate errors in initial values as the dynamic solution does.

Figure 19.48 Static Solution

For estimation, the DYNAMIC and STATIC options in the FIT statement perform the same functions as they do in the SOLVE statement. Components of differential systems that have missing values or are not in the data set are simulated dynamically. For example, often in multiple compartment kinetic models, only one compartment is monitored. The differential equations that describe the unmonitored compartments are simulated dynamically.

For estimation, it is important to have accurate initial values for ODEs that are not in the data set. If an accurate initial value is not known, the initial value can be made an unknown parameter and estimated. This allows for errors in the initial values but increases the number of parameters to estimate by the number of equations.

Estimation of Differential Equations

Consider the kinetic model for the accumulation of mercury (Hg) in mosquito fish (Matis, Miller, and Allen 1991, p. 177). The model for this process is the one-compartment constant infusion model shown in Figure 19.49.

Figure 19.49 One-Compartment Constant Infusion Model

The differential equation that models this process is

$$\begin{aligned}\frac{dconc}{dt} &= k_u - k_e conc \\ conc_0 &= 0\end{aligned}$$

The analytical solution to the model is

$$conc = (k_u/k_e)(1 - \exp(-k_e t))$$

The data for the model are

```
data fish;
  input day conc;
datalines;
0.0 0.0
1.0 0.15
2.0 0.2
3.0 0.26
4.0 0.32
6.0 0.33
;
```

To fit this model in differential form, use the following statements:

```
proc model data=fish;
  parm ku ke;

  dert.conc = ku - ke * conc;

  fit conc / time=day;
run;
```

The results from this estimation are shown in [Figure 19.50](#).

Figure 19.50 Static Estimation Results for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.180159	0.0312	5.78	0.0044
ke	0.524661	0.1181	4.44	0.0113

To perform a dynamic estimation of the differential equation, add the DYNAMIC option to the FIT statement.

```
proc model data=fish;
  parm ku .3 ke .3;

  dert.conc = ku - ke * conc;

  fit conc / time = day dynamic;
run;
```

The equation DERT.CONC is integrated from $conc(0) = 0$. The results from this estimation are shown in Figure 19.51.

Figure 19.51 Dynamic Estimation Results for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.167109	0.0170	9.84	0.0006
ke	0.469033	0.0731	6.42	0.0030

To perform a dynamic estimation of the differential equation and estimate the initial value, use the following statements:

```
proc model data=fish;
  parm ku .3 ke .3 conc0 0;

  dert.conc = ku - ke * conc;

  fit conc initial=(conc = conc0) / time = day dynamic;
run;
```

The INITIAL= option in the FIT statement is used to associate the initial value of a differential equation with a parameter. The results from this estimation are shown in Figure 19.52.

Figure 19.52 Dynamic Estimation with Initial Value for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.164408	0.0230	7.14	0.0057
ke	0.45949	0.0943	4.87	0.0165
conc0	0.003798	0.0174	0.22	0.8414

Finally, to estimate the fish model by using the analytical solution, use the following statements:

```
proc model data=fish;
  parm ku .3 ke .3;

  conc = (ku/ ke)*( 1 -exp(-ke * day));

  fit conc;
run;
```

The results from this estimation are shown in [Figure 19.53](#).

Figure 19.53 Analytical Estimation Results for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.167109	0.0170	9.84	0.0006
ke	0.469033	0.0731	6.42	0.0030

A comparison of the results among the four estimations reveals that the two dynamic estimations and the analytical estimation give nearly identical results (identical to the default precision). The two dynamic estimations are identical because the estimated initial value (0.00013071) is very close to the initial value used in the first dynamic estimation (0). Note also that the static model did not require an initial guess for the parameter values. Static estimation, in general, is more forgiving of bad initial values.

The form of the estimation that is preferred depends mostly on the model and data. If a very accurate initial value is known, then a dynamic estimation makes sense. If, additionally, the model can be written analytically, then the analytical estimation is computationally simpler. If only an approximate initial value is known and not modeled as an unknown parameter, the static estimation is less sensitive to errors in the initial value.

The form of the error in the model is also an important factor in choosing the form of the estimation. If the error term is additive and independent of previous error, then the dynamic mode is appropriate. If, on the

other hand, the errors are cumulative, a static estimation is more appropriate. See the section “[Monte Carlo Simulation](#)” on page 1226 for an example.

Auxiliary Equations

Auxiliary equations can be used with differential equations. These are equations that need to be satisfied with the differential equations at each point between each data value. They are automatically added to the system, so you do not need to specify them in the SOLVE or FIT statement.

Consider the following example.

The Michaelis-Menten equations describe the kinetics of an enzyme-catalyzed reaction. The enzyme is E, and S is called the *substrate*. The enzyme first reacts with the substrate to form the enzyme-substrate complex ES, which then breaks down in a second step to form enzyme and products P.

The reaction rates are described by the following system of differential equations:

$$\begin{aligned}\frac{d[ES]}{dt} &= k_1([E] - [ES])[S] - k_2[ES] - k_3[ES] \\ \frac{d[S]}{dt} &= -k_1([E] - [ES])[S] + k_2[ES] \\ [E] &= [E]_{tot} - [ES]\end{aligned}$$

The first equation describes the rate of formation of ES from E + S. The rate of formation of ES from E + P is very small and can be ignored. The enzyme is in either the complexed or the uncomplexed form. So if the total ($[E]_{tot}$) concentration of enzyme and the amount bound to the substrate is known, $[E]$ can be obtained by conservation.

In this example, the conservation equation is an auxiliary equation and is coupled with the differential equations for integration.

Time Variable

You must provide a time variable in the data set. The name of the time variable defaults to TIME. You can use other variables as the time variable by specifying the TIME= option in the FIT or SOLVE statement. The time intervals need not be evenly spaced. If the time variable for the current observation is less than the time variable for the previous observation, the integration is restarted.

Differential Equations and Goal Seeking

Consider the following differential equation

$$y' = a * x$$

and the data set

```
data t2;
  y=0; time=0; output;
  y=2; time=1; output;
  y=3; time=2; output;
run;
```

The problem is to find values for X that satisfy the differential equation and the data in the data set. Problems of this kind are sometimes referred to as *goal-seeking problems* because they require you to search for values of X that satisfy the goal of Y.

This problem is solved with the following statements:

```
proc model data=t2;
  independent x 0;
  dependent y;
  parm a 5;
  dert.y = a * x;
  solve x / out=goaldata;
run;

proc print data=goaldata;
run;
```

The output from the PROC PRINT statement is shown in [Figure 19.54](#).

Figure 19.54 Dynamic Solution

Obs	_TYPE_	_MODE_	_ERRORS_	x	y	time
1	PREDICT	SIMULATE	0	0.0	0	0
2	PREDICT	SIMULATE	0	0.8	2	1
3	PREDICT	SIMULATE	0	-0.4	3	2

Note that an initial value of 0 is provided for the X variable because it is undetermined at TIME = 0.

In the preceding goal-seeking example, X is treated as a linear function between each set of data points (see [Figure 19.55](#)).

Figure 19.55 Form of X Used for Integration in Goal Seeking

If you integrate $y' = ax$ manually, you have

$$\begin{aligned}
 x(t) &= \frac{t_f - t}{t_f - t_o} x_o + \frac{t - t_o}{t_f - t_o} x_f \\
 y_f - y_o &= \int_{t_o}^{t_f} ax(t) dt \\
 &= a \frac{1}{t_f - t_o} \left(t(t_f x_o - t_o x_f) + \frac{1}{2} t^2 (x_f - x_o) \right) \Bigg|_{t_o}^{t_f}
 \end{aligned}$$

For observation 2, this reduces to

$$\begin{aligned}
 y_f - y_o &= \frac{1}{2} a * x_f \\
 2 &= 2.5 * x_f
 \end{aligned}$$

So $x = 0.8$ for this observation.

Goal seeking for the TIME variable is not allowed.

Restrictions and Bounds on Parameters

Using the BOUNDS and RESTRICT statements, PROC MODEL can compute optimal estimates subject to equality or inequality constraints on the parameter estimates.

Equality restrictions can be written as a vector function:

$$h(\theta) = 0$$

Inequality restrictions are either active or inactive. When an inequality restriction is active, it is treated as an equality restriction. All inactive inequality restrictions can be written as a vector function:

$$F(\theta) \geq 0$$

Strict inequalities, such as $(f(\theta) > 0)$, are transformed into inequalities as $f(\theta) \times (1 - \epsilon) - \epsilon \geq 0$, where the tolerance ϵ is controlled by the EPSILON= option in the FIT statement and defaults to 10^{-8} . The i th inequality restriction becomes active if $F_i < 0$ and remains active until its Lagrange multiplier becomes negative. Lagrange multipliers are computed for all the nonredundant equality restrictions and all the active inequality restrictions.

For the following, assume the vector $\mathbf{h}(\theta)$ contains all the current active restrictions. The constraint matrix \mathbf{A} is

$$\mathbf{A}(\hat{\theta}) = \frac{\partial \mathbf{h}(\hat{\theta})}{\partial \hat{\theta}}$$

The covariance matrix for the restricted parameter estimates is computed as

$$\mathbf{Z}(\mathbf{Z}'\mathbf{H}\mathbf{Z})^{-1}\mathbf{Z}'$$

where \mathbf{H} is Hessian or approximation to the Hessian of the objective function $((\mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{X})$ for OLS), and \mathbf{Z} is the last $(np - nc)$ columns of \mathbf{Q} . \mathbf{Q} is from an LQ factorization of the constraint matrix, nc is the number of active constraints, and np is the number of parameters. For more details on LQ factorization, see Gill, Murray, and Wright (1981). The covariance column in Table 19.2 summarizes the Hessian approximation used for each estimation method.

The covariance matrix for the Lagrange multipliers is computed as

$$(\mathbf{A}\mathbf{H}^{-1}\mathbf{A}')^{-1}$$

The p -value reported for a restriction is computed from a beta distribution rather than a t distribution because the numerator and the denominator of the t ratio for an estimated Lagrange multiplier are not independent.

The Lagrange multipliers for the active restrictions are printed with the parameter estimates. The Lagrange multiplier estimates are computed using the relationship

$$\mathbf{A}'\lambda = \mathbf{g}$$

where the dimensions of the constraint matrix \mathbf{A} are the number of constraints by the number of parameters, λ is the vector of Lagrange multipliers, and \mathbf{g} is the gradient of the objective function at the final estimates.

The final gradient includes the effects of the estimated \mathbf{S} matrix. For example, for OLS the final gradient would be:

$$\mathbf{g} = \mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{r}$$

where \mathbf{r} is the residual vector. Note that when nonlinear restrictions are imposed, the convergence measure R might have values greater than one for some iterations.

Tests on Parameters

In general, the hypothesis tested can be written as

$$H_0 : \mathbf{h}(\theta) = 0$$

where $\mathbf{h}(\theta)$ is a vector-valued function of the parameters θ given by the r expressions specified on the TEST statement.

Let $\hat{\mathbf{V}}$ be the estimate of the covariance matrix of $\hat{\theta}$. Let $\hat{\theta}$ be the unconstrained estimate of θ and $\tilde{\theta}$ be the constrained estimate of θ such that $\mathbf{h}(\tilde{\theta}) = 0$. Let

$$\mathbf{A}(\theta) = \partial \mathbf{h}(\theta) / \partial \theta \big|_{\hat{\theta}}$$

Let r be the dimension of $\mathbf{h}(\theta)$ and n be the number of observations. Using this notation, the test statistics for the three kinds of tests are computed as follows.

The Wald test statistic is defined as

$$W = \mathbf{h}'(\hat{\theta}) \left(\mathbf{A}(\hat{\theta}) \hat{\mathbf{V}} \mathbf{A}'(\hat{\theta}) \right)^{-1} \mathbf{h}(\hat{\theta})$$

The Wald test is not invariant to reparameterization of the model (Gregory and Veall 1985; Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

The Lagrange multiplier test statistic is

$$R = \lambda' \mathbf{A}(\tilde{\theta}) \tilde{\mathbf{V}} \mathbf{A}'(\tilde{\theta}) \lambda$$

where λ is the vector of Lagrange multipliers from the computation of the restricted estimate $\tilde{\theta}$.

The Lagrange multiplier test statistic is equivalent to Rao's efficient score test statistic:

$$R = (\partial L(\tilde{\theta}) / \partial \theta)' \tilde{\mathbf{V}} (\partial L(\tilde{\theta}) / \partial \theta)$$

where L is the log-likelihood function for the estimation method used. For SUR, 3SLS, GMM, and iterated versions of these methods, the likelihood function is computed as

$$L = \text{Objective} \times \text{Nobs} / 2$$

For OLS and 2SLS, the Lagrange multiplier test statistic is computed as:

$$R = [(\partial \hat{S}(\tilde{\theta}) / \partial \theta)' \tilde{\mathbf{V}} (\partial \hat{S}(\tilde{\theta}) / \partial \theta)] / \hat{S}(\tilde{\theta})$$

where $\hat{S}(\tilde{\theta})$ is the corresponding objective function value at the constrained estimate.

The likelihood ratio test statistic is

$$T = 2 \left(L(\hat{\theta}) - L(\tilde{\theta}) \right)$$

where $\tilde{\theta}$ represents the constrained estimate of θ and L is the concentrated log-likelihood value.

For OLS and 2SLS, the likelihood ratio test statistic is computed as:

$$T = (n - nparms) \times (\hat{S}(\tilde{\theta}) - \hat{S}(\hat{\theta})) / \hat{S}(\hat{\theta})$$

This test statistic is an approximation from

$$T = n \times \log \left(1 + \frac{rF}{n - nparms} \right)$$

when the value of $rF/(n - nparms)$ is small (Greene 2004, p. 421).

The likelihood ratio test is not appropriate for models with nonstationary serially correlated errors (Gallant 1987, p. 139). The likelihood ratio test should not be used for dynamic systems, for systems with lagged dependent variables, or with the FIML estimation method unless certain conditions are met (see Gallant 1987, p. 479).

For each kind of test, under the null hypothesis the test statistic is asymptotically distributed as a χ^2 random variable with r degrees of freedom, where r is the number of expressions in the TEST statement. The p -values reported for the tests are computed from the $\chi^2(r)$ distribution and are only asymptotically valid. When both RESTRICT and TEST statements are used in a PROC MODEL step, test statistics are computed by taking into account the constraints imposed by the RESTRICT statement.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation to its small sample distribution than the other two tests. However, the Wald test has the least computational cost, since it does not require computation of the constrained estimate $\tilde{\theta}$.

The following is an example of using the TEST statement to perform a likelihood ratio test for a compound hypothesis.

```
test a*exp(-k) = 1-k, d = 0 , / lr;
```

It is important to keep in mind that although individual t tests for each parameter are printed by default into the parameter estimates table, they are only asymptotically valid for nonlinear models. You should be cautious in drawing any inferences from these t tests for small samples.

Hausman Specification Test

Hausman's specification test, or m -statistic, can be used to test hypotheses in terms of bias or inconsistency of an estimator. This test was also proposed by Wu (1973). Hausman's m -statistic is as follows.

Given two estimators, $\hat{\beta}_0$ and $\hat{\beta}_1$, where under the null hypothesis both estimators are consistent but only $\hat{\beta}_0$ is asymptotically efficient and under the alternative hypothesis only $\hat{\beta}_1$ is consistent, the m -statistic is

$$m = \hat{q}'(\hat{\mathbf{V}}_1 - \hat{\mathbf{V}}_0)^{-1}\hat{q}$$

where $\hat{\mathbf{V}}_1$ and $\hat{\mathbf{V}}_0$ represent consistent estimates of the asymptotic covariance matrices of $\hat{\beta}_1$ and $\hat{\beta}_0$ respectively, and

$$q = \hat{\beta}_1 - \hat{\beta}_0$$

The m -statistic is then distributed χ^2 with k degrees of freedom, where k is the rank of the matrix $(\hat{\mathbf{V}}_1 - \hat{\mathbf{V}}_0)$. A generalized inverse is used, as recommended by Hausman and Taylor (1982).

In the MODEL procedure, Hausman's m -statistic can be used to determine if it is necessary to use an instrumental variables method rather than a more efficient OLS estimation. Hausman's m -statistic can also be used to compare 2SLS with 3SLS for a class of estimators for which 3SLS is asymptotically efficient (similarly for OLS and SUR).

Hausman's m -statistic can also be used, in principle, to test the null hypothesis of normality when comparing 3SLS to FIML. Because of the poor performance of this form of the test, it is not offered in the MODEL procedure. See Fair (1984, pp. 246–247) for a discussion of why Hausman's test fails for common econometric models.

To perform a Hausman's specification test, specify the HAUSMAN option in the FIT statement. The selected estimation methods are compared using Hausman's m -statistic.

In the following example, Hausman's test is used to check the presence of measurement error. Under H_0 of no measurement error, OLS is efficient, while under H_1 , 2SLS is consistent. In the following code, OLS and 2SLS are used to estimate the model, and Hausman's test is requested.

```
proc model data=one out=fiml2;
    endogenous y1 y2;

    y1 = py2 * y2 + px1 * x1 + interc;
    y2 = py1 * y1 + pz1 * z1 + d2;

    fit y1 y2 / ols 2sls hausman;
    instruments x1 z1;
run;
```

The output specified by the HAUSMAN option produces the results shown in Figure 19.56.

Figure 19.56 Hausman's Specification Test Results

The MODEL Procedure				
Hausman's Specification Test Results				
Efficient under H0	Consistent under H1	DF	Statistic	Pr > ChiSq
OLS	2SLS	6	13.86	0.0313

Figure 19.56 indicates that 2SLS is preferred over OLS at 5% level of significance. In this case, the null hypothesis of no measurement error is rejected. Hence, the instrumental variable estimator is required for this example due to the presence of measurement error.

Chow Tests

The Chow test is used to test for break points or structural changes in a model. The problem is posed as a partitioning of the data into two parts of size n_1 and n_2 . The null hypothesis to be tested is

$$H_0 : \beta_1 = \beta_2 = \beta$$

where β_1 is estimated by using the first part of the data and β_2 is estimated by using the second part.

The test is performed as follows (see Davidson and MacKinnon 1993, p. 380).

1. The p parameters of the model are estimated.
2. A second linear regression is performed on the residuals, \hat{u} , from the nonlinear estimation in step one.

$$\hat{u} = \hat{\mathbf{X}}b + \text{residuals}$$

where $\hat{\mathbf{X}}$ is Jacobian columns that are evaluated at the parameter estimates. If the estimation is an instrumental variables estimation with matrix of instruments \mathbf{W} , then the following regression is performed:

$$\hat{u} = \mathbf{P}_{\mathbf{W}^*}\hat{\mathbf{X}}b + \text{residuals}$$

where $\mathbf{P}_{\mathbf{W}^*}$ is the projection matrix.

3. The restricted SSE (RSSE) from this regression is obtained. An SSE for each subsample is then obtained by using the same linear regression.
4. The F statistic is then

$$f = \frac{(RSSE - SSE_1 - SSE_2)/p}{(SSE_1 + SSE_2)/(n - 2p)}$$

This test has p and $n - 2p$ degrees of freedom.

Chow's test is not applicable if $\min(n_1, n_2) < p$, since one of the two subsamples does not contain enough data to estimate β . In this instance, the *predictive Chow test* can be used. The predictive Chow test is defined as

$$f = \frac{(RSSE - SSE_1) \times (n_1 - p)}{SSE_1 \times n_2}$$

where $n_1 > p$. This test can be derived from the Chow test by noting that the $SSE_2 = 0$ when $n_2 \leq p$ and by adjusting the degrees of freedom appropriately.

You can select the Chow test and the predictive Chow test by specifying the `CHOW=arg` and the `PCHOW=arg` options in the FIT statement, where *arg* is either the number of observations in the first sample or a parenthesized list of first sample sizes. If the size of the one of the two groups in which the sample is partitioned is less than the number of parameters, then a predictive Chow test is automatically used. These tests statistics are not produced for GMM and FIML estimations.

The following is an example of the use of the Chow test.

```

data exp;
  x=0;
  do time=1 to 100;
    if time=50 then x=1;
    y = 35 * exp( 0.01 * time ) + rannor( 123 ) + x * 5;
    output;
  end;
run;

proc model data=exp;
  parm zo 35 b;
  dert.z = b * z;
  y=z;
  fit y init=(z=zo) / chow =(40 50 60) pchow=90;
run;

```

The data set introduces an artificial structural change into the model (the structural change effects the intercept parameter). The output from the requested Chow tests are shown in [Figure 19.57](#).

Figure 19.57 Chow's Test Results

The MODEL Procedure					
Structural Change Test					
Test	Break Point	Num DF	Den DF	F Value	Pr > F
Chow	40	2	96	12.95	<.0001
Chow	50	2	96	101.37	<.0001
Chow	60	2	96	26.43	<.0001
Predictive Chow	90	11	87	1.86	0.0566

Profile Likelihood Confidence Intervals

Wald-based and likelihood-ratio-based confidence intervals are available in the MODEL procedure for computing a confidence interval on an estimated parameter. A confidence interval on a parameter θ can be constructed by inverting a Wald-based or a likelihood-ratio-based test.

The approximate $100(1 - \alpha)\%$ Wald confidence interval for a parameter θ is

$$\hat{\theta} \pm z_{1-\alpha/2} \hat{\sigma}$$

where z_p is the 100 p th percentile of the standard normal distribution, $\hat{\theta}$ is the maximum likelihood estimate of θ , and $\hat{\sigma}$ is the standard error estimate of $\hat{\theta}$.

A likelihood-ratio-based confidence interval is derived from the χ^2 distribution of the generalized likelihood ratio test. The approximate $1 - \alpha$ confidence interval for a parameter θ is

$$\theta : 2[l(\hat{\theta}) - l(\theta)] \leq q_{1,1-\alpha} = 2l^*$$

where $q_{1,1-\alpha}$ is the $(1 - \alpha)$ quantile of the χ^2 with one degree of freedom, and $l(\theta)$ is the log likelihood as a function of one parameter. The endpoints of a confidence interval are the zeros of the function $l(\theta) - l^*$. Computing a likelihood-ratio-based confidence interval is an iterative process. This process must be performed twice for each parameter, so the computational cost is considerable. Using a modified form of the algorithm recommended by Venzon and Moolgavkar (1988), you can determine that the cost of each endpoint computation is approximately the cost of estimating the original system.

To request confidence intervals on estimated parameters, specify the PRL= option in the FIT statement. By default, the PRL option produces 95% likelihood ratio confidence limits. The coverage of the confidence interval is controlled by the ALPHA= option in the FIT statement.

The following is an example of the use of the confidence interval options.

```
data exp;
  do time = 1 to 20;
    y = 35 * exp( 0.01 * time ) + 5*rannor( 123 );
  output;
  end;
run;

proc model data=exp;
  parm zo 35 b;
  dert.z = b * z;
  y=z;
  fit y init=(z=zo) / prl=both;
  test zo = 40.475437 ,/ lr;
run;
```

The output from the requested confidence intervals and the TEST statement are shown in [Figure 19.58](#)

Figure 19.58 Confidence Interval Estimation

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
zo	36.58933	1.9471	18.79	<.0001
b	0.006497	0.00464	1.40	0.1780
Test Results				
Test	Type	Statistic	Pr > ChiSq	Label
Test0	L.R.	3.81	0.0509	zo = 40.475437

Figure 19.58 continued

Parameter Wald			
95% Confidence Intervals			
Parameter	Value	Lower	Upper
zo	36.5893	32.7730	40.4056
b	0.00650	-0.00259	0.0156

Parameter Likelihood Ratio			
95% Confidence Intervals			
Parameter	Value	Lower	Upper
zo	36.5893	32.8381	40.4921
b	0.00650	-0.00264	0.0157

In this example the parameter value used in the likelihood ratio test, $z_o = 40.475437$, is close to the upper bound computed for the likelihood ratio confidence interval, $z_o \leq 40.4921$. This coincidence is not germane to the analysis however, since the likelihood ratio test is a test of the null hypothesis $H_0 : z_o = 40.475437$ and the confidence interval can be viewed as a test of the null hypothesis $H_0 : 32.8381 \leq z_o \leq 40.4921$.

Choice of Instruments

Several of the estimation methods supported by PROC MODEL are instrumental variables methods. There is no standard method for choosing instruments for nonlinear regression. Few econometric textbooks discuss the selection of instruments for nonlinear models. See Bowden and Turkington (1984, pp. 180–182) for more information.

The purpose of the instrumental projection is to purge the regressors of their correlation with the residual. For nonlinear systems, the regressors are the partials of the residuals with respect to the parameters.

Possible instrumental variables include the following:

- any variable in the model that is independent of the errors
- lags of variables in the system
- derivatives with respect to the parameters, if the derivatives are independent of the errors
- low-degree polynomials in the exogenous variables
- variables from the data set or functions of variables from the data set

Selected instruments must not have any of the following characteristics:

- depend on any variable endogenous with respect to the equations estimated
- depend on any of the parameters estimated
- be lags of endogenous variables if there is serial correlation of the errors

If the preceding rules are satisfied and there are enough observations to support the number of instruments used, the results should be consistent and the efficiency loss held to a minimum.

You need at least as many instruments as the maximum number of parameters in any equation, or some of the parameters cannot be estimated. Note that *number of instruments* means linearly independent instruments. If you add an instrument that is a linear combination of other instruments, it has no effect and does not increase the effective number of instruments.

You can, however, use too many instruments. In order to get the benefit of instrumental variables, you must have more observations than instruments. Thus, there is a trade-off; the instrumental variables technique completely eliminates the simultaneous equation bias only in large samples. In finite samples, the larger the excess of observations over instruments, the more the bias is reduced. Adding more instruments might improve the efficiency, but after some point efficiency declines as the excess of observations over instruments becomes smaller and the bias grows.

The instruments used in an estimation are printed out at the beginning of the estimation. For example, the following statements produce the instruments list shown in [Figure 19.59](#).

```
proc model data=test2;
  exogenous x1 x2;
  parms b1 a1 a2 b2 2.5 c2 55;
  y1 = a1 * y2 + b1 * exp(x1);
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2;
  fit y1 y2 / n2s1s;
  inst b1 b2 c2 x1 ;
run;
```

Figure 19.59 Instruments Used Message

```

                                The MODEL Procedure

                                The 2 Equations to Estimate

                                y1 = F(b1, a1(y2))
                                y2 = F(a2(y1), b2, c2)
Instruments  1 x1 @y1/@b1 @y2/@b2 @y2/@c2
```

This states that an intercept term, the exogenous variable X1, and the partial derivatives of the equations with respect to B1, B2, and C2, were used as instruments for the estimation.

Examples

Suppose that Y1 and Y2 are endogenous variables, that X1 and X2 are exogenous variables, and that A, B, C, D, E, F, and G are parameters. Consider the following model:

```
y1 = a + b * x1 + c * y2 + d * lag(y1);
y2 = e + f * x2 + g * y1;
fit y1 y2;
instruments exclude=(c g);
```

The INSTRUMENTS statement produces X1, X2, LAG(Y1), and an intercept as instruments.

In order to estimate the Y1 equation by itself, it is necessary to include X2 explicitly in the instruments since F, in this case, is not included in the following estimation:

```
y1 = a + b * x1 + c * y2 + d * lag(y1);
y2 = e + f * x2 + g * y1;
fit y1;
instruments x2 exclude=(c);
```

This produces the same instruments as before. You can list the parameter associated with the lagged variable as an instrument instead of using the EXCLUDE= option. Thus, the following is equivalent to the previous example:

```
y1 = a + b * x1 + c * y2 + d * lag(y1);
y2 = e + f * x2 + g * y1;
fit y1;
instruments x1 x2 d;
```

For an example of declaring instruments when estimating a model involving identities, consider Klein's Model I:

```
proc model data=klien;
  endogenous c p w i x wsum k y;
  exogenous wp g t year;
  parms c0-c3 i0-i3 w0-w3;
  a: c = c0 + c1 * p + c2 * lag(p) + c3 * wsum;
  b: i = i0 + i1 * p + i2 * lag(p) + i3 * lag(k);
  c: w = w0 + w1 * x + w2 * lag(x) + w3 * year;
  x = c + i + g;
  y = c + i + g-t;
  p = x-w-t;
  k = lag(k) + i;
  wsum = w + wp;
run;
```

The three equations to estimate are identified by the labels A, B, and C. The parameters associated with the predetermined terms are C2, I2, I3, W2, and W3 (and the intercepts, which are automatically added to the instruments). In addition, the system includes five identities that contain the predetermined variables G, T, LAG(K), and WP. Thus, the INSTRUMENTS statement can be written as

```
lagk = lag(k);
instruments c2 i2 i3 w2 w3 g t wp lagk;
```

where LAGK is a program variable used to hold LAG(K). However, this is more complicated than it needs to be. Except for LAG(K), all the predetermined terms in the identities are exogenous variables, and LAG(K) is already included as the coefficient of I3. There are also more parameters for predetermined terms than for endogenous terms, so you might prefer to use the EXCLUDE= option. Thus, you can specify the same instruments list with the simpler statement

```
instruments _exog_ exclude=(c1 c3 i1 w1);
```

To illustrate the use of polynomial terms as instrumental variables, consider the following model:

$$y1 = a + b * \exp(c * x1) + d * \log(x2) + e * \exp(f * y2);$$

The parameters are A, B, C, D, E, and F, and the right-hand-side variables are X1, X2, and Y2. Assume that X1 and X2 are exogenous (independent of the error), while Y2 is endogenous. The equation for Y2 is not specified, but assume that it includes the variables X1, X3, and Y1, with X3 exogenous, so the exogenous variables of the full system are X1, X2, and X3. Using as instruments quadratic terms in the exogenous variables, the model is specified to PROC MODEL as follows:

```
proc model;
  parms a b c d e f;
  y1 = a + b * exp( c * x1 ) + d * log( x2 ) + e * exp( f * y2 );
  instruments inst1-inst9;
  inst1 = x1; inst2 = x2; inst3 = x3;
  inst4 = x1 * x1; inst5 = x1 * x2; inst6 = x1 * x3;
  inst7 = x2 * x2; inst8 = x2 * x3; inst9 = x3 * x3;
  fit y1 / 2sls;
run;
```

It is not clear what degree polynomial should be used. There is no way to know how good the approximation is for any degree chosen, although the first-stage R^2 s might help the assessment.

First-Stage R-Squares

When the FSRSQ option is used on the FIT statement, the MODEL procedure prints a column of first-stage R^2 (FSRSQ) statistics along with the parameter estimates. The FSRSQ measures the fraction of the variation of the derivative column associated with the parameter that remains after projection through the instruments.

Ideally, the FSRSQ should be very close to 1.00 for exogenous derivatives. If the FSRSQ is small for an endogenous derivative, it is unclear whether this reflects a poor choice of instruments or a large influence of the errors in the endogenous right-hand-side variables. When the FSRSQ for one or more parameters is small, the standard errors of the parameter estimates are likely to be large.

Note that you can make all the FSRSQs larger (or 1.00) by including more instruments, because of the disadvantage discussed previously. The FSRSQ statistics reported are unadjusted R^2 s and do not include a degrees-of-freedom correction.

Autoregressive Moving-Average Error Processes

Autoregressive moving-average error processes (ARMA errors) and other models that involve lags of error terms can be estimated by using FIT statements and simulated or forecast by using SOLVE statements. ARMA models for the error process are often used for models with autocorrelated residuals. The %AR macro can be used to specify models with autoregressive error processes. The %MA macro can be used to specify models with moving-average error processes.

Autoregressive Errors

A model with first-order autoregressive errors, AR(1), has the form

$$y_t = f(x_t, \theta) + \mu_t$$

$$\mu_t = \phi \mu_{t-1} + \epsilon_t$$

while an AR(2) error process has the form

$$\mu_t = \phi_1 \mu_{t-1} + \phi_2 \mu_{t-2} + \epsilon_t$$

and so forth for higher-order processes. Note that the ϵ_t 's are independent and identically distributed and have an expected value of 0.

An example of a model with an AR(2) component is

$$y = \alpha + \beta x_1 + \mu_t$$

$$\mu_t = \phi_1 \mu_{t-1} + \phi_2 \mu_{t-2} + \epsilon_t$$

You would write this model as

```
proc model data=in;
  parms a b p1 p2;
  y = a + b * x1 + p1 * zlag1(y - (a + b * x1)) +
      p2 * zlag2(y - (a + b * x1));
  fit y;
run;
```

or equivalently using the %AR macro as

```
proc model data=in;
  parms a b;
  y = a + b * x1;
  %ar( y, 2 );
  fit y;
run;
```

Moving-Average Models

A model with first-order moving-average errors, MA(1), has the form

$$y_t = f(x_t) + \mu_t$$

$$\mu_t = \epsilon_t - \theta_1 \epsilon_{t-1}$$

where ϵ_t is identically and independently distributed with mean zero. An MA(2) error process has the form

$$\mu_t = \epsilon_t - \theta_1 \epsilon_{t-1} - \theta_2 \epsilon_{t-2}$$

and so forth for higher-order processes.

For example, you can write a simple linear regression model with MA(2) moving-average errors as

```
proc model data=inma2;
  parms a b ma1 ma2;
  y = a + b * x + ma1 * zlag1( resid.y ) +
      ma2 * zlag2( resid.y );
  fit;
run;
```

where MA1 and MA2 are the moving-average parameters.

Note that RESID.Y is automatically defined by PROC MODEL as

```
pred.y = a + b * x + ma1 * zlag1( resid.y ) +
      ma2 * zlag2( resid.y );
resid.y = pred.y - actual.y;
```

Note that RESID.Y is negative of ϵ_t .

The ZLAG function must be used for MA models to truncate the recursion of the lags. This ensures that the lagged errors start at zero in the lag-priming phase and do not propagate missing values when lag-priming period variables are missing, and it ensures that the future errors are zero rather than missing during simulation or forecasting. For details about the lag functions, see the section “[Lag Logic](#)” on page 1269.

This model written using the %MA macro is as follows:

```
proc model data=inma2;
  parms a b;
  y = a + b * x;
  %ma(y, 2);
  fit;
run;
```

General Form for ARMA Models

The general ARMA(p, q) process has the following form

$$\mu_t = \phi_1 \mu_{t-1} + \dots + \phi_p \mu_{t-p} + \epsilon_t - \theta_1 \epsilon_{t-1} - \dots - \theta_q \epsilon_{t-q}$$

An ARMA(p, q) model can be specified as follows:

```
yhat = ... compute structural predicted value here ... ;
yarma = ar1 * zlag1( y - yhat ) + ... /* ar part */
      + ar(p) * zlag(p)( y - yhat )
      + ma1 * zlag1( resid.y ) + ... /* ma part */
      + ma(q) * zlag(q)( resid.y );
y = yhat + yarma;
```

where AR i and MA j represent the autoregressive and moving-average parameters for the various lags. You can use any names you want for these variables, and there are many equivalent ways that the specification could be written.

Vector ARMA processes can also be estimated with PROC MODEL. For example, a two-variable AR(1) process for the errors of the two endogenous variables Y1 and Y2 can be specified as follows:

```

y1hat = ... compute structural predicted value here ... ;

y1      = y1hat + ar1_1 * zlag1( y1 - y1hat )    /* ar part y1,y1 */
          + ar1_2 * zlag1( y2 - y2hat ); /* ar part y1,y2 */

y21hat = ... compute structural predicted value here ... ;

y2      = y2hat + ar2_2 * zlag1( y2 - y2hat )    /* ar part y2,y2 */
          + ar2_1 * zlag1( y1 - y1hat ); /* ar part y2,y1 */

```

Convergence Problems with ARMA Models

ARMA models can be difficult to estimate. If the parameter estimates are not within the appropriate range, a moving-average model's residual terms grow exponentially. The calculated residuals for later observations can be very large or can overflow. This can happen either because improper starting values were used or because the iterations moved away from reasonable values.

Care should be used in choosing starting values for ARMA parameters. Starting values of 0.001 for ARMA parameters usually work if the model fits the data well and the problem is well-conditioned. Note that an MA model can often be approximated by a high-order AR model, and vice versa. This can result in high collinearity in mixed ARMA models, which in turn can cause serious ill-conditioning in the calculations and instability of the parameter estimates.

If you have convergence problems while estimating a model with ARMA error processes, try to estimate in steps. First, use a FIT statement to estimate only the structural parameters with the ARMA parameters held to zero (or to reasonable prior estimates if available). Next, use another FIT statement to estimate the ARMA parameters only, using the structural parameter values from the first run. Since the values of the structural parameters are likely to be close to their final estimates, the ARMA parameter estimates might now converge. Finally, use another FIT statement to produce simultaneous estimates of all the parameters. Since the initial values of the parameters are now likely to be quite close to their final joint estimates, the estimates should converge quickly if the model is appropriate for the data.

AR Initial Conditions

The initial lags of the error terms of $AR(p)$ models can be modeled in different ways. The autoregressive error startup methods supported by SAS/ETS procedures are the following:

CLS	conditional least squares (ARIMA and MODEL procedures)
ULS	unconditional least squares (AUTOREG, ARIMA, and MODEL procedures)
ML	maximum likelihood (AUTOREG, ARIMA, and MODEL procedures)
YW	Yule-Walker (AUTOREG procedure only)
HL	Hildreth-Lu, which deletes the first p observations (MODEL procedure only)

See Chapter 8, “[The AUTOREG Procedure](#),” for an explanation and discussion of the merits of various $AR(p)$ startup methods.

The CLS, ULS, ML, and HL initializations can be performed by PROC MODEL. For $AR(1)$ errors, these initializations can be produced as shown in [Table 19.3](#). These methods are equivalent in large samples.

Table 19.3 Initializations Performed by PROC MODEL: AR(1) ERRORS

Method	Formula
conditional least squares	$Y = YHAT + AR1 * ZLAG1(Y - YHAT);$
unconditional least squares	$Y = YHAT + AR1 * ZLAG1(Y - YHAT);$ IF _OBS_=1 THEN $RESID.Y = \sqrt{1 - AR1^2} * RESID.Y;$
maximum likelihood	$Y = YHAT + AR1 * ZLAG1(Y - YHAT);$ $W = (1 - AR1^2)^{-1/(2 * _NUSED_)};$ IF _OBS_=1 THEN $W = W * \sqrt{1 - AR1^2};$ $RESID.Y = W * RESID.Y;$
Hildreth-Lu	$Y = YHAT + AR1 * LAG1(Y - YHAT);$

MA Initial Conditions

The initial lags of the error terms of $MA(q)$ models can also be modeled in different ways. The following moving-average error start-up paradigms are supported by the ARIMA and MODEL procedures:

ULS	unconditional least squares
CLS	conditional least squares
ML	maximum likelihood

The conditional least squares method of estimating moving-average error terms is not optimal because it ignores the start-up problem. This reduces the efficiency of the estimates, although they remain unbiased. The initial lagged residuals, extending before the start of the data, are assumed to be 0, their unconditional expected value. This introduces a difference between these residuals and the generalized least squares residuals for the moving-average covariance, which, unlike the autoregressive model, persists through the data set. Usually this difference converges quickly to 0, but for nearly noninvertible moving-average processes the convergence is quite slow. To minimize this problem, you should have plenty of data, and the moving-average parameter estimates should be well within the invertible range.

This problem can be corrected at the expense of writing a more complex program. Unconditional least squares estimates for the $MA(1)$ process can be produced by specifying the model as follows:

```

yhat = ... compute structural predicted value here ... ;
if _obs_ = 1 then do;
  h = sqrt( 1 + ma1 ** 2 );
  y = yhat;
  resid.y = ( y - yhat ) / h;
end;
else do;
  g = ma1 / zlag1( h );
  h = sqrt( 1 + ma1 ** 2 - g ** 2 );
  y = yhat + g * zlag1( resid.y );
  resid.y = ( ( y - yhat ) - g * zlag1( resid.y ) ) / h;
end;

```

Moving-average errors can be difficult to estimate. You should consider using an $AR(p)$ approximation to the moving-average process. A moving-average process can usually be well-approximated by an autoregressive process if the data have not been smoothed or differenced.

The %AR Macro

The SAS macro %AR generates programming statements for PROC MODEL for autoregressive models. The %AR macro is part of SAS/ETS software, and no special options need to be set to use the macro. The autoregressive process can be applied to the structural equation errors or to the endogenous series themselves.

The %AR macro can be used for the following types of autoregression:

- univariate autoregression
- unrestricted vector autoregression
- restricted vector autoregression

Univariate Autoregression

To model the error term of an equation as an autoregressive process, use the following statement after the equation:

```
%ar( varname, nlags )
```

For example, suppose that Y is a linear function of X1, X2, and an AR(2) error. You would write this model as follows:

```
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 2 )
  fit y / list;
run;
```

The calls to %AR must come *after* all of the equations that the process applies to.

The preceding macro invocation, %AR(y,2), produces the statements shown in the LIST output in [Figure 19.60](#).

Figure 19.60 LIST Option Output for an AR(2) Model

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	2502:4	PRED.y = a + b * x1 + c * x2;
1	2502:4	RESID.y = PRED.y - ACTUAL.y;
1	2502:4	ERROR.y = PRED.y - y;
2	2503:14	_PRED__y = PRED.y;
3	2503:15	_OLD_PRED.y = PRED.y + y_l1
		* ZLAG1(y - _PRED__y) + y_l2
		* ZLAG2(y - _PRED__y);
3	2503:15	PRED.y = _OLD_PRED.y;
3	2503:15	RESID.y = PRED.y - ACTUAL.y;
3	2503:15	ERROR.y = PRED.y - y;

The `_PRED__` prefixed variables are temporary program variables used so that the lags of the residuals are the correct residuals and not the ones redefined by this equation. Note that this is equivalent to the statements explicitly written in the section “[General Form for ARMA Models](#)” on page 1197.

You can also restrict the autoregressive parameters to zero at selected lags. For example, if you wanted autoregressive parameters at lags 1, 12, and 13, you can use the following statements:

```
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 13, , 1 12 13 )
  fit y / list;
run;
```

These statements generate the output shown in [Figure 19.61](#).

Figure 19.61 LIST Option Output for an AR Model with Lags at 1, 12, and 13

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	2511:4	PRED.y = a + b * x1 + c * x2;
1	2511:4	RESID.y = PRED.y - ACTUAL.y;
1	2511:4	ERROR.y = PRED.y - y;
2	2512:14	_PRED__y = PRED.y;
3	2512:15	_OLD_PRED.y = PRED.y + y_l1 * ZLAG1(y -
		_PRED__y) + y_l12 * ZLAG12(y -
		_PRED__y) + y_l13 * ZLAG13(
		y - _PRED__y);
3	2512:15	PRED.y = _OLD_PRED.y;
3	2512:15	RESID.y = PRED.y - ACTUAL.y;
3	2512:15	ERROR.y = PRED.y - y;

There are variations on the conditional least squares method, depending on whether observations at the start of the series are used to “warm up” the AR process. By default, the %AR conditional least squares method uses all the observations and assumes zeros for the initial lags of autoregressive terms. By using the M= option, you can request that %AR use the unconditional least squares (ULS) or maximum-likelihood (ML) method instead. For example,

```
proc model data=in;
  y = a + b * x1 + c * x2;
  %ar( y, 2, m=uls )
  fit y;
run;
```

Discussions of these methods is provided in the section “[AR Initial Conditions](#)” on page 1198.

By using the M=CLSn option, you can request that the first n observations be used to compute estimates of the initial autoregressive lags. In this case, the analysis starts with observation $n + 1$. For example:

```
proc model data=in;
  y = a + b * x1 + c * x2;
  %ar( y, 2, m=cls2 )
  fit y;
run;
```

You can use the %AR macro to apply an autoregressive model to the endogenous variable, instead of to the error term, by using the TYPE=V option. For example, if you want to add the five past lags of Y to the equation in the previous example, you could use %AR to generate the parameters and lags by using the following statements:

```
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 5, type=v )
  fit y / list;
run;
```

The preceding statements generate the output shown in [Figure 19.62](#).

Figure 19.62 LIST Option Output for an AR model of Y

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	2534:4	PRED.y = a + b * x1 + c * x2;
1	2534:4	RESID.y = PRED.y - ACTUAL.y;
1	2534:4	ERROR.y = PRED.y - y;
2	2535:15	_OLD_PRED.y = PRED.y + y_l1 * ZLAG1(y) + y_l2 * ZLAG2(y) + y_l3 * ZLAG3(y) + y_l4 * ZLAG4(y) + y_l5 * ZLAG5(y);
2	2535:15	PRED.y = _OLD_PRED.y;
2	2535:15	RESID.y = PRED.y - ACTUAL.y;
2	2535:15	ERROR.y = PRED.y - y;

This model predicts Y as a linear combination of X_1 , X_2 , an intercept, and the values of Y in the most recent five periods.

Unrestricted Vector Autoregression

To model the error terms of a set of equations as a vector autoregressive process, use the following form of the %AR macro after the equations:

```
%ar( process_name, nlags, variable_list )
```

The *process_name* value is any name that you supply for %AR to use in making names for the autoregressive parameters. You can use the %AR macro to model several different AR processes for different sets of equations by using different process names for each set. The process name ensures that the variable names used are unique. Use a short *process_name* value for the process if parameter estimates are to be written to an output data set. The %AR macro tries to construct parameter names less than or equal to eight characters, but this is limited by the length of *process_name*, which is used as a prefix for the AR parameter names.

The *variable_list* value is the list of endogenous variables for the equations.

For example, suppose that errors for equations Y_1 , Y_2 , and Y_3 are generated by a second-order vector autoregressive process. You can use the following statements:

```
proc model data=in;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 2, y1 y2 y3 )
  fit y1 y2 y3;
run;
```

which generate the following for Y_1 and similar code for Y_2 and Y_3 :

```
y1 = pred.y1 + name1_1_1*zlag1(y1-name_y1) +
      name1_1_2*zlag1(y2-name_y2) +
      name1_1_3*zlag1(y3-name_y3) +
      name2_1_1*zlag2(y1-name_y1) +
      name2_1_2*zlag2(y2-name_y2) +
      name2_1_3*zlag2(y3-name_y3) ;
```

Only the conditional least squares ($M=CLS$ or $M=CLSn$) method can be used for vector processes.

You can also use the same form with restrictions that the coefficient matrix be 0 at selected lags. For example, the following statements apply a third-order vector process to the equation errors with all the coefficients at lag 2 restricted to 0 and with the coefficients at lags 1 and 3 unrestricted:

```
proc model data=in;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 3, y1 y2 y3, 1 3 )
  fit y1 y2 y3;
```

You can model the three series Y1–Y3 as a vector autoregressive process in the variables instead of in the errors by using the TYPE=V option. If you want to model Y1–Y3 as a function of past values of Y1–Y3 and some exogenous variables or constants, you can use %AR to generate the statements for the lag terms. Write an equation for each variable for the nonautoregressive part of the model, and then call %AR with the TYPE=V option. For example,

```
proc model data=in;
  parms a1-a3 b1-b3;
  y1 = a1 + b1 * x;
  y2 = a2 + b2 * x;
  y3 = a3 + b3 * x;
  %ar( name, 2, y1 y2 y3, type=v )
  fit y1 y2 y3;
run;
```

The nonautoregressive part of the model can be a function of exogenous variables, or it can be intercept parameters. If there are no exogenous components to the vector autoregression model, including no intercepts, then assign zero to each of the variables. There must be an assignment to each of the variables before %AR is called.

```
proc model data=in;
  y1=0;
  y2=0;
  y3=0;
  %ar( name, 2, y1 y2 y3, type=v )
  fit y1 y2 y3;
run;
```

This example models the vector $Y=(Y1\ Y2\ Y3)'$ as a linear function only of its value in the previous two periods and a white noise error vector. The model has $18=(3 \times 3 + 3 \times 3)$ parameters.

Syntax of the %AR Macro

There are two cases of the syntax of the %AR macro. When restrictions on a vector AR process are not needed, the syntax of the %AR macro has the general form

%AR (name , nlag < ,endolist < , laglist > > < ,M= method > < ,TYPE= V>) ;

where

<i>name</i>	specifies a prefix for %AR to use in constructing names of variables needed to define the AR process. If the <i>endolist</i> is not specified, the endogenous list defaults to <i>name</i> , which must be the name of the equation to which the AR error process is to be applied. The <i>name</i> value cannot exceed 32 characters.
<i>nlag</i>	is the order of the AR process.
<i>endolist</i>	specifies the list of equations to which the AR process is to be applied. If more than one name is given, an unrestricted vector process is created with the structural residuals of all the equations included as regressors in each of the equations. If not specified, <i>endolist</i> defaults to <i>name</i> .
<i>laglist</i>	specifies the list of lags at which the AR terms are to be added. The coefficients of the terms at lags not listed are set to 0. All of the listed lags must be less than or equal to <i>nlag</i> ,

and there must be no duplicates. If not specified, the *laglist* defaults to all lags 1 through *nlag*.

- M=method** specifies the estimation method to implement. Valid values of M= are CLS (conditional least squares estimates), ULS (unconditional least squares estimates), and ML (maximum likelihood estimates). M=CLS is the default. Only M=CLS is allowed when more than one equation is specified. The ULS and ML methods are not supported for vector AR models by %AR.
- TYPE=V** specifies that the AR process is to be applied to the endogenous variables themselves instead of to the structural residuals of the equations.

Restricted Vector Autoregression

You can control which parameters are included in the process, restricting to 0 those parameters that you do not include. First, use %AR with the DEFER option to declare the variable list and define the dimension of the process. Then, use additional %AR calls to generate terms for selected equations with selected variables at selected lags. For example,

```
proc model data=d;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 2, y1 y2 y3, defer )
  %ar( name, y1, y1 y2 )
  %ar( name, y2 y3, , 1 )
  fit y1 y2 y3;
run;
```

The error equations produced are as follows:

```
y1 = pred.y1 + name1_1_1*zlag1(y1-name_y1) +
      name1_1_2*zlag1(y2-name_y2) + name2_1_1*zlag2(y1-name_y1) +
      name2_1_2*zlag2(y2-name_y2) ;
y2 = pred.y2 + name1_2_1*zlag1(y1-name_y1) +
      name1_2_2*zlag1(y2-name_y2) + name1_2_3*zlag1(y3-name_y3) ;
y3 = pred.y3 + name1_3_1*zlag1(y1-name_y1) +
      name1_3_2*zlag1(y2-name_y2) + name1_3_3*zlag1(y3-name_y3) ;
```

This model states that the errors for Y1 depend on the errors of both Y1 and Y2 (but not Y3) at both lags 1 and 2, and that the errors for Y2 and Y3 depend on the previous errors for all three variables, but only at lag 1.

%AR Macro Syntax for Restricted Vector AR

An alternative use of %AR is allowed to impose restrictions on a vector AR process by calling %AR several times to specify different AR terms and lags for different equations.

The first call has the general form

```
%AR( name, nlag, endlst , DEFER ) ;
```

where

<i>name</i>	specifies a prefix for %AR to use in constructing names of variables needed to define the vector AR process.
<i>nlag</i>	specifies the order of the AR process.
<i>endolist</i>	specifies the list of equations to which the AR process is to be applied.
DEFER	specifies that %AR is not to generate the AR process but is to wait for further information specified in later %AR calls for the same <i>name</i> value.

The subsequent calls have the general form

```
%AR( name, eqlist, varlist, laglist, TYPE= )
```

where

<i>name</i>	is the same as in the first call.
<i>eqlist</i>	specifies the list of equations to which the specifications in this %AR call are to be applied. Only names specified in the <i>endolist</i> value of the first call for the <i>name</i> value can appear in the list of equations in <i>eqlist</i> .
<i>varlist</i>	specifies the list of equations whose lagged structural residuals are to be included as regressors in the equations in <i>eqlist</i> . Only names in the <i>endolist</i> of the first call for the <i>name</i> value can appear in <i>varlist</i> . If not specified, <i>varlist</i> defaults to <i>endolist</i> .
<i>laglist</i>	specifies the list of lags at which the AR terms are to be added. The coefficients of the terms at lags not listed are set to 0. All of the listed lags must be less than or equal to the value of <i>nlag</i> , and there must be no duplicates. If not specified, <i>laglist</i> defaults to all lags 1 through <i>nlag</i> .

The %MA Macro

The SAS macro %MA generates programming statements for PROC MODEL for moving-average models. The %MA macro is part of SAS/ETS software, and no special options are needed to use the macro. The moving-average error process can be applied to the structural equation errors. The syntax of the %MA macro is the same as the %AR macro except there is no TYPE= argument.

When you are using the %MA and %AR macros combined, the %MA macro must follow the %AR macro. The following SAS/IML statements produce an ARMA(1, (1 3)) error process and save it in the data set MADAT2.

```
proc iml;
  phi = { 1 .2 };
  theta = { 1 .3 0 .5 };
  y = armasim( phi, theta, 0, .1, 200, 32565 );
  create madat2 from y[colname='y'];
  append from y;
quit;
```

The following PROC MODEL statements are used to estimate the parameters of this model by using maximum likelihood error structure:

```

title 'Maximum Likelihood ARMA(1, (1 3))';
proc model data=madat2;
  y=0;
  %ar( y, 1, , M=m1 )
  %ma( y, 3, , 1 3, M=m1 ) /* %MA always after %AR */
  fit y;
run;
title;

```

The estimates of the parameters produced by this run are shown in Figure 19.63.

Figure 19.63 Estimates from an ARMA(1, (1 3)) Process

Maximum Likelihood ARMA(1, (1 3))							
The MODEL Procedure							
Nonlinear OLS Summary of Residual Errors							
Equation	DF Model	DF Error	SSE	MSE	Root MSE	R-Square	Adj R-Sq
y	3	197	2.6383	0.0134	0.1157	-0.0067	-0.0169
RESID.y		197	1.9957	0.0101	0.1007		
Nonlinear OLS Parameter Estimates							
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t	Label		
y_l1	-0.10067	0.1187	-0.85	0.3973	AR(y) y lag1 parameter		
y_m1	-0.1934	0.0939	-2.06	0.0408	MA(y) y lag1 parameter		
y_m3	-0.59384	0.0601	-9.88	<.0001	MA(y) y lag3 parameter		

Syntax of the %MA Macro

There are two cases of the syntax for the %MA macro. When restrictions on a vector MA process are not needed, the syntax of the %MA macro has the general form

```
%MA ( name , nlag < , endolist < , laglist > > < , M= method > ) ;
```

where

name specifies a prefix for %MA to use in constructing names of variables needed to define the MA process and is the default *endolist*.

nlag is the order of the MA process.

endolist specifies the equations to which the MA process is to be applied. If more than one name is given, CLS estimation is used for the vector process.

<i>laglist</i>	specifies the lags at which the MA terms are to be added. All of the listed lags must be less than or equal to <i>nlag</i> , and there must be no duplicates. If not specified, the <i>laglist</i> defaults to all lags 1 through <i>nlag</i> .
<i>M=method</i>	specifies the estimation method to implement. Valid values of <i>M=</i> are CLS (conditional least squares estimates), ULS (unconditional least squares estimates), and ML (maximum likelihood estimates). <i>M=CLS</i> is the default. Only <i>M=CLS</i> is allowed when more than one equation is specified in the <i>endolist</i> .

%MA Macro Syntax for Restricted Vector Moving-Average

An alternative use of %MA is allowed to impose restrictions on a vector MA process by calling %MA several times to specify different MA terms and lags for different equations.

The first call has the general form

```
%MA( name , nlag , endolist , DEFER ) ;
```

where

<i>name</i>	specifies a prefix for %MA to use in constructing names of variables needed to define the vector MA process.
<i>nlag</i>	specifies the order of the MA process.
<i>endolist</i>	specifies the list of equations to which the MA process is to be applied.
DEFER	specifies that %MA is not to generate the MA process but is to wait for further information specified in later %MA calls for the same <i>name</i> value.

The subsequent calls have the general form

```
%MA( name, eqlist, varlist, laglist )
```

where

<i>name</i>	is the same as in the first call.
<i>eqlist</i>	specifies the list of equations to which the specifications in this %MA call are to be applied.
<i>varlist</i>	specifies the list of equations whose lagged structural residuals are to be included as regressors in the equations in <i>eqlist</i> .
<i>laglist</i>	specifies the list of lags at which the MA terms are to be added.

Distributed Lag Models and the %PDL Macro

In the following example, the variable *y* is modeled as a linear function of *x*, the first lag of *x*, the second lag of *x*, and so forth:

$$y_t = a + b_0x_t + b_1x_{t-1} + b_2x_{t-2} + b_3x_{t-3} + \dots + b_nx_{t-n}$$

Models of this sort can introduce a great many parameters for the lags, and there may not be enough data to compute accurate independent estimates for them all. Often, the number of parameters is reduced by assuming that the lag coefficients follow some pattern. One common assumption is that the lag coefficients follow a polynomial in the lag length

$$b_i = \sum_{j=0}^d \alpha_j (i)^j$$

where d is the degree of the polynomial used. Models of this kind are called *Almon lag models*, *polynomial distributed lag models*, or *PDLs* for short. For example, Figure 19.64 shows the lag distribution that can be modeled with a low-order polynomial. Endpoint restrictions can be imposed on a PDL to require that the lag coefficients be 0 at the 0th lag, or at the final lag, or at both.

Figure 19.64 Polynomial Distributed Lags

For linear single-equation models, SAS/ETS software includes the PDLREG procedure for estimating PDL models. See Chapter 21, “[The PDLREG Procedure](#),” for a more detailed discussion of polynomial distributed lags and an explanation of endpoint restrictions.

Polynomial and other distributed lag models can be estimated and simulated or forecast with PROC MODEL. For polynomial distributed lags, the %PDL macro can generate the needed programming statements automatically.

The %PDL Macro

The SAS macro %PDL generates the programming statements to compute the lag coefficients of polynomial distributed lag models and to apply them to the lags of variables or expressions.

To use the %PDL macro in a model program, you first call it to declare the lag distribution; later, you call it again to apply the PDL to a variable or expression. The first call generates a PARMS statement for the polynomial parameters and assignment statements to compute the lag coefficients. The second call generates an expression that applies the lag coefficients to the lags of the specified variable or expression. A PDL can be declared only once, but it can be used any number of times (that is, the second call can be repeated).

The initial declaratory call has the general form

```
%PDL ( pdlname, nlags, degree , R=code , OUTEST=dataset );
```

where *pdlname* is a name (up to 32 characters) that you give to identify the PDL, *nlags* is the lag length, and *degree* is the degree of the polynomial for the distribution. The *R=code* is optional for endpoint restrictions. The value of *code* can be FIRST (for upper), LAST (for lower), or BOTH (for both upper and lower endpoints). See Chapter 21, “The PDLREG Procedure,” for a discussion of endpoint restrictions. The option *OUTEST=dataset* creates a data set that contains the estimates of the parameters and their covariance matrix.

The later calls to apply the PDL have the general form

```
%PDL( pdlname, expression )
```

where *pdlname* is the name of the PDL and *expression* is the variable or expression to which the PDL is to be applied. The *pdlname* given must be the same as the name used to declare the PDL.

The following statements produce the output in [Figure 19.65](#):

```
proc model data=in list;
  parms int pz;
  %pdl(xpdl,5,2);
  y = int + pz * z + %pdl(xpdl,x);
  %ar(y,2,M=ULS);
  id i;
  fit y / out=model1 outresid converge=1e-6;
run;
```

Figure 19.65 %PDL Macro Estimates

The MODEL Procedure					
Nonlinear OLS Estimates					
Term	Estimate	Approx Std Err	t Value	Approx Pr > t	Label
XPDL_L0	1.568788	0.0935	16.77	<.0001	PDL(XPDL,5,2) coefficient for lag0
XPDL_L1	0.564917	0.0328	17.22	<.0001	PDL(XPDL,5,2) coefficient for lag1
XPDL_L2	-0.05063	0.0593	-0.85	0.4155	PDL(XPDL,5,2) coefficient for lag2
XPDL_L3	-0.27785	0.0517	-5.37	0.0004	PDL(XPDL,5,2) coefficient for lag3
XPDL_L4	-0.11675	0.0368	-3.17	0.0113	PDL(XPDL,5,2) coefficient for lag4
XPDL_L5	0.43267	0.1362	3.18	0.0113	PDL(XPDL,5,2) coefficient for lag5

This second example models two variables, Y1 and Y2, and uses two PDLs:

```
proc model data=in;
  parms int1 int2;
  %pdl( logxpdl, 5, 3 )
  %pdl( zpd1, 6, 4 )
  y1 = int1 + %pdl( logxpdl, log(x) ) + %pdl( zpd1, z );
  y2 = int2 + %pdl( zpd1, z );
  fit y1 y2;
run;
```

A (5,3) PDL of the log of X is used in the equation for Y1. A (6,4) PDL of Z is used in the equations for both Y1 and Y2. Since the same ZPDL is used in both equations, the lag coefficients for Z are the same for the Y1 and Y2 equations, and the polynomial parameters for ZPDL are shared by the two equations. See [Example 19.5](#) for a complete example and comparison with PDLREG.

Input Data Sets

DATA= Input Data Set

For FIT tasks, the DATA= option specifies which input data set to use in estimating parameters. Variables in the model program are looked up in the DATA= data set and, if found, their attributes (type, length, label, and format) are set to be the same as those in the DATA= data set (if not defined otherwise within PROC MODEL).

ESTDATA= Input Data Set

The ESTDATA= option specifies an input data set that contains an observation that gives values for some or all of the model parameters. The data set can also contain observations that give the rows of a covariance matrix for the parameters.

Parameter values read from the ESTDATA= data set provide initial starting values for parameters estimated. Observations that provide covariance values, if any are present in the ESTDATA= data set, are ignored.

The ESTDATA= data set is usually created by the OUTEST= option in a previous FIT statement. You can also create an ESTDATA= data set with a SAS DATA step program. The data set must contain a numeric variable for each parameter to be given a value or covariance column. The name of the variable in the ESTDATA= data set must match the name of the parameter in the model. Parameters with names longer than 32 characters cannot be set from an ESTDATA= data set. The data set must also contain a character variable `_NAME_` of length 32. `_NAME_` has a blank value for the observation that gives values to the parameters. `_NAME_` contains the name of a parameter for observations that define rows of the covariance matrix.

More than one set of parameter estimates and covariances can be stored in the ESTDATA= data set if the observations for the different estimates are identified by the variable `_TYPE_`. `_TYPE_` must be a character variable of length 8. The TYPE= option is used to select for input the part of the ESTDATA= data set for which the `_TYPE_` value matches the value of the TYPE= option.

In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used.

The following SAS statements generate the ESTDATA= data set shown in [Figure 19.66](#). The second FIT statement uses the TYPE= option to select the estimates from the GMM estimation as starting values for the FIML estimation.

```
/* Generate test data */
data gmm2;
  do t=1 to 50;
    x1 = sqrt(t) ;
    x2 = rannor(10) * 10;
    y1 = -.002 * x2 * x2 - .05 / x2 - 0.001 * x1 * x1;
    y2 = 0.002* y1 + 2 * x2 * x2 + 50 / x2 + 5 * rannor(1);
    y1 = y1 + 5 * rannor(1);
    z1 = 1; z2 = x1 * x1; z3 = x2 * x2; z4 = 1.0/x2;
    output;
  end;
run;
```

```

proc model data=gmm2 ;
  exogenous x1 x2;
  parms a1 a2 b1 2.5 b2 c2 55 d1;
  inst b1 b2 c2 x1 x2;
  y1 = a1 * y2 + b1 * x1 * x1 + d1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;

  fit y1 y2 / 3sls gmm kernel=(qs,1,0.2) outest=gmmest;

  fit y1 y2 / fiml type=gmm estdata=gmmest;
run;

proc print data=gmmest;
run;

```

Figure 19.66 ESTDATA= Data Set

		—		S		—			
		N		T		A		U	
		A		Y		T		S	
		O		M		P		E	
		b		E		E		S	
		s		—		—		—	

on the sum of the weights for all observations. See the description of the VARDEF= option for the definition of **D**.

The degrees-of-freedom correction for a shared parameter is computed by using the average number of observations used in its estimation.

The MISSING=PAIRWISE option is not valid for the GMM and FIML estimation methods.

For the instrumental variables estimation methods (2SLS, 3SLS), when an instrument is missing for an observation, that observation is dropped for all equations, regardless of the MISSING= option.

PARMSDATA= Input Data Set

The option PARMSDATA= reads values for all parameters whose names match the names of variables in the PARMSDATA= data set. Values for any or all of the parameters in the model can be reset by using the PARMSDATA= option. The PARMSDATA= option goes in the PROC MODEL statement, and the data set is read before any FIT or SOLVE statements are executed.

In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used. Together, the OUTPARMS= and PARMSDATA= options enable you to change part of a model and recompile the new model program without the need to reestimate equations that were not changed.

Suppose you have a large model with parameters estimated and you now want to replace one equation, **Y**, with a new specification. Although the model program must be recompiled with the new equation, you don't need to reestimate all the equations, just the one that changed.

Using the OUTPARMS= and PARMSDATA= options, you could do the following:

```
proc model model=oldmod outparms=temp; run;
proc model outmodel=newmod parmsdata=temp data=in;
    ... include new model definition with changed y eq. here ...
    fit y;
run;
```

The model file NEWMOD then contains the new model and its estimated parameters plus the old models with their original parameter values.

SDATA= Input Data Set

The SDATA= option allows a cross-equation covariance matrix to be input from a data set. The **S** matrix read from the SDATA= data set, specified in the FIT statement, is used to define the objective function for the OLS, N2SLS, SUR, and N3SLS estimation methods and is used as the initial **S** for the methods that iterate the **S** matrix.

Most often, the SDATA= data set has been created by the OUTS= or OUTSUSED= option in a previous FIT statement. The OUTS= and OUTSUSED= data sets from a FIT statement can be read back in by a FIT statement in the same PROC MODEL step.

You can create an input SDATA= data set by using the DATA step. PROC MODEL expects to find a character variable **_NAME_** in the SDATA= data set as well as variables for the equations in the estimation or solution. For each observation with a **_NAME_** value that matches the name of an equation, PROC MODEL fills the

corresponding row of the **S** matrix with the values of the names of equations found in the data set. If a row or column is omitted from the data set, a 1 is placed on the diagonal for the row or column. Missing values are ignored, and since the **S** matrix is symmetric, you can include only a triangular part of the **S** matrix in the **SDATA=** data set with the omitted part indicated by missing values. If the **SDATA=** data set contains multiple observations with the same **_NAME_**, the last values supplied for the **_NAME_** are used. The structure of the expected data set is further described in the section “**OUTS= Data Set**” on page 1219.

Use the **TYPE=** option in the **PROC MODEL** or **FIT** statement to specify the type of estimation method used to produce the **S** matrix you want to input.

The following SAS statements are used to generate an **S** matrix from a GMM and a 3SLS estimation and to store that estimate in the data set **GMMS**:

```
proc model data=gmm2 ;
  exogenous x1 x2;
  parms a1 a2 b1 2.5 b2 c2 55 d1;
  inst b1 b2 c2 x1 x2;
  y1 = a1 * y2 + b1 * x1 * x1 + d1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;

  fit y1 y2 / 3sls gmm kernel=(qs,1,0.2)
             outest=gmmest outs=gmms;
run;

proc print data=gmms;
run;
```

The data set **GMMS** is shown in Figure 19.67.

Figure 19.67 **SDATA= Data Set**

Obs	_NAME_	_TYPE_	_NUSED_	y1	y2
1	y1	3SLS	50	27.1032	38.1599
2	y2	3SLS	50	38.1599	74.6253
3	y1	GMM	50	27.6248	32.2811
4	y2	GMM	50	32.2811	58.8387

VDATA= Input data set

The **VDATA=** option enables a variance matrix for GMM estimation to be input from a data set. When the **VDATA=** option is used in the **PROC MODEL** or **FIT** statement, the matrix that is input is used to define the objective function and is used as the initial **V** for the methods that iterate the **V** matrix.

Normally the **VDATA=** matrix is created from the **OUTV=** option in a previous **FIT** statement. Alternately an input **VDATA=** data set can be created by using the **DATA** step. Each row and column of the **V** matrix is associated with an equation and an instrument. The position of each element in the **V** matrix can then be indicated by an equation name and an instrument name for the row of the element and an equation name and an instrument name for the column. Each observation in the **VDATA=** data set is an element in the **V** matrix.

The row and column of the element are indicated by four variables (EQ_ROW, INST_ROW, EQ_COL, and INST_COL) that contain the equation name or instrument name. The variable name for an element is VALUE. Missing values are set to 0. Because the variance matrix is symmetric, only a triangular part of the matrix needs to be input.

The following SAS statements are used to generate a **V** matrix estimation from GMM and to store that estimate in the data set GMMV:

```
proc model data=gmm2;
  exogenous x1 x2;
  parms a1 a2 b2 b1 2.5 c2 55 d1;
  inst b1 b2 c2 x1 x2;
  y1 = a1 * y2 + b1 * x1 * x1 + d1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;

  fit y1 y2 / gmm outv=gmmv;
run;

proc print data=gmmv(obs=15);
run;
```

The data set GMM2 was generated by the example in the preceding ESTDATA= section. The **V** matrix stored in GMMV is selected for use in an additional GMM estimation by the following FIT statement:

```
fit y1 y2 / gmm vdata=gmmv;
run;
```

A partial listing of the GMMV data set is shown in Figure 19.68. There are a total of 78 observations in this data set. The **V** matrix is 12 by 12 for this example.

Figure 19.68 The First 15 Observations in the VDATA= Data Set

Output Data Sets

OUT= Data Set

For normalized form equations, the OUT= data set specified in the FIT statement contains residuals, actuals, and predicted values of the dependent variables computed from the parameter estimates. For general form equations, actual values of the endogenous variables are copied for the residual and predicted values.

The variables in the data set are as follows:

- BY variables
- RANGE variable
- ID variables
- `_ESTYPE_`, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, ITSUR, IT2SLS, IT3SLS, GMM, ITGMM, or FIML
- `_TYPE_`, a character variable of length 8 that identifies the type of observation: RESIDUAL, PREDICT, or ACTUAL
- `_WEIGHT_`, the weight of the observation in the estimation. The `_WEIGHT_` value is 0 if the observation was not used. It is equal to the product of the `_WEIGHT_` model program variable and the variable named in the WEIGHT statement, if any, or 1 if weights were not used.
- the WEIGHT statement variable if used
- the model variables. The dependent variables for the normalized form equations in the estimation contain residuals, actuals, or predicted values, depending on the `_TYPE_` variable, whereas the model variables that are not associated with estimated equations always contain actual values from the input data set.
- any other variables named in the OUTVARS statement. These can be program variables computed by the model program, CONTROL variables, parameters, or special variables in the model program.

The following SAS statements are used to generate and print an OUT= data set:

```
proc model data=gmm2;
    exogenous x1 x2;
    parms a1 a2 b2 b1 2.5 c2 55 d1;
    inst b1 b2 c2 x1 x2;
    y1 = a1 * y2 + b1 * x1 * x1 + d1;
    y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;

    fit y1 y2 / 3sls gmm out=resid outall ;
run;

proc print data=resid(obs=20);
run;
```

The data set GMM2 was generated by the example in the preceding ESTDATA= section above. A partial listing of the RESID data set is shown in [Figure 19.69](#).

OUTEST= Data Set

The OUTEST= data set contains parameter estimates and, if requested, estimates of the covariance of the parameter estimates.

The variables in the data set are as follows:

- BY variables
- _NAME_, a character variable of length 32, blank for observations that contain parameter estimates or a parameter name for observations that contain covariances
- _TYPE_, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, ITSUR, IT2SLS, IT3SLS, GMM, ITGMM, or FIML
- _STATUS_, variable that gives the convergence status of estimation. _STATUS_ = 0 when convergence criteria are met, = 1 when estimation converges with a note, = 2 when estimation converges with a warning, and = 3 when estimation fails to converge
- _NUSED_, the number of observations used in estimation
- the parameters estimated

If the COVOUT option is specified, an additional observation is written for each row of the estimate of the covariance matrix of parameter estimates, with the _NAME_ values that contain the parameter names for the rows. Parameter names longer than 32 characters are truncated.

OUTPARMS= Data Set

The option OUTPARMS= writes all the parameter estimates to an output data set. This output data set contains one observation and is similar to the OUTEST= data set, but it contains all the parameters, is not associated with any FIT task, and contains no covariances. The OUTPARMS= option is used in the PROC MODEL statement, and the data set is written at the end, after any FIT or SOLVE steps have been performed.

OUTS= Data Set

The OUTS= SAS data set contains the estimate of the covariance matrix of the residuals across equations. This matrix is formed from the residuals that are computed by using the parameter estimates.

The variables in the OUTS= data set are as follows:

- BY variables
- _NAME_, a character variable that contains the name of the equation
- _TYPE_, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, ITSUR, IT2SLS, IT3SLS, GMM, ITGMM, or FIML
- variables with the names of the equations in the estimation

Each observation contains a row of the covariance matrix. The data set is suitable for use with the SDATA= option in a subsequent FIT or SOLVE statement. (See the section “[Tests on Parameters](#)” on page 1186 in this chapter for an example of the SDATA= option.)

OUTSUDED= Data Set

The OUTSUDED= SAS data set contains the covariance matrix of the residuals across equations that is used to define the objective function. The form of the OUTSUDED= data set is the same as that for the OUTS= data set.

Note that OUTSUDED= is the same as OUTS= for the estimation methods that iterate the **S** matrix (ITOLS, IT2SLS, ITSUR, and IT3SLS). If the SDATA= option is specified in the FIT statement, OUTSUDED= is the same as the SDATA= matrix read in for the methods that do not iterate the **S** matrix (OLS, SUR, N2SLS, and N3SLS).

OUTV= Data Set

The OUTV= data set contains the estimate of the variance matrix, **V**. This matrix is formed from the instruments and the residuals that are computed by using the final parameter estimates obtained from the estimation method chosen.

An estimate of **V** obtained from 2SLS is used in GMM estimation. Hence if you input the dataset obtained from the OUTV statement in 2SLS into the VDATA statement while fitting GMM, you get the same result by fitting GMM directly without specifying the VDATA option.

ODS Table Names

PROC MODEL assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 19.4 ODS Tables Produced in PROC MODEL

ODS Table Name	Description	Option
ODS Tables Created by the FIT Statement		
AugGMMCovariance	Crossproducts matrix	GMM ITALL
ChowTest	Structural change test	CHOW=
CollinDiagnostics	Collinearity diagnostics	
ConfInterval	Profile likelihood confidence intervals	PRL=
ConvCrit	Convergence criteria for estimation	default
ConvergenceStatus	Convergence status	default
CorrB	Correlations of parameters	COVB/CORRB
CorrResiduals	Correlations of residuals	CORRS/COVS
CovB	Covariance of parameters	COVB/CORRB
CovResiduals	Covariance of residuals	CORRS/COVS
Crossproducts	Crossproducts matrix	ITALL/ITPRINT
DatasetOptions	Data sets used	default
DetResidCov	Determinant of the residuals	DETAILS
DWTest	Durbin Watson test	DW=
Equations	Listing of equations to estimate	default
EstSummaryMiss	Model summary statistics for PAIRWISE	MISSING=
EstSummaryStats	Objective, objective * N	default
FirstLagrMultEst	First order Lagrange Multiplier estimates	GMM ITALL
GMMCovariance	Crossproducts matrix	GMM DETAILS
GMMTestStats	GMM test statistics	GMM
Godfrey	Godfrey's serial correlation test	GF=
HausmanTest	Hausman's test table	HAUSMAN
HeteroTest	Heteroscedasticity test tables	BREUSCH/PAGEN
InvXPXMat	X'X inverse for system	I
IterInfo	Iteration printing	ITALL/ITPRINT
LagLength	Model lag length	default
MinSummary	Number of parameters, estimation kind	default
ModSummary	Listing of all categorized variables	default
ModVars	Listing of model variables and parameters	default
NormalityTest	Normality test table	NORMAL
ObsSummary	Identifies observations with errors	default
ObsUsed	Observations read, used, and missing.	default
ParameterEstimates	Parameter estimates	default
ParmChange	Parameter change vector	ITALL
ResidSummary	Summary of the SSE, MSE for the equations	default

TransitiveClosure	Transitive closure graph	GRAPH

The AugGMMCovariance table is the \mathbf{V} matrix augmented with the moment vector at iteration zero, produced when the ITALL option is used with the GMM option. If the \mathbf{V} matrix to be used in GMM is read in by the VDATA option, then AugGMMCovariance would be the same matrix augmented with the moment vectors. The GMMCovariance ODS output is produced only when you read in a covariance matrix to be used in the GMM method. This table is produced by using DETAILS option with the GMM option.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the MODEL procedure.

ODS Graph Names

PROC MODEL assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when you use ODS. The names are listed in Table 19.5.

To request these graphs, ODS Graphics must be enabled.

Table 19.5 ODS Graphics Produced by PROC MODEL

ODS Graph Name	Plot Description
ACFPlot	Autocorrelation of residuals
ActualByPredicted	Predicted versus actual plot
BlockDependencyPlot	Simulation dependency analysis
CooksD	Cook’s D plot
DiagnosticsPanel	Panel of all plots
IACFPlot	Inverse autocorrelation of residuals
QQPlot	Q-Q plot of residuals
PACFPlot	Partial autocorrelation of residuals
ResidualHistogram	Histogram of the residuals
StudentResidualPlot	Studentized residual plot

Details: Simulation by the MODEL Procedure

The *solution*, given the vector \mathbf{k} , of the following nonlinear system of equations is the vector \mathbf{u} that satisfies this equation:

$$\mathbf{q}(\mathbf{u}, \mathbf{k}, \boldsymbol{\theta}) = 0$$

A *simulation* is a set of solutions \mathbf{u}_t for a specific sequence of vectors \mathbf{k}_t .

Model simulation can be performed to do the following:

- check how well the model predicts the actual values over the historical period
- investigate the sensitivity of the solution to changes in the input values or parameters
- examine the dynamic characteristics of the model
- check the stability of the simultaneous solution
- estimate the statistical distribution of the predicted values of the nonlinear model using Monte Carlo methods

By combining the various solution modes with different input data sets, model simulation can answer many different questions about the model. This section presents details of model simulation and solution.

Solution Modes

The following solution modes are commonly used:

- The *dynamic simultaneous forecast* mode is used for forecasting with the model. Collect the historical data on the model variables, the future assumptions of the exogenous variables, and any prior information on the future endogenous values, and combine them in a SAS data set. Use the FORECAST option in the SOLVE statement.
- The *dynamic simultaneous simulation* mode is often called *ex post simulation*, *historical simulation*, or *ex post forecasting*. Use the DYNAMIC option. This mode is the default.
- The *static simultaneous simulation* mode can be used to examine the within-period performance of the model without the complications of previous period errors. Use the STATIC option.
- The *NAHEAD=n dynamic simultaneous simulation* mode can be used to see how well *n*-period-ahead forecasting would have performed over the historical period. Use the NAHEAD=*n* option.

The different solution modes are explained in detail in the following sections.

Dynamic and Static Simulations

In model simulation, either solved values or actual values from the data set can be used to supply lagged values of an endogenous variable. A *dynamic* solution refers to a solution obtained by using only solved values for the lagged values. Dynamic mode is used both for forecasting and for simulating the dynamic properties of the model.

A *static* solution refers to a solution obtained by using the actual values when available for the lagged endogenous values. Static mode is used to simulate the behavior of the model without the complication of previous period errors. Dynamic simulation is the default.

If you want to use static values for lags only for the first n observations, and dynamic values thereafter, specify the `START= n` option. For example, if you want a dynamic simulation to start after observation twenty-four, specify `START=24` on the `SOLVE` statement. If the model being simulated had a value lagged for four time periods, then this value would start using dynamic values when the simulation reached observation number 28.

n -Period-Ahead Forecasting

Suppose you want to regularly forecast 12 months ahead and produce a new forecast each month as more data becomes available. n -period-ahead forecasting allows you to test how well you would have done over time if you had been using your model to forecast one year ahead.

To see how well a model predicts n time periods in the future, perform an n -period-ahead forecast on real data and compare the forecast values with the actual values.

n -period-ahead forecasting refers to using dynamic values for the lagged endogenous variables only for lags 1 through $n-1$. For example, one-period-ahead forecasting, specified by the `NAHEAD=1` option in the `SOLVE` statement, is the same as if a static solution had been requested. Specifying `NAHEAD=2` produces a solution that uses dynamic values for lag one and static, actual, values for longer lags.

The following example is a two-year-ahead dynamic simulation. The output is shown in [Figure 19.70](#).

```
data yearly;
  input year x1 x2 x3 y1 y2 y3;
  datalines;
84 4 9 0 7 4 5
85 5 6 1 1 27 4
86 3 8 2 5 8 2
87 2 10 3 0 10 10
88 4 7 6 20 60 40
89 5 4 8 40 40 40
90 3 2 10 50 60 60
91 2 5 11 40 50 60
;
run;

proc model data=yearly outmodel=yearlyModel;
  endogenous y1 y2 y3;
  exogenous x1 x2 x3;

  y1 = 2 + 3*x1 - 2*x2 + 4*x3;
  y2 = 4 + lag2( y3 ) + 2*y1 + x1;
  y3 = lag3( y1 ) + y2 - x2;
```

```

solve y1 y2 y3 / nahead=2 out=c;
run;

proc print data=c;
run;

```

Figure 19.70 NAHEAD Summary Report

The MODEL Procedure

Solution Summary	
Variables Solved	3
Simulation Lag Length	3
Solution Method	NEWTON
CONVERGE=	1E-8
Maximum CC	0
Maximum Iterations	1
Total Iterations	8
Average Iterations	1
Observations Processed	
Read	20
Lagged	12
Solved	8
First	5
Last	8
Variables Solved For y1 y2 y3	

The C data set is shown in [Figure 19.71](#):

Figure 19.71 C Data Set

Obs	_TYPE_	_MODE_	_LAG_	_ERRORS_	y1	y2	y3	x1	x2	x3
1	PREDICT	SIMULATE	0	0	0	10	7	2	10	3
2	PREDICT	SIMULATE	1	0	24	58	52	4	7	6
3	PREDICT	SIMULATE	1	0	41	101	102	5	4	8
4	PREDICT	SIMULATE	1	0	47	141	139	3	2	10
5	PREDICT	SIMULATE	1	0	42	130	145	2	5	11

The preceding two-year-ahead simulation can be emulated without using the NAHEAD= option by the following PROC MODEL statements:

```
proc model data=yearly model=yearlyModel;
  range year = 87 to 88;
  solve y1 y2 y3 / dynamic solveprint;
run;

  range year = 88 to 89;
  solve y1 y2 y3 / dynamic solveprint;
run;

  range year = 89 to 90;
  solve y1 y2 y3 / dynamic solveprint;
run;

  range year = 90 to 91;
  solve y1 y2 y3 / dynamic solveprint;
```

The totals shown under “Observations Processed” in [Figure 19.70](#) are equal to the sum of the four individual runs.

Simulation and Forecasting

You can perform a simulation of your model or use the model to produce forecasts. *Simulation* refers to the determination of the endogenous or dependent variables as a function of the input values of the other variables, even when actual data for some of the solution variables are available in the input data set. The simulation mode is useful for verifying the fit of the model parameters. Simulation is selected by the SIMULATE option in the SOLVE statement. Simulation mode is the default.

In forecast mode, PROC MODEL solves only for those endogenous variables that are missing in the data set. The actual value of an endogenous variable is used as the solution value whenever nonmissing data for it is available in the input data set. Forecasting is selected by the FORECAST option in the SOLVE statement.

For example, an econometric forecasting model can contain an equation to predict future tax rates, but tax rates are usually set in advance by law. Thus, for the first year or so of the forecast, the predicted tax rate should really be exogenous. Or, you might want to use a prior forecast of a certain variable from a short-run forecasting model to provide the predicted values for the earlier periods of a longer-range forecast of a long-run model. A common situation in forecasting is when historical data needed to fill the initial lags of a dynamic model are available for some of the variables but have not yet been obtained for others. In this case, the forecast must start in the past to supply the missing initial lags. Clearly, you should use the actual data that are available for the lags. In all the preceding cases, the forecast should be produced by running the model in the FORECAST mode; simulating the model over the future periods would not be appropriate.

Monte Carlo Simulation

The accuracy of the forecasts produced by PROC MODEL depends on four sources of error (Pindyck and Rubinfeld 1981, pp. 405–406):

- The system of equations contains an implicit random error term ϵ

$$g(\mathbf{y}, \mathbf{x}, \hat{\boldsymbol{\theta}}) = \epsilon$$

where \mathbf{y} , \mathbf{x} , \mathbf{g} , $\hat{\boldsymbol{\theta}}$, and ϵ are vector valued.

- The estimated values of the parameters, $\hat{\theta}$, are themselves random variables.
- The exogenous variables might have been forecast themselves and therefore might contain errors.
- The system of equations might be incorrectly specified; the model only approximates the process modeled.

The `RANDOM=` option is used to request Monte Carlo (or stochastic) simulations to generate confidence intervals for errors that arise from the first two sources. The Monte Carlo simulations can be performed with ϵ , θ , or both vectors represented as random variables. The `SEED=` option is used to control the random number generator for the simulations. `SEED=0` forces the random number generator to use the system clock as its seed value.

In Monte Carlo simulations, repeated simulations are performed on the model for random perturbations of the parameters and the additive error term. The random perturbations follow a multivariate normal distribution with expected value of 0 and covariance described by a covariance matrix of the parameter estimates in the case of θ , or a covariance matrix of the equation residuals for the case of ϵ . `PROC MODEL` can generate both covariance matrices or you can provide them.

The `ESTDATA=` option specifies a data set that contains an estimate of the covariance matrix of the parameter estimates to use for computing perturbations of the parameters. The `ESTDATA=` data set is usually created by the `FIT` statement with the `OUTEST=` and `OUTCOV` options. When the `ESTDATA=` option is specified, the matrix read from the `ESTDATA=` data set is used to compute vectors of random shocks or perturbations for the parameters. These random perturbations are computed at the start of each repetition of the solution and added to the parameter values. The perturbed parameters are fixed throughout the solution range. If the covariance matrix of the parameter estimates is not provided, the parameters are not perturbed.

The `SDATA=` option specifies a data set that contains the covariance matrix of the residuals to use for computing perturbations of the equations. The `SDATA=` data set is usually created by the `FIT` statement with the `OUTS=` option. When `SDATA=` is specified, the matrix read from the `SDATA=` data set is used to compute vectors of random shocks or perturbations for the equations. These random perturbations are computed at each observation. The simultaneous solution satisfies the model equations plus the random shocks. That is, the solution is not a perturbation of a simultaneous solution of the structural equations; rather, it is a simultaneous solution of the stochastic equations by using the simulated errors. If the `SDATA=` option is not specified, the random shocks are not used.

The different random solutions are identified by the `_REP_` variable in the `OUT=` data set. An unperturbed solution with `_REP_=0` is also computed when the `RANDOM=` option is used. `RANDOM=n` produces $n + 1$ solution observations for each input observation in the solution range. If the `RANDOM=` option is not specified, the `SDATA=` and `ESTDATA=` options are ignored, and no Monte Carlo simulation is performed.

`PROC MODEL` does not have an automatic way of modeling the exogenous variables as random variables for Monte Carlo simulation. If the exogenous variables have been forecast, the error bounds for these variables should be included in the error bounds generated for the endogenous variables. If the models for the exogenous variables are included in `PROC MODEL`, then the error bounds created from a Monte Carlo simulation contain the uncertainty due to the exogenous variables.

Alternatively, if the distribution of the exogenous variables is known, the built-in random number generator functions can be used to perturb these variables appropriately for the Monte Carlo simulation. For example, if you know the forecast of an exogenous variable, X , has a standard error of 5.2 and the error is normally distributed, then the following statements can be used to generate random values for X :

```
x_new = x + 5.2 * rannor(456);
```

During a Monte Carlo simulation, the random number generator functions produce one value at each observation. It is important to use a different seed value for all the random number generator functions in the model program; otherwise, the perturbations will be correlated. For the unperturbed solution, `_REP_=0`, the random number generator functions return 0.

PROC UNIVARIATE can be used to create confidence intervals for the simulation (see the Monte Carlo simulation example in the section “[Getting Started: MODEL Procedure](#)” on page 1058).

Multivariate t Distribution Simulation

To perform a Monte Carlo analysis of models that have residuals distributed as a multivariate t , use the `ERRORMODEL` statement with either the $\sim t(\text{variance}, df)$ option or with the `CDF=t(variance, df)` option. The `CDF=` option specifies the distribution that is used for simulation so that the estimation can be done for one set of distributional assumptions and the simulation for another.

The following is an example of estimating and simulating a system of equations with t distributed errors by using the `ERRORMODEL` statement.

```
/* generate simulation data set */
data five;
  set xfrate end=last;
  if last then do;
    todate = date +5;
    do date = date to todate;
      output;
    end;
  end;
run;
```

The preceding DATA step generates the data set to request a five-days-ahead forecast. The following statements estimate and forecast the three forward-rate models of the following form.

$$\begin{aligned} rate_t &= rate_{t-1} + \mu * rate_{t-1} + v \\ v &= \sigma * rate_{t-1} * \epsilon \\ \epsilon &\sim N(0, 1) \end{aligned}$$

```

run;

```

The Monte Carlo simulation specified in the preceding example draws from a multivariate t distribution with constant degrees of freedom and forecasted variance, and it computes future states of DEMUSD1M, DEMUSD3M, and DEMUSD6M. The OUTSN= option in the FIT statement is used to specify the data set for the normalized Σ matrix. That is, the Σ matrix is created by crossing the normally distributed residuals. The normally distributed residuals are created from the t distributed residuals by using the normal inverse CDF and the t CDF. This matrix is a correlation matrix.

The distribution of DEMUSD1M on the fifth day is shown in the [Figure 19.72](#). The two curves overlaid on the graph are a kernel density estimation and a normal distribution fit to the results.

Figure 19.72 Distribution of DEMUSD1M

Alternate Distribution Simulation

As an alternate to the normal distribution, the `ERRORMODEL` statement can be used in a simulation to specify other distributions. The distributions available for simulation are Cauchy, chi-squared, F , Poisson, t , and uniform. An empirical distribution can also be used if the residuals are specified by using the `RESIDDATA=` option in the `SOLVE` statement.

Except for the t distribution, all of these alternate distributions are univariate but can be used together in a multivariate simulation. The `ERRORMODEL` statement applies to solved for equations only. That is, the normal form or general form equation referred to by the `ERRORMODEL` statement must be one of the equations you have selected in the `SOLVE` statement.

In the following example, two Poisson distributed variables are used to simulate the calls that arrive at and leave a call center.

```
data s;      /* Covariance between arriving and leaving */
  arriving = 1; leaving = 0.7; _name_ = "arriving";
  output;
  arriving = 0.7; leaving = 1.0; _name_ = "leaving";
  output;
run;

data calls;
  date = '20mar2001'd;
  output;
run;
```

The first DATA step generates a data set that contains a covariance matrix for the ARRIVING and LEAVING variables. The covariance is

$$\begin{vmatrix} 1 & .7 \\ .7 & 1 \end{vmatrix}$$

The following statements create the number of waiting clients data:

```
proc model data=calls;
  arriving = 0;
  errormodel arriving ~ poisson( 10 );
  leaving = 4;
  errormodel leaving ~ poisson( 11 );

  waiting = arriving - leaving;
  if waiting < 0 then waiting=0;
  outvars waiting;

  solve arriving leaving / random=500 sdata=s out=sim;
run;

title "Distribution of Clients Waiting";
proc univariate data=sim noprint;
  var waiting ;
  histogram waiting / cfill=ligr;
run;
```

The distribution of number of waiting clients is shown in [Figure 19.73](#).

Figure 19.73 Distribution of Number of Clients Waiting

Mixtures of Distributions—Copulas

The theory of copulas is what enables the MODEL procedure to combine and simulate multivariate distributions with different marginals. This section provides a brief overview of copulas.

Modeling a system of variables accurately is a difficult task. The underlying, ideal, distributional assumptions for each variable are usually different from each other. An individual variable might be best modeled as a t distribution or as a Poisson process. The correlation of the various variables are very important to estimate as well. A joint estimation of a set of variables would make it possible to estimate a correlation structure but would restrict the modeling to single, simple multivariate distribution (for example, the normal). Even with a simple multivariate distribution, the joint estimation would be computationally difficult and would have to deal with issues of missing data.

By using the MODEL procedure `ERRORMODEL` statement, you can combine and simulate from models of different distributions. The covariance matrix for the combined model is constructed by using the copula induced by the multivariate normal distribution. A copula is a function that couples joint distributions to their marginal distributions.

By default, the copula used in the MODEL procedure is based on the multivariate normal. This particular multivariate normal has zero mean and covariance matrix \mathbf{R} . The user provides \mathbf{R} , which can be created by using the following steps:

1. Each model is estimated separately and their residuals are saved.
2. The residuals for each model are converted to a normal distribution by using their CDFs, $F_i(\cdot)$, using the relationship $\Phi^{-1}(F(\epsilon_{it}))$.
3. These normal residuals are crossed to create a covariance matrix \mathbf{R} .

If the model of interest can be estimated jointly, such as multivariate T, then the OUTSN= option can be used to generate the correct covariance matrix.

A draw from this mixture of distributions is created by using the following steps that are performed automatically by the MODEL procedure.

1. Independent $N(0, 1)$ variables are generated.
2. These variables are transformed to a correlated set by using the covariance matrix \mathbf{R} .
3. These correlated normals are transformed to a uniform by using $\Phi(\cdot)$.
4. $F^{-1}(\cdot)$ is used to compute the final sample value.

Alternate Copulas

The Gaussian, t , and the normal mixture copula are available in the MODEL procedure. These copulas support asymmetric parameters and can use alternate estimation methods for creating the base covariance matrix.

The normal (Gaussian) copula is the default. A draw from a Gaussian copula is obtained from

$$\mathbf{x} = \mathbf{A}\mathbf{z}$$

where $\mathbf{z} \in R^d$ is a vector of independent random normal(0, 1) draws, $\mathbf{A} \in R^{d \times d}$ is the square root of the covariance matrix, \mathbf{R} . For the normal mixture and t copula, a draw is created as

$$\mathbf{x} = w\boldsymbol{\gamma} + \sqrt{w}\mathbf{A}\mathbf{z}$$

where w is a scalar random variable and $\boldsymbol{\gamma} \in R^d$ is a vector of asymmetry parameters. $\boldsymbol{\gamma}$ is specified in the SDATA= data set. If $W \sim \text{inverse gamma}(df/2, df/2)$, then \mathbf{x} is multivariate t or skewed t if $\boldsymbol{\gamma}$ is provided. When NORMALMIX is specified, w is distributed as a step function with each of the n positive variances, $v_1 \dots v_n$, having probability $p_1 \dots p_n$.

The covariance matrix $\mathbf{R} = \mathbf{A}'\mathbf{A}$ is specified with the SDATA= option. The vector of asymmetry parameters, $\boldsymbol{\gamma}$, defaults to zero or is specified in the SDATA= data set with _TYPE_=ASYM. The ASYM option specifies that the nonzero asymmetry vector, $\boldsymbol{\gamma}$, is to be used.

In the event the covariance matrix specified with the SDATA= option is not positive semidefinite the matrix is modified to be positive semidefinite. See Rebonato and Jäckel (1999) for more details.

The actual draw for an individual variable, y_i , depends on the marginal distribution of the variable, \tilde{F} , and the chosen copula F as

$$y_i = \tilde{F}_i^{-1}(F(x_i))$$

Archimedean Copulas

The three Archimedean copulas available in the MODEL procedure are the Clayton, Gumbel, and Frank copulas. Archimedean copulas require only a single parameter, θ , to define the joint distribution's covariance structure for a simulation problem. Therefore, a covariance matrix is not required to perform simulations that use Archimedean copulas, and the SDATA= option does not have to be specified for these simulations. For more information about Archimedean copulas, including the functional forms of the Clayton, Gumbel, and Frank copulas, see the section "Archimedean Copulas" in Chapter 10, "The COPULA Procedure."

Asymmetrical Copula Example

In this example, an asymmetrical t copula is used to correlate two uniform distributions. The asymmetrical parameter is varied over a range of values to demonstrate its effect. The resulting graphs is produced by using ODS graphics.

```
data histdata;
  do asym = -1.3 to 1.1 by .3;
    date='01aug2007'd;
    y = .5;
    z = .5;
    output;
  end;
run ;

/* Add the asymmetric parameter to cov mat */
data asym;
  do asym = -1.3 to 1.1 by .3;
    y = asym;
    z = 0;
    _name_ = " ";
    _type_ = "asym";
    output;
    y = 1;
    z = .65;
    _name_ = "y";
    _type_ = "cov";
    output;
    y = .65;
    z = 1;
    _name_ = "z";
    _type_ = "cov";
    output;
  end;
run;
```

```

proc model out=sim(where=(_REP_ > 0)) data=histdata sdata=asym;
  y = 0;
  errormodel y ~ Uniform(0,1);

  z = 0;
  errormodel z ~ Uniform(0,1);

  solve y z / random=500 seed=12345 copula=(t(5) asym );
  by asym;
run;

```

To produce a panel plot of this joint distribution, use the following SAS/GRAPH statements.

```

ods graphics on / height=800 width=800;
proc template;
  define statgraph myplot.panel;
    BeginGraph;
      entrytitle halign=left halign=center
        textattrs=GRAPHTITLETEXT "t Copula with a Range of Asymmetry";

      layout datapanel classvars=(asym) / rows=3 columns=3
        order=rowmajor height=1024 width=1420
        rowaxisopts=(griddisplay=on label=' ')
        columnaxisopts=(griddisplay=on label=' ');
      layout prototype;
        scatterplot x=z y=y ;
      endlayout;
    endlayout;
  EndGraph;
end;
run;

proc sgrender data=sim template='myplot.panel';
run;

```

Figure 19.74 *t* Copula with Asymmetry

Quasi-Random Number Generators

Traditionally high-discrepancy pseudo-random number generators are used to generate innovations in Monte Carlo simulations. Loosely translated, a high-discrepancy pseudo-random number generator is one in which there is very little correlation between the current number generated and the past numbers generated. This property is ideal if indeed independence of the innovations is required. If, on the other hand, the efficient spanning of a multidimensional space is desired, a low discrepancy, quasi-random number generator can be used. A quasi-random number generator produces numbers that have no random component.

A simple one-dimensional quasi-random sequence is the van der Corput sequence. Given a prime number r ($r \geq 2$), any integer has a unique representation in terms of base r . A number in the interval $[0,1)$ can be created by inverting the representation base power by base power. For example, consider $r=3$ and $n=1$, 1 in base 3 is

$$1_{10} = 1 \cdot 3^0 = 1_3$$

When the powers of 3 are inverted,

$$\phi(1) = \frac{1}{3}$$

Also, 11 in base 3 is

$$11_{10} = 1 \cdot 3^2 + 2 \cdot 3^0 = 102_3$$

When the powers of 3 are inverted,

$$\phi(11) = \frac{1}{9} + 2 \cdot \frac{1}{3} = \frac{7}{9}$$

The first 10 numbers in this sequence $\phi(1) \dots \phi(10)$ are provided below

$$0, \frac{1}{3}, \frac{2}{3}, \frac{1}{9}, \frac{4}{9}, \frac{7}{9}, \frac{2}{9}, \frac{5}{9}, \frac{8}{9}, \frac{1}{27}$$

As the sequence proceeds, it fills in the gaps in a uniform fashion.

Several authors have expanded this idea to many dimensions. Two versions supported by the MODEL procedure are the Sobol sequence (QUASI=SOBOL) and the Faure sequence (QUASI=FAURE). The Sobol sequence is based on binary numbers and is generally computationally faster than the Faure sequence. The Faure sequence uses the dimensionality of the problem to determine the number base to use to generate the sequence. The Faure sequence has better distributional properties than the Sobol sequence for dimensions greater than 8.

As an example of the difference between a pseudo-random number and a quasi-random number, consider simulating a bivariate normal with 100 draws.

Figure 19.75 Kernel Density of a Bivariate Normal produced by 100 Faure-Random Draws

Figure 19.76 Kernel Density of a Bivariate Normal produced by 100 Pseudo-Random Draws

Solution Mode Output

The following SAS statements dynamically forecast the solution to a nonlinear equation:

```
proc model data=sashelp.citimon;
  parameters a 0.010708 b -0.478849 c 0.929304;
  lhur = 1/(a * ip) + b + c * lag(lhur);
  solve lhur / out=sim forecast dynamic;
run;
```

The first page of output produced by the SOLVE step is shown in [Figure 19.77](#). This is the summary description of the model. The error message states that the simulation was aborted at observation 144 because of missing input values.

Figure 19.77 Solve Step Summary Output

```

Last	145
Failed	1
Variables Solved For	LHUR

This solution summary table includes the names of the input data set and the output data set followed by a description of the model. The table also indicates that the solution method defaulted to Newton's method. The remaining output is defined as follows.

Maximum CC	is the maximum convergence value accepted by the Newton procedure. This number is always less than the value for the CONVERGE= option.
Maximum Iterations	is the maximum number of Newton iterations performed at each observation and each replication of Monte Carlo simulations.
Total Iterations	is the sum of the number of iterations required for each observation and each Monte Carlo simulation.
Average Iterations	is the average number of Newton iterations required to solve the system at each step.
Solved	is the number of observations used times the number of random replications selected plus one, for Monte Carlo simulations. The one additional simulation is the original unperturbed solution. For simulations that do not involve Monte Carlo, this number is the number of observations used.

Summary Statistics

The STATS and THEIL options are used to select goodness-of-fit statistics. Actual values must be provided in the input data set for these statistics to be printed. When the RANDOM= option is specified, the statistics do not include the unperturbed (_REP_=0) solution.

STATS Option Output

The following statements show the addition of the STATS and THEIL options to the model in the previous section:

```
proc model data=sashelp.citimon;
  parameters a 0.010708 b -0.478849 c 0.929304;
  lhur= 1/(a * ip) + b + c * lag(lhur) ;
  solve lhur / out=sim dynamic stats theil;
  range date to '01nov91'd;
run;
```

The STATS output in Figure 19.80 and the THEIL output in Figure 19.81 are generated.

Figure 19.80 STATS Output

Statistics of fit							
Variable	R-Square		Label				
LHUR	0.7049		UNEMPLOYMENT RATE: ALL WORKERS, 16 YEARS				

The number of observations (Nobs), the number of observations with both predicted and actual values nonmissing (N), and the mean and standard deviation of the actual and predicted values of the determined variables are printed first. The next set of columns in the output are defined as follows:

$$\text{Mean Error} \quad \frac{1}{N} \sum_{j=1}^N (\hat{y}_j - y_j)$$

$$\text{Mean \% Error} \quad \frac{100}{N} \sum_{j=1}^N (\hat{y}_j - y_j)/y_j$$

$$\text{Mean Abs Error} \quad \frac{1}{N} \sum_{j=1}^N |\hat{y}_j - y_j|$$

$$\text{Mean Abs \% Error} \quad \frac{100}{N} \sum_{j=1}^N |(\hat{y}_j - y_j)/y_j|$$

$$\text{RMS Error} \quad \sqrt{\frac{1}{N} \sum_{j=1}^N (\hat{y}_j - y_j)^2}$$

$$\text{RMS \% Error} \quad 100 \sqrt{\frac{1}{N} \sum_{j=1}^N ((\hat{y}_j - y_j)/y_j)^2}$$

$$\text{R-square} \quad 1 - SSE/CSSA$$

$$SSE \quad \sum_{j=1}^N (\hat{y}_j - y_j)^2$$

$$SSA \quad \sum_{j=1}^N (y_j)^2$$

$$CSSA \quad SSA - \left(\sum_{j=1}^N y_j \right)^2$$

\hat{y} predicted value

y actual value

When the RANDOM= option is specified, the statistics do not include the unperturbed (_REP_=0) solution.

THEIL Option Output

The THEIL option specifies that Theil forecast error statistics be computed for the actual and predicted values and for the relative changes from lagged values. Mathematically, the quantities are

$$\hat{y}c = (\hat{y} - \text{lag}(y)) / \text{lag}(y)$$

$$yc = (y - \text{lag}(y)) / \text{lag}(y)$$

where $\hat{y}c$ is the relative change for the predicted value and yc is the relative change for the actual value.

Figure 19.81 THEIL Output

Theil Forecast Error Statistics								
Variable	N	MSE	Corr (R)	MSE Decomposition Proportions				
				Bias (UM)	Reg (UR)	Dist (UD)	Var (US)	Covar (UC)

Theil Forecast Error Statistics			
Variable	Inequality Coef		Label
	U1	U	
LHUR	0.1086	0.0539	UNEMPLOYMENT RATE: ALL WORKERS, 16 YEARS

Theil Relative Change Forecast Error Statistics								
Variable	N	Relative Change MSE	Corr (R)	MSE Decomposition Proportions				
				Bias (UM)	Reg (UR)	Dist (UD)	Var (US)	Covar (UC)
LHUR	142	0.0126	-0.08	0.09	0.85	0.06	0.43	0.47

Theil Relative Change Forecast Error Statistics			
Variable	Inequality Coef		Label
	U1	U	
LHUR	4.1226	0.8348	UNEMPLOYMENT RATE: ALL WORKERS, 16 YEARS

The columns have the following meaning:

Corr (R) is the correlation coefficient, ρ , between the actual and predicted values.

$$\rho = \frac{\text{cov}(y, \hat{y})}{\sigma_a \sigma_p}$$

where σ_p and σ_a are the standard deviations of the predicted and actual values.

Bias (UM) is an indication of systematic error and measures the extent to which the average values of the actual and predicted deviate from each other.

$$\frac{(E(y) - E(\hat{y}))^2}{\frac{1}{N} \sum_{t=1}^N (y_t - \hat{y}_t)^2}$$

Reg (UR) is defined as $(\sigma_p - \rho * \sigma_a)^2 / MSE$. Consider the regression

$$y = \alpha + \beta \hat{y}$$

If $\hat{\beta} = 1$, UR will equal zero.

Dist (UD) is defined as $(1 - \rho^2)\sigma_a\sigma_a / MSE$ and represents the variance of the residuals obtained by regressing y_c on \hat{y}_c .

Var (US) is the variance proportion. US indicates the ability of the model to replicate the degree of variability in the endogenous variable.

$$US = \frac{(\sigma_p - \sigma_a)^2}{MSE}$$

Covar (UC) represents the remaining error after deviations from average values and average variabilities have been accounted for.

$$UC = \frac{2(1 - \rho)\sigma_p\sigma_a}{MSE}$$

U1 is a statistic that measures the accuracy of a forecast defined as follows:

$$U1 = \frac{\sqrt{MSE}}{\sqrt{\frac{1}{N} \sum_{t=1}^N (y_t)^2}}$$

U is the Theil's inequality coefficient defined as follows:

$$U = \frac{\sqrt{MSE}}{\sqrt{\frac{1}{N} \sum_{t=1}^N (y_t)^2 + \frac{1}{N} \sum_{t=1}^N (\hat{y}_t)^2}}$$

MSE is the mean square error. In the case of the relative change Theil statistics, the MSE is computed as follows:

$$MSE = \frac{1}{N} \sum_{t=1}^N (\hat{y}_{c_t} - y_{c_t})^2$$

More information about these statistics can be found in the references Maddala (1977, pp. 344–347) and Pindyck and Rubinfeld (1981, pp. 364–365).

Goal Seeking: Solving for Right-Hand-Side Variables

The process of computing input values that are needed to produce target results is often called *goal seeking*. To compute a goal-seeking solution, use a SOLVE statement that lists the variables you want to solve for and provide a data set that contains values for the remaining variables.

Consider the following demand model for packaged rice

$$\text{quantity demanded} = \alpha_1 + \alpha_2 \text{price}^{2/3} + \alpha_3 \text{income}$$

where *price* is the price of the package and *income* is disposable personal income. The only variable the company has control over is the price it charges for rice. This model is estimated by using the following simulated data and PROC MODEL statements:

```
data demand;
  do t=1 to 40;
    price = (rannor(10) +5) * 10;
    income = 8000 * t ** (1/8);
    demand = 7200 - 1054 * price ** (2/3) +
              7 * income + 100 * rannor(1);
    output;
  end;
run;

data goal;
  demand = 85000;
  income = 12686;
run;
```

The goal is to find the price the company would have to charge to meet a sales target of 85,000 units. To do this, a data set is created with a DEMAND variable set to 85000 and with an INCOME variable set to 12686, the last income value.

The desired price is then determined by using the following PROC MODEL statements:

```
proc model data=demand
  outmodel=demandModel;
  demand = a1 - a2 * price ** (2/3) + a3 * income;
  fit demand / outest=demest;
  solve price / estdata=demest data=goal solveprint;
run;
```

The SOLVEPRINT option prints the solution values, number of iterations, and final residuals at each observation. The SOLVEPRINT output from this solve is shown in [Figure 19.82](#).

Figure 19.82 Goal Seeking, SOLVEPRINT Output

The MODEL Procedure							
Single-Equation Simulation							
Observation	1	Iterations	6	CC	0.000000	ERROR.demand	0.000000

Figure 19.82 *continued*

Solution Values	
	price
	33.59016

The output indicates that it took six Newton iterations to determine the PRICE of 33.5902, which makes the DEMAND value within 16E-11 of the goal of 85,000 units.

Consider a more ambitious goal of 100,000 units. The output shown in [Figure 19.83](#) indicates that the sales target of 100,000 units is not attainable according to this model.

```
data goal;
  demand = 100000;
  income = 12686;
run;

proc model model=demandModel;
  solve price / estdata=demest data=goal solveprint;
run;
```

Figure 19.83 Goal Seeking, Convergence Failure

The MODEL Procedure				
Single-Equation Simulation				
ERROR: Could not reduce norm of residuals in 10 subiterations.				
ERROR: The solution failed because 1 equations are missing or have extreme values for observation 1 at NEWTON iteration 1.				
Observation	1	Iteration	1	CC
		Missing	1	-1.000000
The MODEL Procedure				
Single-Equation Simulation				
--- Listing of Program Data Vector ---				
N:	12	ACTUAL.demand:	100000	ERROR.demand:
PRED.demand:	.	a1:	7126.437997	a2:
a3:	6.992694	demand:	100000	income:
price:	-0.000172			12686
@PRED.demand/@pri:	.			

The program data vector with the error note indicates that even after 10 subiterations, the norm of the residuals could not be reduced. The sales target of 100,000 units are unattainable with the given model. You might need to reformulate your model or collect more data to more accurately reflect the market response.

Numerical Solution Methods

If the SINGLE option is not used, PROC MODEL computes values that simultaneously satisfy the model equations for the variables named in the SOLVE statement. PROC MODEL provides three iterative methods, Newton, Jacobi, and Seidel, for computing a simultaneous solution of the system of nonlinear equations.

Single-Equation Solution

For normalized form equation systems, the solution either can simultaneously satisfy all the equations or can be computed for each equation separately, by using the actual values of the solution variables in the current period to compute each predicted value. By default, PROC MODEL computes a simultaneous solution. The SINGLE option in the SOLVE statement selects single-equation solutions.

Single-equation simulations are often used to produce residuals (which estimate the random terms of the stochastic equations) rather than the predicted values themselves. If the input data and range are the same as those used for parameter estimation, a static single-equation simulation reproduces the residuals of the estimation.

Newton's Method

The NEWTON option in the SOLVE statement requests Newton's method to simultaneously solve the equations for each observation. Newton's method is the default solution method. Newton's method is an iterative scheme that uses the derivatives of the equations with respect to the solution variables, \mathbf{J} , to compute a change vector as

$$\Delta \mathbf{y}^i = \mathbf{J}^{-1} \mathbf{q}(\mathbf{y}^i, \mathbf{x}, \boldsymbol{\theta})$$

PROC MODEL builds and solves \mathbf{J} by using efficient sparse matrix techniques. The solution variables \mathbf{y}^i at the i th iteration are then updated as

$$\mathbf{y}^{i+1} = \mathbf{y}^i + d \times \Delta \mathbf{y}^i$$

where d is a damping factor between 0 and 1 chosen iteratively so that

$$\|\mathbf{q}(\mathbf{y}^{i+1}, \mathbf{x}, \boldsymbol{\theta})\| < \|\mathbf{q}(\mathbf{y}^i, \mathbf{x}, \boldsymbol{\theta})\|$$

The number of subiterations that are allowed for finding a suitable d is controlled by the MAXSUBITER= option. The number of iterations of Newton's method that are allowed for each observation is controlled by MAXITER= option. See Ortega and Rheinbolt (1970) for more details.

Optimization Method

The OPTIMIZE option in the SOLVE statement requests that an optimization algorithm be used to minimize a norm of the errors in equations subject to constraints on the solution variables. The OPTIMIZE method is the only solution method that supports constraints on solution variables that are specified using the BOUNDS and RESTRICT statements. Constraints are ignored by the other solution methods. The OPTIMIZE method performs the following optimization:

$$\begin{array}{ll} \text{minimize} & \|\mathbf{q}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})\| \\ \text{subject to} & \mathbf{y}_l \leq \mathbf{y} \leq \mathbf{y}_u \\ \text{and} & f(\mathbf{y}) \geq 0 \end{array}$$

The norm used in the minimization process is

$$\|\mathbf{q}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})\| = \mathbf{q}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})' \text{diag}(\mathbf{S})^{-1} \mathbf{q}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})$$

where the \mathbf{S} matrix is the covariance of equation errors that is specified by the `SDATA=` option in the `SOLVE` statement. If no `SDATA=` option is specified, the identity matrix is used. Both strict inequality and inequality constraints on the solution variables can be imposed using the `BOUND`s or `RESTRICT` statement. For bounded problems, each lower and upper strict inequality is transformed into an inequality by using the equations

$$y_l = (y_{\text{lower strict}} + \epsilon)/(1 - \epsilon)$$

$$y_u = (y_{\text{upper strict}} - \epsilon)/(1 + \epsilon)$$

When strict inequality expressions are imposed using the `RESTRICT` statement, these expressions are transformed into an inequality by using the equation

$$f(\mathbf{y}) = (f_{\text{strict}}(\mathbf{y}) + \epsilon)/(1 - \epsilon)$$

where $f_{\text{strict}}(\mathbf{y})$ is a nonlinear strict inequality constraint. The tolerance ϵ is controlled by the `EPSILON=` option in the `SOLVE` statement and defaults to 10^{-8} . To achieve the best performance from the minimization algorithm, both the first and second analytic derivatives of the equation errors with respect to the solution variables are used to compute the gradient and second derivatives of the objective function, $\|\mathbf{q}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})\|$. Analytic derivatives of the restriction expressions that are used to specify constraints are also used in the minimization. The gradient of the objective function is

$$\nabla \|\mathbf{q}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})\| = 2 \mathbf{J}' \text{diag}(\mathbf{S})^{-1} \mathbf{q}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})$$

The matrix of second derivatives of the objective function with respect to the solution variables is

$$\frac{\partial^2 \|\mathbf{q}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})\|}{\partial \mathbf{y}^2} = 2 \left(\mathbf{J}' \text{diag}(\mathbf{S})^{-1} \mathbf{J} + \sum_{k=1}^d \frac{\partial^2 q_k(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})}{\partial \mathbf{y}^2} \text{diag}(\mathbf{S})^{-1} q_k(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta}) \right)$$

where d is the number of equations.

The algorithm that is used to find a minimum of $\|\mathbf{q}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})\|$ subject to bounds on the solution variables employs the interior point technique for nonlinear optimization problems. For further information about this optimization method, see Chapter 9, “The Nonlinear Programming Solver” (*SAS/OR User’s Guide: Mathematical Programming*).

When constraints are active in a solution, the minimum value of the objective function, $\|\mathbf{q}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})\|$, is typically greater than 0. The diagnostic quantities that are produced by the `OUTOBJVALS` and `OUTVIOLATIONS` options are available to help identify and characterize solutions that have active bounds constraints. The following program contains a boundary constraint that becomes active in steps 6, 8, 10, 12, 13, and 16 of a Monte Carlo simulation:

```

proc model data=d sdata=s;
  dependent rate stock;
  parms theta    0.2
        kappa    0.002
        sigma    0.4
        sinit    1
        vol      .1;
  id i;

  bounds rate >= 0;

  rate  = zlag(rate) + kappa*(theta - zlag(rate));
  h.rate = sigma**2 * zlag(rate);
  eq.stock = log(stock/sinit) - (rate + vol*vol/2);
  h.stock = vol**2;

  solve / optimize converge=1e-6 seed=1 random=1 out=o outobjvals outviolations;
quit;

proc print data=o(where=(_objval_>1e-6));
run;

```

Figure 19.84 shows how the OUTOBJVALS option can be used to identify simulation steps with an active bounds constraint, and how the OUTVIOLATIONS option can be used to determine that the RATE equation is not satisfied for those steps.

Jacobi Method

The JACOBI option in the SOLVE statement selects a matrix-free alternative to Newton's method. This method is the traditional nonlinear Jacobi method found in the literature. The Jacobi method as implemented in PROC MODEL substitutes predicted values for the endogenous variables and iterates until a fixed point is reached. Then necessary derivatives are computed only for the diagonal elements of the jacobian, **J**.

If the normalized form equation is

$$y = f(y, x, \theta)$$

the Jacobi iteration has the form

$$y^{i+1} = f(y^i, x, \theta)$$

Seidel Method

The Seidel method is an order-dependent alternative to the Jacobi method. You select the Seidel method by specifying the SEIDEL option in the SOLVE statement. The Seidel method is like the Jacobi method, except that in the Seidel method the model is further edited to substitute the predicted values into the solution variables immediately after they are computed. The Seidel method thus differs from the other methods in that the values of the solution variables are not fixed within an iteration. With the other methods, the order of the equations in the model program makes no difference, but the Seidel method might work much differently when the equations are specified in a different sequence. This fixed-point method is the traditional nonlinear Seidel method found in the literature.

The iteration has the form

$$y_j^{i+1} = f(\hat{y}^i, x, \theta)$$

where y_j^{i+1} is the j th equation variable at the i th iteration and

$$\hat{y}^i = (y_1^{i+1}, y_2^{i+1}, y_3^{i+1}, \dots, y_{j-1}^{i+1}, y_j^i, y_{j+1}^i, \dots, y_g^i)'$$

If the model is recursive, and if the equations are in recursive order, the Seidel method converges at once. If the model is block-recursive, the Seidel method might converge faster if the equations are grouped by block and the blocks are placed in block-recursive order. The BLOCK option can be used to determine the block-recursive form.

Jacobi and Seidel Methods with General Form Equations

Jacobi and Seidel solution methods support general form equations.

There are two cases where derivatives are (automatically) computed. The first case is for equations with the solution variable on the right-hand side and on the left-hand side of the equation

$$y^i = f(x, y^i)$$

In this case the derivative of `ERROR.y` with respect to y is computed, and the new y approximation is computed as

$$y^{i+1} = y^i - \frac{f(x, y^i) - y^i}{\partial(f(x, y^i) - y^i)/\partial y}$$

The second case is a system of equations that contains one or more `EQ.var` equations. In this case, the MODEL procedure assigns a unique solution variable to each equation if such an assignment exists. Use the DETAILS option in the SOLVE statement to print a listing of the assigned variables.

Once the assignment is made, the new y approximation is computed as

$$y^{i+1} = y^i - \frac{f(\mathbf{x}, \mathbf{y}^i) - y^i}{\partial(f(\mathbf{x}, \mathbf{y}^i) - y^i)/\partial y}$$

If k is the number of general form equations, then k derivatives are required.

The convergence properties of the Jacobi and Seidel solution methods remain significantly poorer than the default Newton's method.

Comparison of Methods

Newton's method is the default and should work better than the others for most small- to medium-sized models. The Seidel method is always faster than the Jacobi for recursive models with equations in recursive order. For very large models and some highly nonlinear smaller models, the Jacobi or Seidel methods can sometimes be faster. Newton's method uses more memory than the Jacobi or Seidel methods.

Both the Newton's method and the Jacobi method are order-invariant in the sense that the order in which equations are specified in the model program has no effect on the operation of the iterative solution process. In order-invariant methods, the values of the solution variables are fixed for the entire execution of the model program. Assignments to model variables are automatically changed to assignments to corresponding equation variables. Only after the model program has completed execution are the results used to compute the new solution values for the next iteration.

Troubleshooting Problems

In solving a simultaneous nonlinear dynamic model you might encounter some of the following problems.

Missing Values

For SOLVE tasks, there can be no missing parameter values. Missing right-hand-side variables result in missing left-hand-side variables for that observation.

Unstable Solutions

A solution might exist but be unstable. An unstable system can cause the Jacobi and Seidel methods to diverge.

Explosive Dynamic Systems

A model might have well-behaved solutions at each observation but be dynamically unstable. The solution might oscillate wildly or grow rapidly with time.

Propagation of Errors

During the solution process, solution variables can take on values that cause computational errors. For example, a solution variable that appears in a LOG function might be positive at the solution but might be given a negative value during one of the iterations. When computational errors occur, missing values are generated and propagated, and the solution process might collapse.

Convergence Problems

The following items can cause convergence problems:

- There are illegal function values (for example $\sqrt{-1}$).
- There are local minima in the model equation.
- No solution exists.
- Multiple solutions exist.
- Initial values are too far from the solution.
- The CONVERGE= value is too small.

When PROC MODEL fails to find a solution to the system, the current iteration information and the program data vector are printed. The simulation halts if actual values are not available for the simulation to proceed. Consider the following program, which produces the output shown in [Figure 19.85](#):

```
data test1;
  do t=1 to 50;
    x1 = sqrt(t) ;
    y = .;
    output;
  end;

proc model data=test1;
  exogenous x1 ;
  control a1 -1 b1 -29 c1 -4 ;
  y = a1 * sqrt(y) + b1 * x1 * x1 + c1 * lag(x1);
  solve y / out=sim forecast dynamic ;
run;
```

Figure 19.85 SOLVE Convergence Problems

                        The MODEL Procedure
                    Dynamic Single-Equation Forecast

--- Listing of Program Data Vector ---

_N_:          12      ACTUAL.x1:    1.41421      ACTUAL.y:          .
ERROR.y:       .      PRED.y:         .          a1:          -1
b1:          -29      c1:           -4          x1:          1.41421
y:          -0.00109
@PRED.y/@y:      .      @ERROR.y/@y:      .

NOTE: Check for missing input data or uninitialized lags.
      (Note that the LAG and DIF functions return missing values for the
      initial lag starting observations. This is a change from the 1982 and earlier
      versions of SAS/ETS which returned zero for uninitialized lags.)
NOTE: Simulation aborted.

```

At the first observation, a solution to the following equation is attempted:

$$y = -\sqrt{y} - 62$$

There is no solution to this problem. The iterative solution process got as close as it could to making Y negative while still being able to evaluate the model. This problem can be avoided in this case by altering the equation.

In other models, the problem of missing values can be avoided by either altering the data set to provide better starting values for the solution variables or by altering the equations.

You should be aware that, in general, a nonlinear system can have any number of solutions and the solution found might not be the one that you want. When multiple solutions exist, the solution that is found is usually determined by the starting values for the iterations. If the value from the input data set for a solution variable is missing, the starting value for it is taken from the solution of the last period (if nonmissing) or else the solution estimate is started at 0.

Iteration Output

The iteration output, produced by the ITPRINT option, is useful in determining the cause of a convergence problem. The ITPRINT option forces the printing of the solution approximation and equation errors at each iteration for each observation. A portion of the ITPRINT output from the following statements is shown in Figure 19.86.

```

proc model data=test1;
  exogenous x1 ;
  control a1 -1 b1 -29 c1 -4 ;
  y = a1 * sqrt(abs(y)) + b1 * x1 * x1 + c1 * lag(x1);
  solve y / out=sim forecast dynamic itprint;
run;

```

For each iteration, the equation with the largest error is listed in parentheses after the Newton convergence criteria measure. From this output you can determine which equation or equations in the system are not converging well.

Numerical Integration

The differential equation system is numerically integrated to obtain a solution for the derivative variables at each data point. The integration is performed by evaluating the provided model at multiple points between each data point. The integration method used is a variable order, variable step-size backward difference scheme; for more detailed information, see Aiken (1985); Byrne and Hindmarsh (1975). The step size or time step is chosen to satisfy a *local truncation error* requirement. The term *truncation error* comes from the fact that the integration scheme uses a truncated series expansion of the integrated function to do the integration. Because the series is truncated, the integration scheme is within the truncation error of the true value.

To further improve the accuracy of the integration, the total integration time is broken up into small intervals (time steps or step sizes), and the integration scheme is applied to those intervals. The integration at each time step uses the values computed at the previous time step so that the truncation error tends to accumulate. It is usually not possible to estimate the global error with much precision. The best that can be done is to monitor and to control the local truncation error, which is the truncation error committed at each time step relative to

$$d = \max_{0 \leq t \leq T} (\|y(t)\|_{\infty}, 1)$$

where $y(t)$ is the integrated variable. Furthermore, the $y(t)$ s are dynamically scaled to within two orders of magnitude of one to keep the error monitoring well-behaved.

The local truncation error requirement defaults to 1.0E–9. You can specify the `LTEBOUND=` option to modify that requirement. The `LTEBOUND=` option is a relative measure of accuracy, so a value smaller than 1.0E–10 is usually not practical. A larger bound increases the speed of the simulation and estimation but decreases the accuracy of the results. If the `LTEBOUND=` option is set too small, the integrator is not able to take time steps small enough to satisfy the local truncation error requirement and still have enough machine precision to compute the results. Since the integrations are scaled to within 1.0E–2 of one, the simulated values should be correct to at least seven decimal places.

There is a default minimum time step of 1.0E–14. This minimum time step is controlled by the `MINTIMESTEP=` option and the machine epsilon. If the minimum time step is smaller than the machine epsilon times the final time value, the minimum time step is increased automatically.

For the points between each observation in the data set, the values for nonintegrated variables in the data set are obtained from a linear interpolation from the two closest points. Lagged variables can be used with integrations, but their values are discrete and are not interpolated between points. Lagging, therefore, can then be used to input step functions into the integration.

The derivatives necessary for estimation (the gradient with respect to the parameters) and goal seeking (the Jacobian) are computed by numerically integrating analytical derivatives. The accuracy of the derivatives is controlled by the same integration techniques mentioned previously.

Limitations

There are limitations to the types of differential equations that can be solved or estimated. One type is an explosive differential equation (finite escape velocity) for which the following differential equation is an example:

$$y' = a \times y, a > 0$$

If this differential equation is integrated too far in time, y exceeds the maximum value allowed on the computer, and the integration terminates.

Likewise, differential systems that are singular cannot be solved or estimated in general. For example, consider the following differential system:

$$\begin{aligned} x' &= -y' + 2x + 4y + \exp(t) \\ y' &= -x' + y + \exp(4t) \end{aligned}$$

This system has an analytical solution, but an accurate numerical solution is very difficult to obtain. The reason is that y' and x' cannot be isolated on the left-hand side of the equation. If the equation is modified slightly to

$$\begin{aligned} x' &= -y' + 2x + 4y + \exp(t) \\ y' &= x' + y + \exp(4t) \end{aligned}$$

the system is nonsingular, but the integration process could still fail or be extremely slow. If the MODEL procedure encounters either system, a warning message is issued.

This system can be rewritten as the following recursive system, which can be estimated and simulated successfully with the MODEL procedure:

$$\begin{aligned} x' &= 0.5y + 0.5\exp(4t) + x + 1.5y - 0.5\exp(t) \\ y' &= x' + y + \exp(4t) \end{aligned}$$

Petzold (1982) mentions a class of differential algebraic equations that, when integrated numerically, could produce incorrect or misleading results. An example of such a system is

$$\begin{aligned} y_2'(t) &= y_1(t) + g_1(t) \\ 0 &= y_2(t) + g_2(t) \end{aligned}$$

The analytical solution to this system depends on g and its derivatives at the current time only and not on its initial value or past history. You should avoid systems of this and other similar forms mentioned in Petzold (1982).

SOLVE Data Sets

SDATA= Input Data Set

The `SDATA=` option reads a cross-equation covariance matrix from a data set. The covariance matrix read from the `SDATA=` data set specified in the `SOLVE` statement is used to generate random equation errors when the `RANDOM=` option specifies Monte Carlo simulation.

Typically, the `SDATA=` data set is created by the `OUTS=` option in a previous `FIT` statement. (The `OUTS=` data set from a `FIT` statement can be read back in by a `SOLVE` statement in the same `PROC MODEL` step.)

You can create an input `SDATA=` data set by using the `DATA` step. `PROC MODEL` expects to find a character variable `_NAME_` in the `SDATA=` data set as well as variables for the equations in the estimation or solution. For each observation with a `_NAME_` value that matches the name of an equation, `PROC MODEL` fills the corresponding row of the **S** matrix with the values of the names of equations found in the data set. If a row or column is omitted from the data set, an identity matrix row or column is assumed. Missing values are ignored. Since the **S** matrix is symmetric, you can include only a triangular part of the **S** matrix in the `SDATA=` data set with the omitted part indicated by missing values. If the `SDATA=` data set contains multiple observations with the same `_NAME_`, the last values supplied for the `_NAME_` variable are used. The section “[OUTS= Data Set](#)” on page 1219 contains more details on the format of this data set.

Use the `TYPE=` option to specify the type of estimation method used to produce the **S** matrix you want to input.

ESTDATA= Input Data Set

The `ESTDATA=` option specifies an input data set that contains an observation with values for some or all of the model parameters. It can also contain observations with the rows of a covariance matrix for the parameters.

When the `ESTDATA=` option is used, parameter values are set from the first observation. If the `RANDOM=` option is used and the `ESTDATA=` data set contains a covariance matrix, the covariance matrix of the parameter estimates is read and used to generate pseudo-random shocks to the model parameters for Monte Carlo simulation. These random perturbations have a multivariate normal distribution with the covariance matrix read from the `ESTDATA=` data set.

The `ESTDATA=` data set is usually created by the `OUTEST=` option in a `FIT` statement. The `OUTEST=` data set contains the parameter estimates produced by the `FIT` statement and also contains the estimated covariance of the parameter estimates if the `OUTCOV` option is used. This `OUTEST=` data set can be read in by the `ESTDATA=` option in a `SOLVE` statement.

You can also create an `ESTDATA=` data set with a `SAS DATA` step program. The data set must contain a numeric variable for each parameter to be given a value or covariance column. The name of the variable in the `ESTDATA=` data set must match the name of the parameter in the model. Parameters with names longer than 32 characters cannot be set from an `ESTDATA=` data set. The data set must also contain a character variable `_NAME_` of length 32. `_NAME_` has a blank value for the observation that gives values to the parameters. `_NAME_` contains the name of a parameter for observations that define rows of the covariance matrix.

More than one set of parameter estimates and covariances can be stored in the `ESTDATA=` data set if the observations for the different estimates are identified by the variable `_TYPE_`. `_TYPE_` must be a character

variable of length eight. The TYPE= option is used to select for input the part of the ESTDATA= data set for which the value of the _TYPE_ variable matches the value of the TYPE= option.

OUT= Data Set

The OUT= data set contains solution values, residual values, and actual values of the solution variables.

The OUT= data set contains the following variables:

- BY variables
- RANGE variable
- ID variables
- _TYPE_, a character variable of length eight that identifies the type of observation. The _TYPE_ variable can be PREDICT, RESIDUAL, ACTUAL, or ERROR.
- _MODE_, a character variable of length eight that identifies the solution mode. _MODE_ takes the value FORECAST or SIMULATE.
- if lags are used, a numeric variable, _LAG_, that contains the number of dynamic lags that contribute to the solution. The value of _LAG_ is always zero for STATIC mode solutions. _LAG_ is set to a missing value for lag-starting observations.
- if the RANDOM= option is used, _REP_, a numeric variable that contains the replication number. For example, if RANDOM=10, each input observation results in eleven output observations with _REP_ values 0 through 10. The observations with _REP_=0 are from the unperturbed solution. (The random-number generator functions are suppressed, and the parameter and endogenous perturbations are zero when _REP_=0.)
- _ERRORS_, a numeric variable that contains the number of errors that occurred during the execution of the program for the last iteration for the observation. If the solution failed to converge, this is counted as one error, and the _ERRORS_ variable is made negative.
- solution and other variables. The solution variables contain solution or predicted values for _TYPE_=PREDICT observations, residuals for _TYPE_=RESIDUAL observations, or actual values for _TYPE_=ACTUAL observations. The other model variables, and any other variables read from the input data set, are always actual values from the input data set.
- any other variables named in the OUTVARS statement. These can be program variables computed by the model program, CONTROL variables, parameters, or special variables in the model program. Compound variable names longer than 32 characters are truncated in the OUT= data set.

By default, only the predicted values are written to the OUT= data set. The OUTRESID, OUTACTUAL, and OUTERROR options are used to add the residual, actual, and ERROR. values, respectively, to the data set.

For examples of the OUT= data set, see [Example 19.6](#).

DATA= Input Data Set

The input data set should contain all of the exogenous variables and should supply nonmissing values for them for each period to be solved.

Solution variables can be supplied in the input data set and are used as follows:

- to supply initial lags. For example, if the lag length of the model is three, three observations are read in to feed the lags before any solutions are computed.
- to evaluate the goodness of fit. Goodness-of-fit measures are computed based on the difference between the solved values and the actual values supplied from the data set.
- to supply starting values for the iterative solution. If the value from the input data set for a solution variable is missing, the starting value for it is taken from the solution of the last period (if nonmissing) or else the solution estimate is started at zero.
- for STATIC mode solutions, actual values from the data set are used by the lagging functions for the solution variables.
- for FORECAST mode solutions, actual values from the data set are used as the solution values when nonmissing.

Programming Language Overview: MODEL Procedure

Variables in the Model Program

Variable names are alphanumeric but must start with a letter. The length is limited to 32 characters.

PROC MODEL uses several classes of variables, and different variable classes are treated differently. The variable class is controlled by *declaration statements*: the VAR, ENDOGENOUS, and EXOGENOUS statements for model variables, the PARAMETERS statement for parameters, and the CONTROL statement for control class variables. These declaration statements have several valid abbreviations. Various *internal variables* are also made available to the model program to allow communication between the model program and the procedure. RANGE, ID, and BY variables are also available to the model program. Those variables not declared as any of the preceding classes are *program variables*.

Some classes of variables can be lagged; that is, their value at each observation is remembered, and previous values can be referred to by the lagging functions. Other classes have only a single value and are not affected by lagging functions. For example, parameters have only one value and are not affected by lagging functions; therefore, if P is a parameter, $DIF_n(P)$ is always 0, and $LAG_n(P)$ is always the same as P for all values of n .

The different variable classes and their roles in the model are described in the following.

Model Variables

Model variables are declared by VAR, ENDOGENOUS, or EXOGENOUS statements, or by FIT and SOLVE statements. The model variables are the variables that the model is intended to explain or predict.

PROC MODEL enables you to use expressions on the left-hand side of the equal sign to define model equations. For example, a log-linear model for Y can be written as

$$\log(y) = a + b * x;$$

Previously, only a variable name was allowed on the left-hand side of the equal sign.

The text on the left-hand side of the equation serves as the equation name used to identify the equation in printed output, in the OUT= data sets, and in FIT or SOLVE statements. To refer to equations specified by using left-hand side expressions (in the FIT statement, for example), place the left-hand side expression in quotes. For example, the following statements fit a log-linear model to the dependent variable Y:

```
proc model data=in;
    log( y ) = a + b * x;
    fit "log(y)";
run;
```

The estimation and simulation is performed by transforming the models into general form equations. No actual or predicted value is available for general form equations, so no R^2 or adjusted R^2 is computed.

Equation Variables

An equation variable is one of several special variables used by PROC MODEL to control the evaluation of model equations. An equation variable name consists of one of the prefixes EQ, RESID, ERROR, PRED, or ACTUAL, followed by a period and the name of a model equation.

Equation variable names can appear in parts of the PROC MODEL printed output, and they can be used in the model program. For example, RESID-prefixed variables can be used in LAG functions to define equations with moving-average error terms. See the section “[Autoregressive Moving-Average Error Processes](#)” on page 1195 for details.

The meaning of these prefixes is detailed in the section “[Equation Translations](#)” on page 1264.

Parameters

Parameters are variables that have the same value for each observation. Parameters can be given values or can be estimated by fitting the model to data. During the SOLVE stage, parameters are treated as constants. If no estimation is performed, the SOLVE stage uses the initial value provided in the ESTDATA= data set, the MODEL= file, or in the PARAMETER statement, as the value of the parameter.

The PARAMETERS statement declares the parameters of the model. Parameters are not lagged, and they cannot be changed by the model program.

Control Variables

Control variables supply constant values to the model program that can be used to control the model in various ways. The **CONTROL** statement declares control variables and specifies their values. A control variable is like a parameter except that it has a fixed value and is not estimated from the data.

Control variables are not reinitialized before each pass through the data and can thus be used to retain values between passes. You can use control variables to vary the program logic. Control variables are not affected by lagging functions.

For example, if you have two versions of an equation for a variable *Y*, you could put both versions in the model and, by using a **CONTROL** statement to select one of them, produce two different solutions to explore the effect the choice of equation has on the model, as shown in the following statements:

```
select (case);
  when (1) y = ...first version of equation... ;
  when (2) y = ...second version of equation... ;
end;

control case 1;
solve / out=case1;
run;

control case 2;
solve / out=case2;
run;
```

RANGE, ID, and BY Variables

The **RANGE** statement controls the range of observations in the input data set that is processed by PROC MODEL. The **ID** statement lists variables in the input data set that are used to identify observations in the printout and in the output data set. The **BY** statement can be used to make PROC MODEL perform a separate analysis for each BY group. The variable in the **RANGE** statement, the ID variables, and the BY variables are available for the model program to examine, but their values should not be changed by the program. The BY variables are not affected by lagging functions.

Internal Variables

You can use several internal variables in the model program to communicate with the procedure. For example, if you want PROC MODEL to list the values of all the variables when more than 10 iterations are performed and the procedure is past the 20th observation, you can write

```
if _obs_ > 20 then if _iter_ > 10 then _list_ = 1;
```

Internal variables are not affected by lagging functions, and they cannot be changed by the model program except as noted. The following internal variables are available. The variables are all numeric except where noted.

ERRORS is a flag that is set to 0 at the start of program execution and is set to a nonzero value whenever an error occurs. The program can also set the **_ERRORS_** variable.

<code>_ITER_</code>	is the iteration number. For FIT tasks, the value of <code>_ITER_</code> is negative for preliminary grid-search passes. The iterative phase of the estimation starts with iteration 0. After the estimates have converged, a final pass is made to collect statistics with <code>_ITER_</code> set to a missing value. Note that at least one pass, and perhaps several subiteration passes as well, is made for each iteration. For SOLVE tasks, <code>_ITER_</code> counts the iterations used to compute the simultaneous solution of the system.
<code>_LAG_</code>	is the number of dynamic lags that contribute to the solution at the current observation. <code>_LAG_</code> is always 0 for FIT tasks and for STATIC solutions. <code>_LAG_</code> is set to a missing value during the lag starting phase.
<code>_LIST_</code>	is a list flag that is set to 0 at the start of program execution. The program can set <code>_LIST_</code> to a nonzero value to request a listing of the values of all the variables in the program after the program has finished executing.
<code>_METHOD_</code>	is the solution method in use for SOLVE tasks. <code>_METHOD_</code> is set to a blank value for FIT tasks. <code>_METHOD_</code> is a character-valued variable. Values are NEWTON, JACOBI, SIEDEL, or ONEPASS.
<code>_MODE_</code>	takes the value ESTIMATE for FIT tasks and the value SIMULATE or FORECAST for SOLVE tasks. <code>_MODE_</code> is a character-valued variable.
<code>_NMISS_</code>	is the number of missing or otherwise unusable observations during the model estimation. For FIT tasks, <code>_NMISS_</code> is initially set to 0; at the start of each iteration, <code>_NMISS_</code> is set to the number of unusable observations for the previous iteration. For SOLVE tasks, <code>_NMISS_</code> is set to a missing value.
<code>_NUSED_</code>	is the number of nonmissing observations used in the estimation. For FIT tasks, PROC MODEL initially sets <code>_NUSED_</code> to the number of parameters; at the start of each iteration, <code>_NUSED_</code> is reset to the number of observations used in the previous iteration. For SOLVE tasks, <code>_NUSED_</code> is set to a missing value.
<code>_OBS_</code>	counts the observations being processed. <code>_OBS_</code> is negative or 0 for observations in the lag starting phase.
<code>_REP_</code>	is the replication number for Monte Carlo simulation when the RANDOM= option is specified in the SOLVE statement. <code>_REP_</code> is 0 when the RANDOM= option is not used and for FIT tasks. When <code>_REP_=0</code> , the random-number generator functions always return 0.
<code>_WEIGHT_</code>	is the weight of the observation. For FIT tasks, <code>_WEIGHT_</code> provides a weight for the observation in the estimation. <code>_WEIGHT_</code> is initialized to 1.0 at the start of execution for FIT tasks. For SOLVE tasks, <code>_WEIGHT_</code> is ignored.

Program Variables

Variables not in any of the other classes are called program variables. Program variables are used to hold intermediate results of calculations. Program variables are reinitialized to missing values before each observation is processed. Program variables can be lagged. The RETAIN statement can be used to give program variables initial values and enable them to keep their values between observations.

Character Variables

PROC MODEL supports both numeric and character variables. Character variables are not involved in the model specification but can be used to label observations, to write debugging messages, or for documentation purposes. All variables are numeric unless they are the following.

- character variables in a DATA= SAS data set
- program variables assigned a character value
- declared to be character by a LENGTH or ATTRIB statement

Equation Translations

Equations written in normalized form are always automatically converted to general form equations. For example, when a normalized form equation such as

$$y = a + b \cdot x;$$

is encountered, it is translated into the equations

```
PRED.y = a + b*x;
RESID.y = PRED.y - ACTUAL.y;
ERROR.y = PRED.y - y;
```

If the same system is expressed as the following general form equation, then this equation is used unchanged.

$$EQ.y = y - (a + b \cdot x);$$

This makes it easy to solve for arbitrary variables and to modify the error terms for autoregressive or moving average models.

Use the LIST option to see how this transformation is performed. For example, the following statements produce the listing shown in [Figure 19.87](#).

```
proc model data=line list;
  y = a1 + b1*x1 + c1*x2;
  fit y;
run;
```

Figure 19.87 LIST Output

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	4272:4	PRED.y = a1 + b1 * x1 + c1 * x2;
1	4272:4	RESID.y = PRED.y - ACTUAL.y;
1	4272:4	ERROR.y = PRED.y - y;

PRED.Y is the predicted value of Y, and ACTUAL.Y is the value of Y in the data set. The predicted value minus the actual value, RESID.Y, is then the error term, ϵ , for the original Y equation. Note that the residuals obtained from the OUTRESID option in the OUT=dataset for both the FIT and SOLVE statements are defined as *actual – predicted*, the negative of RESID.Y. See the section “[Syntax: MODEL Procedure](#)” on page 1072 for details. ACTUAL.Y and Y have the same value for parameter estimation. For solve tasks, ACTUAL.Y is still the value of Y in the data set but Y becomes the solved value; the value that satisfies $\text{PRED.Y} - Y = 0$.

The following are the equation variable definitions.

- EQ. The value of an EQ.-prefixed equation variable (normally used to define a general form equation) represents the failure of the equation to hold. When the EQ.*name* variable is 0, the *name* equation is satisfied.
- RESID. The RESID.*name* variables represent the stochastic parts of the equations and are used to define the objective function for the estimation process. A RESID.-prefixed equation variable is like an EQ.-prefixed variable but makes it possible to use or transform the stochastic part of the equation. The RESID. equation is used in place of the ERROR. equation for model solutions if it has been reassigned or used in the equation.
- ERROR. An ERROR.*name* variable is like an EQ.-prefixed variable, except that it is used only for model solution and does not affect parameter estimation.
- PRED. For a normalized form equation (specified by assignment to a model variable), the PRED.*name* equation variable holds the predicted value, where *name* is the name of both the model variable and the corresponding equation. (PRED.-prefixed variables are not created for general form equations.)
- ACTUAL. For a normalized form equation (specified by assignment to a model variable), the ACTUAL.*name* equation variable holds the value of the *name* model variable read from the input data set.
- DETR. The DETR.*name* variable defines a differential equation. Once defined, it might be used on the right-hand side of another equation.
- H. The H.*name* variable specifies the functional form for the variance of the named equation.
- GMM_H. This is created for H.*vars* and is the moment equation for the variance for GMM. This variable is used only for GMM.

GMM_H.name = RESID.name2 - H.name;**

MSE. The MSE.*y* variable contains the value of the mean squared error for *y* at each iteration. An MSE. variable is created for each dependent/endogenous variable in the model. These variables can be used to specify the missing lagged values in the estimation and simulation of GARCH type models.

```
demret = intercept ;
h.demret = arch0 +
            arch1 * xlag( resid.demret ** 2, mse.demret) +
            garch1 * xlag(h.demret, mse.demret) ;
```

NRESID. This is created for H.*vars* and is the normalized residual of the variable <*name*>. The formula is

```
NRESID.name = RESID.name / sqrt(H.name) ;
```

The three equation variable prefixes, RESID., ERROR., and EQ. allow for control over the objective function for the FIT, the SOLVE, or both the FIT and the SOLVE stages. For FIT tasks, PROC MODEL looks first for a RESID.*name* variable for each equation. If defined, the RESID.-prefixed equation variable is used to define the objective function for the parameter estimation process. Otherwise, PROC MODEL looks for an EQ.-prefixed variable for the equation and uses it instead.

For SOLVE tasks, PROC MODEL looks first for an ERROR.*name* variable for each equation. If defined, the ERROR.-prefixed equation variable is used for the solution process. Otherwise, PROC MODEL looks for an EQ.-prefixed variable for the equation and uses it instead. To solve the simultaneous equation system, PROC MODEL computes values of the solution variables (the model variables being solved for) that make all of the ERROR.*name* and EQ.*name* variables close to 0.

Derivatives

Nonlinear modeling techniques require the calculation of derivatives of certain variables with respect to other variables. The MODEL procedure includes an analytic differentiator that determines the model derivatives and generates program code to compute these derivatives. When parameters are estimated, the MODEL procedure takes the derivatives of the equation with respect to the parameters. When the model is solved, Newton's method requires the derivatives of the equations with respect to the variables solved for.

PROC MODEL uses exact mathematical formulas for derivatives of non-user-defined functions. For other functions, numerical derivatives are computed and used.

The differentiator differentiates the entire model program, including the conditional logic and flow of control statements. Delayed definitions, as when the LAG of a program variable is referred to before the variable is assigned a value, are also differentiated correctly.

The differentiator includes optimization features that produce efficient code for the calculation of derivatives. However, when flow of control statements such as GOTO statements are used, the optimization process is impeded, and less efficient code for derivatives might be produced. Optimization is also reduced by conditional statements, iterative DO loops, and multiple assignments to the same variable.

The table of derivatives is printed with the LISTDER option. The code generated for the computation of the derivatives is printed with the LISTCODE option.

Derivative Variables

When the differentiator needs to generate code to evaluate the expression for the derivative of a variable, the result is stored in a special derivative variable. Derivative variables are not created when the derivative expression reduces to a previously computed result, a variable, or a constant. The names of derivative variables, which might sometimes appear in the printed output, have the form *@obj/@wrt*, where *obj* is the variable whose derivative is being taken and *wrt* is the variable that the differentiation is with respect to. For example, the derivative variable for the derivative of *Y* with respect to *X* is named *@Y/@X*.

The derivative variables can be accessed or used as part of the model program using the GETDER() function.

GETDER(*x*, *a*) the derivative of *x* with respect to *a*.

GETDER(*x*, *a*, *b*) the second derivative of *x* with respect to *a* and *b*.

The main purpose of the GETDER() function is for surfacing the derivatives so they can be stored in a data set for further processing. Only derivatives that are implied by the problem are available to the GETDER() function. When derivatives are requested that aren't already created, a missing value will be returned. The derivative of the GETDER() function is always zero so the results of the GETDER() function shouldn't be used in any of the equations in the FIT or the SOLVE statement.

The following example adds the gradient of the PRED.y value with respect to the parameters to the OUT= data set.

```
proc model data=line ;
  y = a1 + b1**2 *x1 + c1*x2;
  Dy_a1 = getder(PRED.y, a1);
  Dy_b1 = getder(PRED.y, b1);
  Dy_c1 = getder(PRED.y, c1);
  outvars Dy_a1 Dy_b1 Dy_c1;
  fit y / out=grad;
run;
```

Mathematical Functions

The following is a brief summary of SAS functions that are useful for defining models. Additional functions and details are in *SAS Language: Reference*. Information about creating new functions can be found in *SAS/BASE Software: Procedure Reference*, Chapter 18, “The FCMP Procedure.”

ABS(<i>x</i>)	the absolute value of <i>x</i>
ARCOS(<i>x</i>)	the arccosine in radians of <i>x</i> ; <i>x</i> should be between -1 and 1 .
ARSIN(<i>x</i>)	the arcsine in radians of <i>x</i> ; <i>x</i> should be between -1 and 1 .
ATAN(<i>x</i>)	the arctangent in radians of <i>x</i>
COS(<i>x</i>)	the cosine of <i>x</i> ; <i>x</i> is in radians.
COSH(<i>x</i>)	the hyperbolic cosine of <i>x</i>
EXP(<i>x</i>)	e^x
LOG(<i>x</i>)	the natural logarithm of <i>x</i>

LOG10(x)	the log base ten of x
LOG2(x)	the log base two of x
SIN(x)	the sine of x ; x is in radians.
SINH(x)	the hyperbolic sine of x
SQRT(x)	the square root of x
TAN(x)	the tangent of x ; x is in radians and is not an odd multiple of $\pi/2$.
TANH(x)	the hyperbolic tangent of x

Random-Number Functions

The MODEL procedure provides several functions for generating random numbers for Monte Carlo simulation. These functions use the same generators as the corresponding SAS DATA step functions.

The following random number functions are supported: RANBIN, RANCAU, RAND, RANEXP, RANGAM, RANNOR, RANPOI, RANTBL, RANTRI, and RANUNI. For more information, refer to *SAS Language: Reference*.

Each reference to a random number function sets up a separate pseudo-random sequence. Note that this means that two calls to the same random function with the same seed produce identical results. This is different from the behavior of the random number functions used in the SAS DATA step. For example, the following statements produce identical values for X and Y, but Z is from an independent pseudo-random sequence:

```
x=rannor(123);
y=rannor(123);
z=rannor(567);
q=rand('BETA', 1, 12 );
```

For FIT tasks, all random number functions always return 0. For SOLVE tasks, when Monte Carlo simulation is requested, a random number function computes a new random number on the first iteration for an observation (if it is executed on that iteration) and returns that same value for all later iterations of that observation. When Monte Carlo simulation is not requested, random number functions always return 0.

Functions across Time

PROC MODEL provides four types of special built-in functions that refer to the values of variables and expressions in previous time periods. These functions have the following forms where n represents the number of periods, x is any expression, and the argument i is a variable or expression that gives the lag length ($0 \leq i \leq n$). If the index value i is omitted, the maximum lag length n is used.

LAG n ($< i, > x$) returns the i th lag of x , where n is the maximum lag;

DIF n (x) is the difference of x at lag n

ZLAG n ($< i, > x$) returns the i th lag of x , where n is the maximum lag, with missing lags replaced with zero

- XLAGn** (*x*, *y*) returns the *n*th lag of *x* if *x* is nonmissing, or *y* if *x* is missing
- ZDIFn** (*x*) is the difference with lag length truncated and missing values converted to zero; *x* is the variable or expression to compute the moving average of
- MOVAVGn**(*x*) is the moving average if X_t denotes the observation at time point *t*, to ensure compatibility with the number *n* of observations used to calculate the moving average MOVAVGn, the following definition is used:

$$MOVAVGn(X_t) = \frac{X_t + X_{t-1} + X_{t-2} + \dots + X_{t-n+1}}{n}$$

The moving average calculation for SAS 9.1 and earlier releases is as follows:

$$MOVAVGn(X_t) = \frac{X_t + X_{t-1} + X_{t-2} + \dots + X_{t-n}}{n + 1}$$

Missing values of *x* are omitted in computing the average.

If you do not specify *n*, the number of periods is assumed to be one. For example, LAG(X) is the same as LAG1(X). No more than four digits can be used with a lagging function; that is, LAG9999 is the greatest LAG function, ZDIF9999 is the greatest ZDIF function, and so on.

The LAG functions get values from previous observations and make them available to the program. For example, LAG(X) returns the value of the variable X as it was computed in the execution of the program for the preceding observation. The expression LAG2(X+2*Y) returns the value of the expression X+2*Y, computed by using the values of the variables X and Y that were computed by the execution of the program for the observation two periods ago.

The DIF functions return the difference between the current value of a variable or expression and the value of its LAG. For example, DIF2(X) is a short way of writing X-LAG2(X), and DIF15(SQRT(2*Z)) is a short way of writing SQRT(2*Z)-LAG15(SQRT(2*Z)).

The ZLAG and ZDIF functions are like the LAG and DIF functions, but they are not counted in the determination of the program lag length, and they replace missing values with 0s. The ZLAG function returns the lagged value if the lagged value is nonmissing, or 0 if the lagged value is missing. The ZDIF function returns the differenced value if the differenced value is nonmissing, or 0 if the value of the differenced value is missing. The ZLAG function is especially useful for models with ARMA error processes. See the next section for details.

Lag Logic

The LAG and DIF lagging functions in the MODEL procedure are different from the queuing functions with the same names in the DATA step. Lags are determined by the final values that are set for the program variables by the execution of the model program for the observation. This can have upsetting consequences for programs that take lags of program variables that are given different values at various places in the program, as shown in the following statements:

```
temp = x + w;
t     = lag( temp );
temp = q - r;
s     = lag( temp );
```

The expression LAG(TEMP) always refers to LAG(Q–R), never to LAG(X+W), since Q–R is the final value assigned to the variable TEMP by the model program. If LAG(X+W) is wanted for T, it should be computed as $T = \text{LAG}(X+W)$ and not $T = \text{LAG}(\text{TEMP})$, as in the preceding example.

Care should also be exercised in using the DIF functions with program variables that might be reassigned later in the program. For example, the program

```
temp = x ;
s     = dif( temp ) ;
temp = 3 * y ;
```

computes values for S equivalent to

```
s = x - lag( 3 * y ) ;
```

Note that in the preceding examples, TEMP is a program variable, *not* a model variable. If it were a model variable, the assignments to it would be changed to assignments to a corresponding equation variable.

Note that whereas LAG1(LAG1(X)) is the same as LAG2(X), DIF1(DIF1(X)) is *not* the same as DIF2(X). The DIF2 function is the difference between the current period value at the point in the program where the function is executed and the final value at the end of execution two periods ago; DIF2 is not the second difference. In contrast, DIF1(DIF1(X)) is equal to $\text{DIF1}(X) - \text{LAG1}(\text{DIF1}(X))$, which equals $X - 2 * \text{LAG1}(X) + \text{LAG2}(X)$, which is the second difference of X.

More information about the differences between PROC MODEL and the DATA step LAG and DIF functions is found in Chapter 3, “[Working with Time Series Data](#).”

Lag Lengths

The lag length of the model program is the number of lags needed for any relevant equation. The program lag length controls the number of observations used to initialize the lags.

PROC MODEL keeps track of the use of lags in the model program and automatically determines the lag length of each equation and of the model as a whole. PROC MODEL sets the program lag length to the maximum number of lags needed to compute any equation to be estimated, solved, or needed to compute any instrument variable used.

In determining the lag length, the ZLAG and ZDIF functions are treated as always having a lag length of 0. For example, if Y is computed as

```
y = lag2( x + zdif3( temp ) ) ;
```

then Y has a lag length of 2 (regardless of how TEMP is defined). If Y is computed as

```
y = zlag2( x + dif3( temp ) ) ;
```

then Y has a lag length of 0.

This is so that ARMA errors can be specified without causing the loss of additional observations to the lag starting phase and so that recursive lag specifications, such as moving-average error terms, can be used. Recursive lags are not permitted unless the ZLAG or ZDIF functions are used to truncate the lag length. For example, the following statement produces an error message:

```
t = a + b * lag( t );
```

The program variable *T* depends recursively on its own lag, and the lag length of *T* is therefore undefined.

In the following equation *RESID.Y* depends on the predicted value for the *Y* equation but the predicted value for the *Y* equation depends on the *LAG* of *RESID.Y*, and thus, the predicted value for the *Y* equation depends recursively on its own lag.

```
y = yhat + ma * lag( resid.y );
```

The lag length is infinite, and *PROC MODEL* prints an error message and stops. Since this kind of specification is allowed, the recursion must be truncated at some point. The *ZLAG* and *ZDIF* functions do this.

The following equation is valid and results in a lag length for the *Y* equation equal to the lag length of *YHAT*:

```
y = yhat + ma * zlag( resid.y );
```

Initially, the lags of *RESID.Y* are missing, and the *ZLAG* function replaces the missing residuals with 0s, their unconditional expected values.

The *ZLAG0* function can be used to zero out the lag length of an expression. *ZLAG0(*x*)* returns the current period value of the expression *x*, if nonmissing, or else returns 0, and prevents the lag length of *x* from contributing to the lag length of the current statement.

Initializing Lags

At the start of each pass through the data set or *BY* group, the lag variables are set to missing values and an initialization is performed to fill the lags. During this phase, observations are read from the data set, and the model variables are given values from the data. If necessary, the model is executed to assign values to program variables that are used in lagging functions. The results for variables used in lag functions are saved. These observations are not included in the estimation or solution.

If, during the execution of the program for the lag starting phase, a lag function refers to lags that are missing, the lag function returns missing. Execution errors that occur while starting the lags are not reported unless requested. The modeling system automatically determines whether the program needs to be executed during the lag starting phase.

If *L* is the maximum lag length of any equation being fit or solved, then the first *L* observations are used to prime the lags. If a *BY* statement is used, the first *L* observations in the *BY* group are used to prime the lags. If a *RANGE* statement is used, the first *L* observations prior to the first observation requested in the *RANGE* statement are used to prime the lags. Therefore, there should be at least *L* observations in the data set.

Initial values for the lags of model variables can also be supplied in *VAR*, *ENDOGENOUS*, and *EXOGENOUS* statements. This feature provides initial lags of solution variables for dynamic solution when initial values for the solution variable are not available in the input data set. For example, the statement

```
var x 2 3 y 4 5 z 1;
```

feeds the initial lags exactly like these values in an input data set:

Lag	X	Y	Z
2	3	5	.
1	2	4	1

If initial values for lags are available in the input data set and initial lag values are also given in a declaration statement, the values in the VAR, ENDOGENOUS, or EXOGENOUS statements take priority.

The RANGE statement is used to control the range of observations in the input data set that are processed by PROC MODEL. In the following statement, '01jan1924' specifies the starting period of the range, and '01dec1943' specifies the ending period:

```
range date = '01jan1924'd to '01dec1943'd;
```

The observations in the data set immediately prior to the start of the range are used to initialize the lags.

Language Differences

For the most part, PROC MODEL programming statements work the same as they do in the DATA step as documented in *SAS Language: Reference*. However, there are several differences that should be noted.

DO Statement Differences

The DO statement in PROC MODEL does not allow a character index variable. Thus, the following DO statement is not valid in PROC MODEL, although it is supported in the DATA step:

```
do i = 'A', 'B', 'C'; /* invalid PROC MODEL code */
```

IF Statement Differences

The IF statement in PROC MODEL does not allow a character-valued condition. For example, the following IF statement is not supported by PROC MODEL:

```
if 'this' then statement;
```

Comparisons of character values are supported in IF statements, so the following IF statement is acceptable:

```
if 'this' < 'that' then statement;
```

PROC MODEL allows for embedded conditionals in expressions. For example the following two statements are equivalent:

```
flag = if time = 1 or time = 2 then conc+30/5 + dose*time
      else if time > 5 then (0=1) else (patient * flag);
```

```
if time = 1 or time = 2 then flag= conc+30/5 + dose*time;
else if time > 5 then flag=(0=1); else flag=patient*flag;
```

Note that the ELSE operator involves only the first object or token after it so that the following assignments are not equivalent:

```
total = if sum > 0 then sum else sum + reserve;
total = if sum > 0 then sum else (sum + reserve);
```

The first assignment makes TOTAL always equal to SUM plus RESERVE.

PUT Statement Differences

The PUT statement, mostly used in PROC MODEL for program debugging, supports only some of the features of the DATA step PUT statement. It also has some new features that the DATA step PUT statement does not support.

The PROC MODEL PUT statement does not support line pointers, factored lists, iteration factors, overprinting, the _INFILE_ option, or the colon (:) format modifier.

The PROC MODEL PUT statement does support expressions, but an expression must be enclosed in parentheses. For example, the following statement prints the square root of x:

```
put (sqrt(x));
```

Subscripted array names must be enclosed in parentheses. For example, the following statement prints the *i*th element of the array A:

```
put (a i);
```

However, the following statement is an error:

```
put a i;
```

The PROC MODEL PUT statement supports the print item _PDV_ to print a formatted listing of all the variables in the program. For example, the following statement prints a much more readable listing of the variables than does the _ALL_ print item:

```
put _pdv_;
```

To print all the elements of the array A, use the following statement:

```
put a;
```

To print all the elements of A with each value labeled by the name of the element variable, use the following statement:

```
put a=;
```

ABORT Statement Difference

In the MODEL procedure, the ABORT statement does not allow any arguments.

SELECT/WHEN/OTHERWISE Statement Differences

The WHEN and OTHERWISE statements allow more than one target statement. That is, DO groups are not necessary for multiple statement WHENs. For example in PROC MODEL, the following syntax is valid:

```
select;
  when (exp1)
    stmt1;
    stmt2;
  when (exp2)
    stmt3;
    stmt4;
end;
```

The ARRAY Statement

ARRAY *arrayname* < {*dimensions*} > < \$ [*length*] > < *variables and constants* > ; ;

The ARRAY statement is used to associate a name with a list of variables and constants. The array name can then be used with subscripts in the model program to refer to the items in the list.

In PROC MODEL, the ARRAY statement does not support all the features of the DATA step ARRAY statement. Implicit indexing cannot be used; all array references must have explicit subscript expressions. Only exact array dimensions are allowed; lower-bound specifications are not supported. A maximum of six dimensions is allowed.

On the other hand, the ARRAY statement supported by PROC MODEL does allow both variables and constants to be used as array elements. You cannot make assignments to constant array elements. Both dimension specification and the list of elements are optional, but at least one must be supplied. When the list of elements is not given or fewer elements than the size of the array are listed, array variables are created by suffixing element numbers to the array name to complete the element list.

The following are valid PROC MODEL array statements:

```
array x[120];           /* array X of length 120           */
array q[2,2];           /* Two dimensional array Q           */
array b[4] va vb vc vd; /* B[2] = VB, B[4] = VD             */
array x x1-x30;         /* array X of length 30, X[7] = X7   */
array a[5] (1 2 3 4 5); /* array A initialized to 1,2,3,4,5 */
```

RETAIN Statement

RETAIN *variables initial-values* ;

The RETAIN statement causes a program variable to hold its value from a previous observation until the variable is reassigned. The RETAIN statement can be used to initialize program variables.

The RETAIN statement does not work for model variables, parameters, or control variables because the values of these variables are under the control of PROC MODEL and not programming statements. Use the PARMS and CONTROL statements to initialize parameters and control variables. Use the VAR, ENDOGENOUS, or EXOGENOUS statement to initialize model variables.

Storing Programs in Model Files

Models can be saved in and recalled from SAS catalog files as well as XML-based data sets. SAS catalogs are special files that can store many kinds of data structures as separate units in one SAS file. Each separate unit is called an entry, and each entry has an entry type that identifies its structure to the SAS system. Starting with SAS 9.2, model files are being stored as SAS data sets instead of being stored as members of a SAS catalog as in earlier releases. This makes MODEL files more readily extendable in the future and enables Java-based applications to read the MODEL files directly. You can choose between the two formats by specifying a global CMPMODEL option in an OPTIONS statement. Details are given below.

In general, to save a model, use the OUTMODEL=*name* option in the PROC MODEL statement, where *name* is specified as *libref.catalog.entry*, *libref.entry*, or *entry* for catalog entry and, starting with SAS 9.2, *libref.datasetname* or *datasetname* for XML-based SAS data sets. The *libref*, *catalog*, *datasetnames* and *entry* names must be valid SAS names no more than 32 characters long. The *catalog* name is restricted to seven characters on the CMS operating system. If not given, the *catalog* name defaults to MODELS, and the *libref* defaults to WORK. The entry type is always MODEL. Thus, OUTMODEL=X writes the model to the file WORK.MODELS.X.MODEL in the SAS catalog or creates a WORK.X XML-based dataset in the WORK library depending on the format chosen by using the CMPMODEL= option. By default, both these formats are chosen.

The CMPMODEL= option can be used in an OPTIONS statement to modify the behavior when reading and writing MODEL files. The values allowed are CMPMODEL= BOTH | XML | CATALOG. For example, the following statements restore the previous behavior:

```
options cmpmodel=catalog;
```

The CMPMODEL= option defaults to BOTH in SAS 9.2 and is intended for transitional use. If CMPMODEL=BOTH, the MODEL procedure writes both formats; when loading model files PROC MODEL attempts to load the XML version first and the CATALOG version second (if the XML version is not found). If CMPMODEL=XML, the MODEL procedure reads and writes only the XML format. If CMPMODEL=CATALOG, only the catalog format is used.

The MODEL= option is used to read in a model. A list of model files can be specified in the MODEL= option, and a range of names with numeric suffixes can be given, as in MODEL=(MODEL1–MODEL10). When more than one model file is given, the list must be placed in parentheses, as in MODEL=(A B C), except in case of a single name. If more than one model file is specified, the files are combined in the order listed in the MODEL= option.

The MODEL procedure continues to read and write catalog MODEL files, and model files created by previous releases of SAS/ETS continue to work, so you should experience no direct impact from this change.

When the MODEL= option is specified in the PROC MODEL statement and model definition statements are also given later in the PROC MODEL step, the model files are read in first, in the order listed, and the model program specified in the PROC MODEL step is appended after the model program read from the MODEL= files. The class that is assigned to a variable, when multiple model files are used, is the last declaration of that variable. For example, if Y1 is declared endogenous in the model file M1 and exogenous in the model file M2, the following statement causes Y1 to be declared exogenous:

```
proc model model=(m1 m2);
```

The INCLUDE statement can be used to append model code to the current model code. In contrast, when the MODEL= option is specified in the RESET statement, the current model is deleted before the new model is read.

By default, no model file is output if the PROC MODEL step performs any FIT or SOLVE tasks, or if the MODEL= option or the NOSTORE option is specified. However, to ensure compatibility with previous versions of SAS/ETS software, if the PROC MODEL step does nothing but compile the model program, no input model file is read, and the NOSTORE option is not used, then a model file is written. This model file is the default input file for a later PROC SYSLIN or PROC SIMLIN step. The default output model filename in this case is WORK.MODELS._MODEL_.MODEL.

If FIT statements are used to estimate model parameters, the parameter estimates that are written to the output model file are the estimates from the last estimation performed for each parameter.

Macro Return Codes (SYSINFO)

The MODEL procedure stores a return code in the automatic macro variable SYSINFO upon completion of the PROC MODEL step. In the event any FIT or SOLVE task fails to converge during the completion of a PROC MODEL step, the value 1 is stored in the SYSINFO macro variable. Any subsequent SAS step resets the value of SYSINFO.

Diagnostics and Debugging

PROC MODEL provides several features to aid in finding errors in the model program. These debugging features are not usually needed; most models can be developed without them.

The example model program that follows is used in the following sections to illustrate the diagnostic and debugging capabilities. This example is the estimation of a segmented model.

Figure 19.88 LIST Output for Segmented Model

QUADRATIC MODEL WITH PLATEAU		
The MODEL Procedure

Stmt	Line:Col	Statement as Parsed
1	4318:4	x0 = (-0.5 * b) / c;
2	4319:4	if x < x0 then
3	4320:7	PRED.y = a + b * x + c * x * x;
3	4320:7	RESID.y = PRED.y - ACTUAL.y;
3	4320:7	ERROR.y = PRED.y - y;
4	4321:4	else
5	4322:7	PRED.y = a + b * x0 + c * x0 * x0;
5	4322:7	RESID.y = PRED.y - ACTUAL.y;
5	4322:7	ERROR.y = PRED.y - y;

The LIST option also shows the model translations that PROC MODEL performs. LIST output is useful for understanding the code generated by the %AR and the %MA macros.

Cross-Reference

The XREF option produces a cross-reference listing of the variables in the model program. The XREF listing is usually used in conjunction with the LIST option. The XREF listing does not include derivative (@-prefixed) variables. The XREF listing does not include generated assignments to equation variables, PRED., RESID., and ERROR.-prefixed variables, unless the DETAILS option is used.

The cross-reference from the example program is shown in Figure 19.89.

Compiler Listing

The LISTCODE option lists the model code and derivatives tables produced by the compiler. This listing is useful only for debugging and should not normally be needed.

LISTCODE prints the operator and operands of each operation generated by the compiler for each model program statement. Many of the operands are temporary variables generated by the compiler and given names such as #temp1. When derivatives are taken, the code listing includes the operations generated for the derivatives calculations. The derivatives tables are also listed.

A LISTCODE option prints the transformed equations from the example shown in [Figure 19.90](#) and [Figure 19.91](#).

Analyzing the Structure of Large Models

PROC MODEL provides several features to aid in analyzing the structure of the model program. These features summarize properties of the model in various forms.

Simulation Dependency Analysis

During the development of model programs for simulation, misspecification of the equations or variables that compose the systems of nonlinear equations is common. These misspecification errors can occur both in the original formulation of the model and in the encoding of the model into PROC MODEL statements. For large systems these errors can be difficult and time consuming to isolate and repair. Similarly, the process of becoming familiar with an existing simulation model that is encoded in PROC MODEL can be laborious when available documentation is insufficient to understand the model's implementation. To address these issues, the ANALYZEDEP= option can be applied to SOLVE steps to produce graphical analyses of a model's structure.

The graphical output that is produced by the ANALYZEDEP= option displays the results of two separate, hierarchical analyses that are both based on the dependence of equations on solve variables in the nonlinear system of equations. First, the system is partitioned to identify which equations overdetermine solve variables, which equations underdetermine solve variables, and which equations consistently determine solve variables. These three partitions of equations and their corresponding three partitions of solve variables are identified in the graphical output and listing produced by the ANALYZEDEP= option. Second, each partition from the first analysis is analyzed to identify subpartitions of equations and solve variables such that all the solve variables within each subpartition depend either directly or indirectly on one another. In the graphical output the subpartitions are represented as blocks in a dependency matrix. The subpartition blocks are ordered so that the matrix of dependencies has a block upper-triangular form.

The first-level partitioning of the system into underdetermined, overdetermined, and consistent systems of equations and variables uses a Dulmage-Mendelsohn (DM) decomposition to define the three partitions, following the work by Dulmage and Mendelsohn (1958); Pothén and Fan (1990). The overdetermining equations in a DM decomposition are the set of all equations that do not have dependent variables on the diagonal of any dependency matrix that contains the maximum possible number of entries on the diagonal. The dependency matrices for a problem consist of the set of pairs of orderings of the problem's equations and solve variables. Correspondingly, the DM decomposition defines underdetermined variables as the set of all variables that do not appear on the diagonal of any dependency matrix that contains the maximum number of entries on the diagonal. Therefore, the DM decomposition is canonical in the sense that its partitioning of the system is invariant to the order equations and variables are specified in the model program. The following PROC MODEL statements illustrate how to partition a simple model with five equations and five unknowns:

```
proc model data=_null_;
  endo a b c d e;

  f(a)      = 0;
  g(a,b)    = 0;
  h(a,b)    = 0;
  i(b,d)    = 0;
  j(c,d,e)  = 0;

  solve / analyzedep=(block);
quit;
```

Figure 19.92 Block Dependency Analysis**Figure 19.93** Block Partitions

Equation and Variable Blocks		
Type	Block	Symbols
Underdetermined	Eq 1	$j(c, d, e)$
	Var 1	$c \ e$
Consistent	Eq 2	$i(b, d)$
	Var 2	d
Overdetermined	Eq 3	$f(a) \ g(a, b) \ h(a, b)$
	Var 3	$a \ b$

Figure 19.92 and Figure 19.93 illustrate which equations and variables belong to each block and which blocks are in each partition. The cells that are marked “Nonzero” in the plot represent a dependency between

blocks that are above the diagonal in the dependency matrix. The exact functional forms of the equations in this example are not shown; however, the dependency analysis here reveals that this model is structurally singular because it contains overdetermined and underdetermined components. Some modification of the model specification is necessary before a SOLVE step can be executed.

For large systems of equations, the graphical output that the ANALYZEDEP= option produces can be used as a starting point to explore dependency relationships when the models' programming statement listings and dependency tables are too long to read and comprehend. For example, one econometric model of U.S. agriculture involves thousand of equation and variable dependencies whose structure is difficult to interpret in textual listings of the model. If you examine the block triangular form of its dependency matrix in Figure 19.94, one pattern of dependencies that becomes apparent is the vertical grouping of block dependencies in the middle of the plot. Figure 19.95 shows the dependency matrix for this important subpartition of equations and variables responsible for coupling the vertical grouping of blocks.

Figure 19.94 Block Triangular Form of U.S. Agriculture Model

Figure 19.95 Important Component in U.S. Agriculture Model

Compared to the BLOCK and GRAPH options, the ANALYZESEP= option has the following advantages:

- shows which equations and solve variables are overdetermined, consistent, and underdetermined
- works with any combination of normal form and general form equations
- can display dependency matrices involving many more equations and variables
- can be limited to a subset of the equations and variables in the model

The following Klein's model program is used to introduce the LISTDEP, BLOCK, and GRAPH options:

```
proc model out=m data=klein listdep graph block;
  endogenous c p w i x wsum k y;
  exogenous wp g t year;
  parms c0-c3 i0-i3 w0-w3;
  a: c = c0 + c1 * p + c2 * lag(p) + c3 * wsum;
  b: i = i0 + i1 * p + i2 * lag(p) + i3 * lag(k);
  c: w = w0 + w1 * x + w2 * lag(x) + w3 * year;
  x = c + i + g;
  y = c + i + g-t;
  p = x-w-t;
  k = lag(k) + i;
  wsum = w + wp;
  id year;
quit;
```

Dependency List

The LISTDEP option produces a dependency list for each variable in the model program. For each variable, a list of variables that depend on it and a list of variables it depends on is given. The dependency list produced by the example program is shown in [Figure 19.96](#).

BLOCK Listing

The BLOCK option prints an analysis of the program variables based on the assignments in the model program. The output produced by the example is shown in [Figure 19.97](#).

Figure 19.97 The BLOCK Output for Klein's Model

```

The MODEL Procedure
Model Structure Analysis
(Based on Assignments to Endogenous Model Variables)

Exogenous Variables      wp g t year
Endogenous Variables     c p w i x wsum k y

Block Structure of the System

Block 1      c p w i x wsum

Dependency Structure of the System

Block 1      Depends On All_Exogenous
k            Depends On Block 1 All_Exogenous
y            Depends On Block 1 All_Exogenous

```

One use for the block output is to put a model in recursive form. Simulations of the model can be done with the SEIDEL method, which is efficient if the model is recursive and if the equations are in recursive order. By examining the block output, you can determine how to reorder the model equations for the most efficient simulation.

Adjacency Graph

The GRAPH option displays the same information as the BLOCK option with the addition of an adjacency graph. An X in a column in an adjacency graph indicates that the variable associated with the row depends on the variable associated with the column. The output produced by the example is shown in [Figure 19.98](#).

The first and last graphs are straightforward. The middle graph represents the dependencies of the nonexogenous variables after transitive closure has been performed (that is, A depends on B, and B depends on C, so A depends on C). The preceding transitive closure matrix indicates that K and Y do not directly or indirectly depend on each other.

Examples: MODEL Procedure

Example 19.1: OLS Single Nonlinear Equation

This example illustrates the use of the MODEL procedure for nonlinear ordinary least squares (OLS) regression. The model is a logistic growth curve for the population of the United States. The data is the population in millions recorded at ten-year intervals starting in 1790 and ending in 2000. For an explanation of the starting values given by the START= option, see the section “[Troubleshooting Convergence Problems](#)” on page 1141. Portions of the output from the following statements are shown in [Output 19.1.1](#) through [Output 19.1.3](#).

```

title 'Logistic Growth Curve Model of U.S. Population';
data uspop;
  input pop :6.3 @@;
  retain year 1780;
  year=year+10;
  label pop='U.S. Population in Millions';

Logistic Growth Curve Model of U.S. Population						
The MODEL Procedure						
Nonlinear OLS Summary of Residual Errors						
Equation	DF Model	DF Error	SSE	MSE	R-Square	Adj R-Sq
pop	3	18	345.6	19.2020	0.9972	0.9969
Nonlinear OLS Parameter Estimates						
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t	Label	
a	387.9307	30.0404	12.91	<.0001	Maximum Population	
b	3.990385	0.0695	57.44	<.0001	Location Parameter	
c	0.022703	0.00107	21.22	<.0001	Initial Growth Rate	

The adjusted R^2 value indicates the model fits the data well. There are only 21 observations and the model is nonlinear, so significance tests on the parameters are only approximate. The significance tests and associated approximate probabilities indicate that all the parameters are significantly different from 0.

The FIT statement included the options OUT=RESID and OUTRESID so that the residuals from the estimation are saved to the data set RESID. The residuals are plotted to check for heteroscedasticity by using PROC SGPLOT as follows.

```

title2 "Residuals Plot";
proc sgplot data=resid;
  refline 0;
  scatter x=year y=pop / markerattrs=(symbol=circlefilled);
  xaxis values=(1780 to 2000 by 20);
run;

```

The plot is shown in [Output 19.1.4](#).

Output 19.1.4 Residual for Population Model (Actual–Predicted)

The residuals do not appear to be independent, and the model could be modified to explain the remaining nonrandom errors.

Example 19.2: A Consumer Demand Model

This example shows the estimation of a system of nonlinear consumer demand equations based on the translog functional form by using seemingly unrelated regression (SUR). Expenditure shares and corresponding normalized prices are given for three goods.

Since the shares add up to one, the system is singular; therefore, one equation is omitted from the estimation process. The choice of which equation to omit is arbitrary. The nonlinear system is first estimated in unrestricted form by the following statements:

```

title1 'Consumer Demand--Translog Functional Form';
title2 'Asymmetric Model';

proc model data=tlog1;
  endogenous share1 share2;
  parms a1 a2 b11 b12 b13 b21 b22 b23 b31 b32 b33;

  bm1 = b11 + b21 + b31;
  bm2 = b12 + b22 + b32;
  bm3 = b13 + b23 + b33;
  lp1 = log(p1);
  lp2 = log(p2);
  lp3 = log(p3);
  share1 = ( a1 + b11 * lp1 + b12 * lp2 + b13 * lp3 ) /
            ( -1 + bm1 * lp1 + bm2 * lp2 + bm3 * lp3 );
  share2 = ( a2 + b21 * lp1 + b22 * lp2 + b23 * lp3 ) /
            ( -1 + bm1 * lp1 + bm2 * lp2 + bm3 * lp3 );

  fit share1 share2
    start=( a1 -.14 a2 -.45 b11 .03 b12 .47 b22 .98 b31 .20
            b32 1.11 b33 .71 ) / outsused=smatrix sur;
run;

```

A portion of the printed output produced by this example is shown in [Output 19.2.1](#) through [Output 19.2.3](#).

Hypothesis testing requires that the **S** matrix from the unrestricted model be imposed on the restricted model, as explained in the section “[Tests on Parameters](#)” on page 1186. The **S** matrix saved in the data set **SMATRIX** is requested by the **SDATA=** option.

A chi-square test is used to see if the hypothesis of symmetry is accepted or rejected. $(Oc - Ou)$ has a chi-square distribution asymptotically, where Oc is the constrained **OBJECTIVE*N** and Ou is the unconstrained

OBJECTIVE*N. The degrees of freedom is equal to the difference in the number of free parameters in the two models.

In this example, O_u is 76.9697 and O_c is 78.4097, resulting in a difference of 1.44 with 3 degrees of freedom. You can obtain the probability value by using the following statements:

```
data _null_;
  /* probchi( reduced-full, n-restrictions )*/
  p = 1-probchi( 1.44, 3 );
  put p=;
run;
```

The output from this DATA step run is $p = 0.6961858724$. With this p -value you cannot reject the hypothesis of symmetry. This test is asymptotically valid.

Example 19.3: Vector AR(1) Estimation

This example shows the estimation of a two-variable vector AR(1) error process for the Grunfeld model (Grunfeld and Griliches 1960) by using the %AR macro. First, the full model is estimated. Second, the model is estimated with the restriction that the errors are univariate AR(1) instead of a vector process. The following statements produce [Output 19.3.1](#) through [Output 19.3.5](#).

```
data grunfeld;
  input year gei gef gec whi whf whc;
  label gei = 'Gross Investment GE'
        gec = 'Capital Stock Lagged GE'
        gef = 'Value of Outstanding Shares GE Lagged'
        whi = 'Gross Investment WH'
        whc = 'Capital Stock Lagged WH'
        whf = 'Value of Outstanding Shares Lagged WH';
datalines;
1935      33.1      1170.6      97.8      12.93      191.5      1.8
1936      45.0      2015.8     104.4      25.90      516.0       .8
1937      77.2      2803.3     118.0      35.05      729.0      7.4

... more lines ...

title1 'Example of Vector AR(1) Error Process Using Grunfeld's Model';
/* Note: GE stands for General Electric
   WH stands for Westinghouse */

proc model outmodel=grunmod;
  var gei whi gef gec whf whc;
  parms ge_int ge_f ge_c wh_int wh_f wh_c;
  label ge_int = 'GE Intercept'
        ge_f   = 'GE Lagged Share Value Coef'
        ge_c   = 'GE Lagged Capital Stock Coef'
        wh_int = 'WH Intercept'
        wh_f   = 'WH Lagged Share Value Coef'
        wh_c   = 'WH Lagged Capital Stock Coef';
  gei = ge_int + ge_f * gef + ge_c * gec;
  whi = wh_int + wh_f * whf + wh_c * whc;
run;
```

The preceding PROC MODEL step defines the structural model and stores it in the model file named GRUNMOD.

The following PROC MODEL step reads in the model, adds the vector autoregressive terms using %AR, and requests SUR estimation by using the FIT statement.

```
title2 'With Unrestricted Vector AR(1) Error Process';

proc model data=grunfeld model=grunmod;
  %ar( ar, 1, gei whi )
  fit gei whi / sur;
run;
```

The final PROC MODEL step estimates the restricted model, as shown in the following statements:

```
title2 'With restricted AR(1) Error Process';

proc model data=grunfeld model=grunmod;
  %ar( gei, 1 )
  %ar( whi, 1)
  fit gei whi / sur;
run;
```

Example 19.4: MA(1) Estimation

This example estimates parameters for an MA(1) error process for the Grunfeld model, using both the unconditional least squares and the maximum likelihood methods. The ARIMA procedure estimates for Westinghouse equation are shown for comparison. The output of the following statements is summarized in [Output 19.4.1](#):

```

proc model outmodel=grunmod;
  var gei whi gef gec whf whc;
  parms ge_int ge_f ge_c wh_int wh_f wh_c;
  label ge_int = 'GE Intercept'
        ge_f   = 'GE Lagged Share Value Coef'
        ge_c   = 'GE Lagged Capital Stock Coef'
        wh_int = 'WH Intercept'
        wh_f   = 'WH Lagged Share Value Coef'
        wh_c   = 'WH Lagged Capital Stock Coef';
  gei = ge_int + ge_f * gef + ge_c * gec;
  whi = wh_int + wh_f * whf + wh_c * whc;
run;

Number of Residuals				20			

The model stored in [Example 19.3](#) is read in by using the MODEL= option and the moving-average terms are added using the %MA macro.

The MA(1) model using maximum likelihood is estimated by using the following statements:

```
title2 'MA(1) Error Process Using Maximum Likelihood ';

proc model data=grunfeld model=grunmod;
  %ma(gei,1, m=ml);
  %ma(whi,1, m=ml);
  fit whi gei;
run;
```

For comparison, the model is estimated by using PROC ARIMA as follows:

```
title2 'PROC ARIMA Using Maximum Likelihood ';

proc arima data=grunfeld;
  identify var=whi cross=(whf whc) noprint;
  estimate q=1 input=(whf whc) method=ml;
run;
```

PROC ARIMA does not estimate systems, so only one equation is evaluated.

The estimation results are shown in [Output 19.4.3](#) and [Output 19.4.4](#). The small differences in the parameter values between PROC MODEL and PROC ARIMA can be eliminated by tightening the convergence criteria for both procedures.

Example 19.5: Polynomial Distributed Lags by Using %PDL

This example shows the use of the %PDL macro for polynomial distributed lag models. Simulated data is generated so that Y is a linear function of six lags of X , with the lag coefficients following a quadratic polynomial. The model is estimated by using a fourth-degree polynomial, both with and without endpoint constraints. The example uses simulated data generated from the following model:

$$y_t = 10 + \sum_{z=0}^6 f(z)x_{t-z} + \epsilon$$

$$f(z) = -5z^2 + 1.5z$$

The LIST option prints the model statements added by the %PDL macro. The following statements generate simulated data as shown:

```

/*-----*/
/* Generate Simulated Data for a Linear Model with a PDL on X */
/*      y = 10 + x(6,2) + e                                     */
/*      pdl(x) = -5.*(lg)**2 + 1.5*(lg) + 0.                     */
/*-----*/
data pdl;
  pdl2=-5.; pdl1=1.5; pdl0=0;
  array zz(i) z0-z6;
  do i=1 to 7;
    z=i-1;
    zz=pdl2*z**2 + pdl1*z + pdl0;
  end;
  do n=-11 to 30;
    x =10*ranuni(1234567)-5;
    pdl=z0*x + z1*x11 + z2*x12 + z3*x13 + z4*x14 + z5*x15 + z6*x16;
    e =10*rannor(1234567);
    y =10+pdl+e;
    if n>=1 then output;
    x16=x15; x15=x14; x14=x13; x13=x12; x12=x11; x11=x;
  end;
run;

title1 'Polynomial Distributed Lag Example';
title3 'Estimation of PDL(6,4) Model-- No Endpoint Restrictions';

proc model data=pdl;
  parms int;                                /* declare the intercept parameter */
  %pdl( xpdl, 6, 4 )                        /* declare the lag distribution */
  y = int + %pdl( xpdl, x );                /* define the model equation */
  fit y / list;                             /* estimate the parameters */
run;

```

The LIST output for the model without endpoint restrictions is shown in [Output 19.5.1](#). The first seven statements in the generated program are the polynomial expressions for lag parameters XPDL_L0 through XPDL_L6. The estimated parameters are INT, XPDL_0, XPDL_1, XPDL_2, XPDL_3, and XPDL_4.

Output 19.5.1 PROC MODEL Listing of Generated Program

XPDL_3	-9.3535	1.7602	-5.31	<.0001	PDL(XPDL, 6, 4) parameter for (L)**3		
XPDL_4	1.032421	0.1471	7.02	<.0001	PDL(XPDL, 6, 4) parameter for (L)**4		

Note that XPDL_0 and XPDL_1 are not shown in the estimate summary. They were used to satisfy the endpoint restrictions analytically by the generated %PDL macro code. Their values can be determined by back substitution.

To estimate the PDL model with one or more of the polynomial terms dropped, specify the largest degree of the polynomial desired with the %PDL macro and use the DROP= option in the FIT statement to remove the unwanted terms. The dropped parameters should be set to 0. The following PROC MODEL statements demonstrate estimation with a PDL of degree 2 without the 0th order term.

```

title3 'Estimation of PDL(6,2) Model-- With XPDL_0 Dropped';

proc model data=pd1 list;
  parms int;                      /* declare the intercept parameter */
  %pdl( xpd1, 6, 2 )              /* declare the lag distribution */
  y = int + %pdl( xpd1, x );      /* define the model equation */
  xpd1_0 = 0;
  fit y drop=xpd1_0;              /* estimate the parameters */
run;

```

The results from this estimation are shown in [Output 19.5.4](#).

Example 19.6: General Form Equations

Data for this example are generated. General form equations are estimated and forecast by using PROC MODEL. The system is a basic supply and demand model.

The following statements specify the form of the model:

```

title1 "General Form Equations for Supply-Demand Model";

proc model outmodel=model;
  var price quantity income unitcost;
  parms d0-d2 s0-s2;
  eq.demand=d0+d1*price+d2*income-quantity;
  eq.supply=s0+s1*price+s2*unitcost-quantity;
run;

```

Three data sets are used in this example. The first data set, HISTORY, is used to estimate the parameters of the model. The ASSUME data set is used to produce a forecast of PRICE and QUANTITY. Notice that the ASSUME data set does not need to contain the variables PRICE and QUANTITY. The HISTORY data set is shown as follows:

```
data history;
    input year income unitcost price quantity;
datalines;
1976    2221.87    3.31220    0.17903    266.714
1977    2254.77    3.61647    0.06757    276.049
1978    2285.16    2.21601    0.82916    285.858

... more lines ...
```

The ASSUME data set is shown as follows:

```
data assume;
    input year income unitcost;
datalines;
1986    2571.87    2.31220
1987    2609.12    2.45633
1988    2639.77    2.51647
1989    2667.77    1.65617
1990    2705.16    1.01601
;
```

The third data set, GOAL, used in a forecast of PRICE and UNITCOST as a function of INCOME and QUANTITY is as follows:

```
data goal;
    input year income quantity;
datalines;
1986    2571.87    371.4
1987    2721.08    416.5
1988    3327.05    597.3
1989    3885.85    764.1
1990    3650.98    694.3
;
```

The following statements fit the model to the HISTORY data set and solve the fitted model for the ASSUME data set.

```
proc model model=model outmodel=model;

/* estimate the model parameters */
  fit supply demand / data=history outest=est n2sls;
  instruments income unitcost year;
run;

/* produce forecasts for income and unitcost assumptions */
  solve price quantity / data=assume out=pq;
run;

title2 "Parameter Estimates for the System";
proc print data=est;
run;

title2 "Price Quantity Solution";
proc print data=pq;
run;
```

The model summary of the supply and demand model is shown as follows:

Example 19.7: Spring and Damper Continuous System

This model simulates the mechanical behavior of a spring and damper system shown in Figure 19.99.

Figure 19.99 Spring and Damper System Model

A mass is hung from a spring with spring constant K . The motion is slowed by a damper with damper constant C . The damping force is proportional to the velocity, while the spring force is proportional to the displacement.

This is actually a continuous system; however, the behavior can be approximated by a discrete time model. We approximate the differential equation

$$\frac{\partial \text{disp}}{\partial \text{time}} = \text{velocity}$$

with the difference equation

$$\frac{\Delta \text{disp}}{\Delta \text{time}} = \text{velocity}$$

This is rewritten as

$$\frac{\text{disp} - \text{LAG}(\text{disp})}{dt} = \text{velocity}$$

where dt is the time step used. In PROC MODEL, this is expressed with the program statement

```
disp = lag(disp) + vel * dt;
```

or

```
dert.disp = vel;
```

The first statement is simply a computing formula for Euler's approximation for the integral

$$disp = \int velocity \, dt$$

If the time step is small enough with respect to the changes in the system, the approximation is good. Although PROC MODEL does not have the variable step-size and error-monitoring features of simulators designed for continuous systems, the procedure is a good tool to use for less challenging continuous models.

The second form instructs the MODEL procedure to do the integration for you.

This model is unusual because there are no exogenous variables, and endogenous data are not needed. Although you still need a SAS data set to count the simulation periods, no actual data are brought in.

Since the variables DISP and VEL are lagged, initial values specified in the VAR statement determine the starting state of the system. The mass, time step, spring constant, and damper constant are declared and initialized by a CONTROL statement as shown in the following statements:

```
title1 'Simulation of Spring-Mass-Damper System';

/*- Data to drive the simulation time periods ---*/
data one;
  do n=1 to 100;
    output;
  end;
run;

proc model data=one outmodel=spring;
  var      force -200  disp 10  vel  0  accel -20  time 0;
  control  mass   9.2  c    1.5  dt   .1  k      20;
  force = -k * disp -c * vel;
  disp  = lag(disp) + vel * dt;
  vel   = lag(vel) + accel * dt;
  accel = force / mass;
  time  = lag(time) + dt;
run;
```

The displacement scale is zeroed at the point where the force of gravity is offset, so the acceleration of the gravity constant is omitted from the force equation. The control variable C and K represent the damper and the spring constants respectively.

The model is simulated three times, and the simulation results are written to output data sets. The first run uses the original initial conditions specified in the VAR statement. In the second run, the initial displacement is doubled; the results show that the period of the motion is unaffected by the amplitude. In the third run, the DERT. syntax is used to do the integration. Notice that the path of the displacement is close to the old path, indicating that the original time step is short enough to yield an accurate solution. These simulations are performed by the following statements:

```

proc model data=one model=spring;
  title2 "Simulation of the model for the base case";
  control run '1';
  solve / out=a;
run;

  title2 "Simulation of the model with twice the initial displacement";
  control run '2';
  var disp 20;
  solve / out=b;
run;

data two;
  do time = 0 to 10 by .2; output;end;
run;

title2 "Simulation of the model using the dert. syntax";
proc model data=two;
  var      force -200  disp  10  vel  0  accel -20  time 0;
  control  mass   9.2  c    1.5  dt   .1  k      20;
  control run '3' ;
  force = -k * disp -c * vel;
  dert.disp = vel ;
  dert.vel   = accel;
  accel = force / mass;
  solve / out=c;
  id time ;
run;

```

The output SAS data sets that contain the solution results are merged and the displacement time paths for the three simulations are plotted. The three runs are identified on the plot as 1, 2, and 3. The following statements produce [Output 19.7.1](#) through [Output 19.7.5](#).

```

data p;
  set a b c;
run;

title2 'Overlay Plot of All Three Simulations';
proc sgplot data=p;
  series x=time y=disp / group=run lineattrs=(pattern=1);
  xaxis values=(0 to 10 by 1);
  yaxis values=(-20 to 20 by 10);
run;

```

Example 19.8: Nonlinear FIML Estimation

The data and model for this example were obtained from Bard (1974, pp. 133–138). The example is a two-equation econometric model used by Bodkin and Klein to fit U.S production data for the years 1909–1949. The model is the following:

$$g_1 = c_1 10^{c_2 z_4} (c_5 z_1^{-c_4} + (1 - c_5) z_2^{-c_4})^{-c_3/c_4} - z_3 = 0$$

$$g_2 = [c_5 / (1 - c_5)] (z_1 / z_2)^{(-1 - c_4)} - z_5 = 0$$

where z_1 is capital input, z_2 is labor input, z_3 is real output, z_4 is time in years with 1929 as year zero, and z_5 is the ratio of price of capital services to wage scale. The c_i 's are the unknown parameters. z_1 and z_2 are considered endogenous variables. A FIML estimation is performed by using the following statements:

```

data bodkin;
    input z1 z2 z3 z4 z5;
datalines;
1.33135 0.64629 0.4026 -20 0.24447
1.39235 0.66302 0.4084 -19 0.23454
1.41640 0.65272 0.4223 -18 0.23206

... more lines ...

title1 "Nonlinear FIML Estimation";

proc model data=bodkin;
    parms c1-c5;
    endogenous z1 z2;
    exogenous z3 z4 z5;

    eq.g1 = c1 * 10 ** (c2 * z4) * (c5*z1**(-c4)+
        (1-c5)*z2**(-c4))**(-c3/c4) - z3;
    eq.g2 = (c5/(1-c5))*(z1/z2)**(-1-c4) -z5;

    fit g1 g2 / fiml ;
run;

```

When FIML estimation is selected, the log likelihood of the system is output as the objective value. The results of the estimation are shown in [Output 19.8.1](#).

Example 19.9: Circuit Estimation

Consider the nonlinear circuit shown in Figure 19.100.

Figure 19.100 Nonlinear Resistor Capacitor Circuit

The theory of electric circuits is governed by Kirchhoff's laws: the sum of the currents flowing to a node is zero, and the net voltage drop around a closed loop is zero. In addition to Kirchhoff's laws, there are relationships between the current I through each element and the voltage drop V across the elements. For the circuit in Figure 19.100, the relationships are

$$C \frac{dV}{dt} = I$$

for the capacitor and

$$V = (R_1 + R_2(1 - \exp(-V)))I$$

for the nonlinear resistor. The following differential equation describes the current at node 2 as a function of time and voltage for this circuit:

$$C \frac{dV_2}{dt} - \frac{V_1 - V_2}{R_1 + R_2(1 - \exp(-V))} = 0$$

This equation can be written in the form

$$\frac{dV_2}{dt} = \frac{V_1 - V_2}{(R_1 + R_2(1 - \exp(-V)))C}$$

Consider the following data.

```

data circ;
  input v2 v1 time@@;
datalines;
-0.00007 0.0 0.0000000001 0.00912 0.5 0.0000000002

1.57894 5.0 0.0000000021 1.66471 5.0 0.0000000022
;

```

You can estimate the parameters in the preceding equation by using the following SAS statements:

```

title1 'Circuit Model Estimation Example';

proc model data=circ mintimestep=1.0e-23;
  parm R2 2000 R1 4000 C 5.0e-13;
  dert.v2 = (v1-v2)/((r1 + r2*(1-exp( -(v1-v2)))) * C);
  fit v2;
run;

```

The results of the estimation are shown in [Output 19.9.1](#).

Output 19.9.1 Circuit Estimation

Circuit Model Estimation Example				
The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
R2	3002.471	1517.1	<-----	Biased
R1	4984.842	1466.8	<-----	Biased
C	5E-13	0	<-----	Biased
NOTE: The model was singular. Some estimates are marked 'Biased'.				

In this case, the model equation is such that there is linear dependency that causes biased results and inflated variances. The Jacobian matrix is singular or nearly singular, but eliminating one of the parameters is not a solution in this case.

Example 19.10: Systems of Differential Equations

The following is a simplified reaction scheme for the competitive inhibitors with recombinant human renin (Morelock et al. 1995).

Figure 19.101 Competitive Inhibition of Recombinant Human Renin

In Figure 19.101, E =enzyme, D =probe, and I =inhibitor.

The differential equations that describe this reaction scheme are as follows:

$$\begin{aligned}
 \frac{dD}{dt} &= k1r * ED - k1f * E * D \\
 \frac{dED}{dt} &= k1f * E * D - k1r * ED \\
 \frac{dE}{dt} &= k1r * ED - k1f * E * D + k2r * EI - k2f * E * I \\
 \frac{dEI}{dt} &= k2f * E * I - k2r * EI \\
 \frac{dI}{dt} &= k2r * EI - k2f * E * I
 \end{aligned}$$

For this system, the initial values for the concentrations are derived from equilibrium considerations (as a function of parameters) or are provided as known values.

The experiment used to collect the data was carried out in two ways; preincubation (type='disassoc') and no preincubation (type='assoc'). The data also contain repeated measurements. The data contain values for fluorescence F , which is a function of concentration. Since there are no direct data for the concentrations, all the differential equations are simulated dynamically.

The SAS statements used to fit this model are as follows:

```

title1 'Systems of Differential Equations Example';

proc sort data=fit;
    by type time;

Example 19.11: Monte Carlo Simulation

This example illustrates how the form of the error in a ODE model affects the results from a static and dynamic estimation. The differential equation studied is

$$\frac{dy}{dt} = a - ay$$

The analytical solution to this differential equation is

$$y = 1 - \exp(-at)$$

The first data set contains errors that are strictly additive and independent. The data for this estimation are generated by the following DATA step:

```
data drive1;
  a = 0.5;
  do iter=1 to 100;
    do time = 0 to 50;
      y = 1 - exp(-a*time) + 0.1 *rannor(123);
      output;
    end;
  end;
run;
```

The second data set contains errors that are cumulative in form.

```
data drive2;
  a = 0.5;
  yp = 1.0 + 0.01 *rannor(123);
  do iter=1 to 100;
    do time = 0 to 50;
      y = 1 - exp(-a)*(1 - yp);
      yp = y + 0.01 *rannor(123);
      output;
    end;
  end;
run;
```

The following statements perform the 100 static estimations for each data set:

```

title1 'Monte Carlo Simulation of ODE';

proc model data=drive1 noprint;
  parm a 0.5;
  dert.y = a - a * y;
  fit y / outest=est;
  by iter;
run;

```

Similar statements are used to produce 100 dynamic estimations with a fixed and an unknown initial value. The first value in the data set is used to simulate an error in the initial value. The following PROC UNIVARIATE statements process the estimations:

```

proc univariate data=est noprint;
  var a;
  output out=monte mean=mean p5=p5 p95=p95;
run;

proc print data=monte;
run;

```

The results of these estimations are summarized in [Table 19.6](#).

Table 19.6 Monte Carlo Summary, A=0.5

Estimation Type	Additive Error			Cumulative Error		
	mean	p95	p5	mean	p95	p5
static	0.77885	1.03524	0.54733	0.57863	1.16112	0.31334
dynamic fixed	0.48785	0.63273	0.37644	3.8546E24	8.88E10	-51.9249
dynamic unknown	0.48518	0.62452	0.36754	641704.51	1940.42	-25.6054

For this example model, it is evident that the static estimation is the least sensitive to misspecification.

Example 19.12: Cauchy Distribution Estimation

In this example a nonlinear model is estimated by using the Cauchy distribution. Then a simulation is done for one observation in the data.

The following DATA step creates the data for the model.

```

/* Generate a Cauchy distributed Y */
data c;
  format date monyy.;
  call streaminit(156789);
  do t=0 to 20 by 0.1;
    date=intnx('month', '01jun90'd, (t*10)-1);
    x=rand('normal');
    e=rand('cauchy') + 10 ;
    y=exp(4*x)+e;
    output;
  end;
run;

```

The model to be estimated is

$$y = e^{-a x} + \epsilon$$

$$\epsilon \sim \text{Cauchy}(nc)$$

That is, the residuals of the model are distributed as a Cauchy distribution with noncentrality parameter nc .

The log likelihood for the Cauchy distribution is

$$ll = -\log \pi(1 + (x - nc)^2)$$

The following SAS statements specify the model and the log-likelihood function.

```

title1 'Cauchy Distribution';

proc model data=c ;
  dependent y;
  parm a -2 nc 4;
  y=exp(-a*x);

  /* Likelihood function for the residuals */
  obj = log(constant('pi')*(1+(-resid.y-nc)**2));

  errormodel y ~ general(obj) cdf=cauchy(nc);

  fit y / outsn=s1 method=marquardt;
  solve y / sdata=s1 data=c(obs=1) random=1000
          seed=256789 out=out1;
run;

title 'Distribution of Y';
proc sgplot data=out1;
  histogram y;
run;

```

The FIT statement uses the OUTSN= option to output the Σ matrix for residuals from the normal distribution. The Σ matrix is 1×1 and has value 1.0 because it is a correlation matrix. The OUTS= matrix is the scalar 2989.0. Because the distribution is univariate (no covariances), the OUTS= option would produce the same simulation results. The simulation is performed by using the SOLVE statement.

The distribution of y is shown in the following output.

Output 19.12.1 Distribution of Y

Example 19.13: Switching Regression Example

Take the usual linear regression problem

$$y = \mathbf{X}\beta + u$$

where Y denotes the n column vector of the dependent variable, \mathbf{X} denotes the $(n \times k)$ matrix of independent variables, β denotes the k column vector of coefficients to be estimated, n denotes the number of observations ($i=1, 2, \dots, n$), and k denotes the number of independent variables.

You can take this basic equation and split it into two regimes, where the i th observation on y is generated by one regime or the other:

$$y_i = \sum_{j=1}^k \beta_{1j} X_{ji} + u_{1i} = x_i' \beta_1 + u_{1i}$$

$$y_i = \sum_{j=1}^k \beta_{2j} X_{ji} + u_{2i} = x_i' \beta_2 + u_{2i}$$

where x_{hi} and x_{hj} are the i th and j th observations, respectively, on x_h . The errors, u_{1i} and u_{2i} , are assumed to be distributed normally and independently with mean zero and constant variance. The variance for the first regime is σ_1^2 , and the variance for the second regime is σ_2^2 . If $\sigma_1^2 \neq \sigma_2^2$ and $\beta_1 \neq \beta_2$, the regression system given previously is thought to be switching between the two regimes.

The problem is to estimate β_1 , β_2 , σ_1 , and σ_2 without knowing *a priori* which of the n values of the dependent variable, y , was generated by which regime. If it is known *a priori* which observations belong to which regime, a simple Chow test can be used to test $\sigma_1^2 = \sigma_2^2$ and $\beta_1 = \beta_2$.

Using Goldfeld and Quandt's D-method for switching regression, you can solve this problem. Assume that observations exist on some exogenous variables $z_{1i}, z_{2i}, \dots, z_{pi}$, where z determines whether the i th observation is generated from one equation or the other. The equations are given as follows:

$$y_i = x_i' \beta_1 + u_{1i} \quad \text{if } \sum_{j=1}^p \pi_j z_{ji} \leq 0$$

$$y_i = x_i' \beta_2 + u_{2i} \quad \text{if } \sum_{j=1}^p \pi_j z_{ji} > 0$$

where π_j are unknown coefficients to be estimated. Define $d(z_i)$ as a continuous approximation to a step function. Replacing the unit step function with a continuous approximation by using the cumulative normal integral enables a more practical method that produces consistent estimates.

$$d(z_i) = \frac{1}{\sqrt{2\pi}\sigma} \int_{-\infty}^{\sum \pi_j z_{ji}} \exp \left[-\frac{1}{2} \frac{\xi^2}{\sigma^2} \right] d\xi$$

D is the n dimensional diagonal matrix consisting of $d(z_i)$:

$$\mathbf{D} = \begin{bmatrix} d(z_1) & 0 & 0 & 0 \\ 0 & d(z_2) & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & d(z_n) \end{bmatrix}$$

The parameters to estimate are now the k β_1 's, the k β_2 's, σ_1^2 , σ_2^2 , p π 's, and the σ introduced in the $d(z_i)$ equation. The σ can be considered as given *a priori*, or it can be estimated, in which case, the estimated magnitude provides an estimate of the success in discriminating between the two regimes (Goldfeld and Quandt 1976). Given the preceding equations, the model can be written as:

$$Y = (\mathbf{I} - \mathbf{D}) \mathbf{X} \beta_1 + \mathbf{D} \mathbf{X} \beta_2 + W$$

where $W = (\mathbf{I} - \mathbf{D})U_1 + \mathbf{D}U_2$, and W is a vector of unobservable and heteroscedastic error terms. The covariance matrix of W is denoted by $\mathbf{\Omega}$, where $\mathbf{\Omega} = (\mathbf{I} - \mathbf{D})^2\sigma_1^2 + \mathbf{D}^2\sigma_2^2$. The maximum likelihood parameter estimates maximize the following log-likelihood function.

$$\begin{aligned} \log L = & -\frac{n}{2} \log 2\pi - \frac{1}{2} \log |\mathbf{\Omega}| - \\ & \frac{1}{2} * [[Y - (\mathbf{I} - \mathbf{D})\mathbf{X}\beta_1 - \mathbf{D}\mathbf{X}\beta_2]' \mathbf{\Omega}^{-1} [Y - (\mathbf{I} - \mathbf{D})\mathbf{X}\beta_1 - \mathbf{D}\mathbf{X}\beta_2]] \end{aligned}$$

As an example, you now can use this switching regression likelihood to develop a model of housing starts as a function of changes in mortgage interest rates. The data for this example are from the U.S. Census Bureau and cover the period from January 1973 to March 1999. The hypothesis is that there are different coefficients on your model based on whether the interest rates are going up or down.

So the model for z_i is

$$z_i = p * (\text{rate}_i - \text{rate}_{i-1})$$

where rate_i is the mortgage interest rate at time i and p is a scale parameter to be estimated.

The regression model is

$$\begin{aligned} \text{starts}_i &= \text{intercept}_1 + \text{ar1} * \text{starts}_{i-1} + \text{djf1} * \text{decjanfeb} & z_i < 0 \\ \text{starts}_i &= \text{intercept}_2 + \text{ar2} * \text{starts}_{i-1} + \text{djf2} * \text{decjanfeb} & z_i \geq 0 \end{aligned}$$

where starts_i is the number of housing starts at month i and decjanfeb is a dummy variable that indicates that the current month is one of December, January, or February.

This model is written by using the following SAS statements:

```

title1 'Switching Regression Example';

proc model data=switch;
  parms sig1=10 sig2=10 int1 b11 b13 int2 b21 b23 p;
  bounds 0.0001 < sig1 sig2;

  decjanfeb = ( month(date) = 12 | month(date) <= 2 );

  a = p*dif(rate);          /* Upper bound of integral */
  d = probnorm(a);         /* Normal CDF as an approx of switch */

                                /* Regime 1 */
  y1 = int1 + zlag(starts)*b11 + decjanfeb *b13 ;
                                /* Regime 2 */
  y2 = int2 + zlag(starts)*b21 + decjanfeb *b23 ;
                                /* Composite regression equation */
  starts = (1 - d)*y1 + d*y2;

                                /* Resulting log-likelihood function */
  logL = (1/2)*( (log(2*3.1415)) +
    log( (sig1**2)*((1-d)**2)+(sig2**2)*(d**2) )
    + (resid.starts*( 1/( (sig1**2)*((1-d)**2)+

```

```

      (sig2**2)*(d**2) ) *resid.starts) ) ;

errormodel starts ~ general(logL);

fit starts / method=marquardt converge=1.0e-5;

/* Test for significant differences in the parms */
test int1 = int2 ,/ lm;
test b11 = b21 ,/ lm;
test b13 = b23 ,/ lm;
test sig1 = sig2 ,/ lm;

run;

```

Four TEST statements are added to test the hypothesis that the parameters are the same in both regimes. The parameter estimates and ANOVA table from this run are shown in [Output 19.13.1](#).

Output 19.13.1 Parameter Estimates from the Switching Regression

Switching Regression Example						
The MODEL Procedure

Example 19.14: Simulating from a Mixture of Distributions

This example illustrates how to perform a multivariate simulation by using models that have different error distributions. Three models are used. The first model has t distributed errors. The second model is a GARCH(1,1) model with normally distributed errors. The third model has a noncentral Cauchy distribution.

The following SAS statements generate the data for this example. The t and the CAUCHY data sets use a common seed so that those two series are correlated.

```

/* set distribution parameters */
%let df = 7.5;
%let sig1 = .5;
%let var2 = 2.5;

data t;
  format date monyy.;
  do date='1jun2001'd to '1nov2002'd;
    /* t-distribution with df,sig1 */
    t = .05 * date + 5000 + &sig1*tinv(ranuni(1234),&df);
    output;
  end;
run;

data normal;
  format date monyy.;
  le = &var2;
  lv = &var2;
  do date='1jun2001'd to '1nov2002'd;
    /* Normal with GARCH error structure */
    v = 0.0001 + 0.2 * le**2 + .75 * lv;
    e = sqrt(v) * rannor(12345);
    normal = 25 + e;
    le = e;
    lv = v;
    output;
  end;
run;

```

```

data cauchy;
  format date monyy.;
  PI = 3.1415926;
  do date='1jun2001'd to '1nov2002'd;
    cauchy = -4 + tan((ranuni(1234) - 0.5) * PI);
    output;
  end;
run;

```

Since the multivariate joint likelihood is unknown, the models must be estimated separately. The residuals for each model are saved by using the OUT= option. Also, each model is saved by using the OUTMODEL= option. The ID statement is used to provide a variable in the residual data set to merge by. The XLAG function is used to model the GARCH(1,1) process. The XLAG function returns the lag of the first argument if it is nonmissing, otherwise it returns the second argument.

```

title1 't-distributed Errors Example';

proc model data=t outmod=tModel;
  parms df 10 vt 4;
  t = a * date + c;
  errormodel t ~ t( vt, df );
  fit t / out=tresid;
  id date;
run;

title1 'GARCH-distributed Errors Example';

proc model data=normal outmodel=normalModel;
  normal = b0 ;
  h.normal = arch0 + arch1 * xlag(resid.normal **2 , mse.normal)
    + GARCH1 * xlag(h.normal, mse.normal);

  fit normal /fiml out=nresid;
  id date;
run;

title1 'Cauchy-distributed Errors Example';

proc model data=cauchy outmod=cauchyModel;
  parms nc = 1;
  /* nc is noncentrality parm to Cauchy dist */
  cauchy = nc;
  obj = log(1+resid.cauchy**2 * 3.1415926);
  errormodel cauchy ~ general(obj) cdf=cauchy(nc);

  fit cauchy / out=cresid;
  id date;
run;

```

The simulation requires a covariance matrix created from normal residuals. The following DATA step statements use the inverse CDFs of the t and Cauchy distributions to convert the residuals to the normal distribution. The CORR procedure is used to create a correlation matrix that uses the converted residuals.

```

/* Merge and normalize the 3 residual data sets */
data c; merge tresid nresid cresid; by date;
    t = probit(cdf("T", t/sqrt(0.2789), 16.58 ));
    cauchy = probit(cdf("CAUCHY", cauchy, -4.0623));
run;

proc corr data=c out=s;
    var t normal cauchy;
run;

```

Now the models can be simulated together by using the MODEL procedure SOLVE statement. The data set created by the CORR procedure is used as the correlation matrix.

```

title1 'Simulating Equations with Different Error Distributions';

/* Create one observation driver data set */
data sim; merge t normal cauchy; by date;
data sim; set sim(firstobs = 519 );

proc model data=sim model=( tModel normalModel cauchyModel );
    errormodel t ~ t( vt, df );
    errormodel cauchy ~ cauchy(nc);
    solve t cauchy normal / random=2000 seed=1962 out=monte
                                sdata=s(where=(_type_="CORR"));
run;

```

An estimation of the joint density of the t and Cauchy distribution is created by using the KDE procedure. Bounds are placed on the Cauchy dimension because of its fat tail behavior. The joint PDF is shown in [Output 19.14.1](#).

```

title "T and Cauchy Distribution";

proc kde data=monte;
    univar t          / out=t_dens;
    univar cauchy     / out=cauchy_dens;
    bivar t cauchy    / out=density
                        plots=all;
run;

```

Output 19.14.1 Bivariate Density of t and Cauchy, Distribution of t by Cauchy

Output 19.14.6 Bivariate Density of t and Cauchy, Distribution and Kernel Density for t and Cauchy

Example 19.15: Simulated Method of Moments—Simple Linear Regression

This example illustrates how to use SMM to estimate a simple linear regression model for the following process:

$$y = a + bx + \epsilon, \epsilon \sim iid N(0, s^2)$$

In the following SAS statements, *ysim* is simulated, and the first moment and the second moment of *ysim* are compared with those of the observed endogenous variable *y*.

```
title "Simple regression model";

data regdata;
  do i=1 to 500;
    x = rannor( 1013 );
    Y = 2 + 1.5 * x + 1.5 * rannor( 1013 );
    output;
  end;
run;
```

```

proc model data=regdata;
  parms a b s;
  instrument x;

  ysim = (a+b*x) + s * rannor( 8003 );
  y = ysim;
  eq.ysq = y*y - ysim*ysim;

  fit y ysq / gmm ndraw;
  bound s > 0;
run;

```

Alternatively, the MOMENT statement can be used to specify the moments using the following syntax:

```

proc model data=regdata;
  parms a b s;
  instrument x;

  ysim = (a+b*x) + s * rannor( 8003 );
  y = ysim;
  moment y = (2);

  fit y / gmm ndraw;
  bound s > 0;
run;

```

The output of the MODEL procedure is shown in [Output 19.15.1](#):

Output 19.15.1 PROC MODEL Output

Example 19.16: Simulated Method of Moments—AR(1) Process

This example illustrates how to use SMM to estimate an AR(1) regression model for the following process:

$$\begin{aligned}
 y_t &= a + bx_t + u_t \\
 u_t &= \alpha u_{t-1} + \epsilon_t \\
 \epsilon_t &\sim iid N(0, s^2)
 \end{aligned}$$

In the following SAS statements, *ysim* is simulated by using this model, and the endogenous variable *y* is set to be equal to *ysim*. The **MOMENT** statement creates two more moments for the estimation. One is the second moment, and the other is the first-order autocovariance. The **NPREOBS=10** option instructs PROC MODEL to run the simulation 10 times before *ysim* is compared to the first observation of *y*. Because the initial *zlag(u)* is zero, the first *ysim* is $a + b * x + s * \text{rannor}(8003)$. Without the **NPREOBS** option, this *ysim* is matched with the first observation of *y*. With **NPREOBS**, this *ysim* and the next nine *ysim* are thrown away, and the moment match starts with the eleventh *ysim* with the first observation of *y*. This way, the initial values do not exert a large influence on the simulated endogenous variables.

Example 19.17: Simulated Method of Moments—Stochastic Volatility Model

This example illustrates how to use SMM to estimate a stochastic volatility model as in Andersen and Sorensen (1996):

$$\begin{aligned}y_t &= \sigma_t z_t \\ \log(\sigma_t^2) &= a + b \log(\sigma_{t-1}^2) + s u_t \\ (z_t, u_t) &\sim iid N(0, I_2)\end{aligned}$$

This model is widely used in modeling the return process of stock prices and foreign exchange rates. This is called the stochastic volatility model because the volatility is stochastic as the random variable u_t appears in the volatility equation. The following SAS statements use three moments: absolute value, the second-order moment, and absolute value of the first-order autoregressive moment. Note the ADJSMMV option in the FIT statement to request the SMM covariance adjustment for the parameter estimates. Although these moments have closed form solution as shown by Andersen and Sorensen (1996), the simulation approach significantly simplifies the moment conditions.

Example 19.18: Duration Data Model with Unobserved Heterogeneity

All of the previous three models actually have closed-form moment conditions, so the simulation approach is not necessarily required for the estimation. This example illustrates how to use SMM to estimate a model for which there is no closed-form solution for the moments and thus the traditional GMM method does not apply. The model is the duration data model with unobserved heterogeneity in [Gourieroux and Monfort \(1993\)](#):

$$y_i = -\exp(-bx_i - \sigma u_i) \log(v_i)$$

$$u_i \sim N(0, 1) \quad v_i \sim U_{[0,1]}$$

The SAS statements are:

```

title1 'SMM for Duration Model with Unobserved Heterogeneity';

%let nobs=1000;
data durationdata;

Example 19.19: EMM Estimation of a Stochastic Volatility Model

The efficient method of moments (EMM) (Bansal et al. 1993, 1995; Gallant and Tauchen 2001), can be considered a variant of SMM. The idea is to match the efficiency of the maximum likelihood (ML) estimation with the flexibility of the SMM procedure. ML itself can be interpreted as a method of moments procedure, where the *score vector*, the vector of derivatives of the log-likelihood function with respect to the parameters, provides the exactly identifying moment conditions. EMM employs an auxiliary (or pseudo) model that closely matches the true model. The score vector of the auxiliary model provides the moment conditions in the SMM step.

This example uses the SMM feature of PROC MODEL to estimate the simple stochastic volatility (SV) model of Example 19.17 with the EMM method.

Suppose that your data are the time series $\{y_1, y_2, \dots, y_n\}$, and the model that you want to estimate, or the structural model, is characterized by the vector of parameters θ . For the SV model, θ is given by (a, b, s) .

The first step of the EMM method is to fit the data with an auxiliary model (or score generator) that has transition density $f(y_t|Y_{t-1}, \eta)$, parameterized by the pseudo parameter η , where $Y_{t-1} = \{y_{t-1}, \dots, y_1\}$. The auxiliary model must approximate the true data-generating process as closely as possible and be such that ML estimation is feasible.

The only identification requirement is that the dimension of the pseudo parameter η be greater than or equal to that of the structural parameter θ .

Andersen, Chung, and Sorensen (1999) showed that the GARCH(1,1) is an appropriate auxiliary model that leads to a good performance of the EMM estimator for the SV model.

The analytical expression for the GARCH(1,1) model with mean zero is

$$\begin{aligned} y_t &= \sigma_t z_t \\ \sigma_t^2 &= \omega + \alpha y_{t-1} + \beta \sigma_{t-1}^2 \end{aligned}$$

The pseudo parameter vector η is given by (ω, α, β) .

One advantage of such a class of models is that the conditional density of y_t is Gaussian—that is,

$$f(y_t|Y_{t-1}, \eta) \propto \frac{1}{\sigma_t} \exp\left(-\frac{y_t^2}{2\sigma_t^2}\right)$$

Therefore the score vector can easily be computed analytically.

The AUTOREG procedure provides the ML estimates, $\hat{\eta}_n$. The estimates are stored in the garchest data set.

```

title1 'Efficient Method of Moments for Stochastic Volatility Model';

/* estimate GARCH(1,1) model */
proc autoreg data=svdata(keep=y)
    outest=garchest
    noprint covout;
    model y = / noint garch=(q=1,p=1,type=nonneg);
run;

```

If the pseudo model is close enough to the structural model, in a suitable sense, Gallant and Long (1997) showed that a consistent estimator of the asymptotic covariance matrix of the sample pseudo-score vector can be obtained from the formula

$$\hat{V}_n = \frac{1}{n} \sum_{t=1}^n s_f(Y_t, \hat{\eta}_n) s_f(Y_t, \hat{\eta}_n)'$$

where $s_f(Y_t, \hat{\eta}_n) = (\partial/\partial\eta_n) \log f(y_t|Y_{t-1}, \hat{\eta}_n)$ denotes the score function of the auxiliary model computed at the ML estimates.

The ML estimates of the GARCH(1,1) model are used in the following SAS statements to compute the variance-covariance matrix \hat{V}_n .

```

/* compute the V matrix */
data vvalues;
    set scores;

    array score{*} dlldw dllda dlldb;
    array v_t{*} v_t_1-v_t_6;
    array v{*} v_1-v_6;

    /* compute external product of score vector */
    do i=1 to 3;
        do j=i to 3;
            v_t{j*(j-1)/2 + i} = score{i}*score{j};
        end;
    end;

    /* average them over t */
    do s=1 to 6;
        v{s}+ v_t{s}/&nobs;
    end;
run;

```

The \hat{V} matrix must be formatted to be used with the VDATA= option of the MODEL procedure. See the section “[VDATA= Input data set](#)” on page 1215 for more information about the VDATA= data set.

```

/* Create a VDATA dataset acceptable to PROC MODEL */

/* Transpose the last obs in the dataset */
proc transpose data=vvalues(firstobs=&nobs keep=v_1-v_6)
    out=tempv;
run;

/* Add eq and inst labels */
data vhat;
    set tempv(drop=_name_);
    value = coll;
    drop coll;
    input _type_ $ eq_row $ eq_col $ inst_row $ inst_col $; *$;
    datalines;
        gmm m1 m1 1 1 /* intcpt is the only inst we use */
        gmm m1 m2 1 1
        gmm m2 m2 1 1
        gmm m1 m3 1 1
        gmm m2 m3 1 1
        gmm m3 m3 1 1
    ;

```

The last step of the EMM procedure is to estimate θ by using SMM, where the moment conditions are given by the scores of the auxiliary model.

Given a fixed value of the parameter vector θ and an arbitrarily large T , one can simulate a series $\{\hat{y}_1(\theta), \hat{y}_2(\theta), \dots, \hat{y}_T(\theta)\}$ from the structural model. The EMM estimator is the value $\hat{\theta}_n$ that minimizes the quantity

$$m_T(\theta, \hat{\eta}_n)' \hat{\mathbf{V}}_n^{-1} m_T(\theta, \hat{\eta}_n)$$

where

$$m_T(\theta, \hat{\eta}_n) = \frac{1}{T} \sum_{k=1}^T s_f(\hat{Y}_k(\theta), \hat{\eta}_n)$$

is the sample moment condition evaluated at the fixed estimated pseudo parameter $\hat{\eta}_n$. Note that the target function depends on the parameter θ only through the simulated series \hat{y}_k .

The following statements generate a data set that contains $T = 20,000$ replicates of the estimated pseudo parameter $\hat{\eta}_n$ and that is then input to the MODEL procedure. The EMM estimates are found by using the SMM option of the FIT statement. The $\hat{\mathbf{V}}_n$ matrix computed above serves as weighting matrix by using the VDATA= option, and the scores of the GARCH(1,1) auxiliary model evaluated at the ML estimates are the moment conditions in the GMM step.

Since the number of structural parameters to estimate (3) is equal to the number of moment equations (3) times the number of instruments (1), the model is exactly identified and the objective function has value zero at the minimum.

For simplicity, the starting values are set to the true values of the parameters.

```

/* USE SMM TO FIND EMM ESTIMATES */

/* Generate dataset of length T */

Example 19.20: Illustration of ODS Graphics

This example illustrates graphical output from PROC MODEL. This is a continuation of the section “[Nonlinear Regression Analysis](#)” on page 1059. For information about the graphics available in the MODEL procedure, see the section “[ODS Graphics](#)” on page 1222.

The following statements show how to generate ODS Graphics plots with the MODEL procedure. The plots are displayed in [Output 19.20.1](#) and [Output 19.20.2](#). Note that the variable date in the ID statement is used to define the horizontal tick mark values when appropriate.

```

Overview: PANEL Procedure

The PANEL procedure analyzes a class of linear econometric models that commonly arise when time series and cross-sectional data are combined. This type of pooled data on time series cross-sectional bases is often referred to as panel data. Typical examples of panel data include observations over time on households, countries, firms, trade, and so on. For example, in the case of survey data on household income, the panel is created by repeatedly surveying the same households in different time periods (years).

The panel data models can be grouped into several categories depending on the structure of the error term. The PANEL procedure uses the following error structures and the corresponding methods to analyze data:

- one-way and two-way models
- fixed-effects and random-effects models
- autoregressive models
- moving average models

A one-way model depends only on the cross section to which the observation belongs. A two-way model depends on both the cross section and the time period to which the observation belongs.

Apart from the possible one-way or two-way nature of the effect, the other dimension of difference between the possible specifications is the nature of the cross-sectional or time-series effect. The models are referred to as fixed-effects models if the effects are nonrandom and as random-effects models otherwise.

If the effects are fixed, the models are essentially regression models with dummy variables that correspond to the specified effects. For fixed-effects models, ordinary least squares (OLS) estimation is the best linear unbiased estimator. Random-effects models use a two-stage approach. In the first stage, variance components are calculated by using methods described by: Fuller and Battese (1974); Wansbeek and Kapteyn (1989); Wallace and Hussain (1969); Nerlove (1971). In the second stage, variance components are used to standardize the data, and ordinary least squares (OLS) regression is performed.

Two types of models in the PANEL procedure accommodate an autoregressive structure: The Parks method estimates a first-order autoregressive model with contemporaneous correlation, and the dynamic panel estimator estimates an autoregressive model with lagged dependent variable.

The Da Silva method estimates a mixed variance-component moving-average error process. The regression parameters are estimated by using a two-step generalized least squares (GLS)-type estimator.

The PANEL procedure enhances the features that were implemented in the TSCSREG procedure. The following list shows the most important additions.

- New estimation methods include between estimators, pooled estimators, and dynamic panel estimators that use the generalized method of moments (GMM). The variance components for random-effects models can be calculated for both balanced and unbalanced panels by using the methods described by: Fuller and Battese (1974); Wansbeek and Kapteyn (1989); Wallace and Hussain (1969); Nerlove (1971).
- The CLASS statement creates classification variables that are used in the analysis.
- The TEST statement includes new options for Wald, LaGrange multiplier, and the likelihood ratio tests.
- The new RESTRICT statement specifies linear restrictions on the parameters.
- The FLATDATA statement enables the data to be in a compressed form.
- Several methods that produce heteroscedasticity-consistent (HCCME) and heteroscedasticity- and Autocorrelation-Consistent (HAC) covariance matrices are added because the presence of heteroscedasticity and autocorrelation can result in inefficient and biased estimates of the covariance matrix in the OLS framework.
- Tests are added for poolability, panel stationarity, the existence of cross sectional and time effects, autocorrelation, and cross sectional dependence.
- The LAG statement can generate a large number of missing values, depending on lag order. Typically, it is difficult to create lagged variables in the panel setting. If lagged variables are created in a DATA step, several programming steps that include loops are often needed. By including the LAG statement, the PANEL procedure makes the creation of lagged values easy. The missing values can be replaced with zeros, overall mean, time mean, or cross section mean by using the LAG, ZLAG, XLAG, SLAG, and CLAG statements.
- The OUTPUT statement enables you to output data and estimates that can be used in other analyses.

Getting Started: PANEL Procedure

The following statements use the cost function data from Greene (1990) to estimate the variance components model. The variable PRODUCTION is the log of output in millions of kilowatt-hours, and COST is the log of cost in millions of dollars. See Greene (1990) for details.

```
data greene;
  input firm year production cost @@;
datalines;
1 1955 5.36598 1.14867 1 1960 6.03787 1.45185
1 1965 6.37673 1.52257 1 1970 6.93245 1.76627
2 1955 6.54535 1.35041 2 1960 6.69827 1.71109
2 1965 7.40245 2.09519 2 1970 7.82644 2.39480
3 1955 8.07153 2.94628 3 1960 8.47679 3.25967

... more lines ...
```

You decide to fit the following model to the data:

$$C_{it} = \text{Intercept} + \beta P_{it} + v_i + e_t + \epsilon_{it} \quad i = 1, \dots, N; t = 1, \dots, T$$

where C_{it} and P_{it} represent the cost and production, and v_i , e_t and ϵ_{it} are the cross-sectional, time series, and error variance components.

If you assume that the time and cross-sectional effects are random, you are left with four possible estimators for the variance components. You choose Fuller-Battese.

The following statements fit this model.

```
proc sort data=greene;
  by firm year;
run;

proc panel data=greene;
  model cost = production / rantwo vcomp = fb;
  id firm year;
run;
```

The PANEL procedure output is shown in [Figure 20.1](#). A model description is printed first, which reports the estimation method used and the number of cross sections and time periods. The variance components estimates are printed next. Finally, the table of regression parameter estimates shows the estimates, standard errors, and t tests.

Figure 20.1 The Variance Components Estimates

The PANEL Procedure					
Fuller and Battese Variance Components (RanTwo)					
Dependent Variable: cost					
Model Description					
Estimation Method	RanTwo				
Number of Cross Sections	6

  TEST equation1 < ,equation2... > ;

```

Functional Summary

The statements and options used with the PANEL procedure are summarized in the following table.

Description	Statement	Option
Data Set Options		
Includes correlations in the OUTEST= data set	PANEL	CORROUT
Includes covariances in the OUTEST= data set	PANEL	COVOUT
Specifies the input data set	PANEL	DATA=
Specifies variables to keep but not transform	FLATDATA	KEEP=
Specifies the output data set for CLASS STATEMENT	CLASS	OUT =
Specifies the output data set	FLATDATA	OUT =
Specifies the name of an output SAS data set	OUTPUT	OUT=
Writes parameter estimates to an output data set	PANEL	OUTEST=
Writes the transformed series to an output data set	PANEL	OUTTRANS=
Requests that the procedure produce graphics via the Output Delivery System	PANEL	PLOTS=
Declaring the Role of Variables		
Specifies BY-group processing	BY	
Specifies the classification variables	CLASS	
Transfers the data into uncompressed form	FLATDATA	
Specifies the cross section and time ID variables	ID	
Declares instrumental variables	INSTRUMENTS	

Description	Statement	Option
Lag Generation		
Specifies output data set for lags where missing values are replaced with the cross section mean	CLAG	OUT=
Specifies output data set for lags with missing values included	LAG	OUT=
Specifies output data set for lags where missing values are replaced with the time period mean	SLAG	OUT=
Specifies output data set for lags where missing values are replaced with overall mean	XLAG	OUT=
Specifies output data set for lags where missing values are replaced with zero	ZLAG	OUT=
Printing Control Options		
Prints correlations of the estimates	MODEL	CORRB
Prints covariances of the estimates	MODEL	COVB
Suppresses printed output	MODEL	NOPRINT
Requests that the procedure produce graphics via the Output Delivery System	MODEL	PLOTS=
Prints fixed effects	MODEL	PRINTFIXED
Performs tests of linear hypotheses	TEST	
Model Estimation Options		
Requests the Breusch-Pagan test for one-way random effects	MODEL	BP
Requests the Breusch-Pagan test for two-way random effects	MODEL	BP2
Specifies the between-groups model	MODEL	BTWNG
Specifies the between-time-periods model	MODEL	BTWNT
Requests the clustered HCCME estimator for the covariance matrix	MODEL	CLUSTER
Specifies the Da Silva method	MODEL	DASILVA
Specifies the one-way fixed-effects model	MODEL	FIXONE
Specifies the one-way fixed-effects model with respect to time	MODEL	FIXONETIME
Specifies the two-way fixed-effects model	MODEL	FIXTWO
Specifies the Moore-Penrose generalized inverse	MODEL	GINV = G4
Specifies the dynamic panel estimator model (one-step GMM)	MODEL	GMM1
Specifies the dynamic panel estimator model (two-step GMM)	MODEL	GMM2
Requests the HAC estimator for the variance-covariance matrix	MODEL	HAC=
Requests the HCCME estimator for the covariance matrix	MODEL	HCCME=

Description	Statement	Option
Specifies the dynamic panel estimator model (iterated GMM)	MODEL	ITGMM
Specifies the order of the moving average error process for Da Silva method	MODEL	M=
Suppresses the intercept term	MODEL	NOINT
Specifies the Parks method	MODEL	PARKS
Prints the Φ matrix for Parks method	MODEL	PHI
Specifies the pooled model	MODEL	POOLED
Requests poolability tests for one-way fixed effects and pooled model	MODEL	POOLTEST
Specifies the one-way random-effects model	MODEL	RANONE
Specifies the two-way random-effects model	MODEL	RANTWO
Prints autocorrelation coefficients for Parks method	MODEL	RHO
Controls the check for singularity	MODEL	SINGULAR=
Specifies the method for panel unit root/stationarity test	MODEL	UROOTTEST=
Specifies the method for the variance components estimator	MODEL	VCOMP=
Specifies linear equality restrictions on the parameters	RESTRICT	
Specifies the TEST statement	TEST	WALD, LM, LR

PROC PANEL Statement

PROC PANEL *options* ;

The following options can be specified on the PROC PANEL statement.

DATA=SAS-data-set

names the input data set. The input data set must be sorted by cross section and by time period within cross section. If you omit the DATA= option, the most recently created SAS data set is used.

OUTEST=SAS-data-set

names an output data set to contain the parameter estimates. When the OUTEST= option is not specified, the OUTEST= data set is not created. See the section “[OUTEST= Data Set](#)” on page 1454 for details about the structure of the OUTEST= data set.

OUTTRANS=SAS-data-set

names an output data set to contain the transformed series for further analysis and computation of models with time observations greater than two. See the section “[OUTTRANS= Data Set](#)” on page 1455 for details about the structure of the OUTTRANS= data set.

OUTCOV**COVOUT**

writes the standard errors and covariance matrix of the parameter estimates to the OUTEST= data set. See the section “[OUTEST= Data Set](#)” on page 1454 for details.

OUTCORR**CORROUT**

writes the correlation matrix of the parameter estimates to the OUTEST= data set. See the section “[OUTEST= Data Set](#)” on page 1454 for details.

PLOTS < (*global-plot-options* < (**NCROSS**=*value*) >) > < = (*specific-plot-options*) >

selects plots to be produced via the Output Delivery System. For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*). The *global-plot-options* apply to all relevant plots generated by the PANEL procedure.

Global Plot Options

The following *global-plot-options* are supported:

ONLY

suppresses the default plots. Only the plots specifically requested are produced.

UNPACKPANEL**UNPACK**

displays each graph separately. (By default, some graphs can appear together in a single panel.)

NCROSS=*value*

specifies the number of cross sections to be combined into one time series plot.

Specific Plot Options

The following *specific-plot-options* are supported:

ACTSURFACE

produces a surface plot of actual values.

ALL

produces all appropriate plots.

FITPLOT

plots the predicted and actual values.

NONE

suppresses all plots.

PRESURFACE

produces a surface plot of predicted values.

QQ

produces a QQ plot of residuals.

RESIDSTACK | **RESSTACK**

produces a stacked plot of residuals.

RESIDSURFACE

produces a surface plot of residual values.

RESIDUAL | **RES**

plots the residuals.

RESIDUALHISTOGRAM | **RESIDHISTOGRAM**

plots the histogram of residuals.

For more details, see the section “[Creating ODS Graphics](#)” on page 1453.

In addition, any of the following MODEL statement options can be specified in the PROC PANEL statement: CORRB, COVB, FIXONE, FIXONETIME, FIXTWO, BTWNG, BTWNT, POOLED, RANONE, RANTWO, PARKS, DASILVA, NOINT, NOPRINT, PRINTFIXED, M=, PHI, RHO, VCOMP=, and SINGULAR=. When specified in the PROC PANEL statement, these options are equivalent to specifying the options for every MODEL statement. See the section “[MODEL Statement](#)” on page 1386 for a complete description of each of these options.

BY Statement

BY *variables* ;

A BY statement obtains separate analyses on observations in groups that are defined by the BY variables. When a BY statement appears, the input data set must be sorted both by the BY variables and by cross section and time period within the BY groups.

The following statements show an example:

```
proc sort data=a;
  by byvar1 byvar2 csid tsid;
run;

proc panel data=a;
  by byvar1 byvar2;
  id csid tsid;
  ...
run;
```

CLASS Statement

CLASS *variables* </ out= SAS-data-set> ;

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric.

In PROC PANEL, the CLASS statement enables you to output class variables to a data set that contains a copy of the original data.

FLATDATA Statement

FLATDATA *options* </ out= SAS-data-set> ;

The following options must be specified in the FLATDATA statement:

BASE=*(variable, variable, ..., variable)*

specifies the variables that are to be transformed into a proper PROC PANEL format. All variables to be transformed must be named according to the convention: *basename_timeperiod*. You supply just the *basename*, and the procedure extracts the appropriate variables to transform. If some year's data are missing for a variable, then PROC PANEL detects this and fills in with missing values.

INDID=*variable*

names the variable in the input data set that uniquely identifies each individual. The INDID variable can be a character or numeric variable.

KEEP=*(variable, variable, ..., variable)*

specifies the variables that are to be copied without any transformation. These variables remain constant with respect to time when the data are converted to PROC PANEL format. This is an optional item.

TSNAME=*name*

specifies a name for the generated time identifier. The name must satisfy the requirements for the name of a SAS variable. The name can be quoted, but it must not be the name of a variable in the input data set.

The following options can be specified on the FLATDATA statement after the slash (/):

OUT =*SAS-data-set*

saves the converted flat data set to a PROC PANEL formatted data set.

ID Statement

ID *cross-section-id time-series-id ;*

The ID statement is used to specify variables in the input data set that identify the cross section and time period for each observation.

When an ID statement is used, the PANEL procedure verifies that the input data set is sorted by the cross section ID variable and by the time series ID variable within each cross section. The PANEL procedure also verifies that the time series ID values are the same for all cross sections.

To make sure the input data set is correctly sorted, use PROC SORT to sort the input data set with a BY statement with the variables listed exactly as they are listed in the ID statement, as shown in the following statements:

```
proc sort data=a;
  by csid tsid;
run;

proc panel data=a;
  id csid tsid;
  ... etc. ...
run;
```

INSTRUMENTS Statement

INSTRUMENTS *options* ;

The INSTRUMENTS statement denotes which variables are used in the moment condition equations of the dynamic panel estimator. The following options can be used with the INSTRUMENTS statement.

CONSTANT

includes an intercept (column of ones) as an uncorrelated exogenous instrument.

CORRELATED=(*variable, variable, . . . , variable*)

specifies a list of variables correlated with the unobserved individual effects. These variables are correlated with the error terms in the level equations so they are not used in forming moment conditions from those equations.

DEPVAR<(LEVEL | DIFF | DIFFERENCE | BOTH)>

specifies instruments related to the dependent variable. With LEVEL, the lagged dependent variables are included as instruments for differenced equations. With DIFFERENCE, the differenced dependent variable is included as instruments for equations. With BOTH or nothing specified, both level and differenced dependent variables are included in the instrument matrix.

EXOGENOUS=(*variable, variable, . . . , variable*)

specifies a list of variables that are not correlated with the disturbances given the unobserved individual effects.

PREDETERMINED=(*variable, variable, . . . , variable*)

specifies a list of variables whose future realizations can be correlated with the disturbances but whose present and past realizations are not conditional on the individual effects.

Because a variable can be used as an instrument only if it is either exogenous or predetermined, the variables listed in the CORRELATED= option must be included in either the EXOGENOUS= list or the PREDETERMINED= list. If a variable listed in the EXOGENOUS= list is not included in the CORRELATED= list, then it is considered to be uncorrelated to the error term in the level equations, which consist only of the individual effects and the disturbances. Moreover, it is uncorrelated with the error term in the differenced equations, which consist only of the disturbances. For example, in the following statements, the exogenous instruments are Z1, Z2 and X1. Because Z1 is an instrument that is correlated to the individual fixed effects, it is included in the level equations but not in the differenced equations. Because Z2 is not correlated with either the individual effects or the disturbances, it is included in both the level equations and the differenced equations.

```
proc panel data=a;
  inst exogenous=(Z1 Z2 X1)
    correlated = (Z1) constant depvar;
  model Y = X1 X2 X3 / gmm1;
run;
```

For a detailed discussion of the model set up and the use of the INSTRUMENTS statement, see “[Dynamic Panel Estimator](#)” on page 1423.

Note that for each MODEL statement, one INSTRUMENT statement is required. In other words, if there are two models to be estimated by using GMM1 within one PANEL procedure, then there should be two INSTRUMENT statements. For example,

```

proc panel data=test;
  inst depvar pred=(x1 x2) exog=(x3 x4 x5) correlated=(x3 x4 x5);
  model y = y_1 x1 x2 / gmm1 maxband=6 nolevels ginv=g4 artest=5;
  inst pred=(x2 x4) exog=(x3 x5) correlated=(x3 x4);
  model y = y_1 x2 / gmm1 maxband=6 nolevels ginv=g4 artest=5;
  id cs ts;
run;

```

LAG, ZLAG, XLAG, SLAG, or CLAG Statement

LAG $var_1(lag_1 lag_2 \dots lag_T), \dots, var_N(lag_1 lag_2 \dots lag_T) < / OUT= SAS-data-set > ;$

Generally, creating lags of variables in a panel setting is a tedious process in which you must generate many DATA step statements. The PANEL procedure now enables you to generate lags of any series without jumping across the boundary of any individual series. The LAG statement is a data set generation tool. Using the data created by a LAG statement requires a subsequent PROC PANEL call. You can specify more than one LAG statement in each call to PROC PANEL.

You must specify the OUT= option in the LAG statement. The output data set includes all variables in the input set, plus the lags that are denoted with the convention *var_lag*. The LAG statement tends to generate many missing values in the data. This can be problematic, because the number of usable observations diminishes with the lag length. Therefore, PROC PANEL offers the following alternatives to the LAG statement. The following statements can be used instead of LAG with otherwise identical syntax:

CLAG $var_1(lag_1 lag_2 \dots lag_T), \dots, var_N(lag_1 lag_2 \dots lag_T) < / OUT= SAS-data-set > ;$

replaces missing values with the cross section mean for that variable in that cross section. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

SLAG $var_1(lag_1 lag_2 \dots lag_T), \dots, var_N(lag_1 lag_2 \dots lag_T) < / OUT= SAS-data-set > ;$

replaces missing values with the time mean for that variable in that time period. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

XLAG $var_1(lag_1 lag_2 \dots lag_T), \dots, var_N(lag_1 lag_2 \dots lag_T) < / OUT= SAS-data-set > ;$

replaces missing values with the overall mean for that variable. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

ZLAG $var_1(lag_1 lag_2 \dots lag_T), \dots, var_N(lag_1 lag_2 \dots lag_T) < / OUT= SAS-data-set > ;$

replaces missing values with 0 for that variable. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

Assume that data set A has been sorted by cross section and by time period within cross section (or that the FLATDATA statement has been specified) and that the variables are Y, X1, X2, and X3. The following PROC PANEL statements generate a series with lags 1 and 3 of the X1 variable; lags 3, 6, and 9 of the X2 variable; and lag 2 of the X3 variable.

```

proc panel data=A;
  id i t;
  lag X1(1 3) X2(3 6 9) X3(2) / out=A_lag;
run;

```

If you want a zeroing instead of missing values, then you specify the following:

```
proc panel data=A;
  id i t;
  zlag X1(1 3) X2(3 6 9) X3(2) / out=A_zlag;
run;
```

Similarly, you can specify XLAG to replace with overall means, SLAG to replace with time means, and CLAG to replace with cross section means.

MODEL Statement

MODEL *response* = *regressors* </ *options* > ;

The MODEL statement specifies the regression model and the error structure assumed for the regression residuals. The response variable on the left side of the equal sign is regressed on the independent variables listed after the equal sign. Any number of MODEL statements can be used. For each model statement, only one response variable can be specified on the left side of the equal sign.

The error structure is specified by the PARKS, DASILVA, FIXONE, FIXONETIME, FIXTWO, RANONE, RANTWO, GMM1, GMM2, and ITGMM options. More than one of these options can be used, in which case the analysis is repeated for each error structure model specified.

Models can be given labels. Model labels are used in the printed output to identify the results for different models. If no label is specified, the response variable name is used as the label for the model. The model label is specified as follows:

label : MODEL ...;

The following *options* can be specified in the MODEL statement after a slash (/).

ARTEST=*integer*

specifies the maximum order of the test for the presence of AR effects in the residual in the dynamic panel model. The acceptable range of values for this option is 1 to $t - 3$.

ATOL=*number*

specifies the convergence criterion for iterated GMM when convergence of the method is determined by convergence in the weighting matrix. The convergence criterion must be positive. The default option is the BTOL= option unless the ATOL= option is specified. See the section “[Dynamic Panel Estimator](#)” on page 1423 for details.

BANDOPT=TRAILING | CENTERED | LEADING

specifies which observations are included in the instrument list when the MAXBAND= option is specified. This option should be used only for exogenous instruments. BANDOPT=TRAILING is the default. See the section “[Dynamic Panel Estimator](#)” on page 1423 for details.

BP

requests the Breusch-Pagan one-way test for random effects.

BP2

requests the Breusch-Pagan two-way test for random effects.

BTOL=number

specifies the convergence criterion for iterated GMM when convergence of the method is determined by convergence in the parameter matrix. The convergence criterion must be positive. The default is BTOL=1E-8. See the section “[Dynamic Panel Estimator](#)” on page 1423 for details.

BTWNG

specifies that a between-groups model be estimated.

BTWNT

specifies that a between-time-periods model be estimated.

CLUSTER

specifies the cluster correction for the covariance matrix. The cluster correction can be requested with HCCME=0, 1, 2 or 3.

CORRB**CORR**

prints the matrix of estimated correlations between the parameter estimates.

COVB**VAR**

prints the matrix of estimated covariances between the parameter estimates.

DASILVA

specifies that the model be estimated by using the Da Silva method, which assumes a mixed variance-component moving average model for the error structure. See the section “[Da Silva Method \(Variance-Component Moving Average Model\)](#)” on page 1421 for details.

FIXONE

specifies that a one-way fixed-effects model be estimated with the one-way model corresponding to cross-sectional effects only.

FIXONETIME

specifies that a one-way fixed-effects model be estimated with the one-way model corresponding to time effects only.

FIXTWO

specifies that a two-way fixed-effects model be estimated.

GINV= G2 | G4

specifies what type of generalized inverse to use. The default is a G2 inverse. The G4 inverse is generally more desirable except that it is a more numerically intensive methodology.

GMM1

requests that the model be estimated in a single step by using the dynamic panel estimator method, which allows for autoregressive processes. When you specify this option, you must specify one INSTRUMENT statement for each MODEL statement. For more information, see the section “[Dynamic Panel Estimator](#)” on page 1423.

GMM2

requests that the model be estimated in two steps by using the dynamic panel estimator method. An initial first step is used to form an estimator for the weighting matrix that is used in the second step. For more information, see the section “[Dynamic Panel Estimator](#)” on page 1423.

HAC <(hac-options) >

specifies the heteroscedasticity- and autocorrelation-consistent (HAC) covariance matrix estimator. This option is not available for between models and cannot be specified with the HCCME option. When you specify this option, you can also specify the following *hac-options* within parentheses:

KERNEL=*value*

specifies the type of kernel function. You can specify the following *values*:

BARTLETT	specifies the Bartlett kernel function.
PARZEN	specifies the Parzen kernel function.
QS	specifies the quadratic spectral kernel function.
TH	specifies the Turkey-Hanning kernel function.
TRUNCATED	specifies the truncated kernel function.

The default is **KERNEL=TRUNCATED**.

KERNELLB=*number*

specifies the lower bound of the kernel weight value. Any kernel weight less than this lower bound is regarded as 0, which accelerates the calculation for big samples, especially for the quadratic spectral kernel function. By default, **KERNELLB=0**.

BANDWIDTH=*value*

specifies the fixed bandwidth value or bandwidth selection method which is used in the kernel function. You can specify the following *values*:

ANDREWS91 | ANDREWS

specifies the Andrews (1991) bandwidth selection method.

NEWWEYWEST94<(C=*number*)>**NW94** <(C=*number*)>

specifies the Newey and West (1994) bandwidth selection method. The C= option can be specified within parentheses for the calculation of lag selection parameter; the default is C=12.

SAMPLESIZE<(option-list)>**SS**<(option-list)>

specifies that the bandwidth be calculated according to the following equation based on the sample size

$$b = \gamma T^r + c$$

where b is the bandwidth parameter, T is the sample size, and γ , r and c are values specified by the following options within parentheses and separated by commas.

GAMMA=number

specifies the coefficient γ in the equation. The default is $\gamma = 0.75$.

RATE=number

specifies the growth rate r in the equation. The default is $r = 0.3333$.

CONSTANT=number

specifies the constant c in the equation. The default is $c = 0.5$.

INT

specifies that the bandwidth parameter must be integer; that is, $b = \lfloor \gamma T^r + c \rfloor$, where $\lfloor x \rfloor$ denotes the largest integer less than or equal to x .

number

specifies the fixed value of the bandwidth parameter.

The default is **BANDWIDTH=ANDREWS91**.

PREWHITENING

specifies that prewhitening is required in the covariance calculation.

ADJUSTDF

specifies that the adjustment of degrees of freedom is required in the covariance calculation.

See the section “[Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrices](#)” on page 1436 for details.

HCCME= NO | number

specifies the type of HCCME covariance matrix requested. If you specify **HCCME=NO**, the covariance matrix is not corrected. The value *number* can be any integer from 0 to 4, inclusive. See the section “[Heteroscedasticity-Corrected Covariance Matrices](#)” on page 1433 for details. By default, **HCCME=NO**.

ITGMM

specifies that the model be estimated by using the dynamic panel estimator method, but that PROC PANEL keep updating the weighting matrix until either the parameter vector converges or the weighting matrix converges. See the section “[Dynamic Panel Estimator](#)” on page 1423 for details.

ITPRINT

prints out the iteration history of the parameter and transformed sum of error squared.

M=number

specifies the order of the moving-average process in the Da Silva method. The value of the **M=**option must be less than $T - 1$. The default is **M=1**.

MAXBAND=integer

specifies the maximum number of time periods (per instrumental variable) that are allowed into the moment condition. The acceptable range of values for this option is 1 to $T - 1$. If **BANDOPT=LEADING** or **CENTERED**, then the default value of **MAXBAND** is 2. If **BANDOPT=TRAILING**, then the default value of **MAXBAND** is 1. If no **BANDOPT** option is specified such as when no exogenous instruments are used, then the default value of **MAXBAND** is 1. See the section “[Dynamic Panel Estimator](#)” on page 1423 for details.

MAXITER=integer

specifies the maximum number of iterations allowed for the iterated GMM option. The default value is MAXITER=200. See the section “[Dynamic Panel Estimator](#)” on page 1423 for details.

NEWKEYWEST=<(option-list)>

specifies the well-known Newey-West estimator, a special HAC estimator with (1) the Bartlett kernel, (2) the bandwidth parameter determined by the equation based on the sample size, $b = \lfloor \gamma T^r + c \rfloor$, and (3) no adjustment for degrees of freedom and no prewhitening. By default the bandwidth parameter for Newey-West estimator is $\lfloor 0.75 T^{0.3333} + 0.5 \rfloor$, as shown in the equation (15.17) in Stock and Watson (2002). When you specify COVEST=NEWKEYWEST, you can specify the following options in parentheses and separate them with commas:

GAMMA= number

specifies the coefficient γ in the equation. The default is $\gamma = 0.75$.

RATE= number

specifies the growth rate r in the equation. The default is $r = 0.3333$.

CONSTANT= number

specifies the constant c in the equation. The default is $c = 0.5$.

NOIFFS

specifies that the dynamic panel model be estimated without moment conditions from the difference equations. See the section “[Dynamic Panel Estimator](#)” on page 1423 for details.

NOESTIM

limits the estimation of a FIXONE, FIXONETIME, RANONE model to the generation of the transformed series. This option is intended for use with an OUTTRANS= data set.

NOINT

suppresses the intercept parameter from the model.

NOLEVELS

specifies that the dynamic panel model be estimated without moment conditions from the level equations. See the section “[Dynamic Panel Estimator](#)” on page 1423 for details.

NOPRINT

suppresses the normal printed output.

PARKS

specifies that the model be estimated by using the Parks method, which assumes a first-order autoregressive model for the error structure. See the section “[Parks Method \(Autoregressive Model\)](#)” on page 1418 for details.

PHI

prints the Φ matrix of estimated covariances of the observations for the Parks method. The PHI option is relevant only when the PARKS option is used. See the section “[Parks Method \(Autoregressive Model\)](#)” on page 1418 for details.

POOLED

specifies that a pooled (OLS) model be estimated.

POOLTEST

requests poolability tests for one-way fixed effects and pooled models.

PRINTFIXED

prints the fixed effects.

RANONE

specifies that a one-way random-effects model be estimated.

RANTWO

specifies that a two-way random-effects model be estimated.

RHO

prints the estimated autocorrelation coefficients for the Parks method.

ROBUST

specifies that the robust weighting matrix be used in the calculation of the covariance matrix of the single-step, two-step and iterated GMM dynamic panel estimator. See the section “[Dynamic Panel Estimator](#)” on page 1423 for details.

SINGULAR=number

specifies a singularity criterion for the inversion of the matrix. The default depends on the precision of the computer system.

TIME

specifies that the model be estimated by using the dynamic panel estimator method, but that PROC PANEL includes time dummy variables to model any time effects present in the data. See the section “[Dynamic Panel Estimator](#)” on page 1423 for details.

UROOTTEST(*test1*<(test-options), *test2*<(test-options)>... > < *option1* < *option2*... > >)

STATIONARITY(*test1*<(test-options), *test2*<(test-options)>... > < *option1* < *option2*... > >)

specifies tests of stationarity or unit root for panel data and the options for each test. The panel unit root test (or stationarity test) will test the existence of unit root for the dependent variables only. Six tests are available. You can specify all or some of these tests, separated by commas. If you specify one or more *test-options* (separated by spaces) inside the parentheses after a particular test, they apply only to that test. If you specify one or more *options* separated by spaces after you specify the tests, they apply to all the tests. If you specify both *test-options* and *options*, the *test-options* override the *options*.

ALL

requests that all panel unit root and stationarity tests be performed.

BREITUNG<(test-options) >

requests Breitung’s unbiased test, *t* test and GLS *t* test that are robust to cross-sectional dependence. The tests are described in Breitung and Meyer (1994); Breitung (2000); Breitung and Das (2005). The following *test-options* are available for this test:

DETAIL

requests that intermediate results (lag order) be printed.

LAGS=type | value

specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regressions. You can specify a *value* for the order of lags. If the specified lag order is too big to run linear regression ($\text{LAGS} > T - k$, where T is the number of observations and k is the number of parameters), then the lag order is set to $\lfloor 12(T/100)^{1/4} \rfloor$ or $T - k - 1$, whichever is smaller. Alternatively, you can specify one of the following *types*:

GS

selects the order of lags by Hall's (1994) sequential testing method: from the most general model (maximum lags) to lower order of lag terms.

SG

selects the order of lags by Hall's (1994) sequential testing method: from no lag term to maximum allowed lags.

AIC

selects the order of lags by AIC.

SBC**SIC****SBIC**

selects the order of lags by Bayesian information criterion (or Schwarz criterion).

HQIC

selects the order of lags by the Hannan-Quinn information criterion.

MAIC

selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is $\text{LAGS}=\text{MAIC}$.

MAXLAGS=value

specifies the maximum lag order that the model allows. The default value is $\lfloor 12(T/100)^{1/4} \rfloor$. If *value* is larger than 0 and larger than $T - k$, then the maximum lag order is set to be the default value of $\lfloor 12(T/100)^{1/4} \rfloor$ or $T - k - 1$, whichever is smaller. This option is ignored if you specify $\text{LAGS}=\text{value}$.

COMBINATION < (test-options) >**FISHER < (test-options) >**

specifies combination tests proposed by Choi (2001); Maddala and Wu (1999). Fisher's test, as proposed by Maddala and Wu (1999), is a special case of combination tests. You can specify one or more of the following *test-options*:

TEST=ADF | PP

selects the time series unit root test for combination tests (Fisher's test). ADF specifies the augmented Dickey-Fuller (ADF) test, and ignores the BANDWIDTH and KERNEL options for the combination tests. PP specifies the Phillips and Perron (1988) unit root test. When

you specifies TEST = PP, the LAGS and MAXLAGS options are ignored for the combination tests.

The default is TEST=PP.

KERNEL=*value*

specifies the type of kernel function. You can specify the following *values*:

BARTLETT	specifies the Bartlett kernel function.
PARZEN	specifies the Parzen kernel function.
QS	specifies the quadratic spectral kernel function.
TH	specifies the Turkey-Hanning kernel function.
TRUNCATED	specifies the truncated kernel function.

The default is KERNEL=QS.

BANDWIDTH=ANDREWS | *number*

specifies the bandwidth for the kernel. If you specify BANDWIDTH=ANDREWS, the bandwidth is selected by the Andrews method. If you specify a nonnegative *number*, the bandwidth is set to that value. The default is BANDWIDTH=ANDREWS.

DETAIL

requests that intermediate results (lag order and long-run variance for each cross section) be printed.

LAGS=*type* | *value*

specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regressions. You can specify a *value* for the order of lags. If the specified lag order is too big to run linear regression ($\text{LAGS} > T - k$, where T is the number of observations and k is the number of parameters), then the lag order is set to $\left\lfloor 12(T/100)^{1/4} \right\rfloor$ or $T - k - 1$, whichever is smaller. Alternatively, you can specify one of the following *types*:

GS

selects the order of lags by Hall's (1994) sequential testing method: from the most general model (maximum lags) to lower order of lag terms.

SG

selects the order of lags by Hall's (1994) sequential testing method: from no lag term to maximum allowed lags.

AIC

selects the order of lags by AIC.

SBC

SIC

SBIC

selects the order of lags by Bayesian information criterion (or Schwarz criterion).

HQIC

selects the order of lags by the Hannan-Quinn information criterion.

MAIC

selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is LAGS=MAIC.

MAXLAGS=value

specifies the maximum lag order that the model allows. The default value is $\lfloor 12(T/100)^{1/4} \rfloor$. If *value* is larger than 0 and larger than $T - k$, then the maximum lag order is set to be the default value of $\lfloor 12(T/100)^{1/4} \rfloor$ or $T - k - 1$, whichever is smaller. This option is ignored if you specify LAGS=*value*.

HADRI < (test-options) >

specifies Hadri's (2000) panel stationarity test. You can specify the following *test-options*:

DETAIL

requests that intermediate results (lag order and long-run variance for each cross section) be printed.

KERNEL=value

specifies the type of kernel function. You can specify the following *values*:

BARTLETT	specifies the Bartlett kernel function.
PARZEN	specifies the Parzen kernel function.
QS	specifies the quadratic spectral kernel function.
TH	specifies the Turkey-Hanning kernel function.
TRUNCATED	specifies the truncated kernel function.

The default is KERNEL=QS.

BANDWIDTH=ANDREWS | number

specifies the bandwidth for the kernel. If you specify BANDWIDTH=ANDREWS, the bandwidth is selected with the Andrews method. If you specify a nonnegative *number*, the bandwidth is set to that value. The default is BANDWIDTH=ANDREWS.

HT

specifies Harris and Tzavalis (1999) panel unit root test. No options are available for this test.

IPS < (test-options) >

specifies the Im, Pesaran, and Shin (2003) panel unit root test. You can specify the following *test-options*:

DETAIL

requests that intermediate results (lag order) be printed.

LAGS=type | value

specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regressions. You can specify a *value* for the order of lags. If the specified lag order is too big to run linear regression ($\text{LAGS} > T - k$, where T is the number of observations and k is the number of parameters), then the lag order is set to $\lfloor 12(T/100)^{1/4} \rfloor$ or $T - k - 1$, whichever is smaller. Alternatively, you can specify one of the following *types*:

GS

selects the order of lags by Hall's (1994) sequential testing method: from the most general model (maximum lags) to lower order of lag terms.

SG

selects the order of lags by Hall's (1994) sequential testing method: from no lag term to maximum allowed lags.

AIC

selects the order of lags by AIC.

SBC**SIC****SBIC**

selects the order of lags by Bayesian information criterion (or Schwarz criterion).

HQIC

selects the order of lags by the Hannan-Quinn information criterion.

MAIC

selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is $\text{LAGS}=\text{MAIC}$.

MAXLAGS=value

specifies the maximum lag order that the model allows. The default value is $\lfloor 12(T/100)^{1/4} \rfloor$. If *value* is larger than 0 and larger than $T - k$, then the maximum lag order is set to be the default value of $\lfloor 12(T/100)^{1/4} \rfloor$ or $T - k - 1$, whichever is smaller. This option is ignored if you specify $\text{LAGS}=\text{value}$.

LLC < (test-options) >

specifies the Levin, Lin, and Chu (2002) panel unit root test. You can specify the following *test-options*:

DETAIL

requests that intermediate results (lag order and long-run variance for each cross section) be printed.

KERNEL=value

specifies the type of kernel function. You can specify the following *values*:

BARTLETT	specifies the Bartlett kernel function.
PARZEN	specifies the Parzen kernel function.
QS	specifies the quadratic spectral kernel function.
TH	specifies the Turkey-Hanning kernel function.
TRUNCATED	specifies the truncated kernel function.

The default is `KERNEL=QS`.

BANDWIDTH=ANDREWS | *number*

specifies the bandwidth for the kernel. If you specify `BANDWIDTH=ANDREWS`, the bandwidth is selected with the Andrews method. If you specify a nonnegative *number*, the bandwidth is set to that value. The default is `BANDWIDTH=LLCBAND`, where the bandwidth is set to be $\bar{k} = \left\lfloor 3.21T^{\frac{1}{3}} \right\rfloor$, according to Levin, Lin, and Chu (2002).

LAGS=type | *value*

specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regressions. You can specify a *value* for the order of lags. If the specified lag order is too big to run linear regression ($\text{LAGS} > T - k$, where T is the number of observations and k is the number of parameters), then the lag order is set to $\left\lfloor 12(T/100)^{1/4} \right\rfloor$ or $T - k - 1$, whichever is smaller. Alternatively, you can specify one of the following *types*:

GS

selects the order of lags by Hall's (1994) sequential testing method: from the most general model (maximum lags) to lower order of lag terms.

SG

selects the order of lags by Hall's (1994) sequential testing method: from no lag term to maximum allowed lags.

AIC

selects the order of lags by AIC.

SBC

SIC

SBIC

selects the order of lags by Bayesian information criterion (or Schwarz criterion).

HQIC

selects the order of lags by the Hannan-Quinn information criterion.

MAIC

selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is `LAGS=MAIC`.

MAXLAGS=*value*

specifies the maximum lag order that the model allows. The default value is $\left\lfloor 12(T/100)^{1/4} \right\rfloor$. If *value* is larger than 0 and larger than $T - k$, then the maximum lag order is set to be the default value of $\left\lfloor 12(T/100)^{1/4} \right\rfloor$ or $T - k - 1$, whichever is smaller. This option is ignored if you specify `LAGS=`*value*.

Two tests, LLC and BREITUNG's, are specified in the following UROOTTEST option specification:

```
urootest = (llc=(kernel=parzen lags=aic), breitung= (lags=gs ) maxlags=2
kernel=bartlett)
```

For the LLC test, the lag order is selected by AIC with maximum lag order 2, and the kernel is specified as Parzen (overriding Bartlett). For the BREITUNG's test, the lag order is GS with a maximum lag order 2. The KERNEL option is ignored by BREITUNG's test because it is not a valid option.

VCOMP=FB | NL | WH | WK

specifies the type of variance component estimate to use. The default is VCOMP=FB for balanced data and VCOMP=WK for unbalanced data. See the section “[One-Way Random-Effects Model](#)” on page 1410 and “[Two-Way Random-Effects Model](#)” on page 1413 for details.

OUTPUT Statement

OUTPUT OUT=SAS-data-set < = options ... > ;

The OUTPUT statement creates an output SAS data set as specified by the following options:

OUT=SAS-data-set

names the output SAS data set to contain the predicted and transformed values. If the OUT= option is not specified, the new data set is named according to the DATA n convention.

PREDICTED=name

P=name

writes the predicted values to the output data set.

RESIDUAL=name

R=name

writes the residuals from the predicted values based on both the structural and time series parts of the model to the output data set.

RESTRICT Statement

RESTRICT < "string" > equation < ,equation2... > ;

The RESTRICT statement specifies linear equality restrictions on the parameters in the previous model statement. There can be as many unique restrictions as the number of parameters in the preceding model statement. Multiple RESTRICT statements are understood as joint restrictions on a model's parameters. Restrictions on the intercept are obtained by the use of the keyword INTERCEPT.

Currently, only linear equality restrictions are permitted in PROC PANEL. Tests and restriction expressions can only be composed of algebraic operations that involve the addition symbol (+), subtraction symbol (−), and multiplication symbol (*).

The RESTRICT statement accepts labels that are produced in the printed output. RESTRICT statement can be labeled in two ways. A RESTRICT statement can be preceded by a label followed by a colon. This is

illustrated in **rest1** in the example below. Alternatively, the keyword **RESTRICT** can be followed by a quoted string.

The following statements illustrate the use of the **RESTRICT** statement:

```
proc panel;
  model y = x1 x2 x3;
  restrict x1 = 0, x2 * .5 + 2 * x3 = 0;
  rest1: restrict x2 = 0, x3 = 0;
  restrict "rest2" intercept=1;
run;
```

Note that a restrict statement cannot include a division sign in its formulation.

TEST Statement

TEST <"string"> equation <,equation2...> /options ;

The **TEST** statement performs Wald, LaGrange multiplier and likelihood ratio tests of linear hypotheses about the regression parameters in the preceding **MODEL** statement. **TEST** and **RESTRICT** statements before the first **MODEL** statement are automatically associated with the first **MODEL** statement, in addition to any **TEST** and **RESTRICT** statements that follow it but precede subsequent **MODEL** statements. Each equation specifies a linear hypothesis to be tested. All hypotheses in one **TEST** statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding **MODEL** statement, and each name represents the coefficient of the corresponding regressor. The keyword **INTERCEPT** refers to the coefficient of the intercept.

The following options can be specified on the **TEST** statement after the slash (/):

ALL

specifies Wald, LaGrange multiplier and likelihood ratio tests.

WALD

specifies the **WALD** test.

LM

specifies the LaGrange multiplier test.

LR

specifies the likelihood ratio test.

The Wald test is performed by default.

The following statements illustrate the use of the **TEST** statement:

```
proc panel;
  id csid tsid;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0;
  test_int: test intercept = 0, x3 = 0;
run;
```

The first test investigates the joint hypothesis that

$$\beta_1 = 0$$

and

$$.5\beta_2 + 2\beta_3 = 0$$

Currently, only linear equality restrictions and tests are permitted in PROC PANEL. Tests and restriction expressions can be composed only of algebraic operations that involve the addition symbol (+), subtraction symbol (−), and multiplication symbol (*).

The TEST statement accepts labels that are produced in the printed output. The TEST statement can be labeled in two ways. A TEST statement can be preceded by a label followed by a colon. Alternatively, the keyword TEST can be followed by a quoted string. If both are presented, PROC PANEL uses the quoted string. In the event no label is present, PROC PANEL automatically labels the tests. If both a TEST and a RESTRICT statement are specified, the test is run with restrictions applied.

Note that for the DaSilva method, only the WALD test is available.

Details: PANEL Procedure

Specifying the Input Data

The PANEL procedure is similar to other regression procedures in SAS. Suppose you want to regress the variable Y on regressors X1 and X2. Cross sections are identified by the variable STATE, and time periods are identified by the variable DATE. The input data set used by PROC PANEL must be sorted by cross section and by time within each cross section. Therefore, the first step in PROC PANEL is to make sure that the input data set is sorted. The following statements sort the data set A appropriately:

```
proc sort data=a;
  by state date;
run;
```

The next step is to invoke the PANEL procedure and specify the cross section and time series variables in an ID statement. The following statements shows the correct syntax:

```
proc panel data=a;
  id state date;
  model y = x1 x2;
run;
```

Alternatively, PROC PANEL has the capability to read “flat” data. Say that you are using the data set A, which has observations on states. Specifically, the data are composed of observations on Y, X1, and X2. Unlike the previous case, the data is not recorded with a PROC PANEL structure. Instead, you have all of a state’s information on a single row. You have variables to denote the name of the state (say state). The

time observations for the Y variable are recorded horizontally. So the variable Y_1 is the first period's time observation, Y_10 is the tenth period's observation for some state. The same holds for the other variables. You have variables $X1_1$ to $X1_10$, $X2_1$ to $X2_10$, and $X3_1$ to $X3_10$ for others. With such data, PROC PANEL could be called by using the following syntax:

```
proc panel data=a;
  flatdata indid = state base = (Y X1 X2) tsname = t;
  id state t;
  model Y = X1 X2;
run;
```

See “[FLATDATA Statement](#)” on page 1382 and [Example 20.2](#) for more information about the use of the FLATDATA statement.

Specifying the Regression Model

The MODEL statement in PROC PANEL is specified like the MODEL statement in other SAS regression procedures: the dependent variable is listed first, followed by an equal sign, followed by the list of regressor variables, as shown in the following statements:

```
proc panel data=a;
  id state date;
  model y = x1 x2;
run;
```

The major advantage of using PROC PANEL is that you can incorporate a model for the structure of the random errors. It is important to consider what kind of error structure model is appropriate for your data and to specify the corresponding option in the MODEL statement.

The error structure options supported by the PANEL procedure are FIXONE, FIXONETIME, FIXTWO, RANONE, RANTWO, PARKS, DASILVA, GMM1, GMM2, and ITGMM (iterated GMM). See the following sections for more information about these methods and the error structures they assume. The following statements fit a Fuller-Battese one-way random-effects model:

```
proc panel data=a;
  id state date;
  model y = x1 x2 / ranone vcomp=fb;
run;
```

You can specify more than one error structure option in the MODEL statement; the analysis is repeated using each specified method. You can use any number of MODEL statements to estimate different regression models or estimate the same model by using different options. See [Example 20.1](#) for more information.

To aid in model specification within this class of models, PROC PANEL provides two specification test statistics. The first is an F statistic that tests the null hypothesis that the fixed-effects parameters are all 0. The second is a Hausman m statistic that provides information about the appropriateness of the random-effects specification. The m statistic is based on the idea that, under the null hypothesis of no correlation between the effects variables and the regressors, OLS and GLS are consistent. However, OLS is inefficient. Hence, a test

can be based on the result that the covariance of an efficient estimator with its difference from an inefficient estimator is 0. Rejection of the null hypothesis might suggest that the fixed-effects model is more appropriate.

The PANEL procedure also provides the Buse R-square measure. This number is interpreted as a measure of the proportion of the transformed sum of squares of the dependent variable that is attributable to the influence of the independent variables. In the case of OLS estimation, the Buse R-square measure is equivalent to the usual R-square measure.

Unbalanced Data

For fixed-effects models, random-effects models, between estimators, and dynamic panel estimators, the PANEL procedure can process data with different numbers of time series observations across different cross sections. The Parks and Da Silva methods cannot be used with unbalanced data. The missing time series observations are recognized by the absence of time series ID variable values in some of the cross sections in the input data set. Moreover, if an observation with a particular time series ID value and cross-sectional ID value is present in the input data set, but one or more of the model variables are missing, that time series point is treated as missing for that cross section.

Missing Values

Any observation in the input data set with a missing value for one or more of the regressors is ignored by PROC PANEL and is not used in the model fit.

If there are observations in the input data set with missing dependent variable values but with nonmissing regressors, PROC PANEL can compute predicted values and store them in an output data set by using the OUTPUT statement. Note that the presence of such observations with missing dependent variable values does not affect the model fit because these observations are excluded from the calculation.

If either some regressors or the dependent variable values are missing, the model is estimated as unbalanced where the number of time series observations across different cross sections does not have to be equal. The Parks and Da Silva methods cannot be used with unbalanced data.

Computational Resources

The more parameters there are to be estimated, the more memory and time are required to estimate the model. Also affecting these resources are the estimation method chosen and the method to calculate variance components. If the model has p parameters including the intercept, there are at least $p + [p * (p + 1)]/2$ numbers being held in the memory.

If the Arellano and Bond GMM approach is used, the amount of memory grows proportionately to the number of instruments in the INSTRUMENT statement. If the ITGMM (iterated GMM) option is selected, the computation time also depends on the convergence criteria selected and the maximum number of iterations allowed.

Restricted Estimates

A consequence of estimating a linear model with a restriction is that the error degrees of freedom increase by the number of restrictions. PROC PANEL produces the LaGrange multiplier associated with each restriction.

Say that you are interested in linear regression in which there are r restrictions. A linear restriction implies the following set of equations that relate the regression coefficients:

$$\begin{aligned} R_{1,1}\beta_1 + R_{1,2}\beta_2 + \cdots + R_{1,p}\beta_p &= q_1 \\ R_{2,1}\beta_1 + R_{2,2}\beta_2 + \cdots + R_{2,p}\beta_p &= q_2 \\ &\dots\dots\dots \\ R_{r,1}\beta_1 + R_{r,2}\beta_2 + \cdots + R_{r,p}\beta_p &= q_r \end{aligned}$$

To economize on notation, you can represent the restriction structure in the following matrix notation $\mathbf{R}\boldsymbol{\beta} = \mathbf{q}$. The restricted $\boldsymbol{\beta}$ estimator is given by:

$$\boldsymbol{\beta}^* = \boldsymbol{\beta} - (\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1} (\mathbf{R}\boldsymbol{\beta} - \mathbf{q})$$

The LaGrange multipliers are given as:

$$\boldsymbol{\lambda}_* = \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1} (\mathbf{R}\boldsymbol{\beta} - \mathbf{q})$$

The standard errors of the LaGrange Multipliers are calculated from the following relationship:

$$\text{Var}(\boldsymbol{\lambda}_*) = \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1} \mathbf{R} \text{Var}(\boldsymbol{\beta}) \mathbf{R}' \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1}$$

A significant LaGrange multiplier implies that you can reject the null hypothesis that the restrictions are not binding.

Note that in the special case of the fixed-effects models, the NOINT option and RESTRICT INTERCEPT=0 option give different estimates. This is not an error; it reflects two perspectives on the same issue. In the FIXONE case, the intercept is the last cross section's fixed effect (or the last time affecting the case of FIXONETIME). Specifying the NOINT option removes the intercept, but allows the last effect in. The NOINT command simply reclassifies the effects. The dummy variables become true cross section effects. If you specify the NOINT option with the FIXTWO option, the restriction is imposed that the last time effect is zero. A RESTRICT INTERCEPT=0 statement suppresses the estimation of the last effect in the FIXONE and FIXONETIME case. A RESTRICT INTERCEPT=0 has similar effects on the FIXTWO estimator. In general, restricting the intercept to zero is not recommended because OLS loses its unbiased nature.

Notation

The following notation represents the usual panel structure, with the specification of u_{it} dependent on the particular model:

$$y_{it} = \sum_{k=1}^K x_{itk}\beta_k + u_{it} \quad i = 1, \dots, N; t = 1, \dots, T_i$$

The total number of observations $M = \sum_{i=1}^N T_i$. For the balanced data case, $T_i = T$ for all i . The $M \times M$ covariance matrix of u_{it} is denoted by \mathbf{V} . Let \mathbf{X} and \mathbf{y} be the independent and dependent variables arranged by cross section and by time within each cross section. Let \mathbf{X}_s be the X matrix without the intercept. All other notation is specific to each section.

One-Way Fixed-Effects Model

The specification for the one-way fixed-effects model is

$$u_{it} = \gamma_i + \epsilon_{it}$$

where the γ_i s are nonrandom parameters to be estimated.

Let $\mathbf{Q}_0 = \text{diag}(\mathbf{E}_{T_i})$, with $\bar{\mathbf{J}}_{T_i} = \mathbf{J}_{T_i}/T_i$ and $\mathbf{E}_{T_i} = \mathbf{I}_{T_i} - \bar{\mathbf{J}}_{T_i}$, where \mathbf{J}_{T_i} is a matrix of T_i ones.

The matrix \mathbf{Q}_0 represents the within transformation. In the one-way model, the within transformation is the conversion of the raw data to deviations from a cross section's mean. The vector $\tilde{\mathbf{x}}_{it}$ is a row of the general matrix \mathbf{X}_s , where the subscripted s implies the constant (column of ones) is missing.

Let $\tilde{\mathbf{X}}_s = \mathbf{Q}_0\mathbf{X}_s$ and $\tilde{\mathbf{y}} = \mathbf{Q}_0\mathbf{y}$. The estimator of the slope coefficients is given by

$$\tilde{\beta}_s = (\tilde{\mathbf{X}}_s' \tilde{\mathbf{X}}_s)^{-1} \tilde{\mathbf{X}}_s' \tilde{\mathbf{y}}$$

Once the slope estimates are in hand, the estimation of an intercept or the cross-sectional fixed effects is handled as follows. First, you obtain the cross-sectional effects:

$$\gamma_i = \bar{y}_i - \tilde{\beta}_s \bar{x}_i \quad \text{for } i = 1 \dots N$$

If the NOINT option is specified, then the dummy variables' coefficients are set equal to the fixed effects. If an intercept is desired, then the i th dummy variable is obtained from the following expression:

$$D_i = \gamma_i - \gamma_N \quad \text{for } i = 1 \dots N - 1$$

The intercept is the N th fixed effect γ_N .

The within model sum of squared errors is:

$$\text{SSE} = \sum_{i=1}^N \sum_{t=1}^{T_i} (y_{it} - \gamma_i - \mathbf{X}_s \tilde{\beta}_s)^2$$

The estimated error variance can be written:

$$\hat{\sigma}_\epsilon^2 = \text{SSE}/(M - N - (K - 1))$$

Alternatively, an equivalent way to express the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{Q}_0 \tilde{\mathbf{u}} / (M - N - (K - 1))$$

where the residuals $\tilde{\mathbf{u}}$ are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M \mathbf{j}_M' / M)(\mathbf{y} - \mathbf{X}_s \tilde{\beta}_s)$ if there is an intercept and by $\tilde{\mathbf{u}} = (\mathbf{y} - \mathbf{X}_s \tilde{\beta}_s)$ if there is not. The drawback is that the formula changes (but the results do not) with the inclusion of a constant.

The variance covariance matrix of $\tilde{\beta}_s$ is given by:

$$\text{Var}[\tilde{\beta}_s] = \hat{\sigma}_\epsilon^2 (\tilde{\mathbf{X}}_s' \tilde{\mathbf{X}}_s)^{-1}$$

The covariance of the dummy variables and the dummy variables with the $\tilde{\beta}_s$ is dependent on whether the intercept is included in the model.

- *no intercept:*

$$\text{Var}[\gamma_i] = \text{Var}[D_i] = \frac{\hat{\sigma}_\epsilon^2}{T_i} + \bar{\mathbf{x}}_i' \text{Var}[\tilde{\beta}_s] \bar{\mathbf{x}}_i.$$

$$\text{Cov}[\gamma_i, \gamma_j] = \text{Cov}[D_i, D_j] = \bar{\mathbf{x}}_i' \text{Var}[\tilde{\beta}_s] \bar{\mathbf{x}}_j.$$

$$\text{Cov}[\gamma_i, \tilde{\beta}_s] = \text{Cov}[D_i, \tilde{\beta}_s] = -\bar{\mathbf{x}}_i' \text{Var}[\tilde{\beta}_s]$$

- *intercept:*

$$\text{Var}[D_i] = \frac{\hat{\sigma}_\epsilon^2}{T_i} + \frac{\hat{\sigma}_\epsilon^2}{T_N} + (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})' \text{Var}[\tilde{\beta}_s] (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})$$

$$\text{Cov}[D_i, D_j] = \frac{\hat{\sigma}_\epsilon^2}{T_N} + (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})' \text{Var}[\tilde{\beta}_s] (\bar{\mathbf{x}}_j - \bar{\mathbf{x}}_{N\cdot})$$

$$\text{Var}[\text{Intercept}] = \text{Var}[\gamma_N] = \frac{\hat{\sigma}_\epsilon^2}{T_N} + \bar{\mathbf{x}}_N' \text{Var}[\tilde{\beta}_s] \bar{\mathbf{x}}_N.$$

$$\text{Cov}[D_i, \tilde{\beta}_s] = -(\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})' \text{Var}[\tilde{\beta}_s]$$

$$\text{Cov}[\text{Intercept}, D_i] = -\frac{\hat{\sigma}_\epsilon^2}{T_i} + \bar{\mathbf{x}}_N' \text{Var}[\tilde{\beta}_s] (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})$$

$$\text{Cov}[\text{Intercept}, \tilde{\beta}_s] = -\bar{\mathbf{x}}_N' \text{Var}[\tilde{\beta}_s]$$

Alternatively, the model option `FIXONETIME` estimates a one-way model where the heterogeneity comes from time effects. This option is analogous to re-sorting the data by time and then by cross section and running a `FIXONE` model. The advantage of using the `FIXONETIME` option is that sorting is avoided and the model remains labeled correctly.

Two-Way Fixed-Effects Model

The specification for the two-way fixed-effects model is

$$u_{it} = \gamma_i + \alpha_t + \epsilon_{it}$$

where the γ_i s and α_t s are nonrandom parameters to be estimated.

If you do not specify the `NOINT` option, which suppresses the intercept, the estimates for the fixed effects are reported under the restriction that $\gamma_N = 0$ and $\alpha_T = 0$. If you specify the `NOINT` option to suppress the intercept, only the restriction $\alpha_T = 0$ is imposed.

Balanced Panels

Assume that the data are balanced (for example, all cross sections have T observations). Then you can write the following:

$$\tilde{y}_{it} = y_{it} - \bar{y}_{i\cdot} - \bar{y}_{\cdot t} + \bar{\bar{y}}$$

$$\tilde{\mathbf{x}}_{it} = \mathbf{x}_{it} - \bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{\cdot t} + \bar{\bar{\mathbf{x}}}$$

where the symbols:

y_{it} and \mathbf{x}_{it} are the dependent variable (a scalar) and the explanatory variables (a vector whose columns are the explanatory variables not including a constant), respectively

$\bar{y}_{i\cdot}$ and $\bar{\mathbf{x}}_{i\cdot}$ are cross section means

$\bar{y}_{\cdot t}$ and $\bar{\mathbf{x}}_{\cdot t}$ are time means

$\bar{\bar{y}}$ and $\bar{\bar{\mathbf{x}}}$ are the overall means

The two-way fixed-effects model is simply a regression of \tilde{y}_{it} on $\tilde{\mathbf{x}}_{it}$. Therefore, the two-way β is given by:

$$\tilde{\beta}_s = (\tilde{\mathbf{X}}' \tilde{\mathbf{X}})^{-1} \tilde{\mathbf{X}}' \tilde{\mathbf{y}}$$

The calculations of cross section dummy variables, time dummy variables, and intercepts follow in a fashion similar to that used in the one-way model.

First, you obtain the net cross-sectional and time effects. Denote the cross-sectional effects by γ and the time effects by α . These effects are calculated from the following relations:

$$\hat{\gamma}_i = (\bar{y}_{i\cdot} - \bar{\bar{y}}) - \tilde{\beta}_s (\bar{x}_{i\cdot} - \bar{\bar{x}})$$

$$\hat{\alpha}_t = (\bar{y}_{\cdot t} - \bar{\bar{y}}) - \tilde{\beta}_s (\bar{x}_{\cdot t} - \bar{\bar{x}})$$

Denote the cross-sectional dummy variables and time dummy variables with the superscript C and T. Under the NOINT option the following equations give the dummy variables:

$$D_i^C = \hat{\gamma}_i + \hat{\alpha}_T$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

When an intercept is specified, the equations for dummy variables and intercept are:

$$D_i^C = \hat{\gamma}_i - \hat{\gamma}_N$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

$$\text{Intercept} = \hat{\gamma}_N + \hat{\alpha}_T$$

The sum of squared errors is:

$$\text{SSE} = \sum_{i=1}^N \sum_{t=1}^{T_i} (y_{it} - \gamma_i - \alpha_t - \mathbf{X}_s \tilde{\beta}_s)^2$$

The estimated error variance is:

$$\hat{\sigma}_\epsilon^2 = \text{SSE} / (M - N - T - (K - 1))$$

With or without a constant, the variance covariance matrix of $\tilde{\beta}_s$ is given by:

$$\text{Var}[\tilde{\beta}_s] = \hat{\sigma}_\epsilon^2 (\tilde{\mathbf{X}}_s' \tilde{\mathbf{X}}_s)^{-1}$$

Variance Covariance of Dummy Variables with No Intercept

The variances and covariances of the dummy variables are given with the NOINT specification as follows:

$$\begin{aligned} \text{Var} \left(D_i^C \right) &= \hat{\sigma}_\epsilon^2 \left(\frac{1}{T} + \frac{1}{N} - \frac{1}{NT} \right) \\ &+ \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}} \right) \end{aligned}$$

$$\text{Var} \left(D_t^T \right) = \frac{2\hat{\sigma}_\epsilon^2}{N} + \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)$$

$$\begin{aligned} \text{Cov} \left(D_i^C, D_j^C \right) &= \hat{\sigma}_\epsilon^2 \left(\frac{1}{N} - \frac{1}{NT} \right) \\ &+ \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{j\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right) \end{aligned}$$

$$\text{Cov} \left(D_t^T, D_u^T \right) = \frac{\hat{\sigma}_\epsilon^2}{N} + \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{\cdot u} - \bar{\mathbf{x}}_{\cdot T} \right)$$

$$\text{Cov} \left(D_i^C, D_t^T \right) = -\frac{\hat{\sigma}_\epsilon^2}{N} + \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)$$

$$\text{Cov} \left(D_i^C, \beta \right) = -\left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)' \text{Var} \left[\tilde{\beta}_s \right]$$

$$\text{Cov} \left(D_t^T, \beta \right) = -\left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var} \left[\tilde{\beta}_s \right]$$

Variance Covariance of Dummy Variables with Intercept

The variances and covariances of the dummy variables are given when the intercept is included as follows:

$$\begin{aligned}
 \text{Var} \left(D_i^C \right) &= \frac{2\hat{\sigma}_\epsilon^2}{T} + (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot}) \\
 \text{Var} \left(D_t^T \right) &= \frac{2\hat{\sigma}_\epsilon^2}{N} + (\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T}) \\
 \text{Var} (\text{Intercept}) &= \hat{\sigma}_\epsilon^2 \left(\frac{1}{T} + \frac{1}{N} - \frac{1}{NT} \right) + (\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}}) \\
 \text{Cov} \left(D_i^C, D_j^C \right) &= \frac{\hat{\sigma}_\epsilon^2}{T} + (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{j\cdot} - \bar{\mathbf{x}}_{N\cdot}) \\
 \text{Cov} \left(D_t^T, D_u^T \right) &= \frac{\hat{\sigma}_\epsilon^2}{N} + (\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{\cdot u} - \bar{\mathbf{x}}_{\cdot T}) \\
 \text{Cov} \left(D_i^C, D_u^T \right) &= (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{\cdot u} - \bar{\mathbf{x}}_{\cdot T}) \\
 \text{Cov} \left(D_i^C, \text{Intercept} \right) &= - \left(\frac{\hat{\sigma}_\epsilon^2}{T} \right) + (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}}) \\
 \text{Cov} \left(D_t^T, \text{Intercept} \right) &= - \left(\frac{\hat{\sigma}_\epsilon^2}{N} \right) + (\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}}) \\
 \text{Cov} \left(D_i^C, \tilde{\beta} \right) &= - (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot})' \text{Var} \left[\tilde{\beta}_s \right] \\
 \text{Cov} \left(D_t^T, \tilde{\beta} \right) &= - (\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T})' \text{Var} \left[\tilde{\beta}_s \right] \\
 \text{Cov} \left(\text{Intercept}, \tilde{\beta} \right) &= - (\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}})' \text{Var} \left[\tilde{\beta}_s \right]
 \end{aligned}$$

Unbalanced Panels

Let \mathbf{X}_* and \mathbf{y}_* be the independent and dependent variables arranged by time and by cross section within each time period. (Note that the input data set used by the PANEL procedure must be sorted by cross section and then by time within each cross section.) Let M_t be the number of cross sections observed in year t and let $\sum_t M_t = M$. Let \mathbf{D}_t be the $M_t \times N$ matrix obtained from the $N \times N$ identity matrix from which rows that correspond to cross sections not observed at time t have been omitted. Consider

$$\mathbf{Z} = (\mathbf{Z}_1, \mathbf{Z}_2)$$

where $\mathbf{Z}_1 = (\mathbf{D}_1', \mathbf{D}_2', \dots, \mathbf{D}_T')'$ and $\mathbf{Z}_2 = \text{diag}(\mathbf{D}_1 \mathbf{j}_N, \mathbf{D}_2 \mathbf{j}_N, \dots, \mathbf{D}_T \mathbf{j}_N)$. The matrix \mathbf{Z} gives the dummy variable structure for the two-way model.

Let

$$\begin{aligned}
 \mathbf{\Delta}_N &= \mathbf{Z}_1' \mathbf{Z}_1 \\
 \mathbf{\Delta}_T &= \mathbf{Z}_2' \mathbf{Z}_2 \\
 \mathbf{A} &= \mathbf{Z}_2' \mathbf{Z}_1 \\
 \bar{\mathbf{Z}} &= \mathbf{Z}_2 - \mathbf{Z}_1 \mathbf{\Delta}_N^{-1} \mathbf{A}' \\
 \mathbf{Q} &= \mathbf{\Delta}_T - \mathbf{A} \mathbf{\Delta}_N^{-1} \mathbf{A}' \\
 \mathbf{P} &= (\mathbf{I}_M - \mathbf{Z}_1 \mathbf{\Delta}_N^{-1} \mathbf{Z}_1') - \bar{\mathbf{Z}} \mathbf{Q}^{-1} \bar{\mathbf{Z}}'
 \end{aligned}$$

The estimate of the regression slope coefficients is given by

$$\tilde{\beta}_s = (\mathbf{X}_{*s}' \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}_{*s}' \mathbf{P} \mathbf{y}_*$$

where \mathbf{X}_{*s} is the \mathbf{X}_* matrix without the vector of 1s.

The estimator of the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{P} \tilde{\mathbf{u}} / (M - T - N + 1 - (K - 1))$$

where the residuals are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M \mathbf{j}_M' / M)(\mathbf{y}_* - \mathbf{X}_{*s} \tilde{\beta}_s)$ if there is an intercept in the model and by $\tilde{\mathbf{u}} = \mathbf{y}_* - \mathbf{X}_{*s} \tilde{\beta}_s$ if there is no intercept.

The actual implementation is quite different from the theory. The PANEL procedure transforms all series using the \mathbf{P} matrix.

$$\tilde{\mathbf{v}} = \mathbf{P} \mathbf{v}$$

The variable being transformed is v , which could be \mathbf{y} or any column of \mathbf{X} . After the data are properly transformed, OLS is run on the resulting series.

Given $\tilde{\beta}_s$, the next step is estimating the cross-sectional and time effects. Given that $\boldsymbol{\gamma}$ is the column vector of cross-sectional effects and $\boldsymbol{\alpha}$ is the column vector of time effects,

$$\tilde{\boldsymbol{\alpha}} = \mathbf{Q}^{-1} \tilde{\mathbf{Z}}' \mathbf{y} - \mathbf{Q}^{-1} \tilde{\mathbf{Z}}' \mathbf{X}_s \tilde{\beta}_s$$

$$\tilde{\boldsymbol{\gamma}} = (\Theta_1 + \Theta_2 - \Theta_3) \mathbf{y} - (\Theta_1 + \Theta_2 - \Theta_3) \mathbf{X}_s \tilde{\beta}_s$$

$$\Theta_1 = \Delta_N^{-1} \mathbf{Z}_1'$$

$$\Theta_2 = \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{Z}_2'$$

$$\Theta_3 = \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1} \mathbf{Z}_1'$$

Given the cross-sectional and time effects, the next step is to derive the associated dummy variables. Using the NOINT option, the following equations give the dummy variables:

$$D_i^C = \hat{\gamma}_i + \hat{\alpha}_T$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

When an intercept is desired, the equations for dummy variables and intercept are:

$$D_i^C = \hat{\gamma}_i - \hat{\gamma}_N$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

$$\text{Intercept} = \hat{\gamma}_N + \hat{\alpha}_T$$

The calculation of the covariance matrix is as follows:

$$\begin{aligned} \text{Var}[\hat{\boldsymbol{\gamma}}] &= \hat{\sigma}_\epsilon^2 (\Delta_N^{-1} - \Sigma_1 + \Sigma_2) \\ &+ (\Theta_1 + \Theta_2 - \Theta_3) \text{Var}[\tilde{\beta}_s] (\Theta_1 + \Theta_2 - \Theta_3)' \end{aligned}$$

where

$$\begin{aligned}
\Sigma_1 &= \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1} \\
\Sigma_2 &= \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \Delta_T \mathbf{Q}^{-1} \mathbf{A} \Delta_N \\
\text{Var}[\hat{\alpha}] &= \hat{\sigma}_\epsilon^2 \left(\mathbf{Q}^{-1} \bar{\mathbf{Z}}' \bar{\mathbf{Z}} \mathbf{Q}^{-1} \right) + \left(\mathbf{Q}^{-1} \bar{\mathbf{Z}}' \mathbf{X}_s \right) \text{Var}[\tilde{\beta}_s] \left(\mathbf{X}_s' \bar{\mathbf{Z}} \mathbf{Q}^{-1} \right) \\
\text{Cov}[\hat{\alpha}, \hat{\gamma}'] &= \hat{\sigma}_\epsilon^2 \Delta_N^{-1} \left[\mathbf{A}' \mathbf{Q}^{-1} \Delta_T - \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1} \mathbf{A}' \right] \mathbf{Q}^{-1} \\
&\quad + (\Theta_1 + \Theta_2 - \Theta_3) \text{Var}[\tilde{\beta}_s] \left(\mathbf{X}_s' \bar{\mathbf{Z}} \mathbf{Q}^{-1} \right) \\
\text{Cov}[\hat{\gamma}, \tilde{\beta}] &= (\Theta_1 + \Theta_2 - \Theta_3) \text{Var}[\tilde{\beta}_s] \\
\text{Cov}[\hat{\alpha}, \tilde{\beta}] &= \left(\mathbf{Q}^{-1} \bar{\mathbf{Z}}' \mathbf{X}_s \right) \text{Var}[\tilde{\beta}_s]
\end{aligned}$$

Now you work out the variance covariance estimates for the dummy variables.

Variance Covariance of Dummy Variables with No Intercept

The variances and covariances of the dummy variables are given under the NOINT selection as follows:

$$\begin{aligned}
\text{Cov}(D_i^C, D_j^C) &= \text{Cov}(\hat{\gamma}_i, \hat{\gamma}_j) + \text{Cov}(\hat{\gamma}_i, \hat{\alpha}_T) + \text{Cov}(\hat{\gamma}_j, \hat{\alpha}_T) + \text{Var}(\hat{\alpha}_T) \\
\text{Cov}(D_t^T, D_u^T) &= \text{Cov}(\hat{\alpha}_t, \hat{\alpha}_u) - \text{Cov}(\hat{\alpha}_t, \hat{\alpha}_T) - \text{Cov}(\hat{\alpha}_u, \hat{\alpha}_T) + \text{Var}(\hat{\alpha}_T) \\
\text{Cov}(D_i^C, D_t^T) &= \text{Cov}(\hat{\gamma}_i, \hat{\alpha}_t) + \text{Cov}(\hat{\gamma}_i, \hat{\alpha}_T) - \text{Cov}(\hat{\gamma}_i, \hat{\alpha}_T) - \text{Var}(\hat{\alpha}_T) \\
\text{Cov}(D_i^C, \tilde{\beta}) &= -\text{Cov}(\hat{\gamma}_i, \tilde{\beta}) - \text{Cov}(\hat{\alpha}_T, \tilde{\beta}) \\
\text{Cov}(D_t^T, \tilde{\beta}) &= -\text{Cov}(\hat{\alpha}_t, \tilde{\beta}) + \text{Cov}(\hat{\alpha}_T, \tilde{\beta})
\end{aligned}$$

Variance Covariance of Dummy Variables with Intercept

The variances and covariances of the dummy variables are given as follows when the intercept is included:

$$\begin{aligned}
\text{Cov}(D_i^C, D_j^C) &= \text{Cov}(\hat{\gamma}_i, \hat{\gamma}_j) - \text{Cov}(\hat{\gamma}_i, \hat{\gamma}_N) - \text{Cov}(\hat{\gamma}_j, \hat{\gamma}_N) + \text{Var}(\hat{\gamma}_N) \\
\text{Cov}(D_t^T, D_u^T) &= \text{Cov}(\hat{\alpha}_t, \hat{\alpha}_u) - \text{Cov}(\hat{\alpha}_t, \hat{\alpha}_T) - \text{Cov}(\hat{\alpha}_u, \hat{\alpha}_T) + \text{Var}(\hat{\alpha}_T) \\
\text{Cov}(D_i^C, D_t^T) &= \text{Cov}(\hat{\gamma}_i, \hat{\alpha}_t) - \text{Cov}(\hat{\gamma}_i, \hat{\alpha}_T) - \text{Cov}(\hat{\gamma}_N, \hat{\alpha}_t) + \text{Cov}(\hat{\gamma}_N, \hat{\alpha}_T) \\
\text{Cov}(D_i^C, \text{Intercept}) &= \text{Cov}(\hat{\gamma}_i, \hat{\gamma}_N) + \text{Cov}(\hat{\gamma}_i, \hat{\alpha}_T) - \text{Cov}(\hat{\gamma}_j, \hat{\alpha}_T) - \text{Var}(\hat{\gamma}_N) \\
\text{Cov}(D_t^T, \text{Intercept}) &= \text{Cov}(\hat{\alpha}_t, \hat{\alpha}_T) + \text{Cov}(\hat{\alpha}_t, \hat{\gamma}_N) - \text{Cov}(\hat{\alpha}_T, \hat{\alpha}_N) - \text{Var}(\hat{\alpha}_T) \\
\text{Cov}(D_i^C, \tilde{\beta}) &= -\text{Cov}(\hat{\gamma}_i, \tilde{\beta}) - \text{Cov}(\hat{\gamma}_N, \tilde{\beta}) \\
\text{Cov}(D_t^T, \tilde{\beta}) &= -\text{Cov}(\hat{\alpha}_t, \tilde{\beta}) + \text{Cov}(\hat{\alpha}_T, \tilde{\beta}) \\
\text{Cov}(\text{Intercept}, \tilde{\beta}_f) &= -\text{Cov}(\hat{\alpha}_T, \tilde{\beta}) - \text{Cov}(\hat{\gamma}_N, \tilde{\beta})
\end{aligned}$$

Between Estimators

The between-groups estimator is the regression of the cross section means of y on the cross section means of \tilde{X}_s . In other words, you fit the following regression:

$$\bar{y}_{i\cdot} = \bar{x}_{i\cdot}\beta^{BG} + \eta_i$$

The between-time-periods estimator is the regression of the time means of y on the time means of \tilde{X}_s . In other words, you fit the following regression:

$$\bar{y}_{\cdot t} = \bar{x}_{\cdot t}\beta^{BT} + \zeta_t$$

In either case, the error is assumed to be normally distributed with mean zero and a constant variance.

Pooled Estimator

PROC PANEL allows you to pool time series cross-sectional data and run regressions on the data. Pooling is admissible if there are no fixed effects or random effects present in the data. This feature is included to aid in analysis and comparison across model types and to give you access to HCCME standard errors and other panel diagnostics. In general, this model type should not be used with time series cross-sectional data.

One-Way Random-Effects Model

The specification for the one-way random-effects model is

$$u_{it} = v_i + \epsilon_{it}$$

Let $Z_0 = \text{diag}(\mathbf{J}_{T_i})$, $P_0 = \text{diag}(\bar{\mathbf{J}}_{T_i})$, and $Q_0 = \text{diag}(\mathbf{E}_{T_i})$, with $\bar{\mathbf{J}}_{T_i} = \mathbf{J}_{T_i}/T_i$ and $\mathbf{E}_{T_i} = \mathbf{I}_{T_i} - \bar{\mathbf{J}}_{T_i}$. Define $\tilde{X}_s = Q_0 X_s$ and $\tilde{y} = Q_0 y$ and \mathbf{J} as a vector of ones T_i long.

In the one-way model, estimation proceeds in a two-step fashion. First, you obtain estimates of the variance of the σ_ϵ^2 and σ_v^2 . There are multiple ways to derive these estimates; PROC PANEL provides four options. All four options are valid for balanced or unbalanced panels. Once these estimates are in hand, they are used to form a weighting factor θ , and estimation proceeds via OLS on partial deviations from group means.

PROC PANEL gives the following options for variance component estimators.

Fuller and Battese's Method

The Fuller and Battese method for estimating variance components can be obtained with the option VCOMP = FB and the option RANONE. The variance components are given by the following equations (For the approach in the two-way model, see Baltagi and Chang (1994); Fuller and Battese (1974)). Let

$$R(v) = y'Z_0(Z_0'Z_0)^{-1}Z_0'y$$

$$R(\beta|v) = ((\tilde{X}_s'\tilde{X}_s)^{-1}\tilde{X}_s'\tilde{y})'(\tilde{X}_s'\tilde{y})$$

$$R(\beta) = (\mathbf{X}'_s \mathbf{y})' (\mathbf{X}'_s \mathbf{X}_s)^{-1} \mathbf{X}'_s \mathbf{y}$$

$$R(v|\beta) = R(\beta|v) + R(v) - R(\beta)$$

The estimator of the error variance is given by

$$\hat{\sigma}_\epsilon^2 = (\mathbf{y}' \mathbf{y} - R(\beta|v) - R(v)) / (M - N - (K - 1))$$

If the NOINT option is specified, the estimator is

$$\hat{\sigma}_\epsilon^2 = (\mathbf{y}' \mathbf{y} - R(\beta|v) - R(v)) / (M - N - K)$$

The estimator of the cross-sectional variance component is given by

$$\hat{\sigma}_v^2 = (R(v|\beta) - (N - 1)\hat{\sigma}_\epsilon^2) / (M - \text{tr}(\mathbf{Z}'_0 \mathbf{X}_s (\mathbf{X}'_s \mathbf{X}_s)^{-1} \mathbf{X}'_s \mathbf{Z}_0))$$

Note that the error variance is the variance of the residual of the within estimator.

According to Baltagi and Chang (1994), the Fuller and Battese method is appropriate to apply to both balanced and unbalanced data. The Fuller and Battese method is the default for estimation of one-way random-effects models with balanced panels. However, the Fuller and Battese method does not always obtain nonnegative estimates for the cross section (or group) variance. In the case of a negative estimate, a warning is printed and the estimate is set to zero.

Wansbeek and Kapteyn's Method

The Wansbeek and Kapteyn method for estimating variance components can be obtained by setting VCOMP = WK (together with the option RANONE). The estimation of the one-way unbalanced data model is performed by using a specialization (Baltagi and Chang 1994) of the approach used by Wansbeek and Kapteyn (1989) for unbalanced two-way models. The Wansbeek and Kapteyn method is the default for unbalanced data. If just RANONE is specified, without the VCOMP= option, PROC PANEL estimates the variance component under Wansbeek and Kapteyn's method.

The estimation of the variance components is performed by using a quadratic unbiased estimation (QUE) method. This involves focusing on quadratic forms of the centered residuals, equating their expected values to the realized quadratic forms, and solving for the variance components.

Let

$$q_1 = \tilde{\mathbf{u}}' \mathbf{Q}_0 \tilde{\mathbf{u}}$$

$$q_2 = \tilde{\mathbf{u}}' \mathbf{P}_0 \tilde{\mathbf{u}}$$

where the residuals $\tilde{\mathbf{u}}$ are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M \mathbf{j}'_M / M)(\mathbf{y} - \mathbf{X}_s (\tilde{\mathbf{X}}'_s \tilde{\mathbf{X}}_s)^{-1} \tilde{\mathbf{X}}'_s \tilde{\mathbf{y}})$ if there is an intercept and by $\tilde{\mathbf{u}} = \mathbf{y} - \mathbf{X}_s (\tilde{\mathbf{X}}'_s \tilde{\mathbf{X}}_s)^{-1} \tilde{\mathbf{X}}'_s \tilde{\mathbf{y}}$ if there is not. A vector of M ones is represented by \mathbf{j} .

Consider the expected values

$$E(q_1) = (M - N - (K - 1))\sigma_\epsilon^2$$

$$E(q_2) = (N - 1 + \text{tr}[(\mathbf{X}'_s \mathbf{Q}_0 \mathbf{X}_s)^{-1} \mathbf{X}'_s \mathbf{P}_0 \mathbf{X}_s] - \text{tr}[(\mathbf{X}'_s \mathbf{Q}_0 \mathbf{X}_s)^{-1} \mathbf{X}'_s \tilde{\mathbf{J}}_M \mathbf{X}_s])\sigma_\epsilon^2 \\ [M - (\sum_i T_i^2 / M)]\sigma_v^2$$

where $\hat{\sigma}_\epsilon^2$ and $\hat{\sigma}_v^2$ are obtained by equating the quadratic forms to their expected values.

The estimator of the error variance is the residual variance of the within estimate. The Wansbeek and Kapteyn method can also generate negative variance components estimates.

Wallace and Hussain's Method

The Wallace and Hussain method for estimating variance components can be obtained by setting VCOMP = WH (together with the option RANONE). Wallace-Hussain estimates start from OLS residuals on a data that are assumed to exhibit groupwise heteroscedasticity. As in the Wansbeek and Kapteyn method, you start with

$$q_1 = \tilde{\mathbf{u}}'_{OLS} \mathbf{Q}_0 \tilde{\mathbf{u}}_{OLS}$$

$$q_2 = \tilde{\mathbf{u}}'_{OLS} \mathbf{P}_0 \tilde{\mathbf{u}}_{OLS}$$

However, instead of using the 'true' errors, you substitute the OLS residuals. You solve the system

$$E(\hat{q}_1) = E(\hat{\mathbf{u}}'_{OLS} \mathbf{Q}_0 \hat{\mathbf{u}}_{OLS}) = \delta_{11} \hat{\sigma}_v^2 + \delta_{12} \hat{\sigma}_\epsilon^2$$

$$E(\hat{q}_2) = E(\hat{\mathbf{u}}'_{OLS} \mathbf{P}_0 \hat{\mathbf{u}}_{OLS}) = \delta_{21} \hat{\sigma}_v^2 + \delta_{22} \hat{\sigma}_\epsilon^2$$

The constants δ_{11} , δ_{12} , δ_{21} , δ_{22} are given by

$$\delta_{11} = \text{tr} \left(\left(\mathbf{X}' \mathbf{X} \right)^{-1} \mathbf{X}' \mathbf{Z}_0 \mathbf{Z}_0' \mathbf{X} \right) - \text{tr} \left(\left(\mathbf{X}' \mathbf{X} \right)^{-1} \mathbf{X}' \mathbf{P}_0 \mathbf{X} \left(\mathbf{X}' \mathbf{X} \right)^{-1} \mathbf{X}' \mathbf{Z}_0 \mathbf{Z}_0' \mathbf{X} \right)$$

$$\delta_{12} = M - N - K + \text{tr} \left(\left(\mathbf{X}' \mathbf{X} \right)^{-1} \mathbf{X}' \mathbf{P}_0 \mathbf{X} \right)$$

$$\delta_{21} = M - 2 \text{tr} \left(\left(\mathbf{X}' \mathbf{X} \right)^{-1} \mathbf{X}' \mathbf{Z}_0 \mathbf{Z}_0' \mathbf{X} \right) + \text{tr} \left(\left(\mathbf{X}' \mathbf{X} \right)^{-1} \mathbf{X}' \mathbf{P}_0 \mathbf{X} \right)$$

$$\delta_{22} = N - \text{tr} \left(\left(\mathbf{X}' \mathbf{X} \right)^{-1} \mathbf{X}' \mathbf{P}_0 \mathbf{X} \right)$$

where $\text{tr}()$ is the trace operator on a square matrix.

Solving this system produces the variance components. This method is applicable to balanced and unbalanced panels. However, there is no guarantee of positive variance components. Any negative values are fixed equal to zero.

Nerlove's Method

The Nerlove method for estimating variance components can be obtained by setting VCOMP = NL. The Nerlove method (see Baltagi 1995, p. 17) is assured to give estimates of the variance components that are always positive. Furthermore, it is simple in contrast to the previous estimators.

If γ_i is the i th fixed effect, Nerlove's method uses the variance of the fixed effects as the estimate of $\hat{\sigma}_v^2$. You have $\hat{\sigma}_v^2 = \sum_{i=1}^N \frac{(\gamma_i - \bar{\gamma})^2}{N-1}$, where $\bar{\gamma}$ is the mean fixed effect. The estimate of σ_ϵ^2 is simply the residual sum of squares of the one-way fixed-effects regression divided by the number of observations.

Transformation and Estimation

After you calculate the variance components from any method, the next task is to estimate the regression model of interest. For each individual, you form a weight (θ_i) as

$$\theta_i = 1 - \sigma_\epsilon / w_i$$

$$w_i^2 = T_i \sigma_v^2 + \sigma_\epsilon^2$$

where T_i is the i th cross section's time observations.

Taking the θ_i , you form the partial deviations,

$$\tilde{y}_{it} = y_{it} - \theta_i \bar{y}_i.$$

$$\tilde{x}_{it} = x_{it} - \theta_i \bar{x}_i.$$

where \bar{y}_i and \bar{x}_i are cross-sectional means of the dependent variable and independent variables (including the constant if any), respectively.

The random effects β is then the result of simple OLS on the transformed data.

Two-Way Random-Effects Model

The specification for the two-way random-effects model is

$$u_{it} = v_i + e_t + \epsilon_{it}$$

As in the one-way random-effects model, the PANEL procedure provides four options for variance component estimators. Unlike the one-way random-effects model, unbalanced panels present some special concerns.

Let \mathbf{X}_* and \mathbf{y}_* be the independent and dependent variables arranged by time and by cross section within each time period. (Note that the input data set used by the PANEL procedure must be sorted by cross section and then by time within each cross section.) Let M_t be the number of cross sections observed in time t and $\sum_t M_t = M$. Let \mathbf{D}_t be the $M_t \times N$ matrix obtained from the $N \times N$ identity matrix from which rows that correspond to cross sections not observed at time t have been omitted. Consider

$$\mathbf{Z} = (\mathbf{Z}_1, \mathbf{Z}_2)$$

where $\mathbf{Z}_1 = (\mathbf{D}'_1, \mathbf{D}'_2, \dots, \mathbf{D}'_T)'$ and $\mathbf{Z}_2 = \text{diag}(\mathbf{D}_1 \mathbf{j}_N, \mathbf{D}_2 \mathbf{j}_N, \dots, \mathbf{D}_T \mathbf{j}_N)$.

The matrix \mathbf{Z} gives the dummy variable structure for the two-way model.

For notational ease, let

$$\Delta_N = \mathbf{Z}'_1 \mathbf{Z}_1, \Delta_T = \mathbf{Z}'_2 \mathbf{Z}_2, \mathbf{A} = \mathbf{Z}'_2 \mathbf{Z}_1$$

$$\bar{\mathbf{Z}} = \mathbf{Z}_2 - \mathbf{Z}_1 \Delta_N^{-1} \mathbf{A}'$$

$$\bar{\Delta}_1 = \mathbf{I}_M - \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1$$

$$\bar{\Delta}_2 = \mathbf{I}_M - \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}'_2$$

$$\mathbf{Q} = \Delta_T - \mathbf{A} \Delta_N^{-1} \mathbf{A}'$$

$$\mathbf{P} = (\mathbf{I}_M - \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1) - \bar{\mathbf{Z}} \mathbf{Q}^{-1} \bar{\mathbf{Z}}'$$

Fuller and Battese's Method

The Fuller and Battese method for estimating variance components can be obtained by setting VCOMP = FB (with the option RANTWO). FB is the default method for a RANTWO model with balanced panel. If RANTWO is requested without specifying the VCOMP= option, PROC PANEL proceeds under the Fuller and Battese method.

Following the discussion in Baltagi, Song, and Jung (2002), the Fuller and Battese method forms the estimates as follows.

The estimator of the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{P} \tilde{\mathbf{u}} / (M - T - N + 1 - (K - 1))$$

where \mathbf{P} is the Wansbeek and Kapteyn within estimator for unbalanced (or balanced) panel in a two-way setting.

The estimator of the error variance is the same as that in the Wansbeek and Kapteyn method.

Consider the expected values

$$\begin{aligned} E(q_N) &= \sigma_\epsilon^2 [M - T - K + 1] \\ &+ \sigma_v^2 \left[M - T - \text{tr} \left(\mathbf{X}'_s \bar{\Delta}_2 \mathbf{Z}_1 \mathbf{Z}'_1 \bar{\Delta}_2 \mathbf{X}_s \left(\mathbf{X}'_s \bar{\Delta}_2 \mathbf{X}_s \right)^{-1} \right) \right] \\ E(q_T) &= \sigma_\epsilon^2 [M - N - K + 1] \\ &+ \sigma_e^2 \left[M - N - \text{tr} \left(\mathbf{X}'_s \bar{\Delta}_1 \mathbf{Z}_2 \mathbf{Z}'_2 \bar{\Delta}_1 \mathbf{X}_s \left(\mathbf{X}'_s \bar{\Delta}_1 \mathbf{X}_s \right)^{-1} \right) \right] \end{aligned}$$

Just as in the one-way case, there is always the possibility that the (estimated) variance components will be negative. In such a case, the negative components are fixed to equal zero. After substituting the group sum of the within residuals for (q_N) , the time sums of the within residuals for (q_T) , and $\hat{\sigma}_\epsilon^2$, the two equations are solved for $\hat{\sigma}_v^2$ and $\hat{\sigma}_e^2$.

Wansbeek and Kapteyn's Method

The Wansbeek and Kapteyn method for estimating variance components can be obtained by setting VCOMP = WK. The following methodology, outlined in Wansbeek and Kapteyn (1989) is used to handle both balanced and unbalanced data. The Wansbeek and Kapteyn method is the default for a RANTWO model with unbalanced panel. If RANTWO is requested without specifying the VCOMP= option, PROC PANEL proceeds under the Wansbeek and Kapteyn method if the panel is unbalanced.

The estimator of the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{P} \tilde{\mathbf{u}} / (M - T - N + 1 - (K - 1))$$

where the $\tilde{\mathbf{u}}$ are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M \mathbf{j}'_M / M)(\mathbf{y}_* - \mathbf{X}_{*s}(\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{P} \mathbf{y}_*)$ if there is an intercept and by $\tilde{\mathbf{u}} = (\mathbf{y}_* - \mathbf{X}_{*s}(\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{P} \mathbf{y}_*)$ if there is not.

The estimation of the variance components is performed by using a quadratic unbiased estimation (QUE) method that involves computing on quadratic forms of the residuals $\tilde{\mathbf{u}}$, equating their expected values to the realized quadratic forms, and solving for the variance components.

Let

$$q_N = \tilde{\mathbf{u}}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \tilde{\mathbf{u}}$$

$$q_T = \tilde{\mathbf{u}}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \tilde{\mathbf{u}}$$

The expected values are

$$E(q_N) = (T + k_N - (1 + k_0))\sigma^2 + (T - \frac{\lambda_1}{M})\sigma_v^2 + (M - \frac{\lambda_2}{M})\sigma_e^2$$

$$\begin{aligned} E(q_T) &= (N + k_T - (1 + k_0))\sigma^2 \\ &+ (M - \frac{\lambda_1}{M})\sigma_v^2 + (N - \frac{\lambda_2}{M})\sigma_e^2 \end{aligned}$$

where

$$k_0 = \mathbf{j}_M' \mathbf{X}_{*s} (\mathbf{X}_{*s}' \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}_{*s}' \mathbf{j}_M / M$$

$$k_N = \text{tr}((\mathbf{X}_{*s}' \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}_{*s}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \mathbf{X}_{*s})$$

$$k_T = \text{tr}((\mathbf{X}_{*s}' \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}_{*s}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \mathbf{X}_{*s})$$

$$\lambda_1 = \mathbf{j}_M' \mathbf{Z}_1 \mathbf{Z}_1' \mathbf{j}_M$$

$$\lambda_2 = \mathbf{j}_M' \mathbf{Z}_2 \mathbf{Z}_2' \mathbf{j}_M$$

The quadratic unbiased estimators for σ_v^2 and σ_e^2 are obtained by equating the expected values to the quadratic forms and solving for the two unknowns.

When the NOINT option is specified, the variance component equations change slightly. In particular, the following is true (Wansbeek and Kapteyn 1989):

$$E(q_N) = (T + k_N)\sigma^2 + T\sigma_v^2 + M\sigma_e^2$$

$$E(q_T) = (N + k_T)\sigma^2 + M\sigma_v^2 + N\sigma_e^2$$

Wallace and Hussain's Method

The Wallace and Hussain method for estimating variance components can be obtained by setting VCOMP = WH. Wallace and Hussain's method is by far the most computationally intensive. It uses the OLS residuals to estimate the variance components. In other words, the Wallace and Hussain method assumes that the following holds:

$$q_\epsilon = \tilde{\mathbf{u}}_{OLS}' \mathbf{P} \tilde{\mathbf{u}}_{OLS}$$

$$q_N = \tilde{\mathbf{u}}_{OLS}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \tilde{\mathbf{u}}_{OLS}$$

$$q_T = \tilde{\mathbf{u}}_{OLS}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \tilde{\mathbf{u}}_{OLS}$$

Taking expectations yields

$$E(q_\epsilon) = E(\tilde{\mathbf{u}}_{OLS}' \mathbf{P} \tilde{\mathbf{u}}_{OLS}) = \delta_{11}\sigma_\epsilon^2 + \delta_{12}\sigma_v^2 + \delta_{13}\sigma_e^2$$

$$E(q_N) = E\left(\tilde{\mathbf{u}}'_{OLS} \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \tilde{\mathbf{u}}_{OLS}\right) = \delta_{21}\sigma_\epsilon^2 + \delta_{22}\sigma_v^2 + \delta_{23}\sigma_e^2$$

$$E(q_T) = E\left(\tilde{\mathbf{u}}'_{OLS} \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \tilde{\mathbf{u}}_{OLS}\right) = \delta_{31}\sigma_\epsilon^2 + \delta_{32}\sigma_v^2 + \delta_{33}\sigma_e^2$$

where the δ_{js} constants are defined by

$$\delta_{11} = M - N - T + 1 - \text{tr}\left(\mathbf{X}'\mathbf{P}\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right)$$

$$\delta_{12} = \text{tr}\left(\mathbf{X}'\mathbf{Z}_1\mathbf{Z}_1'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\left(\mathbf{X}'\mathbf{P}\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right)\right)$$

$$\delta_{13} = \text{tr}\left(\mathbf{X}'\mathbf{Z}_2\mathbf{Z}_2'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\left(\mathbf{X}'\mathbf{P}\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right)\right)$$

$$\delta_{21} = T - \text{tr}\left(\mathbf{X}'\mathbf{Z}_2\Delta_T^{-1}\mathbf{Z}_2'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right)$$

$$\begin{aligned}\delta_{22} &= T - 2\text{tr}\left(\mathbf{X}'\mathbf{Z}_2\Delta_T^{-1}\mathbf{Z}_2'\mathbf{Z}_1\mathbf{Z}_1'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right) \\ &+ \text{tr}\left(\mathbf{X}'\mathbf{Z}_2\Delta_T^{-1}\mathbf{Z}_2'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Z}_1\mathbf{Z}_1'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right)\end{aligned}$$

$$\begin{aligned}\delta_{23} &= T - 2\text{tr}\left(\mathbf{X}'\mathbf{Z}_2\mathbf{Z}_2'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right) \\ &+ \text{tr}\left(\mathbf{X}'\mathbf{Z}_2\Delta_T^{-1}\mathbf{Z}_2'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Z}_2\mathbf{Z}_2'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right)\end{aligned}$$

$$\delta_{31} = N - \text{tr}\left(\mathbf{X}'\mathbf{Z}_1\Delta_N^{-1}\mathbf{Z}_1'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right)$$

$$\begin{aligned}\delta_{32} &= M - 2\text{tr}\left(\mathbf{X}'\mathbf{Z}_1\mathbf{Z}_1'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right) \\ &+ \text{tr}\left(\mathbf{X}'\mathbf{Z}_1\Delta_N^{-1}\mathbf{Z}_1'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Z}_1\mathbf{Z}_1'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right)\end{aligned}$$

$$\begin{aligned}\delta_{33} &= N - 2\text{tr}\left(\mathbf{X}'\mathbf{Z}_1\Delta_N^{-1}\mathbf{Z}_1'\mathbf{Z}_2\mathbf{Z}_2'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right) \\ &+ \text{tr}\left(\mathbf{X}'\mathbf{Z}_1\Delta_N^{-1}\mathbf{Z}_1'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Z}_2\mathbf{Z}_2'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\right)\end{aligned}$$

The PANEL procedure solves this system for the estimates $\hat{\sigma}_\epsilon$, $\hat{\sigma}_v$, and $\hat{\sigma}_e$. Some of the estimated variance components can be negative. Negative components are set to zero and estimation proceeds.

Nerlove's Method

The Nerlove method for estimating variance components can be obtained with by setting VCOMP = NL.

The estimator of the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{P} \tilde{\mathbf{u}} / M$$

The variance components for cross section and time effects are:

$$\hat{\sigma}_v^2 = \sum_{i=1}^N \frac{(\gamma_i - \bar{\gamma})^2}{N-1} \text{ where } \gamma_i \text{ is the } i\text{th cross section effect}$$

and

$$\hat{\sigma}_e^2 = \sum_{t=1}^T \frac{(\alpha_t - \bar{\alpha})^2}{T-1} \text{ where } \alpha_t \text{ is the } t\text{th time effect}$$

Transformation and Estimation

After you calculate the estimates of the variance components, you can proceed to the final estimation. If the panel is balanced, partial mean deviations are used:

$$\tilde{y}_{it} = y_{it} - \theta_1 \bar{y}_{i\cdot} - \theta_2 \bar{y}_{\cdot t} + \theta_3 \bar{y}_{\cdot\cdot}$$

$$\tilde{x}_{it} = x_{it} - \theta_1 \bar{x}_{i\cdot} - \theta_2 \bar{x}_{\cdot t} + \theta_3 \bar{x}_{\cdot\cdot}$$

The θ estimates are obtained from:

$$\theta_1 = 1 - \frac{\sigma_\epsilon}{\sqrt{T\sigma_v^2 + \sigma_\epsilon^2}}$$

$$\theta_2 = 1 - \frac{\sigma_\epsilon}{\sqrt{N\sigma_e^2 + \sigma_\epsilon^2}}$$

$$\theta_3 = \theta_1 + \theta_2 + \frac{\sigma_\epsilon}{\sqrt{T\sigma_v^2 + N\sigma_e^2 + \sigma_\epsilon^2}} - 1;$$

With these partial deviations, PROC PANEL uses OLS on the transformed series (including an intercept if you want).

The case of an unbalanced panel is somewhat more complicated. You could naively substitute the variance components in the equation below:

$$\Omega = \sigma_\epsilon^2 \mathbf{I}_M + \sigma_v^2 \mathbf{Z}_1 \mathbf{Z}_1' + \sigma_e^2 \mathbf{Z}_2 \mathbf{Z}_2'$$

After inverting the expression for Ω , it is possible to do GLS on the data (even if the panel is unbalanced). However, the inversion of Ω is no small matter because the dimension is at least $\frac{M(M+1)}{2}$.

Wansbeek and Kapteyn show that the inverse of Ω can be written as

$$\sigma_\epsilon^2 \Omega^{-1} = \mathbf{V} - \mathbf{V} \mathbf{Z}_2 \tilde{\mathbf{P}}^{-1} \mathbf{Z}_2' \mathbf{V}$$

with the following:

$$\begin{aligned}\mathbf{V} &= \mathbf{I}_M - \mathbf{Z}_1 \tilde{\Delta}_N^{-1} \mathbf{Z}_1' \\ \tilde{\mathbf{P}} &= \tilde{\Delta}_T - \mathbf{A} \tilde{\Delta}_N^{-1} \mathbf{A}' \\ \tilde{\Delta}_N &= \Delta_N + \left(\frac{\sigma_\epsilon^2}{\sigma_v^2} \right) \mathbf{I}_N \\ \tilde{\Delta}_T &= \Delta_T + \left(\frac{\sigma_\epsilon^2}{\sigma_e^2} \right) \mathbf{I}_T\end{aligned}$$

Computationally, this is a much less intensive approach.

By using the inverse of the covariance matrix of the error, it becomes possible to complete GLS on the unbalanced panel.

Parks Method (Autoregressive Model)

Parks (1967) considered the first-order autoregressive model in which the random errors u_{it} , $i = 1, 2, \dots, N$, and $t = 1, 2, \dots, T$ have the structure

$$\begin{aligned}E(u_{it}^2) &= \sigma_{ii}(\text{heteroscedasticity}) \\ E(u_{it}u_{jt}) &= \sigma_{ij}(\text{contemporaneously correlated}) \\ u_{it} &= \rho_i u_{i,t-1} + \epsilon_{it}(\text{autoregression})\end{aligned}$$

where

$$\begin{aligned}E(\epsilon_{it}) &= 0 \\ E(u_{i,t-1}\epsilon_{jt}) &= 0 \\ E(\epsilon_{it}\epsilon_{jt}) &= \phi_{ij} \\ E(\epsilon_{it}\epsilon_{js}) &= 0(s \neq t) \\ E(u_{i0}) &= 0 \\ E(u_{i0}u_{j0}) &= \sigma_{ij} = \phi_{ij}/(1 - \rho_i \rho_j)\end{aligned}$$

The model assumed is first-order autoregressive with contemporaneous correlation between cross sections. In this model, the covariance matrix for the vector of random errors \mathbf{u} can be expressed as

$$E(\mathbf{u}\mathbf{u}') = \mathbf{V} = \begin{bmatrix} \sigma_{11}P_{11} & \sigma_{12}P_{12} & \dots & \sigma_{1N}P_{1N} \\ \sigma_{21}P_{21} & \sigma_{22}P_{22} & \dots & \sigma_{2N}P_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{N1}P_{N1} & \sigma_{N2}P_{N2} & \dots & \sigma_{NN}P_{NN} \end{bmatrix}$$

where

$$P_{ij} = \begin{bmatrix} 1 & \rho_j & \rho_j^2 & \dots & \rho_j^{T-1} \\ \rho_i & 1 & \rho_j & \dots & \rho_j^{T-2} \\ \rho_i^2 & \rho_i & 1 & \dots & \rho_j^{T-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \rho_i^{T-1} & \rho_i^{T-2} & \rho_i^{T-3} & \dots & 1 \end{bmatrix}$$

The matrix \mathbf{V} is estimated by a two-stage procedure, and $\boldsymbol{\beta}$ is then estimated by generalized least squares. The first step in estimating \mathbf{V} involves the use of ordinary least squares to estimate $\boldsymbol{\beta}$ and obtain the fitted residuals, as follows:

$$\hat{\mathbf{u}} = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{OLS}$$

A consistent estimator of the first-order autoregressive parameter is then obtained in the usual manner, as follows:

$$\hat{\rho}_i = \left(\sum_{t=2}^T \hat{u}_{it} \hat{u}_{i,t-1} \right) / \left(\sum_{t=2}^T \hat{u}_{i,t-1}^2 \right) \quad i = 1, 2, \dots, N$$

Finally, the autoregressive characteristic of the data is removed (asymptotically) by the usual transformation of taking weighted differences. That is, for $i = 1, 2, \dots, N$,

$$y_{i1} \sqrt{1 - \hat{\rho}_i^2} = \sum_{k=1}^p X_{i1k} \beta_k \sqrt{1 - \hat{\rho}_i^2} + u_{i1} \sqrt{1 - \hat{\rho}_i^2}$$

$$y_{it} - \hat{\rho}_i y_{i,t-1} = \sum_{k=1}^p (X_{itk} - \hat{\rho}_i X_{i,t-1,k}) \beta_k + u_{it} - \hat{\rho}_i u_{i,t-1} \quad t = 2, \dots, T$$

which is written

$$y_{it}^* = \sum_{k=1}^p X_{itk}^* \beta_k + u_{it}^* \quad i = 1, 2, \dots, N; \quad t = 1, 2, \dots, T$$

Notice that the transformed model has not lost any observations (Seely and Zyskind 1971).

The second step in estimating the covariance matrix \mathbf{V} is applying ordinary least squares to the preceding transformed model, obtaining

$$\hat{\mathbf{u}}^* = \mathbf{y}^* - \mathbf{X}^* \hat{\boldsymbol{\beta}}_{OLS}^*$$

from which the consistent estimator of σ_{ij} is calculated as follows:

$$s_{ij} = \frac{\hat{\phi}_{ij}}{(1 - \hat{\rho}_i \hat{\rho}_j)}$$

where

$$\hat{\phi}_{ij} = \frac{1}{(T-p)} \sum_{t=1}^T \hat{u}_{it}^* \hat{u}_{jt}^*$$

Estimated generalized least squares (EGLS) then proceeds in the usual manner,

$$\hat{\beta}_P = (\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X})^{-1}\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{y}$$

where $\hat{\mathbf{V}}$ is the derived consistent estimator of \mathbf{V} . For computational purposes, $\hat{\beta}_P$ is obtained directly from the transformed model,

$$\hat{\beta}_P = (\mathbf{X}^{*'}(\hat{\Phi}^{-1} \otimes I_T)\mathbf{X}^*)^{-1}\mathbf{X}^{*'}(\hat{\Phi}^{-1} \otimes I_T)\mathbf{y}^*$$

where $\hat{\Phi} = [\hat{\phi}_{ij}]_{i,j=1,\dots,N}$.

The preceding procedure is equivalent to Zellner's two-stage methodology applied to the transformed model (Zellner 1962).

Parks demonstrates that this estimator is consistent and asymptotically, normally distributed with

$$\text{Var}(\hat{\beta}_P) = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}$$

Standard Corrections

For the PARKS option, the first-order autocorrelation coefficient must be estimated for each cross section. Let ρ be the $N \times 1$ vector of true parameters and $R = (r_1, \dots, r_N)'$ be the corresponding vector of estimates. Then, to ensure that only range-preserving estimates are used in PROC PANEL, the following modification for R is made:

$$r_i = \begin{cases} r_i & \text{if } |r_i| < 1 \\ \max(.95, \text{rmax}) & \text{if } r_i \geq 1 \\ \min(-.95, \text{rmin}) & \text{if } r_i \leq -1 \end{cases}$$

where

$$\text{rmax} = \begin{cases} 0 & \text{if } r_i < 0 \text{ or } r_i \geq 1 \quad \forall i \\ \max_j[r_j : 0 \leq r_j < 1] & \text{otherwise} \end{cases}$$

and

$$\text{rmin} = \begin{cases} 0 & \text{if } r_i > 0 \text{ or } r_i \leq -1 \quad \forall i \\ \max_j[r_j : -1 < r_j \leq 0] & \text{otherwise} \end{cases}$$

Whenever this correction is made, a warning message is printed.

Da Silva Method (Variance-Component Moving Average Model)

The Da Silva method assumes that the observed value of the dependent variable at the t th time point on the i th cross-sectional unit can be expressed as

$$y_{it} = \mathbf{x}'_{it}\beta + a_i + b_t + e_{it} \quad i = 1, \dots, N; t = 1, \dots, T$$

where

$\mathbf{x}'_{it} = (x_{it1}, \dots, x_{itp})$ is a vector of explanatory variables for the t th time point and i th cross-sectional unit

$\beta = (\beta_1, \dots, \beta_p)'$ is the vector of parameters

a_i is a time-invariant, cross-sectional unit effect

b_t is a cross-sectionally invariant time effect

e_{it} is a residual effect unaccounted for by the explanatory variables and the specific time and cross-sectional unit effects

Since the observations are arranged first by cross sections, then by time periods within cross sections, these equations can be written in matrix notation as

$$\mathbf{y} = \mathbf{X}\beta + \mathbf{u}$$

where

$$\mathbf{u} = (\mathbf{a} \otimes \mathbf{1}_T) + (\mathbf{1}_N \otimes \mathbf{b}) + \mathbf{e}$$

$$\mathbf{y} = (y_{11}, \dots, y_{1T}, y_{21}, \dots, y_{NT})'$$

$$\mathbf{X} = (\mathbf{x}_{11}, \dots, \mathbf{x}_{1T}, \mathbf{x}_{21}, \dots, \mathbf{x}_{NT})'$$

$$\mathbf{a} = (a_1 \dots a_N)'$$

$$\mathbf{b} = (b_1 \dots b_T)'$$

$$\mathbf{e} = (e_{11}, \dots, e_{1T}, e_{21}, \dots, e_{NT})'$$

Here $\mathbf{1}_N$ is an $N \times 1$ vector with all elements equal to 1, and \otimes denotes the Kronecker product.

The following conditions are assumed:

1. \mathbf{x}_{it} is a sequence of nonstochastic, known $p \times 1$ vectors in \Re^p whose elements are uniformly bounded in \Re^p . The matrix \mathbf{X} has a full column rank p .
2. β is a $p \times 1$ constant vector of unknown parameters.
3. \mathbf{a} is a vector of uncorrelated random variables such that $E(a_i) = 0$ and $\text{var}(a_i) = \sigma_a^2$, $\sigma_a^2 > 0$, $i = 1, \dots, N$.
4. \mathbf{b} is a vector of uncorrelated random variables such that $E(b_t) = 0$ and $\text{var}(b_t) = \sigma_b^2$ where $\sigma_b^2 > 0$ and $t = 1, \dots, T$.

5. $\mathbf{e}_i = (e_{i1}, \dots, e_{iT})'$ is a sample of a realization of a finite moving-average time series of order $m < T - 1$ for each i ; hence,

$$e_{it} = \alpha_0 \epsilon_{it} + \alpha_1 \epsilon_{it-1} + \dots + \alpha_m \epsilon_{it-m} \quad t = 1, \dots, T; i = 1, \dots, N$$

where $\alpha_0, \alpha_1, \dots, \alpha_m$ are unknown constants such that $\alpha_0 \neq 0$ and $\alpha_m \neq 0$, and $\{\epsilon_{ij}\}_{j=-\infty}^{j=\infty}$ is a white noise process for each i —that is, a sequence of uncorrelated random variables with $E(\epsilon_t) = 0$, $E(\epsilon_t^2) = \sigma_\epsilon^2$, and $\sigma_\epsilon^2 > 0$. $\{\epsilon_{ij}\}_{j=-\infty}^{j=\infty}$ for $i = 1, \dots, N$ are mutually uncorrelated.

6. The sets of random variables $\{a_i\}_{i=1}^N$, $\{b_t\}_{t=1}^T$, and $\{e_{it}\}_{t=1}^T$ for $i = 1, \dots, N$ are mutually uncorrelated.
7. The random terms have normal distributions $a_i \sim N(0, \sigma_a^2)$, $b_t \sim N(0, \sigma_b^2)$, and $\epsilon_{t-k} \sim N(0, \sigma_\epsilon^2)$, for $i = 1, \dots, N$; $t = 1, \dots, T$; and $k = 1, \dots, m$.

If assumptions 1–6 are satisfied, then

$$E(\mathbf{y}) = \mathbf{X}\beta$$

and

$$\text{var}(\mathbf{y}) = \sigma_a^2(I_N \otimes J_T) + \sigma_b^2(J_N \otimes I_T) + (I_N \otimes \Psi_T)$$

where Ψ_T is a $T \times T$ matrix with elements ψ_{ts} as follows:

$$\text{Cov}(e_{it}e_{is}) = \begin{cases} \psi(|t-s|) & \text{if } |t-s| \leq m \\ 0 & \text{if } |t-s| > m \end{cases}$$

where $\psi(k) = \sigma_\epsilon^2 \sum_{j=0}^{m-k} \alpha_j \alpha_{j+k}$ for $k = |t-s|$. For the definition of I_N , I_T , J_N , and J_T , see the section “Fuller and Battese’s Method” on page 1410.

The covariance matrix, denoted by \mathbf{V} , can be written in the form

$$\mathbf{V} = \sigma_a^2(I_N \otimes J_T) + \sigma_b^2(J_N \otimes I_T) + \sum_{k=0}^m \psi(k)(I_N \otimes \Psi_T^{(k)})$$

where $\Psi_T^{(0)} = I_T$, and, for $k = 1, \dots, m$, $\Psi_T^{(k)}$ is a band matrix whose k th off-diagonal elements are 1’s and all other elements are 0’s.

Thus, the covariance matrix of the vector of observations \mathbf{y} has the form

$$\text{Var}(\mathbf{y}) = \sum_{k=1}^{m+3} v_k V_k$$

where

$$\begin{aligned} v_1 &= \sigma_a^2 \\ v_2 &= \sigma_b^2 \\ v_k &= \psi(k-3) \quad k = 3, \dots, m+3 \\ V_1 &= I_N \otimes J_T \\ V_2 &= J_N \otimes I_T \\ V_k &= I_N \otimes \Psi_T^{(k-3)} \quad k = 3, \dots, m+3 \end{aligned}$$

The estimator of β is a two-step GLS-type estimator—that is, GLS with the unknown covariance matrix replaced by a suitable estimator of \mathbf{V} . It is obtained by substituting Seely estimates for the scalar multiples $v_k, k = 1, 2, \dots, m + 3$.

Seely (1969) presents a general theory of unbiased estimation when the choice of estimators is restricted to finite dimensional vector spaces, with a special emphasis on quadratic estimation of functions of the form $\sum_{i=1}^n \delta_i v_i$.

The parameters v_i ($i = 1, \dots, n$) are associated with a linear model $E(\mathbf{y}) = \mathbf{X} \beta$ with covariance matrix $\sum_{i=1}^n v_i V_i$ where V_i ($i = 1, \dots, n$) are real symmetric matrices. The method is also discussed by Seely (1970b, a); Seely and Zyskind (1971). Seely and Soong (1971) consider the MINQUE principle, using an approach along the lines of Seely (1969).

Dynamic Panel Estimator

For an example on dynamic panel estimation using GMM option, see “[Example 20.6: The Cigarette Sales Data: Dynamic Panel Estimation with GMM](#)” on page 1475.

Consider the case of the following general model:

$$y_{it} = \sum_{l=1}^{maxlag} \phi_l y_{i(t-l)} + \sum_{k=1}^K \beta_k x_{itk} + \gamma_i + \alpha_t + \epsilon_{it}$$

The x variables can include ones that are correlated or uncorrelated to the individual effects, predetermined, or strictly exogenous. The variable x_{it}^p is defined as predetermined in the sense that $E(x_{it}^p \epsilon_{is}) \neq 0$ for $s < t$ and zero otherwise. The variable x_{it}^e is defined as strictly exogenous if $E(x_{it}^e \epsilon_{is}) = 0$ for all s and t . The γ_i and α_t are cross-sectional and time series fixed effects, respectively. Arellano and Bond (1991) show that it is possible to define conditions that should result in a consistent estimator.

Consider the simple case of an autoregression in a panel setting (with only individual effects):

$$y_{it} = \phi y_{i(t-1)} + \gamma_i + \epsilon_{it}$$

Differencing the preceding relationship results in:

$$\Delta y_{it} = \phi \Delta y_{i(t-1)} + v_{it}$$

where $v_{it} = \epsilon_{it} - \epsilon_{it-1}$.

Obviously, y_{it} is not exogenous. However, Arellano and Bond (1991) show that it is still useful as an instrument, if properly lagged. This instrument is required with the option `DEPVAR(LEVEL)`.

For $t = 2$ (assuming the first observation corresponds to time period 1) you have,

$$\Delta y_{i2} = \phi \Delta y_{i1} + v_{i2}$$

Using y_{i1} as an instrument is not a good idea since $\text{Cov}(\epsilon_{i1}, v_{i2}) \neq 0$. Therefore, since it is not possible to form a moment restriction, you discard this observation.

For $t = 3$ you have,

$$\Delta y_{i3} = \phi \Delta y_{i2} + v_{i3}$$

Clearly, you have every reason to suspect that $\text{Cov}(\epsilon_{i1}, v_{i3}) = 0$. This condition forms one restriction.

For $t = 4$, both $\text{Cov}(\epsilon_{i1}, v_{i4}) = 0$ and $\text{Cov}(\epsilon_{i2}, v_{i4}) = 0$ must hold.

Proceeding in that fashion, you have the following matrix of instruments,

$$\mathbf{Z}_i = \begin{pmatrix} y_{i1} & 0 & 0 & \cdots & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & y_{i1} & y_{i2} & 0 & \cdots & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & y_{i1} & y_{i2} & y_{i3} & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & & & & \vdots & & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & y_{i1} & \cdots & y_{i(T-2)} \end{pmatrix}$$

Using the instrument matrix, you form the weighting matrix \mathbf{A}_N as

$$\mathbf{A}_N = \left(\frac{1}{N} \sum_i^N \mathbf{Z}_i' \mathbf{H}_i \mathbf{Z}_i \right)^{-1}$$

The initial weighting matrix is

$$\mathbf{H}_i = \begin{pmatrix} 2 & -1 & 0 & \cdots & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & \cdots & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 & \cdots & 0 & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & & & & \vdots & & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 2 & -1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 2 \end{pmatrix}$$

Note that the maximum size of the \mathbf{H}_i matrix is $T-2$. The origins of the initial weighting matrix are the expected error covariances. Notice that on the diagonals,

$$E(v_{it}v_{it}) = E(\epsilon_{it}^2 - 2\epsilon_{it}\epsilon_{i(t-1)} + \epsilon_{i(t-1)}^2) = 2\sigma_\epsilon^2$$

and off diagonals,

$$E(v_{it}v_{i(t-1)}) = E(\epsilon_{it}\epsilon_{i(t-1)} - \epsilon_{it}\epsilon_{i(t-2)} - \epsilon_{i(t-1)}\epsilon_{i(t-1)} + \epsilon_{i(t-1)}\epsilon_{i(t-2)}) = -\sigma_\epsilon^2$$

If you let the vector of lagged differences (in the series y_{it}) be denoted as Δy_{i-} and the dependent variable as Δy_i , then the optimal GMM estimator is

$$\phi = \left[\left(\sum_i \Delta y_{i-}' \mathbf{Z}_i \right) \mathbf{A}_N \left(\sum_i \mathbf{Z}_i' \Delta y_{i-} \right) \right]^{-1} \left(\sum_i \Delta y_{i-}' \mathbf{Z}_i \right) \mathbf{A}_N \left(\sum_i \mathbf{Z}_i' \Delta y_i \right)$$

Using the estimate, $\hat{\phi}$, you can obtain estimates of the errors, $\hat{\epsilon}$, or the differences, \hat{v} . From the errors, the variance is calculated as,

$$\sigma^2 = \frac{\hat{\epsilon}' \hat{\epsilon}}{M - 1}$$

where $M = \sum_{i=1}^N T_i$ is the total number of observations. With differenced equations, since we lose the first two observations, $M = \sum_{i=1}^N (T_i - 2)$.

Furthermore, you can calculate the variance of the parameter as,

$$\sigma^2 \left[\left(\sum_i \Delta y_{i-} \mathbf{Z}_i' \right) \mathbf{A}_N \left(\sum_i \mathbf{Z}_i' \Delta y_{i-} \right) \right]^{-1}$$

Alternatively, you can view the initial estimate of the ϕ as a first step. That is, by using $\hat{\phi}$, you can improve the estimate of the weight matrix, \mathbf{A}_N .

Instead of imposing the structure of the weighting, you form the \mathbf{H}_i matrix through the following:

$$\mathbf{H}_i = \hat{\mathbf{v}}_i \hat{\mathbf{v}}_i'$$

You then complete the calculation as previously shown. The PROC PANEL option GMM2 specifies this estimation.

The case of multiple right-hand-side variables illustrates more clearly the power of Arellano and Bond (1991); Arellano and Bover (1995).

Considering the general case you have:

$$y_{it} = \sum_{l=1}^{maxlag} \phi_l y_{i(t-l)} + \beta \mathbf{X}_i + \gamma_i + \alpha_t + \epsilon_{it}$$

It is clear that lags of the dependent variable are both not exogenous and correlated to the fixed effects. However, the independent variables can fall into one of several categories. An independent variable can be correlated¹ and exogenous, uncorrelated and exogenous, correlated and predetermined, and uncorrelated and predetermined. The category in which an independent variable is found influences when or whether it becomes a suitable instrument. Note, however, that neither PROC PANEL nor Arellano and Bond require that a regressor be an instrument or that an instrument be a regressor.

First, suppose that the variables are all correlated with the individual effects γ_i . Consider the question of exogenous or predetermined. An exogenous variable is not correlated with the error term $\epsilon_{it} - \epsilon_{it-1}$ in the differenced equations. Therefore, all observations (on the exogenous variable) become valid instruments at all time periods. If the model has only one instrument and it happens to be exogenous, then the optimal instrument matrix looks like,

$$\mathbf{Z}_i = \begin{pmatrix} x_{i1} \cdots x_{iT} & 0 & 0 & 0 & 0 \\ 0 & x_{i1} \cdots x_{iT} & 0 & 0 & 0 \\ 0 & 0 & x_{i1} \cdots x_{iT} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & x_{i1} \cdots x_{iT} \end{pmatrix}$$

The situation for the predetermined variables becomes a little more difficult. A predetermined variable is one whose future realizations can be correlated to current shocks in the dependent variable. With such an

¹In this section, “correlated” means correlated with the individual effects and “uncorrelated” means uncorrelated with the individual effects.

understanding, it is admissible to allow all current and lagged realizations as instruments. In other words you have,

$$\mathbf{Z}_i = \begin{pmatrix} x_{i1} & 0 & 0 & 0 & 0 \\ 0 & x_{i1}x_{i2} & 0 & 0 & 0 \\ 0 & 0 & x_{i1} \cdots x_{i3} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & x_{i1} \cdots x_{i(T-1)} \end{pmatrix}$$

When the data contain a mix of endogenous, exogenous, and predetermined variables, the instrument matrix is formed by combining the three. The third observation would have one observation on the dependent variable as an instrument, three observations on the predetermined variables as instruments, and all observations on the exogenous variables.

Now consider some variables, denoted as x_{1it} , that are not correlated with the individual effects γ_i . There is yet another set of moment restrictions that can be used. An uncorrelated variable means that the variable's level is not affected by the individual specific effect. You write the preceding general model as

$$y_{it} = \sum_{l=1}^{maxlag} \phi_l y_{i(t-l)} + \sum_{k=1}^K \beta_k x_{itk} + \alpha_t + \mu_{it}$$

where $\mu_{it} = \gamma_i + \epsilon_{it}$.

Because the variables are uncorrelated with γ_i and thus uncorrelated with the error term μ_{it} in the level equations, you can use the difference and level equations to perform a system estimation. That is, the uncorrelated variables imply moment restrictions on the level equations. Given the previously used restrictions for the equations in first differences, there are T extra restrictions. For predetermined variables, Arellano and Bond (1991) use the extra restrictions $E(\mu_{i2}x_{1i1}^p) = 0$ and $E(\mu_{it}x_{1it}^p) = 0$ for $t = 2, \dots, T$. The instrument matrix becomes

$$\mathbf{Z}_i^* = \begin{pmatrix} \mathbf{Z}_i & 0 & 0 & 0 & \cdots & 0 \\ 0 & x_{1i1}^p & x_{1i2}^p & 0 & \cdots & 0 \\ 0 & 0 & 0 & x_{1i3}^p & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & x_{1iT}^p \end{pmatrix}$$

For exogenous variables x_{1it}^e Arellano and Bond (1991) use $E\left(T^{-1} \sum_{s=1}^T \mu_{is}x_{1it}^e\right) = 0$. PROC PANEL uses the same ones as the predetermined variables—that is, $E(\mu_{i2}x_{1i1}^e) = 0$ and $E(\mu_{it}x_{1it}^e) = 0$ for $t = 2, \dots, T$. If you denote the new instrument matrix by using the full complement of instruments available by an asterisk and if both x^p and x^e are uncorrelated, then you have

$$\mathbf{Z}_i^* = \begin{pmatrix} \mathbf{Z}_i & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & x_{1i1}^p & x_{1i2}^e & x_{1i2}^p & x_{1i2}^e & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & x_{1i3}^p & x_{1i3}^e & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & \cdots & x_{1iT}^p & x_{1iT}^e \end{pmatrix}$$

When the lagged dependent variable is included as the explanatory variable (as in the dynamic panel data models), Blundell and Bond (1998) suggest the system GMM to use $T - 2$ extra-moment restrictions, which

use the lagged differences as the instruments for the level:

$$E(\mu_{it} \Delta y_{i,t-1}) = 0 \quad \text{for } t = 3, \dots, T$$

This additional set of moment conditions are required by DEPVAR(DIFF) option. The corresponding instrument matrix is

$$\mathbf{Z}_{li}^y = \begin{pmatrix} 0 & 0 & 0 & \cdots & 0 \\ 0 & \Delta y_{i2} & 0 & \cdots & 0 \\ 0 & 0 & \Delta y_{i3} & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & \Delta y_{i(T-1)} \end{pmatrix}$$

Blundell and Bond (1998) argue that the system GMM that uses these extra conditions significantly increases the efficiency of the estimator, especially under strong serial correlation in the dependent variables².

The formation of the initial weighting matrix becomes somewhat problematic. If you denote the new weighting matrix with an asterisk, then you can write the following:

$$\mathbf{A}_N^* = \left(\frac{1}{N} \sum_i \mathbf{Z}_i^{*'} \mathbf{H}_i^* \mathbf{Z}_i^* \right)^{-1}$$

where

$$\mathbf{H}_i^* = \begin{pmatrix} \mathbf{H}_i & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{pmatrix}$$

To finish, you write out the two equations (or two stages) that are estimated.

$$\Delta y_{it} = \boldsymbol{\beta}^* \Delta \mathbf{S}_{it} + \alpha_t - \alpha_{t-1} + v_{it} \quad y_{it} = \boldsymbol{\beta}^* \mathbf{S}_{it} + \gamma_i + \alpha_t + \epsilon_{it}$$

where \mathbf{S}_{it} is the matrix of all explanatory variables, lagged endogenous, exogenous, and predetermined.

Let \mathbf{y}_{it}^* be given by

$$\mathbf{y}_{it}^* = \begin{pmatrix} \Delta y_{it} \\ y_{it} \end{pmatrix} \quad \boldsymbol{\beta}^* = \begin{pmatrix} \boldsymbol{\phi} & \boldsymbol{\beta} \end{pmatrix} \quad \mathbf{S}_{it}^* = \begin{pmatrix} \Delta \mathbf{S}_{it} \\ \mathbf{S}_{it} \end{pmatrix} \quad \mathbf{e}_i^* = \begin{pmatrix} v_i \\ \boldsymbol{\mu}_i = \boldsymbol{\epsilon}_i + \gamma_i \end{pmatrix}$$

Using the information above, we can get the one-step GMM estimator,

$$\hat{\boldsymbol{\beta}}_1^* = \left[\left(\sum_i \mathbf{S}_{it}^{*'} \mathbf{Z}_{it}^* \right) \mathbf{A}_N^* \left(\sum_i \mathbf{Z}_{it}^{*'} \mathbf{S}_{it} \right) \right]^{-1} \left(\sum_i \mathbf{S}_{it}^{*'} \mathbf{Z}_{it}^* \right) \mathbf{A}_N^* \left(\sum_i \mathbf{Z}_{it}^{*'} \mathbf{y}_{it}^* \right)$$

If the GMM2 or ITGMM option is not requested, estimation terminates here. If it terminates, you can obtain the following information.

²This happens when $\phi \rightarrow 1$ or as $\sigma_\gamma^2 / \sigma_\epsilon^2 \rightarrow \infty$. In this case, the lagged dependent variables $y_{i(t-l)}$ become weak instruments for the differenced variables Δy_{it} .

Variance of the error term comes from the second stage (level) equations—that is,

$$\sigma^2 = \frac{\hat{\mu}' \hat{\mu}}{M - p} = \frac{(y_{it} - \hat{\beta}_1^* S_{it})' (y_{it} - \hat{\beta}_1^* S_{it})}{M - p}$$

where p is the number of regressors and M is the number of observations as defined before.

The variance covariance matrix can be obtained from

$$\left[\left(\sum_i S_i^{*'} Z_i^* \right) A_N^* \left(\sum_i Z_i^{*'} S_i^* \right) \right]^{-1} \sigma^2$$

Alternatively, a robust estimate of the variance covariance matrix can be obtained by specifying the ROBUST option. Without further reestimation of the model, the H_i^* matrix is recalculated as follows:

$$H_{i,2}^* = \begin{pmatrix} \hat{v}_i \hat{v}_i' & 0 \\ 0 & \hat{\epsilon}_i \hat{\epsilon}_i' \end{pmatrix}$$

And the weighting matrix becomes

$$A_N^* (\hat{\beta}_1^*) = \left(\frac{1}{N} \sum_i Z_i^{*'} H_{i,2}^* Z_i^* \right)^{-1}$$

Using the preceding information, you construct the robust covariance matrix from the following:

Let G denote a temporary matrix:

$$G = \left[\left(\sum_i S_i^{*'} Z_i^* \right) A_N^* \left(\sum_i Z_i^{*'} S_i^* \right) \right]^{-1} \left(\sum_i S_i^{*'} Z_i^* \right) A_N^*$$

The robust covariance estimate of $\hat{\beta}_1^*$ is

$$V^r (\hat{\beta}_1^*) = G A_N^{*-1} (\hat{\beta}_1^*) G'$$

Alternatively, you can use the new weighting matrix to form an updated estimate of the regression parameters, as requested by the GMM2 option. In short,

$$\hat{\beta}_2^* = \left[\left(\sum_i S_i^{*'} Z_i^* \right) A_N^* (\hat{\beta}_1^*) \left(\sum_i Z_i^{*'} S_i^* \right) \right]^{-1} \left(\sum_i S_i^{*'} Z_i^* \right) A_N^* (\hat{\beta}_1^*) \left(\sum_i Z_i^{*'} y_i^* \right)$$

The covariance estimate of the two-step $\hat{\beta}_2^*$ becomes

$$V (\hat{\beta}_2^*) = \left[\left(\sum_i S_i^{*'} Z_i^* \right) A_N^* (\hat{\beta}_1^*) \left(\sum_i Z_i^{*'} S_i^* \right) \right]^{-1}$$

Similarly, you construct the robust covariance matrix from the following:

Let \mathbf{G}_2 denote a temporary matrix.

$$\mathbf{G}_2 = \left[\left(\sum_i \mathbf{S}_i^{*'} \mathbf{Z}_i^* \right) \mathbf{A}_N^* (\hat{\boldsymbol{\beta}}_1^*) \left(\sum_i \mathbf{Z}_i^{*'} \mathbf{S}_i^* \right) \right]^{-1} \left(\sum_i \mathbf{S}_i^{*'} \mathbf{Z}_i^* \right) \mathbf{A}_N^* (\hat{\boldsymbol{\beta}}_1^*)$$

The robust covariance estimate of $\hat{\boldsymbol{\beta}}_2^*$ is

$$\mathbf{V}^r(\hat{\boldsymbol{\beta}}_2^*) = \mathbf{G}_2 \mathbf{A}_N^{*-1}(\hat{\boldsymbol{\beta}}_2^*) \mathbf{G}_2'$$

As a final note, it is possible to iterate more than twice by specifying the ITGMM option. At each iteration, the parameter estimates and its variance-covariance matrix (standard or robust) can be constructed as the one-step and/or two-step GMM estimators. Such a multiple iteration should result in a more stable estimate of the covariance estimate. PROC PANEL allows two convergence criteria. Convergence can occur in the parameter estimates or in the weighting matrices. Let $\mathbf{A}_{N,k+1}^*$ denote the robust covariance matrix from iteration k , which is used as the weighting matrix in iteration $k + 1$. Iterate until

$$\max_{i,j \leq \dim(\mathbf{A}_{N,k}^*)} \frac{|\mathbf{A}_{N,k+1}^*(i,j) - \mathbf{A}_{N,k}^*(i,j)|}{|\mathbf{A}_{N,k}^*(i,j)|} \leq \text{ATOL}$$

or

$$\max_{i \leq \dim(\boldsymbol{\beta}_k^*)} \frac{|\boldsymbol{\beta}_{k+1}^*(i) - \boldsymbol{\beta}_k^*(i)|}{|\boldsymbol{\beta}_k^*(i)|} \leq \text{BTOL}$$

where ATOL is the tolerance for convergence in the weighting matrix and BTOL is the tolerance for convergence in the parameter estimate matrix. The default convergence criteria is BTOL = 1E-8 for PROC PANEL.

Specification Testing For Dynamic Panel

Specification tests under the GMM in PROC PANEL follow Arellano and Bond (1991) very generally. The first test available is a Sargan/Hansen test of over-identification. The test for a one-step estimation is constructed as

$$\left(\sum_i \eta_i' \mathbf{Z}_i^* \right) \mathbf{A}_N^* \left(\sum_i \mathbf{Z}_i^{*'} \eta_i \right) \sigma^2$$

where η_i is the stacked error term (of the differenced equation and level equation).

When the robust weighting matrix is used, the test statistic is computed as

$$\left(\sum_i \eta_i' \mathbf{Z}_i^* \right) \mathbf{A}_{N,2}^* \left(\sum_i \mathbf{Z}_i^{*'} \eta_i \right)$$

This definition of the Sargan test is used for all iterated estimations. The Sargan test is distributed as a χ^2 with degrees of freedom equal to the number of moment conditions minus the number of parameters.

In addition to the Sargan test, PROC PANEL tests for autocorrelation in the residuals. These tests are distributed as standard normal. PROC PANEL tests the hypothesis that the autocorrelation of the l th lag is significant.

Define ω_l as the lag of the differenced error, with zero padding for the missing values generated. Symbolically,

$$\omega_{l,i} = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ v_{i,2} \\ \vdots \\ v_{i,T-1-l} \end{pmatrix}$$

You define the constant k_0 as

$$k_0(l) = \sum_i \omega'_{l,i} v_i$$

You next define the constant k_1 as

$$k_1(l) = \sum_i \omega'_{l,i} \mathbf{H}_i \omega_{l,i}$$

Note that the choice of \mathbf{H}_i is dependent on the stage of estimation. If the estimation is first stage, then you would use the matrix with twos along the main diagonal, and minus ones along the primary subdiagonals. In a robust estimation or multi-step estimation, this matrix would be formed from the outer product of the residuals (from the previous step).

Define the constant k_2 as

$$k_2(l) = -2 \left(\sum_i \omega'_{l,i} \Delta S_i \right) \mathbf{G} \left(\sum_i \Delta S'_i \mathbf{Z}_i \right) \mathbf{A}_{N,k} \left(\sum_i \mathbf{Z}'_i \mathbf{H}_i \omega_{l,i} \right)$$

The matrix \mathbf{G} is defined as

$$\mathbf{G} = \left[\left(\sum_i \Delta S_i^* \mathbf{Z}_i^* \right) \mathbf{A}_{N,k}^* \left(\sum_i \mathbf{Z}_i^{*'} \Delta S_i^* \right) \right]^{-1}$$

The constant k_3 is defined as

$$k_3(l) = \left(\sum_i \omega'_{l,i} \Delta S_i \right) V(\beta^*) \left(\sum_i \Delta S'_i \omega_{l,i} \right)$$

Using the four quantities, the test for autoregressive structure in the differenced residual is

$$m(l) = \frac{k_0(l)}{\sqrt{k_1(l) + k_2(l) + k_3(l)}}$$

The m statistic is distributed as a normal random variable with mean zero and standard deviation of one.

Instrument Choice

Arellano and Bond's technique is a very useful method for dealing with any autoregressive characteristics in the data. However, there is one caveat to consider. Too many instruments bias the estimator to the within estimate. Furthermore, many instruments make this technique not scalable. The weighting matrix becomes very large, so every operation that involves it becomes more computationally intensive. The PANEL procedure enables you to specify a bandwidth for instrument selection. For example, specifying MAXBAND=10 means that at most there will be ten time observations for each variable that enters as an instrument. The default is to follow the Arellano-Bond methodology.

In specifying a maximum bandwidth, you can also specify the selection of the time observations. There are three possibilities: leading, trailing (default), and centered. The exact consequence of choosing any of those possibilities depends on the variable type (correlated, exogenous, or predetermined) and the time period of the current observation.

If the MAXBAND option is specified, then the following is true under any selection criterion (let t be the time subscript for the current observation). The first observation for the endogenous variable (as instrument) is $\max(t - \text{MAXBAND}, 1)$ and the last instrument is $t - 2$. The first observation for a predetermined variable is $\max(t - \text{MAXBAND}, 1)$ and the last is $t - 1$. The first and last observation for an exogenous variable is given in the following list:

- *Trailing*: If $t < \text{MAXBAND}$, then the first instrument is for the first time period and the last observation is MAXBAND. Otherwise, if $t \geq \text{MAXBAND}$, then the first observation is $t - \text{MAXBAND} + 1$ and the last instrument to enter is t .
- *Centered*: If $t \leq \frac{\text{MAXBAND}}{2}$, then the first observation is the first time period and the last observation is MAXBAND. If $t > T - \frac{\text{MAXBAND}}{2}$, then the first instrument included is $T - \text{MAXBAND} + 1$ and the last observation is T . If $\frac{\text{MAXBAND}}{2} < t \leq T - \frac{\text{MAXBAND}}{2}$, then the first included instrument is $t - \frac{\text{MAXBAND}}{2} + 1$ and the last observation is $t + \frac{\text{MAXBAND}}{2}$. If the MAXBAND value is an odd number, the procedure decrements by one.
- *Leading* : If $t > T - \text{MAXBAND}$, then the first instrument corresponds to time period $T - \text{MAXBAND} + 1$ and the last observation is T . Otherwise, if $t \leq T - \text{MAXBAND}$, then the first observation is t and the last observation is $t + \text{MAXBAND} + 1$.

The PANEL procedure enables you to include dummy variables to deal with the presence of time effects that are not captured by including the lagged dependent variable. The dummy variables directly affect the level equations. However, this implies that the difference of the dummy variable for time period t and $t - 1$ enters the difference equation. The first usable observation occurs at $t = 3$. If the level equation is not used in the estimation, then there is no way to identify the dummy variables. Selecting the TIME option gives the same result as that which would be obtained by creating dummy variables in the data set and using those in the regression.

The PANEL procedure gives you several options when it comes to missing values and unbalanced panel. By default, any time period for which there are missing values is skipped. The corresponding rows and columns of \mathbf{H} matrices are zeroed, and the calculation is continued. Alternatively, you can elect to replace missing values and missing observations with zeros (ZERO), the overall mean of the series (OAM), the cross-sectional mean (CSM), or the time series mean (TSM).

Linear Hypothesis Testing

For a linear hypothesis of the form $\mathbf{R}\beta = \mathbf{r}$ where \mathbf{R} is $J \times K$ and \mathbf{r} is $J \times 1$, the F -statistic with $J, M - K$ degrees of freedom is computed as

$$(\mathbf{R}\beta - \mathbf{r})' [\mathbf{R}\hat{\mathbf{V}}\mathbf{R}']^{-1} (\mathbf{R}\beta - \mathbf{r})$$

However, it is also possible to write the F statistic as

$$F = \frac{(\hat{\mathbf{u}}_*' \hat{\mathbf{u}}_* - \hat{\mathbf{u}}' \hat{\mathbf{u}}) / J}{\hat{\mathbf{u}}' \hat{\mathbf{u}} / (M - K)}$$

where

- $\hat{\mathbf{u}}_*$ is the residual vector from the restricted regression
- $\hat{\mathbf{u}}$ is the residual vector from the unrestricted regression
- J is the number of restrictions
- $(M - K)$ are the degrees of freedom, M is the number of observations, and K is the number of parameters in the model

The Wald, likelihood ratio (LR) and LaGrange multiplier (LM) tests are all related to the F test. You use this relationship of the F test to the likelihood ratio and LaGrange multiplier tests. The Wald test is calculated from its definition.

The Wald test statistic is:

$$W = (\mathbf{R}\beta - \mathbf{r})' [\mathbf{R}\hat{\mathbf{V}}\mathbf{R}']^{-1} (\mathbf{R}\beta - \mathbf{r})$$

The advantage of calculating Wald in this manner is that it enables you to substitute a heteroscedasticity-corrected covariance matrix for the matrix \mathbf{V} . PROC PANEL makes such a substitution if you request the HCCME option in the MODEL statement.

The likelihood ratio is:

$$LR = M \ln \left[1 + \frac{1}{M - K} JF \right]$$

The LaGrange multiplier test statistic is:

$$LM = M \left[\frac{JF}{M - K + JF} \right]$$

where JF represents the number of restrictions multiplied by the result of the F test.

Note that only the Wald is changed when the HCCME option is selected. The LR and LM tests are unchanged.

The distribution of these test statistics is the χ^2 with degrees of freedom equal to the number of restrictions imposed (J). The three tests are asymptotically equivalent, but they have differing small sample properties. Greene (2000, p. 392) and Davidson and MacKinnon (1993, pp. 456–458) discuss the small sample properties of these statistics.

Heteroscedasticity-Corrected Covariance Matrices

The HCCME= option in the MODEL statement selects the type of heteroscedasticity-consistent covariance matrix. In the presence of heteroscedasticity, the covariance matrix has a complicated structure that can result in inefficiencies in the OLS estimates and biased estimates of the covariance matrix. The variances for cross-sectional and time dummy variables and the covariances with or between the dummy variables are not corrected for heteroscedasticity in the one-way and two-way models. Whether or not HCCME is specified, they are the same. For the two-way models, the variance and the covariances for the intercept are not corrected.³

Consider the simple linear model:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$$

This discussion parallels the discussion in Davidson and MacKinnon 1993, pp. 548–562. For panel data models, we apply HCCME on the transformed data ($\tilde{\mathbf{y}}$ and $\tilde{\mathbf{X}}$). In other words, we first remove the random or fixed effects through transforming/demean the data⁴, then correct heteroscedasticity (also auto-correlation with HAC option) in the residual. The assumptions that make the linear regression best linear unbiased estimator (BLUE) are $E(\boldsymbol{\epsilon}) = 0$ and $E(\boldsymbol{\epsilon}\boldsymbol{\epsilon}') = \Omega$, where Ω has the simple structure $\sigma^2\mathbf{I}$. Heteroscedasticity results in a general covariance structure, so that it is not possible to simplify Ω . The result is the following:

$$\tilde{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'(\mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}) = \boldsymbol{\beta} + (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\boldsymbol{\epsilon}$$

As long as the following is true, then you are assured that the OLS estimate is consistent and unbiased:

$$plim_{n \rightarrow \infty} \left(\frac{1}{n} \mathbf{X}'\boldsymbol{\epsilon} \right) = 0$$

If the regressors are nonrandom, then it is possible to write the variance of the estimated $\boldsymbol{\beta}$ as the following:

$$\text{Var}(\boldsymbol{\beta} - \tilde{\boldsymbol{\beta}}) = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\Omega\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}$$

The effect of structure in the covariance matrix can be ameliorated by using generalized least squares (GLS), provided that Ω^{-1} can be calculated. Using Ω^{-1} , you premultiply both sides of the regression equation,

$$\mathbf{L}^{-1}\mathbf{y} = \mathbf{L}^{-1}\mathbf{X}\boldsymbol{\beta} + \mathbf{L}^{-1}\boldsymbol{\epsilon}$$

where \mathbf{L} denotes the Cholesky root of Ω . (that is, $\Omega = \mathbf{L}\mathbf{L}'$ with \mathbf{L} lower triangular).

The resulting GLS $\boldsymbol{\beta}$ is

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'\Omega^{-1}\mathbf{y}$$

³The dummy variables are removed by the within transformations, so their variances and covariances cannot be calculated the same way as the other regressors. They are recovered by the formulas listed in the sections “One-Way Fixed-Effects Model” on page 1403 and “Two-Way Fixed-Effects Model” on page 1404. The formulas assume homoscedasticity, so they do not apply when HCCME is specified. Therefore, standard errors, variances, and covariances are reported only when the HCCME option is ignored. HCCME standard errors for dummy variables and intercept can be calculated by the dummy variable approach with the pooled model.

⁴Please refer to “One-Way Fixed-Effects Model” on page 1403, “Two-Way Fixed-Effects Model” on page 1404, “One-Way Random-Effects Model” on page 1410, and “Two-Way Random-Effects Model” on page 1413 for details about transforming the data.

Using the GLS β , you can write

$$\begin{aligned}\hat{\beta} &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'\Omega^{-1}\mathbf{y} \\ &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'(\Omega^{-1}\mathbf{X}_e + \Omega^{-1}\epsilon) \\ &= \beta + (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'\Omega^{-1}\epsilon\end{aligned}$$

The resulting variance expression for the GLS estimator is

$$\begin{aligned}\text{Var}(\beta - \hat{\beta}) &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'\Omega^{-1}\epsilon\epsilon'\Omega^{-1}\mathbf{X}(\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \\ &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'\Omega^{-1}\Omega\Omega^{-1}\mathbf{X}(\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \\ &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\end{aligned}$$

The difference in variance between the OLS estimator and the GLS estimator can be written as

$$(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\Omega\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1} - (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}$$

By the Gauss-Markov theorem, the difference matrix must be positive definite under most circumstances (zero if OLS and GLS are the same, when the usual classical regression assumptions are met). Thus, OLS is not efficient under a general error structure. It is crucial to realize that OLS does not produce biased results. It would suffice if you had a method for estimating a consistent covariance matrix and you used the OLS β . Estimation of the Ω matrix is certainly not simple. The matrix is square and has M^2 elements; unless some sort of structure is assumed, it becomes an impossible problem to solve. However, the heteroscedasticity can have quite a general structure. White (1980) shows that it is not necessary to have a consistent estimate of Ω . On the contrary, it suffices to calculate an estimate of the middle expression. That is, you need an estimate of:

$$\Lambda = \mathbf{X}'\Omega\mathbf{X}$$

This matrix, Λ , is easier to estimate because its dimension is K . PROC PANEL provides the following classical HCCME estimators for Λ :

The matrix is approximated by:

- HCCME=N0:

$$\sigma^2\mathbf{X}'\mathbf{X}$$

This is the simple OLS estimator. If you do not specify the HCCME= option, PROC PANEL defaults to this estimator.

- HCCME=0:

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}'$$

where N is the number of cross sections and T_i is the number of observations in i th cross section. The \mathbf{x}_{it}' is from the t th observation in the i th cross section, constituting the $(\sum_{j=1}^{i-1} T_j + t)$ th row of the matrix \mathbf{X} . If the CLUSTER option is specified, one extra term is added to the preceding equation so that the estimator of matrix Λ is

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}' + \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \hat{\epsilon}_{it} \hat{\epsilon}_{is} (\mathbf{x}_{it} \mathbf{x}_{is}' + \mathbf{x}_{is} \mathbf{x}_{it}')$$

- HCCME=1:

$$\frac{M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}'$$

where M is the total number of observations, $\sum_{j=1}^N T_j$, and K is the number of parameters. With the CLUSTER option, the estimator becomes

$$\frac{M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}' + \frac{2M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \hat{\epsilon}_{it} \hat{\epsilon}_{is} \mathbf{x}_{it} \mathbf{x}_{is}'$$

- HCCME=2:

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{1 - \hat{h}_{it}} \mathbf{x}_{it} \mathbf{x}_{it}'$$

The \hat{h}_{it} term is the $(\sum_{j=1}^{i-1} T_j + t)$ th diagonal element of the hat matrix. The expression for \hat{h}_{it} is $\mathbf{x}_{it}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_{it}$. The hat matrix attempts to adjust the estimates for the presence of influence or leverage points. With the CLUSTER option, the estimator becomes

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{1 - \hat{h}_{it}} \mathbf{x}_{it} \mathbf{x}_{it}' + 2 \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \frac{\hat{\epsilon}_{it}}{\sqrt{1 - \hat{h}_{it}}} \frac{\hat{\epsilon}_{is}}{\sqrt{1 - \hat{h}_{is}}} \mathbf{x}_{it} \mathbf{x}_{is}'$$

- HCCME=3:

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{(1 - \hat{h}_{it})^2} \mathbf{x}_{it} \mathbf{x}_{it}'$$

With the CLUSTER option, the estimator becomes

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{(1 - \hat{h}_{it})^2} \mathbf{x}_{it} \mathbf{x}_{it}' + 2 \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \frac{\hat{\epsilon}_{it}}{1 - \hat{h}_{it}} \frac{\hat{\epsilon}_{is}}{1 - \hat{h}_{is}} \mathbf{x}_{it} \mathbf{x}_{is}'$$

- HCCME=4: PROC PANEL includes this option for the calculation of the Arellano (1987) version of the White (1980) HCCME in the panel setting. Arellano's insight is that there are N covariance matrices in a panel, and each matrix corresponds to a cross section. Forming the White HCCME for each panel, you need to take only the average of those N estimators that yield Arellano. The details of the estimation follow. First, you arrange the data such that the first cross section occupies the first T_i observations. You treat the panels as separate regressions with the form:

$$\mathbf{y}_i = \alpha_i \mathbf{i} + \mathbf{X}_{is} \tilde{\boldsymbol{\beta}} + \boldsymbol{\epsilon}_i$$

The parameter estimates $\tilde{\boldsymbol{\beta}}$ and α_i are the result of least squares dummy variables (LSDV) or within estimator regressions, and \mathbf{i} is a vector of ones of length T_i . The estimate of the i th cross section's $\mathbf{X}'\Omega\mathbf{X}$ matrix (where the s subscript indicates that no constant column has been suppressed to avoid confusion) is $\mathbf{X}_i'\Omega\mathbf{X}_i$. The estimate for the whole sample is:

$$\mathbf{X}_s'\Omega\mathbf{X}_s = \sum_{i=1}^N \mathbf{X}_i'\Omega\mathbf{X}_i$$

The Arellano standard error is in fact a White-Newey-West estimator with constant and equal weight on each component. In the between estimators, selecting HCCME=4 returns the HCCME=0 result since there is no ‘other’ variable to group by.

In their discussion, Davidson and MacKinnon (1993, p. 554) argue that HCCME=1 should always be preferred to HCCME=0. Although HCCME=3 is generally preferred to 2 and 2 is preferred to 1, the calculation of HCCME=1 is as simple as the calculation of HCCME=0. Therefore, it is clear that HCCME=1 is preferred when the calculation of the hat matrix is too tedious.

All HCCME estimators have well-defined asymptotic properties. The small sample properties are not well-known, and care must be exercised when sample sizes are small.

The HCCME estimator of $\text{Var}(\boldsymbol{\beta})$ is used to drive the covariance matrices for the fixed effects and the LaGrange multiplier standard errors. Robust estimates of the covariance matrix for $\boldsymbol{\beta}$ imply robust covariance matrices for all other parameters.

Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrices

The HAC option in the MODEL statement selects the type of heteroscedasticity- and autocorrelation-consistent covariance matrix. As with the HCCME option, an estimator of the middle expression Λ in sandwich form is needed. With the HAC option, it is estimated as

$$\Lambda_{\text{HAC}} = a \sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}' + a \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} k\left(\frac{s-t}{b}\right) \hat{\epsilon}_{it} \hat{\epsilon}_{is} \left(\mathbf{x}_{it} \mathbf{x}_{is}' + \mathbf{x}_{is} \mathbf{x}_{it}' \right)$$

, where $k(\cdot)$ is the real-valued kernel function⁵, b is the bandwidth parameter, and a is the adjustment factor of small sample degrees of freedom (that is, $a = 1$ if the ADJUSTDF option is not specified and otherwise $a = NT/(NT - k)$, where k is the number of parameters including dummy variables). The types of kernel functions are listed in Table 20.2.

Table 20.2 Kernel Functions

Kernel Name	Equation
Bartlett	$k(x) = \begin{cases} 1 - x & x \leq 1 \\ 0 & \text{otherwise} \end{cases}$
Parzen	$k(x) = \begin{cases} 1 - 6x^2 + 6 x ^3 & 0 \leq x \leq 1/2 \\ 2(1 - x)^3 & 1/2 \leq x \leq 1 \\ 0 & \text{otherwise} \end{cases}$
Quadratic spectral	$k(x) = \frac{25}{12\pi^2 x^2} \left(\frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right)$
Truncated	$k(x) = \begin{cases} 1 & x \leq 1 \\ 0 & \text{otherwise} \end{cases}$
Tukey-Hanning	$k(x) = \begin{cases} (1 + \cos(\pi x))/2 & x \leq 1 \\ 0 & \text{otherwise} \end{cases}$

⁵The HCCME=0 with CLUSTER option sets $k(\cdot) = 1$.

When the BANDWIDTH=ANDREWS option is specified, the bandwidth parameter is estimated as shown in Table 20.3.

Table 20.3 Bandwidth Parameter Estimation

Kernel Name	Bandwidth Parameter
Bartlett	$b = 1.1447(\alpha(1)T)^{1/3}$
Parzen	$b = 2.6614(\alpha(2)T)^{1/5}$
Quadratic spectral	$b = 1.3221(\alpha(2)T)^{1/5}$
Truncated	$b = 0.6611(\alpha(2)T)^{1/5}$
Tukey-Hanning	$b = 1.7462(\alpha(2)T)^{1/5}$

Let $\{g_{ait}\}$ denote each series in $\{g_{it} = \hat{\epsilon}_{it}\mathbf{x}_{it}\}$, and let (ρ_a, σ_a^2) denote the corresponding estimates of the autoregressive and innovation variance parameters of the AR(1) model on $\{g_{ait}\}$, $a = 1, \dots, k$, where the AR(1) model is parameterized as $g_{ait} = \rho g_{ait-1} + \epsilon_{ait}$ with $Var(\epsilon_{ait}) = \sigma_a^2$. The $\alpha(1)$ and $\alpha(2)$ are estimated with the following formulas:

$$\alpha(1) = \frac{\sum_{a=1}^k \frac{4\rho_a^2\sigma_a^4}{(1-\rho_a)^6(1+\rho_a)^2}}{\sum_{a=1}^k \frac{\sigma_a^4}{(1-\rho_a)^4}} \quad \alpha(2) = \frac{\sum_{a=1}^k \frac{4\rho_a^2\sigma_a^4}{(1-\rho_a)^8}}{\sum_{a=1}^k \frac{\sigma_a^4}{(1-\rho_a)^4}}$$

When you specify BANDWIDTH=NEWKEYWEST94, according to Newey and West (1994) the bandwidth parameter is estimated as shown in Table 20.4.

Table 20.4 Bandwidth Parameter Estimation

Kernel Name	Bandwidth Parameter
Bartlett	$b = 1.1447(\{s_1/s_0\}^2 T)^{1/3}$
Parzen	$b = 2.6614(\{s_1/s_0\}^2 T)^{1/5}$
Quadratic spectral	$b = 1.3221(\{s_1/s_0\}^2 T)^{1/5}$
Truncated	$b = 0.6611(\{s_1/s_0\}^2 T)^{1/5}$
Tukey-Hanning	$b = 1.7462(\{s_1/s_0\}^2 T)^{1/5}$

The s_1 and s_0 are estimated with the following formulas:

$$s_1 = 2 \sum_{j=1}^n j\sigma_j \quad s_0 = \sigma_0 + 2 \sum_{j=1}^n \sigma_j$$

where n is the lag selection parameter and is determined by kernels, as listed in Table 20.5.

Table 20.5 Lag Selection Parameter Estimation

Kernel Name	Lag Selection Parameter
Bartlett	$n = c(T/100)^{2/9}$
Parzen	$n = c(T/100)^{4/25}$
Quadratic Spectral	$n = c(T/100)^{2/25}$
Truncated	$n = c(T/100)^{1/5}$
Tukey-Hanning	$n = c(T/100)^{1/5}$

The c in Table 20.5 is specified by the C= option; by default, C=12.

The σ_j is estimated with the equation

$$\sigma_j = T^{-1} \sum_{t=j+1}^T \left(\sum_{a=i}^k g_{at} \sum_{a=i}^k g_{at-j} \right), j = 0, \dots, n$$

where g_{at} is the same as in the Andrews method and i is 1 if the NOINT option in the MODEL statement is specified, and 2 otherwise.

When you specify BANDWIDTH=SAMPLESIZE, the bandwidth parameter is estimated with the equation

$$b = \begin{cases} \lfloor \gamma T^r + c \rfloor & \text{if BANDWIDTH=SAMPLESIZE(INT) option is specified} \\ \gamma T^r + c & \text{otherwise} \end{cases}$$

where T is the sample size, $\lfloor x \rfloor$ is the largest integer less than or equal to x , and γ , r , and c are values specified by BANDWIDTH=SAMPLESIZE(GAMMA=, RATE=, CONSTANT=) options, respectively.

If the PREWHITENING option is specified in the MODEL statement, g_{it} is prewhitened by the VAR(1) model,

$$g_{it} = A_i g_{i,t-1} + w_{it}$$

Then Λ_{HAC} is calculated by

$$\Lambda_{\text{HAC}} = a \sum_{i=1}^N \left\{ ((I - A_i)^{-1})' \left(\sum_{t=1}^{T_i} w_{it} w_{it}' + \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} k\left(\frac{s-t}{b}\right) (w_{it} w_{is}' + w_{is} w_{it}') \right) (I - A_i)^{-1} \right\}$$

R-Square

The conventional R-square measure is inappropriate for all models that the PANEL procedure estimates by using GLS because a number outside the [0,1] range might be produced. Hence, a generalization of the R-square measure is reported. The following goodness-of-fit measure (Buse 1973) is reported:

$$R^2 = 1 - \frac{\hat{\mathbf{u}}' \hat{\mathbf{V}}^{-1} \hat{\mathbf{u}}}{\mathbf{y}' \mathbf{D}' \hat{\mathbf{V}}^{-1} \mathbf{D} \mathbf{y}}$$

where $\hat{\mathbf{u}}$ are the residuals of the transformed model, $\hat{\mathbf{u}} = \mathbf{y} - \mathbf{X}(\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X})^{-1}\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{y}$,

and $\mathbf{D} = \mathbf{I}_M - \mathbf{j}_M\mathbf{j}_M'(\frac{\hat{\mathbf{V}}^{-1}}{\mathbf{j}_M'\hat{\mathbf{V}}^{-1}\mathbf{j}_M})$.

This is a measure of the proportion of the transformed sum of squares of the dependent variable that is attributable to the influence of the independent variables.

If there is no intercept in the model, the corresponding measure (Theil 1961) is

$$R^2 = 1 - \frac{\hat{\mathbf{u}}'\hat{\mathbf{V}}^{-1}\hat{\mathbf{u}}}{\mathbf{y}'\hat{\mathbf{V}}^{-1}\mathbf{y}}$$

However, the fixed-effects models are somewhat different. In the case of a fixed-effects model, the choice of including or excluding an intercept becomes merely a choice of classification. Suppressing the intercept in the FIXONE or FIXONETIME case merely changes the name of the intercept to a fixed effect. It makes no sense to redefine the R-square measure since nothing material changes in the model. Similarly, for the FIXTWO model there is no reason to change the R-square measure. In the case of the FIXONE, FIXONETIME, and FIXTWO models, the R-square is defined as the Theil (1961) R-square as shown in the preceding equation. This makes intuitive sense since you are regressing a transformed (demeaned) series on transformed regressors, excluding a constant. In other words, you are looking at 1 minus the sum of squared errors divided by the sum of squares of the (transformed) dependent variable.

In the case of OLS estimation, both of the R-square formulas given here reduce to the usual R-square formula.

Specification Tests

The PANEL procedure outputs the results of one specification test for fixed effects and two specification tests for random effects.

For fixed effects, let β_f be the n dimensional vector of fixed-effects parameters. The specification test reported is the conventional F statistic for the hypothesis $\beta_f = \mathbf{0}$. The F statistic with n , $M - K$ degrees of freedom is computed as

$$\hat{\beta}_f'\hat{\mathbf{S}}_f^{-1}\hat{\beta}_f/n$$

where $\hat{\mathbf{S}}_f$ is the estimated covariance matrix of the fixed-effects parameters.

Hausman (1978) specification test or m statistic can be used to test hypotheses in terms of bias or inconsistency of an estimator. This test was also proposed by Wu (1973) and further extended in Hausman and Taylor (1982). Hausman's m statistic is as follows.

Consider two estimators, $\hat{\beta}_a$ and $\hat{\beta}_b$, which under the null hypothesis are both consistent, but only $\hat{\beta}_a$ is asymptotically efficient. Under the alternative hypothesis, only $\hat{\beta}_b$ is consistent. The m statistic is

$$m = (\hat{\beta}_b - \hat{\beta}_a)'(\hat{\mathbf{S}}_b - \hat{\mathbf{S}}_a)^{-1}(\hat{\beta}_b - \hat{\beta}_a)$$

where $\hat{\mathbf{S}}_b$ and $\hat{\mathbf{S}}_a$ are consistent estimates of the asymptotic covariance matrices of $\hat{\beta}_b$ and $\hat{\beta}_a$. Then m is distributed χ^2 with k degrees of freedom, where k is the dimension of $\hat{\beta}_a$ and $\hat{\beta}_b$.

In the random-effects specification, the null hypothesis of no correlation between effects and regressors implies that the OLS estimates of the slope parameters are consistent and inefficient but the GLS estimates of

the slope parameters are consistent and efficient. This facilitates a Hausman specification test. The reported χ^2 statistic has degrees of freedom equal to the number of slope parameters. If the null hypothesis holds, the random-effects specification should be used.

Breusch and Pagan (1980) lay out a LaGrange multiplier test for random effects based on the simple OLS (pooled) estimator. If \hat{u}_{it} is the it th residual from the OLS regression, then the Breusch-Pagan (BP) test for one-way random effects is

$$BP = \frac{NT}{2(T-1)} \left[\frac{\sum_{i=1}^N \left[\sum_{t=1}^T \hat{u}_{it} \right]^2}{\sum_{i=1}^N \sum_{t=1}^T \hat{u}_{it}^2} - 1 \right]^2$$

The BP test generalizes to the case of a two-way random-effects model (Greene 2000, p. 589). Specifically,

$$\begin{aligned} BP2 &= \frac{NT}{2(T-1)} \left[\frac{\sum_{i=1}^n \left[\sum_{t=1}^T \hat{u}_{it} \right]^2}{\sum_{i=1}^N \sum_{t=1}^T \hat{u}_{it}^2} - 1 \right]^2 \\ &+ \frac{NT}{2(N-1)} \left[\frac{\sum_{t=1}^T \left[\sum_{i=1}^N \hat{u}_{it} \right]^2}{\sum_{i=1}^N \sum_{t=1}^T \hat{u}_{it}^2} - 1 \right]^2 \end{aligned}$$

is distributed as a χ^2 statistic with two degrees of freedom. Since the BP2 test generalizes (nests the BP test) the test for random effects, the absence of random effects (nonrejection of the null of no random effects) in the BP2 is a fairly clear indication that there will probably not be any one-way effects either. In both cases (BP and BP2), the residuals are obtained from a pooled regression. There is very little extra cost in selecting both the BP and BP2 test. Notice that in the case of just groupwise heteroscedasticity, the BP2 test approaches BP. In the case of time based heteroscedasticity, the BP2 test reduces to a BP test of time effects. In the case of unbalanced panels, neither the BP nor BP2 statistics are valid.

Finally, you should be aware that the BP option generates different results depending on whether the estimation is FIXONE or FIXONETIME. Specifically, under the FIXONE estimation technique, the BP tests for cross-sectional random effects. Under the FIXONETIME estimation, the BP tests for time random effects.

While the Hausman statistic is automatically generated, you request Breusch-Pagan via the BP or BP2 option (see Baltagi 1995 for details).

Panel Data Poolability Test

The null hypothesis of poolability assumes homogeneous slope coefficients. An F test can be applied to test for the poolability across cross sections in panel data models.

F Test

For the unrestricted model, run a regression for each cross section and save the sum of squared residuals as SSE_u . For the restricted model, save the sum of squared residuals as SSE_r . If the test applies to all coefficients (including the constant), then the restricted model is the pooled model (OLS); if the test applies

to coefficients other than the constant, then the restricted model is the fixed one-way model with cross-sectional fixed effects. If N and T denote the number of cross sections and time periods, then the number of observations is $n = NT$.⁶ Let k be the number of regressors except the constant. The degree of freedom for the unrestricted model is $df_u = n - N(k + 1)$. If the constant is restricted to be the same, the degree of freedom for the restricted model is $df_r = n - k - 1$ and the number of restrictions is $q = (N - 1)(k + 1)$. If the restricted model is the fixed one-way model, the degree of freedom is $df_r = n - k - N$ and the number of restrictions is $q = (N - 1)k$. So the F test is

$$F = \frac{(SSE_r - SSE_u)/q}{SSE_u/df_u} \sim F(q, df_u)$$

For large N and T , you can use a chi-square distribution to approximate the limiting distribution, namely, $qF \implies \chi^2(q)$. The error term is assumed to be homogeneous; therefore, $\epsilon \sim \mathcal{N}(0, \sigma^2 I_n)$, and an OLS regression is sufficient. The test is the same as the Chow test (Chow 1960) extended to N linear regressions.

LR Test

Zellner (1962) also proved that the likelihood ratio test for null hypothesis of poolability can be based on the F statistic. The likelihood ratio can be expressed as $LR = -2 \log \left((1 + qF/df_u)^{-NT/2} \right) \implies LR = qF + O(n^{-1})$. Under H_0 , LR is asymptotically distributed as a chi-square with q degrees of freedom.

Panel Data Unit Root Tests

Levin, Lin, and Chu (2002)

Levin, Lin, and Chu (2002) propose a panel unit root test for the null hypothesis of unit root against a homogeneous stationary hypothesis. The model is specified as

$$\Delta y_{it} = \delta y_{it-1} + \sum_{L=1}^{p_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mt} + \varepsilon_{it} \quad m = 1, 2, 3$$

Three models are considered: (1) $d_{1t} = \phi$ (the empty set) with no individual effects, (2) $d_{2t} = \{1\}$ in which the series y_{it} has an individual-specific mean but no time trend, and (3) $d_{3t} = \{1, t\}$ in which the series y_{it} has an individual-specific mean and linear and individual-specific time trend. The panel unit root test evaluates the null hypothesis of $H_0 : \delta = 0$, for all i , against the alternative hypothesis $H_1 : \delta < 0$ for all i . The lag order p_i is unknown and is allowed to vary across individuals. It can be selected by the methods that are described in the section “[Lag Order Selection in the ADF Regression](#)” on page 1443. Denote the selected lag orders as \hat{p}_i . The test is implemented in three steps.

Step 1 The ADF regressions are implemented for each individual i , and then the orthogonalized residuals are generated and normalized. That is, the following model is estimated:

$$\Delta y_{it} = \delta_i y_{it-1} + \sum_{L=1}^{\hat{p}_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mt} + \varepsilon_{it} \quad m = 1, 2, 3$$

⁶For the unbalanced panel, the number of time series T_i might be different. The number of observations needs to be redefined accordingly.

The two orthogonalized residuals are generated by the following two auxiliary regressions:

$$\Delta y_{it} = \sum_{L=1}^{\hat{p}_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mi} + e_{it}$$

$$y_{it-1} = \sum_{L=1}^{\hat{p}_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mi} + v_{it-1}$$

The residuals are saved at \hat{e}_{it} and \hat{v}_{it-1} , respectively. To remove heteroscedasticity, the residuals \hat{e}_{it} and \hat{v}_{it-1} are normalized by the regression standard error from the ADF regression. Denote the standard error as $\hat{\sigma}_{\varepsilon i}^2 = \sum_{t=\hat{p}_i+2}^T (\hat{e}_{it} - \hat{\delta}_i \hat{v}_{it-1})^2 / (T - p_i - 1)$, and normalize residuals as

$$\tilde{e}_{it} = \frac{\hat{e}_{it}}{\hat{\sigma}_{\varepsilon i}}, \quad \tilde{v}_{it-1} = \frac{\hat{v}_{it-1}}{\hat{\sigma}_{\varepsilon i}}$$

Step 2 The ratios of long-run to short-run standard deviations of Δy_{it} are estimated. Denote the ratios and the long-run variances as s_i and σ_{yi} , respectively. The long-run variances are estimated by the HAC (heteroscedasticity- and autocorrelation-consistent) estimators, which are described in the section “Long-Run Variance Estimation” on page 1443. Then the ratios are estimated by $\hat{s}_i = \hat{\sigma}_{yi} / \hat{\sigma}_{\varepsilon i}$. Let the average standard deviation ratio be $S_N = (1/N) \sum_{i=1}^N s_i$, and let its estimator be $\hat{S}_N = (1/N) \sum_{i=1}^N \hat{s}_i$.

Step 3 The panel test statistics are calculated. To calculate the t statistic and the adjusted t statistic, the following equation is estimated:

$$\tilde{e}_{it} = \delta \tilde{v}_{it-1} + \tilde{\varepsilon}_{it}$$

The total number of observations is $N\tilde{T}$, with $\tilde{p} = \sum_{i=1}^N \hat{p}_i / N$, $\tilde{T} = T - \tilde{p} - 1$. The standard t statistic for testing $\delta = 0$ is $t_\delta = \hat{\delta} / STD(\hat{\delta})$, with OLS estimator $\hat{\delta}$ and standard deviation $STD(\hat{\delta})$. However, the standard t statistic diverges to negative infinity for models (2) and (3). Let $\hat{\sigma}_{\tilde{\varepsilon}}$ be the root mean square error from the step 3 regression, and denote it as

$$\hat{\sigma}_{\tilde{\varepsilon}}^2 = \left[\frac{1}{N\tilde{T}} \sum_{i=1}^N \sum_{t=2+\hat{p}_i}^T (\tilde{e}_{it} - \hat{\delta} \tilde{v}_{it-1})^2 \right]$$

Levin, Lin, and Chu (2002) propose the following adjusted t statistic:

$$t_\delta^* = \frac{t_\delta - N\tilde{T}\hat{S}_N\hat{\sigma}_{\tilde{\varepsilon}}^{-2}STD(\hat{\delta})\mu_{m\tilde{T}}^*}{\sigma_{m\tilde{T}}^*}$$

The mean and standard deviation adjustments $(\mu_{m\tilde{T}}^*, \sigma_{m\tilde{T}}^*)$ depend on the time series dimension \tilde{T} and model specification m , which can be found in Table 2 of Levin, Lin, and Chu (2002). The adjusted t statistic converges to the standard normal distribution. Therefore, the standard normal critical values are used in hypothesis testing.

Lag Order Selection in the ADF Regression

The methods for selecting the individual lag orders in the ADF regressions can be divided into two categories: selection based on information criteria and selection via sequential testing.

Lag Selection Based on Information Criteria In this method, the following information criteria can be applied to lag order selection: AIC, SBC, HQIC (HQC), and MAIC. As with other model selection applications, the lag order is selected from 0 to the maximum p_{max} to minimize the objective function, plus a penalty term, which is a function of the number of parameters in the regression. Let k be the number of parameters and T_o be the number of effective observations. For regression models, the objective function is $T_o \log(SSR/T_o)$, where SSR is the sum of squared residuals. For AIC, the penalty term equals $2k$. For SBC, this term is $k \log T_o$. For HQIC, it is $2ck \log [\log(T_o)]$ with c being a constant greater than 1.⁷ For MAIC, the penalty term equals $2(\tau_T(k) + k)$, where

$$\tau_T(k) = (SSR/T_o)^{-1} \hat{\delta}^2 \sum_{t=p_{max}+2}^T y_{t-1}^2$$

and $\hat{\delta}$ is the estimated coefficient of the lagged dependent variable y_{t-1} in the ADF regression.

Lag Selection via Sequential Testing In this method, the lag order estimation is based on the statistical significance of the estimated AR coefficients. Hall (1994) proposed general-to-specific (GS) and specific-to-general (SG) strategies. Levin, Lin, and Chu (2002) recommend the first strategy, following Campbell and Perron (1991). In the GS modeling strategy, starting with the maximum lag order p_{max} , the t test for the largest lag order in $\hat{\theta}_i$ is performed to determine whether a smaller lag order is preferred. Specifically, when the null of $\hat{\theta}_{iL} = 0$ is not rejected given the significance level (5%), a smaller lag order is preferred. This procedure continues until a statistically significant lag order is reached. On the other hand, the SG modeling strategy starts with lag order 0 and moves toward the maximum lag order p_{max} .

Long-Run Variance Estimation

The long-run variance of Δy_{it} is estimated by a HAC-type estimator. For model (1), given the lag truncation parameter \bar{K} and kernel weights $w_{\bar{K}L}$, the formula is

$$\hat{\sigma}_{yi}^2 = \frac{1}{T-1} \sum_{t=2}^T \Delta y_{it}^2 + 2 \sum_{L=1}^{\bar{K}} w_{\bar{K}L} \left[\frac{1}{T-1} \sum_{t=2+L}^T \Delta y_{it} \Delta y_{it-L} \right]$$

To achieve consistency, the lag truncation parameter must satisfy $\bar{K}/T \rightarrow 0$ and $\bar{K} \rightarrow \infty$ as $T \rightarrow \infty$. Levin, Lin, and Chu (2002) suggest $\bar{K} = \lfloor 3.21 T^{1/3} \rfloor$. The weights $w_{\bar{K}L}$ depend on the kernel function. Andrews (1991) proposes data-driven bandwidth (lag truncation parameter + 1 if integer-valued) selection procedures to minimize the asymptotic mean squared error (MSE) criterion. For details about the kernel functions and Andrews (1991) data-driven bandwidth selection procedure, see the section “**Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrices**” on page 1436 for details. Because Levin, Lin, and Chu (2002) truncate the bandwidth as an integer, when LLCBAND is specified as the BANDWIDTH option, it corresponds to $\text{BANDWIDTH} = \lfloor 3.21 T^{1/3} \rfloor + 1$. Furthermore, kernel weights $w_{\bar{K}L} = k(L/(\bar{K} + 1))$ with kernel function $k(\cdot)$.

⁷In practice c is set to 1, following the literature (Hannan and Quinn 1979; Hall 1994).

For model (2), the series Δy_{it} is demeaned individual by individual first. Therefore, Δy_{it} is replaced by $\Delta y_{it} - \overline{\Delta y_{it}}$, where $\overline{\Delta y_{it}}$ is the mean of Δy_{it} for individual i . For model (3) with individual fixed effects and time trend, both the individual mean and trend should be removed before the long-run variance is estimated. That is, first regress Δy_{it} on $\{1, t\}$ for each individual and save the residual $\widehat{\Delta y_{it}}$, and then replace Δy_{it} with the residual.

Cross-Sectional Dependence via Time-Specific Aggregate Effects

The Levin, Lin, and Chu (2002) testing procedure is based on the assumption of cross-sectional independence. It is possible to relax this assumption and allow for a limited degree of dependence via time-specific aggregate effects. Let θ_t denote the time-specific aggregate effects; then the data generating process (DGP) becomes

$$\Delta y_{it} = \delta y_{it-1} + \sum_{L=1}^{p_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mt} + \theta_t + \varepsilon_{it} \quad m = 1, 2, 3$$

By subtracting the cross-sectional averages $\bar{y}_t = \sum_{i=1}^N y_{it}$ from the observed dependent variable y_{it} , or equivalently, by including the time-specific intercepts θ_t in the ADF regression, the cross-sectional dependence is removed. The impact of a single aggregate common factor that has an identical impact on all individuals but changes over time can also be removed in this way. After cross-sectional dependence is removed, the three-step procedure is applied to calculate the Levin, Lin, and Chu (2002) adjusted t statistic.

Deterministic Variables

Three deterministic variables can be included in the model for the first-stage estimation: CS_FixedEffects (cross-sectional fixed effects), TS_FixedEffects (time series fixed effects), and TimeTrend (individual linear time trend). When a linear time trend is included, the individual fixed effects are also included. Otherwise the time trend is not identified. Moreover, if the time fixed effects are included, the time trend is not identified either. Therefore, we have 5 identified models: model (1), no deterministic variables; model (2), CS_FixedEffects; model (3), CS_FixedEffects and TimeTrend; model (4), TS_FixedEffects; model (5), CS_FixedEffects TS_FixedEffects. PROC PANEL outputs the test results for all 5 model specifications.

Im, Pesaran, and Shin (2003)

To test for the unit root in heterogeneous panels, Im, Pesaran, and Shin (2003) propose a standardized t -bar test statistic based on averaging the (augmented) Dickey-Fuller statistics across the groups. The limiting distribution is standard normal. The stochastic process y_{it} is generated by the first-order autoregressive process. If $\Delta y_{it} = y_{it} - y_{i,t-1}$, the data generating process can be expressed as in LLC:

$$\Delta y_{it} = \beta_i y_{it-1} + \sum_{j=1}^{p_i} \rho_{ij} \Delta y_{i,t-j} + \alpha_{mi} d_{mt} + \varepsilon_{it} \quad m = 1, 2, 3$$

Unlike the DGP in LLC, β_i is allowed to differ across groups. The null hypothesis of unit roots is

$$H_0 : \beta_i = 0 \quad \text{for all } i$$

against the heterogeneous alternative,

$$H_1 : \beta_i < 0 \quad \text{for } i = 1, \dots, N_1, \quad \beta_i = 0 \quad \text{for } i = N_1 + 1, \dots, N$$

The Im, Pesaran, and Shin test also allows for some (but not all) of the individual series to have unit roots under the alternative hypothesis. But the fraction of the individual processes that are stationary is positive,

$\lim_{N \rightarrow \infty} N_1/N = \delta \in (0, 1]$. The t -bar statistic, denoted by $t\text{-bar}_{NT}$, is formed as a simple average of the individual t statistics for testing the null hypothesis of $\beta_i = 0$. If $t_{iT}(p_i, \rho_i)$ is the standard t statistic, then

$$t\text{-bar}_{NT} = \frac{1}{N} \sum_{i=1}^N t_{iT}(p_i, \rho_i)$$

If $T \rightarrow \infty$, then for each i the t statistic (without time trend) converges to the Dickey-Fuller distribution, η_i , defined by

$$\eta_i = \frac{\frac{1}{2}\{[W_i(1)]^2 - 1\} - W_i(1) \int_0^1 W_i(u) du}{\int_0^1 [W_i(u)]^2 du - [\int_0^1 W_i(u) du]^2}$$

where W_i is the standard Brownian motion. The limiting distribution is different when a time trend is included in the regression (Hamilton 1994, p. 499). The mean and variance of the limiting distributions are reported in Nabeya (1999). The standardized t -bar statistic satisfies

$$Z_{tbar}(p, \rho) = \frac{\sqrt{N}\{t\text{-bar}_{NT} - E(\eta)\}}{\sqrt{Var(\eta)}} \Rightarrow \mathcal{N}(0, 1)$$

where the standard normal is the sequential limit with $T \rightarrow \infty$ followed by $N \rightarrow \infty$. To obtain better finite sample approximations, Im, Pesaran, and Shin (2003) propose standardizing the t -bar statistic by means and variances of $t_{iT}(p_i, 0)$ under the null hypothesis $\beta_i = 0$. The alternative standardized t -bar statistic is

$$W_{tbar}(p, \rho) = \frac{\sqrt{N}\{t\text{-bar}_{NT} - \sum_{i=1}^N E[t_{iT}(p_i, 0)|\beta_i = 0]/N\}}{\sqrt{\sum_{i=1}^N Var[t_{iT}(p_i, 0)|\beta_i = 0]/N}} \Rightarrow \mathcal{N}(0, 1)$$

Im, Pesaran, and Shin (2003) simulate the values of $E[t_{iT}(p_i, 0)|\beta_i = 0]$ and $Var[t_{iT}(p_i, 0)|\beta_i = 0]$ for different values of T and p . The lag order in the ADF regression can be selected by the same method as in Levin, Lin, and Chu (2002). See the section “[Lag Order Selection in the ADF Regression](#)” on page 1443 for details.

When T is fixed, Im, Pesaran, and Shin (2003) assume serially uncorrelated errors, $p_i = 0$; t_{iT} is likely to have finite second moment, which is not established in the paper. The t statistic is modified by imposing the null hypothesis of a unit root. Denote $\tilde{\sigma}_{iT}$ as the estimated standard error from the [restricted regression](#) ($\beta_i = 0$),

$$\tilde{t}\text{-bar}_{NT} = \sum_{i=1}^N \tilde{t}_{iT}/N = \sum_{i=1}^N \left[\hat{\beta}_{iT} (y'_{i,-1} M_{\tau} y_{i,-1})^{1/2} / \tilde{\sigma}_{iT} \right] / N$$

where $\hat{\beta}_{iT}$ is the OLS estimator of β_i (unrestricted model), $\tau_T = (1, 1, \dots, 1)'$, $M_{\tau} = I_T - \tau_T (\tau'_T \tau_T)^{-1} \tau'_T$, and $y_{i,-1} = (y_{i0}, y_{i1}, \dots, y_{iT-1})'$. Under the null hypothesis, the standardized \tilde{t} -bar statistic converges to a standard normal variate,

$$Z_{\tilde{t}bar} = \frac{\sqrt{N}\{\tilde{t}\text{-bar}_{NT} - E(\tilde{t}_T)\}}{\sqrt{Var(\tilde{t}_T)}} \Rightarrow \mathcal{N}(0, 1)$$

where $E(\tilde{t}_T)$ and $Var(\tilde{t}_T)$ are the mean and variance of \tilde{t}_{iT} , respectively. The limit is taken as $N \rightarrow \infty$ and T is fixed. Their values are simulated for finite samples without a time trend. The $Z_{\tilde{t}bar}$ is also likely to converge to standard normal.

When N and T are both finite, an exact test that assumes no serial correlation can be used. The critical values of $t\text{-bar}_{NT}$ and $\tilde{t}\text{-bar}_{NT}$ are simulated.

Combination Tests (Experimental)

Combining the observed significance levels (p -values) from N independent tests of the unit root null hypothesis was proposed by Maddala and Wu (1999); Choi (2001). Suppose G_i is the test statistic to test the unit root null hypothesis for individual $i = 1, \dots, N$, and $F(\cdot)$ is the cdf (cumulative distribution function) of the asymptotic distribution as $T \rightarrow \infty$. Then the asymptotic p -value is defined as

$$p_i = F(G_i)$$

There are different ways to combine these p -values. The first one is the inverse chi-square test (Fisher 1932); this test is referred to as P test in Choi (2001) and λ in Maddala and Wu (1999):

$$Chi - Square = -2 \sum_{i=1}^N \ln(p_i)$$

When the test statistics $\{G_i\}_{i=1, \dots, N}$ are continuous, $\{p_i\}_{i=1, \dots, N}$ are independent uniform $(0, 1)$ variables. Therefore, $P \Rightarrow \chi^2(2N)$ as $T \rightarrow \infty$ and N fixed. But as $N \rightarrow \infty$, P diverges to infinity in probability. Therefore, it is not applicable for large N . To derive a nondegenerate limiting distribution, the P test (Fisher test with $N \rightarrow \infty$) should be modified to

$$P_m = FI = \sum_{i=1}^N (-2 \ln(p_i) - 2) / 2\sqrt{N} = - \sum_{i=1}^N (\ln(p_i) + 1) / \sqrt{N}$$

Under the null as $T_i \rightarrow \infty$,⁸ and then $N \rightarrow \infty$, $P_m \Rightarrow \mathcal{N}(0, 1)$.⁹

The second way of combining individual p -values is the inverse normal test,

$$Z = \sum_{i=1}^N \Phi^{-1}(p_i)$$

where $\Phi(\cdot)$ is the standard normal cdf. When $T_i \rightarrow \infty$, $Z \Rightarrow \mathcal{N}(0, 1)$ as N is fixed. When N and T_i are both large, the sequential limit is also standard normal if $T_i \rightarrow \infty$ first and $N \rightarrow \infty$ next.

The third way of combining p -values is the logit test,

$$L^* = \sqrt{k}L = \sqrt{k} \sum_{i=1}^N \ln\left(\frac{p_i}{1-p_i}\right)$$

where $k = 3(5N + 4) / (\pi^2 N (5N + 2))$. When $T_i \rightarrow \infty$ and N is fixed, $L^* \Rightarrow t_{5N+4}$. In other words, the limiting distribution is the t distribution with degree of freedom $5N + 4$. The sequential limit is $L^* \Rightarrow \mathcal{N}(0, 1)$ as $T_i \rightarrow \infty$ and then $N \rightarrow \infty$. Simulation results in Choi (2001) suggest that the Z test outperforms other combination tests. For the time series unit root test G_i , Maddala and Wu (1999) apply the augmented Dickey-Fuller test. According to Choi (2006), the Elliott, Rothenberg, and Stock (1996) Dickey-Fuller generalized least squares (DF-GLS) test brings significant size and power advantages in finite samples.

⁸The time series length T is subindexed by $i = 1, \dots, N$ because the panel can be unbalanced.

⁹Choi (2001) also points out that the joint limit result where N and $\{T_i\}_{i=1, \dots, N}$ go to infinity simultaneously is the same as the sequential limit, but it requires more moment conditions.

Breitung's Unbiased Tests

To account for the nonzero mean of the t statistic in the OLS detrending case, bias-adjusted t statistics were proposed by: Levin, Lin, and Chu (2002); Im, Pesaran, and Shin (2003). The bias corrections imply a severe loss of power. Breitung and associates take an alternative approach to avoid the bias, by using alternative estimates of the deterministic terms (Breitung and Meyer 1994; Breitung 2000; Breitung and Das 2005). The DGP is the same as in the Im, Pesaran, and Shin approach. When serial correlation is absent, for model (2) with individual specific means, the constant terms are estimated by the initial values y_{i1} . Therefore, the series y_{it} is adjusted by subtracting the initial value. The equation becomes

$$\Delta y_{it} = \delta^* (y_{i,t-1} - y_{i1}) + v_{it}$$

For model (3) with individual specific means and time trends, the time trend can be estimated by $\hat{\beta}_i = (T-1)^{-1} (y_{iT} - y_{i1})$. The levels can be transformed as

$$\tilde{y}_{it} = y_{it} - y_{i1} - \hat{\beta}_i t = y_{it} - y_{i1} - t (y_{iT} - y_{i1}) / (T-1)$$

The Helmert transformation is applied to the dependent variable to remove the mean of the differenced variable:

$$\Delta y_{it}^* = \sqrt{\frac{T-t}{T-t+1}} [\Delta y_{it} - (\Delta y_{i,t+1} + \dots + \Delta y_{iT}) / (T-t)]$$

The transformed model is

$$\Delta y_{it}^* = \delta^* \tilde{y}_{i,t-1} + v_{it}$$

The pooled t statistic has a standard normal distribution. Therefore, no adjustment is needed for the t statistic. To adjust for heteroscedasticity across cross sections, Breitung (2000) proposes a UB (unbiased) statistic based on the transformed data,

$$UB = \frac{\sum_{i=1}^N \sum_{t=2}^T \Delta y_{it}^* \tilde{y}_{i,t-1} / \sigma_i^2}{\sqrt{\sum_{i=1}^N \sum_{t=2}^T \tilde{y}_{i,t-1}^2 / \sigma_i^2}}$$

where $\sigma_i^2 = E (\Delta y_{it} - \beta_i)^2$. When σ_i^2 is unknown, it can be estimated as

$$\hat{\sigma}_i^2 = \sum_{t=2}^T \left(\Delta y_{it} - \sum_{t=2}^T \Delta y_{it} / (T-1) \right)^2 / (T-2)$$

The UB statistic has a standard normal limiting distribution as $T \rightarrow \infty$ followed by $N \rightarrow \infty$ sequentially. To account for the short-run dynamics, Breitung and Das (2005) suggest applying the test to the prewhitened series, \hat{y}_{it} . For model (1) and model (2) (constant-only case), they suggested the same method as in step 1 of Levin, Lin, and Chu (2002).¹⁰ For model (3) (with a constant and linear time trend), the prewhitened series can be obtained by running the following restricted ADF regression under the null hypothesis of a unit root ($\delta = 0$) and no intercept and linear time trend ($\mu_i = 0, \beta_i = 0$):

$$\Delta y_{it} = \sum_{L=1}^{\hat{p}_i} \theta_{iL} \Delta y_{it-L} + \mu_i + \varepsilon_{it}$$

¹⁰See the section "Levin, Lin, and Chu (2002)" on page 1441 for details. The only difference is the standard error estimate $\hat{\sigma}_{\varepsilon_i}^2$. Breitung suggests using $T - p_i - 2$ instead of $T - p_i - 1$ as in LLC to normalize the standard error.

where \hat{p}_i is a consistent estimator of the true lag order p_i and can be estimated by the procedures listed in the section “[Lag Order Selection in the ADF Regression](#)” on page 1443. For LLC and IPS tests, the lag orders are selected by running the ADF regressions. But for Breitung and his coauthors’ tests, the restricted ADF regressions are used to be consistent with the prewhitening method. Let $(\hat{\mu}_i, \hat{\theta}_{iL})$ be the estimated coefficients.¹¹ The prewhitened series can be obtained by

$$\Delta \hat{y}_{it} = \Delta y_{it} - \sum_{L=1}^{\hat{p}_i} \hat{\theta}_{iL} \Delta y_{it-L}$$

and

$$\hat{y}_{it} = y_{it} - \sum_{L=1}^{\hat{p}_i} \hat{\theta}_{iL} y_{it-L}$$

The transformed series are random walks under the null hypothesis,

$$\Delta \hat{y}_{it} = \delta \hat{y}_{i,t-1} + v_{it}$$

where $y_{is} = 0$ for $s < 0$. When the cross-section units are independent, the t statistic converges to standard normal under the null, as $T \rightarrow \infty$ followed by $N \rightarrow \infty$,

$$t_{OLS} = \frac{\sum_{i=1}^N \sum_{t=2}^T y_{i,t-1} \Delta y_{it}}{\hat{\sigma} \sqrt{\sum_{i=1}^N \sum_{t=2}^T y_{i,t-1}^2}} \Rightarrow \mathcal{N}(0, 1)$$

where $\hat{\sigma}^2 = \sum_{i=1}^N \sum_{t=2}^T (\Delta y_{it} - \hat{\delta} y_{i,t-1})^2 / N(T-1)$ with OLS estimator $\hat{\delta}$.

To take account for cross-sectional dependence, Breitung and Das (2005) propose the robust t statistic and a GLS version of the test statistic. Let $v_t = (v_{1t}, \dots, v_{Nt})'$ be the error vector for time t , and let $\Omega = E(v_t v_t')$ be a positive definite matrix with eigenvalues $\lambda_1 \geq \dots \geq \lambda_N$. Let $y_t = (y_{1t}, \dots, y_{Nt})'$ and $\Delta y_t = (\Delta y_{1t}, \dots, \Delta y_{Nt})'$. The model can be written as a SUR-type system of equations,

$$\Delta y_t = \delta y_{t-1} + v_t$$

The unknown covariance matrix Ω can be estimated by its sample counterpart,

$$\hat{\Omega} = \sum_{t=2}^T (\Delta y_t - \hat{\delta} y_{t-1}) (\Delta y_t - \hat{\delta} y_{t-1})' / (T-1)$$

The sequential limit $T \rightarrow \infty$ followed by $N \rightarrow \infty$ of the standard t statistic t_{OLS} is normal with mean 0 and variance $v_{\Omega} = \lim_{N \rightarrow \infty} \text{tr}(\Omega^2 / N) / (\text{tr} \Omega / N)^2$. The variance v_{Ω} can be consistently estimated by

$\hat{v}_{\hat{\delta}} = \left(\sum_{t=2}^T y'_{t-1} \hat{\Omega} y_{t-1} \right) / \left(\sum_{t=2}^T y'_{t-1} y_{t-1} \right)^2$. Thus the robust t statistic can be calculated as

$$t_{rob} = \frac{\hat{\delta}}{\hat{v}_{\hat{\delta}}} = \frac{\sum_{t=2}^T y'_{t-1} \Delta y_t}{\sqrt{\sum_{t=2}^T y'_{t-1} \hat{\Omega} y_{t-1}}} \Rightarrow \mathcal{N}(0, 1)$$

¹¹Breitung (2000) suggests the approach in step 1 of Levin, Lin, and Chu (2002), while Breitung and Das (2005) suggest the prewhitening method as described above. In Breitung’s code, to be consistent with the papers, different approaches are adopted for model (2) and (3). Meanwhile, for the order of variable transformation and prewhitening, in model (2), the initial values are deducted (variable transformation) first, and then the prewhitening was applied. For model (3), the order is reversed. The series is prewhitened and then transformed to remove the mean and linear time trend.

as $T \rightarrow \infty$ followed by $N \rightarrow \infty$ under the null hypothesis of random walk. Since the finite sample distribution can be quite different, Breitung and Das (2005) list the 1%, 5%, and 10% critical values for different N 's.

When $T > N$, a (feasible) GLS estimator is applied; it is asymptotically more efficient than the OLS estimator. The data are transformed by multiplying $\hat{\Omega}^{-1/2}$ as defined before, $\hat{z}_t = \hat{\Omega}^{-1/2} y_t$. Thus the model is transformed into

$$\Delta \hat{z}_t = \delta \hat{z}_{t-1} + e_t$$

The feasible GLS (FGLS) estimator of δ and the corresponding t statistic are obtained by estimating the transformed model by OLS and denoted by $\hat{\delta}_{GLS}$ and t_{GLS} , respectively:

$$t_{GLS} = \frac{\sum_{t=2}^T y'_{t-1} \hat{\Omega}^{-1} \Delta y_t}{\sqrt{\sum_{t=2}^T y'_{t-1} \hat{\Omega}^{-1} y_{t-1}}} \Rightarrow \mathcal{N}(0, 1)$$

Hadri (2000) Stationarity Tests

Hadri (2000) adopts a component representation where an individual time series is written as a sum of a deterministic trend, a random walk, and a white-noise disturbance term. Under the null hypothesis of stationary, the variance of the random walk equals 0. Specifically, two models are considered:

- For model (1), the time series y_{it} is stationary around a level r_{i0} ,

$$y_{it} = r_{it} + \epsilon_{it} \quad i = 1, \dots, N, \quad t = 1, \dots, T$$

- For model (2), y_{it} is trend stationary,

$$y_{it} = r_{it} + \beta_i t + \epsilon_{it} \quad i = 1, \dots, N, \quad t = 1, \dots, T$$

where r_{it} is the random walk component,

$$r_{it} = r_{it-1} + u_{it} \quad i = 1, \dots, N, \quad t = 1, \dots, T$$

The initial values of the random walks, $\{r_{i0}\}_{i=1, \dots, N}$, are assumed to be fixed unknowns and can be considered as heterogeneous intercepts. The errors ϵ_{it} and u_{it} satisfy $\epsilon_{it} \sim \text{iid}\mathcal{N}(0, \sigma_\epsilon^2)$, $u_{it} \sim \text{iid}\mathcal{N}(0, \sigma_u^2)$ and are mutually independent.

The null hypothesis of stationarity is $H_0 : \sigma_u^2 = 0$ against the alternative random walk hypothesis $H_1 : \sigma_u^2 > 0$.

In matrix form, the models can be written as

$$y_i = X_i \beta_i + e_i$$

where $y'_i = (y_{i1}, \dots, y_{iT})$, $e'_i = (e_{i1}, \dots, e_{iT})$ with $e_{it} = \sum_{j=1}^t u_{ij} + \epsilon_{it}$, and $X_i = (\iota_T, a_T)$ with ι_T being a $T \times 1$ vector of ones, $a'_T = (1, \dots, T)$, and $\beta'_i = (r_{i0}, \beta_i)$.

Let $\hat{\epsilon}_{it}$ be the residuals from the regression of y_i on X_i ; then the LM statistic is

$$LM = \frac{\frac{1}{N} \sum_{i=1}^N \frac{1}{T^2} \sum_{t=1}^T S_{it}^2}{\hat{\sigma}_\epsilon^2}$$

where $S_{it} = \sum_{j=1}^t \hat{\epsilon}_{ij}$ is the partial sum of the residuals and $\hat{\sigma}_\epsilon^2$ is a consistent estimator of σ_ϵ^2 under the null hypothesis of stationarity. With some regularity conditions,

$$LM \xrightarrow{p} E \left[\int_0^1 V^2(r) dr \right]$$

where $V(r)$ is a standard Brownian bridge in model (1) and a second-level Brownian bridge in model (2). Let $W(r)$ be a standard Wiener process (Brownian motion),

$$V(r) = \begin{cases} W(r) - rW(1) & \text{for model (1)} \\ W(r) + (2r - 3r^2)W(1) + 6r(r-1) \int_0^1 W(s) ds & \text{for model (2)} \end{cases}$$

The mean and variance of the random variable $\int V^2$ can be calculated by using the characteristic functions,

$$\xi = E \left[\int_0^1 V^2(r) dr \right] = \begin{cases} \frac{1}{6} & \text{for model (1)} \\ \frac{1}{15} & \text{for model (2)} \end{cases}$$

and

$$\zeta^2 = \text{var} \left[\int_0^1 V^2(r) dr \right] = \begin{cases} \frac{1}{45} & \text{for model (1)} \\ \frac{11}{6300} & \text{for model (2)} \end{cases}$$

The LM statistics can be standardized to obtain the standard normal limiting distribution,

$$Z = \frac{\sqrt{N} (LM - \xi)}{\zeta} \implies \mathcal{N}(0, 1)$$

Consistent Estimator of σ_ϵ^2

Hadri's (2000) test can be applied to the general case of heteroscedasticity and serially correlated disturbance errors. Under homoscedasticity and serially uncorrelated errors, σ_ϵ^2 can be estimated as

$$\hat{\sigma}_\epsilon^2 = \sum_{i=1}^N \sum_{t=1}^T \hat{\epsilon}_{it}^2 / N(T-k)$$

where k is the number of regressors. Therefore, $k = 1$ for model (1) and $k = 2$ for model (2).

When errors are heteroscedastic across individuals, the standard errors $\sigma_{\epsilon,i}^2$ can be estimated by $\hat{\sigma}_{\epsilon,i}^2 = \sum_{t=1}^T \hat{\epsilon}_{it}^2 / (T-k)$ for each individual i and the LM statistic needs to be modified to

$$LM = \frac{1}{N} \sum_{i=1}^N \left(\frac{\frac{1}{T^2} \sum_{t=1}^T S_{it}^2}{\hat{\sigma}_{\epsilon,i}^2} \right)$$

To allow for temporal dependence over t , σ_ϵ^2 has to be replaced by the long-run variance of ϵ_{it} , which is defined as $\sigma^2 = \sum_{i=1}^N \lim_{T \rightarrow \infty} T^{-1} (S_{iT}^2) / N$. A HAC estimator can be used to consistently estimate the long-run variance σ^2 . For more information, see the section “[Long-Run Variance Estimation](#)” on page 1443.

Harris and Tzavalis (1999) Panel Unit Root Tests (Experimental)

Harris and Tzavalis (1999) derive the panel unit root test under fixed T and large N . Three models are considered as in Levin, Lin, and Chu (2002). Model (1) is the homogeneous panel,

$$y_{it} = \varphi y_{it-1} + v_{it}$$

Under the null hypothesis, $\varphi = 0$. For model (2), each series is a unit root process with a heterogeneous drift,

$$y_{it} = \alpha_i + \varphi y_{it-1} + v_{it}$$

Model (3) includes heterogeneous drifts and linear time trends,

$$y_{it} = \alpha_i + \beta_i t + \varphi y_{it-1} + v_{it}$$

Under the null hypothesis $H_0 : \varphi = 1, \beta_i = 0$, so the series is random walks with drift.

Let $\hat{\varphi}$ be the OLS estimator of φ ; then

$$\hat{\varphi} - 1 = \left[\sum_{i=1}^N y'_{i,-1} Q_T y_{i,-1} \right]^{-1} \cdot \left[\sum_{i=1}^N y'_{i,-1} Q_T v_i \right]$$

where $y_{i,-1} = (y_{i0}, \dots, y_{iT-1})$, $v'_i = (v_{i1}, \dots, v_{iT})$, and Q_T is the projection matrix. For model (1), there are no regressors other than the lagged dependent value, so Q_T is the identity matrix I_T . For model (2), a constant is included, so $Q_T = I_T - e_T e'_T / T$ with e_T a $T \times 1$ column of ones. For model (3), a constant and time trend are included. Thus $Q_T = I_T - Z_T (Z'_T Z_T)^{-1} Z'_T / T$, where $Z_T = (e_T, \tau_T)$ and $\tau_T = (1, \dots, T)$.

When $y_{i0} = 0$ in model (1) under the null hypothesis,

$$\sqrt{NT(T-1)/2} (\hat{\varphi} - 1) \xrightarrow{y_{i0}=0, H_0} \mathcal{N}(0, 1)$$

As $T \rightarrow \infty$, it becomes $T \sqrt{N} (\hat{\varphi} - 1) \xrightarrow{H_0} \mathcal{N}(0, 1)$.

When the drift is absent in model (2) under the null hypothesis, $\alpha_i = 0$,

$$\sqrt{\frac{5N(T+1)^3(T-1)}{3(17T^2 - 20T + 17)}} \left(\hat{\varphi} - 1 - \frac{3}{(T+1)} \right) \xrightarrow{H_0} \mathcal{N}(0, 1)$$

As T grows large, $(T \sqrt{N} (\hat{\varphi} - 1) + 3\sqrt{N}) / \sqrt{51/5} \xrightarrow{H_0} \mathcal{N}(0, 1)$.

When the time trend is absent in model (3) under the null hypothesis, $\beta_i = 0$,

$$\sqrt{\frac{112N(T+2)^3(T-2)}{15(193T^2 - 728T + 1147)}} \left(\hat{\varphi} - 1 - \frac{15}{2(T+2)} \right) \xrightarrow{H_0} \mathcal{N}(0, 1)$$

When T is sufficiently large, it implies $(T \sqrt{N} (\hat{\varphi} - 1) + 7.5\sqrt{N}) / \sqrt{2895/112} \xrightarrow{H_0} \mathcal{N}(0, 1)$.

Troubleshooting

You need to follow some guidelines when you use PROC PANEL for analysis. For each cross section, PROC PANEL requires at least two time series observations that have nonmissing values for all model variables. There should be at least two cross sections for each time point in the data. If these two conditions are not met, then an error message is printed in the log that states that there is only one cross section or time series observation and further computations will be terminated. You must provide adequate data for an estimation method to produce results, and you should check the log for any errors that are related to data.

If PROC PANEL uses the Parks method and the number of cross sections is greater than the number of time series observations per cross section, then PROC PANEL produces an error message that states that the ϕ matrix is singular. This is analogous to seemingly unrelated regression that has fewer observations than equations in the model. To avoid the problem, reduce the number of cross sections.

Your data set could have multiple observations for each time ID within a particular cross section. However, you can use PROC PANEL only in cases where you have only a single observation for each time ID within each cross section. In such a case, after you have sorted the data, an error warning is printed in the log that states that the data have not been sorted in ascending sequence with respect to time series ID.

The cause of the error is due to multiple observations for each time ID for a given cross section. PROC PANEL allows only one observation for each time ID within each cross section.

The following data set shown in [Figure 20.2](#) illustrates the preceding instance with the correct representation.

Figure 20.2 Single Observation for Each Time Series

Obs	firm	year	production	cost
1	1	1955	5.36598	1.14867
2	1	1960	6.03787	1.45185
3	1	1965	6.37673	1.52257
4	1	1970	6.93245	1.76627
5	2	1955	6.54535	1.35041
6	2	1960	6.69827	1.71109
7	2	1965	7.40245	2.09519
8	2	1970	7.82644	2.39480

In this case, you can observe that there are no multiple observations with respect to a given time series ID within a cross section. This is the correct representation of a data set where PROC PANEL is applicable.

If for state ID 1 you have two observations for the year=1955, then PROC PANEL produces the following error message:

“The data set is not sorted in ascending sequence with respect to time series ID. The current time period has year=1955 and the previous time period has year=1955 in cross section firm=1.”

A data set similar to the previous example with multiple observations for the YEAR=1955 is shown in [Figure 20.3](#); this data set results in an error message due to multiple observations while using PROC PANEL.

Figure 20.3 Multiple Observations for Each Time Series

Obs	firm	year	production	cost
1	1	1955	5.36598	1.14867
2	1	1955	6.37673	1.52257
3	1	1960	6.03787	1.45185
4	1	1970	6.93245	1.76627
5	2	1955	6.54535	1.35041
6	2	1960	6.69827	1.71109
7	2	1965	7.40245	2.09519
8	2	1970	7.82644	2.39480

In order to use PROC PANEL, you need to aggregate the data so that you have unique time ID values within each cross section. One possible way to do this is to run a PROC MEANS on the input data set and compute the mean of all the variables by FIRM and YEAR, and then use the output data set.

Creating ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the PANEL procedure. The table below lists the graph names, the plot descriptions, and the options used.

Table 20.6 ODS Graphics Produced by PROC PANEL

ODS Graph Name	Plot Description	Plots=Option
DiagnosticsPanel	All applicable plots listed below	
ResidualPlot	Plot of the residuals	RESIDUAL, RESID
FitPlot	Predicted versus actual plot	FITPLOT
QQPlot	Plot of the quantiles of the residuals	QQ
ResidSurfacePlot	Surface plot of the residuals	RESIDSURFACE
PredSurfacePlot	Surface plot of the predicted values	PREDSURFACE
ActSurfacePlot	Surface plot of the actual values	ACTSURFACE
ResidStackPlot	Stack plot of the residuals	RESIDSTACK, RESSTACK
ResidHistogram	Plot of the histogram of residuals	RESIDUALHISTOGRAM, RESIDHISTOGRAM

OUTPUT OUT= Data Set

PROC PANEL writes the initial data of the estimated model, predicted values, and residuals to an output data set when the OUTPUT OUT= statement is specified. The OUT= data set contains the following variables:

<code>_MODELL_</code>	is a character variable that contains the label for the MODEL statement if a label is specified.
<code>_METHOD_</code>	is a character variable that identifies the estimation method.
<code>_MODLNO_</code>	is the number of the model estimated.
<code>_ACTUAL_</code>	contains the value of the dependent variable.
<code>_WEIGHT_</code>	contains the weighing variable.
<code>_CSID_</code>	is the value of the cross section ID.
<code>_TSID_</code>	is the value of the time period in the dynamic model.
regressors	are the values of regressor variables specified in the MODEL statement.
<i>name</i>	if PRED= <i>name1</i> and/or RESIDUAL= <i>name2</i> options are specified, then <i>name1</i> and <i>name2</i> are the columns of predicted values of dependent variable and residuals of the regression, respectively.

OUTEST= Data Set

PROC PANEL writes the parameter estimates to an output data set when the OUTEST= option is specified. The OUTEST= data set contains the following variables:

<code>_MODEL_</code>	is a character variable that contains the label for the MODEL statement if a label is specified.
<code>_METHOD_</code>	is a character variable that identifies the estimation method.
<code>_TYPE_</code>	is a character variable that identifies the type of observation. Values of the <code>_TYPE_</code> variable are CORR, COVB, CSPARMS, STD, and the type of model estimated. The CORR observation contains correlations of the parameter estimates, the COVB observation contains covariances of the parameter estimates, the CSPARMS observation contains cross-sectional parameter estimates, the STD observation indicates the row of standard deviations of the corresponding coefficients, and the type of model estimated observation contains the parameter estimates.
<code>_NAME_</code>	is a character variable that contains the name of a regressor variable for COVB and CORR observations and is left blank for other observations. The <code>_NAME_</code> variable is used in conjunction with the <code>_TYPE_</code> values COVB and CORR to identify rows of the correlation or covariance matrix.
<code>_DEPVAR_</code>	is a character variable that contains the name of the response variable.
<code>_MSE_</code>	is the mean square error of the transformed model.

<code>_CSID_</code>	is the value of the cross section ID for CSPARMS observations. The <code>_CSID_</code> variable is used with the <code>_TYPE_</code> value CSPARMS to identify the cross section for the first-order autoregressive parameter estimate contained in the observation. The <code>_CSID_</code> variable is missing for observations with other <code>_TYPE_</code> values. (Currently, only the <code>_A_1</code> variable contains values for CSPARMS observations.)
<code>_VARCS_</code>	is the variance component estimate due to cross sections. The <code>_VARCS_</code> variable is included in the OUTEST= data set when a one-way or two-way random effects models is estimated.
<code>_VARTS_</code>	is the variance component estimate due to time series. The <code>_VARTS_</code> variable is included in the OUTEST= data set when a two-way random effects model is estimated.
<code>_VARERR_</code>	is the variance component estimate due to error. The <code>_VARERR_</code> variable is included in the OUTEST= data set when a one-way or two-way random effects models is estimated.
<code>_A_1</code>	is the first-order autoregressive parameter estimate. The <code>_A_1</code> variable is included in the OUTEST= data set when the PARKS option is specified. The values of <code>_A_1</code> are cross-sectional parameters, meaning that they are estimated for each cross section separately. The <code>_A_1</code> variable has a value only for <code>_TYPE_=CSPARMS</code> observations. The cross section to which the estimate belongs is indicated by the <code>_CSID_</code> variable.
Intercept	is the intercept parameter estimate. (Intercept is missing for models when the NOINT option is specified.)
regressors	are the regressor variables specified in the MODEL statement. The regressor variables in the OUTEST= data set contain the corresponding parameter estimates for the model identified by <code>_MODEL_</code> for <code>_TYPE_=PARMS</code> observations, and the corresponding covariance or correlation matrix elements for <code>_TYPE_=COVB</code> and <code>_TYPE_=CORRB</code> observations. The response variable contains the value-1 for the <code>_TYPE_=PARMS</code> observation for its model.

OUTTRANS= Data Set

PROC PANEL writes the transformed series to an output data set. That is, if the user selects FIXONE, FIXONETIME, or RANONE and supplies the OUTTRANS = option, the transformed dependent variable and independent variables are written out to a SAS data set; other variables in the input data set are copied unchanged.

Say that your data set contains variables `y`, `x1`, `x2`, `x3`, and `z2`. The following statements result in a SAS data set:

```
proc panel data=datain outtrans=dataout;
    id cs ts;
    model y = x1 x2 x3 / fixone;
run;
```

First, `z2` is copied over. Then `_Int`, `x1`, `x2`, `y`, and `x3`, are replaced with their mean deviates (from cross sections). Furthermore, two new variables are created.

<code>_MODEL_</code>	is the model's label (if it exists).
<code>_METHOD_</code>	is the model's transformation type. In the <code>FIXONE</code> case, this is <code>_FIXONE_</code> or <code>_FIXONE-TIME_</code> . If the model <code>RANONE</code> model is selected, the <code>_METHOD_</code> variable is either <code>_Ran1FB_</code> , <code>_Ran1WK_</code> , <code>_Ran1WH_</code> , or <code>_Ran1NL_</code> , depending on the variance component estimators chosen.

Printed Output

For each `MODEL` statement, the printed output from `PROC PANEL` includes the following:

- a model description, which gives the estimation method used, the model statement label if specified, the number of cross sections and the number of observations in each cross section, and the order of moving average error process for the `DASILVA` option. For fixed-effects model analysis, an F test for the absence of fixed effects is produced, and for random-effects model analysis, a Hausman test is used for the appropriateness of the random-effects specification.
- the estimates of the underlying error structure parameters
- the regression parameter estimates and analysis. For each regressor, this includes the name of the regressor, the degrees of freedom, the parameter estimate, the standard error of the estimate, a t statistic for testing whether the estimate is significantly different from 0, and the significance probability of the t statistic.

Optionally, `PROC PANEL` prints the following:

- the covariance and correlation of the resulting regression parameter estimates for each model and assumed error structure
- the $\hat{\Phi}$ matrix that is the estimated contemporaneous covariance matrix for the `PARKS` option

ODS Table Names

`PROC PANEL` assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in [Table 20.7](#).

Example: PANEL Procedure

Example 20.1: Analyzing Demand for Liquid Assets

In this example, the demand equations for liquid assets are estimated. The demand function for the demand deposits is estimated under three error structures while demand equations for time deposits and savings and loan (S&L) association shares are calculated using the Parks method. The data for seven states (CA, DC, FL, IL, NY, TX, and WA) are selected out of 49 states. See Feige (1964) for data description. All variables were transformed via natural logarithm. The data set A is shown below.

```
data a;
  length state $ 2;
  input state $ year d t s y rd rt rs;
  label d = 'Per Capita Demand Deposits'
        t = 'Per Capita Time Deposits'
        s = 'Per Capita S & L Association Shares'
        y = 'Permanent Per Capita Personal Income'
        rd = 'Service Charge on Demand Deposits'
        rt = 'Interest on Time Deposits'
        rs = 'Interest on S & L Association Shares';
datalines;
CA  1949  6.2785  6.1924  4.4998  7.2056 -1.0700  0.1080  1.0664
CA  1950  6.4019  6.2106  4.6821  7.2889 -1.0106  0.1501  1.0767
CA  1951  6.5058  6.2729  4.8598  7.3827 -1.0024  0.4008  1.1291
CA  1952  6.4785  6.2729  5.0039  7.4000 -0.9970  0.4492  1.1227
CA  1953  6.4118  6.2538  5.1761  7.4200 -0.8916  0.4662  1.2110
CA  1954  6.4520  6.2971  5.3613  7.4478 -0.6951  0.4756  1.1924

... more lines ...
```

As shown in the following statements, the SORT procedure is used to sort the data into the required time series cross-sectional format; then PROC PANEL analyzes the data.

```
proc sort data=a;
  by state year;
run;

proc panel data=a;
  model d = y rd rt rs / fuller parks dasilva m=7;
  model t = y rd rt rs / parks;
  model s = y rd rt rs / parks;
  id state year;
run;
```

The income elasticities for liquid assets are greater than 1 except for the demand deposit income elasticity (0.692757) estimated by the Da Silva method. In [Output 20.1.1](#), [Output 20.1.2](#), and [Output 20.1.3](#), the coefficient estimates (−0.29094, −0.43591, and −0.27736) of demand deposits (RD) imply that demand deposits increase significantly as the service charge is reduced. The price elasticities (0.227152 and 0.408066) for time deposits (RT) and S&L association shares (RS) have the expected sign. Thus an increase in the interest rate on time deposits or S&L shares will increase the demand for the corresponding liquid asset. Demand deposits and S&L shares appear to be substitutes (see [Output 20.1.2](#), [Output 20.1.3](#), and [Output 20.1.5](#)). Time deposits are also substitutes for S&L shares in the time deposit demand equation (see [Output 20.1.4](#)), while these liquid assets are independent of each other in [Output 20.1.5](#) (insignificant coefficient estimate of RT, −0.02705). Demand deposits and time deposits appear to be weak complements in [Output 20.1.3](#) and [Output 20.1.4](#), while the cross elasticities between demand deposits and time deposits are not significant in [Output 20.1.2](#) and [Output 20.1.5](#).

Example 20.2: The Airline Cost Data: Fixtwo Model

The Christenson Associates airline data are a frequently cited data set (see Greene 2000). The data measure costs, prices of inputs, and utilization rates for six airlines over the time span 1970–1984. This example analyzes the log transformations of the cost, price and quantity, and the raw (not logged) capacity utilization measure. You speculate the following model:

$$\ln(TC_{it}) = \alpha_N + \gamma_T + (\alpha_i - \alpha_N) + (\gamma_t - \gamma_T) + \beta_1 \ln(Q_{it}) + \beta_2 \ln(PF_{it}) + \beta_3 LF_{it} + \epsilon_{it}$$

where the α are the pure cross-sectional effects and γ are the time effects. The actual model speculated is highly nonlinear in the original variables. It would look like the following:

$$TC_{it} = \exp(\alpha_i + \gamma_t + \beta_3 LF_{it} + \epsilon_{it}) Q_{it}^{\beta_1} PF_{it}^{\beta_2}$$

The data and preliminary SAS statements are:

```
data airline;
  input  Obs I T C Q PF LF;
  label obs = "Observation number";
  label I   = "Firm Number (CSID)";
  label T   = "Time period (TSID)";
  label Q   = "Output in revenue passenger miles (index)";
  label C   = "Total cost, in thousands";
  label PF  = "Fuel price";
  label LF  = "Load Factor (utilization index)";
datalines;
1    1    1    1140640    0.95276    106650    0.53449
... more lines ...
```

```

data airline;
  set airline;
  lC = log(C);
  lQ = log(Q);
  lPF = log(PF);
  label lC = "Log transformation of costs";
  label lQ = "Log transformation of quantity";
  label lPF= "Log transformation of price of fuel";
run;

```

The following statements fit the model.

```

proc panel data=airline printfixed;
  id i t;
  model lC = lQ lPF LF / fixtwo;
run;

```

First, you see the model's description in [Output 20.2.1](#). The model is a two-way fixed-effects model. There are six cross sections and fifteen time observations.

Output 20.2.1 The Airline Cost Data—Model Description

<p style="text-align: center;">The PANEL Procedure Fixed Two Way Estimates</p>	
<p>Dependent Variable: lC Log transformation of costs</p>	
<p style="text-align: center;">Model Description</p>	
Estimation Method	FixTwo
Number of Cross Sections	6
Time Series Length	15

The R-square and degrees of freedom can be seen in [Table 20.2.2](#). On the whole, you see a large R-square, so there is a reasonable fit. The degrees of freedom of the estimate are 90 minus 14 time dummy variables minus 5 cross section dummy variables and 4 regressors.

Output 20.2.2 The Airline Cost Data—Fit Statistics

Fit Statistics			
SSE	0.1768	DFE	67
MSE	0.0026	Root MSE	0.0514
R-Square	0.9984		

The F test for fixed effects is shown in [Table 20.2.3](#). Testing the hypothesis that there are no fixed effects, you easily reject the null of poolability. There are group effects, or time effects, or both. The test is highly significant. OLS would not give reasonable results.

Output 20.2.3 The Airline Cost Data—Test for Fixed Effects

F Test for No Fixed Effects			
Num DF	Den DF	F Value	Pr > F
19	67	23.10	<.0001

Looking at the parameters, you see a more complicated pattern. Most of the cross-sectional effects are highly significant (with the exception of CS2). This means that the cross sections are significantly different from the sixth cross section. Many of the time effects show significance, but this is not uniform. It looks like the significance might be driven by a large 16th period effect, since the first six time effects are negative and of similar magnitude. The time dummy variables taper off in size and lose significance from time period 12 onward. There are many causes to which you could attribute this decay of time effects. The time period of the data spans the OPEC oil embargoes and the dissolution of the Civil Aeronautics Board (CAB). These two forces are two possible reasons to observe the decay and parameter instability. As for the regression parameters, you see that quantity affects cost positively, and the price of fuel has a positive effect, but load factors negatively affect the costs of the airlines in this sample. The somewhat disturbing result is that the fuel cost is not significant. If the time effects are proxies for the effect of the oil embargoes, then an insignificant fuel cost parameter would make some sense. If the dummy variables proxy for the dissolution of the CAB, then the effect of load factors is also not being precisely estimated.

ODS Graphics Plots

ODS graphics plots can be obtained to graphically analyze the results. The following statements show how to generate the plots. If the PLOTS=ALL option is specified, all available plots are produced in two panels. For a complete list of options, see the section “Creating ODS Graphics” on page 1453.

```
proc panel data=airline;
  id i t;
  model lC = lQ lPF LF / fixtwo plots = all;
run;
```

The preceding statements result in plots shown in [Output 20.2.5](#) and [Output 20.2.6](#).

Output 20.2.5 Diagnostic Panel 1

Output 20.2.6 Diagnostic Panel 2

The UNPACK and ONLY options produce individual detail images of paneled plots. The graph shown in [Output 20.2.7](#) shows a detail plot of residuals by cross section. The packed version always puts all cross sections on one plot while the unpacked one shows the cross sections in groups of ten to avoid loss of detail.

```
proc panel data=airline;
  id i t;
  model lC = lQ lPF lF / fixtwo plots(unpack only) = residsurface;
run;
```

Output 20.2.7 Surface Plot of the Residual

Example 20.3: The Airline Cost Data: Further Analysis

Using the same data as in [Example 20.2](#), you further investigate the ‘true’ effect of fuel prices. Specifically, you run the FixOne model, ignoring time effects. You specify the following statements in PROC PANEL to run this model:

```
proc panel data=airline;
  id i t;
  model lC = lQ lPF LF / fixone;
run;
```

The preceding statements result in [Output 20.3.1](#). The fit seems to have deteriorated somewhat. The SSE rises from 0.1768 to 0.2926.

Output 20.3.1 The Airline Cost Data—Fit Statistics

The PANEL Procedure			
Fixed One Way Estimates			
Dependent Variable: lC Log transformation of costs			
Fit Statistics			
SSE	0.2926	DFE	81
MSE	0.0036	Root MSE	0.0601
R-Square	0.9974		

You still reject poolability based on the F test in [Output 20.3.2](#) at all accepted levels of significance.

Output 20.3.2 The Airline Cost Data—Test for Fixed Effects

F Test for No Fixed Effects			
Num DF	Den DF	F Value	Pr > F
5	81	57.74	<.0001

The parameters change somewhat dramatically as shown in [Output 20.3.3](#). The effect of fuel costs comes in very strong and significant. The load factor's coefficient increases, although not as dramatically. This suggests that the fixed time effects might be proxies for both the oil shocks and deregulation.

Output 20.3.3 The Airline Cost Data—Parameter Estimates

Parameter Estimates						
Variable	DF	Estimate	Standard Error	t Value	Pr > t	Label

Example 20.4: The Airline Cost Data: Random-Effects Models

This example continues to use the Christenson Associates airline data, which measures costs, prices of inputs, and utilization rates for six airlines over the time span 1970–1984. There are six cross sections and fifteen time observations. Here, you examine the different estimates generated from the one-way random-effects and two-way random-effects models, by using four different methods to estimate the variance components: Fuller and Battese, Wansbeek and Kapteyn, Wallace and Hussain, and Nerlove.

The data for this example is created by the PROC PANEL statements shown in [Example 20.2](#). The PROC PANEL statements necessary to generate the estimates are as follows:

```
proc panel data=airline outest=estimates;
  id I T;
  RANONE:   model lC = lQ lPF lF / ranone vcomp=fb;
  RANONEwk: model lC = lQ lPF lF / ranone vcomp=wk;
  RANONEwh: model lC = lQ lPF lF / ranone vcomp=wh;
  RANONEnl: model lC = lQ lPF lF / ranone vcomp=nl;
  RANTWO:   model lC = lQ lPF lF / rantwo vcomp=fb;
  RANTWOwk: model lC = lQ lPF lF / rantwo vcomp=wk;
  RANTWOwh: model lC = lQ lPF lF / rantwo vcomp=wh;
  RANTWOnl: model lC = lQ lPF lF / rantwo vcomp=nl;
  POOLED:   model lC = lQ lPF lF / pooled;
  BTWNG:    model lC = lQ lPF lF / btwng;
  BTWNT:    model lC = lQ lPF lF / btwnt;
run;

data table;
  set estimates;
  VarCS = round(_VARCS_, .00001);
  VarTS = round(_VARTS_, .00001);
  VarErr = round(_VARERR_, .00001);
  Int = round(Intercept, .0001);
  lQ2 = round(lQ, .0001);
  lPF2 = round(lPF, .0001);
  lF2 = round(lF, .0001);
  if _n_ >= 9 then do;
    VarCS = . ;
    VarTS = . ;
  end;
  keep _MODEL_ _METHOD_ VarCS VarTS VarErr Int lQ2 lPF2 lF2;
run;
```

The parameter estimates and variance components for both models are reported in [Output 20.4.1](#) and [Output 20.4.2](#).

In the random-effects model, individual constant terms are viewed as randomly distributed across cross-sectional units and not as parametric shifts of the regression function, as in the fixed-effects model. This is appropriate when the sampled cross-sectional units are drawn from a large population. Clearly, in this example, the six airlines are a sample of all the airlines in the industry and not an exhaustive, or nearly exhaustive, list.

There are four ways of computing the variance components in the one-way random-effects model. The method by Fuller and Battese (1974) (FB), uses a “fitting of constants” methods to estimate them. The Wansbeek and Kapteyn (1989) (WK) method uses the true disturbances, while the Wallace and Hussain (WH) method uses ordinary least squares residuals.

Looking at the estimates of the variance components for cross section and error in [Output 20.4.2](#), you see that equal variance components for error are computed for both FB and WK, while WH and NL are nearly equal.

All four techniques produce different variance components for cross sections. These estimates are then used to estimate the values of the parameters in [Output 20.4.1](#). All the parameters appear to have similar and equally plausible estimates. Both the index for output in revenue passenger miles (IQ) and fuel price (IPF) have small, positive effects on total costs, which you would expect. The load factor (LF) has a somewhat larger and negative effect on total costs, suggesting that as utilization increases, costs decrease.

As in the one-way random-effects model, the variance components for error produced by the FB and WK methods are equal. However, in this case, the WH and NL methods produce variance estimates that are dissimilar. The estimates of the variance component for cross sections are all different, but in a close range. The same cannot be said for the variance component for time series. As varied as each of the variance estimates may be, they produce parameter estimates that are similar and plausible. As with the one-way effects model, the index for output (IQ) and fuel price (IPF) are small and positive. The load factor (LF) estimates are all negative and, with the exception of the estimate produced by the WH method, somewhat smaller than the estimates produced in the one-way model. During the time the data were collected, the Civil Aeronautics Board dissolved, so it is possible that the dummy variables are proxies for this dissolution. This would lead to the decay of time effects and an imprecise estimation of the effects of the load factors, even though the estimates are statistically significant.

The pooled estimates give you something to compare the random-effects estimates against. You see that signs and magnitudes of output and fuel price are similar but that the magnitude of the load factor coefficient is somewhat larger under pooling. Since the model appears to have both cross-sectional and time series effects, the pooled model should not be used.

Finally, you examine the between groups estimators. For the between groups estimate, you are looking at each airline's data averaged across time. You see in [Output 20.4.1](#) that the between groups parameter estimates are radically different from all other parameter estimates. This could indicate that the time component is not being appropriately handled with this technique. For the between times estimate, you are looking at the average across all airlines in each time period. In this case, the parameter estimates are of the same sign and closer in magnitude to the previously computed estimates. Both the output and load factor effects appear to have more bearing on total costs.

Example 20.5: Using the FLATDATA Statement

Sometimes the data can be found in compressed form, where each line consists of all observations for the dependent and independent variables for the cross section. To illustrate, suppose you have a data set with 20 cross sections where each cross section consists of observations for six time periods. Each time period has values for dependent and independent variables $Y_1 \dots Y_6$ and $X_1 \dots X_6$. The *cs* and *num* variables represent other character and numeric variables that are constant across each cross section.

The observations for first five cross sections along with other variables are shown in [Output 20.5.1](#). In this example, *i* represents the cross section. The time period is identified by the subscript on the *Y* and *X* variables; it ranges from 1 to 6.

Output 20.5.1 Compressed Data Set

Since the PANEL procedure cannot work directly with the data in compressed form, the FLATDATA statement can be used to transform the data. The OUT= option can be used to output transformed data to a data set.

```
proc panel data=flattest;
  flatdata indid=i tsname="t" base=(X Y)
    keep=( cs num seed ) / out=flat_out;
  id i t;
  model y = x / fixone noint;
run;
```

First, six observations for the uncompressed data set and results for the one-way fixed-effects model fitted are shown in [Output 20.5.2](#) and [Output 20.5.3](#).

Output 20.5.2 Uncompressed Data Set

Example 20.6: The Cigarette Sales Data: Dynamic Panel Estimation with GMM

In this example, a dynamic panel demand model for cigarette sales is estimated. It illustrates the application of the method described in the section “[Dynamic Panel Estimator](#)” on page 1423. The data are a panel from 46 American states over the period 1963–92. For data description see: Baltagi and Levin (1992); Baltagi (1995). All variables were transformed by taking the natural logarithm. The data set CIGAR is shown in the following statements.

```
data cigar;
  input state year price pop pop_16 cpi ndi sales pimin;
  label
    state = 'State abbreviation'
    year = 'YEAR'
    price = 'Price per pack of cigarettes'
    pop = 'Population'
    pop_16 = 'Population above the age of 16'
    cpi = 'Consumer price index with (1983=100)'
    ndi = 'Per capita disposable income'
    sales = 'Cigarette sales in packs per capita'
    pimin = 'Minimum price in adjoining states per pack of cigarettes';
datalines;

... more lines ...
```

The following statements sort the data by STATE and YEAR variables.

```
proc sort data=cigar;
  by state year;
run;
```

Next, logarithms of the variables required for regression estimation are calculated, as shown in the following statements:

```
data cigar;
  set cigar;
  lsales = log(sales);
  lprice = log(price);
  lndi = log(ndi);
  lpimin = log(pimin);
  label lprice = 'Log price per pack of cigarettes';
  label lndi = 'Log per capita disposable income';
  label lsales = 'Log cigarette sales in packs per capita';
  label lpimin = 'Log minimum price in adjoining states
                  per pack of cigarettes';
run;
```

The following statements create the CIGAR_LAG data set with lagged variable for each cross section.

```
proc panel data=cigar;
  id state year;
  clag lsales(1) / out=cigar_lag;
run;

data cigar_lag;
  set cigar_lag;
  label lsales_1 = 'Lagged log cigarette sales in packs per capita';
run;
```

Finally, the model is estimated by a two step GMM method. Five lags (MAXBAND=5) of the dependent variable are used as instruments. NOLEVELS options is specified to avoid use of level equations, as shown in the following statements:

```
proc panel data=cigar_lag;
  inst depvar;
  model lsales = lsales_1 lprice lndi lpimin
    / gmm2 nolevels maxband=5 noint;
  id state year;
run;
```

Output 20.6.1 Estimation with GMM

Overview: PDLREG Procedure

The PDLREG procedure estimates regression models for time series data in which the effects of some of the regressor variables are distributed across time. The distributed lag model assumes that the effect of an input variable X on an output Y is distributed over time. If you change the value of X at time t , Y will experience some immediate effect at time t , and it will also experience a delayed effect at times $t + 1$, $t + 2$, and so on up to time $t + p$ for some limit p .

The regression model supported by PROC PDLREG can include any number of regressors with distribution lags and any number of covariates. (Simple regressors without lag distributions are called covariates.) For example, the two-regressor model with a distributed lag effect for one regressor is written

$$y_t = \alpha + \sum_{i=0}^p \beta_i x_{t-i} + \gamma z_t + u_t$$

Here, x_t is the regressor with a distributed lag effect, z_t is a simple covariate, and u_t is an error term.

The distribution of the lagged effects is modeled by Almon lag polynomials. The coefficients b_i of the lagged values of the regressor are assumed to lie on a polynomial curve. That is,

$$b_i = \alpha_0^* + \sum_{j=1}^d \alpha_j^* i^j$$

where $d(\leq p)$ is the degree of the polynomial. For the numerically efficient estimation, the PDLREG procedure uses *orthogonal polynomials*. The preceding equation can be transformed into orthogonal polynomials:

$$b_i = \alpha_0 + \sum_{j=1}^d \alpha_j f_j(i)$$

where $f_j(i)$ is a polynomial of degree j in the lag length i , and α_j is a coefficient estimated from the data.

The PDLREG procedure supports endpoint restrictions for the polynomial. That is, you can constrain the estimated polynomial lag distribution curve so that $b_{-1} = 0$ or $b_{p+1} = 0$, or both. You can also impose linear restrictions on the parameter estimates for the covariates.

You can specify a minimum degree and a maximum degree for the lag distribution polynomial, and the procedure fits polynomials for all degrees in the specified range. (However, if distributed lags are specified for more than one regressor, you can specify a range of degrees for only one of them.)

The PDLREG procedure can also test for autocorrelated residuals and perform autocorrelated error correction by using the autoregressive error model. You can specify any order autoregressive error model and can specify several different estimation methods for the autoregressive model, including exact maximum likelihood.

The PDLREG procedure computes generalized Durbin-Watson statistics to test for autocorrelated residuals. For models with lagged dependent variables, the procedure can produce Durbin h and Durbin t statistics. You can request significance level p -values for the Durbin-Watson, Durbin h , and Durbin t statistics. See Chapter 8, “[The AUTOREG Procedure](#),” for details about these statistics.

The PDLREG procedure assumes that the input observations form a time series. Thus, the PDLREG procedure should be used only for ordered and equally spaced time series data.

Getting Started: PDLREG Procedure

Use the MODEL statement to specify the regression model. The PDLREG procedure’s MODEL statement is written like MODEL statements in other SAS regression procedures, except that a regressor can be followed by a lag distribution specification enclosed in parentheses.

For example, the following MODEL statement regresses Y on X and Z and specifies a distributed lag for X:

```
model y = x(4,2) z;
```

The notation X(4,2) specifies that the model includes X and 4 lags of X, with the coefficients of X and its lags constrained to follow a second-degree (quadratic) polynomial. Thus, the regression model specified by this MODEL statement is

$$y_t = a + b_0 x_t + b_1 x_{t-1} + b_2 x_{t-2} + b_3 x_{t-3} + b_4 x_{t-4} + c z_t + u_t$$

$$b_i = \alpha_0 + \alpha_1 f_1(i) + \alpha_2 f_2(i)$$

where $f_1(i)$ is a polynomial of degree 1 in i and $f_2(i)$ is a polynomial of degree 2 in i .

Lag distribution specifications are enclosed in parentheses and follow the name of the regressor variable. The general form of the lag distribution specification is

regressor-name (length, degree, minimum-degree, end-constraint)

where

<i>length</i>	is the length of the lag distribution—that is, the number of lags of the regressor to use.
<i>degree</i>	is the degree of the distribution polynomial.
<i>minimum-degree</i>	is an optional minimum degree for the distribution polynomial.
<i>end-constraint</i>	is an optional endpoint restriction specification, which can have the value FIRST, LAST, or BOTH.

If the *minimum-degree* option is specified, the PDLREG procedure estimates models for all degrees between *minimum-degree* and *degree*.

Introductory Example

The following statements generate simulated data for variables Y and X. Y depends on the first three lags of X, with coefficients .25, .5, and .25. Thus, the effect of changes of X on Y takes effect 25% after one period, 75% after two periods, and 100% after three periods.

```
data test;
  x11 = 0; x12 = 0; x13 = 0;
  do t = -3 to 100;
    x = ranuni(1234);
    y = 10 + .25 * x11 + .5 * x12 + .25 * x13
        + .1 * rannor(1234);
    if t > 0 then output;
    x13 = x12; x12 = x11; x11 = x;
  end;
run;
```

The following statements use the PDLREG procedure to regress Y on a distributed lag of X. The length of the lag distribution is 4, and the degree of the distribution polynomial is specified as 3.

```
proc pdlreg data=test;
  model y = x( 4, 3 );
run;
```

The PDLREG procedure first prints a table of statistics for the residuals of the model, as shown in [Figure 21.1](#). See Chapter 8, “[The AUTOREG Procedure](#),” for an explanation of these statistics.

Figure 21.1 Residual Statistics

The PDLREG Procedure			
Dependent Variable		y	
Ordinary Least Squares Estimates			
SSE	0.86604442	DFE	91
MSE	0.00952	Root MSE	0.09755
SBC	-156.72612	AIC	-169.54786
MAE	0.07761107	AICC	-168.88119
MAPE	0.73971576	HQC	-164.3651
Durbin-Watson	1.9920	Regress R-Square	0.7711
		Total R-Square	0.7711

The PDLREG procedure next prints a table of parameter estimates, standard errors, and t tests, as shown in Figure 21.2.

Figure 21.2 Parameter Estimates

Parameter Estimates					
Variable	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	10.0030	0.0431	231.87	<.0001
x**0	1	0.4406	0.0378	11.66	<.0001
x**1	1	0.0113	0.0336	0.34	0.7377
x**2	1	-0.4108	0.0322	-12.75	<.0001
x**3	1	0.0331	0.0392	0.84	0.4007

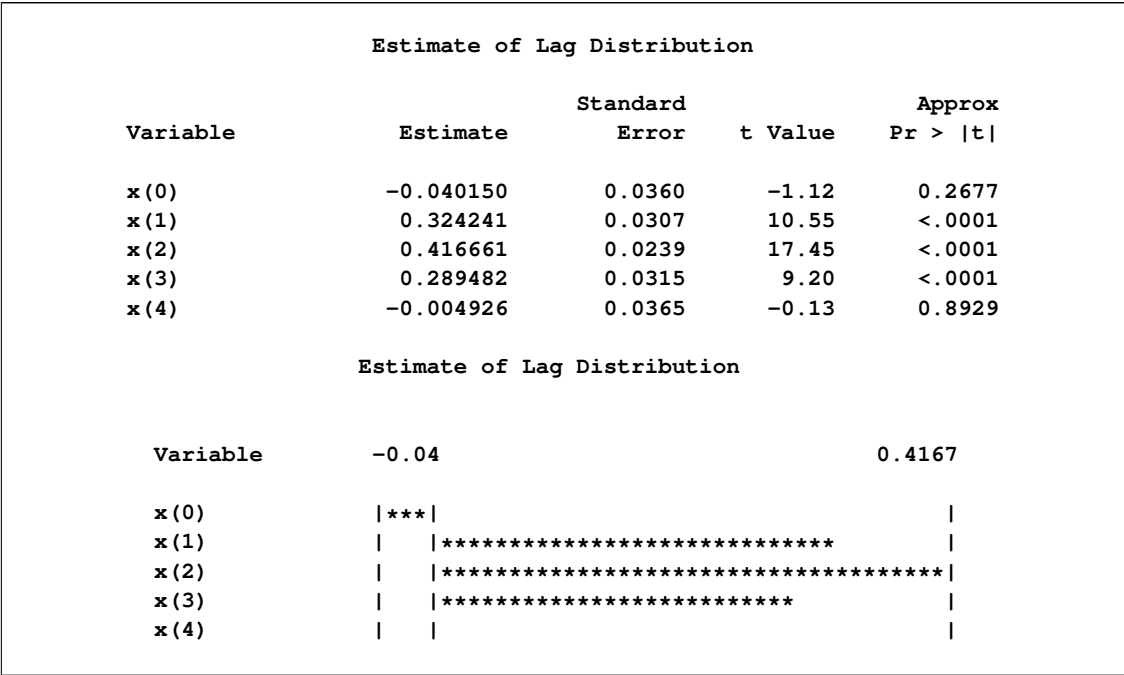

The table in Figure 21.2 shows the model intercept and the estimated parameters of the lag distribution polynomial. The parameter labeled X**0 is the constant term, α_0 , of the distribution polynomial. X**1 is the linear coefficient, α_1 ; X**2 is the quadratic coefficient, α_2 ; and X**3 is the cubic coefficient, α_3 .

The parameter estimates for the distribution polynomial are not of interest in themselves. Since the PDLREG procedure does not print the orthogonal polynomial basis that it constructs to represent the distribution polynomial, these coefficient values cannot be interpreted.

However, because these estimates are for an orthogonal basis, you can use these results to test the degree of the polynomial. For example, this table shows that the X**3 estimate is not significant; the p -value for its t ratio is 0.4007, while the X**2 estimate is highly significant ($p < .0001$). This indicates that a second-degree polynomial might be more appropriate for this data set.

The PDLREG procedure next prints the lag distribution coefficients and a graphical display of these coefficients, as shown in Figure 21.3.

Figure 21.3 Coefficients and Graph of Estimated Lag Distribution

The lag distribution coefficients are the coefficients of the lagged values of X in the regression model. These coefficients lie on the polynomial curve defined by the parameters shown in Figure 21.2. Note that the estimated values for X(1), X(2), and X(3) are highly significant, while X(0) and X(4) are not significantly different from 0. These estimates are reasonably close to the true values used to generate the simulated data.

The graphical display of the lag distribution coefficients plots the estimated lag distribution polynomial reported in Figure 21.2. The roughly quadratic shape of this plot is another indication that a third-degree distribution curve is not needed for this data set.

Syntax: PDLREG Procedure

The following statements can be used with the PDLREG procedure:

```
PROC PDLREG option ;
  BY variables ;
  MODEL dependents = effects / options ;
  OUTPUT OUT= SAS-data-set keyword = variables ;
  RESTRICT restrictions ;
```

Functional Summary

The statements and options used with the PDLREG procedure are summarized in the following table.

Table 21.1 PDLREG Functional Summary

Description	Statement	Option
Data Set Options		
specify the input data set	PDLREG	DATA=
write predicted values to an output data set	OUTPUT	OUT=
BY-Group Processing		
specify BY-group processing	BY

output upper confidence limit for the structural predicted values	OUTPUT	UCLM=

PROC PDLREG Statement

PROC PDLREG *option* ;

The PROC PDLREG statement has the following option:

DATA= *SAS-data-set*

specifies the name of the SAS data set containing the input data. If you do not specify the DATA= option, the most recently created SAS data set is used.

In addition, you can place any of the following MODEL statement options in the PROC PDLREG statement, which is equivalent to specifying the option for every MODEL statement: ALL, COEF, CONVERGE=, CORRB, COVB, DW=, DWPROB, GINV, ITPRINT, MAXITER=, METHOD=, NOINT, NOPRINT, and PARTIAL.

BY Statement

BY *variables* ;

A BY statement can be used with PROC PDLREG to obtain separate analyses on observations in groups defined by the BY variables.

MODEL Statement

MODEL *dependent = effects / options* ;

The MODEL statement specifies the regression model. The keyword MODEL is followed by the dependent variable name, an equal sign, and a list of independent effects. Only one MODEL statement is allowed.

Every variable in the model must be a numeric variable in the input data set. Specify an independent effect with a variable name optionally followed by a polynomial lag distribution specification.

Specifying Independent Effects

The general form of an effect is

variable (*length*, *degree*, *minimum-degree*, *constraint*)

The term in parentheses following the variable name specifies a polynomial distributed lag (PDL) for the variable. The PDL specification is as follows:

<i>length</i>	specifies the number of lags of the variable to include in the lag distribution.
<i>degree</i>	specifies the maximum degree of the distribution polynomial. If not specified, the degree defaults to the lag length.
<i>minimum-degree</i>	specifies the minimum degree of the polynomial. By default <i>minimum-degree</i> is the same as <i>degree</i> .
<i>constraint</i>	specifies endpoint restrictions on the polynomial. The value of <i>constraint</i> can be FIRST, LAST, or BOTH. If a value is not specified, there are no endpoint restrictions.

If you do not specify the *degree* or *minimum-degree* parameter, but you do specify endpoint restrictions, you must use commas to show which parameter, *degree* or *minimum-degree*, is left out.

MODEL Statement Options

The following options can appear in the MODEL statement after a slash (/).

ALL

prints all the matrices computed during the analysis of the model.

COEF

prints the transformation coefficients for the first p observations. These coefficients are formed from a scalar multiplied by the inverse of the Cholesky root of the Toeplitz matrix of autocovariances.

CORRB

prints the matrix of estimated correlations between the parameter estimates.

COVB

prints the matrix of estimated covariances between the parameter estimates.

DW= j

prints the generalized Durbin-Watson statistics up to the order of j . The default is DW=1. When you specify the LAGDEP or LAGDEP=*name* option, the Durbin-Watson statistic is not printed unless you specify the DW= option.

DWPROB

prints the marginal probability of the Durbin-Watson statistic.

CONVERGE= *value*

sets the convergence criterion. If the maximum absolute value of the change in the autoregressive parameter estimates between iterations is less than this amount, then convergence is assumed. The default is CONVERGE=.001.

GINV

prints the inverse of the Toeplitz matrix of autocovariances for the Yule-Walker solution.

I

prints $(\mathbf{X}'\mathbf{X})^{-1}$, the inverse of the crossproducts matrix for the model; or, if restrictions are specified, it prints $(\mathbf{X}'\mathbf{X})^{-1}$ adjusted for the restrictions.

ITPRINT

prints information on each iteration.

LAGDEP**LAGDV**

prints the t statistic for testing residual autocorrelation when regressors contain lagged dependent variables.

LAGDEP= *name*

LAGDV= *name*

prints the Durbin h statistic for testing the presence of first-order autocorrelation when regressors contain the lagged dependent variable whose name is specified as **LAGDEP=***name*. When the h statistic cannot be computed, the asymptotically equivalent t statistic is given.

MAXITER= *number*

sets the maximum number of iterations allowed. The default is **MAXITER=50**.

METHOD= *value*

specifies the type of estimates for the autoregressive component. The values of the **METHOD=** option are as follows:

METHOD=ML	specifies the maximum likelihood method.
METHOD=ULS	specifies unconditional least squares.
METHOD=YW	specifies the Yule-Walker method.
METHOD=ITYW	specifies iterative Yule-Walker estimates.

The default is **METHOD=ML** if you specified the **LAGDEP** or **LAGDEP=** option; otherwise, **METHOD=YW** is the default.

NLAG= *m*

NLAG= (*number-list*)

specifies the order of the autoregressive process or the subset of autoregressive lags to be fit. If you do not specify the **NLAG=** option, PROC PDLREG does not fit an autoregressive model.

NOINT

suppresses the intercept parameter from the model.

NOPRINT

suppresses the printed output.

PARTIAL

prints partial autocorrelations if the NLAG= option is specified.

STB

prints standardized parameter estimates. Sometimes known as a standard partial regression coefficient, a *standardized parameter estimate* is a parameter estimate multiplied by the standard deviation of the associated regressor and divided by the standard deviation of the regressed variable.

XPX

prints the crossproducts matrix, $\mathbf{X}'\mathbf{X}$, used for the model. \mathbf{X} refers to the transformed matrix of regressors for the regression.

OUTPUT Statement

OUTPUT *OUT= SAS-data-set keyword= option ... ;*

The OUTPUT statement creates an output SAS data set with variables as specified by the following keyword options. See the section “Predicted Values” in Chapter 8, “[The AUTOREG Procedure](#),” for a description of the associated computations for these options.

ALPHACLI= *number*

sets the confidence limit size for the estimates of future values of the current realization of the response time series to *number*, where *number* is less than one and greater than zero. The resulting confidence interval has $1-\textit{number}$ confidence. The default value for *number* is 0.05, corresponding to a 95% confidence interval.

ALPHACLM= *number*

sets the confidence limit size for the estimates of the structural or regression part of the model to *number*, where *number* is less than one and greater than zero. The resulting confidence interval has $1-\textit{number}$ confidence. The default value for *number* is 0.05, corresponding to a 95% confidence interval.

OUT= *SAS-data-set*

names the output data.

The following specifications are of the form *KEYWORD=names*, where *KEYWORD=* specifies the statistic to include in the output data set and *names* gives names to the variables that contain the statistics.

CONSTANT= *variable*

writes the transformed intercept to the output data set.

LCL= *name*

requests that the lower confidence limit for the predicted value (specified in the PREDICTED= option) be added to the output data set under the name given.

LCLM= *name*

requests that the lower confidence limit for the structural predicted value (specified in the PREDICTEDM= option) be added to the output data set under the name given.

PREDICTED= *name***P=** *name*

stores the predicted values in the output data set under the name given.

PREDICTEDM= *name***PM=** *name*

stores the structural predicted values in the output data set under the name given. These values are formed from only the structural part of the model.

RESIDUAL= *name***R=** *name*

stores the residuals from the predicted values based on both the structural and time series parts of the model in the output data set under the name given.

RESIDUALM= *name***RM=** *name*

requests that the residuals from the structural prediction be given.

TRANSFORM= *variables*

requests that the specified variables from the input data set be transformed by the autoregressive model and put in the output data set. If you need to reproduce the data suitable for reestimation, you must also transform an intercept variable. To do this, transform a variable that only takes the value 1 or use the CONSTANT= option.

UCL= *name*

stores the upper confidence limit for the predicted value (specified in the PREDICTED= option) in the output data set under the name given.

UCLM= *name*

stores the upper confidence limit for the structural predicted value (specified in the PREDICTEDM= option) in the output data set under the name given.

For example, the SAS statements

```
proc pdlreg data=a;
  model y=x1 x2;
  output out=b p=yhat r=resid;
run;
```

create an output data set named B. In addition to the input data set variables, the data set B contains the variable YHAT, whose values are predicted values of the dependent variable Y, and RESID, whose values are the residual values of Y.

RESTRICT Statement

RESTRICT *equation* , . . . , *equation* ;

The RESTRICT statement places restrictions on the parameter estimates for covariates in the preceding MODEL statement. A parameter produced by a distributed lag cannot be restricted with the RESTRICT statement.

Each restriction is written as a linear equation. If you specify more than one restriction in a RESTRICT statement, the restrictions are separated by commas.

You can refer to parameters by the name of the corresponding regressor variable. Each name used in the equation must be a regressor in the preceding MODEL statement. Use the keyword INTERCEPT to refer to the intercept parameter in the model.

RESTRICT statements can be given labels. You can use labels to distinguish results for different restrictions in the printed output. Labels are specified as follows:

label : **RESTRICT** . . .

The following is an example of the use of the RESTRICT statement, in which the coefficients of the regressors X1 and X2 are required to sum to 1:

```
proc pdlreg data=a;
  model y = x1 x2;
  restrict x1 + x2 = 1;
run;
```

Parameter names can be multiplied by constants. When no equal sign appears, the linear combination is set equal to 0. Note that the parameters associated with the variables are restricted, not the variables themselves. Here are some examples of valid RESTRICT statements:

```
restrict x1 + x2 = 1;
restrict x1 + x2 - 1;
restrict 2 * x1 = x2 + x3 , intercept + x4 = 0;
restrict x1 = x2 = x3 = 1;
restrict 2 * x1 - x2;
```

Restricted parameter estimates are computed by introducing a Lagrangian parameter λ for each restriction (Pringle and Rayner 1971). The estimates of these Lagrangian parameters are printed in the parameter estimates table. If a restriction cannot be applied, its parameter value and degrees of freedom are listed as 0.

The Lagrangian parameter, λ , measures the sensitivity of the SSE to the restriction. If the restriction is changed by a small amount ϵ , the SSE is changed by $2\lambda\epsilon$.

The t ratio tests the significance of the restrictions. If λ is zero, the restricted estimates are the same as the unrestricted ones.

You can specify any number of restrictions in a RESTRICT statement, and you can use any number of RESTRICT statements. The estimates are computed subject to all restrictions specified. However, restrictions should be consistent and not redundant.

Details: PDLREG Procedure

Missing Values

The PDLREG procedure skips any observations at the beginning of the data set that have missing values. The procedure uses all observations with nonmissing values for all the independent and dependent variables such that the lag distribution has sufficient nonmissing lagged independent variables.

Polynomial Distributed Lag Estimation

The simple finite distributed lag model is expressed in the form

$$y_t = \alpha + \sum_{i=0}^p \beta_i x_{t-i} + \epsilon_t$$

When the lag length (p) is long, severe multicollinearity can occur. Use the Almon or *polynomial distributed lag* model to avoid this problem, since the relatively low-degree d ($\leq p$) polynomials can capture the true lag distribution. The lag coefficient can be written in the Almon polynomial lag

$$\beta_i = \alpha_0^* + \sum_{j=1}^d \alpha_j^* i^j$$

Emerson (1968) proposed an efficient method of constructing orthogonal polynomials from the preceding polynomial equation as

$$\beta_i = \alpha_0 + \sum_{j=1}^d \alpha_j f_j(i)$$

where $f_j(i)$ is a polynomial of degree j in the lag length i . The polynomials $f_j(i)$ are chosen so that they are orthogonal:

$$\sum_{i=1}^n w_i f_j(i) f_k(i) = \begin{cases} 1 & \text{if } j = k \\ 0 & \text{if } j \neq k \end{cases}$$

where w_i is the weighting factor, and $n = p + 1$. PROC PDLREG uses the equal weights ($w_i = 1$) for all i . To construct the orthogonal polynomials, the following recursive relation is used:

$$f_j(i) = (A_j i + B_j) f_{j-1}(i) - C_j f_{j-2}(i) \quad j = 1, \dots, d$$

The constants A_j , B_j , and C_j are determined as follows:

$$A_j = \left\{ \sum_{i=1}^n w_i i^2 f_{j-1}^2(i) - \left(\sum_{i=1}^n w_i i f_{j-1}^2(i) \right)^2 - \left(\sum_{i=1}^n w_i i f_{j-1}(i) f_{j-2}(i) \right)^2 \right\}^{-1/2}$$

$$B_j = -A_j \sum_{i=1}^n w_i i f_{j-1}^2(i)$$

$$C_j = A_j \sum_{i=1}^n w_i i f_{j-1}(i) f_{j-2}(i)$$

where $f_{-1}(i) = 0$ and $f_0(i) = 1/\sqrt{\sum_{i=1}^n w_i}$.

PROC PDLREG estimates the orthogonal polynomial coefficients, $\alpha_0, \dots, \alpha_d$, to compute the coefficient estimate of each independent variable (X) with distributed lags. For example, if an independent variable is specified as X(9,3), a third-degree polynomial is used to specify the distributed lag coefficients. The third-degree polynomial is fit as a constant term, a linear term, a quadratic term, and a cubic term. The four terms are constructed to be orthogonal. In the output produced by the PDLREG procedure for this case, parameter estimates with names X**0, X**1, X**2, and X**3 correspond to $\hat{\alpha}_0, \hat{\alpha}_1, \hat{\alpha}_2$, and $\hat{\alpha}_3$, respectively. A test using the t statistic and the approximate p -value (“Approx Pr > | t |”) associated with X**3 can determine whether a second-degree polynomial rather than a third-degree polynomial is appropriate. The estimates of the 10 lag coefficients associated with the specification X(9,3) are labeled X(0), X(1), X(2), X(3), X(4), X(5), X(6), X(7), X(8), and X(9).

Autoregressive Error Model Estimation

The PDLREG procedure uses the same autoregressive error model estimation methods as the AUTOREG procedure. These two procedures share the same computational resources for computing estimates. See Chapter 8, “[The AUTOREG Procedure](#),” for details about estimation methods for autoregressive error models.

OUT= Data Set

The OUT= data set produced by the PDLREG procedure’s OUTPUT statement is similar in form to the OUT= data set produced by the AUTOREG procedure. See Chapter 8, “[The AUTOREG Procedure](#),” for details on the OUT= data set.

Printed Output

The PDLREG procedure prints the following items:

1. the name of the dependent variable
2. the ordinary least squares (OLS) estimates
3. the estimates of autocorrelations and of the autocovariance, and if line size permits, a graph of the autocorrelation at each lag. The autocorrelation for lag 0 is 1. These items are printed if you specify the NLAG= option.
4. the partial autocorrelations if the PARTIAL and NLAG= options are specified. The first partial autocorrelation is the autocorrelation for lag 1.
5. the preliminary mean square error, which results from solving the Yule-Walker equations if you specify the NLAG= option
6. the estimates of the autoregressive parameters, their standard errors, and the ratios of estimates to standard errors (t) if you specify the NLAG= option
7. the statistics of fit for the final model if you specify the NLAG= option. These include the error sum of squares (SSE), the degrees of freedom for error (DFE), the mean square error (MSE), the root mean square error (Root MSE), the mean absolute error (MAE), the mean absolute percentage error (MAPE), the Schwarz information criterion (SBC), the Akaike's information criterion (AIC), Akaike's information criterion corrected (AICC), the regression R^2 (Regress R-Square), the total R^2 (Total R-Square), and the Durbin-Watson statistic (Durbin-Watson). See Chapter 8, “[The AUTOREG Procedure](#),” for details of the regression R^2 and the total R^2 .
8. the parameter estimates for the structural model (B), a standard error estimate, the ratio of estimate to standard error (t), and an approximation to the significance probability for the parameter being 0 (“Approx Pr > $|t|$ ”)
9. a plot of the lag distribution (estimate of lag distribution)
10. the covariance matrix of the parameter estimates if the COVB option is specified

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User's Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

PROC PDLREG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 21.2 ODS Tables Produced in PROC PDLREG

ODS Table Name	Description	Option
ODS Tables Created by the MODEL Statement		
ARParameterEstimates	Estimates of autoregressive parameters	NLAG=
CholeskyFactor	Cholesky root of gamma	NLAG= and ALL
Coefficients	Coefficients for first NLAG observations	NLAG= and (COEF or ALL)
ConvergenceStatus	Convergence status table	default
CorrB	Correlation of parameter estimates	CORRB
CorrGraph	Estimates of autocorrelations	NLAG=
CovB	Covariance of parameter estimates	COVB
DependenceEquations	Linear dependence equation	
Dependent	Dependent variable	default
DWTest	Durbin-Watson statistics	DW=
DWTestProb	Durbin-Watson statistics and p -values	DW= and DWPROB
ExpAutocorr	Expected autocorrelations	{NLAG= and (COEF or ALL)} or {NLAG=($l_1 \dots l_m$) where $l_m > m$ }
FitSummary	Summary of regression	default
GammaInverse	Gamma inverse	NLAG= and (GINV or ALL)
IterHistory	Iteration history	ITPRINT
LagDist	Lag distribution	default
ParameterEstimates	Parameter estimates	default
ParameterEstimatesGivenAR	Parameter estimates assuming AR parameters are given	NLAG=
PartialAutoCorr	Partial autocorrelation	PARTIAL
PreMSE	Preliminary MSE	NLAG=
XPXIMatrix	$(X'X)^{-1}$ matrix	XPX
XPXMatrix	$X'X$ matrix	XPX
YWIterSSE	Yule-Walker iteration sum of squared error	METHOD=ITYW
ODS Tables Created by the RESTRICT Statement		
Restrict	Restriction table	default

Examples: PDLREG Procedure

Example 21.1: Industrial Conference Board Data

In this example, a second-degree Almon polynomial lag model is fit to a model with a five-period lag, and dummy variables are used for quarter effects. The PDL model is estimated using capital appropriations data series for the period 1952 to 1967. The estimation model is written

$$CE_t = a_0 + b_1 Q1_t + b_2 Q2_t + b_3 Q3_t + c_0 CA_t + c_1 CA_{t-1} + \dots + c_5 CA_{t-5}$$

where CE represents capital expenditures and CA represents capital appropriations.

The following statements use the REG procedure to fit the same polynomial distributed lag model. A DATA step computes lagged values of the regressor X, and RESTRICT statements are used to impose the polynomial lag distribution. Refer to Judge et al. (1985, pp. 357–359) for the restricted least squares estimation of the Almon distributed lag model.

```
data b;
  set a;
  ca_1 = lag( ca );
  ca_2 = lag2( ca );
  ca_3 = lag3( ca );
  ca_4 = lag4( ca );
  ca_5 = lag5( ca );
run;

proc reg data=b;

Example 21.2: Money Demand Model

This example estimates the demand for money by using the following dynamic specification:

$$m_t = a_0 + b_0 m_{t-1} + \sum_{i=0}^5 c_i y_{t-i} + \sum_{i=0}^2 d_i r_{t-i} + \sum_{i=0}^3 f_i p_{t-i} + u_t$$

where

m_t = log of real money stock (M1)

y_t = log of real GNP

r_t = interest rate (commercial paper rate)

p_t = inflation rate

c_i , d_i , and f_i ($i > 0$) are coefficients for the lagged variables

The following DATA step reads the data and transforms the real money and real GNP variables using the natural logarithm. Refer to Balke and Gordon (1986) for a description of the data.

```
data a;
  input m1 gnp gdf r @@;
  m    = log( 100 * m1 / gdf );
  lagm = lag( m );
  y    = log( gnp );
  p    = log( gdf / lag( gdf ) );
  date = intnx( 'qtr', '1jan1968'd, _n_-1 );
  format date yyqc6.;
  label m      = 'Real Money Stock (M1)'
        lagm   = 'Lagged Real Money Stock'
        y      = 'Real GNP'
        r      = 'Commercial Paper Rate'
        p      = 'Inflation Rate';
datalines;

Overview: QLIM Procedure

The QLIM (qualitative and limited dependent variable model) procedure analyzes univariate and multivariate limited dependent variable models in which dependent variables take discrete values or in which dependent variables are observed only in a limited range of values. These models include logit, probit, tobit, selection, and multivariate models. The multivariate model can contain discrete choice and limited endogenous variables in addition to continuous endogenous variables.

The QLIM procedure supports the following models:

- linear regression model with heteroscedasticity
- Box-Cox regression with heteroscedasticity
- probit with heteroscedasticity
- logit with heteroscedasticity
- tobit (censored and truncated) with heteroscedasticity
- bivariate probit
- bivariate tobit
- sample selection and switching regression models
- multivariate limited dependent variables
- stochastic frontier production and cost models

In the linear regression models with heteroscedasticity, the assumption that error variance is constant across observations is relaxed. The QLIM procedure allows for a number of different linear and nonlinear variance specifications. Another way to make the linear model more appropriate to fit the data and reduce skewness is to apply Box-Cox transformation. If the nature of the data is such that the dependent variable is discrete and it takes only two possible values, ordinary least squares (OLS) estimates are inconsistent. The QLIM procedure offers probit and logit models to overcome these estimation problems. Assumptions about the error variance can also be relaxed in order to estimate probit or logit with heteroscedasticity.

The QLIM procedure also offers a class of models in which the dependent variable is censored or truncated from below or above or both. When a continuous dependent variable is observed only within a certain range and values outside this range are not available, the QLIM procedure offers a class of models that adjust for truncation. In some cases, the dependent variable is continuous only in a certain range and all values outside this range are reported as being on its boundary. For example, if it is not possible to observe negative values, the value of the dependent variable is reported as equal to 0. Because the data are censored, OLS results are inconsistent, and it cannot be guaranteed that the predicted values from the model fall in the appropriate region.

Most of the models in the QLIM procedure can be extended to accommodate bivariate and multivariate scenarios. The assumption that one variable is observed only if another variable takes on certain values lead to the introduction of sample selection models. If the dependent variables are mutually exclusive and observed only for certain ranges of the selection variable, the sample selection can be extended to include cases of switching regression. Stochastic frontier production and cost models allow for random shocks of the production or cost. They include a systematic positive component in the error term that adjusts for technological or cost inefficiency.

The QLIM procedure can use the maximum likelihood method and the Bayesian method for both univariate and multivariate models. Initial starting values for the nonlinear optimizations are typically calculated by OLS.

Getting Started: QLIM Procedure

The QLIM procedure is similar in use to the other regression or simultaneous equations model procedures in the SAS System. For example, the following statements are used to estimate a binary choice model by using the probit probability function:

```
proc qlim data=a;
  model y = x1;
  endogenous y ~ discrete;
run;
```

The response variable, *y*, is numeric and has discrete values. PROC QLIM enables the user to specify the type of endogenous variables in the ENDOGENOUS statement. The binary probit model can be also specified as follows:

```
model y = x1 / discrete;
```

When multiple endogenous variables are specified in the QLIM procedure, these equations are estimated as a system. Multiple endogenous variables can be specified with one MODEL statement in the QLIM procedure when these models have the same exogenous variables:

```
model y1 y2 = x1 x2 / discrete;
```

The preceding specification is equivalent to the following statements:

```
proc qlim data=a;
  model y1 = x1 x2;
  model y2 = x1 x2;
  endogenous y1 y2 ~ discrete;
run;
```

Some equations in multivariate models can be continuous while other equations can be discrete. A bivariate model with a discrete and a continuous equation is specified as follows:

```
proc qlim data=a;
  model y1 = x1 x2;
  model y2 = x3 x4;
  endogenous y1 ~ discrete;
run;
```

The standard tobit model is estimated by specifying the endogenous variable to be truncated or censored. The limits of the dependent variable can be specified with the CENSORED or TRUNCATED option in the ENDOGENOUS or MODEL statement when the data are limited by specific values or variables. For example, the two-limit censored model requires two variables that contain the lower (bottom) and upper (top) bound:

```
proc qlim data=a;
  model y = x1 x2 x3;
  endogenous y ~ censored(lb=bottom ub=top);
run;
```

The bounds can be numbers if they are fixed for all observations in the data set. For example, the standard tobit model can be specified as follows:

```
proc qlim data=a;
  model y = x1 x2 x3;
  endogenous y ~ censored(lb=0);
run;
```

Introductory Example: Binary Probit and Logit Models

The following example illustrates the use of PROC QLIM. The data were originally published by Mroz (1987) and downloaded from Wooldridge (2002). This data set is based on a sample of 753 married white women. The dependent variable is a discrete variable of labor force participation (lnlf). Explanatory variables

are the number of children ages 5 or younger (kidslt6), the number of children ages 6 to 18 (kidsge6), the woman's age (age), the woman's years of schooling (educ), wife's labor experience (exper), square of experience (expersq), and the family income excluding the wife's wage (nwifeinc). The program (with data values omitted) is as follows:

```
/*-- Binary Probit --*/
proc qlim data=mroz plots=predicted;
  model inlf = nwifeinc educ exper expersq
              age kidslt6 kidsge6 / discrete;
run;
```

Results of this analysis are shown in the following four figures. In the first table, shown in [Figure 22.1](#), PROC QLIM provides frequency information about each choice. In this example, 428 women participate in the labor force (inlf =1).

Figure 22.1 Choice Frequency Summary

Binary Data		
The QLIM Procedure		
Discrete Response Profile of inlf		
Index	Value	Total Frequency
1	0	325
2	1	428

The second table is the estimation summary table shown in [Figure 22.2](#). Included are the number of dependent variables, names of dependent variables, the number of observations, the log-likelihood function value, the maximum absolute gradient, the number of iterations, AIC, and Schwarz criterion.

Figure 22.2 Fit Summary Table of Binary Probit

AIC		818.60439
Schwarz Criterion		855.59691

Goodness-of-fit measures are displayed in Figure 22.3. All measures except McKelvey-Zavoina's definition are based on the log-likelihood function value. The likelihood ratio test statistic has chi-square distribution conditional on the null hypothesis that all slope coefficients are zero. In this example, the likelihood ratio statistic is used to test the hypothesis that $\text{kidslt6} = \text{kidge6} = \text{age} = \text{educ} = \text{exper} = \text{expersq} = \text{nwifeinc} = 0$.

Figure 22.3 Goodness of Fit

Goodness-of-Fit Measures		
Measure	Value	Formula
Likelihood Ratio (R)	227.14	$2 * (\text{LogL} - \text{LogL0})$
Upper Bound of R (U)	1029.7	$- 2 * \text{LogL0}$
Aldrich-Nelson	0.2317	$R / (R+N)$
Cragg-Uhler 1	0.2604	$1 - \exp(-R/N)$
Cragg-Uhler 2	0.3494	$(1 - \exp(-R/N)) / (1 - \exp(-U/N))$
Estrella	0.2888	$1 - (1 - R/U)^{(U/N)}$
Adjusted Estrella	0.2693	$1 - ((\text{LogL} - K) / \text{LogL0})^{(-2/N * \text{LogL0})}$
McFadden's LRI	0.2206	R / U
Veall-Zimmermann	0.4012	$(R * (U+N)) / (U * (R+N))$
McKelvey-Zavoina	0.4025	
N = # of observations, K = # of regressors		

The parameter estimates and standard errors are shown in Figure 22.4.

Figure 22.4 Parameter Estimates of Binary Probit

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.270077	0.508590	0.53	0.5954
nwifeinc	1	-0.012024	0.004840	-2.48	0.0130
educ	1	0.130905	0.025255	5.18	<.0001
exper	1	0.123348	0.018720	6.59	<.0001
expersq	1	-0.001887	0.000600	-3.14	0.0017
age	1	-0.052853	0.008477	-6.24	<.0001
kidslt6	1	-0.868329	0.118519	-7.33	<.0001
kidsge6	1	0.036005	0.043477	0.83	0.4076

Finally, the QLIM procedure profiles the predicted outcome with respect to the regressors. For example, [Output 22.5](#) shows the predicted values profiled with respect to nwifeinc, educ, exper, expersq, age, and kidslt6.

Figure 22.5 Predictions by Regressors: nwifeinc, educ, exper, expersq, age, and kidslt6

When the error term has a logistic distribution, the binary logit model is estimated. To specify a logistic distribution, add D=LOGIT option as follows:

```
/*-- Binary Logit --*/
proc qlim data=mroz;
  model inlf = nwifeinc educ exper expersq
              age kidslt6 kidsge6 / discrete(d=logit);
run;
```

The estimated parameters are shown in Figure 22.6.

Figure 22.6 Parameter Estimates of Binary Logit

Binary Data					
The QLIM Procedure					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.425452	0.860365	0.49	0.6210
nwifeinc	1	-0.021345	0.008421	-2.53	0.0113
educ	1	0.221170	0.043441	5.09	<.0001
exper	1	0.205870	0.032070	6.42	<.0001
expersq	1	-0.003154	0.001017	-3.10	0.0019
age	1	-0.088024	0.014572	-6.04	<.0001
kidslt6	1	-1.443354	0.203575	-7.09	<.0001
kidsge6	1	0.060112	0.074791	0.80	0.4215

The heteroscedastic logit model can be estimated using the HETERO statement. If the variance of the logit model is a function of the family income level excluding wife's income (nwifeinc), the variance can be specified as

$$\text{Var}(\epsilon_i) = \sigma^2 \exp(\gamma * \text{nwifeinc}_i)$$

where σ^2 is normalized to 1 because the dependent variable is discrete. The following SAS statements estimate the heteroscedastic logit model:

```
/*-- Binary Logit with Heteroscedasticity --*/
proc qlim data=mroz;
  model inlf = nwifeinc educ exper expersq
              age kidslt6 kidsge6 / discrete(d=logit);
  hetero inlf ~ nwifeinc / noconst;
run;
```

The parameter estimate, γ , of the heteroscedasticity variable is listed as _H.nwifeinc; see Figure 22.7.

Figure 22.7 Parameter Estimates of Binary Logit with Heteroscedasticity

Binary Data					
The QLIM Procedure					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.510445	0.983538	0.52	0.6038
nwifeinc	1	-0.026778	0.012108	-2.21	0.0270
educ	1	0.255547	0.061728	4.14	<.0001
exper	1	0.234105	0.046639	5.02	<.0001

kidslt6	1	-1.645206	0.311296	-5.29	<.0001
kidsge6	1	0.066941	0.085633	0.78	0.4344
_H.nwifeinc	1	0.013280	0.013606	0.98	0.3291

Syntax: QLIM Procedure

The QLIM procedure is controlled by the following statements:

```

PROC QLIM options ;
  BAYES <options> ;
  BOUNDS bound1 < , bound2 ... > ;
  BY variables ;
  CLASS variables ;
  FREQ variable ;
  ENDOGENOUS variables ~ options ;
  HETERO dependent variables ~ exogenous variables / options ;
  INIT initvalue1 < , initvalue2 ... > ;
  MODEL dependent variables = regressors / options ;
  NLOPTIONS options ;
  OUTPUT options ;
  PRIOR variables ~ distributions ;
  RESTRICT restriction1 < , restriction2 ... > ;
  TEST options ;
  WEIGHT variable ;

```

At least one MODEL statement is required. If more than one MODEL statement is used, the QLIM procedure estimates a system of models. If a FREQ or WEIGHT statement is specified more than once, the variable specified in the first instance is used. Main effects and higher-order terms can be specified in the MODEL statement, as in the GLM procedure and PROBIT procedure in SAS/STAT. If a CLASS statement is used, it must precede the MODEL statement.

Functional Summary

Table 22.1 summarizes the statements and options used with the QLIM procedure.

Table 22.1 PROC QLIM Functional Summary

Description	Statement	Option
Data Set Options		
Specifies the input data set	QLIM	DATA=
Writes parameter estimates to an output data set	QLIM	OUTEST=
Writes predictions to an output data set	OUTPUT	OUT=
Declaring the Role of Variables		
Specifies BY-group processing	BY	
Specifies classification variables	CLASS	
Specifies a frequency variable	FREQ	
Specifies a weight variable	WEIGHT	NONNORMALIZE
Printing Control Options		
Requests all printing options	QLIM	PRINTALL
Prints correlation matrix of the estimates	QLIM	CORRB
Prints covariance matrix of the estimates	QLIM	COVB
Prints a summary iteration listing	QLIM	ITPRINT
Suppresses the normal printed output	QLIM	NOPRINT
Plotting Options		
Displays plots	QLIM	PLOTS=
Options to Control the Optimization Process		
Specifies the optimization method	QLIM	METHOD=
Specifies the optimization options	NLOPTIONS	see Chapter 6, “Nonlinear Optimization Methods,”
Sets initial values for parameters	INIT	
Specifies upper and lower bounds for the parameter estimates	BOUNDS	
Specifies linear restrictions on the parameter estimates	RESTRICT	
Model Estimation Options		
Specifies options specific to Box-Cox transformation	MODEL	BOXCOX()
Suppresses the intercept parameter	MODEL	NOINT
Specifies variable selection	MODEL	SELECTVAR=()
Specifies a seed for pseudo-random number generation	QLIM	SEED=
Specifies the number of draws for Monte Carlo integration	QLIM	NDRAW=

Table 22.1 *continued*

Description	Statement	Option
Specifies the method to calculate parameter covariance	QLIM	COVEST=
Requests estimation by Heckman's two-step method	QLIM	HECKIT
Bayesian MCMC Options		
Specifies the initial values of the MCMC	INIT	
Specifies the maximum number of tuning phases	BAYES	MAXTUNE=
Specifies the minimum number of tuning phases	BAYES	MINTUNE=
Specifies the number of burn-in iterations	BAYES	NBI=
Specifies the number of iterations during the sampling phase	BAYES	NMC=
Specifies the number of samples for the prior predictive analysis	BAYES	NMCPRIOR=
Specifies the number of threads to use during the sampling phase	BAYES	NTRDS=
Specifies the number of iterations during the tuning phase	BAYES	NTU=
Controls options for constructing the initial proposal covariance matrix	BAYES	PROPCOV=
Specifies the sampling scheme	BAYES	SAMPLING=
Specifies the random number generator seed	BAYES	SEED=
Prints the time required for the MCMC sampling	BAYES	SIMTIME
Controls the thinning of the Markov chain	BAYES	THIN=
Bayesian Summary Statistics and Convergence Diagnostics		
Displays convergence diagnostics	BAYES	DIAGNOSTICS=
Displays summary statistics of the posterior samples	BAYES	STATISTICS=
Bayesian Prior and Posterior Samples		
Specifies a SAS data set for the posterior samples	BAYES	OUTPOST=
Specifies a SAS data set for the prior samples	BAYES	OUTPRIOR=
Bayesian Analysis		
Specifies normal prior distribution	PRIOR	NORMAL(MEAN=, VAR=)
Specifies gamma prior distribution	PRIOR	GAMMA(SHAPE=, SCALE=)
Specifies inverse gamma prior distribution	PRIOR	IGAMMA(SHAPE=, SCALE=)
Specifies uniform prior distribution	PRIOR	UNIFORM(MIN=, MAX=)
Specifies beta prior distribution	PRIOR	BETA(SHAPE1=, SHAPE2=, MIN=, MAX=)
Specifies <i>t</i> prior distribution	PRIOR	T(LOCATION=, DF=)
Endogenous Variable Options		
Specifies discrete variable	ENDOGENOUS	DISCRETE()
Specifies censored variable	ENDOGENOUS	CENSORED()
Specifies truncated variable	ENDOGENOUS	TRUNCATED()

Table 22.1 *continued*

Description	Statement	Option
Specifies variable selection condition	ENDOGENOUS	SELECT()
Specifies stochastic frontier variable	ENDOGENOUS	FRONTIER()
Endogeneity and Overidentification Test Options		
Requests the variable addition test for endogeneity	ENDOGENOUS	ENDOTEST()
Requests the overidentification test	ENDOGENOUS	OVERID()
Heteroscedasticity Model Options		
Specifies the function for heteroscedasticity models	HETERO	LINK=
Squares the function for heteroscedasticity models	HETERO	SQUARE
Specifies no constant for heteroscedasticity models	HETERO	NOCONST
Output Control Options		
Outputs predicted values	OUTPUT	PREDICTED
Outputs structured part	OUTPUT	XBETA
Outputs residuals	OUTPUT	RESIDUAL
Outputs error standard deviation	OUTPUT	ERRSTD
Outputs marginal effects	OUTPUT	MARGINAL
Outputs probability for the current response	OUTPUT	PROB
Outputs probability for all responses	OUTPUT	PROBALL
Outputs expected value	OUTPUT	EXPECTED
Outputs conditional expected value	OUTPUT	CONDITIONAL
Outputs inverse Mills ratio	OUTPUT	MILLS
Outputs technical efficiency measures	OUTPUT	TE1
	OUTPUT	TE2
Includes covariances in the OUTEST= data set	QLIM	COVOUT
Includes correlations in the OUTEST= data set	QLIM	CORROUT
Test Request Options		
Requests Wald, Lagrange multiplier, and likelihood ratio tests	TEST	ALL
Requests the WALD test	TEST	WALD
Requests the Lagrange multiplier test	TEST	LM
Requests the likelihood ratio test	TEST	LR

PROC QLIM Statement

PROC QLIM *options* ;

The following options can be used in the PROC QLIM statement.

Data Set Options

DATA=SAS-data-set

specifies the input SAS data set. If the DATA= option is not specified, PROC QLIM uses the most recently created SAS data set.

Output Data Set Options

OUTEST=SAS-data-set

writes the parameter estimates to an output data set.

COVOUT

writes the covariance matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

CORROUT

writes the correlation matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

Printing Options

NOPRINT

suppresses the normal printed output but does not suppress error listings. If NOPRINT option is set, then any other print option is turned off.

PRINTALL

turns on all the printing-control options. The options set by PRINTALL are COVB and CORRB.

CORRB

prints the correlation matrix of the parameter estimates.

COVB

prints the covariance matrix of the parameter estimates.

ITPRINT

prints the initial parameter estimates, convergence criteria, and all constraints of the optimization. At each iteration, objective function value, step size, maximum gradient, and slope of search direction are printed as well.

Model Estimation Options

COVEST=covariance-option

specifies the method to calculate the covariance matrix of parameter estimates. The supported covariance types are as follows:

OP	specifies the covariance from the outer product matrix.
HESSIAN	specifies the covariance from the inverse Hessian matrix.
QML	specifies the covariance from the outer product and Hessian matrices (the quasi-maximum likelihood estimates).

The default is COVEST=HESSIAN.

HECKIT <(heckit-options)>

requests that the selection model be estimated by Heckman's two-step estimation method. You must specify exactly two MODEL statements when you use the HECKIT option. One of the models must be a binary probit model; therefore, you must specify the DISCRETE option in the MODEL or ENDOGENOUS statement. You base the selection on the binary probit model for the second model; therefore, you must specify the SELECT option for this model.

You can specify one or both of the following *heckit-options*:

SECONDSTAGE=OLS | ML

specifies the estimation method of the second stage of Heckman's two-step method.

SECONDSTAGE=OLS requests the ordinary least squares method for the second stage. If you specify SECONDSTAGE=OLS, then the model of interest—that is, the model that uses the SELECT option—must be linear and contain a continuous dependent variable. Therefore, you cannot specify the DISCRETE, CENSORED, or TRUNCATED option along with the SELECT option for the model of interest. When you specify the SECONDSTAGE=OLS option, you cannot test or restrict the parameters of the model of interest. However, you can test or restrict the parameters of the selection model—that is, the model that defines the selection rule.

If you specify SECONDSTAGE=ML, then PROC QLIM uses the maximum likelihood method in the second stage, as it does in the first stage. When you specify SECONDSTAGE=ML, the model of interest can be nonlinear. Moreover, you can also use the TEST or RESTRICT statement to test or restrict the parameters of the model of interest.

By default, SECONDSTAGE=OLS.

UNCORRECTED

requests the conventional OLS standard errors when the second-stage estimation method is the ordinary least squares method. If you do not specify the UNCORRECTED option, PROC QLIM reports the corrected OLS standard errors. For more information about the corrected standard errors, see the section “[Heckman's Two-Step Selection Method](#)” on page 1553.

If you specify both the UNCORRECTED and SECONDSTAGE=ML options, PROC QLIM ignores the UNCORRECTED option, because the UNCORRECTED option is related to the OLS standard errors.

NDRAW=*value*

specifies the number of draws for Monte Carlo integration.

SEED=*value*

specifies a seed for pseudo-random number generation in Monte Carlo integration.

Optimization Process Control Options

PROC QLIM uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. You can use any of the NLO options in the NLOPTIONS statement. For more information, see Chapter 6, “[Nonlinear Optimization Methods](#).”

METHOD=*value*

specifies the optimization method. If this option is specified, it overwrites the TECH= option in NLOPTIONS statement. Valid values are as follows:

CONGRA	performs a conjugate-gradient optimization
DBLDOG	performs a version of double-dogleg optimization
NMSIMP	performs a Nelder-Mead simplex optimization
NEWRAP	performs a Newton-Raphson optimization combining a line-search algorithm with ridging
NRRIDG	performs a Newton-Raphson optimization with ridging
QUANEW	performs a quasi-Newton optimization
TRUREG	performs a trust region optimization

The default method is METHOD=QUANEW.

Plotting Options

PLOTS< (*global-plot-options*) > = *plot-request* | (*plot-requests*)

controls the display of plots. By default, the plots are displayed in panels unless the UNPACK *global-plot-option* is specified. When you specify only one *plot-request*, you can omit the parentheses around the *plot-request*.

Global Plot Options

You can specify the following *global-plot-options*:

ONLY

displays only the requested plot.

PRIOR

displays the prior predictive graph that is associated with the requested posterior predictive plot BAYESPRED. This option is available only for Bayesian analysis.

UNPACKPANEL

UNPACK

specifies that all paneled plots be unpacked, meaning that each plot in a panel is displayed separately.

Plot Requests

You can specify the following *plot-requests*:

ALL

specifies all types of available plots.

AUTOCORR< (LAGS=*n*) >

displays the autocorrelation function plots for the parameters. This *plot-request* is available only for Bayesian analysis. The optional LAGS= suboption the number (up to lag *n*) of autocorrelations to be plotted in the AUTOCORR plot. If this suboption is not specified, autocorrelations are plotted up to lag 50.

BAYESDIAG

displays the TRACE, AUTOCORR, and DENSITY plots. This *plot-request* is available only for Bayesian analysis.

BAYESPRED

displays the predictive analysis. The predictive analysis takes into account the variability of the error term, whereas the PREDICTED *plot-request* does not. The BAYESPRED *plot-request* is available only for Bayesian analysis.

BAYESSUM

displays the posterior distribution, the prior distribution, and the maximum likelihood estimates. This *plot-request* is available only for Bayesian analysis.

CONDITIONAL

displays the conditional expected values for continuous endogenous variables. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

DENSITY< (FRINGE) >

displays the kernel density plots for the parameters. This *plot-request* is available only for Bayesian analysis. If you specify the FRINGE suboption, a fringe plot is created on the X axis of the kernel density plot. This *plot-request* is available only for Bayesian analysis.

ERRSTD

displays the error standard deviation versus observed regressors when you also specify a HETERO statement. This *plot-request* is not available for Bayesian analysis.

EXPECTED

displays the expected values for continuous endogenous variables. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

MARGINAL

displays the marginal effects. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

MILLS

displays the inverse Mills ratio. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

NONE

suppresses all diagnostic plots.

PREDICTED

displays the model predicted values. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

PROB

displays the predicted response probability. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

PROBALL

displays the predicted probabilities for each level of the response. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

PROFLIK

displays the profiled log likelihood. Each profiled graph is obtained by setting all the parameters to their maximum likelihood estimate except for the profiling parameter. The profiling parameter takes values on a predefined grid that is determined by the maximum likelihood estimate of the corresponding standard deviation.

RESIDUAL

displays the residuals versus observed regressors. This *plot-request* is not available for Bayesian analysis.

TE1

displays the technical efficiency for the stochastic frontier model as suggested by Battese and Coelli (1988). Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

TE2

displays the technical efficiency for the stochastic frontier model as suggested by Jondrow et al. (1982). Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

TRACE<(SMOOTH)>

displays the trace plots for the parameters. This *plot-request* is available only for Bayesian analysis. The SMOOTH suboption displays a fitted penalized B-spline curve for each TRACE plot.

XBETA

displays the structural part on the right-hand side of the model. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This is not available for Bayesian analysis.

BAYES Statement

BAYES < options > ;

The BAYES statement controls the Metropolis sampling scheme that is used to obtain samples from the posterior distribution of the underlying model and data.

DIAGNOSTICS=ALL | NONE | (*keyword-list*)

DIAG=ALL | NONE | (*keyword-list*)

controls which diagnostics are produced. All the following diagnostics are produced with **DIAGNOSTICS=ALL**. If you do not want any of these diagnostics, specify **DIAGNOSTICS=NONE**. If you want some but not all of the diagnostics, or if you want to change certain settings of these diagnostics, specify a subset of the following keywords. By default, **DIAGNOSTICS=NONE**.

AUTOCORR <(LAGS= *numeric-list*)>

computes the autocorrelations at lags that are specified in the *numeric-list*. Elements in the *numeric-list* are truncated to integers, and repeated values are removed. If the LAGS= option is not specified, autocorrelations of lags 1, 5, 10, and are computed.

ESS

computes Carlin's estimate of the effective sample size, the correlation time, and the efficiency of the chain for each parameter.

GEWEKE <(geweke-options)>

computes the Geweke spectral density diagnostics, which are essentially a two-sample t test between the first f_1 portion and the last f_2 portion of the chain. The default is $f_1 = 0.1$ and $f_2 = 0.5$, but you can choose other fractions by using the following *geweke-options*:

FRAC1=*value*

specifies the fraction f_1 for the first window.

FRAC2=*value*

specifies the fraction f_2 for the second window.

HEIDELBERGER <(heidel-options)>

computes the Heidelberg and Welch diagnostic for each variable, which consists of a stationarity test of the null hypothesis that the sample values form a stationary process. If the stationarity test is not rejected, a halfwidth test is then carried out. Optionally, you can specify one or more of the following *heidel-options*:

SALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the stationarity test.

HALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the halfwidth test.

EPS=*value*

specifies a positive number ϵ such that if the halfwidth is less than ϵ times the sample mean of the retained iterates, the halfwidth test is passed.

MCSE**MCERROR**

computes the Monte Carlo standard error for each parameter. The Monte Carlo standard error, which measures the simulation accuracy, is the standard error of the posterior mean estimate and is calculated as the posterior standard deviation divided by the square root of the effective sample size.

RAFTERY<(raftery-options)>

computes the Raftery and Lewis diagnostics, which evaluate the accuracy of the estimated quantile ($\hat{\theta}_Q$ for a given $Q \in (0, 1)$) of a chain. $\hat{\theta}_Q$ can achieve any degree of accuracy when the chain is allowed to run for a long time. The computation is stopped when the estimated probability $\hat{P}_Q = \Pr(\theta \leq \hat{\theta}_Q)$ reaches within $\pm R$ of the value Q with probability S ; that is, $\Pr(Q - R \leq \hat{P}_Q \leq Q + R) = S$. The following *raftery-options* enable you to specify Q , R , S , and a precision level ϵ for the test:

QUANTILE | Q=value

specifies the order (a value between 0 and 1) of the quantile of interest. The default is 0.025.

ACCURACY | R=value

specifies a small positive number as the margin of error for measuring the accuracy of estimation of the quantile. The default is 0.005.

PROBABILITY | S=value

specifies the probability of attaining the accuracy of the estimation of the quantile. The default is 0.95.

EPSILON | EPS=value

specifies the tolerance level (a small positive number) for the stationary test. The default is 0.001.

MINTUNE=number

specifies the minimum number of tuning phases. The default is 2.

MAXTUNE=number

specifies the maximum number of tuning phases. The default is 24.

NBI=number

specifies the number of burn-in iterations before the chains are saved. The default is 1,000.

NMC=number

specifies the number of iterations after the burn-in. The default is 1,000.

NMCPRIOR=number

specifies the number of samples for the prior predictive analysis when **PLOTS(PRIOR)=BAYESPRED** is requested. The default is 10,000.

NTRDS=number**THREADS=number**

specifies the number of threads to be used. The number of threads cannot exceed the number of computer cores available. Each core samples the number of iterations that is specified by the NMC option. The default is 1.

NTU=number

specifies the number of samples for each tuning phase. The default is 500.

OUTPOST=SAS-data-set

names the SAS data set to contain the posterior samples. Alternatively, you can create the output data set by specifying an ODS OUTPUT statement as follows:

ODS OUTPUT POSTERIORSAMPLE = < SAS-data-set> ;

OUTPRIOR=SAS-data-set

names the SAS data set to contain the prior samples used to generate the prior predictive analysis when you request the prior predictive plots. Alternatively, you can create the output data set by specifying an ODS OUTPUT statement as follows:

ODS OUTPUT PRIORSAMPLE = < SAS-data-set> ;

PROPCOV=value

specifies the method used in constructing the initial covariance matrix for the Metropolis-Hastings algorithm. The QUANEW and NMSIMP methods find numerically approximated covariance matrices at the optimum of the posterior density function with respect to all continuous parameters. The tuning phase starts at the optimized values; in some problems, this can greatly increase convergence performance. If the approximated covariance matrix is not positive definite, then an identity matrix is used instead. You can specify the following values:

CONGRA

performs a conjugate-gradient optimization.

DBLDOG

performs a version of double-dogleg optimization.

NEWRAP

performs a Newton-Raphson optimization that combines a line-search algorithm with ridging.

NMSIMP

performs a Nelder-Mead simplex optimization.

NRRIDG

performs a Newton-Raphson optimization with ridging.

QUANEW

performs a quasi-Newton optimization.

TRUREG

performs a trust-region optimization.

SAMPLING=MULTIMETROPOLIS | UNIMETROPOLIS | MODELMETROPOLIS

specifies how to sample from the posterior distribution. **SAMPLING=MULTIMETROPOLIS** implements a Metropolis sampling scheme on a single block that contains all the parameters of the model. **SAMPLING=MODELMETROPOLIS** implements a Metropolis sampling scheme on multiple blocks: one block for each model (all the parameters of the model) plus a block for all the correlation parameters across the models. **SAMPLING=UNIMETROPOLIS** implements a Metropolis sampling scheme on multiple blocks, one for each parameter of the model. By default, **SAMPLING=MULTIMETROPOLIS**.

SEED=number

specifies an integer seed in the range 1 to $2^{31} - 1$ for the random number generator in the simulation. Specifying a seed enables you to reproduce identical Markov chains for the same specification. If you do not specify the **SEED=** option, or if you specify a nonpositive seed, a random seed is derived from the time of day.

SIMTIME

prints the time required for the MCMC sampling.

STATISTICS <(global-options)> = ALL | NONE | keyword | (keyword-list)**STATS <(global-options)> = ALL | NONE | keyword | (keyword-list)**

controls the number of posterior statistics produced. Specifying **STATISTICS=ALL** is equivalent to specifying **STATISTICS= (CORR COV INTERVAL PRIOR SUMMARY)**. If you do not want any posterior statistics, specify **STATISTICS=NONE**. The default is **STATISTICS=(SUMMARY INTERVAL)**. You can specify the following *global-options*:

ALPHA=*numeric-list*

controls the probabilities of the credible intervals. The ALPHA= values must be between 0 and 1. Each ALPHA= value produces a pair of 100(1-ALPHA)% equal-tail and HPD intervals for each parameter. The default is ALPHA=0.05, which yields the 95% credible intervals for each parameter.

PERCENT=*numeric-list*

requests the percentile points of the posterior samples. The PERCENT= values must be between 0 and 100. The default is PERCENT=25, 50, 75, which yields the 25th, 50th, and 75th percentile points, respectively, for each parameter.

You can specify the following *keywords*:

CORR

produces the posterior correlation matrix.

COV

produces the posterior covariance matrix.

INTERVAL

produces equal-tail credible intervals and HPD intervals. The default is to produce the 95% equal-tail credible intervals and 95% HPD intervals, but you can use the ALPHA= *global-option* to request intervals of any probabilities.

NONE

suppresses printing of all summary statistics.

PRIOR

produces a summary table of the prior distributions used in the Bayesian analysis.

SUMMARY

produces the means, standard deviations, and percentile points (25th, 50th, and 75th) for the posterior samples. You can use the global PERCENT= *global-option* to request specific percentile points.

THIN=*number*

THINNING=*number*

controls the thinning of the Markov chain. Only one in every k samples is used when THIN= k , and if NBI= n_0 and NMC= n , the number of samples that are kept is

$$\left[\frac{n_0 + n}{k} \right] - \left[\frac{n_0}{k} \right]$$

where $[a]$ represents the integer part of the number a . The default is THIN=1.

BOUNDS Statement

BOUNDS *bound1* < , *bound2* ... > ;

The BOUNDS statement imposes simple boundary constraints on the parameter estimates. BOUNDS statement constraints refer to the parameters estimated by the QLIM procedure. Any number of BOUNDS statements can be specified.

Each *bound* is composed of parameters and constants and inequality operators. Parameters associated with regressor variables are referred to by the names of the corresponding regressor variables:

item operator item < operator item < operator item ... > >

Each *item* is a constant, the name of a parameter, or a list of parameter names. See the section “[Naming of Parameters](#)” on page 1574 for more details on how parameters are named in the QLIM procedure. Each *operator* is '<', '>', '<=', or '>='.

Both the BOUNDS statement and the RESTRICT statement can be used to impose boundary constraints; however, the BOUNDS statement provides a simpler syntax for specifying these kinds of constraints. See the “[RESTRICT Statement](#)” on page 1537 for more information.

The following BOUNDS statement constrains the estimates of the parameters associated with the variable *ttime* and the variables *x1* through *x10* to be between 0 and 1. This example illustrates the use of parameter lists to specify boundary constraints.

```
bounds 0 < ttime x1-x10 < 1;
```

The following BOUNDS statement constrains the estimates of the correlation (*_RHO*) and sigma (*_SIGMA*) in the bivariate model:

```
bounds _rho >= 0, _sigma.y1 > 1, _sigma.y2 < 5;
```

The BOUNDS statement is not supported if a BAYES statement is also specified. In Bayesian analysis, the restrictions on parameters are usually introduced through the prior distribution.

BY Statement

BY *variables* ;

A BY statement can be used with PROC QLIM to obtain separate analyses on observations in groups defined by the BY variables.

CLASS Statement

CLASS *variables* ;

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric.

Class levels are determined from the formatted values of the CLASS variables. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in *SAS Language Reference: Dictionary* for details.

ENDOGENOUS Statement

ENDOGENOUS *variables ~ options ;*

The ENDOGENOUS statement specifies the type of dependent variables that appear on the left-hand side of the equation. Endogenous variables listed refer to the dependent variables that appear on the left-hand side of the equation.

Discrete Variable Options

DISCRETE *<(discrete-options)>*

specifies that the endogenous variables in this statement are discrete. Valid *discrete-options* are as follows:

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sorting order for the levels of the discrete variables specified in the ENDOGENOUS statement. This ordering determines which parameters in the model correspond to each level in the data. The following table shows how PROC QLIM interprets values of the ORDER= option.

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	Formatted value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, ORDER=FORMATTED. For the values FORMATTED and INTERNAL, the sort order is machine dependent. For more information about sorting order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide*.

DISTRIBUTION=NORMAL | LOGISTIC

DIST=NORMAL | LOGISTIC

D=NORMAL | LOGISTIC

specifies the cumulative distribution function used to model the response probabilities. DISTRIBUTION=NORMAL specifies the normal distribution for the probit model. DISTRIBUTION=LOGISTIC specifies the logistic distribution for the logit model.

By default, DISTRIBUTION=NORMAL.

If a multivariate model is specified, logistic distribution is not allowed. Only normal distribution is supported.

Censored Variable Options

CENSORED *(censored-options)*

specifies that the endogenous variables in this statement be censored. Valid *censored-options* are as follows:

LB=*value or variable*

LOWERBOUND=*value or variable*

specifies the lower bound of the censored variables. If *value* is missing or the value in *variable* is missing, no lower bound is set. By default, no lower bound is set.

UB=*value or variable*

UPPERBOUND=*value or variable*

specifies the upper bound of the censored variables. If *value* is missing or the value in *variable* is missing, no upper bound is set. By default, no upper bound is set.

Truncated Variable Options

TRUNCATED (*truncated-options*)

specifies that the endogenous variables in this statement be truncated. Valid *truncated-options* are as follows:

LB=*value or variable*

LOWERBOUND=*value or variable*

specifies the lower bound of the truncated variables. If *value* is missing or the value in *variable* is missing, no lower bound is set. By default, no lower bound is set.

UB=*value or variable*

UPPERBOUND=*value or variable*

specifies the upper bound of the truncated variables. If *value* is missing or the value in *variable* is missing, no upper bound is set. By default, no upper bound is set.

Stochastic Frontier Variable Options

FRONTIER <(*frontier-options*)>

specifies that the endogenous variable in this statement follow a production or cost frontier. Valid *frontier-options* are as follows:

TYPE=HALF | EXPONENTIAL | TRUNCATED

specifies the model type:

HALF specifies a half-normal model.

EXPONENTIAL specifies an exponential model.

TRUNCATED specifies a truncated normal model.

PRODUCTION

specifies that the model estimated be a production function.

COST

specifies that the model estimated be a cost function.

If neither PRODUCTION nor COST option is specified, production function is estimated by default.

Selection Options

SELECT (*select-option*)

specifies selection criteria for sample selection model. The BAYES statement does not support the SELECT option. The *select-option* specifies the condition for the endogenous variable to be selected. It is written as a variable name, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a number:

variable operator number

The *variable* is the endogenous variable that the selection is based on. The *operator* can be =, <, >, <=, or >=. Multiple *select-options* can be combined with the logic operators: AND, OR. The following example illustrates the use of the SELECT option:

```
endogenous y1 ~ select(z=0);
endogenous y2 ~ select(z=1 or z=2);
```

The SELECT option can be used together with the DISCRETE, CENSORED, or TRUNCATED option. For example:

```
endogenous y1 ~ select(z=0) discrete;
endogenous y2 ~ select(z=1) censored (lb=0);
endogenous y3 ~ select(z=1 or z=2) truncated (ub=10);
```

For more information about selection models with censoring or truncation, see the section “[Selection Models](#)” on page 1551.

Endogeneity and Overidentification Test Options

ENDOTEST (*regressors*)

requests the test of endogeneity for a list of regressors in the model. More specifically, this option tests the null hypothesis that the specified regressors are exogenous. Each of these regressors must also have a model of its own. The former model is considered the structural model, and the latter models are considered reduced form models.

The following example illustrates the use of the ENDOTEST option by testing whether the regressors y2 and y3 are endogenous in the model for y1:

```
proc qlim;
  model y1 = y2 y3 x1;
  model y2 = x1 x2 x3 x4 x5;
  model y3 = x1 x2 x3 x4 x5;
  endogenous y1 ~ endotest(y2 y3);
run;
```

The ENDOTEST option is not available when you specify the SELECT or FRONTIER option. You can specify the ENDOTEST option only once for each ENDOGENOUS statement.

For more information about the test for endogeneity, see the section “[Test for Endogeneity](#)” on page 1561.

OVERID (*variables*)

requests the overidentification test for a list of variables. These variables are the overidentifying instrumental variables that you provide from the reduced form models. For more information, see the section “[Overidentification Test](#)” on page 1562.

The following example illustrates the use of the OVERID option:

```
proc qlim;
  model y1 = y2 y3 x1;
  model y2 = x1 x2 x3 x4 x5;
  model y3 = x1 x2 x3 x4 x5;
  endogenous y1 ~ overid(y2.x4 y3.x5);
run;
```

The regressors y_2 and y_3 in the model for y_1 are the endogenous variables. Therefore, each of these variables has its own models, which are considered reduced form models. The overidentifying instrumental variables are x_4 and x_5 . If you specify the OVERID option as

```
endogenous y1 ~ overid(y2.x4 y2.x5);
```

then you consider only the regressor y_2 to be endogenous, and the model for y_3 is ignored during the testing process.

The OVERID option is not available when you specify the SELECT or FRONTIER option. You can specify the OVERID option only once for each ENDOGENOUS statement.

FREQ Statement

FREQ *variable* ;

The FREQ statement identifies a variable that contains the frequency of occurrence of each observation. PROC QLIM treats each observation as if it appears n times, where n is the value of the FREQ variable for the observation. If it is not an integer, the frequency value is truncated to an integer. If the frequency value is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not specified, each observation is assigned a frequency of 1. If you specify more than one FREQ statement, then the first FREQ statement is used.

HETERO Statement

HETERO *dependent variables* ~ *exogenous variables* </ options > ;

The HETERO statement specifies variables that are related to the heteroscedasticity of the residuals and the way these variables are used to model the error variance. The heteroscedastic regression model supported by PROC QLIM is

$$y_i = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$\epsilon_i \sim N(0, \sigma_i^2)$$

See the section “[Heteroscedasticity](#)” on page 1549 for more details on the specification of functional forms.

LINK=value

The functional form can be specified using the LINK= option. The following option values are allowed:

EXP specifies the exponential link function

$$\sigma_i^2 = \sigma^2(1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma}))$$

LINEAR specifies the linear link function

$$\sigma_i^2 = \sigma^2(1 + \mathbf{z}_i' \boldsymbol{\gamma})$$

When the LINK= option is not specified, the exponential link function is specified by default.

NOCONST

specifies that there be no constant in the exponential heteroscedasticity model.

$$\sigma_i^2 = \sigma^2 \exp(\mathbf{z}_i' \boldsymbol{\gamma})$$

SQUARE

estimates the model by using the square of linear heteroscedasticity function. For example, you can specify the following heteroscedasticity function:

$$\sigma_i^2 = \sigma^2(1 + (\mathbf{z}_i' \boldsymbol{\gamma})^2)$$

```
model y = x1 x2 / discrete;
hetero y ~ z1 / link=linear square;
```

The option SQUARE does not apply to exponential heteroscedasticity function because the square of an exponential function of $\mathbf{z}_i' \boldsymbol{\gamma}$ is the same as the exponential of $2\mathbf{z}_i' \boldsymbol{\gamma}$. Hence the only difference is that all $\boldsymbol{\gamma}$ estimates are divided by two.

You can use the HETERO statement within a Bayesian framework, but you should do this carefully because convergence can be slower than in the homoscedastic case. For more information see “[Priors for Heteroscedastic Models](#)” on page 1566.

INIT Statement

```
INIT initvalue1 < , initvalue2 ... > ;
```

The INIT statement sets initial values for parameters in the optimization. You can specify any number of INIT statements.

Each *initvalue* is written as a parameter or parameter list, followed by an optional equality operator (=), followed by a number:

```
parameter <=> number
```

If you also specify the BAYES statement, the INIT statement also initializes the Markov chain Monte Carlo (MCMC) algorithm. In particular, the INIT statement does one of the following:

- It initializes the tuning phase (this also includes the PROPCOV option).
- It initializes the sampling phase, if there is no tuning phase.

MODEL Statement

MODEL *dependent* = *regressors* < / *options* > ;

The MODEL statement specifies the dependent variable and independent regressor variables for the regression model.

You can specify the following *options* after a slash (/).

LIMIT1=ZERO | VARYING

specifies the restriction of the threshold value of the first category when the ordinal probit or logit model is estimated. LIMIT1=ZERO is the default option. When LIMIT1=VARYING is specified, the threshold value is estimated.

NOINT

suppresses the intercept parameter.

Endogenous Variable Options

The endogenous variable options are the same as the options that you can specify in the ENDOGENOUS statement. If you specify an ENDOGENOUS statement, all endogenous options in the MODEL statement are ignored.

Endogeneity and Overidentification Test Options

The endogeneity and overidentification test options are the same as the options that you can specify in the ENDOGENOUS statement. If you specify an ENDOGENOUS statement, all endogeneity and overidentification test options in the MODEL statement are ignored.

BOXCOX Estimation Options

BOXCOX (*option-list*)

specifies options that are used for Box-Cox regression or regressor transformation. For example, the Box-Cox regression is specified as

```
model y = x1 x2 / boxcox(y=lambda,x1 x2)
```

PROC QLIM estimates the following Box-Cox regression model:

$$y_i^{(\lambda)} = \beta_0 + \beta_1 x_{1i}^{(\lambda_2)} + \beta_2 x_{2i}^{(\lambda_2)} + \epsilon_i$$

The *option-list* takes the form *variable-list* < = *varname* > separated by commas. The *variable-list* specifies that the list of variables have the same Box-Cox transformation; *varname* specifies the name of this Box-Cox coefficient. If *varname* is not specified, the coefficient is called *_Lambdai*, where *i* increments sequentially.

Variable Selection Options

SELECTVAR <=(*selectvar-option*)>

enables variable selection. The *selectvar-option* specifies a variable selection method based on an information criterion. For more information, see the section “[Variable Selection](#)” on page 1555. You can specify the following *selectvar-options*:

DIRECTION=FORWARD | BACKWARD

specifies the searching algorithm to use in the variable selection method. By default, DIRECTION=FORWARD.

CRITER=AIC | SBC

specifies the information criterion to use for the variable selection. By default, CRITER=AIC.

MAXSTEPS=value

specifies the maximum number of steps that are allowed in the search algorithm. The default is infinite; that is, the algorithm does not stop until the stopping criterion is satisfied.

LSTOP=value

specifies the stopping criterion. The *value* represents the percentage of decrease or increase in the AIC or SBC that is required for the algorithm to proceed; it must be a positive number less than 1. The default is 0.

RETAIN(*regressors*)

specifies a list of regressors that are to be retained in any model that the variable selection process considers.

The following rules apply to how regressors are handled when you specify more than one MODEL statement and use the SELECTVAR option:

- If you do not specify the SELECTVAR option in a particular MODEL statement, then all regressors in the original model are included in any model that the variable selection algorithm considers. In other words, omitting the SELECTVAR option is equivalent to providing the option: SELECTVAR=(RETAIN(*all-regressors*)).
- If you specify the SELECTVAR option without any =(*option*) clause in a MODEL statement, then all regressors in that model (other than the intercept, if present) are eligible for potential exclusion as the variable selection process is executed.

The following example specifies 10 possible regressor candidates, out of which five are selected using the AIC criterions:

```
proc qlim data=one;
  model y = x1-x10 /selectvar=(direction=forward criter=AIC maxsteps=5);
run;
```

NLOPTIONS Statement

NLOPTIONS < *options* > ;

PROC QLIM uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. For a list of all the options of the NLOPTIONS statement, see Chapter 6, “[Nonlinear Optimization Methods](#).”

OUTPUT Statement

OUTPUT <OUT=SAS-data-set> <output-options> ;

The OUTPUT statement creates a new SAS data set containing all variables in the input data set and, optionally, the estimates of $\mathbf{x}'\boldsymbol{\beta}$, predicted value, residual, marginal effects, probability, standard deviation of the error, expected value, conditional expected value, technical efficiency measures, and inverse Mills ratio. When the response values are missing for the observation, all output estimates except residual are still computed as long as none of the explanatory variables is missing. This enables you to compute these statistics for prediction. You can specify only one OUTPUT statement.

Details on the specifications in the OUTPUT statement are as follows:

CONDITIONAL

outputs estimates of conditional expected values of continuous endogenous variables.

ERRSTD

outputs estimates of σ_j , the standard deviation of the error term.

EXPECTED

outputs estimates of expected values of continuous endogenous variables.

MARGINAL

outputs marginal effects.

MILLS

outputs estimates of inverse Mills ratios of censored or truncated continuous, binary discrete, and selection endogenous variables.

OUT=SAS-data-set

names the output data set.

PREDICTED

outputs estimates of predicted endogenous variables.

PROB

outputs estimates of probability of discrete endogenous variables taking the current observed responses.

PROBALL

outputs estimates of probability of discrete endogenous variables for all possible responses.

RESIDUAL

outputs estimates of residuals of continuous endogenous variables.

XBETA

outputs estimates of $\mathbf{x}'\boldsymbol{\beta}$.

TE1

outputs estimates of technical efficiency for each producer in the stochastic frontier model suggested by Battese and Coelli (1988).

TE2

outputs estimates of technical efficiency for each producer in the stochastic frontier model suggested by Jondrow et al. (1982).

PRIOR Statement

PRIOR *_REGRESSORS* | *parameter-list* ~ *distribution* ;

The PRIOR statement specifies the prior distribution of the model parameters. You must specify a single parameter or a list of parameter, a tilde ~, and then a distribution with its parameters. Multiple PRIOR statements are allowed.

You can specify the following *distributions*:

NORMAL(MEAN= μ , VAR= σ^2)

specifies a normal distribution with parameters MEAN and VAR.

GAMMA(SHAPE= a , SCALE= b)

specifies a gamma distribution with parameters SHAPE and SCALE.

IGAMMA(SHAPE= a , SCALE= b)

specifies an inverse gamma distribution with parameters SHAPE and SCALE.

UNIFORM(MIN= m , MAX= M)

specifies a uniform distribution that is defined between MIN and MAX.

BETA(SHAPE1= a , SHAPE2= b , MIN= m , MAX= M)

specifies a beta distribution with parameters SHAPE1 and SHAPE2 and defined between MIN and MAX.

T(LOCATION= μ , DF= ν)

specifies a noncentral t distribution with DF degrees of freedom and location parameter equal to LOCATION.

See the section “[Standard Distributions](#)” on page 1567 for details about how to specify *distributions*.

You can specify the special keyword REGRESSORS to select all the parameters used in the linear regression component of the model.

RESTRICT Statement

RESTRICT *restriction1* <, *restriction2* ... > ;

The RESTRICT statement is used to impose linear restrictions on the parameter estimates. Any number of RESTRICT statements can be specified, but the number of restrictions imposed is limited by the number of regressors.

Each *restriction* is written as an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

expression operator expression

The *operator* can be =, <, >, <=, or >=. The operator and second expression are optional.

Restriction expressions can be composed of parameter names, multiplication (*), addition (+) and substitution (−) operators, and constants. Parameters named in restriction expressions must be among the parameters estimated by the model. Parameters associated with a regressor variable are referred to by the name of the corresponding regressor variable. The restriction expressions must be a linear function of the parameters.

The following is an example of the use of the RESTRICT statement:

```
proc qlim data=one;
  model y = x1-x10 / discrete;
  restrict x1*2 <= x2 + x3;
run;
```

The RESTRICT statement can also be used to impose cross-equation restrictions in multivariate models. The following RESTRICT statement imposes an equality restriction on coefficients of x_1 in equation y_1 and x_1 in equation y_2 :

```
proc qlim data=one;
  model y1 = x1-x10;
  model y2 = x1-x4;
  endogenous y1 y2 ~ discrete;
  restrict y1.x1=y2.x1;
run;
```

The RESTRICT statement is not supported if a BAYES statement is also specified. In Bayesian analysis, the restrictions on parameters are usually introduced through the prior distribution.

TEST Statement

<'label':> TEST <'string':> equation [,equation...] / options ;

The TEST statement performs Wald, Lagrange multiplier, and likelihood ratio tests of linear hypotheses about the regression parameters in the preceding MODEL statement. Each equation specifies a linear hypothesis to be tested. All hypotheses in one TEST statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. The keyword INTERCEPT refers to the coefficient of the intercept.

The following options can be specified in the TEST statement after the slash (/):

ALL

requests Wald, Lagrange multiplier, and likelihood ratio tests.

WALD

requests the Wald test.

LM

requests the Lagrange multiplier test.

LR

requests the likelihood ratio test.

The following illustrates the use of the TEST statement:

```
proc qlim;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0;
  test _int: test intercept = 0, x3 = 0;
run;
```

The first test investigates the joint hypothesis that

$$\beta_1 = 0$$

and

$$0.5\beta_2 + 2\beta_3 = 0$$

In case there is more than one MODEL statement in one QLIM procedure, then TEST statement is capable of testing cross-equation restrictions. Each parameter reference should be preceded by the name of the dependent variable of the particular model and the dot sign. For example,

```
proc qlim;
  model y1 = x1 x2 x3;
  model y2 = x3 x5 x6;
  test y1.x1 + y2.x6 = 1;
run;
```

This cross-equation test investigates the null hypothesis that

$$\beta_{1,1} + \beta_{2,3} = 1$$

in the system of equations

$$y_{1,i} = \alpha_1 + \beta_{1,1}x_{1,i} + \beta_{1,2}x_{2,i} + \beta_{1,3}x_{3,i}$$

$$y_{2,i} = \alpha_2 + \beta_{2,1}x_{3,i} + \beta_{2,2}x_{5,i} + \beta_{2,3}x_{6,i}$$

Only linear equality restrictions and tests are permitted in PROC QLIM. Tests expressions can be composed only of algebraic operations involving the addition symbol (+), subtraction symbol (-), and multiplication symbol (*).

The TEST statement accepts labels that are reproduced in the printed output. TEST statement can be labeled in two ways. A TEST statement can be preceded by a label followed by a colon. Alternatively, the keyword TEST can be followed by a quoted string. If both are present, PROC QLIM uses the label preceding the colon. In the event no label is present, PROC QLIM automatically labels the tests.

You cannot specify both the TEST statement and the BAYES statement.

WEIGHT Statement

WEIGHT *variable* *</option>* ;

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters. The log likelihood for each observation is multiplied by the corresponding weight variable value.

If the weight of an observation is nonpositive, that observation is not used in the estimation.

The following option can be added to the WEIGHT statement after a slash (/).

NONNORMALIZE

specifies that the weights are required to be used as is. When this option is not specified, the weights are normalized so that they add up to the actual sample size. Weights w_i are normalized by multiplying them by $\frac{n}{\sum_{i=1}^n w_i}$, where n is the sample size.

Details: QLIM Procedure

Ordinal Discrete Choice Modeling

Binary Probit and Logit Model

The binary choice model is

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

where value of the latent dependent variable, y_i^* , is observed only as follows:

$$\begin{aligned} y_i &= 1 && \text{if } y_i^* > 0 \\ &= 0 && \text{otherwise} \end{aligned}$$

The disturbance, ϵ_i , of the probit model has standard normal distribution with the distribution function (CDF)

$$\Phi(x) = \int_{-\infty}^x \frac{1}{\sqrt{2\pi}} \exp(-t^2/2) dt$$

The disturbance of the logit model has standard logistic distribution with the CDF

$$\Lambda(x) = \frac{\exp(x)}{1 + \exp(x)} = \frac{1}{1 + \exp(-x)}$$

The binary discrete choice model has the following probability that the event $\{y_i = 1\}$ occurs:

$$P(y_i = 1) = F(\mathbf{x}_i' \boldsymbol{\beta}) = \begin{cases} \Phi(\mathbf{x}_i' \boldsymbol{\beta}) & \text{(probit)} \\ \Lambda(\mathbf{x}_i' \boldsymbol{\beta}) & \text{(logit)} \end{cases}$$

The log-likelihood function is

$$\ell = \sum_{i=1}^N \{y_i \log[F(\mathbf{x}'_i \boldsymbol{\beta})] + (1 - y_i) \log[1 - F(\mathbf{x}'_i \boldsymbol{\beta})]\}$$

where the CDF $F(x)$ is defined as $\Phi(x)$ for the probit model while $F(x) = \Lambda(x)$ for logit. The first order derivatives of the logit model are

$$\frac{\partial \ell}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N (y_i - \Lambda(\mathbf{x}'_i \boldsymbol{\beta})) \mathbf{x}_i$$

The probit model has more complicated derivatives

$$\frac{\partial \ell}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N \left[\frac{(2y_i - 1)\phi(\mathbf{x}'_i \boldsymbol{\beta})}{\Phi(\mathbf{x}'_i \boldsymbol{\beta})} \right] \mathbf{x}_i = \sum_{i=1}^N r_i \mathbf{x}_i$$

where

$$r_i = \frac{(2y_i - 1)\phi(\mathbf{x}'_i \boldsymbol{\beta})}{\Phi(\mathbf{x}'_i \boldsymbol{\beta})}$$

Note that the logit maximum likelihood estimates are $\frac{\pi}{\sqrt{3}}$ times greater than probit maximum likelihood estimates, since the probit parameter estimates, $\boldsymbol{\beta}$, are standardized, and the error term with logistic distribution has a variance of $\frac{\pi^2}{3}$.

Ordinal Probit/Logit

When the dependent variable is observed in sequence with M categories, binary discrete choice modeling is not appropriate for data analysis. McKelvey and Zavoina (1975) proposed the ordinal (or ordered) probit model.

Consider the following regression equation:

$$y_i^* = \mathbf{x}'_i \boldsymbol{\beta} + \epsilon_i$$

where error disturbances, ϵ_i , have the distribution function F . The unobserved continuous random variable, y_i^* , is identified as M categories. Suppose there are $M + 1$ real numbers, μ_0, \dots, μ_M , where $\mu_0 = -\infty$, $\mu_1 = 0$, $\mu_M = \infty$, and $\mu_0 \leq \mu_1 \leq \dots \leq \mu_M$. Define

$$R_{i,j} = \mu_j - \mathbf{x}'_i \boldsymbol{\beta}$$

The probability that the unobserved dependent variable is contained in the j th category can be written as

$$P[\mu_{j-1} < y_i^* \leq \mu_j] = F(R_{i,j}) - F(R_{i,j-1})$$

The log-likelihood function is

$$\ell = \sum_{i=1}^N \sum_{j=1}^M d_{ij} \log [F(R_{i,j}) - F(R_{i,j-1})]$$

where

$$d_{ij} = \begin{cases} 1 & \text{if } \mu_{j-1} < y_i \leq \mu_j \\ 0 & \text{otherwise} \end{cases}$$

The first derivatives are written as

$$\frac{\partial \ell}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N \sum_{j=1}^M d_{ij} \left[\frac{f(R_{i,j-1}) - f(R_{i,j})}{F(R_{i,j}) - F(R_{i,j-1})} \mathbf{x}_i \right]$$

$$\frac{\partial \ell}{\partial \mu_k} = \sum_{i=1}^N \sum_{j=1}^M d_{ij} \left[\frac{\delta_{j,k} f(R_{i,j}) - \delta_{j-1,k} f(R_{i,j-1})}{F(R_{i,j}) - F(R_{i,j-1})} \right]$$

where $f(x) = \frac{dF(x)}{dx}$ and $\delta_{j,k} = 1$ if $j = k$, and $\delta_{j,k} = 0$ otherwise. When the ordinal probit is estimated, it is assumed that $F(R_{i,j}) = \Phi(R_{i,j})$. The ordinal logit model is estimated if $F(R_{i,j}) = \Lambda(R_{i,j})$. The first threshold parameter, μ_1 , is estimated when the LIMIT1=VARYING option is specified. By default (LIMIT1=ZERO), so that $M - 2$ threshold parameters (μ_2, \dots, μ_{M-1}) are estimated.

The ordered probit models are analyzed by Aitchison and Silvey (1957), and Cox (1970) discussed ordered response data by using the logit model. They defined the probability that y_i^* belongs to j th category as

$$P[\mu_{j-1} < y_i \leq \mu_j] = F(\mu_j + \mathbf{x}_i' \boldsymbol{\theta}) - F(\mu_{j-1} + \mathbf{x}_i' \boldsymbol{\theta})$$

where $\mu_0 = -\infty$ and $\mu_M = \infty$. Therefore, the ordered response model analyzed by Aitchison and Silvey can be estimated if the LIMIT1=VARYING option is specified. Note that $\boldsymbol{\theta} = -\boldsymbol{\beta}$.

Goodness-of-Fit Measures

The goodness-of-fit measures discussed in this section apply only to discrete dependent variable models.

McFadden (1974) suggested a likelihood ratio index that is analogous to the R^2 in the linear regression model:

$$R_M^2 = 1 - \frac{\ln L}{\ln L_0}$$

where L is the value of the maximum likelihood function and L_0 is the value of a likelihood function when regression coefficients except an intercept term are zero. It can be shown that L_0 can be written as

$$L_0 = \sum_{j=1}^M N_j \ln\left(\frac{N_j}{N}\right)$$

where N_j is the number of responses in category j .

Estrella (1998) proposes the following requirements for a goodness-of-fit measure to be desirable in discrete choice modeling:

- The measure must take values in $[0, 1]$, where 0 represents no fit and 1 corresponds to perfect fit.
- The measure should be directly related to the valid test statistic for significance of all slope coefficients.

- The derivative of the measure with respect to the test statistic should comply with corresponding derivatives in a linear regression.

Estrella's (1998) measure is written

$$R_{E1}^2 = 1 - \left(\frac{\ln L}{\ln L_0} \right)^{-\frac{2}{N} \ln L_0}$$

An alternative measure suggested by Estrella (1998) is

$$R_{E2}^2 = 1 - [(\ln L - K) / \ln L_0]^{-\frac{2}{N} \ln L_0}$$

where $\ln L_0$ is computed with null slope parameter values, N is the number observations used, and K represents the number of estimated parameters.

Other goodness-of-fit measures are summarized as follows:

$$R_{CU1}^2 = 1 - \left(\frac{L_0}{L} \right)^{\frac{2}{N}} \quad (\text{Cragg} - \text{Uhler1})$$

$$R_{CU2}^2 = \frac{1 - (L_0/L)^{\frac{2}{N}}}{1 - L_0^{\frac{2}{N}}} \quad (\text{Cragg} - \text{Uhler2})$$

$$R_A^2 = \frac{2(\ln L - \ln L_0)}{2(\ln L - \ln L_0) + N} \quad (\text{Aldrich} - \text{Nelson})$$

$$R_{VZ}^2 = R_A^2 \frac{2 \ln L_0 - N}{2 \ln L_0} \quad (\text{Veall} - \text{Zimmermann})$$

$$R_{MZ}^2 = \frac{\sum_{i=1}^N (\hat{y}_i - \bar{\hat{y}})^2}{N + \sum_{i=1}^N (\hat{y}_i - \bar{\hat{y}})^2} \quad (\text{McKelvey} - \text{Zavoina})$$

where $\hat{y}_i = \mathbf{x}_i' \hat{\boldsymbol{\beta}}$ and $\bar{\hat{y}} = \sum_{i=1}^N \hat{y}_i / N$.

Limited Dependent Variable Models

Censored Regression Models

When the dependent variable is censored, values in a certain range are all transformed to a single value. For example, the standard tobit model can be defined as

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$y_i = \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases}$$

where $\epsilon_i \sim iidN(0, \sigma^2)$. The log-likelihood function of the standard censored regression model is

$$\ell = \sum_{i \in \{y_i=0\}} \ln[1 - \Phi(\mathbf{x}_i' \boldsymbol{\beta} / \sigma)] + \sum_{i \in \{y_i>0\}} \ln \left[\phi \left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma} \right) / \sigma \right]$$

where $\Phi(\cdot)$ is the cumulative density function of the standard normal distribution and $\phi(\cdot)$ is the probability density function of the standard normal distribution.

The tobit model can be generalized to handle observation-by-observation censoring. The censored model on both of the lower and upper limits can be defined as

$$y_i = \begin{cases} R_i & \text{if } y_i^* \geq R_i \\ y_i^* & \text{if } L_i < y_i^* < R_i \\ L_i & \text{if } y_i^* \leq L_i \end{cases}$$

The log-likelihood function can be written as

$$\begin{aligned} \ell = & \sum_{i \in \{L_i < y_i < R_i\}} \ln \left[\phi\left(\frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma}\right) / \sigma \right] + \sum_{i \in \{y_i = R_i\}} \ln \left[\Phi\left(-\frac{R_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma}\right) \right] + \\ & \sum_{i \in \{y_i = L_i\}} \ln \left[\Phi\left(\frac{L_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma}\right) \right] \end{aligned}$$

Log-likelihood functions of the lower- or upper-limit censored model are easily derived from the two-limit censored model. The log-likelihood function of the lower-limit censored model is

$$\ell = \sum_{i \in \{y_i > L_i\}} \ln \left[\phi\left(\frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma}\right) / \sigma \right] + \sum_{i \in \{y_i = L_i\}} \ln \left[\Phi\left(\frac{L_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma}\right) \right]$$

The log-likelihood function of the upper-limit censored model is

$$\ell = \sum_{i \in \{y_i < R_i\}} \ln \left[\phi\left(\frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma}\right) / \sigma \right] + \sum_{i \in \{y_i = R_i\}} \ln \left[1 - \Phi\left(\frac{R_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma}\right) \right]$$

Types of Tobit Models

Amemiya (1984) classified Tobit models into five types based on characteristics of the likelihood function. For notational convenience, let P denote a distribution or density function, y_{ji}^* is assumed to be normally distributed with mean $\mathbf{x}'_{ji} \boldsymbol{\beta}_j$ and variance σ_j^2 .

Type 1 Tobit

The Type 1 Tobit model was already discussed in the preceding section.

$$\begin{aligned} y_{1i}^* &= \mathbf{x}'_{1i} \boldsymbol{\beta}_1 + u_{1i} \\ y_{1i} &= y_{1i}^* \quad \text{if } y_{1i}^* > 0 \\ &= 0 \quad \text{if } y_{1i}^* \leq 0 \end{aligned}$$

The likelihood function is characterized as $P(y_1 < 0)P(y_1)$.

Type 2 Tobit

The Type 2 Tobit model is defined as

$$\begin{aligned}
 y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + u_{1i} \\
 y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + u_{2i} \\
 y_{1i} &= 1 \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{2i} &= y_{2i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0
 \end{aligned}$$

where $(u_{1i}, u_{2i}) \sim N(0, \Sigma)$. The likelihood function is described as $P(y_1 < 0)P(y_1 > 0, y_2)$.

Type 3 Tobit

The Type 3 Tobit model is different from the Type 2 Tobit in that y_{1i}^* of the Type 3 Tobit is observed when $y_{1i}^* > 0$.

$$\begin{aligned}
 y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + u_{1i} \\
 y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + u_{2i} \\
 y_{1i} &= y_{1i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{2i} &= y_{2i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0
 \end{aligned}$$

where $(u_{1i}, u_{2i})' \sim iidN(0, \Sigma)$.

The likelihood function is characterized as $P(y_1 < 0)P(y_1, y_2)$.

Type 4 Tobit

The Type 4 Tobit model consists of three equations:

$$\begin{aligned}
 y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + u_{1i} \\
 y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + u_{2i} \\
 y_{3i}^* &= \mathbf{x}_{3i}'\boldsymbol{\beta}_3 + u_{3i} \\
 y_{1i} &= y_{1i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{2i} &= y_{2i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{3i} &= y_{3i}^* \quad \text{if } y_{1i}^* \leq 0 \\
 &= 0 \quad \text{if } y_{1i}^* > 0
 \end{aligned}$$

where $(u_{1i}, u_{2i}, u_{3i})' \sim iidN(0, \Sigma)$. The likelihood function of the Type 4 Tobit model is characterized as $P(y_1 < 0, y_3)P(y_1, y_2)$.

Type 5 Tobit

The Type 5 Tobit model is defined as follows:

$$\begin{aligned}
 y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + u_{1i} \\
 y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + u_{2i} \\
 y_{3i}^* &= \mathbf{x}_{3i}'\boldsymbol{\beta}_3 + u_{3i} \\
 y_{1i} &= 1 \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{2i} &= y_{2i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{3i} &= y_{3i}^* \quad \text{if } y_{1i}^* \leq 0 \\
 &= 0 \quad \text{if } y_{1i}^* > 0
 \end{aligned}$$

where $(u_{1i}, u_{2i}, u_{3i})'$ are from *iid* trivariate normal distribution. The likelihood function of the Type 5 Tobit model is characterized as $P(y_1 < 0, y_3)P(y_1 > 0, y_2)$.

Code examples for these models can be found in “[Example 22.6: Types of Tobit Models](#)” on page 1588.

Truncated Regression Models

In a truncated model, the observed sample is a subset of the population where the dependent variable falls in a certain range. For example, when neither a dependent variable nor exogenous variables are observed for $y_i^* \leq 0$, the truncated regression model can be specified.

$$\ell = \sum_{i \in \{y_i > 0\}} \left\{ -\ln \Phi(\mathbf{x}_i'\boldsymbol{\beta}/\sigma) + \ln \left[\frac{\phi((y_i - \mathbf{x}_i'\boldsymbol{\beta})/\sigma)}{\sigma} \right] \right\}$$

Two-limit truncation model is defined as

$$y_i = y_i^* \text{ if } L_i < y_i^* < R_i$$

The log-likelihood function of the two-limit truncated regression model is

$$\ell = \sum_{i=1}^N \left\{ \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right)/\sigma \right] - \ln \left[\Phi\left(\frac{R_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right) - \Phi\left(\frac{L_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right) \right] \right\}$$

The log-likelihood functions of the lower- and upper-limit truncation model are

$$\begin{aligned}
 \ell &= \sum_{i=1}^N \left\{ \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right)/\sigma \right] - \ln \left[1 - \Phi\left(\frac{L_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right) \right] \right\} \quad (\text{lower}) \\
 \ell &= \sum_{i=1}^N \left\{ \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right)/\sigma \right] - \ln \left[\Phi\left(\frac{R_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right) \right] \right\} \quad (\text{upper})
 \end{aligned}$$

Stochastic Frontier Production and Cost Models

Stochastic frontier production models were first developed by Aigner, Lovell, and Schmidt (1977); Meeusen and van den Broeck (1977). Specification of these models allow for random shocks of the production or cost but also include a term for technological or cost inefficiency. Assuming that the production function takes a log-linear Cobb-Douglas form, the stochastic frontier production model can be written as

$$\ln(y_i) = \beta_0 + \sum_n \beta_n \ln(x_{ni}) + \epsilon_i$$

where $\epsilon_i = v_i - u_i$. The v_i term represents the stochastic error component and u_i is the nonnegative, technology inefficiency error component. The v_i error component is assumed to be distributed iid normal and independently from u_i . If $u_i > 0$, the error term, ϵ_i , is negatively skewed and represents technology inefficiency. If $u_i < 0$, the error term ϵ_i is positively skewed and represents cost inefficiency. PROC QLIM models the u_i error component as a half normal, exponential, or truncated normal distribution.

The Normal-Half Normal Model

In case of the normal-half normal model, v_i is iid $N(0, \sigma_v^2)$, u_i is iid $N^+(0, \sigma_u^2)$ with v_i and u_i independent of each other. Given the independence of error terms, the joint density of v and u can be written as

$$f(u, v) = \frac{2}{2\pi\sigma_u\sigma_v} \exp \left\{ -\frac{u^2}{2\sigma_u^2} - \frac{v^2}{2\sigma_v^2} \right\}$$

Substituting $v = \epsilon + u$ into the preceding equation gives

$$f(u, \epsilon) = \frac{2}{2\pi\sigma_u\sigma_v} \exp \left\{ -\frac{u^2}{2\sigma_u^2} - \frac{(\epsilon + u)^2}{2\sigma_v^2} \right\}$$

Integrating u out to obtain the marginal density function of ϵ results in the following form:

$$\begin{aligned} f(\epsilon) &= \int_0^\infty f(u, \epsilon) du \\ &= \frac{2}{\sqrt{2\pi}\sigma} \left[1 - \Phi \left(\frac{\epsilon\lambda}{\sigma} \right) \right] \exp \left\{ -\frac{\epsilon^2}{2\sigma^2} \right\} \\ &= \frac{2}{\sigma} \phi \left(\frac{\epsilon}{\sigma} \right) \Phi \left(-\frac{\epsilon\lambda}{\sigma} \right) \end{aligned}$$

where $\lambda = \sigma_u/\sigma_v$ and $\sigma = \sqrt{\sigma_u^2 + \sigma_v^2}$.

In the case of a stochastic frontier cost model, $v = \epsilon - u$ and

$$f(\epsilon) = \frac{2}{\sigma} \phi \left(\frac{\epsilon}{\sigma} \right) \Phi \left(\frac{\epsilon\lambda}{\sigma} \right)$$

The log-likelihood function for the production model with N producers is written as

$$\ln L = \text{constant} - N \ln \sigma + \sum_i \ln \Phi \left(-\frac{\epsilon_i \lambda}{\sigma} \right) - \frac{1}{2\sigma^2} \sum_i \epsilon_i^2$$

The Normal-Exponential Model

Under the normal-exponential model, v_i is iid $N(0, \sigma_v^2)$ and u_i is iid exponential with scale parameter σ_u . Given the independence of error term components u_i and v_i , the joint density of v and u can be written as

$$f(u, v) = \frac{1}{\sqrt{2\pi}\sigma_u\sigma_v} \exp \left\{ -\frac{u}{\sigma_u} - \frac{v^2}{2\sigma_v^2} \right\}$$

The marginal density function of ϵ for the production function is

$$\begin{aligned} f(\epsilon) &= \int_0^\infty f(u, \epsilon) du \\ &= \left(\frac{1}{\sigma_u} \right) \Phi \left(-\frac{\epsilon}{\sigma_v} - \frac{\sigma_v}{\sigma_u} \right) \exp \left\{ \frac{\epsilon}{\sigma_u} + \frac{\sigma_v^2}{2\sigma_u^2} \right\} \end{aligned}$$

and the marginal density function for the cost function is equal to

$$f(\epsilon) = \left(\frac{1}{\sigma_u} \right) \Phi \left(\frac{\epsilon}{\sigma_v} - \frac{\sigma_v}{\sigma_u} \right) \exp \left\{ -\frac{\epsilon}{\sigma_u} + \frac{\sigma_v^2}{2\sigma_u^2} \right\}$$

The log-likelihood function for the normal-exponential production model with N producers is

$$\ln L = \text{constant} - N \ln \sigma_u + N \left(\frac{\sigma_v^2}{2\sigma_u^2} \right) + \sum_i \frac{\epsilon_i}{\sigma_u} + \sum_i \ln \Phi \left(-\frac{\epsilon_i}{\sigma_v} - \frac{\sigma_v}{\sigma_u} \right)$$

The Normal-Truncated Normal Model

The normal-truncated normal model is a generalization of the normal-half normal model by allowing the mean of u_i to differ from zero. Under the normal-truncated normal model, the error term component v_i is iid $N(0, \sigma_v^2)$ and u_i is iid $N^+(\mu, \sigma_u^2)$. The joint density of v_i and u_i can be written as

$$f(u, v) = \frac{1}{2\pi\sigma_u\sigma_v\Phi(\mu/\sigma_u)} \exp \left\{ -\frac{(u-\mu)^2}{2\sigma_u^2} - \frac{v^2}{2\sigma_v^2} \right\}$$

The marginal density function of ϵ for the production function is

$$\begin{aligned} f(\epsilon) &= \int_0^\infty f(u, \epsilon) du \\ &= \frac{1}{\sqrt{2\pi}\sigma\Phi(\mu/\sigma_u)} \Phi \left(\frac{\mu}{\sigma\lambda} - \frac{\epsilon\lambda}{\sigma} \right) \exp \left\{ -\frac{(\epsilon + \mu)^2}{2\sigma^2} \right\} \\ &= \frac{1}{\sigma} \phi \left(\frac{\epsilon + \mu}{\sigma} \right) \Phi \left(\frac{\mu}{\sigma\lambda} - \frac{\epsilon\lambda}{\sigma} \right) \left[\Phi \left(\frac{\mu}{\sigma_u} \right) \right]^{-1} \end{aligned}$$

and the marginal density function for the cost function is

$$f(\epsilon) = \frac{1}{\sigma} \phi \left(\frac{\epsilon - \mu}{\sigma} \right) \Phi \left(\frac{\mu}{\sigma\lambda} + \frac{\epsilon\lambda}{\sigma} \right) \left[\Phi \left(\frac{\mu}{\sigma_u} \right) \right]^{-1}$$

The log-likelihood function for the normal-truncated normal production model with N producers is

$$\ln L = \text{constant} - N \ln \sigma - N \ln \Phi \left(\frac{\mu}{\sigma_u} \right) + \sum_i \ln \Phi \left(\frac{\mu}{\sigma \lambda} - \frac{\epsilon_i \lambda}{\sigma} \right) - \frac{1}{2} \sum_i \left(\frac{\epsilon_i + \mu}{\sigma} \right)^2$$

For more detail on normal-half normal, normal-exponential, and normal-truncated models, see Kumbhakar and Lovell (2000); Coelli, Prasada Rao, and Battese (1998).

Heteroscedasticity and Box-Cox Transformation

Heteroscedasticity

If the variance of regression disturbance, (ϵ_i) , is heteroscedastic, the variance can be specified as a function of variables

$$E(\epsilon_i^2) = \sigma_i^2 = f(\mathbf{z}_i' \boldsymbol{\gamma})$$

The following table shows various functional forms of heteroscedasticity and the corresponding options to request each model.

No.	Model	Options
1	$f(\mathbf{z}_i' \boldsymbol{\gamma}) = \sigma^2(1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma}))$	LINK=EXP (default)
2	$f(\mathbf{z}_i' \boldsymbol{\gamma}) = \sigma^2 \exp(\mathbf{z}_i' \boldsymbol{\gamma})$	LINK=EXP NOCONST
3	$f(\mathbf{z}_i' \boldsymbol{\gamma}) = \sigma^2(1 + \sum_{l=1}^L \gamma_l z_{li})$	LINK=LINEAR
4	$f(\mathbf{z}_i' \boldsymbol{\gamma}) = \sigma^2(1 + (\sum_{l=1}^L \gamma_l z_{li})^2)$	LINK=LINEAR SQUARE

For discrete choice models, σ^2 is normalized ($\sigma^2 = 1$) since this parameter is not identified. Note that in models 3 and 5, it may be possible that variances of some observations are negative. Although the QLIM procedure assigns a large penalty to move the optimization away from such region, it is possible that the optimization cannot improve the objective function value and gets locked in the region. Signs of such outcome include extremely small likelihood values or missing standard errors in the estimates. In models 2 and 6, variances are guaranteed to be greater or equal to zero, but it may be possible that variances of some observations are very close to zero. In these scenarios, standard errors may be missing. Models 1 and 4 do not have such problems. Variances in these models are always positive and never close to zero.

The heteroscedastic regression model is estimated using the following log-likelihood function:

$$\ell = -\frac{N}{2} \ln(2\pi) - \sum_{i=1}^N \frac{1}{2} \ln(\sigma_i^2) - \frac{1}{2} \sum_{i=1}^N \left(\frac{e_i}{\sigma_i} \right)^2$$

where $e_i = y_i - \mathbf{x}_i' \boldsymbol{\beta}$.

Box-Cox Modeling

The Box-Cox transformation on x is defined as

$$x^{(\lambda)} = \begin{cases} \frac{x^\lambda - 1}{\lambda} & \text{if } \lambda \neq 0 \\ \ln(x) & \text{if } \lambda = 0 \end{cases}$$

The Box-Cox regression model with heteroscedasticity is written as

$$\begin{aligned} y_i^{(\lambda_0)} &= \beta_0 + \sum_{k=1}^K \beta_k x_{ki}^{(\lambda_k)} + \epsilon_i \\ &= \mu_i + \epsilon_i \end{aligned}$$

where $\epsilon_i \sim N(0, \sigma_i^2)$ and transformed variables must be positive. In practice, too many transformation parameters cause numerical problems in model fitting. It is common to have the same Box-Cox transformation performed on all the variables — that is, $\lambda_0 = \lambda_1 = \dots = \lambda_K$. It is required for the magnitude of transformed variables to be in the tolerable range if the corresponding transformation parameters are $|\lambda| > 1$.

The log-likelihood function of the Box-Cox regression model is written as

$$\ell = -\frac{N}{2} \ln(2\pi) - \sum_{i=1}^N \ln(\sigma_i) - \frac{1}{2\sigma_i^2} \sum_{i=1}^N e_i^2 + (\lambda_0 - 1) \sum_{i=1}^N \ln(y_i)$$

where $e_i = y_i^{(\lambda_0)} - \mu_i$.

When the dependent variable is discrete, censored, or truncated, the Box-Cox transformation can be applied only to explanatory variables.

Bivariate Limited Dependent Variable Modeling

The generic form of a bivariate limited dependent variable model is

$$\begin{aligned} y_{1i}^* &= \mathbf{x}_{1i}' \boldsymbol{\beta}_1 + \epsilon_{1i} \\ y_{2i}^* &= \mathbf{x}_{2i}' \boldsymbol{\beta}_2 + \epsilon_{2i} \end{aligned}$$

where the disturbances, ϵ_{1i} and ϵ_{2i} , have joint normal distribution with zero mean, standard deviations σ_1 and σ_2 , and correlation of ρ . y_1^* and y_2^* are latent variables. The dependent variables y_1 and y_2 are observed if the latent variables y_1^* and y_2^* fall in certain ranges:

$$\begin{aligned} y_1 &= y_{1i} \text{ if } y_{1i}^* \in D_1(y_{1i}) \\ y_2 &= y_{2i} \text{ if } y_{2i}^* \in D_2(y_{2i}) \end{aligned}$$

D is a transformation from (y_{1i}^*, y_{2i}^*) to (y_{1i}, y_{2i}) . For example, if y_1 and y_2 are censored variables with lower bound 0, then

$$\begin{aligned} y_1 &= y_{1i} \text{ if } y_{1i}^* > 0, & y_1 &= 0 \text{ if } y_{1i}^* \leq 0 \\ y_2 &= y_{2i} \text{ if } y_{2i}^* > 0, & y_2 &= 0 \text{ if } y_{2i}^* \leq 0 \end{aligned}$$

There are three cases for the log likelihood of (y_{1i}, y_{2i}) . The first case is that $y_{1i} = y_{1i}^*$ and $y_{2i} = y_{2i}^*$. That is, this observation is mapped to one point in the space of latent variables. The log likelihood is computed from a bivariate normal density,

$$\ell_i = \ln \left[\phi_2 \left(\frac{y_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}, \frac{y_2 - \mathbf{x}_2' \boldsymbol{\beta}_2}{\sigma_2}, \rho \right) \right] - \ln \sigma_1 - \ln \sigma_2$$

where $\phi_2(u, v, \rho)$ is the density function for standardized bivariate normal distribution with correlation ρ ,

$$\phi_2(u, v, \rho) = \frac{e^{-(1/2)(u^2 + v^2 - 2\rho uv)/(1-\rho^2)}}{2\pi(1-\rho^2)^{1/2}}$$

The second case is that one observed dependent variable is mapped to a point of its latent variable and the other dependent variable is mapped to a segment in the space of its latent variable. For example, in the bivariate censored model specified, if observed $y_1 > 0$ and $y_2 = 0$, then $y_1^* = y_1$ and $y_2^* \in (-\infty, 0]$. In general, the log likelihood for one observation can be written as follows (the subscript i is dropped for simplicity): If one set is a single point and the other set is a range, without loss of generality, let $D_1(y_1) = \{y_1\}$ and $D_2(y_2) = [L_2, R_2]$,

$$\begin{aligned} \ell_i = & \ln \left[\phi \left(\frac{y_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1} \right) \right] - \ln \sigma_1 \\ & + \ln \left[\Phi \left(\frac{R_2 - \mathbf{x}_2' \boldsymbol{\beta}_2 - \rho \frac{y_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}}{\sigma_2} \right) - \Phi \left(\frac{L_2 - \mathbf{x}_2' \boldsymbol{\beta}_2 - \rho \frac{y_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}}{\sigma_2} \right) \right] \end{aligned}$$

where ϕ and Φ are the density function and the cumulative probability function for standardized univariate normal distribution.

The third case is that both dependent variables are mapped to segments in the space of latent variables. For example, in the bivariate censored model specified, if observed $y_1 = 0$ and $y_2 = 0$, then $y_1^* \in (-\infty, 0]$ and $y_2^* \in (-\infty, 0]$. In general, if $D_1(y_1) = [L_1, R_1]$ and $D_2(y_2) = [L_2, R_2]$, the log likelihood is

$$\ell_i = \ln \int_{\frac{L_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}}^{\frac{R_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}} \int_{\frac{L_2 - \mathbf{x}_2' \boldsymbol{\beta}_2}{\sigma_2}}^{\frac{R_2 - \mathbf{x}_2' \boldsymbol{\beta}_2}{\sigma_2}} \phi_2(u, v, \rho) du dv$$

Selection Models

In sample selection models, one or several dependent variables are observed when another variable takes certain values. For example, the standard Heckman selection model can be defined as

$$\begin{aligned} z_i^* &= \mathbf{w}_i' \boldsymbol{\gamma} + u_i \\ z_i &= \begin{cases} 1 & \text{if } z_i^* > 0 \\ 0 & \text{if } z_i^* \leq 0 \end{cases} \\ y_i &= \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i \quad \text{if } z_i = 1 \end{aligned}$$

where u_i and ϵ_i are jointly normal with 0 mean, standard deviations of 1 and σ , respectively, and correlation of ρ . Selection is based on the variable z , and y is observed when z has a value of 1. Least squares regression

that uses the observed data of y produces inconsistent estimates of β . The maximum likelihood method is used to estimate selection models. It is also possible to estimate these models by using Heckman's method, which is more computationally efficient. But it can be shown that the resulting estimates, although consistent, are not asymptotically efficient under a normality assumption. Moreover, this method often violates the constraint on the correlation coefficient $|\rho| \leq 1$.

The log-likelihood function of the Heckman selection model is written as

$$\begin{aligned} \ell &= \sum_{i \in \{z_i=0\}} \ln[1 - \Phi(\mathbf{w}'_i \boldsymbol{\gamma})] \\ &+ \sum_{i \in \{z_i=1\}} \left\{ \ln \phi\left(\frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma}\right) - \ln \sigma + \ln \Phi\left(\frac{\mathbf{w}'_i \boldsymbol{\gamma} + \rho \frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma}}{\sqrt{1 - \rho^2}}\right) \right\} \end{aligned}$$

The selection can be based on only one variable, but the selection can lead to several variables. For example, selection is based on the variable z in the following switching regression model:

$$\begin{aligned} z_i^* &= \mathbf{w}'_i \boldsymbol{\gamma} + u_i \\ z_i &= \begin{cases} 1 & \text{if } z_i^* > 0 \\ 0 & \text{if } z_i^* \leq 0 \end{cases} \\ y_{1i} &= \mathbf{x}'_{1i} \boldsymbol{\beta}_1 + \epsilon_{1i} \quad \text{if } z_i = 0 \\ y_{2i} &= \mathbf{x}'_{2i} \boldsymbol{\beta}_2 + \epsilon_{2i} \quad \text{if } z_i = 1 \end{aligned}$$

If $z = 0$, then y_1 is observed. If $z = 1$, then y_2 is observed. Because y_1 and y_2 are never observed at the same time, the correlation between y_1 and y_2 cannot be estimated. Only the correlation between z and y_1 and the correlation between z and y_2 can be estimated. This estimation uses the maximum likelihood method.

A brief example of the SAS statements for this model can be found in “[Example 22.4: Sample Selection Model](#)” on page 1584.

The Heckman selection model can include censoring or truncation. For a brief example of the SAS statements for these models see “[Example 22.5: Sample Selection Model with Truncation and Censoring](#)” on page 1585. The following example shows a variable y_i that is censored from below at zero:

$$\begin{aligned} z_i^* &= \mathbf{w}'_i \boldsymbol{\gamma} + u_i \\ z_i &= \begin{cases} 1 & \text{if } z_i^* > 0 \\ 0 & \text{if } z_i^* \leq 0 \end{cases} \\ y_i^* &= \mathbf{x}'_i \boldsymbol{\beta} + \epsilon_i \quad \text{if } z_i = 1 \\ y_i &= \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases} \end{aligned}$$

In this case, the log-likelihood function of the Heckman selection model needs to be modified as follows to include the censored region:

$$\begin{aligned}\ell &= \sum_{\{i|z_i=0\}} \ln[1 - \Phi(\mathbf{w}_i' \boldsymbol{\gamma})] \\ &+ \sum_{\{i|z_i=1, y_i=y_i^*\}} \left\{ \ln \left[\phi \left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma} \right) \right] - \ln \sigma + \ln \left[\Phi \left(\frac{\mathbf{w}_i' \boldsymbol{\gamma} + \rho \frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}}{\sqrt{1 - \rho^2}} \right) \right] \right\} \\ &+ \sum_{\{i|z_i=1, y_i=0\}} \ln \int_{-\infty}^{-\frac{\mathbf{x}_i' \boldsymbol{\beta}}{\sigma}} \int_{-\mathbf{w}_i' \boldsymbol{\gamma}}^{\infty} \phi_2(u, v, \rho) du dv\end{aligned}$$

In case y_i is truncated from below at 0 instead of censored, the likelihood function can be written as

$$\begin{aligned}\ell &= \sum_{\{i|z_i=0\}} \ln[1 - \Phi(\mathbf{w}_i' \boldsymbol{\gamma})] \\ &+ \sum_{\{i|z_i=1\}} \left\{ \ln \left[\phi \left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma} \right) \right] - \ln \sigma + \ln \left[\Phi \left(\frac{\mathbf{w}_i' \boldsymbol{\gamma} + \rho \frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}}{\sqrt{1 - \rho^2}} \right) \right] - \ln [\Phi(\mathbf{x}_i' \boldsymbol{\beta} / \sigma)] \right\}\end{aligned}$$

Heckman's Two-Step Selection Method

Sample selection bias arises from nonrandom selection of the sample from the population. A classic example is using a sample of market wages for working women to estimate female labor supply function. This sample is nonrandom because it includes only the wages of women whose market wage exceeds their home wage at zero hours of work.

A simple selection model can be written as the latent model

$$\begin{aligned}z_i^* &= \mathbf{w}_i' \boldsymbol{\gamma} + u_i \\ z_i &= \begin{cases} 1 & \text{if } z_i^* > 0 \\ 0 & \text{if } z_i^* \leq 0 \end{cases} \\ y_i &= \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i \quad \text{if } z_i = 1\end{aligned}$$

where u_i and ϵ_i are jointly normal with 0 mean, standard deviations of 1 and σ , respectively, and correlation of ρ . The dependent variable y_i (wage) is observed if the latent variable z_i^* (the difference between market wage and reservation wage) is positive or if the indicator variable z_i (labor force participation) is 1.

The model of interest that applies to the observations in the selected sample can be written as

$$E(y_i | \mathbf{x}_i, z_i = 1) = \mathbf{x}_i' \boldsymbol{\beta} + \rho \sigma \lambda(\mathbf{w}_i' \boldsymbol{\gamma})$$

where $\lambda(\mathbf{w}_i' \boldsymbol{\gamma}) = \phi(\mathbf{w}_i' \boldsymbol{\gamma}) / \Phi(\mathbf{w}_i' \boldsymbol{\gamma})$. Hence, the following regression equation is valid for the observations for which $z_i = 1$:

$$y_i = \mathbf{x}_i' \boldsymbol{\beta} + \rho \sigma \lambda(\mathbf{w}_i' \boldsymbol{\gamma}) + v_i$$

Therefore, estimates of β that are obtained from the OLS regression of y on x by using the selected sample (that is, the sample for which $z_i = 1$) suffer from omitted variable bias if selection bias is really the case. Although maximum likelihood estimation of β is consistent and efficient, Heckman's two-step method is more frequently used. Heckman's two-step method can be requested by specifying the HECKIT option of the QLIM statement.

Heckman's two-step method is as follows:

1. Obtain $\hat{\gamma}$, the estimate of the parameters of the probability that $z_i^* > 0$, by using regressors w_i and the binary dependent variable z_i by probit analysis for the full sample. Compute $\hat{\lambda}_i = \lambda(w_i' \hat{\gamma})$.
2. Obtain $\hat{\beta}$ and $\hat{\beta}_\lambda$, the estimates of β and $\rho\sigma$, by least squares regression of y_i on x_i and $\hat{\lambda}_i$ by using observations on the selected subsample.

The standard least squares estimators of the population variance σ^2 and the variances of the estimated coefficients are incorrect. To test hypotheses, the correct ones need to be calculated. An estimator of σ^2 is

$$\hat{\sigma}^2 = \frac{1}{N_1} \sum_{i=1}^{N_1} e_i^2 + \hat{\beta}_\lambda^2 \frac{1}{N_1} \sum_{i=1}^{N_1} \hat{\delta}_i$$

where N_1 is the selected subsample size, e_i is the residual for the i th observation obtained from step 2, and $\hat{\delta}_i = \hat{\lambda}_i^2 + \hat{\lambda}_i w_i' \hat{\gamma}$. Let X_* be an $N_1 \times (K + 1)$ matrix with i th row $[x_i' \ \lambda_i]$, and define W similarly with i th row w_i' . Then the estimator of the asymptotic covariance of $[\hat{\beta}, \hat{\beta}_\lambda]$ is

$$\text{EstAsyVar}[\hat{\beta}, \hat{\beta}_\lambda] = \hat{\sigma}^2 [X_*' X_*]^{-1} [X_*' (I - \hat{\rho}^2 \hat{\Delta}) X_* + Q] [X_*' X_*]^{-1}$$

where $\hat{\rho}^2 = \hat{\beta}_\lambda^2 / \hat{\sigma}^2$, $\hat{\Delta} = \text{diag}(\hat{\delta}_i)$, and

$$Q = \hat{\sigma}^2 (X_*' \hat{\Delta} W) \text{Est.Asy.Var}(\hat{\gamma}) (W' \hat{\Delta} X_*)$$

where $\text{Est.Asy.Var}(\hat{\gamma})$ is the estimator of the asymptotic covariance of the probit coefficients that are obtained in step 1. When you specify the HECKIT option, PROC QLIM uses a numerical estimated asymptotic variance.

When the HECKIT option is specified, PROC QLIM reports the corrected standard errors for $[\hat{\beta}, \hat{\beta}_\lambda]$ automatically. However, if you need the conventional OLS standard errors, you can specify the HECKIT(UNCORRECTED) option.

In the selected regression model, when the coefficient of $\lambda(w_i' \gamma)$ is 0, you do not need Heckman's two-step estimation method; a simple regression of y on x produces consistent estimates for β , and the OLS standard errors are correct. Thus, a standard t test on $\hat{\beta}_\lambda$ (which uses the estimate from step 2 and the uncorrected standard errors) is a valid test of the null hypothesis of no selection bias.

Although Heckman's two-step method uses the OLS method in the second stage, you can request the ML method by specifying the HECKIT(SECONDSTAGE=ML) option. When the second-stage method is the ML method, the model for y_i can be nonlinear.

Multivariate Limited Dependent Models

The multivariate model is similar to bivariate models. The generic form of the multivariate limited dependent variable model is

$$\begin{aligned} y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + \epsilon_{1i} \\ y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + \epsilon_{2i} \\ &\dots \\ y_{mi}^* &= \mathbf{x}_{mi}'\boldsymbol{\beta}_m + \epsilon_{mi} \end{aligned}$$

where m is the number of models to be estimated. The vector ϵ has multivariate normal distribution with mean 0 and variance-covariance matrix Σ . Similar to bivariate models, the likelihood may involve computing multivariate normal integrations. This is done using Monte Carlo integration. (See Genz (1992); Hajivassiliou and McFadden (1998).)

When the number of equations, N , increases in a system, the number of parameters increases at the rate of N^2 because of the correlation matrix. When the number of parameters is large, sometimes the optimization converges but some of the standard deviations are missing. This usually means that the model is over-parameterized. The default method for computing the covariance is to use the inverse Hessian matrix. The Hessian is computed by finite differences, and in over-parameterized cases, the inverse cannot be computed. It is recommended that you reduce the number of parameters in such cases. Sometimes using the outer product covariance matrix (COVEST=OP option) may also help.

Variable Selection

Variable Selection

Variable selection uses either Akaike's information criterion (AIC) or the Schwartz Bayesian criterion (SBC) and either a forward selection method or a backward elimination method.

Forward selection starts from a small subset of variables. In each step, the variable that gives the largest decrease in the value of the information criterion specified in the CRITER= option (AIC or SBC) is added. The process stops when the next candidate to be added does not reduce the value of the information criterion by more than the amount specified in the LSTOP= option in the MODEL statement.

Backward elimination starts from a larger subset of variables. In each step, one variable is dropped based on the information criterion that is chosen.

Tests on Parameters

Tests on Parameters

In general, the hypothesis tested can be written as

$$H_0 : \mathbf{h}(\theta) = 0$$

where $\mathbf{h}(\theta)$ is an r by 1 vector valued function of the parameters θ given by the r expressions specified in the TEST statement.

Let \hat{V} be the estimate of the covariance matrix of $\hat{\theta}$. Let $\hat{\theta}$ be the unconstrained estimate of θ and $\tilde{\theta}$ be the constrained estimate of θ such that $h(\tilde{\theta}) = 0$. Let

$$A(\theta) = \partial h(\theta) / \partial \theta \big|_{\hat{\theta}}$$

Using this notation, the test statistics for the three kinds of tests are computed as follows.

The Wald test statistic is defined as

$$W = h'(\hat{\theta}) \left(A(\hat{\theta}) \hat{V} A'(\hat{\theta}) \right)^{-1} h(\hat{\theta})$$

The Wald test is not invariant to reparameterization of the model (Gregory and Veall 1985, Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

The Lagrange multiplier test statistic is

$$LM = \lambda' A(\tilde{\theta}) \tilde{V} A'(\tilde{\theta}) \lambda$$

where λ is the vector of Lagrange multipliers from the computation of the restricted estimate $\tilde{\theta}$.

The likelihood ratio test statistic is

$$LR = 2 \left(L(\hat{\theta}) - L(\tilde{\theta}) \right)$$

where $\tilde{\theta}$ represents the constrained estimate of θ and L is the concentrated log-likelihood value.

For each kind of test, under the null hypothesis the test statistic is asymptotically distributed as a χ^2 random variable with r degrees of freedom, where r is the number of expressions in the TEST statement. The p -values reported for the tests are computed from the $\chi^2(r)$ distribution and are only asymptotically valid.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation to its small sample distribution than that of the other two tests. However, the Wald test has the lowest computational cost, since it does not require computation of the constrained estimate $\tilde{\theta}$.

The following is an example of using the TEST statement to perform a likelihood ratio test:

```
proc qlim;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0 /lr;
run;
```

Endogeneity and Instrumental Variables

The PROC QLIM models such as qualitative response or limited dependent variable models assume that the errors are independent of the explanatory variables. If this assumption fails to hold, the distributional form that the likelihood is based on is misspecified and the obtained coefficients are inconsistent.

To begin, consider a linear model

$$y_i = y_i^* = \beta_0 + \beta_1 x_{1i} + \cdots + \beta_k x_{ki} + u_i$$

Assume that $E(u) = 0$, $\text{Cov}(x_j, u) = 0$ for $j = 1, \dots, k-1$, and $\text{Cov}(x_k, u) = \rho \neq 0$. Therefore, x_k is endogenous. The endogeneity comes from many sources, such as x_k having measurement error or omitting a variable that is correlated with x_k . If you ignore the endogeneity, you can estimate this model in PROC QLIM as follows (assuming $k = 4$):

```
proc qlim data=a;
  model y = x1 x2 x3 x4;
run;
```

However, this approach produces inconsistent maximum likelihood estimates. To obtain consistent maximum likelihood estimates, you should consider the joint density of the dependent variable and the endogenous variables. To do this in PROC QLIM, you need at least one instrument—that is, an observable variable, z_1 —that is not in the [structural equation](#) and that satisfies two conditions: z_1 is exogenous (that is, $\text{Cov}(z_1, u) = 0$), and z_1 must be correlated with the endogenous regressor x_k . Then, you can model x_k as

$$x_{ki} = \pi_0 + \pi_1 x_{1i} + \cdots + \pi_{k-1} x_{(k-1)i} + \theta z_{1i} + \epsilon_i$$

You can now write this reduced form equation along with the [structural equation](#) to obtain the consistent maximum likelihood estimates as follows:

```
proc qlim data=a;
  model y = x1 x2 x3 x4;
  model x4 = x1 x2 x3 z1;
run;
```

Estimating the structural model together with the reduced form models for the endogenous explanatory variables gives you the full information maximum likelihood (FIML) estimates. Because of the linearity of the model, you can estimate it efficiently and more simply by using the two-stage least squares estimator. However, PROC QLIM handles nonlinear models such as qualitative response and limited dependent variable models, and in their estimation it maximizes the corresponding joint likelihood function. In the case of endogeneity, when the reduced form models for the endogenous explanatory variables are written along with the structural model, PROC QLIM maximizes the likelihood function that is obtained from the joint density of the response variable and the endogenous explanatory variables. For example, consider the following censored regression model in which one of the explanatory variables is a continuous endogenous variable:

$$\begin{aligned} y_{1i}^* &= \alpha y_{2i} + \mathbf{z}_{1i}' \boldsymbol{\beta} + u_i \\ y_{2i} &= \mathbf{z}_i' \boldsymbol{\pi} + \epsilon_i \\ y_{1i} &= \begin{cases} y_{1i}^* & \text{if } y_{1i}^* > 0 \\ 0 & \text{if } y_{1i}^* \leq 0 \end{cases} \end{aligned}$$

The exogenous explanatory variables are \mathbf{z}_{1i} , and the continuous endogenous explanatory variable is y_{2i} .

The likelihood function to maximize is

$$L = \prod_{i \in \{y_{1i} > 0\}} f(y_{1i}, y_{2i}) \cdot \prod_{i \in \{y_{1i} = 0\}} \int_{-\infty}^0 f(y_{1i}^*, y_{2i}) dy_{1i}^*$$

where $f(y_{1i}^*, y_{2i})$ is the joint density of y_{1i}^* and y_{2i} . Note that y_{1i} is substituted for y_{1i}^* when $y_{1i} > 0$. If you assume $(u_i, \epsilon_i) \stackrel{iid}{\sim} N(\mathbf{0}, \Sigma)$ with $\Sigma = \begin{bmatrix} \sigma_u^2 & \eta \\ \eta & \sigma_\epsilon^2 \end{bmatrix}$, then, by using $f(y_{1i}^*, y_{2i}) = f(y_{1i}^* | y_{2i}) \cdot f(y_{2i})$, you can write the likelihood function for each i as a multiplication of two parts. The first part is the probability density function of the normal distribution with mean $\mathbf{z}_i' \boldsymbol{\pi}$ and variance σ_ϵ^2 , and the second part follows a Tobit model that has latent mean $\alpha y_{2i} + \mathbf{z}_{1i}' \boldsymbol{\pi} + (\eta/\sigma_\epsilon^2)(y_{2i} - \mathbf{z}_i' \boldsymbol{\pi})$ and variance $\sigma_u^2 - (\eta^2/\sigma_\epsilon^2)$. Then, you can obtain the log-likelihood function by taking the log of this multiplication and summing over i (for more information, see Wooldridge (2002, chapter 16)). This is the log-likelihood function that PROC QLIM maximizes. The parameters $(\hat{\alpha}, \hat{\boldsymbol{\beta}}, \hat{\boldsymbol{\pi}}, \hat{\sigma}_u^2, \hat{\sigma}_\epsilon^2, \hat{\eta})$ that are obtained from this maximization are the FIML estimators. Assuming that the latent model includes two instrumental variables and two exogenous explanatory variables, you can estimate this model in PROC QLIM as follows:

```
proc qlim data=a;
  model y1 = y2 z11 z12 / censored(lb=0);
  model y2 = z11 z12 z21 z22;
run;
```

For simple examples like the preceding ones, you can derive the likelihood function easily. However, as the number of endogenous explanatory variables increases, if these variables have a discontinuous nature, if simultaneity among equations exists, or if a combination of these occurs, then the derivation of the likelihood function becomes cumbersome, or, in some cases, the likelihood function does not even have a closed analytical form.

PROC QLIM can handle endogeneity regardless of the nature of the endogenous explanatory variables for a single structural model. In the case of one endogenous explanatory variable, PROC QLIM reports the FIML estimates that are calculated by using the analytical likelihood function that is obtained from the joint distribution of the dependent variable and the endogenous variable. When there is more than one endogenous explanatory variable, the analytical form of the likelihood function is usually not available; in this case PROC QLIM reports the simulated maximum likelihood estimates. For the simulated maximum likelihood estimation method, PROC QLIM uses the Geweke-Hajivassiliou-Keane (GHK) simulator (see, among others, Hajivassiliou, McFadden, and Ruud (1996)) to simulate the joint distribution of the dependent variable and the endogenous variables. The simulation is facilitated by assuming that the error terms in the latent models for the dependent variable and the endogenous explanatory variables are distributed as multivariate normal.

When you estimate a model in PROC QLIM, you can take the endogeneity into account by writing the structural model along with the reduced form models for each endogenous variable. Examples are provided in the following sections.

Probit Model with a Continuous Endogenous Explanatory Variable

Consider a probit model that contains a single endogenous explanatory variable in addition to two instruments and two exogenous explanatory variables. The model is

$$\begin{aligned} y_{1i}^* &= \alpha_1 y_{2i} + \beta_1 z_{1i} + \beta_2 z_{2i} + u_i \\ y_{2i}^* &= \pi_1 z_{1i} + \pi_2 z_{2i} + \pi_3 z_{3i} + \pi_4 z_{4i} + \epsilon_i \\ y_{1i} &= \begin{cases} 1 & \text{if } y_{1i}^* > 0 \\ 0 & \text{if } y_{1i}^* \leq 0 \end{cases} \\ y_{2i} &= y_{2i}^* \end{aligned}$$

where $\text{Cov}(u, \epsilon) = \eta$. You can estimate this model by using the following statements:

```
proc qlim data=a;
  model y1 = y2 z1 z2 / discrete;
  model y2 = z1 z2 z3 z4;
run;
```

Probit Model with a Binary Endogenous Explanatory Variable

Consider a probit model that contains a single binary endogenous explanatory variable in addition to two instruments and two exogenous explanatory variables. The model is

$$\begin{aligned}
 y_{1i}^* &= \alpha_1 y_{2i} + \beta_1 z_{1i} + \beta_2 z_{2i} + u_i \\
 y_{2i}^* &= \pi_1 z_{1i} + \pi_2 z_{2i} + \pi_3 z_{3i} + \pi_4 z_{4i} + \epsilon_i \\
 y_{1i} &= \begin{cases} 1 & \text{if } y_{1i}^* > 0 \\ 0 & \text{if } y_{1i}^* \leq 0 \end{cases} \\
 y_{2i} &= \begin{cases} 1 & \text{if } y_{2i}^* > 0 \\ 0 & \text{if } y_{2i}^* \leq 0 \end{cases}
 \end{aligned}$$

where $\text{Cov}(u, \epsilon) = \eta$. You can estimate this model by using the following statements:

```
proc qlim data=a;
  model y1 = y2 z1 z2 / discrete;
  model y2 = z1 z2 z3 z4 / discrete;
run;
```

Probit Model with a Censored Endogenous Explanatory Variable

Consider a probit model that contains a single censored (below zero) endogenous explanatory variable in addition to two instruments and two exogenous explanatory variables. The model is

$$\begin{aligned}
 y_{1i}^* &= \alpha_1 y_{2i} + \beta_1 z_{1i} + \beta_2 z_{2i} + u_i \\
 y_{2i}^* &= \pi_1 z_{1i} + \pi_2 z_{2i} + \pi_3 z_{3i} + \pi_4 z_{4i} + \epsilon_i \\
 y_{1i} &= \begin{cases} 1 & \text{if } y_{1i}^* > 0 \\ 0 & \text{if } y_{1i}^* \leq 0 \end{cases} \\
 y_{2i} &= \begin{cases} y_{2i}^* & \text{if } y_{2i}^* > 0 \\ 0 & \text{if } y_{2i}^* \leq 0 \end{cases}
 \end{aligned}$$

where $\text{Cov}(u, \epsilon) = \eta$. You can estimate this model by using the following statements:

```
proc qlim data=a;
  model y1 = y2 z1 z2 / discrete;
  model y2 = z1 z2 z3 z4 / censored(lb=0);
run;
```

Censored Regression Model with a Binary Endogenous Explanatory Variable

Consider a Type 1 Tobit model that contains a single binary endogenous explanatory variable in addition to two instruments and two exogenous explanatory variables. The model is

$$\begin{aligned}
 y_{1i}^* &= \alpha_1 y_{2i} + \beta_1 z_{1i} + \beta_2 z_{2i} + u_i \\
 y_{2i}^* &= \pi_1 z_{1i} + \pi_2 z_{2i} + \pi_3 z_{3i} + \pi_4 z_{4i} + \epsilon_i \\
 y_{1i} &= \begin{cases} y_{1i}^* & \text{if } y_{1i}^* > 0 \\ 0 & \text{if } y_{1i}^* \leq 0 \end{cases} \\
 y_{2i} &= \begin{cases} 1 & \text{if } y_{2i}^* > 0 \\ 0 & \text{if } y_{2i}^* \leq 0 \end{cases}
 \end{aligned}$$

where $\text{Cov}(u, \epsilon) = \eta$. You can estimate this model by using the following statements:

```
proc qlim data=a;
  model y1 = y2 z1 z2 / censored(lb=0);
  model y2 = z1 z2 z3 z4 / discrete;
run;
```

Censored Regression Model with Binary and Continuous Endogenous Explanatory Variables

Consider a Type 1 Tobit model that contain binary and continuous endogenous explanatory variables in addition to two instruments and two exogenous explanatory variables. The model is

$$\begin{aligned}
 y_{1i}^* &= \alpha_1 y_{21i} + \alpha_2 y_{22i} + \beta_1 z_{1i} + \beta_2 z_{2i} + u_i \\
 y_{21i}^* &= \pi_{11} z_{1i} + \pi_{12} z_{2i} + \pi_{13} z_{3i} + \pi_{14} z_{4i} + \epsilon_{1i} \\
 y_{22i}^* &= \pi_{21} z_{1i} + \pi_{22} z_{2i} + \pi_{23} z_{3i} + \pi_{24} z_{4i} + \epsilon_{2i} \\
 y_{1i} &= \begin{cases} y_{1i}^* & \text{if } y_{1i}^* > 0 \\ 0 & \text{if } y_{1i}^* \leq 0 \end{cases} \\
 y_{21i} &= \begin{cases} 1 & \text{if } y_{21i}^* > 0 \\ 0 & \text{if } y_{21i}^* \leq 0 \end{cases} \\
 y_{22i} &= y_{22i}^*
 \end{aligned}$$

where $\text{Cov}(u, \epsilon_1, \epsilon_2) = \eta$. You can estimate this model by using the following statements:

```
proc qlim data=a;
  model y1 = y21 y22 z1 z2 / censored(lb=0);
  model y21 = z1 z2 z3 z4 / discrete;
  model y22 = z1 z2 z3 z4;
run;
```

Probit Model with Binary, Censored, and Truncated Endogenous Explanatory Variables

Consider a probit model that contains binary, censored (below zero), and truncated (below zero) endogenous explanatory variables. The model is

$$\begin{aligned}
 y_{1i}^* &= \alpha_1 y_{21i} + \alpha_2 y_{22i} + \alpha_3 y_{23i} + u_i \\
 y_{21i}^* &= \pi_{11} z_{1i} + \pi_{12} z_{2i} + \pi_{13} z_{3i} + \pi_{14} z_{4i} + \epsilon_{1i} \\
 y_{22i}^* &= \pi_{21} z_{1i} + \pi_{22} z_{2i} + \pi_{23} z_{3i} + \pi_{24} z_{4i} + \epsilon_{2i} \\
 y_{23i}^* &= \pi_{31} z_{1i} + \pi_{32} z_{2i} + \pi_{33} z_{3i} + \pi_{34} z_{4i} + \epsilon_{3i} \\
 y_{1i} &= \begin{cases} 1 & \text{if } y_{1i}^* > 0 \\ 0 & \text{if } y_{1i}^* \leq 0 \end{cases} \\
 y_{21i} &= \begin{cases} 1 & \text{if } y_{21i}^* > 0 \\ 0 & \text{if } y_{21i}^* \leq 0 \end{cases} \\
 y_{22i} &= \begin{cases} y_{22i}^* & \text{if } y_{22i}^* > 0 \\ 0 & \text{if } y_{22i}^* \leq 0 \end{cases} \\
 y_{23i} &= y_{23i}^* \text{ if } y_{23i}^* > 0
 \end{aligned}$$

where z_1, \dots, z_4 are the instrumental variables that are independent of the errors. You can estimate this model by using the following statements:

```

proc qlim data=a;
  model y1 = y21 y22 y23 / discrete;
  model y21 = z1 z2 z3 z4 / discrete;
  model y22 = z1 z2 z3 z4 / censored(lb=0);
  model y23 = z1 z2 z3 z4 / truncated(lb=0);
run;

```

Note that the dependent variable y_1 should not occur in the models for the endogenous explanatory variables, because this causes inconsistent coefficient estimates. In other words, you should write the models for the endogenous explanatory variables as reduced form models. PROC QLIM does not handle simultaneous equations models.

Test for Endogeneity

PROC QLIM has two ways to test the null hypothesis that an endogenous explanatory variable (EEV) is in fact exogenous. In the case of a single EEV, the first testing method involves a likelihood ratio test of $H_0 : \rho = 0$. For example, consider the probit model with a binary endogenous explanatory variable that was considered earlier; y_2 is exogenous if the error term in the model for y_1^* is uncorrelated with the error term in the model for y_2^* . Therefore, testing to determine whether this correlation is 0 or not provides an endogeneity test for y_2 . You can do this in PROC QLIM as follows:

```

proc qlim data=a;
  model y1 = y2 z1 z2 / discrete;
  model y2 = z1 z2 z3 z4 / discrete;
  test _rho = 0 / LR;
run;

```

Failing to reject the null hypothesis favors the decision that y_2 is exogenous in the model for y_1 .

When there are two or more EEVs, the test becomes the joint likelihood ratio test of whether corresponding correlations are 0 or not.

The second testing method is similar to the approach of Rivers and Vuong (1988). Considering the same model, you can write

$$u_i = \theta\epsilon_i + e_i$$

where $\theta = \eta/\sigma_\epsilon^2$ and e is independent of z s and ϵ . You can now write

$$y_{1i}^* = \alpha_1 y_{2i} + \beta_1 z_{1i} + \beta_2 z_{2i} + \theta\epsilon_i + e_i$$

Testing $H_0 : \theta = 0$ is the same as testing whether u_i is correlated with ϵ_i or testing whether y_{2i} is endogenous or not. Because ϵ_i are unobserved, you can replace them with the OLS residuals from the model for y_{2i}^* and apply a robust t test. Note that even though y_{2i} is binary (or censored), the test is still correct under H_0 .

This approach can be summarized as a two-step procedure. In the first step, generated regressors—that is, the OLS residuals from the models for each of the EEVs—are obtained. In the second step, the structural model that includes the generated regressors as additional explanatory variables is estimated by the maximum likelihood method and the joint significance of these generated regressors is tested by the Wald test.

In PROC QLIM, you can apply the second method for the same test that was considered previously as follows:

```
proc qlim data=a;
  model y1 = y2 z1 z2 / discrete endotest(y2);
  model y2 = z1 z2 z3 z4 / discrete;
run;
```

Overidentification Test

In PROC QLIM you can test the validity of instrumental variables (IVs) by specifying the OVERID option in the ENDOGENOUS or MODEL statement. The OVERID test is a maximum likelihood version of the overidentifying restrictions test in the IV framework. If you have more IVs than are necessary for identification—that is, overidentifying IVs—you can use them to test the validity of your IVs. When you use the OVERID option to specify the overidentifying IVs, it applies the likelihood ratio test of the joint significance of these IVs, included as additional explanatory variables in the structural model that it estimates by the MLE jointly with the reduced form models. In effect, you test whether the overidentifying IVs are correlated with the error term in the structural model. You specify the reduced form models through the overidentifying IVs. The structural model is the model that includes the OVERID option. For example, consider the probit model that contains a continuous endogenous explanatory variable. You can consider z_3 or z_4 in the model for y_2 as an overidentifying IV; therefore, you can specify the OVERID test as follows:

```
proc qlim data=a;
  model y1 = y2 z1 z2 / discrete overid(y2.z4);
  model y2 = z1 z2 z3 z4;
run;
```

In this case, PROC QLIM estimates the structural model y_1 , including the overidentifying IV z_4 as an additional explanatory variable in this model, jointly with the reduced form model y_2 . Then it uses the likelihood ratio test to test the hypothesis that the overidentifying IV is insignificant. Rejecting this hypothesis raises doubts about the validity of the instruments z_3 and z_4 .

Note that, as long as you have continuous endogenous explanatory variables, the test result is invariant to which overidentifying IVs you specify in the test.

Bayesian Analysis

To perform Bayesian analysis, you must specify a BAYES statement. Unless otherwise stated, all options in this section are options in the BAYES statement.

By default, PROC QLIM uses the random walk Metropolis algorithm to obtain posterior samples. For the implementation details of the Metropolis algorithm in PROC QLIM, such as the blocking of the parameters and tuning of the covariance matrices, see the sections “[Blocking of Parameters](#)” on page 1563 and “[Tuning the Proposal Distribution](#)” on page 1563.

The Bayes theorem states that

$$p(\theta|y) \propto \pi(\theta)L(y|\theta)$$

where θ is a parameter or a vector of parameters and $\pi(\theta)$ is the product of the prior densities that are specified in the [PRIOR](#) statement. The term $L(y|\theta)$ is the likelihood associated with the [MODEL](#) statement.

Blocking of Parameters

In a multivariate parameter model, all the parameters are updated in one single block (by default or when you specify the `SAMPLING=MULTIMETROPOLIS` option). This could be inefficient, especially when parameters have vastly different scales. As an alternative, you could update the parameters one at the time (by specifying `SAMPLING=UNIMETROPOLIS`).

Tuning the Proposal Distribution

One key factor in achieving high efficiency of a Metropolis-based Markov chain is finding a good proposal distribution for each block of parameters. This process is called tuning. The tuning phase consists of a number of loops controlled by the options `MINTUNE` and `MAXTUNE`. The `MINTUNE=` option controls the minimum number of tuning loops and has a default value of 2. The `MAXTUNE=` option controls the maximum number of tuning loops and has a default value of 24. Each loop is iterated the number of times specified by the `NTU=` option, which has a default of 500. At the end of every loop, PROC QLIM examines the acceptance probability for each block. The acceptance probability is the percentage of NTU proposed values that have been accepted. If this probability does not fall within the acceptance tolerance range (see the following section), the proposal distribution is modified before the next tuning loop.

A good proposal distribution should resemble the actual posterior distribution of the parameters. Large sample theory states that the posterior distribution of the parameters approaches a multivariate normal distribution (see Gelman et al. 2004, Appendix B; Schervish 1995, Section 7.4). That is why a normal proposal distribution often works well in practice. The default proposal distribution in PROC QLIM is the normal distribution.

Scale Tuning

The acceptance rate is closely related to the sampling efficiency of a Metropolis chain. For a random walk Metropolis, a high acceptance rate means that most new samples occur right around the current data point. Their frequent acceptance means that the Markov chain is moving rather slowly and not exploring the parameter space fully. A low acceptance rate means that the proposed samples are often rejected; hence the chain is not moving much. An efficient Metropolis sampler has an acceptance rate that is neither too high nor too low. The scale c in the proposal distribution $q(\cdot|\cdot)$ effectively controls this acceptance probability. Roberts, Gelman, and Gilks (1997) show that if both the target and proposal densities are normal, the optimal acceptance probability for the Markov chain should be around 0.45 in a one-dimension problem and should asymptotically approach 0.234 in higher-dimension problems. The corresponding optimal scale is 2.38, which is the initial scale that is set for each block.

Because of the nature of stochastic simulations, it is impossible to fine-tune a set of variables so that the Metropolis chain has exactly the desired acceptance rate that you want. In addition, Roberts and Rosenthal (2001) empirically demonstrate that an acceptance rate between 0.15 and 0.5 is at least 80% efficient, so there is really no need to fine-tune the algorithms to reach an acceptance probability that is within a small tolerance of the optimal values. PROC QLIM works with a probability range, determined by `TargetAcceptance` ± 0.075 . If the observed acceptance rate in a given tuning loop is less than the lower bound of the range, the scale is reduced; if the observed acceptance rate is greater than the upper bound of the range, the scale is increased. During the tuning phase, a scale parameter in the normal distribution is adjusted as a function of the observed acceptance rate and the target acceptance rate. PROC QLIM uses the following updating scheme: ¹

$$c_{\text{new}} = \frac{c_{\text{cur}} \cdot \Phi^{-1}(p_{\text{opt}}/2)}{\Phi^{-1}(p_{\text{cur}}/2)}$$

where c_{cur} is the current scale, p_{cur} is the current acceptance rate, and p_{opt} is the optimal acceptance probability.

Covariance Tuning

To tune a covariance matrix, PROC QLIM takes a weighted average of the old proposal covariance matrix and the recent observed covariance matrix, based on the number samples (as specified by the `NTU=` option) NTU samples in the current loop. The formula to update the covariance matrix is:

$$\text{COV}_{\text{new}} = 0.75 \text{COV}_{\text{cur}} + 0.25 \text{COV}_{\text{old}}$$

There are two ways to initialize the covariance matrix:

- The default is an identity matrix that is multiplied by the initial scale of 2.38 and divided by the square root of the number of estimated parameters in the model. A number of tuning phases might be required before the proposal distribution is tuned to its optimal stage, because the Markov chain needs to spend time to learn about the posterior covariance structure. If the posterior variances of your parameters vary by more than a few orders of magnitude, if the variances of your parameters are much different from 1, or if the posterior correlations are high, then the proposal tuning algorithm might have difficulty forming an acceptable proposal distribution.

¹ Roberts and associates demonstrate that the relationship between acceptance probability and scale in a random walk Metropolis scheme is $p = 2\Phi(-\sqrt{I}c/2)$, where c is the scale, p is the acceptance rate, Φ is the CDF of a standard normal, and $I \equiv E_f[(f'(x)/f(x))^2]$, $f(x)$ is the density function of samples (Roberts, Gelman, and Gilks 1997; Roberts and Rosenthal 2001). This relationship determines the updating scheme, with I replaced by the identity matrix to simplify calculation.

- Alternatively, you can use a numerical optimization routine, such as the quasi-Newton method, to find a starting covariance matrix. The optimization is performed on the joint posterior distribution, and the covariance matrix is a quadratic approximation at the posterior mode. In some cases this is a better and more efficient way of initializing the covariance matrix. However, there are cases, such as when the number of parameters is large, where the optimization could fail to find a matrix that is positive definite. In those cases, the tuning covariance matrix is reset to the identity matrix.

A by-product of the optimization routine is that it also finds the maximum a posteriori (MAP) estimates with respect to the posterior distribution. The MAP estimates are used as the initial values of the Markov chain.

For more information, see the section “[INIT Statement](#)” on page 1533.

Initial Values of the Markov Chains

You can assign initial values to any parameters. (For more information, see the [INIT](#) statement.) If you use the optimization option [PROPCOV=](#), then PROC QLIM starts the tuning at the optimized values. This option overwrites the provided initial values.

Prior Distributions

The PRIOR statement is used to specify the prior distribution of the model parameters. You must specify a list of parameters, a tilde \sim , and then a distribution with its parameters. You can specify multiple [PRIOR](#) statements to define independent priors. Parameters that are associated with a regressor variable are referred to by the name of the corresponding regressor variable.

You can specify the special keyword `_REGRESSORS` to consider all the regressors of a model. If multiple prior statements affect the same parameter, the prior that is specified is used. For example, in a regression with three regressors (X1, X2, X3) the following statements imply that the prior on X1 is `NORMAL(MEAN=0, VAR=1)`, the prior on X2 is `GAMMA(SHAPE=3, SCALE=4)`, and the prior on X3 is `UNIFORM(MIN=0, MAX=1)`:

```
...
prior _Regressors ~ uniform(min=0, max=1);
prior X1 X2 ~ gamma(shape=3, scale=4);
prior X1 ~ normal(mean=0, var=1);
...
```

If a parameter is not associated with a PRIOR statement or if some of the prior hyperparameters are missing, then the following default choices are considered:

Table 22.2 Default values for prior distributions.

PRIOR distribution	Hyperparameter ₁	Hyperparameter ₂	Min	Max	Parameters Default Choice
NORMAL	MEAN=0	VAR=1E6	$-\infty$	∞	Regression-Location-Threshold Scale
IGAMMA	SHAPE=2.000001	SCALE=1	> 0	∞	
GAMMA	SHAPE=1	SCALE=1	0	∞	
UNIFORM			$-\infty$	∞	Cross-correlation
UNIFORM			> -1	< 1	
BETA	SHAPE1=1	SHAPE2=1	$-\infty$	∞	
T	LOCATION=0	DF=3	$-\infty$	∞	

See the section “[Standard Distributions](#)” on page 1567 for density specification.

Priors for Heteroscedastic Models

The choice of the prior distribution for a heteroscedastic model is particularly interesting. Based on the notation provided in section “[HETERO Statement](#)” on page 1532, you need to provide a prior for $\boldsymbol{\gamma}$. This prior is enough to induce different σ_i^2 into the analysis. The resulting inference is a compromise between two cases: the inference based on the entire sample and the inference based on a single unit \mathbf{z}_i . The degree of compromise is determined by $\pi(\boldsymbol{\gamma})$.

This type of modeling is similar to a method called “hierarchical Bayes,” in which the prior is characterized by two levels: one for each individual $\pi(\sigma_i^2|\boldsymbol{\gamma})$ and one for the entire population $\pi(\boldsymbol{\gamma})$. In this scenario the degree of compromise between the information provided by a unit and the information provided by the entire sample is determined by the data.

The choice of the prior might not be straightforward, and it can heavily affect sampling performance. Depending on how the heteroscedastic effects are modeled, the default priors are

$$\begin{aligned} \text{if } [1 + \exp(\mathbf{z}'_i \boldsymbol{\gamma})], \quad \pi(\gamma_j) &= \text{normal} \left\{ \text{mean} = \frac{1}{\bar{z}_j J} \left[\log \left(\frac{\varepsilon^4}{1 + \varepsilon^2} \right) \right], \text{var} = \frac{1}{\bar{z}_j^2 J} \left[\log \left(\frac{1 + \varepsilon^2}{\varepsilon^2} \right) \right] \right\} \\ \text{if } [\exp(\mathbf{z}'_i \boldsymbol{\gamma})], \quad \pi(\gamma_j) &= \text{normal} \left\{ \text{mean} = \frac{1}{\bar{z}_j J} \left[\log \left(\frac{1}{2} \right) \right], \text{var} = \frac{1}{\bar{z}_j^2 J} [\log(2)] \right\} \\ \text{if } (1 + \mathbf{z}'_i \boldsymbol{\gamma}), \quad \pi(\gamma_j) &= \text{normal} \left\{ \text{mean} = 0, \text{var} = \frac{1}{\bar{z}_j^2 J} \right\} \\ \text{if } [1 + (\mathbf{z}'_i \boldsymbol{\gamma})^2], \quad \pi(\gamma_j) &= \text{normal} \left\{ \text{mean} = \frac{(\varepsilon^2 - 1/2)^{1/4}}{\bar{z}_j J}, \text{var} = \frac{\varepsilon - (\varepsilon^2 - 1/2)^{1/2}}{\bar{z}_j^2 J} \right\} \end{aligned}$$

where $\bar{z}_j = \frac{1}{n} \sum_{i=1}^n z_{ij}$, $\forall j$, and ε is a small number (by default, $\varepsilon = 0.1$ for the EXPONENTIAL link function and $\varepsilon = 0.71$ for the QUADRATIC link function).

The priors for the EXPONENTIAL and QUADRATIC link functions are not straightforward. To understand the choices, do the following:

1. Assume that

$$\mathbf{z}'_i \boldsymbol{\gamma} = z_{i1}\gamma_1 + \dots + z_{iJ}\gamma_J \approx \bar{z}_1\gamma_1 + \dots + \bar{z}_J\gamma_J, \quad \forall i$$

2. Set the priors according to the link function type:

- For the EXPONENTIAL link function, set

$$\begin{aligned} \text{E}[\exp(\mathbf{z}'_i \boldsymbol{\gamma})] &\approx \text{E}[\exp(\bar{z}_1\gamma_1)] \times \dots \times \text{E}[\exp(\bar{z}_J\gamma_J)] = \varepsilon \\ \text{V}[\exp(\mathbf{z}'_i \boldsymbol{\gamma})] &\approx \text{E}[\exp(2\bar{z}_1\gamma_1)] \times \dots \times \text{E}[\exp(2\bar{z}_J\gamma_J)] - \varepsilon^2 = 1 \end{aligned}$$

Assume a normal prior for $\pi(\gamma_j)$, and set

$$\begin{aligned} \text{E}[\exp(\bar{z}_j\gamma_j)] &= \varepsilon^{\frac{1}{J}}, \forall j \\ \text{E}[\exp(2\bar{z}_j\gamma_j)] &= (1 + \varepsilon^2)^{\frac{1}{J}}, \forall j \end{aligned}$$

Based on the properties of the lognormal distribution, the prior hyperparameters for γ_j can be derived. Notice that J is the number of regressors that are used in the heterogeneous regression. If the intercept is excluded, then $\varepsilon = 1$.

- For the QUADRATIC link function, set

$$\begin{aligned} E[(\mathbf{z}'_i \boldsymbol{\gamma})^2] &\approx [E(\bar{z}_1 \gamma_1 + \dots + \bar{z}_J \gamma_J)]^2 + V[\bar{z}_1 \gamma_1 + \dots + \bar{z}_J \gamma_J] = \varepsilon \\ V[(\mathbf{z}'_i \boldsymbol{\gamma})^2] &\approx E[(\bar{z}_1 \gamma_1 + \dots + \bar{z}_J \gamma_J)^4] - \varepsilon^2 = 1 \end{aligned}$$

Assume a normal prior for $\pi(\gamma_j)$. Based on the properties of the normal distribution, the preceding expressions return

$$\begin{aligned} E[\bar{z}_1 \gamma_1 + \dots + \bar{z}_J \gamma_J] &= (\varepsilon^2 - 1/2)^{1/4} \\ V[\bar{z}_1 \gamma_1 + \dots + \bar{z}_J \gamma_J] &= \varepsilon - (\varepsilon^2 - 1/2)^{1/2} \\ \varepsilon &> (1/2)^{1/2} \end{aligned}$$

The prior hyperparameters for γ_j can be derived by setting

$$\begin{aligned} E[\bar{z}_j \gamma_j] &= \frac{(\varepsilon^2 - 1/2)^{1/4}}{J}, \forall j \\ V[\bar{z}_j \gamma_j] &= \frac{\varepsilon - (\varepsilon^2 - 1/2)^{1/2}}{J}, \forall j \end{aligned}$$

Notice that J is the number of regressors that are used in the heterogeneous regression. It is important to emphasize that the restriction $\varepsilon > (1/2)^{1/2} \approx 0.71$ is likely to introduce some distortion because ε cannot be any “small” number.

Standard Distributions

Table 22.3 through Table 22.8 show all the distribution density functions that PROC QLIM recognizes. You specify these distribution densities in the **PRIOR** statement.

Table 22.3 Beta Distribution

PRIOR statement	BETA(SHAPE1= a , SHAPE2= b , MIN= m , MAX= M)
	Note: Commonly $m = 0$ and $M = 1$.
Density	$\frac{(\theta-m)^{a-1}(M-\theta)^{b-1}}{B(a,b)(M-m)^{a+b-1}}$
Parameter restriction	$a > 0, \quad b > 0, \quad -\infty < m < M < \infty$
Range	$\begin{cases} [m, M] & \text{when } a = 1, b = 1 \\ [m, M) & \text{when } a = 1, b \neq 1 \\ (m, M] & \text{when } a \neq 1, b = 1 \\ (m, M) & \text{otherwise} \end{cases}$
Mean	$\frac{a}{a+b} \times (M - m) + m$
Variance	$\frac{ab}{(a+b)^2(a+b+1)} \times (M - m)^2$

Mode	$\begin{cases} \frac{a-1}{a+b-2} \times M + \frac{b-1}{a+b-2} \times m & a > 1, b > 1 \\ m \text{ and } M & a < 1, b < 1 \\ m & \begin{cases} a < 1, b \geq 1 \\ a = 1, b > 1 \end{cases} \\ M & \begin{cases} a \geq 1, b < 1 \\ a > 1, b = 1 \end{cases} \\ \text{not unique} & a = b = 1 \end{cases}$
Defaults	SHAPE1=SHAPE2=1, MIN $\rightarrow -\infty$, MAX $\rightarrow \infty$

Table 22.4 Gamma Distribution

PRIOR statement	GAMMA(SHAPE= a , SCALE= b)
Density	$\frac{1}{b^a \Gamma(a)} \theta^{a-1} e^{-\theta/b}$
Parameter restriction	$a > 0, b > 0$
Range	$[0, \infty)$
Mean	ab
Variance	ab^2
Mode	$(a - 1)b$
Defaults	SHAPE=SCALE=1

Table 22.5 Inverse-Gamma Distribution

PRIOR statement	IGAMMA(SHAPE= a , SCALE= b)
Density	$\frac{b^a}{\Gamma(a)} \theta^{-(a+1)} e^{-b/\theta}$
Parameter restriction	$a > 0, b > 0$
Range	$0 < \theta < \infty$
Mean	$\frac{b}{a-1}, \quad a > 1$
Variance	$\frac{b^2}{(a-1)^2(a-2)}, \quad a > 2$
Mode	$\frac{b}{a+1}$
Defaults	SHAPE=2.000001, SCALE=1

Table 22.6 Normal Distribution

PRIOR statement	NORMAL(MEAN= μ , VAR= σ^2)
Density	$\frac{1}{\sigma \sqrt{2\pi}} \exp\left(-\frac{(\theta-\mu)^2}{2\sigma^2}\right)$
Parameter restriction	$\sigma^2 > 0$
Range	$-\infty < \theta < \infty$

Mean	μ
Variance	σ^2
Mode	μ
Defaults	MEAN=0, VAR=1000000

Table 22.7 *t* Distribution

PRIOR statement	T(LOCATION= μ , DF= ν)
Density	$\frac{\Gamma(\frac{\nu+1}{2})}{\Gamma(\frac{\nu}{2})\sqrt{\pi\nu}} \left[1 + \frac{(\theta-\mu)^2}{\nu} \right]^{-\frac{\nu+1}{2}}$
Parameter restriction	$\nu > 0$
Range	$-\infty < \theta < \infty$
Mean	μ , for $\nu > 1$
Variance	$\frac{\nu}{\nu-2}$, for $\nu > 2$
Mode	μ
Defaults	LOCATION=0, DF=3

Table 22.8 Uniform Distribution

PRIOR statement	UNIFORM(MIN= m , MAX= M)
Density	$\frac{1}{M-m}$
Parameter restriction	$-\infty < m < M < \infty$
Range	$\theta \in [m, M]$
Mean	$\frac{m+M}{2}$
Variance	$\frac{(M-m)^2}{12}$
Mode	Not unique
Defaults	MIN $\rightarrow -\infty$, MAX $\rightarrow \infty$

Output to SAS Data Set

XBeta, Predicted, Residual

Xbeta is the structural part on the right-hand side of the model. Predicted value is the predicted dependent variable value. For censored variables, if the predicted value is outside the boundaries, it is reported as the closest boundary. For discrete variables, it is the level whose boundaries Xbeta falls between. Residual is defined only for continuous variables and is defined as

$$\text{Residual} = \text{Observed} - \text{Predicted}$$

Error Standard Deviation

Error standard deviation is σ_i in the model. It varies only when the HETERO statement is used.

Marginal Effects

Marginal effect is defined as a contribution of one control variable to the response variable. For the binary choice model with two response categories, $\mu_0 = -\infty$, $\mu_1 = 0$, $\mu_2 = \infty$; and ordinal response model with M response categories, μ_0, \dots, μ_M , define

$$R_{i,j} = \mu_j - \mathbf{x}'_i \boldsymbol{\beta}$$

The probability that the unobserved dependent variable is contained in the j th category can be written as

$$P[\mu_{j-1} < y_i^* \leq \mu_j] = F(R_{i,j}) - F(R_{i,j-1})$$

The marginal effect of changes in the regressors on the probability of $y_i = j$ is then

$$\frac{\partial \text{Prob}[y_i = j]}{\partial \mathbf{x}} = [f(\mu_{j-1} - \mathbf{x}'_i \boldsymbol{\beta}) - f(\mu_j - \mathbf{x}'_i \boldsymbol{\beta})] \boldsymbol{\beta}$$

where $f(x) = \frac{dF(x)}{dx}$. In particular,

$$f(x) = \frac{dF(x)}{dx} = \begin{cases} \frac{1}{\sqrt{2\pi}} e^{-x^2/2} & (\text{probit}) \\ \frac{e^{-x}}{[1+e^{(-x)}]^2} & (\text{logit}) \end{cases}$$

The marginal effects in the Box-Cox regression model are

$$\frac{\partial E[y_i]}{\partial \mathbf{x}} = \boldsymbol{\beta} \frac{x^{\lambda_k - 1}}{y^{\lambda_0 - 1}}$$

The marginal effects in the truncated regression model are

$$\frac{\partial E[y_i | L_i < y_i^* < R_i]}{\partial \mathbf{x}} = \boldsymbol{\beta} \left[1 - \frac{(\phi(a_i) - \phi(b_i))^2}{(\Phi(b_i) - \Phi(a_i))^2} + \frac{a_i \phi(a_i) - b_i \phi(b_i)}{\Phi(b_i) - \Phi(a_i)} \right]$$

where $a_i = \frac{L_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma_i}$ and $b_i = \frac{R_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma_i}$.

The marginal effects in the censored regression model are

$$\frac{\partial E[y | \mathbf{x}_i]}{\partial \mathbf{x}} = \boldsymbol{\beta} \times \text{Prob}[L_i < y_i^* < R_i]$$

Inverse Mills Ratio, Expected and Conditionally Expected Values

Expected and conditionally expected values are computed only for continuous variables. The inverse Mills ratio is computed for censored or truncated continuous, binary discrete, and selection endogenous variables.

Let L_i and R_i be the lower boundary and upper boundary, respectively, for the y_i . Define $a_i = \frac{L_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma_i}$ and $b_i = \frac{R_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma_i}$. Then the inverse Mills ratio is defined as

$$\lambda = \frac{(\phi(a_i) - \phi(b_i))}{(\Phi(b_i) - \Phi(a_i))}$$

for a continuous variable and defined as

$$\lambda = \frac{\phi(\mathbf{x}_i' \boldsymbol{\beta})}{\Phi(\mathbf{x}_i' \boldsymbol{\beta})}$$

for a binary discrete variable.

The expected value is the unconditional expectation of the dependent variable. For a censored variable, it is

$$E[y_i] = \Phi(a_i)L_i + (\mathbf{x}_i' \boldsymbol{\beta} + \lambda\sigma_i)(\Phi(b_i) - \Phi(a_i)) + (1 - \Phi(b_i))R_i$$

For a left-censored variable ($R_i = \infty$), this formula is

$$E[y_i] = \Phi(a_i)L_i + (\mathbf{x}_i' \boldsymbol{\beta} + \lambda\sigma_i)(1 - \Phi(a_i))$$

where $\lambda = \frac{\phi(a_i)}{1 - \Phi(a_i)}$.

For a right-censored variable ($L_i = -\infty$), this formula is

$$E[y_i] = (\mathbf{x}_i' \boldsymbol{\beta} + \lambda\sigma_i)\Phi(b_i) + (1 - \Phi(b_i))R_i$$

where $\lambda = -\frac{\phi(b_i)}{\Phi(b_i)}$.

For a noncensored variable, this formula is

$$E[y_i] = \mathbf{x}_i' \boldsymbol{\beta}$$

The conditional expected value is the expectation given that the variable is inside the boundaries:

$$E[y_i | L_i < y_i < R_i] = \mathbf{x}_i' \boldsymbol{\beta} + \lambda\sigma_i$$

Probability

Probability applies only to discrete responses. It is the marginal probability that the discrete response is taking the value of the observation. If the PROBALL option is specified, then the probability for all of the possible responses of the discrete variables is computed.

Technical Efficiency

Technical efficiency for each producer is computed only for stochastic frontier models.

In general, the stochastic production frontier can be written as

$$y_i = f(x_i; \boldsymbol{\beta}) \exp\{v_i\} TE_i$$

where y_i denotes producer i 's actual output, $f(\cdot)$ is the deterministic part of production frontier, $\exp\{v_i\}$ is a producer-specific error term, and TE_i is the technical efficiency coefficient, which can be written as

$$TE_i = \frac{y_i}{f(x_i; \boldsymbol{\beta}) \exp\{v_i\}}.$$

In the case of a Cobb-Douglas production function, $TE_i = \exp\{-u_i\}$. See the section “[Stochastic Frontier Production and Cost Models](#)” on page 1547.

Cost frontier can be written in general as

$$E_i = c(y_i, w_i; \beta) \exp\{v_i\} / CE_i$$

where w_i denotes producer i 's input prices, $c(\cdot)$ is the deterministic part of cost frontier, $\exp\{v_i\}$ is a producer-specific error term, and CE_i is the cost efficiency coefficient, which can be written as

$$CE_i = \frac{c(x_i, w_i; \beta) \exp\{v_i\}}{E_i}$$

In the case of a Cobb-Douglas cost function, $CE_i = \exp\{-u_i\}$. See the section “[Stochastic Frontier Production and Cost Models](#)” on page 1547. Hence, both technical and cost efficiency coefficients are the same. The estimates of technical efficiency are provided in the following subsections.

Normal-Half Normal Model

Define $\mu_* = -\epsilon\sigma_u^2/\sigma^2$ and $\sigma_*^2 = \sigma_u^2\sigma_v^2/\sigma^2$. Then, as it is shown by Jondrow et al. (1982), conditional density is as follows:

$$f(u|\epsilon) = \frac{f(u, \epsilon)}{f(\epsilon)} = \frac{1}{\sqrt{2\pi}\sigma_*} \exp\left\{-\frac{(u - \mu_*)^2}{2\sigma_*^2}\right\} \Bigg/ \left[1 - \Phi\left(-\frac{\mu_*}{\sigma_*}\right)\right]$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\mu_*, \sigma_*^2)$.

Using this result, it follows that the estimate of technical efficiency (Battese and Coelli 1988) is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \left[\frac{1 - \Phi(\sigma_* - \mu_{*i}/\sigma_*)}{1 - \Phi(-\mu_{*i}/\sigma_*)}\right] \exp\left\{-\mu_{*i} + \frac{1}{2}\sigma_*^2\right\}$$

The second version of the estimate (Jondrow et al. 1982) is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \mu_{*i} + \sigma_* \left[\frac{\phi(-\mu_{*i}/\sigma_*)}{1 - \Phi(-\mu_{*i}/\sigma_*)}\right] = \sigma_* \left[\frac{\phi(\epsilon_i\lambda/\sigma)}{1 - \Phi(\epsilon_i\lambda/\sigma)} - \left(\frac{\epsilon_i\lambda}{\sigma}\right)\right]$$

Normal-Exponential Model

Define $A = -\tilde{\mu}/\sigma_v$ and $\tilde{\mu} = -\epsilon - \sigma_v^2/\sigma_u$. Then, as it is shown by Kumbhakar and Lovell (2000), conditional density is as follows:

$$f(u|\epsilon) = \frac{1}{\sqrt{2\pi}\sigma_v\Phi(-\tilde{\mu}/\sigma_v)} \exp\left\{-\frac{(u - \tilde{\mu})^2}{2\sigma^2}\right\}$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\tilde{\mu}, \sigma_v^2)$.

Using this result, it follows that the estimate of technical efficiency is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \left[\frac{1 - \Phi(\sigma_v - \tilde{\mu}_i/\sigma_v)}{1 - \Phi(-\tilde{\mu}_i/\sigma_v)}\right] \exp\left\{-\tilde{\mu}_i + \frac{1}{2}\sigma_v^2\right\}$$

The second version of the estimate is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \tilde{\mu}_i + \sigma_v \left[\frac{\phi(-\tilde{\mu}_i/\sigma_v)}{1 - \Phi(-\tilde{\mu}_i/\sigma_v)} \right] = \sigma_v \left[\frac{\phi(A)}{\Phi(-A)} - A \right]$$

Normal-Truncated Normal Model

Define $\tilde{\mu} = (-\sigma_u^2\epsilon_i + \mu\sigma_v^2)/\sigma^2$ and $\sigma_*^2 = \sigma_u^2\sigma_v^2/\sigma^2$. Then, as it is shown by Kumbhakar and Lovell (2000), conditional density is as follows:

$$f(u|\epsilon) = \frac{1}{\sqrt{2\pi}\sigma_*[1 - \Phi(-\tilde{\mu}/\sigma_*)]} \exp \left\{ -\frac{(u - \tilde{\mu})^2}{2\sigma_*^2} \right\}$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\tilde{\mu}, \sigma_*^2)$.

Using this result, it follows that the estimate of technical efficiency is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \frac{1 - \Phi(\sigma_* - \tilde{\mu}_i/\sigma_*)}{1 - \Phi(-\tilde{\mu}_i/\sigma_*)} \exp \left\{ -\tilde{\mu}_i + \frac{1}{2}\sigma_*^2 \right\}$$

The second version of the estimate is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \tilde{\mu}_i + \sigma_* \left[\frac{\phi(\tilde{\mu}_i/\sigma_*)}{1 - \Phi(-\tilde{\mu}_i/\sigma_*)} \right]$$

OUTEST= Data Set

The OUTEST= data set contains all the parameters estimated in a MODEL statement. The OUTEST= option can be used when the PROC QLIM call contains one MODEL statement:

```
proc qlim data=a outest=e;
  model y = x1 x2 x3;
  endogenous y ~ censored(lb=0);
run;
```

Each parameter contains the estimate for the corresponding parameter in the corresponding model. In addition, the OUTEST= data set contains the following variables:

<code>_NAME_</code>	the name of the independent variable
<code>_TYPE_</code>	type of observation. PARM indicates the row of coefficients; STD indicates the row of standard deviations of the corresponding coefficients.
<code>_STATUS_</code>	convergence status for optimization

The rest of the columns correspond to the explanatory variables.

The OUTEST= data set contains one observation for the MODEL statement, giving the parameter estimates for that model. If the COVOUT option is specified, the OUTEST= data set includes additional observations for the MODEL statement, giving the rows of the covariance matrix of parameter estimates. For covariance observations, the value of the _TYPE_ variable is COV, and the _NAME_ variable identifies the parameter associated with that row of the covariance matrix. If the CORROUT option is specified, the OUTEST= data set includes additional observations for the MODEL statement, giving the rows of the correlation matrix of parameter estimates. For correlation observations, the value of the _TYPE_ variable is CORR, and the _NAME_ variable identifies the parameter associated with that row of the correlation matrix.

Naming

Naming of Parameters

When there is only one equation in the estimation, parameters are named in the same way as in other SAS procedures such as REG, PROBIT, and so on. The constant in the regression equation is called Intercept. The coefficients on independent variables are named by the independent variables. The standard deviation of the errors is called _Sigma. If there are Box-Cox transformations, the coefficients are named _Lambdai, where i increments from 1, or as specified by the user. The limits for the discrete dependent variable are named _Limiti. If the LIMIT=varying option is specified, then _Limiti starts from 1. If the LIMIT=varying option is not specified, then _Limit1 is set to 0 and the limit parameters start from $i = 2$. If the HETERO statement is included, the coefficients of the independent variables in the hetero equation are called _H.x, where x is the name of the independent variable. If the parameter name includes interaction terms, it needs to be enclosed in quotation marks followed by N . The following example restricts the parameter that includes the interaction term to be greater than zero:

```
proc qlim data=a;
  model y = x1|x2;
  endogenous y ~ discrete;
  restrict "x1*x2">0;
run;
```

When there are multiple equations in the estimation, the parameters in the main equation are named in the format of $y.x$, where y is the name of the dependent variable and x is the name of the independent variable. The standard deviation of the errors is called _Sigma.y. The correlation of the errors is called _Rho for bivariate model. For the model with three variables it is _Rho.y1.y2, _Rho.y1.y3, _Rho.y2.y3. The construction of correlation names for multivariate models is analogous. Box-Cox parameters are called _Lambdai.y and limit variables are called _Limiti.y. Parameters in the HETERO statement are named as _H.y.x. In the OUTEST= data set, all variables are changed from '.' to '_ '.

Naming of Output Variables

The following table shows the option in the OUTPUT statement, with the corresponding variable names and their explanation.

Option	Name	Explanation
PREDICTED	P_y	Predicted value of y
RESIDUAL	RESID_y	Residual of y , (y -Predicted Y)
XBETA	XBETA_y	Structure part ($\mathbf{x}'\boldsymbol{\beta}$) of y equation
ERRSTD	ERRSTD_y	Standard deviation of error term
PROB	PROB_y	Probability that y is taking the observed value in this observation (discrete y only)
PROBALL	PROB i _y	Probability that y is taking the i th value (discrete y only)
MILLS	MILLS_y	Inverse Mills ratio for y
EXPECTED	EXPCT_y	Unconditional expected value of y
CONDITIONAL	CEXPCT_y	Conditional expected value of y , condition on the truncation.
MARGINAL	MEFF_x	Marginal effect of x on y ($\frac{\partial y}{\partial x}$) with single equation
	MEFF_y_x	Marginal effect of x on y ($\frac{\partial y}{\partial x}$) with multiple equations
	MEFF_Pi_x	Marginal effect of x on y ($\frac{\partial Prob(y=i)}{\partial x}$) with single equation and discrete y
	MEFF_Pi_y_x	Marginal effect of x on y ($\frac{\partial Prob(y=i)}{\partial x}$) with multiple equations and discrete y
TE1	TE1	Technical efficiency estimate for each producer proposed by Battese and Coelli (1988)
TE2	TE2	Technical efficiency estimate for each producer proposed by Jondrow et al. (1982)

If you prefer to name the output variables differently, you can use the RENAME option in the data set. For example, the following statements rename the residual of y as *Resid*:

```
proc qlim data=one;
  model y = x1-x10 / censored;
  output out=outds(rename=(resid_y=resid)) residual;
run;
```

ODS Table Names

PROC QLIM assigns a name to each table it creates. You can use these names to denote the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 22.9.

Table 22.9 ODS Tables Produced in PROC QLIM by the MODEL Statement and TEST Statement

ODS Table Name	Description	Option

Examples: QLIM Procedure

Example 22.1: Ordered Data Modeling

Cameron and Trivedi (1986, 1998) studied the number of doctor visits from the Australian Health Survey 1977-78. In the following data set, the dependent variable, DVISITS, contains the number of doctor visits in the past 2 weeks (0, 1, or more than 2). The explanatory variables are: SEX indicates if the patient is female; AGE is the age in years divided by 100; INCOME is the annual income (\$10,000); LEVYPLUS indicates if the patient has private health insurance; FREEPOOR indicates free government health insurance due to low income; FREEREPA indicates free government health insurance for other reasons; ILLNESS is the number of illnesses in the past 2 weeks; ACTDAYS is the number of days the illness caused reduced activity; HSCORE is a questionnaire score; CHCOND1 indicates a chronic condition that does not limit activity; and CHCOND2 indicates a chronic condition that limits activity.

```
data docvisit;
  input sex age agesq income levyplus freepoor freerepa
        illness actdays hscore chcond1 chcond2 dvisits;
  y = (dvisits > 0);
  if ( dvisits > 8 ) then dvisits = 8;
datalines;
1 0.19 0.0361 0.55 1 0 0 1 4 1 0 0 1
1 0.19 0.0361 0.45 1 0 0 1 2 1 0 0 1

... more lines ...

1 0.37 0.1369 0.25 0 0 1 1 0 1 0 0 0
1 0.52 0.2704 0.65 0 0 0 0 0 0 0 0 0
0 0.72 0.5184 0.25 0 0 1 0 0 0 0 0 0
;
```

The dependent variable, `dvisits`, has nine ordered values. The following SAS statements estimate the ordinal probit model:

```

/*-- Ordered Discrete Responses --*/
proc qlim data=docvisit;
  model dvisits = sex age agesq income levyplus
               freepoor freerepa illness actdays hscore
               chcond1 chcond2 / discrete;
run;

```

The output of the QLIM procedure for ordered data modeling is shown in [Output 22.1.1](#).

_Limit8	1	2.789796	0.156189	17.86	<.0001

By default, ordinal probit/logit models are estimated assuming that the first threshold or limit parameter (μ_1) is 0. However, this parameter can also be estimated when the LIMIT1=VARYING option is specified. The probability that y_i^* belongs to the j th category is defined as

$$P[\mu_{j-1} < y_i^* < \mu_j] = F(\mu_j - x_i' \beta) - F(\mu_{j-1} - x_i' \beta)$$

where $F(\cdot)$ is the logistic or standard normal CDF, $\mu_0 = -\infty$ and $\mu_9 = \infty$. Output 22.1.2 lists ordinal probit estimates computed in the following program. Note that the intercept term is suppressed for model identification when μ_1 is estimated.

```

/*-- Ordered Probit --*/
proc qlim data=docvisit;
    model dvisits = sex age agesq income levyplus
               freepoor freerepa illness actdays hscore
               chcond1 chcond2 / discrete(d=normal) limit1=varying;
run;

```

Example 22.2: Tobit Analysis

The following statements show a subset of the Mroz (1987) data set. In these data, Hours is the number of hours the wife worked outside the household in a given year, Yrs_Ed is the years of education, and Yrs_Exp is the years of work experience. A Tobit model will be fit to the hours worked with years of education and experience as covariates.

By the nature of the data it is clear that there are a number of women who committed some positive number of hours to outside work ($y_i > 0$ is observed). There are also a number of women who did not work at all ($y_i = 0$ is observed). This gives us the following model:

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$y_i = \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases}$$

where $\epsilon_i \sim iidN(0, \sigma^2)$. The set of explanatory variables is denoted by x_i .

```

In the “Parameter Estimates” table there are four rows. The first three of these rows correspond to the vector estimate of the regression coefficients β . The last one is called `_Sigma`, which corresponds to the estimate of the error variance σ .

Example 22.3: Bivariate Probit Analysis

This example shows how to estimate a bivariate probit model. Note the `INIT` statement in the following program, which sets the initial values for some parameters in the optimization:

```
data a;
  keep y1 y2 x1 x2;
  do i = 1 to 500;
    x1 = rannor( 19283 );
    x2 = rannor( 19283 );
    u1 = rannor( 19283 );
    u2 = rannor( 19283 );
    y1l = 1 + 2 * x1 + 3 * x2 + u1;
    y2l = 3 + 4 * x1 - 2 * x2 + u1*.2 + u2;

Example 22.4: Sample Selection Model

This example illustrates the use of PROC QLIM for sample selection models. The data set is the same one from Mroz (1987). The goal is to estimate a wage offer function for married women, accounting for potential selection bias. Of the 753 women, the wage is observed for 428 working women. The labor force participation equation estimated in the introductory example is used for selection. The wage equation uses log wage (`lwage`) as the dependent variable. The explanatory variables in the wage equation are the woman's years of schooling (`educ`), wife's labor experience (`exper`), and square of experience (`expersq`). The program is as follows:

```

/*-- Sample Selection --*/
proc qlim data=mroz;
  model inlf = nwifeinc educ exper expersq
              age kidslt6 kidsge6 /discrete;
  model lwage = educ exper expersq / select(inlf=1);
run;

```

The output of the QLIM procedure is shown in [Output 22.4.1](#).

Output 22.4.1 Sample Selection

Binary Data					
The QLIM Procedure					
Model Fit Summary					
Number of Endogenous Variables					2
Endogenous Variable				inlf lwage	
Number of Observations					753
Log Likelihood				-832.88509	
Maximum Absolute Gradient				0.00502

Optimization Method				Quasi-Newton	
AIC					1694
Schwarz Criterion					1759
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
lwage.Intercept	1	-0.552716	0.260371	-2.12	0.0338
lwage.educ	1	0.108351	0.014861	7.29	<.0001
lwage.exper	1	0.042837	0.014878	2.88	0.0040
lwage.expersq	1	-0.000837	0.000417	-2.01	0.0449
_Sigma.lwage	1	0.663397	0.022706	29.22	<.0001
inlf.Intercept	1	0.266459	0.508954	0.52	0.6006
inlf.nwifeinc	1	-0.012132	0.004877	-2.49	0.0129
inlf.educ	1	0.131341	0.025383	5.17	<.0001
inlf.exper	1	0.123282	0.018728	6.58	<.0001
inlf.expersq	1	-0.001886	0.000601	-3.14	0.0017
inlf.age	1	-0.052829	0.008479	-6.23	<.0001
inlf.kidslt6	1	-0.867398	0.118647	-7.31	<.0001
inlf.kidsge6	1	0.035872	0.043476	0.83	0.4093
_Rho	1	0.026617	0.147073	0.18	0.8564

Note the correlation estimate is insignificant. This indicates that selection bias is not a big problem in the estimation of wage equation.

Example 22.5: Sample Selection Model with Truncation and Censoring

In this example the data are generated such that the selection variable is discrete and the variable Y is truncated from below by zero. The program follows, with the results shown in [Output 22.5.1](#):

```

data trunc;
  keep z y x1 x2;
  do i = 1 to 500;
    x1 = rannor( 19283 );
    x2 = rannor( 19283 );
    u1 = rannor( 19283 );
    u2 = rannor( 19283 );
    z1 = 1 + 2 * x1 + 3 * x2 + u1;
    y = 3 + 4 * x1 - 2 * x2 + u1*.2 + u2;
    if ( z1 > 0 ) then z = 1;
    else z = 0;
    if y>=0 then output;
  end;
run;

/*-- Sample Selection with Truncation --*/
proc qlim data=trunc method=qn;
  model z = x1 x2 / discrete;
  model y = x1 x2 / select(z=1) truncated(lb=0);
run;

```

Output 22.5.1 Sample Selection with Truncation

Example 22.7: Stochastic Frontier Models

This example illustrates the estimation of stochastic frontier production and cost models.

First, a production function model is estimated. The data for this example were collected by Christensen Associates; they represent a sample of 125 observations on inputs and output for 10 airlines between 1970 and 1984. The explanatory variables (inputs) are fuel (LF), materials (LM), equipment (LE), labor (LL), and property (LP), and (LQ) is an index that represents passengers, charter, mail, and freight transported.

The following statements create the dataset:

```

title1 'Stochastic Frontier Production Model';
data airlines;
    input TS FIRM NI LQ LF LM LE LL LP;
datalines;
1 1 15 -0.0484 0.2473 0.2335 0.2294 0.2246 0.2124

```

The following statements estimate a stochastic frontier exponential production model that uses Christensen Associates data:

```

/*-- Stochastic Frontier Production Model --*/
proc qlim data=airlines;
    model LQ=LF LM LE LL LP;
    endogenous LQ ~ frontier (type=exponential production);
run;

```

Figure 22.7.1 shows the results from this production model.

Output 22.7.1 Stochastic Frontier Production Model

Similarly, the stochastic frontier production function can be estimated with (type=half) or (type=truncated) options that represent half-normal and truncated normal production models.

In the next step, stochastic frontier cost function is estimated. The data for the cost model are provided by Christensen and Greene (1976). The data describe costs and production inputs of 145 U.S. electricity producers in 1955. The model being estimated follows the nonhomogeneous version of the Cobb-Douglas cost function:

$$\log\left(\frac{\text{Cost}}{\text{FPrice}}\right) = \beta_0 + \beta_1 \log\left(\frac{\text{KPrice}}{\text{FPrice}}\right) + \beta_2 \log\left(\frac{\text{LPrice}}{\text{FPrice}}\right) + \beta_3 \log(\text{Output}) + \beta_4 \frac{1}{2} \log(\text{Output})^2 + \epsilon$$

All dollar values are normalized by fuel price. The quadratic log of the output is added to capture nonlinearities due to scale effects in cost functions. New variables, log_C_PF, log_PK_PF, log_PL_PF, log_y, and log_y_sq, are created to reflect transformations. The following statements create the data set and transformed variables:

```

title1 'Stochastic Frontier Cost Model';

_Mu	1	0.477097	0.116295	4.10	<.0001

If no (Production) or (Cost) option is specified, the stochastic frontier production model is estimated by default.

Example 22.8: Bayesian Modeling

This example illustrates how to use the QLIM procedure to perform Bayesian analysis. The generated data mimic a hypothetical scenario in which you study the number of tickets sold for a sports event given the probability of the hosting team winning and the price of the tickets. The following statements create the dataset:

```

title1 'Bayesian Analysis';

ods graphics on;

data test;
  do i=1 to 200;
    e1 = rannor(8726)*2000;
    WinChance = ranuni(8772);
    Price = 10+ranexp(8773)*4;
    y = 48000 + 5000*WinChance - 100 * price + e1;
    if y>50000 then TicketSales = 50000;
    if y<=50000 then TicketSales = y;
    output;
  end;
  keep WinChance price y TicketSales;
run;

```

The following statements perform Bayesian analysis of a Tobit model:

```

proc qlim data=test plots(prior)=all;
  model TicketSales = WinChance price;
  endogenous TicketSales ~ censored(lb=0 ub= 50000);
  prior intercept~normal(mean=48000);
  prior WinChance~normal(mean=5000);
  prior Price~normal(mean=-100);
  bayes NBI=10000 NMC=30000 THIN=1 ntrds=1 DIAG=ALL STATS=ALL seed=2;
run;

```

Output 22.8.1 shows the results from the maximum likelihood estimation and the Bayesian analysis with diffuse prior of this Tobit model.

Output 22.8.1 Bayesian Tobit Model

Overview: SEVERITY Procedure

The SEVERITY procedure estimates parameters of any arbitrary continuous probability distribution that is used to model the magnitude (severity) of a continuous-valued event of interest. Some examples of such events are loss amounts paid by an insurance company and demand of a product as depicted by its sales. PROC SEVERITY is especially useful when the severity of an event does not follow typical distributions such as the normal distribution that are often assumed by standard statistical methods.

PROC SEVERITY provides a default set of probability distribution models that includes the Burr, exponential, gamma, generalized Pareto, inverse Gaussian (Wald), lognormal, Pareto, Tweedie, and Weibull distributions. In the simplest form, you can estimate the parameters of any of these distributions by using a list of severity values that are recorded in a SAS data set. You can optionally group the values by a set of BY variables. PROC SEVERITY computes the estimates of the model parameters, their standard errors, and their covariance structure by using the maximum likelihood method for each of the BY groups.

PROC SEVERITY can fit multiple distributions at the same time and choose the best distribution according to a selection criterion that you specify. You can use seven different statistics of fit as selection criteria. They are log likelihood, Akaike's information criterion (AIC), corrected Akaike's information criterion (AICC), Schwarz Bayesian information criterion (BIC), Kolmogorov-Smirnov statistic (KS), Anderson-Darling statistic (AD), and Cramér-von Mises statistic (CvM).

You can request the procedure to output the status of the estimation process, the parameter estimates and their standard errors, the estimated covariance structure of the parameters, the statistics of fit, estimated cumulative distribution function (CDF) for each of the specified distributions, and the empirical distribution function (EDF) estimate (which is used to compute the KS, AD, and CvM statistics of fit).

A high-performance version of PROC SEVERITY is available as the HPSEVERITY procedure in the SAS High-Performance Econometrics product. The following key features make PROC SEVERITY and PROC HPSEVERITY unique among SAS procedures that can estimate continuous probability distributions:

- Both procedures enable you to fit a distribution model when the severity values are truncated or censored or both. You can specify any combination of the following types of censoring and truncation effects: left-censoring, right-censoring, left-truncation, or right-truncation. This is especially useful in applications with an insurance-type model where a severity (loss) is reported and recorded only if it is greater than the deductible amount (left-truncation) and where a severity value greater than or equal to the policy limit is recorded at the limit (right-censoring). Another useful application is that of interval-censored data, where you know both the lower limit (right-censoring) and upper limit (left-censoring) on the severity, but you do not know the exact value.

PROC SEVERITY also enables you to specify a *probability of observability* for the left-truncated data, which is a probability of observing values greater than the left-truncation threshold. This additional information can be useful in certain applications to more correctly model the distribution of the severity of events.

Both procedures use an appropriate estimator of the empirical distribution function (EDF). EDF is required to compute the KS, AD, and CvM statistics-of-fit. The procedures also provide the EDF estimates to your custom parameter initialization method. When you specify truncation or censoring, the EDF is estimated by using either Kaplan-Meier's product-limit estimator or Turnbull's estimator. The former is used by default when you specify only one form of censoring effect (right-censoring or left-censoring), whereas the latter is used by default when you specify both left-censoring and right-censoring effects. PROC SEVERITY also computes the standard errors for the EDF estimates.

- Both procedures enable you to define any arbitrary continuous parametric distribution model and to estimate its parameters. You just need to define the key components of the distribution, such as its probability density function (PDF) and cumulative distribution function (CDF), as a set of functions and subroutines written with the FCMP procedure, which is part of Base SAS software. As long as the functions and subroutines follow certain rules, the SEVERITY and HPSEVERITY procedures can fit the distribution model defined by them.
- Both procedures can model the effect of exogenous or regressor variables on a probability distribution, as long as the distribution has a scale parameter. A linear combination of the regressor variables is assumed to affect the scale parameter via an exponential link function.

If a distribution does not have a scale parameter, then either it needs to have another parameter that can be derived from a scale parameter by using a supported transformation or it needs to be reparameterized to have a scale parameter. If neither of these is possible, then regression effects cannot be modeled.

- Both procedures enable you to specify your own objective function to be optimized for estimating the parameters of a model. You can write SAS programming statements to specify the contribution of each observation to the objective function. You can use keyword functions such as `_PDF_` and `_CDF_` to generalize the objective function to any distribution. If you do not specify your own objective function, then the parameters of a model are estimated by maximizing the likelihood function of the data.
- Both procedures enable you to create scoring functions that offer a convenient way to evaluate any distribution function, such as PDF, CDF, QUANTILE, or your custom distribution function, for a fitted model on new observations.
- Both procedures use multithreading to significantly reduce the time it takes to fit a distribution model.

Getting Started: SEVERITY Procedure

This section outlines the use of the SEVERITY procedure to fit continuous probability distribution models. Three examples illustrate different features of the procedure.

A Simple Example of Fitting Predefined Distributions

The simplest way to use PROC SEVERITY is to fit all the predefined distributions to a set of values and let the procedure identify the best fitting distribution.

Consider a lognormal distribution, whose probability density function (PDF) f and cumulative distribution function (CDF) F are as follows, respectively, where Φ denotes the CDF of the standard normal distribution:

$$f(x; \mu, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2} \quad \text{and} \quad F(x; \mu, \sigma) = \Phi\left(\frac{\log(x)-\mu}{\sigma}\right)$$

The following DATA step statements simulate a sample from a lognormal distribution with population parameters $\mu = 1.5$ and $\sigma = 0.25$, and store the sample in the variable Y of a data set Work.Test_sev1:

```
/*----- Simple Lognormal Example -----*/
data test_sev1(keep=y label='Simple Lognormal Sample');
  call streaminit(45678);
  label y='Response Variable';
  Mu = 1.5;
  Sigma = 0.25;
  do n = 1 to 100;
    y = exp(Mu) * rand('LOGNORMAL')**Sigma;
    output;
  end;
run;
```

The following statements fit all the predefined distribution models to the values of Y and identify the best distribution according to the corrected Akaike's information criterion (AICC):

```
proc severity data=test_sev1 crit=aicc;
  loss y;
  dist _predefined_;
run;
```

The PROC SEVERITY statement specifies the input data set along with the model selection criterion, the LOSS statement specifies the variable to be modeled, and the DIST statement with the _PREDEFINED_ keyword specifies that all the predefined distribution models be fitted.

Some of the default output displayed by this step is shown in Figure 23.1 through Figure 23.5. First, information about the input data set is displayed followed by the “Model Selection Table”, as shown in Figure 23.1. The model selection table displays the convergence status, the value of the selection criterion, and the selection status for each of the candidate models. The Converged column indicates whether the estimation process for a given distribution model has converged, might have converged, or failed. The Selected column indicates whether a given distribution has the best fit for the data according to the selection criterion. For this example, the lognormal distribution model is selected, because it has the lowest value for the selection criterion.

Figure 23.1 Data Set Information and Model Selection Table

The SEVERITY Procedure			
Input Data Set			
Name	WORK.TEST_SEV1		
Label	Simple Lognormal Sample		
Model Selection			
Distribution	Converged	AICC	Selected
Burr	Yes	322.50845	No
Exp	Yes	508.12287	No
Gamma	Yes	320.50264	No
Igauss	Yes	319.61652	No
Logn	Yes	319.56579	Yes
Pareto	Yes	510.28172	No
Gpd	Yes	510.20576	No
Weibull	Yes	334.82373	No

Next, two comparative plots are prepared. These plots enable you to visually verify how the models differ from each other and from the nonparametric estimates. The plot in Figure 23.2 displays the cumulative distribution function (CDF) estimates of all the models and the estimates of the empirical distribution function (EDF). The CDF plot indicates that the Exp (exponential), Pareto, and Gpd (generalized Pareto) distributions are a poor fit as compared to the EDF estimate. The Weibull distribution is also a poor fit, although not as poor as exponential, Pareto, and Gpd. The other four distributions seem to be quite close to each other and to the EDF estimate.

Figure 23.2 Comparison of EDF and CDF Estimates of the Fitted Models

The plot in [Figure 23.3](#) displays the probability density function (PDF) estimates of all the models and the nonparametric kernel and histogram estimates. The PDF plot enables better visual comparison between the Burr, Gamma, Igauss (inverse Gaussian), and Logn (lognormal) models. The Burr and Gamma differ significantly from the Igauss and Logn distributions in the central portion of the range of Y values, while the latter two fit the data almost identically. This provides a visual confirmation of the information in the “Model Selection Table” of [Figure 23.1](#), which indicates that the AICC values of Igauss and Logn distributions are very close.

Figure 23.3 Comparison of PDF Estimates of the Fitted Models

The comparative plots are followed by the estimation information for each of the candidate models. The information for the lognormal model, which is the best fitting model, is shown in Figure 23.4. The first table displays a summary of the distribution. The second table displays the convergence status. This is followed by a summary of the optimization process which indicates the technique used, the number of iterations, the number of times the objective function was evaluated, and the log likelihood attained at the end of the optimization. Since the model with lognormal distribution has converged, PROC SEVERITY displays its statistics of fit and parameter estimates. The estimates of $\mu=1.49605$ and $\sigma=0.26243$ are quite close to the population parameters of $\mu=1.5$ and $\sigma=0.25$ from which the sample was generated. The p -value for each estimate indicates the rejection of the null hypothesis that the estimate is 0, implying that both the estimates are significantly different from 0.

An Example with Left-Truncation and Right-Censoring

PROC SEVERITY enables you to specify that the response variable values are left-truncated or right-censored. The following DATA step expands the data set of the previous example to simulate a scenario that is typically encountered by an automobile insurance company. The values of the variable Y represent the loss values on claims that are reported to an auto insurance company. The variable THRESHOLD records the deductible on the insurance policy. If the actual value of Y is less than or equal to the deductible, then it is unobservable and does not get recorded. In other words, THRESHOLD specifies the left-truncation of Y. LIMIT records the policy limit. If the value of Y is equal to or greater than the recorded value, then the observation is right-censored.

```

/*----- Lognormal Model with left-truncation and censoring -----*/
data test_sev2(keep=y threshold limit
    label='A Lognormal Sample With Censoring and Truncation');
    set test_sev1;
    label y='Censored & Truncated Response';
    if _n_ = 1 then call streaminit(45679);

    /* make about 20% of the observations left-truncated */
    if (rand('UNIFORM') < 0.2) then
        threshold = y * (1 - rand('UNIFORM'));
    else
        threshold = .;
    /* make about 15% of the observations right-censored */
    iscens = (rand('UNIFORM') < 0.15);
    if (iscens) then
        limit = y;
    else
        limit = .;
run;

```

The following statements use the AICC criterion to analyze which of the four predefined distributions (lognormal, Burr, gamma, and Weibull) has the best fit for the data:

```
proc severity data=test_sev2 crit=aicc
    print=all plots=(cdfperdist pp qq);
    loss y / lt=threshold rc=limit;

    dist logn burr gamma weibull;
run;
```

The LOSS statement specifies the left-truncation and right-censoring variables. The DIST statement specifies the candidate distributions. The PRINT= option in the PROC SEVERITY statement requests that all the displayed output be prepared. The PLOTS= option in the PROC SEVERITY statement requests that the CDF plot, P-P plot, and Q-Q plot be prepared for each candidate distribution in addition to the default plots.

Some of the key results prepared by PROC SEVERITY are shown in Figure 23.6 through Figure 23.13. In addition to the estimates of the range, mean, and standard deviation of Y, the “Descriptive Statistics for Y” table shown in Figure 23.6 also indicates the number of observations that are left-truncated or right-censored. The “Model Selection Table” in Figure 23.6 shows that models with all the candidate distributions have converged and that the Logn (lognormal) model has the best fit for the data according to the AICC criterion.

Figure 23.6 Summary Results for the Truncated and Censored Data

The SEVERITY Procedure

Burr	Yes	302.66229	No
Gamma	Yes	299.45293	No
Weibull	Yes	309.26779	No

PROC SEVERITY also prepares a table that shows all the fit statistics for all the candidate models. It is useful to see which model would be the best fit according to each of the criteria. The “All Fit Statistics Table” prepared for this example is shown in Figure 23.7. It indicates that the lognormal model is chosen by all the criteria.

Figure 23.7 Comparing All Statistics of Fit for the Truncated and Censored Data

All Fit Statistics					
Distribution	-2 Log Likelihood	AIC	AICC	BIC	KS
Logn	294.80301*	298.80301*	298.92672*	304.01335*	0.51824*
Burr	296.41229	302.41229	302.66229	310.22780	0.66984

Weibull	305.14408	309.14408	309.26779	314.35442	0.93307
Note: The asterisk (*) marks the best model according to each column's criterion.					

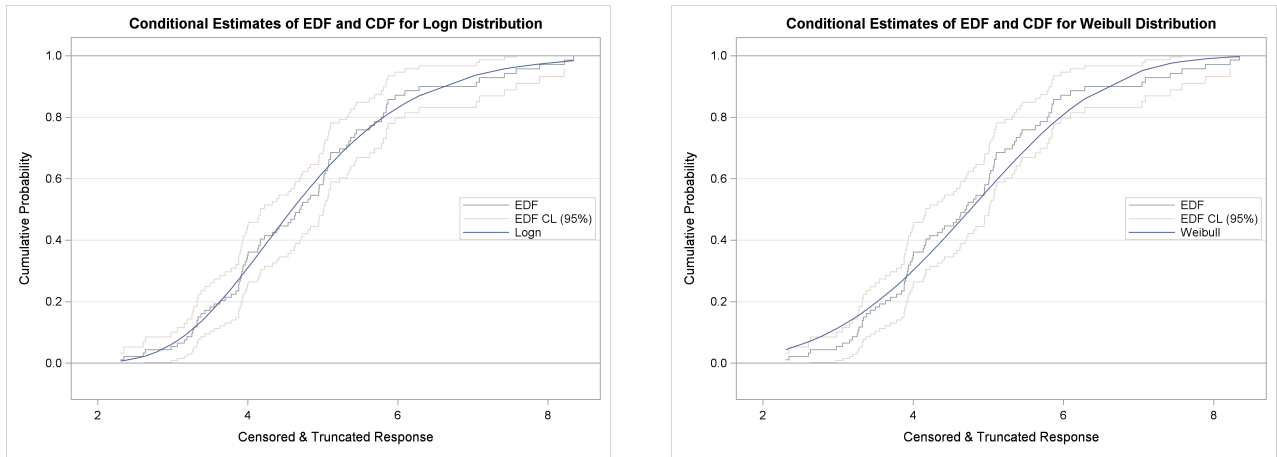

All Fit Statistics		
Distribution	AD	CvM
Logn	0.34736*	0.05159*
Burr	0.36712	0.05726
Gamma	0.42921	0.05526
Weibull	1.40699	0.17465
Note: The asterisk (*) marks the best model according to each column's criterion.		

The plot that compares EDF and CDF estimates is shown in Figure 23.8. When you specify left-truncation, both the EDF and CDF estimates are conditional on the response variable being greater than the smallest left-truncation threshold in the sample.

Figure 23.8 EDF and CDF Estimates for the Truncated and Censored Data

When you specify the `PLOTS=CDFPERDIST` option, PROC SEVERITY prepares a plot that compares the nonparametric EDF estimates with the parametric CDF estimates for each distribution. These plots for lognormal and Weibull distributions are shown in Figure 23.9. These plots also contain the lower and upper confidence limits of EDF for the specified confidence level. Because no confidence level is specified in the `EDFALPHA=` option in the PROC SEVERITY statement, a default confidence level of 95% is used, which is equivalent to specifying `EDFALPHA=0.05`. If the CDF estimates lie entirely within the EDF confidence interval, then you can be 95% confident that the parametric and nonparametric estimates are in agreement.

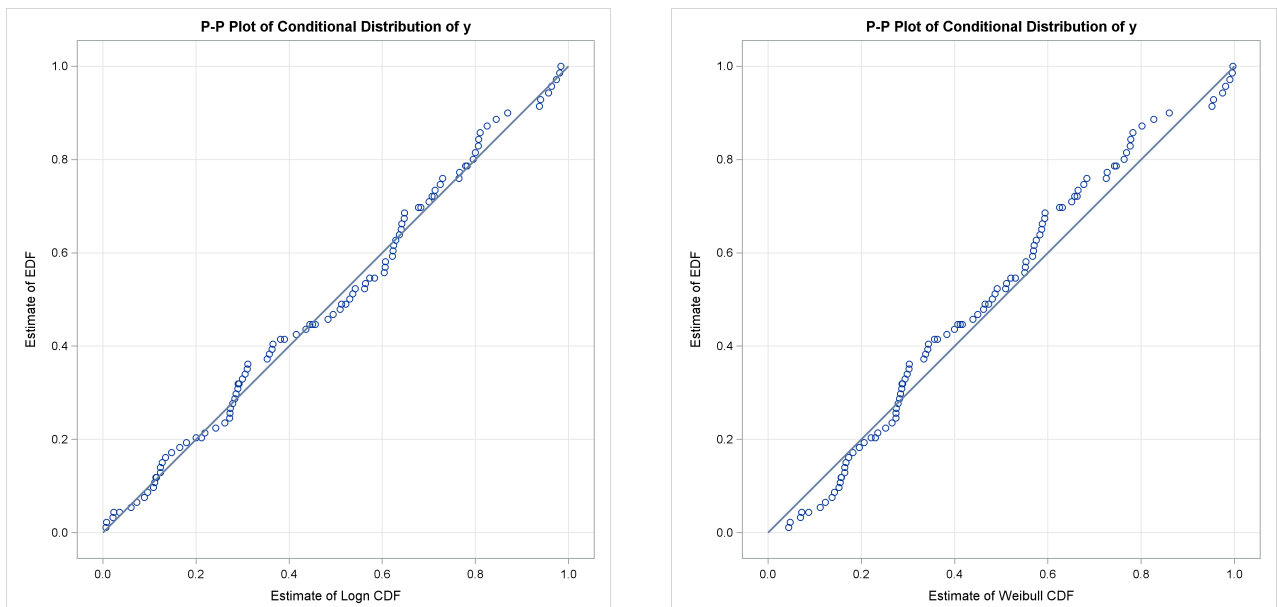

Figure 23.9 Comparing EDF and CDF Estimates for Lognormal and Weibull Models Fitted to Truncated and Censored Data

There are two additional ways to compare nonparametric (empirical) and parametric estimates for each model that has not failed to converge:

- A P-P plot is a scatter plot of the EDF and the CDF estimates. The model for which the points are scattered closer to the unit-slope reference line is a better fit. The P-P plot for the lognormal distribution is shown in Figure 23.10. It indicates that the EDF and the CDF match very closely. In contrast, the P-P plot for the Weibull distribution, also shown in Figure 23.10, indicates a poor fit.

Figure 23.10 P-P Plots for Lognormal and Weibull Models Fitted to Truncated and Censored Data

- A Q-Q plot is a scatter plot of empirical quantiles and the quantiles of a parametric distribution. Like the P-P plot, points scattered closer to the unit-slope reference line indicate a better fit. The Q-Q plots of lognormal and Weibull distributions are shown in Figure 23.11, which confirm the conclusions arrived at by comparing the P-P plots.

Figure 23.11 Q-Q Plots for Lognormal and Weibull Models Fitted to Truncated and Censored Data

Specifying Initial Values for Parameters

All the predefined distributions have parameter initialization functions built into them. For the current example, Figure 23.12 shows the initial values that are obtained by the predefined method for the Burr distribution. It also shows the summary of the optimization process and the final parameter estimates.

Figure 23.12 Burr Model Summary for the Truncated and Censored Data

Initial Parameter Values and Bounds			
Parameter	Initial Value	Lower Bound	Upper Bound
Theta	4.78102	1.05367E-8	Infty
Alpha	2.00000	1.05367E-8	Infty
Gamma	2.00000	1.05367E-8	Infty
Optimization Summary			
Optimization Technique		Trust Region	
Iterations		8	
Function Calls		23	
Log Likelihood		-148.20614	

Figure 23.12 continued

Parameter Estimates				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Theta	4.76980	0.62492	7.63	<.0001
Alpha	1.16363	0.58859	1.98	0.0509
Gamma	5.94081	1.05004	5.66	<.0001

You can specify a different set of initial values if estimates are available from fitting the distribution to similar data. For this example, the parameters of the Burr distribution can be initialized with the final parameter estimates of the Burr distribution that were obtained in the first example (shown in Figure 23.5). One of the ways in which you can specify the initial values is as follows:

```
/*----- Specifying initial values using INIT= option -----*/
proc severity data=test_sev2 crit=aicc print=all plots=none;
  loss y / lt=threshold rc=limit;

  dist burr(init=(theta=4.62348 alpha=1.15706 gamma=6.41227));
run;
```

The names of the parameters that are specified in the INIT option must match the parameter names in the definition of the distribution. The results obtained with these initial values are shown in Figure 23.13. These results indicate that new set of initial values causes the optimizer to reach the same solution with fewer iterations and function evaluations as compared to the default initialization.

An Example of Modeling Regression Effects

Consider a scenario in which the magnitude of the response variable might be affected by some regressor (exogenous or independent) variables. The SEVERITY procedure enables you to model the effect of such variables on the distribution of the response variable via an exponential link function. In particular, if you have k random regressor variables denoted by x_j ($j = 1, \dots, k$), then the distribution of the response variable Y is assumed to have the form

$$Y \sim \exp\left(\sum_{j=1}^k \beta_j x_j\right) \cdot \mathcal{F}(\Theta)$$

where \mathcal{F} denotes the distribution of Y with parameters Θ and β_j ($j = 1, \dots, k$) denote the regression parameters (coefficients). For the effective distribution of Y to be a valid distribution from the same parametric family as \mathcal{F} , it is necessary for \mathcal{F} to have a scale parameter. The effective distribution of Y can be written as

$$Y \sim \mathcal{F}(\theta, \Omega)$$

where θ denotes the scale parameter and Ω denotes the set of nonscale parameters. The scale θ is affected by the regressors as

$$\theta = \theta_0 \cdot \exp\left(\sum_{j=1}^k \beta_j x_j\right)$$

where θ_0 denotes a *base* value of the scale parameter.

Given this form of the model, PROC SEVERITY allows a distribution to be a candidate for modeling regression effects only if it has an untransformed or a log-transformed scale parameter.

All the predefined distributions, except the lognormal distribution, have a direct scale parameter (that is, a parameter that is a scale parameter without any transformation). For the lognormal distribution, the parameter μ is a log-transformed scale parameter. This can be verified by replacing μ with a parameter $\theta = e^\mu$, which results in the following expressions for the PDF f and the CDF F in terms of θ and σ , respectively, where Φ denotes the CDF of the standard normal distribution:

$$f(x; \theta, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x) - \log(\theta)}{\sigma}\right)^2} \quad \text{and} \quad F(x; \theta, \sigma) = \Phi\left(\frac{\log(x) - \log(\theta)}{\sigma}\right)$$

With this parameterization, the PDF satisfies the $f(x; \theta, \sigma) = \frac{1}{\theta} f\left(\frac{x}{\theta}; 1, \sigma\right)$ condition and the CDF satisfies the $F(x; \theta, \sigma) = F\left(\frac{x}{\theta}; 1, \sigma\right)$ condition. This makes θ a scale parameter. Hence, $\mu = \log(\theta)$ is a log-transformed scale parameter and the lognormal distribution is eligible for modeling regression effects.

The following DATA step simulates a lognormal sample whose scale is decided by the values of the three regressors X1, X2, and X3 as follows:

$$\mu = \log(\theta) = 1 + 0.75 X1 - X2 + 0.25 X3$$

```

/*----- Lognormal Model with Regressors -----*/
data test_sev3(keep=y x1-x3
              label='A Lognormal Sample Affected by Regressors');
  array x{*} x1-x3;
  array b{4} _TEMPORARY_ (1 0.75 -1 0.25);
  call streaminit(45678);
  label y='Response Influenced by Regressors';
  Sigma = 0.25;
  do n = 1 to 100;
    Mu = b(1); /* log of base value of scale */
    do i = 1 to dim(x);
      x(i) = rand('UNIFORM');
      Mu = Mu + b(i+1) * x(i);
    end;
    y = exp(Mu) * rand('LOGNORMAL')**Sigma;
    output;
  end;
run;

```

The following PROC SEVERITY step fits the lognormal, Burr, and gamma distribution models to this data. The regressors are specified in the SCALEMODEL statement. The DFMIXTURE= option in the SCALEMODEL statement specifies the method of computing the CDF estimates that are used to compute the EDF-based statistics of fit.

```

proc severity data=test_sev3 crit=aicc print=all;
  loss y;
  scalemodel x1-x3 / dfmixture=full;

  dist logn burr gamma;
run;

```

Some of the key results prepared by PROC SEVERITY are shown in [Figure 23.14](#) through [Figure 23.18](#). The descriptive statistics of all the variables are shown in [Figure 23.14](#).

Figure 23.14 Summary Results for the Regression Example

The final parameter estimates of the lognormal model are shown in [Figure 23.17](#). All the estimates are significantly different from 0. The estimate that is reported for the parameter Mu is the base value for the log-transformed scale parameter μ . Let x_i ($1 \leq i \leq 3$) denote the observed value for regressor X_i . If the lognormal distribution is chosen to model Y , then the effective value of the parameter μ varies with the observed values of regressors as

$$\mu = 1.04047 + 0.65221 x_1 - 0.91116 x_2 + 0.16243 x_3$$

These estimated coefficients are reasonably close to the population parameters (that is, within one or two standard errors).

Figure 23.17 Parameter Estimates for the Lognormal Model with Regressors

Parameter Estimates				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t

x3	0.16243	0.07782	2.09	0.0395

The estimates of the gamma distribution model, which is the best model according to a majority of the EDF-based statistics, are shown in Figure 23.18. The estimate that is reported for the parameter *Theta* is the base value for the scale parameter θ . If the gamma distribution is chosen to model Y , then the effective value of the scale parameter is $\theta = 0.14293 \exp(0.64562 x_1 - 0.89831 x_2 + 0.14901 x_3)$.

Figure 23.18 Parameter Estimates for the Gamma Model with Regressors

Parameter Estimates				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Theta	0.14293	0.02329	6.14	<.0001
Alpha	20.37726	2.93277	6.95	<.0001
x1	0.64562	0.08224	7.85	<.0001
x2	-0.89831	0.07962	-11.28	<.0001
x3	0.14901	0.07870	1.89	0.0613

Syntax: SEVERITY Procedure

The following statements are available in the SEVERITY procedure:

```

PROC SEVERITY options ;
  BY variable-list ;
  LOSS < response-variable > < / censoring-truncation-options > ;
  WEIGHT weight-variable ;
  SCALEMODEL regressor-variable-list < / scalemodel-options > ;
  DIST distribution-name-or-keyword < (distribution-option) > < distribution-name-or-keyword
    < (distribution-option) > > ... > < / preprocess-options > ;
  OUTSCORELIB < OUTLIB= > fcmp-library-name options ;
  NLOPTIONS options ;
  Programming statements ;

```

Functional Summary

Table 23.1 summarizes the statements and options that control the SEVERITY procedure.

Table 23.1 SEVERITY Functional Summary

Description	Statement	Option
Statements		
Specifies BY-group processing	BY	
Specifies the response variable to model along with censoring and truncation effects	LOSS	
Specifies the weight variable	WEIGHT	
Specifies the regression variables to model	SCALEMODEL	
Specifies distributions to fit	DIST	
Specifies the library to write scoring functions to	OUTSCORELIB	
Specifies optimization options	NLOPTIONS	
Specifies programming statements that define an objective function	Programming statements	
Data Set Options		
Specifies that the OUTEST= data set contain covariance estimates	PROC SEVERITY	COVOUT
Specifies the input data set	PROC SEVERITY	DATA=
Specifies the input data set for parameter estimates	PROC SEVERITY	INEST=
Specifies the output data set for CDF estimates	PROC SEVERITY	OUTCDF=
Specifies the output data set for parameter estimates	PROC SEVERITY	OUTEST=
Specifies the output data set for model information	PROC SEVERITY	OUTMODELINFO=
Specifies the output data set for statistics of fit	PROC SEVERITY	OUTSTAT=
Data Interpretation Options		
Specifies left-censoring	LOSS	LEFTCENSORED=
Specifies left-truncation	LOSS	LEFTTRUNCATED=
Specifies the probability of observability	LOSS	PROBOBSERVED=
Specifies right-censoring	LOSS	RIGHTCENSORED=
Specifies right-truncation	LOSS	RIGHTTRUNCATED=
Model Estimation Options		
Specifies the model selection criterion	PROC SEVERITY	CRITERION=
Specifies the method for computing mixture distribution	SCALEMODEL	DFMIXTURE=
Specifies initial values for model parameters	DIST	INIT=
Specifies the objective function symbol	PROC SEVERITY	OBJECTIVE=
Specifies the offset variable in the scale regression model	SCALEMODEL	OFFSET=
Specifies the denominator for computing covariance estimates	PROC SEVERITY	VARDEF=

Table 23.1 *continued*

Description	Statement	Option
Empirical Distribution Function (EDF)		
Estimation Options		
Specifies the nonparametric method of CDF estimation	PROC SEVERITY	EMPIRICALCDF=
Specifies the confidence level for reporting the confidence interval for EDF estimates	PROC SEVERITY	EDFALPHA=
EMPIRICALCDF=MODIFIEDKM Options		
Specifies the α value for the lower bound on risk set size	PROC SEVERITY	ALPHA=
Specifies the c value for the lower bound on risk set size	PROC SEVERITY	C=
Specifies the absolute lower bound on risk set size	PROC SEVERITY	RSLB=
EMPIRICALCDF=TURNBULL Options		
Specifies that the final EDF estimates be maximum likelihood estimates	PROC SEVERITY	ENSUREMLE
Specifies the relative convergence criterion	PROC SEVERITY	EPS=
Specifies the maximum number of iterations	PROC SEVERITY	MAXITER=
Specifies the threshold below which an EDF estimate is deemed to be 0	PROC SEVERITY	ZEROPROB=
Scoring Function Generation Options		
Specifies that scoring functions of all models be written to one package	OUTSCORELIB	COMMONPACKAGE
Specifies the output data set for BY-group identifiers	OUTSCORELIB	OUTBYID=
Specifies the output library for scoring functions	OUTSCORELIB	OUTLIB=
Displayed Output and Plotting Options		
Suppresses all displayed and graphical output	PROC SEVERITY	NOPRINT
Specifies which graphical output to prepare	PROC SEVERITY	PLOTS=
Specifies which displayed output to prepare	PROC SEVERITY	PRINT=
Specifies the verbosity of messages printed to the log	PROC SEVERITY	VERBOSE=
Specifies that distributions be listed to the log without estimating any models that use them	DIST	LISTONLY
Specifies that distributions be validated without estimating any models that use them	DIST	VALIDATEONLY

PROC SEVERITY Statement

PROC SEVERITY *options* ;

The PROC SEVERITY statement invokes the procedure. You can specify two types of *options* in the PROC SEVERITY statement. One set of *options* controls input and output. The other set of *options* controls the model estimation and selection process.

The following *options* control the input data sets used by PROC SEVERITY and various forms of output generated by PROC SEVERITY. The *options* are listed in alphabetical order:

COVOUT

specifies that the OUTEST= data set contain the estimate of the covariance structure of the parameters. This option has no effect if you do not specify the OUTEST= option. For more information about how the covariance is reported in the OUTEST= data set, see the section “[OUTEST= Data Set](#)” on page 1709.

DATA=SAS-data-set

names the input data set. If you do not specify the DATA= option, then the most recently created SAS data set is used.

INEST=SAS-data-set

names the input data set that contains the initial values of the parameter estimates to start the optimization process. The initial values that you specify in the INIT= option in the DIST statement take precedence over any initial values that you specify in the INEST= data set. For more information about the variables in this data set, see the section “[INEST= Data Set](#)” on page 1707.

NOPRINT

turns off all displayed and graphical output. If you specify this option, then any value that you specify for the PRINT= and PLOTS= options is ignored.

OUTCDF=SAS-data-set

names the output data set to contain estimates of the cumulative distribution function (CDF) value at each of the observations. The information is output for each specified model whose parameter estimation process converges. The data set also contains the estimates of the empirical distribution function (EDF). For more information about the variables in this data set, see the section “[OUTCDF= Data Set](#)” on page 1708.

OUTEST=SAS-data-set

names the output data set to contain estimates of the parameter values and their standard errors for each model whose parameter estimation process converges. For more information about the variables in this data set, see the section “[OUTEST= Data Set](#)” on page 1709.

OUTMODELINFO=SAS-data-set

names the output data set to contain the information about each candidate distribution. For more information about the variables in this data set, see the section “[OUTMODELINFO= Data Set](#)” on page 1710.

OUTSTAT=SAS-data-set

names the output data set to contain the values of statistics of fit for each model whose parameter estimation process converges. For more information about the variables in this data set, see the section “[OUTSTAT= Data Set](#)” on page 1711.

PLOTS < (*global-plot-options*) > < =(*plot-request-option*) >**PLOTS** < (*global-plot-options*) > < =(*plot-request-option* . . . *plot-request-option*) >

specifies the desired graphical output. If you specify more than one *global-plot-option*, then separate them with spaces and enclose them in parentheses. If you specify more than one *plot-request-option*, then separate them with spaces and enclose them in parentheses.

The following *global-plot-options* are available:

HISTOGRAM

plots the histogram of the response variable on the PDF plots.

KERNEL

plots the kernel estimate of the probability density of the response variable on the PDF plots.

ONLY

turns off the default graphical output and prepares only the requested plots.

The following *plot-request-options* are available:

ALL

displays all the graphical output.

CDF

prepares a plot that compares the cumulative distribution function (CDF) estimates of all the candidate distribution models and the empirical distribution function (EDF) estimate. The plot does not contain CDF estimates for models whose parameter estimation process does not converge.

CDFPERDIST

prepares a plot of the CDF estimates of each candidate distribution model. A plot is not prepared for models whose parameter estimation process does not converge.

NONE

displays none of the graphical output. If you specify this option, then it overrides all the other plot request options. The default graphical output is also suppressed.

PDF

prepares a plot that compares the probability density function (PDF) estimates of all the candidate distribution models. The plot does not contain PDF estimates for models whose parameter estimation process does not converge.

PDFPERDIST

prepares a plot of the PDF estimates of each candidate distribution model. A plot is not prepared for models whose parameter estimation process does not converge.

PP

prepares the probability-probability plot (known as the P-P plot), which compares the CDF estimate of each candidate distribution model against the empirical distribution function (EDF). The data shown in this plot are used for computing the EDF-based statistics of fit.

QQ

prepares the quantile-quantile plot (known as the Q-Q plot), which compares the empirical quantiles against the quantiles of each candidate distribution model.

If you do not specify the PLOTS= option or if you do not specify the ONLY *global-plot-option*, then the default graphical output is equivalent to specifying PLOTS=(CDF PDF).

PRINT <(global-display-option)> <=(display-option)>

PRINT <(global-display-option)> <=(display-option ... display-option)>

specifies the desired displayed output. If you specify more than one *display-option*, then separate them with spaces and enclose them in parentheses.

The following *global-display-option* is available:

ONLY

turns off the default displayed output and displays only the requested output.

The following *display-options* are available:

ALL

displays all the output.

ALLFITSTATS

displays the comparison of all the statistics of fit for all the models in one table. The table does not include the models whose parameter estimation process does not converge.

CONVSTATUS

displays the convergence status of the parameter estimation process.

DESCSTATS

displays the descriptive statistics for the response variable. If you specify the SCALEMODEL statement, then this option also displays the descriptive statistics for the regressor variables.

DISTINFO

displays the information about each specified distribution. For each distribution, the information includes the name, description, validity status, and number of distribution parameters.

ESTIMATES | PARMEST

displays the final estimates of parameters. The estimates are not displayed for models whose parameter estimation process does not converge.

INITIALVALUES

displays the initial values and bounds used for estimating each model.

NLOHISTORY

displays the iteration history of the nonlinear optimization process used for estimating the parameters.

NLOSUMMARY

displays the summary of the nonlinear optimization process used for estimating the parameters.

NONE

displays none of the output. If you specify this option, then it overrides all other display options. The default displayed output is also suppressed.

SELECTION | SELECT

displays the model selection table.

STATISTICS | FITSTATS

displays the statistics of fit for each model. The statistics of fit are not displayed for models whose parameter estimation process does not converge.

If you do not specify the PRINT= option or if you do not specify the ONLY *global-display-option*, then the default displayed output is equivalent to specifying PRINT=(SELECTION CONVSTATUS NLOSUMMARY STATISTICS ESTIMATES).

VARDEF=option

specifies the denominator to use for computing the covariance estimates. You can specify one of the following values for *option*:

DF

specifies that the number of nonmissing observations minus the model degrees of freedom (number of parameters) be used.

N

specifies that the number of nonmissing observations be used.

For more information about the covariance estimation, see the section “[Estimating Covariance and Standard Errors](#)” on page 1662.

VERBOSE=verbosity-level

specifies the amount of messages printed to the SAS log by PROC SEVERITY. A higher number prints messages with the same or more detail.

The following options control the model estimation and selection process:

CRITERION | CRITERIA | CRIT=criterion-option

specifies the model selection criterion.

If you specify two or more candidate models for estimation, then the one with the best value for the selection criterion is chosen as the best model. If you specify the OUTSTAT= data set, then the best model’s observation has a value of 1 for the `_SELECTED_` variable. You can specify one of the following *criterion-options*:

AD

specifies the Anderson-Darling (AD) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

AIC

specifies the Akaike's information criterion (AIC) as the selection criterion. A lower value is deemed better.

AICC

specifies the finite-sample corrected Akaike's information criterion (AICC) as the selection criterion. A lower value is deemed better.

BIC

specifies Schwarz Bayesian information criterion (BIC) as the selection criterion. A lower value is deemed better.

CUSTOM

specifies the custom objective function as the selection criterion. You can specify this only if you also specify the **OBJECTIVE=** option. A lower value is deemed better.

CVM

specifies the Cramér-von Mises (CvM) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

KS

specifies the Kolmogorov-Smirnov (KS) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

LOGLIKELIHOOD | LL

specifies $-2 * \log(L)$ as the selection criterion, where L is the likelihood of the data. A lower value is deemed better. This is the default.

For more information about these *criterion-options*, see the section “[Statistics of Fit](#)” on page 1675.

EMPIRICALCDF | EDF=method

specifies the method to use for computing the nonparametric or empirical estimate of the cumulative distribution function of the data. You can specify one of the following values for *method*:

AUTOMATIC | AUTO

specifies that the method be chosen automatically based on the data specification. This option is the default.

If you do not specify censoring or truncation, then the standard empirical estimation method (STANDARD) is chosen. If you specify both right-censoring and left-censoring, then Turnbull's estimation method (TURNBULL) is chosen. For all other combinations of censoring and truncation, the Kaplan-Meier method (KAPLANMEIER) is chosen.

KAPLANMEIER | KM

specifies that the product limit estimator proposed by Kaplan and Meier (1958) be used. Specification of this method has no effect when you specify both right-censoring and left-censoring.

MODIFIEDKM | MKM <(options)>

specifies that the modified product limit estimator be used. Specification of this method has no effect when you specify both right-censoring and left-censoring.

This method allows Kaplan-Meier's product limit estimates to be more robust by ignoring the contributions to the estimate due to small risk-set sizes. The risk set is the set of observations at the risk of failing, where an observation is said to fail if it has not been processed yet and might experience censoring or truncation. You can specify the minimum risk-set size that makes it eligible to be included in the estimation either as an absolute lower bound on the size (RSLB= option) or a relative lower bound determined by the formula cn^α proposed by Lai and Ying (1991). You can specify the values of c and α by using the C= and ALPHA= options, respectively. By default, the relative lower bound is used with values of $c = 1$ and $\alpha = 0.5$. However, you can modify the default by using the following *options*:

ALPHA | **A=***number*

specifies the value to use for α when the lower bound on the risk set size is defined as cn^α . This value must satisfy $0 < \alpha < 1$.

C=*number*

specifies the value to use for c when the lower bound on the risk set size is defined as cn^α . This value must satisfy $c > 0$.

RSLB=*number*

specifies the absolute lower bound on the risk set size to be included in the estimate.

STANDARD | **STD**

specifies that the standard empirical estimation method be used. If you specify both right-censoring and left-censoring, then the specification of this method has no effect. If you specify any other combination of censoring or truncation effects, then this method ignores such effects, and can thus result in estimates that are more biased than those obtained with other methods that are more suitable for censored or truncated data.

TURNBULL | **EM** <(options)>

specifies that the Turnbull's method be used. This method is used when you specify both right-censoring and left-censoring. An iterative expectation-maximization (EM) algorithm proposed by Turnbull (1976) is used to compute the empirical estimates. If you also specify truncation, then the modification suggested by Frydman (1994) is used. You can modify the default behavior of the EM algorithm by using the following *options*:

ENSUREMLE

specifies that the final EDF estimates be maximum likelihood estimates. The Kuhn-Tucker conditions are computed for the likelihood maximization problem and checked to ensure that EM algorithm converges to maximum likelihood estimates. The method generalizes the method proposed by Gentleman and Geyer (1994) by taking into account any truncation information that you might specify.

EPS=*number*

specifies the maximum relative error to be allowed between estimates of two consecutive iterations. This criterion is used to check the convergence of the algorithm. If you do not specify this option, then PROC SEVERITY uses a default value of $1.0E-8$.

MAXITER=number

specifies the maximum number of iterations to attempt to find the empirical estimates. If you do not specify this option, then PROC SEVERITY uses a default value of 500.

ZEROPROB=number

specifies the threshold below which an empirical estimate of the probability is considered zero. This option is used to decide if the final estimate is a maximum likelihood estimate. This option does not have an effect if you do not specify the ENSUREMLE option. If you specify the ENSUREMLE option, but do not specify this option, then PROC SEVERITY uses a default value of $1.0E-8$.

For more information about each of the methods, see the section “[Empirical Distribution Function Estimation Methods](#)” on page 1669.

EDFALPHA=confidence-level

specifies the confidence level in the (0,1) range that is used for computing the confidence intervals for the EDF estimates. The lower and upper confidence limits that correspond to this level are reported in the OUTCDF= data set, if specified, and displayed in the plot that is prepared when you specify the PLOTS=CDFPERDIST option.

If you do not specify this option, then PROC SEVERITY uses a default value of 0.05.

OBJECTIVE=symbol-name

names the symbol that represents the objective function in the SAS programming statements that you specify. For each model to be estimated, PROC SEVERITY executes the programming statements to compute the value of this symbol for each observation. The values are added across all observations to obtain the value of the objective function. The optimization algorithm estimates the model parameters such that the objective function value is *minimized*. A separate optimization problem is solved for each candidate distribution. If you specify a BY statement, then a separate optimization problem is solved for each candidate distribution within each BY group.

For more information about writing SAS programming statements to define your own objective function, see the section “[Custom Objective Functions](#)” on page 1703.

BY Statement

A BY statement can be used in the SEVERITY procedure to process the input data set in groups of observations defined by the BY variables.

When a BY statement appears, the procedure expects the input data set to be sorted in the order of the BY variables.

DIST Statement

DIST *distribution-name-or-keyword* < (*distribution-option*) < *distribution-name-or-keyword* < (*distribution-option*) > > ... > < / *preprocess-options* > ;

The DIST statement specifies candidate distributions to be estimated by the SEVERITY procedure. You can specify multiple DIST statements, and each statement can contain one or more distribution specifications.

For your convenience, PROC SEVERITY provides the following 10 different predefined distributions (the name in the parentheses is the name to use in the DIST statement): Burr (BURR), exponential (EXP), gamma (GAMMA), generalized Pareto (GPD), inverse Gaussian or Wald (IGAUSS), lognormal (LOGN), Pareto (PARETO), Tweedie (TWEEDIE), scaled Tweedie (STWEEDIE), and Weibull (WEIBULL). These are described in detail in the section “[Predefined Distributions](#)” on page 1649.

You can specify any of the predefined distributions or any distribution that you have defined. If a distribution that you specify is not a predefined distribution, then you must submit the CMPLIB= system option with appropriate libraries before you submit the PROC SEVERITY step to enable the procedure to find the functions associated with your distribution. The predefined distributions are defined in the Sashelp.SvrtDIST library. However, you are not required to specify this library in the CMPLIB= system option. For more information about defining your own distributions, see the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1679.

As a convenience, you can also use a shortcut keyword to indicate a list of distributions. You can specify one or more of the following keywords:

ALL

specifies all the predefined distributions and the distributions that you have defined in the libraries that you specify in the CMPLIB= system option. In addition to the eight predefined distributions included by the `_PREDEFINED_` keyword, this list also includes the Tweedie and scaled Tweedie distributions that are defined in the Sashelp.SvrtDIST library.

PREDEFINED

specifies the list of eight predefined distributions: BURR, EXP, GAMMA, GPD, IGAUSS, LOGN, PARETO, and WEIBULL. Although the TWEEDIE and STWEEDIE distributions are available in the Sashelp.SvrtDIST library along with these eight distributions, they are not included by this keyword. If you want to fit the TWEEDIE and STWEEDIE distributions, then you must specify them explicitly or use the `_ALL_` keyword.

USER

specifies the list of all the distributions that you have defined in the libraries that you specify in the CMPLIB= system option. This list does not include the distributions defined in the Sashelp.SvrtDIST library, even if you specify the Sashelp.SvrtDIST library in the CMPLIB= option.

The use of these keywords, especially `_ALL_`, can result in a large list of distributions, which might take a longer time to estimate. A warning is printed to the SAS log if the number of total distribution models to estimate exceeds 10.

If you specify the OUTCDF= option or request a CDF plot and you do not specify any DIST statement, then PROC SEVERITY does not fit any distributions and produces the empirical estimates of the cumulative distribution function.

The following *distribution-option* values can be used in the DIST statement for a distribution name that is not a shortcut keyword:

INIT=(name=value ... name=value)

specifies the initial values to be used for the distribution parameters to start the parameter estimation process. You must specify the values by parameter names and the parameter names must match the names used in the model definition.

For example, let a model M's definition contain a M_PDF function with following signature:

```
function M_PDF(x, alpha, beta);
```

For this model, the names **alpha** and **beta** must be used for the INIT option. The names are case-insensitive. If you do not specify initial values for some parameters in the INIT statement, then a default value of 0.001 is assumed for those parameters. If you specify an incorrect parameter, PROC SEVERITY prints a warning to the SAS log and does not fit the model. All specified values must be nonmissing.

If you are modeling regression effects, then the initial value of the first distribution parameter (**alpha** in the preceding example) should be the initial *base* value of the scale parameter or log-transformed scale parameter. For more information, see the section “[Estimating Regression Effects](#)” on page 1664.

The use of INIT= option is one of the three methods available for initializing the parameters. For more information, see the section “[Parameter Initialization](#)” on page 1663. If none of the initialization methods is used, then PROC SEVERITY initializes all parameters to 0.001.

You can specify the following *preprocess-options* in the DIST statement:

LISTONLY

specifies that the list of all candidate distributions be printed to the SAS log without doing any further processing on them. This option is especially useful when you use a shortcut keyword to include a list of distributions. It enables you to find out which distributions are included by the keyword.

VALIDATEONLY

specifies that all candidate distributions be checked for validity without doing any further processing on them. If a distribution is invalid, the reason for invalidity is written to the SAS log. If all distributions are valid, then the distribution information is written to the SAS log. The information includes name, description, validity status (valid or invalid), and number of distribution parameters. The information is not written to the SAS log if you specify an OUTMODELINFO= data set or the PRINT=DISTINFO or PRINT=ALL option in the PROC SEVERITY statement. This option is especially useful when you specify your own distributions or when you specify the `_USER_` or `_ALL_` keywords in the DIST statement. It enables you to check whether your custom distribution definitions satisfy PROC SEVERITY's requirements for the specified modeling task. It is recommended that you specify the SCALEMODEL statement if you intend to fit a model with regression effects, because the SCALEMODEL statement instructs PROC SEVERITY to perform additional checks to validate whether regression effects can be modeled on each candidate distribution.

LOSS Statement

```
LOSS < response-variable-name > < / censoring-truncation-options > ;
```

The LOSS statement specifies the name of the response or loss variable whose distribution needs to be modeled. You can also specify additional options to indicate any truncation or censoring of the response. The specification of response variable is optional if you specify at least one type of censoring. You must specify a response variable if you do not specify any censoring. If you specify more than one LOSS statement, then the first statement is used.

All the analysis variables that you specify in this statement must be present in the input data set that you specify by using the DATA= option in the PROC SEVERITY statement. The response variable is expected to have nonmissing values. If the variable has a missing value in an observation, then a warning is written to the SAS log and that observation is ignored.

The following *censoring-truncation-options* can be used in the LOSS statement:

LEFTCENSORED | **LC=***variable-name*

LEFTCENSORED | **LC=***number*

specifies the left-censoring variable or a global left-censoring limit.

You can use the *variable-name* argument to specify a data set variable that contains the left-censoring limit. If the value of this variable is missing, then PROC SEVERITY assumes that such observations are not left-censored.

Alternatively, you can use the *number* argument to specify a left-censoring limit value that applies to all the observations in the data set. This limit must be a nonzero positive number.

By definition of left-censoring, an exact value of the response is not known when it is less than or equal to the left-censoring limit. If you specify the response variable and the value of that variable is less than or equal to the value of the left-censoring limit for some observations, then PROC SEVERITY treats such observations as left-censored and the value of the response variable is ignored. If you specify the response variable and the value of that variable is greater than the value of the left-censoring limit for some observations, then PROC SEVERITY assumes that such observations are not left-censored and the value of the left-censoring limit is ignored.

If you specify both right-censoring and left-censoring limits, then the left-censoring limit must be greater than or equal to the right-censoring limit. If both limits are identical, then the observation is assumed to be uncensored.

For more information about left-censoring, see the section “[Censoring and Truncation](#)” on page 1659.

LEFTTRUNCATED | **LT=***variable-name* < (*left-truncation-option*) >

LEFTTRUNCATED | **LT=***number* < (*left-truncation-option*) >

specifies the left-truncation variable or a global left-truncation threshold.

You can use the *variable-name* argument to specify a data set variable that contains the left-truncation threshold. If the value of this variable is missing or 0 for some observations, then PROC SEVERITY assumes that such observations are not left-truncated.

Alternatively, you can use the *number* argument to specify a left-truncation threshold that applies to all the observations in the data set. This threshold must be a nonzero positive number.

It is assumed that the response variable contains the observed values. By definition of left-truncation, you can observe only a value that is greater than the left-truncation threshold. If a response variable value is less than or equal to the left-truncation threshold, a warning is printed to the SAS log, and the observation is ignored. For more information about left-truncation, see the section “[Censoring and Truncation](#)” on page 1659.

You can specify the following *left-truncation-option* for an alternative interpretation of the left-truncation threshold:

PROBOBSERVED | POBS=*number*

specifies the probability of observability, which is defined as the probability that the underlying severity event is observed (and recorded) for the specified left-threshold value.

The specified *number* must lie in the (0.0, 1.0] interval. A value of 1.0 is equivalent to specifying that there is no left-truncation, because it means that no severity events can occur with a value less than or equal to the threshold. If you specify value of 1.0, PROC SEVERITY prints a warning to the SAS log and proceeds by assuming that LEFTTRUNCATED= option is not specified.

For more information, see the section “[Probability of Observability](#)” on page 1660.

RIGHTCENSORED | RC=*variable-name***RIGHTCENSORED | RC=*number***

specifies the right-censoring variable or a global right-censoring limit.

You can use the *variable-name* argument to specify a data set variable that contains the right-censoring limit. If the value of this variable is missing, then PROC SEVERITY assumes that such observations are not right-censored.

Alternatively, you can use the *number* argument to specify a right-censoring limit value that applies to all the observations in the data set. This limit must be a nonzero positive number.

By definition of right-censoring, an exact value of the response is not known when it is greater than or equal to the right-censoring limit. If you specify the response variable and the value of that variable is greater than or equal to the value of the right-censoring limit for some observations, then PROC SEVERITY treats such observations as right-censored and the value of the response variable is ignored. If you specify the response variable and the value of that variable is less than the value of the right-censoring limit for some observations, then PROC SEVERITY assumes that such observations are not right-censored and the value of the right-censoring limit is ignored.

If you specify both right-censoring and left-censoring limits, then the left-censoring limit must be greater than or equal to the right-censoring limit. If both limits are identical, then the observation is assumed to be uncensored.

For more information about right-censoring, see the section “[Censoring and Truncation](#)” on page 1659.

RIGHTTRUNCATED | RT=*variable-name***RIGHTTRUNCATED | RT=*number***

specifies the right-truncation variable or a global right-truncation threshold.

You can use the *variable-name* argument to specify a data set variable that contains the right-truncation threshold. If the value of this variable is missing for some observations, then PROC SEVERITY assumes that such observations are not right-truncated.

Alternatively, you can use the *number* argument to specify a right-truncation threshold that applies to all the observations in the data set. This threshold must be a nonzero positive number.

It is assumed that the response variable contains the observed values. By definition of right-truncation, you can observe only a value that is less than or equal to the right-truncation threshold. If a response variable value is greater than the right-truncation threshold, a warning is printed to the SAS log, and the observation is ignored. For more information about right-truncation, see the section “[Censoring and Truncation](#)” on page 1659.

NLOPTIONS Statement

NLOPTIONS *options* ;

The SEVERITY procedure uses the nonlinear optimization (NLO) subsystem to perform the nonlinear optimization of the likelihood function to obtain the estimates of distribution and regression parameters. You can use the NLOPTIONS statement to control different aspects of this optimization process. For most problems, the default settings of the optimization process are adequate. However, in some cases it might be useful to change the optimization technique or to change the maximum number of iterations. The following statement uses the MAXITER= option to set the maximum number of iterations to 200 and uses the TECH= option to change the optimization technique to the double-dogleg optimization (DBLDOG) rather than the default technique, the trust region optimization (TRUREG), used in the SEVERITY procedure:

```
nloptions tech=dbldog maxiter=200;
```

A discussion of the full range of *options* that can be used with the NLOPTIONS statement is given in Chapter 6, “Nonlinear Optimization Methods.” The SEVERITY procedure supports all of those options except the options that are related to displaying the optimization information. You can use the PRINT= option in the PROC SEVERITY statement to request the optimization summary and iteration history. If you specify more than one NLOPTIONS statement, then the first statement is used.

OUTSCORELIB Statement (Experimental)

OUTSCORELIB <OUTLIB=> *fcmp-library-name options* ;

The OUTSCORELIB statement specifies the library to write scoring functions to. Scoring functions enable you to easily execute a distribution function on the fitted parameters of the distribution without going through a potentially complex process of extracting the fitted parameter estimates from other output such as the OUTEST= data set that is created by PROC SEVERITY.

You must specify the following option as the first option in the statement:

OUTLIB=*fcmp-library-name*

names the FCMP library to contain the scoring functions. PROC SEVERITY writes the scoring functions to the FCMP library named *fcmp-library-name*. If a library or data set named *fcmp-library-name* already exists, PROC SEVERITY deletes it before proceeding.

This option is similar to the OUTLIB= option that you would specify in a PROC FCMP statement, except that *fcmp-library-name* must be a two-level name whereas the OUTLIB= option in the PROC FCMP statement requires a three-level name. The third level of a three-level name specifies the package to which the functions belong. You do not need to specify the package name in the *fcmp-library-name*, because PROC SEVERITY automatically creates the package for you. By default, a separate package is created for each distribution that has not failed to converge. Each package is named for a distribution.

For example, if you define and fit a distribution named *mydist*, and if *mydist* does not fail to converge, then PROC SEVERITY creates a package named *mydist* in the OUTLIB= library that you specify. Further, let the definition of the *mydist* distribution contain three distribution functions, *mydist_PDF*(*x*,*Parm1*,*Parm2*), *mydist_LOGCDF*(*x*,*Parm1*,*Parm2*), and *mydist_XYZ*(*x*,*Parm1*,*Parm2*). If you specify the OUTSCORELIB statement

```
outscorelib outlib=sasuser.scorefunc;
```

then the Sasuser.Scorefunc library contains the following three functions in a package named *mydist*: *SEV_PDF*(*x*), *SEV_LOGCDF*(*x*), and *SEV_XYZ*(*x*).

The key feature of scoring functions is that they do not require the parameter arguments (*Parm1* and *Parm2* in this example). The fitted parameter estimates are encoded inside the scoring function so that you can compute or score the value of each function for a given value of the loss variable without having to know or extract the parameter estimates through some other means.

For convenience, you can omit the OUTLIB= portion of the specification and just specify the name, as in the following example:

```
outscorelib sasuser.scorefunc;
```

When the SEVERITY procedure executes successfully, the *fcmp-library-name* is appended to the CMPLIB system option, so you can immediately start using the scoring functions in a DATA step or PROC FCMP step.

You can specify the following *options* in the OUTSCORELIB statement:

COMMONPACKAGE

ONEPACKAGE

requests that only one common package be created to contain all the scoring functions.

If you specify this option, then all the scoring functions are created in a package called *sevfit*. For each distribution function that has the name *distribution_suffix*, the name of the corresponding scoring function is formed as *SEV_suffix_distribution*. For example, the scoring function of the distribution function 'MYDIST_BAR' is named 'SEV_BAR_MYDIST'.

If you do not specify this option, then all scoring functions for a distribution are created in a package that has the same name as the distribution, and for each distribution function that has the name *distribution_suffix*, the name of the corresponding scoring function is formed as *SEV_suffix*. For example, the scoring function of the distribution function 'MYDIST_BAR' is named 'SEV_BAR'.

OUTBYID=SAS-data-set

names the output data set to contain the unique identifier for each BY group. This unique identifier is used as part of the name of the package or scoring function for each distribution. This is a required option when you specify a BY statement in PROC SEVERITY.

The OUTBYID= data set contains one observation per BY group and a variable named *_ID_* in addition to the BY variables that you specify in the BY statement. The *_ID_* variable contains the unique identifier for each BY group. The identifier of the BY group is the decimal representation of the sequence number of the BY group. The first BY group has an identifier of 1, the second BY group has an identifier of 2, the tenth BY group has an identifier of 10, and so on.

If you do not specify the COMMONPACKAGE option in the OUTSCORELIB statement, then for each distribution, PROC SEVERITY creates as many packages as the number of BY groups. The unique BY-group identifier is used as a suffix for the package name. For example, if your DATA= data set has three BY groups and if you specify the OUTSCORELIB statement

```
outscorelib outlib=sasuser.byscorefunc outbyid=sasuser.byid;
```

then for the distribution ‘MYDIST’, the Sasuser.Byscorefunc library contains the three packages ‘MYDIST1’, ‘MYDIST2’, and ‘MYDIST3’, and each package contains one scoring function named ‘SEV_BAR’ for each distribution function named ‘MYDIST_BAR’.

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, PROC SEVERITY creates as many versions of the distribution function as the number of BY groups. The unique BY-group identifier is used as a suffix for the function name. Extending the previous example, if you specify the OUTSCORELIB statement with the COMMONPACKAGE option,

```
outscorelib outlib=sasuser.byscorefunc outbyid=sasuser.byid commonpackage;
```

then for the distribution function ‘MYDIST_BAR’ of the distribution ‘MYDIST’, the Sasuser.Byscorefunc library contains the following three scoring functions: ‘SEV_BAR_MYDIST1’, ‘SEV_BAR_MYDIST2’, and ‘SEV_BAR_MYDIST3’. All the scoring functions are created in one common package named *sevfit*.

For both the preceding examples, the Sasuser.Byid data set contains three observations, one for each BY group. The value of the _ID_ variable is 1 for the first BY group, 2 for the second BY group, and 3 for the third BY group.

For more information about scoring functions, see the section “[Scoring Functions \(Experimental\)](#)” on page 1696.

SCALEMODEL Statement

```
SCALEMODEL regressor-variable-list < / scalemodel-options > ;
```

The SCALEMODEL statement specifies regression variables. All the variables that you specify in this statement must be present in the input data set that you specify by using the DATA= option in the PROC SEVERITY statement. The scale parameter of each candidate distribution is linked to a linear combination of these regression variables along with an intercept. If a distribution does not have a scale parameter, then a model based on that distribution is not estimated. If you specify more than one SCALEMODEL statement, then the first statement is used.

The regressor variables are expected to have nonmissing values. If any of the variables has a missing value in an observation, then a warning is written to the SAS log and that observation is ignored.

For more information about modeling regression effects, see the section “[Estimating Regression Effects](#)” on page 1664.

You can specify the following *scalemodel-options* in the SCALEMODEL statement:

DFMIXTURE=*method-name* < (*method-options*) >

specifies the method for computing representative estimates of the cumulative distribution function (CDF) and the probability density function (PDF).

When you specify regression variables, the scale of the distribution depends on the values of the regressors. For a given distribution family, each observation in the input data set implies a different scaled version of the distribution. To compute estimates of CDF and PDF that are comparable across different distribution families, PROC SEVERITY needs to construct a single representative distribution from all such distributions. You can specify one of the following *method-name* values to specify the method that is used to construct the representative distribution. For more information about each of the methods, see the section “CDF and PDF Estimates with Regression Effects” on page 1667.

FULL

specifies that the representative distribution be the mixture of N distributions such that each distribution has a scale value that is implied by each of the N observations that are used for estimation. This method is the slowest.

MEAN

specifies that the representative distribution be the one-point mixture of the distribution whose scale value is the mean of the N scale values that are implied by the N observations that are used for estimation. If you do not specify the DFMIXTURE= option, then this method is used by default. This is also the fastest method.

QUANTILE < (**K=** q) >

specifies that the representative distribution be the mixture of a fixed number of distributions whose scale values are the quantiles from the sample of N scale values that are implied by the N observations in the current BY group (or in the entire DATA= data set if you do not specify the BY statement).

You can use the K= option to specify the number of distributions in the mixture. If you specify K= q , then the mixture contains $(q - 1)$ distributions such that each distribution has as its scale one of the $(q - 1)$ -quantiles.

If you do not specify the K= option, then PROC SEVERITY uses the default of 2, which implies the use of a one-point mixture with a distribution whose scale value is the median of all scale values.

RANDOM < (*random-method-options*) >

specifies that the representative distribution be the mixture of a fixed number of distributions whose scale values are the scale values that are implied by a randomly chosen subset of the set of all observations in the current BY group (or in the entire DATA= data set if you do not specify the BY statement). The same subset of observations is used for each distribution family.

You can specify the following *random-method-options* to specify how the subset is chosen:

K= r

specifies the number of distributions to include in the mixture. If you do not specify this option, then PROC SEVERITY uses the default of 15.

SEED=number

specifies the seed that is used to generate the uniform random sample of observation indices. If you do not specify this option, then PROC SEVERITY generates a seed internally that is based on the current value of the system clock.

OFFSET=offset-variable-name

specifies the name of the offset variable in the scale regression model. An offset variable is a regressor variable whose regression coefficient is known to be 1. For more information, see the section “[Offset Variable](#)” on page 1665.

WEIGHT Statement

WEIGHT variable-name ;

The WEIGHT statement specifies the name of a variable whose values represent the weight of each observation. PROC SEVERITY associates a weight of w to each observation, where w is the value of the WEIGHT variable for the observation. If the weight value is missing or less than or equal to 0, then the observation is ignored and a warning is written to the SAS log. When you do not specify the WEIGHT statement, each observation is assigned a weight of 1. If you specify more than one WEIGHT statement, then the last statement is used.

The weights are normalized so that they add up to the actual sample size. In particular, weight of each observation is multiplied by $\frac{N}{\sum_{i=1}^N w_i}$, where N is the sample size.

Programming Statements

You can use a series of programming statements that use variables in the input data set that you specify in the DATA= option in the PROC SEVERITY statement to assign a value to an objective function symbol. You must specify the objective function symbol by using the **OBJECTIVE=** option in the PROC SEVERITY statement. If you do not specify the **OBJECTIVE=** option in the PROC SEVERITY statement, then the programming statements are ignored and models are estimated using the maximum likelihood method.

You can use most DATA step statements and functions in your program. Any additional functions, restrictions, and differences are listed in the section “[Custom Objective Functions](#)” on page 1703.

Details: SEVERITY Procedure

Predefined Distributions

PROC SEVERITY assumes the following model for the response variable Y

$$Y \sim \mathcal{F}(\Theta)$$

where \mathcal{F} is a continuous probability distribution with parameters Θ . The model hypothesizes that the observed response is generated from a stochastic process that is governed by the distribution \mathcal{F} . This model is typically referred to as the error model. Given a representative input sample of response variable values, PROC SEVERITY estimates the model parameters for any distribution \mathcal{F} and computes the statistics of fit for each model. This enables you to find the distribution that is most likely to generate the observed sample.

A set of predefined distributions is provided with the SEVERITY procedure. A summary of the distributions is provided in [Table 23.2](#). For each distribution, the table lists the name of the distribution that should be used in the DIST statement, the parameters of the distribution along with their bounds, and the mathematical expressions for the probability density function (PDF) and cumulative distribution function (CDF) of the distribution.

All the predefined distributions, except LOGN and TWEEDIE, are parameterized such that their first parameter is the scale parameter. For LOGN, the first parameter μ is a log-transformed scale parameter. TWEEDIE does not have a scale parameter. The presence of scale parameter or a log-transformed scale parameter enables you to use all of the predefined distributions, except TWEEDIE, as a candidate for estimating regression effects.

A distribution model is associated with each predefined distribution. You can also define your own distribution model, which is a set of functions and subroutines that you define by using the FCMP procedure. See the section [“Defining a Distribution Model with the FCMP Procedure”](#) on page 1679 for more information.

Table 23.2 Predefined SEVERITY Distributions

Name	Distribution	Parameters	PDF (f) and CDF (F)
BURR	Burr	$\theta > 0, \alpha > 0,$ $\gamma > 0$	$f(x) = \frac{\alpha \gamma z^\gamma}{x(1+z^\gamma)^{(\alpha+1)}}$ $F(x) = 1 - \left(\frac{1}{1+z^\gamma}\right)^\alpha$
EXP	Exponential	$\theta > 0$	$f(x) = \frac{1}{\theta} e^{-z}$ $F(x) = 1 - e^{-z}$
GAMMA	Gamma	$\theta > 0, \alpha > 0$	$f(x) = \frac{z^\alpha e^{-z}}{x \Gamma(\alpha)}$ $F(x) = \frac{\gamma(\alpha, z)}{\Gamma(\alpha)}$
GPD	Generalized Pareto	$\theta > 0, \xi > 0$	$f(x) = \frac{1}{\theta} (1 + \xi z)^{-1-1/\xi}$ $F(x) = 1 - (1 + \xi z)^{-1/\xi}$
IGAUSS	Inverse Gaussian (Wald)	$\theta > 0, \alpha > 0$	$f(x) = \frac{1}{\theta} \sqrt{\frac{\alpha}{2\pi z^3}} e^{\frac{-\alpha(z-1)^2}{2z}}$ $F(x) = \Phi\left((z-1)\sqrt{\frac{\alpha}{z}}\right) + \Phi\left(-(z+1)\sqrt{\frac{\alpha}{z}}\right) e^{2\alpha}$
LOGN	Lognormal	μ (no bounds), $\sigma > 0$	$f(x) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2}$ $F(x) = \Phi\left(\frac{\log(x)-\mu}{\sigma}\right)$
PARETO	Pareto	$\theta > 0, \alpha > 0$	$f(x) = \frac{\alpha \theta^\alpha}{(x+\theta)^{\alpha+1}}$ $F(x) = 1 - \left(\frac{\theta}{x+\theta}\right)^\alpha$
TWEEDIE	Tweedie ⁶	$p > 1, \mu > 0,$ $\phi > 0$	$f(x) = a(x, \phi) \exp\left[\frac{1}{\phi} \left(\frac{x\mu^{1-p}}{1-p} - \kappa(\mu, p)\right)\right]$ $F(x) = \int_0^x f(t) dt$
STWEEDIE	Scaled Tweedie ⁶	$\theta > 0, \lambda > 0,$ $1 < p < 2$	$f(x) = a(x, \theta, \lambda, p) \exp\left(-\frac{x}{\theta} - \lambda\right)$ $F(x) = \int_0^x f(t) dt$
WEIBULL	Weibull	$\theta > 0, \tau > 0$	$f(x) = \frac{1}{x} \tau z^\tau e^{-z^\tau}$ $F(x) = 1 - e^{-z^\tau}$

Notes:

1. $z = x/\theta$, wherever z is used.
2. θ denotes the scale parameter for all the distributions. For LOGN, $\log(\theta) = \mu$.
3. Parameters are listed in the order in which they are defined in the distribution model.
4. $\gamma(a, b) = \int_0^b t^{a-1} e^{-t} dt$ is the lower incomplete gamma function.
5. $\Phi(y) = \frac{1}{2} \left(1 + \operatorname{erf}\left(\frac{y}{\sqrt{2}}\right)\right)$ is the standard normal CDF.
6. See the section “[Tweedie Distributions](#)” on page 1651 for more information.

Tweedie Distributions

Tweedie distributions are a special case of the exponential dispersion family (Jørgensen 1987) with a property that the variance of the distribution is equal to $\phi\mu^p$, where μ is the mean of the distribution, ϕ is a dispersion parameter, and p is an index parameter as discovered by Tweedie (1984). The distribution is defined for all values of p except for values of p in the open interval $(0, 1)$. Many important known distributions are a special case of Tweedie distributions including normal ($p=0$), Poisson ($p=1$), gamma ($p=2$), and the inverse Gaussian ($p=3$). Apart from these special cases, the probability density function (PDF) of the Tweedie distribution does not have an analytic expression. For $p > 1$, it has the form (Dunn and Smyth 2005),

$$f(x; \mu, \phi, p) = a(x, \phi) \exp \left[\frac{1}{\phi} \left(\frac{x\mu^{1-p}}{1-p} - \kappa(\mu, p) \right) \right]$$

where $\kappa(\mu, p) = \mu^{2-p}/(2-p)$ for $p \neq 2$ and $\kappa(\mu, p) = \log(\mu)$ for $p = 2$. The function $a(x, \phi)$ does not have an analytical expression. It is typically evaluated using series expansion methods described in Dunn and Smyth (2005).

For $1 < p < 2$, the Tweedie distribution is a compound Poisson-gamma mixture distribution, which is the distribution of S defined as

$$S = \sum_{i=1}^N X_i$$

where $N \sim \text{Poisson}(\lambda)$ and $X_i \sim \text{gamma}(\alpha, \theta)$ are iid gamma random variables with shape parameter α and scale parameter θ . At $X = 0$, the density is a probability mass that is governed by the Poisson distribution, and for values of $X > 0$, it is a mixture of gamma variates with Poisson mixing probability. The parameters λ , α and θ are related to the natural parameters μ , ϕ , and p of the Tweedie distribution as

$$\begin{aligned} \lambda &= \frac{\mu^{2-p}}{\phi(2-p)} \\ \alpha &= \frac{2-p}{p-1} \\ \theta &= \phi(p-1)\mu^{p-1} \end{aligned}$$

The mean of a Tweedie distribution is positive for $p > 1$.

Two predefined versions of the Tweedie distribution are provided with the SEVERITY procedure. The first version, named TWEEDIE and defined for $p > 1$, has the natural parameterization with parameters μ , ϕ , and p . The second version, named STWEEDIE and defined for $1 < p < 2$, is the version with a scale parameter. It corresponds to the compound Poisson-gamma distribution with gamma scale parameter θ , Poisson mean parameter λ , and the index parameter p . The index parameter decides the shape parameter α of the gamma distribution as

$$\alpha = \frac{2-p}{p-1}$$

The parameters θ and λ of the STWEEDIE distribution are related to the parameters μ and ϕ of the TWEEDIE distribution as

$$\begin{aligned} \mu &= \lambda\theta\alpha \\ \phi &= \frac{(\lambda\theta\alpha)^{2-p}}{\lambda(2-p)} = \frac{\theta}{(p-1)(\lambda\theta\alpha)^{p-1}} \end{aligned}$$

You can fit either version when there are no regression variables. Each version has its own merits. If you fit the TWEEDIE version, you have the direct estimate of the overall mean of the distribution. If you are interested in the most practical range of the index parameter $1 < p < 2$, then you can fit the STWEEDIE version, which provides you direct estimates of the Poisson and gamma components that comprise the distribution (an estimate of the gamma shape parameter α is easily obtained from the estimate of p).

If you want to estimate the effect of exogenous (regression) variables on the distribution, then you must use the STWEEDIE version, because PROC SEVERITY requires a distribution to have a scale parameter in order to estimate regression effects. See the section “[Estimating Regression Effects](#)” on page 1664 for more information. The gamma scale parameter θ is the scale parameter of the STWEEDIE distribution. If you are interested in determining the effect of regression variables on the mean of the distribution, you can do so by first fitting the STWEEDIE distribution to determine the effect of the regression variables on the scale parameter θ . Then, you can easily estimate how the mean of the distribution μ is affected by the regression variables using the relationship $\mu = c\theta$, where $c = \lambda\alpha = \lambda(2 - p)/(p - 1)$. The estimates of the regression parameters remain the same, whereas the estimate of the intercept parameter is adjusted by the estimates of the λ and p parameters.

Parameter Initialization for Predefined Distributions

The parameters are initialized by using the method of moments for all the distributions, except for the gamma and the Weibull distributions. For the gamma distribution, approximate maximum likelihood estimates are used. For the Weibull distribution, the method of percentile matching is used.

Given n observations of the severity value y_i ($1 \leq i \leq n$), the estimate of k th raw moment is denoted by m_k and computed as

$$m_k = \frac{1}{n} \sum_{i=1}^n y_i^k$$

The 100 p th percentile is denoted by π_p ($0 \leq p \leq 1$). By definition, π_p satisfies

$$F(\pi_p-) \leq p \leq F(\pi_p)$$

where $F(\pi_p-) = \lim_{h \downarrow 0} F(\pi_p - h)$. PROC SEVERITY uses the following practical method of computing π_p . Let $\hat{F}_n(y)$ denote the empirical distribution function (EDF) estimate at a severity value y . Let y_p^- and y_p^+ denote two consecutive values in the ascending sequence of y values such that $\hat{F}_n(y_p^-) < p$ and $\hat{F}_n(y_p^+) \geq p$. Then, the estimate $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = y_p^- + \frac{p - \hat{F}_n(y_p^-)}{\hat{F}_n(y_p^+) - \hat{F}_n(y_p^-)}(y_p^+ - y_p^-)$$

Let ϵ denote the smallest double-precision floating-point number such that $1 + \epsilon > 1$. This machine precision constant can be obtained by using the CONSTANT function in Base SAS software.

The details of how parameters are initialized for each predefined distribution are as follows:

BURR The parameters are initialized by using the method of moments. The k th raw moment of the Burr distribution is:

$$E[X^k] = \frac{\theta^k \Gamma(1 + k/\gamma) \Gamma(\alpha - k/\gamma)}{\Gamma(\alpha)}, \quad -\gamma < k < \alpha\gamma$$

Three moment equations $E[X^k] = m_k$ ($k = 1, 2, 3$) need to be solved for initializing the three parameters of the distribution. In order to get an approximate closed form solution, the second shape parameter $\hat{\gamma}$ is initialized to a value of 2. If $2m_3 - 3m_1m_2 > 0$, then simplifying and solving the moment equations yields the following feasible set of initial values:

$$\hat{\theta} = \sqrt{\frac{m_2m_3}{2m_3 - 3m_1m_2}}, \quad \hat{\alpha} = 1 + \frac{m_3}{2m_3 - 3m_1m_2}, \quad \hat{\gamma} = 2$$

If $2m_3 - 3m_1m_2 < \epsilon$, then the parameters are initialized as follows:

$$\hat{\theta} = \sqrt{m_2}, \quad \hat{\alpha} = 2, \quad \hat{\gamma} = 2$$

EXP The parameters are initialized by using the method of moments. The k th raw moment of the exponential distribution is:

$$E[X^k] = \theta^k \Gamma(k + 1), \quad k > -1$$

Solving $E[X] = m_1$ yields the initial value of $\hat{\theta} = m_1$.

GAMMA The parameter α is initialized by using its *approximate* maximum likelihood (ML) estimate. For a set of n iid observations y_i ($1 \leq i \leq n$), drawn from a gamma distribution, the log likelihood, l , is defined as follows:

$$\begin{aligned} l &= \sum_{i=1}^n \log \left(y_i^{\alpha-1} \frac{e^{-y_i/\theta}}{\theta^\alpha \Gamma(\alpha)} \right) \\ &= (\alpha - 1) \sum_{i=1}^n \log(y_i) - \frac{1}{\theta} \sum_{i=1}^n y_i - n\alpha \log(\theta) - n \log(\Gamma(\alpha)) \end{aligned}$$

Using a shorter notation of \sum to denote $\sum_{i=1}^n$ and solving the equation $\partial l / \partial \theta = 0$ yields the following ML estimate of θ :

$$\hat{\theta} = \frac{\sum y_i}{n\alpha} = \frac{m_1}{\alpha}$$

Substituting this estimate in the expression of l and simplifying gives

$$l = (\alpha - 1) \sum \log(y_i) - n\alpha - n\alpha \log(m_1) + n\alpha \log(\alpha) - n \log(\Gamma(\alpha))$$

Let d be defined as follows:

$$d = \log(m_1) - \frac{1}{n} \sum \log(y_i)$$

Solving the equation $\partial l / \partial \alpha = 0$ yields the following expression in terms of the digamma function, $\psi(\alpha)$:

$$\log(\alpha) - \psi(\alpha) = d$$

The digamma function can be approximated as follows:

$$\hat{\psi}(\alpha) \approx \log(\alpha) - \frac{1}{\alpha} \left(0.5 + \frac{1}{12\alpha + 2} \right)$$

This approximation is within 1.4% of the true value for all the values of $\alpha > 0$ except when α is arbitrarily close to the positive root of the digamma function (which is approximately 1.461632). Even for the values of α that are close to the positive root, the absolute error between true and approximate values is still acceptable ($|\hat{\psi}(\alpha) - \psi(\alpha)| < 0.005$ for $\alpha > 1.07$). Solving the equation that arises from this approximation yields the following estimate of α :

$$\hat{\alpha} = \frac{3 - d + \sqrt{(d - 3)^2 + 24d}}{12d}$$

If this approximate ML estimate is infeasible, then the method of moments is used. The k th raw moment of the gamma distribution is:

$$E[X^k] = \theta^k \frac{\Gamma(\alpha + k)}{\Gamma(\alpha)}, \quad k > -\alpha$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial value for α :

$$\hat{\alpha} = \frac{m_1^2}{m_2 - m_1^2}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance), then α is initialized as follows:

$$\hat{\alpha} = 1$$

After computing the estimate of α , the estimate of θ is computed as follows:

$$\hat{\theta} = \frac{m_1}{\hat{\alpha}}$$

Both the maximum likelihood method and the method of moments arrive at the same relationship between $\hat{\alpha}$ and $\hat{\theta}$.

GPD

The parameters are initialized by using the method of moments. Notice that for $\xi > 0$, the CDF of the generalized Pareto distribution (GPD) is:

$$\begin{aligned} F(x) &= 1 - \left(1 + \frac{\xi x}{\theta}\right)^{-1/\xi} \\ &= 1 - \left(\frac{\theta/\xi}{x + \theta/\xi}\right)^{1/\xi} \end{aligned}$$

This is equivalent to a Pareto distribution with scale parameter $\theta_1 = \theta/\xi$ and shape parameter $\alpha = 1/\xi$. Using this relationship, the parameter initialization method used for the PARETO distribution is used to get the following initial values for the parameters of the GPD distribution:

$$\hat{\theta} = \frac{m_1 m_2}{2(m_2 - m_1^2)}, \quad \hat{\xi} = \frac{m_2 - 2m_1^2}{2(m_2 - m_1^2)}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance) or $m_2 - 2m_1^2 < \epsilon$, then the parameters are initialized as follows:

$$\hat{\theta} = \frac{m_1}{2}, \quad \hat{\xi} = \frac{1}{2}$$

IGAUSS

The parameters are initialized by using the method of moments. Note that the standard parameterization of the inverse Gaussian distribution (also known as the Wald distribution), in terms of the location parameter μ and shape parameter λ , is as follows (Klugman, Panjer, and Willmot 1998, p. 583):

$$f(x) = \sqrt{\frac{\lambda}{2\pi x^3}} \exp\left(\frac{-\lambda(x - \mu)^2}{2\mu^2 x}\right)$$

$$F(x) = \Phi\left(\left(\frac{x}{\mu} - 1\right) \sqrt{\frac{\lambda}{x}}\right) + \Phi\left(-\left(\frac{x}{\mu} + 1\right) \sqrt{\frac{\lambda}{x}}\right) \exp\left(\frac{2\lambda}{\mu}\right)$$

For this parameterization, it is known that the mean is $E[X] = \mu$ and the variance is $Var[X] = \mu^3/\lambda$, which yields the second raw moment as $E[X^2] = \mu^2(1 + \mu/\lambda)$ (computed by using $E[X^2] = Var[X] + (E[X])^2$).

The predefined IGAUSS distribution in PROC SEVERITY uses the following alternate parameterization to allow the distribution to have a scale parameter, θ :

$$f(x) = \sqrt{\frac{\alpha\theta}{2\pi x^3}} \exp\left(\frac{-\alpha(x - \theta)^2}{2x\theta}\right)$$

$$F(x) = \Phi\left(\left(\frac{x}{\theta} - 1\right) \sqrt{\frac{\alpha\theta}{x}}\right) + \Phi\left(-\left(\frac{x}{\theta} + 1\right) \sqrt{\frac{\alpha\theta}{x}}\right) \exp(2\alpha)$$

The parameters θ (scale) and α (shape) of this alternate form are related to the parameters μ and λ of the preceding form such that $\theta = \mu$ and $\alpha = \lambda/\mu$. Using this relationship, the first and second raw moments of the IGAUSS distribution are:

$$E[X] = \theta$$

$$E[X^2] = \theta^2 \left(1 + \frac{1}{\alpha}\right)$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial values:

$$\hat{\theta} = m_1, \quad \hat{\alpha} = \frac{m_1^2}{m_2 - m_1^2}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance), then the parameters are initialized as follows:

$$\hat{\theta} = m_1, \quad \hat{\alpha} = 1$$

LOGN The parameters are initialized by using the method of moments. The k th raw moment of the lognormal distribution is:

$$E[X^k] = \exp\left(k\mu + \frac{k^2\sigma^2}{2}\right)$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial values:

$$\hat{\mu} = 2 \log(m_1) - \frac{\log(m_2)}{2}, \quad \hat{\sigma} = \sqrt{\log(m_2) - 2 \log(m_1)}$$

PARETO The parameters are initialized by using the method of moments. The k th raw moment of the Pareto distribution is:

$$E[X^k] = \frac{\theta^k \Gamma(k+1) \Gamma(\alpha-k)}{\Gamma(\alpha)}, \quad -1 < k < \alpha$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial values:

$$\hat{\theta} = \frac{m_1 m_2}{m_2 - 2m_1^2}, \quad \hat{\alpha} = \frac{2(m_2 - m_1^2)}{m_2 - 2m_1^2}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance) or $m_2 - 2m_1^2 < \epsilon$, then the parameters are initialized as follows:

$$\hat{\theta} = m_1, \quad \hat{\alpha} = 2$$

TWEEDIE The parameter p is initialized by assuming that the sample is generated from a gamma distribution with shape parameter α and by computing $\hat{p} = \frac{\hat{\alpha}+2}{\hat{\alpha}+1}$. The initial value $\hat{\alpha}$ is obtained from using the method previously described for the GAMMA distribution. The parameter μ is the mean of the distribution. Hence, it is initialized to the sample mean as

$$\hat{\mu} = m_1$$

Variance of a Tweedie distribution is equal to $\phi\mu^p$. Thus, the sample variance is used to initialize the value of ϕ as

$$\hat{\phi} = \frac{m_2 - m_1^2}{\hat{\mu} \hat{p}}$$

STWEEDIE STWEEDIE is a compound Poisson-gamma mixture distribution with mean $\mu = \lambda\theta\alpha$, where α is the shape parameter of the gamma random variables in the mixture and the parameter p is determined solely by α . First, the parameter p is initialized by assuming that the sample is generated from a gamma distribution with shape parameter α and by computing $\hat{p} = \frac{\hat{\alpha}+2}{\hat{\alpha}+1}$. The initial value $\hat{\alpha}$ is obtained from using the method previously described for the GAMMA distribution. As done for initializing the parameters of the TWEEDIE distribution, the sample mean and variance are used to compute the values $\hat{\mu}$ and $\hat{\phi}$ as

$$\begin{aligned}\hat{\mu} &= m_1 \\ \hat{\phi} &= \frac{m_2 - m_1^2}{\hat{\mu}\hat{p}}\end{aligned}$$

Based on the relationship between the parameters of TWEEDIE and STWEEDIE distributions described in the section “[Tweedie Distributions](#)” on page 1651, values of θ and λ are initialized as

$$\begin{aligned}\hat{\theta} &= \hat{\phi}(\hat{p} - 1)\hat{\mu}^{p-1} \\ \hat{\lambda} &= \frac{\hat{\mu}}{\hat{\theta}\hat{\alpha}}\end{aligned}$$

WEIBULL The parameters are initialized by using the percentile matching method. Let $q1$ and $q3$ denote the estimates of the 25th and 75th percentiles, respectively. Using the formula for the CDF of Weibull distribution, they can be written as

$$\begin{aligned}1 - \exp(-(q1/\theta)^\tau) &= 0.25 \\ 1 - \exp(-(q3/\theta)^\tau) &= 0.75\end{aligned}$$

Simplifying and solving these two equations yields the following initial values:

$$\hat{\theta} = \exp\left(\frac{r \log(q1) - \log(q3)}{r - 1}\right), \quad \hat{\tau} = \frac{\log(\log(4))}{\log(q3) - \log(\hat{\theta})}$$

where $r = \log(\log(4))/\log(\log(4/3))$. These initial values agree with those suggested in Klugman, Panjer, and Willmot (1998).

A summary of the initial values of all the parameters for all the predefined distributions is given in [Table 23.3](#). The table also provides the names of the parameters to use in the **INIT=** option in the DIST statement if you want to provide a different initial value.

Table 23.3 Parameter Initialization for Predefined Distributions

Distribution	Parameter	Name for INIT option	Default Initial Value
BURR	θ	theta	$\sqrt{\frac{m_2 m_3}{2m_3 - 3m_1 m_2}}$
	α	alpha	$1 + \frac{m_3}{2m_3 - 3m_1 m_2}$
	γ	gamma	2
EXP	θ	theta	m_1
GAMMA	θ	theta	m_1/α
	α	alpha	$\frac{3-d+\sqrt{(d-3)^2+24d}}{12d}$
GPD	θ	theta	$m_1 m_2 / (2(m_2 - m_1^2))$
	ξ	xi	$(m_2 - 2m_1^2) / (2(m_2 - m_1^2))$
IGAUSS	θ	theta	m_1
	α	alpha	$m_1^2 / (m_2 - m_1^2)$
LOGN	μ	mu	$2 \log(m_1) - \log(m_2)/2$
	σ	sigma	$\sqrt{\log(m_2) - 2 \log(m_1)}$
PARETO	θ	theta	$m_1 m_2 / (m_2 - 2m_1^2)$
	α	alpha	$2(m_2 - m_1^2) / (m_2 - 2m_1^2)$
TWEEDIE	μ	mu	m_1
	ϕ	phi	$(m_2 - m_1^2) / m_1^p$
	p	p	$(\alpha + 2) / (\alpha + 1)$
			where $\alpha = \frac{3-d+\sqrt{(d-3)^2+24d}}{12d}$
STWEEDIE	θ	theta	$(m_2 - m_1^2)(p - 1) / m_1$
	λ	lambda	$m_1^2 / (\alpha(m_2 - m_1^2)(p - 1))$
	p	p	$(\alpha + 2) / (\alpha + 1)$
			where $\alpha = \frac{3-d+\sqrt{(d-3)^2+24d}}{12d}$
WEIBULL	θ	theta	$\exp\left(\frac{r \log(q1) - \log(q3)}{r-1}\right)$
	τ	tau	$\log(\log(4)) / (\log(q3) - \log(\hat{\theta}))$

Notes:

- m_k denotes the k th raw moment
- $d = \log(m_1) - (\sum \log(y_i)) / n$
- $q1$ and $q3$ denote the 25th and 75th percentiles, respectively
- $r = \log(\log(4)) / \log(\log(4/3))$

Censoring and Truncation

One of the key features of PROC SEVERITY is that it enables you to specify whether the severity event's magnitude is observable and if it is observable, then whether the exact value of the magnitude is known. If an event is unobservable when the magnitude is in certain intervals, then it is referred to as a truncation effect. If the exact magnitude of the event is not known, but it is known to have a value in a certain interval, then it is referred to as a censoring effect.

PROC SEVERITY allows a severity event to be subject to any combination of the following four censoring and truncation effects:

- **Left-truncation:** An event is said to be left-truncated if it is observed only when $Y > T^l$, where Y denotes the random variable for the magnitude and T^l denotes a random variable for the truncation threshold. You can specify left-truncation using the `LEFTTRUNCATED=` option in the LOSS statement.
- **Right-truncation:** An event is said to be right-truncated if it is observed only when $Y \leq T^r$, where Y denotes the random variable for the magnitude and T^r denotes a random variable for the truncation threshold. You can specify right-truncation using the `RIGHTTRUNCATED=` option in the LOSS statement.
- **Left-censoring:** An event is said to be left-censored if it is known that the magnitude is $Y \leq C^l$, but the exact value of Y is not known. C^l is a random variable for the censoring limit. You can specify left-censoring using the `LEFTCENSORED=` option in the LOSS statement.
- **Right-censoring:** An event is said to be right-censored if it is known that the magnitude is $Y > C^r$, but the exact value of Y is not known. C^r is a random variable for the censoring limit. You can specify right-censoring using the `RIGHTCENSORED=` option in the LOSS statement.

For each effect, you can specify a different threshold or limit for each observation or specify a single threshold or limit that applies to all the observations.

If all the four types of effects are present on an event, then the following relationship holds: $T^l < C^r \leq C^l \leq T^r$. PROC SEVERITY checks these relationships and write a warning to the SAS log if any is violated.

If you specify the response variable in the LOSS statement, then PROC SEVERITY also checks whether each observation satisfies the definitions of the specified censoring and truncation effects. If you specify left-truncation, then PROC SEVERITY ignores observations where $Y \leq T^l$, because such observations are not observable by definition. Similarly, if you specify right-truncation, then PROC SEVERITY ignores observations where $Y > T^r$. If you specify left-censoring, then PROC SEVERITY treats an observation with $Y > C^l$ as uncensored and ignores the value of C^l . The observations with $Y \leq C^l$ are considered as left-censored, and the value of Y is ignored. If you specify right-censoring, then PROC SEVERITY treats an observation with $Y \leq C^r$ as uncensored and ignores the value of C^r . The observations with $Y > C^r$ are considered as right-censored, and the value of Y is ignored. If you specify both left-censoring and right-censoring, it is referred to as interval-censoring. If $C^r < C^l$ is satisfied for an observation, then it is considered as interval-censored and the value of the response variable is ignored. If $C^r = C^l$ for an observation, then PROC SEVERITY assumes that observation to be uncensored. If all the observations in a data set are censored in some form, then the specification of the response variable in the LOSS statement is optional, because the actual value of the response variable is not required for the purposes of estimating a model.

Specification of censoring and truncation affects the likelihood of the data (see the section “[Likelihood Function](#)” on page 1661) and how the empirical distribution function (EDF) is estimated (see the section “[Empirical Distribution Function Estimation Methods](#)” on page 1669).

Probability of Observability

For left-truncated data, PROC SEVERITY also enables you to provide additional information in the form of *probability of observability* by using the `PROBOBSERVED=` option. It is defined as the probability that the underlying severity event gets observed (and recorded) for the specified left-truncation threshold value. For example, if you specify a value of 0.75, then for every 75 observations recorded above a specified threshold, 25 more events have happened with a severity value less than or equal to the specified threshold. Although the exact severity value of those 25 events is not known, PROC SEVERITY can use the information about the number of those events.

In particular, for each left-truncated observation, PROC SEVERITY assumes a presence of $(1 - p)/p$ additional observations with $y_i = t_i$. These additional observations are then used for computing the likelihood (see the section “[Probability of Observability and Likelihood](#)” on page 1662) and an unconditional estimate of the empirical distribution function (see the section “[EDF Estimates and Truncation](#)” on page 1673).

Truncation and Conditional CDF Estimates

If you specify left-truncation without the probability of observability or if you specify right-truncation, then the EDF estimates that are computed by all methods except the STANDARD method are conditional on the truncation information. See the section “[EDF Estimates and Truncation](#)” on page 1673 for more information. In such cases, PROC SEVERITY uses conditional estimates of the CDF whenever they are used for computational or visual comparison with the EDF estimates.

Let $t_{\min}^l = \min_i \{t_i^l\}$ be the smallest value of the left-truncation threshold (t_i^l is the left-truncation threshold for observation i) and $t_{\max}^r = \max_i \{t_i^r\}$ be the largest value of the right-truncation threshold (t_i^r is the right-truncation threshold for observation i). If $\hat{F}(y)$ denotes the unconditional estimate of the CDF at y , then the conditional estimate $\hat{F}^c(y)$ is computed as follows:

- If you do not specify the probability of observability, then the EDF estimates are conditional on the left-truncation information. If an observation is both left-truncated and right-truncated, then

$$\hat{F}^c(y) = \frac{\hat{F}(y) - \hat{F}(t_{\min}^l)}{\hat{F}(t_{\max}^r) - \hat{F}(t_{\min}^l)}$$

If an observation is left-truncated but not right-truncated, then

$$\hat{F}^c(y) = \frac{\hat{F}(y) - \hat{F}(t_{\min}^l)}{1 - \hat{F}(t_{\min}^l)}$$

If an observation is right-truncated but not left-truncated, then

$$\hat{F}^c(y) = \frac{\hat{F}(y)}{\hat{F}(t_{\max}^r)}$$

- If you specify the probability of observability, then EDF estimates are not conditional on the left-truncation information. If an observation is not right-truncated, then the conditional estimate is the

same as the unconditional estimate. If an observation is right-truncated, then the conditional estimate is computed as

$$\hat{F}^c(y) = \frac{\hat{F}(y)}{\hat{F}(t_{\max}^r)}$$

If you specify regressors, then $\hat{F}(y)$, $\hat{F}(t_{\min}^l)$, and $\hat{F}(t_{\max}^r)$ are all computed from a mixture distribution, as described in the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1667.

Parameter Estimation Method

If you do not specify a custom objective function by specifying programming statements and the **OBJECTIVE=** option in the PROC SEVERITY statement, then PROC SEVERITY uses the maximum likelihood (ML) method to estimate the parameters of each model. A nonlinear optimization process is used to maximize the log of the likelihood function. If you specify a custom objective function, then PROC SEVERITY uses a nonlinear optimization algorithm to estimate the parameters of each model that minimize the value of your specified objective function. For more information, see the section “[Custom Objective Functions](#)” on page 1703.

Likelihood Function

Let $f_{\Theta}(x)$ and $F_{\Theta}(x)$ denote the PDF and CDF, respectively, evaluated at x for a set of parameter values Θ . Let Y denote the random response variable, and let y denote its value recorded in an observation in the input data set. Let T^l and T^r denote the random variables for the left-truncation and right-truncation threshold, respectively, and let t^l and t^r denote their values for an observation, respectively. If there is no left-truncation, then $t^l = \tau^l$, where τ^l is the smallest value in the support of the distribution; so $F(t^l) = 0$. If there is no right-truncation, then $t^r = \tau_h$, where τ_h is the largest value in the support of the distribution; so $F(t^r) = 1$. Let C^l and C^r denote the random variables for the left-censoring and right-censoring limit, respectively, and let c^l and c^r denote their values for an observation, respectively. If there is no left-censoring, then $c^l = \tau_h$, so $F(c^l) = 1$. If there is no right-censoring, then $c^r = \tau^l$, so $F(c^r) = 0$.

The set of input observations can be categorized into the following four subsets within each BY group:

- E is the set of uncensored and untruncated observations. The likelihood of an observation in E is

$$l_E = \Pr(Y = y) = f_{\Theta}(y)$$

- E_t is the set of uncensored observations that are truncated. The likelihood of an observation in E_t is

$$l_{E_t} = \Pr(Y = y | t^l < Y \leq t^r) = \frac{f_{\Theta}(y)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)}$$

- C is the set of censored observations that are not truncated. The likelihood of an observation C is

$$l_C = \Pr(c^r < Y \leq c^l) = F_{\Theta}(c^l) - F_{\Theta}(c^r)$$

- C_t is the set of censored observations that are truncated. The likelihood of an observation C_t is

$$l_{C_t} = \Pr(c^r < Y \leq c^l | t^l < Y \leq t^r) = \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)}$$

Note that $(E \cup E_t) \cap (C \cup C_t) = \emptyset$. Also, the sets E_t and C_t are empty when you do not specify truncation, and the sets C and C_t are empty when you do not specify censoring.

Given this, the likelihood of the data L is as follows:

$$L = \prod_E f_{\Theta}(y) \prod_{E_t} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)} \prod_C F_{\Theta}(c^l) - F_{\Theta}(c^r) \prod_{C_t} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)}$$

The maximum likelihood procedure used by PROC SEVERITY finds an optimal set of parameter values $\hat{\Theta}$ that maximizes $\log(L)$ subject to the boundary constraints on parameter values. For a distribution *dist*, you can specify such boundary constraints by using the *dist_LOWERBOUNDS* and *dist_UPPERBOUNDS* subroutines. See the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1679 for more information. Some aspects of the optimization process can be controlled by using the *NLOPTIONS* statement.

Probability of Observability and Likelihood

If you specify the probability of observability for the left-truncation, then PROC SEVERITY uses a modified likelihood function for each truncated observation. If the probability of observability is $p \in (0.0, 1.0]$, then for each left-truncated observation with truncation threshold t^l , there exist $(1-p)/p$ observations with a response variable value less than or equal to t^l . Each such observation has a probability of $\Pr(Y \leq t^l) = F_{\Theta}(t^l)$. The right-truncation and censoring information does not apply to these added observations. Thus, following the notation of the section “[Likelihood Function](#)” on page 1661, the likelihood of the data is as follows:

$$L = \prod_E f_{\Theta}(y) \prod_{E_t, t^l = \tau^l} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r)} \prod_{E_t, t^l > \tau^l} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r)} F_{\Theta}(t^l)^{\frac{1-p}{p}} \\ \prod_C F_{\Theta}(c^l) - F_{\Theta}(c^r) \prod_{C_t, t^l = \tau^l} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r)} \prod_{C_t, t^l > \tau^l} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r)} F_{\Theta}(t^l)^{\frac{1-p}{p}}$$

Note that the likelihood of the observations that are not left-truncated (observations in sets E and C , and observations in sets E_t and C_t for which $t^l = \tau^l$) is not affected.

If you specify a custom objective function, then PROC SEVERITY accounts for the probability of observability only while computing the empirical distribution function estimate. The parameter estimates are affected only by your custom objective function.

Estimating Covariance and Standard Errors

PROC SEVERITY computes an estimate of the covariance matrix of the parameters by using the asymptotic theory of the maximum likelihood estimators (MLE). If N denotes the number of observations used for estimating a parameter vector θ , then the theory states that as $N \rightarrow \infty$, the distribution of $\hat{\theta}$, the estimate of θ , converges to a normal distribution with mean θ and covariance \hat{C} such that $\mathbf{I}(\theta) \cdot \hat{C} \rightarrow 1$, where $\mathbf{I}(\theta) = -E[\nabla^2 \log(L(\theta))]$ is the information matrix for the likelihood of the data, $L(\theta)$. The covariance estimate is obtained by using the inverse of the information matrix.

In particular, if $\mathbf{G} = \nabla^2(-\log(L(\boldsymbol{\theta})))$ denotes the Hessian matrix of the negative of log likelihood, then the covariance estimate is computed as

$$\hat{\mathbf{C}} = \frac{N}{d} \mathbf{G}^{-1}$$

where d is a denominator that is determined by the `VARDEF=` option. If `VARDEF=N`, then $d = N$, which yields the asymptotic covariance estimate. If `VARDEF=DF`, then $d = N - k$, where k is number of parameters (the model's degrees of freedom). The `VARDEF=DF` option is the default, because it attempts to correct the potential bias introduced by the finite sample.

The standard error s_i of the parameter θ_i is computed as the square root of the i th diagonal element of the estimated covariance matrix; that is, $s_i = \sqrt{\hat{C}_{ii}}$.

If you specify a custom objective function, then the covariance matrix of the parameters is still computed by inverting the information matrix, except that the Hessian matrix \mathbf{G} is computed as $\mathbf{G} = \nabla^2 \log(U(\boldsymbol{\theta}))$, where U denotes your custom objective function that is minimized by the optimizer.

Covariance and standard error estimates might not be available if the Hessian matrix is found to be singular at the end of the optimization process. This can especially happen if the optimization process stops without converging.

Parameter Initialization

PROC SEVERITY enables you to initialize parameters of a model in different ways. There can be two kinds of parameters in a model: distribution parameters and regression parameters.

The distribution parameters can be initialized by using one of the following three methods:

INIT= option	You can use the INIT= option in the DIST statement.
INEST= data set	You can use the <code>INEST=</code> data set.
PARMINIT subroutine	You can define a dist_PARMINIT subroutine in the distribution model. See the section “ Defining a Distribution Model with the FCMP Procedure ” on page 1679 for more information.

Note that only one of the initialization methods is used. You cannot combine them. They are used in the following order:

- The method that uses the `INIT=` option takes the highest precedence. If you use the `INIT=` option to provide an initial value for at least one parameter, then other initialization methods (`INEST=` and `PARMINIT`) are not used. If you specify initial values for some but not all the parameters by using the `INIT=` option, then the uninitialized parameters are initialized to the default value of 0.001.

If you use this option and if you specify the regression effects, then the value of the first distribution parameter must be related to the initial value for the *base* value of the scale or log-transformed scale parameter. See the section “[Estimating Regression Effects](#)” on page 1664 for more information.

- The method that uses the `INEST=` data set takes the second precedence. If you specify a nonmissing value for even one distribution parameter, then the `PARMINIT` method is not used and any uninitialized parameters are initialized to the default value of 0.001.

- If none of the distribution parameters are initialized by using the INIT= option or the INEST= data set, but the distribution model defines a PARMINIT subroutine, then PROC SEVERITY invokes that subroutine with appropriate inputs to initialize the parameters. If the PARMINIT subroutine returns missing values for some parameters, then those parameters are initialized to the default value of 0.001.
- If none of the initialization methods are used, each distribution parameter is initialized to the default value of 0.001.

See the section “[Estimating Regression Effects](#)” on page 1664 for more information about regression models and initialization of regression parameters.

Estimating Regression Effects

The SEVERITY procedure enables you to estimate the effects of regressor (exogenous) variables while fitting a distribution if the distribution has a scale parameter or a log-transformed scale parameter.

Let x_j ($j = 1, \dots, k$) denote the k regressor variables. Let β_j denote the regression parameter that corresponds to the regressor x_j . If you do not specify regression effects, then the model for the response variable Y is of the form

$$Y \sim \mathcal{F}(\Theta)$$

where \mathcal{F} is the distribution of Y with parameters Θ . This model is typically referred to as the error model. The regression effects are modeled by extending the error model to the following form:

$$Y \sim \exp\left(\sum_{j=1}^k \beta_j x_j\right) \cdot \mathcal{F}(\Theta)$$

Under this model, the distribution of Y is valid and belongs to the same parametric family as \mathcal{F} if and only if \mathcal{F} has a scale parameter. Let θ denote the scale parameter and Ω denote the set of nonscale distribution parameters of \mathcal{F} . Then the model can be rewritten as

$$Y \sim \mathcal{F}(\theta, \Omega)$$

such that θ is affected by the regressors as

$$\theta = \theta_0 \cdot \exp\left(\sum_{j=1}^k \beta_j x_j\right)$$

where θ_0 is the *base* value of the scale parameter. Thus, the scale regression model consists of the following parameters: θ_0 , Ω , and β_j ($j = 1, \dots, k$).

Given this form of the model, distributions without a scale parameter cannot be considered when regression effects are to be modeled. If a distribution does not have a direct scale parameter, then PROC SEVERITY accepts it only if it has a log-transformed scale parameter — that is, if it has a parameter $p = \log(\theta)$.

Offset Variable

You can specify that an offset variable be included in the scale regression model by specifying it in the **OFFSET=** option of the **SCALEMODEL** statement. The offset variable is a regressor whose regression coefficient is known to be 1. If x_o denotes the offset variable, then the scale regression model becomes

$$\theta = \theta_0 \cdot \exp(x_o + \sum_{j=1}^k \beta_j x_j)$$

The regression coefficient of the offset variable is fixed at 1 and not estimated, so it is not reported in the ParameterEstimates ODS table. However, if you specify the **OUTEST=** data set, then the regression coefficient is added as a variable to that data set. The value of the offset variable in **OUTEST=** data set is equal to 1 for the estimates row (**_TYPE_='EST'**) and is equal to a special missing value (.F) for the standard error (**_TYPE_='STDERR'**) and covariance (**_TYPE_='COV'**) rows.

An offset variable is useful to model the scale parameter per unit of some measure of exposure. For example, in the automobile insurance context, measure of exposure can be the number of car-years insured or the total number of miles driven by a fleet of cars at a rental car company. For worker's compensation insurance, if you want to model the expected loss per enterprise, then you can use the number of employees or total employee salary as the measure of exposure. For epidemiological data, measure of exposure can be the number of people who are exposed to a certain pathogen when you are modeling the loss associated with an epidemic. In general, if e denotes the value of the exposure measure and if you specify $x_o = \log(e)$ as the offset variable, then you are modeling the effect of other regressors (x_j) on the size of the scale of the distribution *per unit of exposure*.

Another use for an offset variable is when you have a priori knowledge of the effect of some exogenous variables that cannot be included in the **SCALEMODEL** statement. You can model the combined effect of such variables as an offset variable in order to correct for the omitted variable bias.

Parameter Initialization for Regression Models

The regression parameters are initialized either by using the values that you specify or by the default method.

- If you provide initial values for the regression parameters, then you must provide valid, nonmissing initial values for θ_0 and β_j parameters for all j .

You can specify the initial value for θ_0 by using either the **INEST=** data set or the **INIT=** option in the **DIST** statement. If the distribution has a direct scale parameter (no transformation), then the initial value for the first parameter of the distribution is used as an initial value for θ_0 . If the distribution has a log-transformed scale parameter, then the initial value for the first parameter of the distribution is used as an initial value for $\log(\theta_0)$.

You can use only the **INEST=** data set to specify the initial values for β_j . The **INEST=** data set must contain nonmissing initial values for all the regressors that you specify in the **SCALEMODEL** statement. The only missing value allowed is the special missing value .R, which indicates that the regressor is linearly dependent on other regressors. If you specify .R for a regressor for one distribution in a BY group, you must specify it so for all the distributions in that BY group.

- If you do not specify valid initial values for θ_0 or β_j parameters for all j , then PROC SEVERITY initializes those parameters by using the following method:

Let a random variable Y be distributed as $\mathcal{F}(\theta, \Omega)$, where θ is the scale parameter. By definition of the scale parameter, a random variable $W = Y/\theta$ is distributed as $\mathcal{G}(\Omega)$ such that $\mathcal{G}(\Omega) = \mathcal{F}(1, \Omega)$. Given a random error term e that is generated from a distribution $\mathcal{G}(\Omega)$, a value y from the distribution of Y can be generated as

$$y = \theta \cdot e$$

Taking the logarithm of both sides and using the relationship of θ with the regressors yields:

$$\log(y) = \log(\theta_0) + \sum_{j=1}^k \beta_j x_j + \log(e)$$

PROC SEVERITY makes use of the preceding relationship to initialize parameters of a regression model with distribution *dist* as follows:

1. The following linear regression problem is solved to obtain initial estimates of β_0 and β_j :

$$\log(y) = \beta_0 + \sum_{j=1}^k \beta_j x_j$$

The estimates of $\beta_j (j = 1, \dots, k)$ in the solution of this regression problem are used to initialize the respective regression parameters of the model. The estimate of β_0 is later used to initialize the value of θ_0 .

The results of this regression are also used to detect whether any regressors are linearly dependent on the other regressors. If any such regressors are found, then a warning is written to the SAS log and the corresponding regressor is eliminated from further analysis. The estimates for linearly dependent regressors are denoted by a special missing value of .R in the OUTEST= data set and in any displayed output.

2. Let s_0 denote the initial value of the scale parameter.

If the distribution model of *dist* does not contain the *dist_PARMINIT* subroutine, then s_0 and all the nonscale distribution parameters are initialized to the default value of 0.001.

However, it is strongly recommended that each distribution's model contain the *dist_PARMINIT* subroutine. See the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1679 for more information. If that subroutine is defined, then s_0 is initialized as follows:

Each input value y_i of the response variable is transformed to its scale-normalized version w_i as

$$w_i = \frac{y_i}{\exp(\beta_0 + \sum_{j=1}^k \beta_j x_{ij})}$$

where x_{ij} denotes the value of j th regressor in the i th input observation. These w_i values are used to compute the input arguments for the *dist_PARMINIT* subroutine. The values that are computed by the subroutine for nonscale parameters are used as their respective initial values. If the distribution has an untransformed scale parameter, then s_0 is set to the value of the scale parameter that is computed by the subroutine. If the distribution has a log-transformed scale parameter P , then s_0 is computed as $s_0 = \exp(l_0)$, where l_0 is the value of P computed by the subroutine.

3. The value of θ_0 is initialized as

$$\theta_0 = s_0 \cdot \exp(\beta_0)$$

Reporting Estimates of Regression Parameters

When you request estimates to be written to the output (either ODS displayed output or in the OUTEST= data set), the estimate of the base value of the first distribution parameter is reported. If the first parameter is the log-transformed scale parameter, then the estimate of $\log(\theta_0)$ is reported; otherwise, the estimate of θ_0 is reported. The transform of the first parameter of a distribution *dist* is controlled by the *dist_SCALETRANSFORM* function that is defined for it.

CDF and PDF Estimates with Regression Effects

When regression effects are estimated, the estimate of the scale parameter depends on the values of the regressors and the estimates of the regression parameters. This dependency results in a potentially different distribution for each observation. To make estimates of the cumulative distribution function (CDF) and probability density function (PDF) comparable across distributions and comparable to the empirical distribution function (EDF), PROC SEVERITY reports the CDF and PDF estimates from a representative distribution. The *representative distribution* is a mixture of a certain number of distributions, where each distribution differs only in the value of the scale parameter. You can specify the number of distributions in the mixture and how their scale values are chosen by using the *DFMIXTURE=* option in the SCALEMODEL statement.

Let N denote the number of observations used for estimation, K denote the number of components in the mixture distribution, s_k denote the scale parameter of the k th mixture component, and d_k denote the weight associated with k th mixture component.

Let $f(y; s_k, \hat{\Omega})$ and $F(y; s_k, \hat{\Omega})$ denote the PDF and CDF, respectively, of the k th component distribution, where $\hat{\Omega}$ denotes the set of estimates of all parameters of the distribution other than the scale parameter. Then, the PDF and CDF estimates, $f^*(y)$ and $F^*(y)$, respectively, of the mixture distribution at y are computed as follows:

$$f^*(y) = \frac{1}{D} \sum_{k=1}^K d_k f(y; s_k, \hat{\Omega})$$

$$F^*(y) = \frac{1}{D} \sum_{k=1}^K d_k F(y; s_k, \hat{\Omega})$$

where D is the normalization factor ($D = \sum_{k=1}^K d_k$).

The CDF estimates reported in OUTCDF= data set, plotted in CDF plots, and used for computing the EDF-based statistics of fit are the $F^*(y)$ values. The PDF estimates plotted in PDF plots are the $f^*(y)$ values.

The scale values s_k for the K mixture components are derived from the set $\{\hat{\theta}_i\}$ ($i = 1 \dots N$) of N scale values, where $\hat{\theta}_i$ denotes the estimate of the scale parameter due to observation i . It is computed as

$$\hat{\theta}_i = \hat{\theta}_0 \cdot \exp\left(\sum_{j=1}^k \hat{\beta}_j x_{ij}\right)$$

where $\hat{\theta}_0$ is an estimate of the base value of the scale parameter, $\hat{\beta}_j$ are the estimates of regression coefficients, and x_{ij} is the value of regressor j in observation i .

Let w_i denote the weight of observation i . If you specify the WEIGHT statement, then the weight is equal to the value of the specified weight variable for the corresponding observation in the DATA= data set; otherwise, the weight is set to 1.

You can specify one of the following *method-names* in the `DFMIXTURE=` option in the SCALEMODEL statement to specify the method of choosing K and the corresponding s_k and d_k values:

FULL In this method, there are as many mixture components as the number of observations that are used for estimation. In other words, $K = N$, $s_k = \hat{\theta}_k$, and $d_k = w_k$ ($k = 1 \dots N$). This is the slowest method, because it requires $O(N)$ computations to compute the mixture CDF $F^*(y_i)$ or the mixture PDF $f^*(y_i)$ of one observation. For N observations, the computational complexity in terms of number of PDF or CDF evaluations is $O(N^2)$. Even for moderately large values of N , the time taken to compute the mixture CDF and PDF can significantly exceed the time taken to estimate the model parameters. So, it is recommended that you use this method only for small data sets.

MEAN In this method, the mixture contains only one distribution, whose scale value is the mean of the scale values that are implied by all the observations. In other words, s_1 is computed as

$$s_1 = \frac{1}{W} \sum_{i=1}^N w_i \hat{\theta}_i$$

where W is the total weight ($W = \sum_{i=1}^N w_i$).

This method is the fastest because it requires only one CDF or PDF evaluation per observation. The computational complexity is $O(N)$ for N observations.

If you do not specify the `DFMIXTURE=` option in the SCALEMODEL statement, then this is the default method.

QUANTILE In this method, a certain number of quantiles are chosen from the set of all scale values. If you specify a value of q for the `K=` option when specifying this method, then $K = q - 1$ and s_k are set to be the $(q - 1)$ q -quantiles from the set $\{\hat{\theta}_i\}$ ($i = 1 \dots N$). The weight of each of the components (d_k) is assumed to be 1 for this method.

The default value of q is 2, which implies a one-point mixture with a distribution whose scale value is equal to the median scale value.

For this method, PROC SEVERITY needs to sort the N scale values in the set $\{\hat{\theta}_i\}$, which requires $O(N \log(N))$ computations. Then, computing mixture estimate of one observation requires $(q - 1)$ CDF or PDF evaluations. Hence, the computational complexity of this method is $O(qN) + O(N \log(N))$ for computing a mixture PDF or CDF of N observations. For $q \ll N$, it is significantly faster than the FULL method.

RANDOM In this method, a uniform random sample of observations is chosen and the mixture contains the distributions that are implied by those observations. If you specify a value of r for the **K=** option when specifying this method, then the size of the sample is r . Hence, $K = r$. If l_j denotes the index of j th observation in the sample ($j = 1 \dots r$), such that $1 \leq l_j \leq N$, then the scale of k th component distribution in the mixture is $s_k = \hat{\theta}_{l_k}$ and the weight associated with it is $d_k = w_{l_k}$.

You can also specify the seed to be used for generating the random sample by using the **SEED=** option for this method. The same sample of observations is used for all models.

Computing a mixture estimate of one observation requires r CDF or PDF evaluations. Hence, the computational complexity of this method is $O(rN)$ for computing a mixture PDF or CDF of N observations. For $r \ll N$, it is significantly faster than the **FULL** method.

Empirical Distribution Function Estimation Methods

The empirical distribution function (EDF) is a nonparametric estimate of the cumulative distribution function (CDF) of the distribution. PROC SEVERITY uses EDF estimates for computing the EDF-based statistics of fit.

If you specify both right-censoring and left-censoring, then the EDF is estimated using Turnbull's method as described in the section “[EDF Estimation for Right-Censored and Left-Censored Data](#)” on page 1672. If all the observations are uncensored or there is only one type of censoring, then a choice of methods is available as described in the section “[EDF Estimation for No Censoring or Single Type of Censoring](#)” on page 1669.

Notation

Let there be a set of N observations, each containing a quintuplet of values $(y_i, t_i^l, t_i^r, c_i^r, c_i^l)$, $i = 1, \dots, N$, where y_i is the value of the response variable, t_i^l is the value of the left-truncation threshold, t_i^r is the value of the right-truncation threshold, c_i^r is the value of the right-censoring limit, and c_i^l is the value of the left-censoring limit.

If an observation is not left-truncated, then $t_i^l = \tau^l$, where τ^l is the smallest value in the support of the distribution; so $F(t_i^l) = 0$. If an observation is not right-truncated, then $t_i^r = \tau_h$, where τ_h is the largest value in the support of the distribution; so $F(t_i^r) = 1$. If an observation is not right-censored, then $c_i^r = \tau^r$; so $F(c_i^r) = 0$. If an observation is not left-censored, then $c_i^l = \tau_h$; so $F(c_i^l) = 1$.

Let w_i denote the weight associated with i th observation. If you specify the **WEIGHT** statement, then w_i is the normalized value of the weight variable; otherwise, it is set to 1. The weights are normalized such that they sum up to N .

An indicator function $I[e]$ takes a value of 1 or 0 if the expression e is true or false, respectively.

EDF Estimation for No Censoring or Single Type of Censoring

The method descriptions assume that all observations are either uncensored or right-censored; that is, each observation is of the form $(y_i, t_i^l, t_i^r, c_i^r, \tau_h)$.

If all observations are either uncensored or left-censored, then each observation is of the form $(y_i, t_i^l, t_i^r, \tau_l, c_i^l)$. It is converted to an observation $(-y_i, -t_i^r, -t_i^l, -c_i^l, \tau_h)$; that is, the signs of all the

response variable values are reversed, the new left-truncation threshold is equal to the negative of the original right-truncation threshold, the new right-truncation threshold is equal to the negative of the original left-truncation threshold, and the negative of the original left-censoring limit becomes the new right-censoring limit. With this transformation, each observation is either uncensored or right-censored. The methods described for handling uncensored or right-censored data are now applicable. After the EDF estimates are computed, the observations are transformed back to the original form and EDF estimates are adjusted such $F_n(y_i) = 1 - F_n(-y_i-)$, where $F_n(-y_i-)$ denotes the EDF estimate of the value slightly less than the transformed value $-y_i$.

A set of uncensored or right-censored observations can be converted to a set of observations of the form $(y_i, t_i^l, t_i^r, \delta_i)$, where δ_i is the indicator of right-censoring. $\delta_i = 0$ indicates a right-censored observation, in which case y_i is assumed to record the right-censoring limit c_i^r . $\delta_i = 1$ indicates an uncensored observation, and y_i records the exact observed value. In other words, $\delta_i = I[Y \leq C^r]$ and $y_i = \min(y_i, c_i^r)$.

Given this notation, the EDF is estimated as

$$F_n(y) = \begin{cases} 0 & \text{if } y < y^{(1)} \\ \hat{F}_n(y^{(k)}) & \text{if } y^{(k)} \leq y < y^{(k+1)}, k = 1, \dots, N-1 \\ \hat{F}_n(y^{(N)}) & \text{if } y^{(N)} \leq y \end{cases}$$

where $y^{(k)}$ denotes the k th order statistic of the set $\{y_i\}$ and $\hat{F}_n(y^{(k)})$ is the estimate computed at that value. The definition of \hat{F}_n depends on the estimation method. You can specify a particular method or let PROC SEVERITY choose an appropriate method by using the **EMPIRICALCDF=** option in the PROC SEVERITY statement. Each method computes \hat{F}_n as follows:

STANDARD

This method is the standard way of computing EDF. The EDF estimate at observation i is computed as follows:

$$\hat{F}_n(y_i) = \frac{1}{N} \sum_{j=1}^N w_j \cdot I[y_j \leq y_i]$$

If you do not specify any censoring or truncation information, this is the default method chosen. If you specify this method, then PROC SEVERITY ignores any censoring and truncation information that you specify in the LOSS statement.

The standard error of $\hat{F}_n(y_i)$ is computed by using the normal approximation method:

$$\hat{\sigma}_n(y_i) = \sqrt{\hat{F}_n(y_i)(1 - \hat{F}_n(y_i))/N}$$

KAPLANMEIER

The Kaplan-Meier (KM) estimator, also known as the product-limit estimator, was first introduced by Kaplan and Meier (1958) for censored data. Lynden-Bell (1971) derived a similar estimator for left-truncated data. PROC SEVERITY uses the definition that combines both censoring and truncation information (Klein and Moeschberger 1997; Lai and Ying 1991).

The EDF estimate at observation i is computed as

$$\hat{F}_n(y_i) = 1 - \prod_{\tau \leq y_i} \left(1 - \frac{n(\tau)}{R_n(\tau)}\right)$$

where $n(\tau)$ and $R_n(\tau)$ are defined as follows:

- $n(\tau) = \sum_{k=1}^N w_k \cdot I[y_k = \tau \text{ and } \tau \leq t_k^r \text{ and } \delta_k = 1]$, which is the number of uncensored observations ($\delta_k = 1$) for which the response variable value is equal to τ and τ is observable according to the right-truncation threshold of that observation ($\tau \leq t_k^r$).
- $R_n(\tau) = \sum_{k=1}^N w_k \cdot I[y_k \geq \tau > t_k^l]$, which is the size (cardinality) of the risk set at τ . The term *risk set* has its origins in survival analysis; it contains the events that are at risk of failure at a given time, τ . In other words, it contains the events that have survived up to time τ and might fail at or after τ . For PROC SEVERITY, *time* is equivalent to the magnitude of the event and *failure* is equivalent to an uncensored and observable event, where observable means it satisfies the truncation thresholds.

If you do not explicitly specify a method of computing EDF, then this is the default method used if you specify either right-censoring or left-censoring, but not both. This is also the default method when you specify truncation without any censoring.

The standard error of $\hat{F}_n(y_i)$ is computed by using Greenwood's formula (Greenwood 1926):

$$\hat{\sigma}_n(y_i) = \sqrt{(1 - \hat{F}_n(y_i))^2 \cdot \sum_{\tau \leq y_i} \left(\frac{n(\tau)}{R_n(\tau)(R_n(\tau) - n(\tau))} \right)}$$

MODIFIEDKM

The product-limit estimator used by the KAPLANMEIER method does not work well if the risk set size becomes very small. For right-censored data, the size can become small towards the right tail. For left-truncated data, the size can become small at the left tail and can remain so for the entire range of data. This was demonstrated by Lai and Ying (1991). They proposed a modification to the estimator that ignores the effects due to small risk set sizes.

The EDF estimate at observation i is computed as

$$\hat{F}_n(y_i) = 1 - \prod_{\tau \leq y_i} \left(1 - \frac{n(\tau)}{R_n(\tau)} \cdot I[R_n(\tau) \geq cN^\alpha] \right)$$

where the definitions of $n(\tau)$ and $R_n(\tau)$ are identical to those used for the KAPLANMEIER method described previously.

You can specify the values of c and α by using the **C=** and **ALPHA=** options. If you do not specify a value for c , the default value used is $c = 1$. If you do not specify a value for α , the default value used is $\alpha = 0.5$.

As an alternative, you can also specify an absolute lower bound, say L , on the risk set size by using the **RSLB=** option, in which case $I[R_n(\tau) \geq cN^\alpha]$ is replaced by $I[R_n(\tau) \geq L]$ in the definition.

The standard error of $\hat{F}_n(y_i)$ is computed by using Greenwood's formula (Greenwood 1926):

$$\hat{\sigma}_n(y_i) = \sqrt{(1 - \hat{F}_n(y_i))^2 \cdot \sum_{\tau \leq y_i} \left(\frac{n(\tau)}{R_n(\tau)(R_n(\tau) - n(\tau))} \cdot I[R_n(\tau) \geq cN^\alpha] \right)}$$

EDF Estimation for Right-Censored and Left-Censored Data

If the response variable is subject to both left-censoring and right-censoring effects, then the SEVERITY procedure uses a method proposed by Turnbull (1976) to compute the nonparametric estimates of the cumulative distribution function. The original Turnbull's method is modified using the suggestions made by Frydman (1994) when truncation effects are present.

Let the input data consist of N observations in the form of quintuplets of values $(y_i, t_i^l, t_i^r, c_i^r, c_i^l)$, $i = 1, \dots, N$ with notation described in the section “Notation” on page 1669. For each observation, let $A_i = (c_i^r, c_i^l]$ be the censoring interval; that is, the response variable value is known to lie in the interval A_i , but the exact value is not known. If an observation is uncensored, then $A_i = (y_i - \epsilon, y_i]$ for any arbitrarily small value of $\epsilon > 0$. If an observation is censored, then the value y_i is ignored. Similarly, for each observation, let $B_i = (t_i^l, t_i^r]$ be the truncation interval; that is, the observation is drawn from a truncated (conditional) distribution $F(y, B_i) = P(Y \leq y | Y \in B_i)$.

Two sets, L and R , are formed using A_i and B_i as follows:

$$\begin{aligned} L &= \{c_i^r, 1 \leq i \leq N\} \cup \{t_i^r, 1 \leq i \leq N\} \\ R &= \{c_i^l, 1 \leq i \leq N\} \cup \{t_i^l, 1 \leq i \leq N\} \end{aligned}$$

The sets L and R represent the left endpoints and right endpoints, respectively. A set of disjoint intervals $C_j = [q_j, p_j]$, $1 \leq j \leq M$ is formed such that $q_j \in L$ and $p_j \in R$ and $q_j \leq p_j$ and $p_j < q_{j+1}$. The value of M is dependent on the nature of censoring and truncation intervals in the input data. Turnbull (1976) showed that the maximum likelihood estimate (MLE) of the EDF can increase only inside intervals C_j . In other words, the MLE estimate is constant in the interval (p_j, q_{j+1}) . The likelihood is independent of the behavior of F_n inside any of the intervals C_j . Let s_j denote the increase in F_n inside an interval C_j . Then, the EDF estimate is as follows:

$$F_n(y) = \begin{cases} 0 & \text{if } y < q_1 \\ \sum_{k=1}^j s_k & \text{if } p_j < y < q_{j+1}, 1 \leq j \leq M-1 \\ 1 & \text{if } y > p_M \end{cases}$$

PROC SEVERITY reports the estimates $F_n(p_j+) = F_n(q_{j+1}-) = \sum_{k=1}^j s_k$ at points p_j and q_{j+1} and reports $F_n(q_1-) = 0$ at point q_1 , where $F_n(x+)$ denotes the limiting estimate at a point that is infinitesimally larger than x when approaching x from values larger than x and where $F_n(x-)$ denotes the limiting estimate at a point that is infinitesimally smaller than x when approaching x from values smaller than x .

PROC SEVERITY uses the expectation-maximization (EM) algorithm proposed by Turnbull (1976), who referred to the algorithm as the self-consistency algorithm. By default, the algorithm runs until one of the following criteria is met:

- Relative-error criterion: The maximum relative error between the two consecutive estimates of s_j falls below a threshold ϵ . If l indicates an index of the current iteration, then this can be formally stated as

$$\arg \max_{1 \leq j \leq M} \left\{ \frac{|s_j^l - s_j^{l-1}|}{s_j^{l-1}} \right\} \leq \epsilon$$

You can control the value of ϵ by specifying the `EPS=` suboption of the `EDF=TURNBULL` option in the PROC SEVERITY statement. The default value is 1.0E-8.

- Maximum-iteration criterion: The number of iterations exceeds an upper limit that you specify for the **MAXITER=** suboption of the EDF=TURNBULL option in the PROC SEVERITY statement. The default number of maximum iterations is 500.

The self-consistent estimates obtained in this manner might not be maximum likelihood estimates. Gentleman and Geyer (1994) suggested the use of the Kuhn-Tucker conditions for the maximum likelihood problem to ensure that the estimates are MLE. If you specify the **ENSUREMLE** suboption of the EDF=TURNBULL option in the PROC SEVERITY statement, then PROC SEVERITY computes the Kuhn-Tucker conditions at the end of each iteration to determine whether the estimates $\{s_j\}$ are MLE. If you do not specify any truncation effects, then the Kuhn-Tucker conditions derived by Gentleman and Geyer (1994) are used. If you specify any truncation effects, then PROC SEVERITY uses modified Kuhn-Tucker conditions that account for the truncation effects. An integral part of checking the conditions is to determine whether an estimate s_j is zero or whether an estimate of the Lagrange multiplier or the reduced gradient associated with the estimate s_j is zero. PROC SEVERITY declares these values to be zero if they are less than or equal to a threshold δ . You can control the value of δ by specifying the **ZEROPROB=** suboption of the EDF=TURNBULL option in the PROC SEVERITY statement. The default value is $1.0E-8$. The algorithm continues until the Kuhn-Tucker conditions are satisfied or the number of iterations exceeds the upper limit. The relative-error criterion stated previously is not used when you specify the **ENSUREMLE** option.

The standard errors for Turnbull's EDF estimates are computed by using the asymptotic theory of the maximum likelihood estimators (MLE), even though the final estimates might not be MLE. Turnbull's estimator essentially attempts to maximize the likelihood L , which depends on the parameters s_j ($j = 1 \dots M$). Let $\mathbf{s} = \{s_j\}$ denote the set of these parameters. If $\mathbf{G}(\mathbf{s}) = \nabla^2(-\log(L(\mathbf{s})))$ denotes the Hessian matrix of the negative of log likelihood, then the variance-covariance matrix of \mathbf{s} is estimated as $\hat{\mathbf{C}}(\mathbf{s}) = \mathbf{G}^{-1}(\mathbf{s})$. Given this matrix, the standard error of $F_n(y)$ is computed as

$$\sigma_n(y) = \sqrt{\sum_{k=1}^j \left(\hat{C}_{kk} + 2 \cdot \sum_{l=1}^{k-1} \hat{C}_{kl} \right)}, \text{ if } p_j < y < q_{j+1}, 1 \leq j \leq M-1$$

The standard error is undefined outside of these intervals.

EDF Estimates and Truncation

If you specify truncation, then the estimate $\hat{F}_n(y)$ that is computed by any method other than the STANDARD method is a *conditional* estimate. In other words, $\hat{F}_n(y) = \Pr(Y \leq y | \tau_G < Y \leq \tau_H)$, where G and H denote the (unknown) distribution functions of the left-truncation threshold variable T^l and the right-truncation threshold variable T^r , respectively, τ_G denotes the smallest left-truncation threshold with a nonzero cumulative probability, and τ_H denotes the largest right-truncation threshold with a nonzero cumulative probability. Formally, $\tau_G = \inf\{s : G(s) > 0\}$ and $\tau_H = \sup\{s : H(s) > 0\}$. For computational purposes, PROC SEVERITY estimates τ_G and τ_H by t_{\min}^l and t_{\max}^r , respectively, defined as

$$t_{\min}^l = \min\{t_k^l : 1 \leq k \leq N\}$$

$$t_{\max}^r = \max\{t_k^r : 1 \leq k \leq N\}$$

These estimates are used to compute conditional estimates of the CDF as described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1660.

If you specify left-truncation *with* the probability of observability p , then PROC SEVERITY uses the additional information provided by p to compute an estimate of the EDF that is not conditional on the

left-truncation information. In particular, for each left-truncated observation i with response variable value y_i and truncation threshold t_i^l , an observation j is added with *weight* $w_j = (1 - p)/p$ and $y_j = t_i^l$. Each added observation is assumed to be uncensored and untruncated. Then, your specified EDF method is used by assuming no left-truncation. The EDF estimate that is obtained using this method is not conditional on the left-truncation information. For the KAPLANMEIER and MODIFIEDKM methods with uncensored or right-censored data, definitions of $n(\tau)$ and $R_n(\tau)$ are modified to account for the added observations. If N^a denotes the total number of observations including the added observations, then $n(\tau)$ is defined as $n(\tau) = \sum_{k=1}^{N^a} w_k I[y_k = \tau \text{ and } \tau \leq t_k^r \text{ and } \delta_k = 1]$, and $R_n(\tau)$ is defined as $R_n(\tau) = \sum_{k=1}^{N^a} w_k I[y_k \geq \tau]$. In the definition of $R_n(\tau)$, the left-truncation information is not used, because it was used along with p to add the observations.

If the original data are a combination of left- and right-censored data, then Turnbull's method is applied to the appended set that contains no left-truncated observations.

Supplying EDF Estimates to Functions and Subroutines

The parameter initialization subroutines in distribution models and some predefined utility functions require EDF estimates. See the sections “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1679 and “[Predefined Utility Functions](#)” on page 1691 for more information.

PROC SEVERITY supplies the EDF estimates to these subroutines and functions by using two arrays, x and F , the dimension of each array, and a type of the EDF estimates. The type identifies how the EDF estimates are computed and stored. They are as follows:

- Type 1 specifies that EDF estimates are computed using the STANDARD method; that is, the data used for estimation are neither censored nor truncated.
- Type 2 specifies that EDF estimates are computed using either the KAPLANMEIER or the MODIFIEDKM method; that is, the data used for estimation are subject to truncation and one type of censoring (left or right, but not both).
- Type 3 specifies that EDF estimates are computed using the TURNBULL method; that is, the data used for estimation are subject to both left- and right-censoring. The data might or might not be truncated.

For Types 1 and 2, the EDF estimates are stored in arrays x and F of dimension N such that the following holds:

$$F_n(y) = \begin{cases} 0 & \text{if } y < x[1] \\ F[k] & \text{if } x[k] \leq y < x[k+1], k = 1, \dots, N-1 \\ F[N] & \text{if } x[N] \leq y \end{cases}$$

where $[k]$ denotes k th element of the array ($[1]$ denotes the first element of the array).

For Type 3, the EDF estimates are stored in arrays x and F of dimension N such that the following holds:

$$F_n(y) = \begin{cases} 0 & \text{if } y < x[1] \\ \text{undefined} & \text{if } x[2k-1] \leq y < x[2k], k = 1, \dots, (N-1)/2 \\ F[2k] = F[2k+1] & \text{if } x[2k] \leq y < x[2k+1], k = 1, \dots, (N-1)/2 \\ F[N] & \text{if } x[N] \leq y \end{cases}$$

Although the behavior of EDF is theoretically undefined for the interval $[x[2k-1], x[2k])$, for computational purposes, all predefined functions and subroutines assume that the EDF increases linearly from $F[2k-1]$

to $F[2k]$ in that interval if $x[2k - 1] < x[2k]$. If $x[2k - 1] = x[2k]$, which can happen when the EDF is estimated from a combination of uncensored and interval-censored data, the predefined functions and subroutines assume that $F_n(x[2k - 1]) = F_n(x[2k]) = F[2k]$.

Statistics of Fit

PROC SEVERITY computes and reports various statistics of fit to indicate how well the estimated model fits the data. The statistics belong to two categories: likelihood-based statistics and EDF-based statistics. Statistics Neg2LogLike, AIC, AICC, and BIC are likelihood-based statistics, and statistics KS, AD, and CvM are EDF-based statistics. The following subsections provide definitions of each.

Likelihood-Based Statistics

Let $y_i, i = 1, \dots, N$ denote the response variable values. Let L be the likelihood as defined in the section “Likelihood Function” on page 1661. Let p denote the number of model parameters estimated. Note that $p = p_d + (k - k_r)$, where p_d is the number of distribution parameters, k is the number of regressors, if any, that you specify in the SCALEMODEL statement, and k_r is the number of regressors found to be linearly dependent (redundant) on other regressors. Given this notation, the likelihood-based statistics are defined as follows:

Neg2LogLike The log likelihood is reported as

$$\text{Neg2LogLike} = -2 \log(L)$$

The multiplying factor -2 makes it easy to compare it to the other likelihood-based statistics. A model with a smaller value of Neg2LogLike is deemed better.

AIC The Akaike’s information criterion (AIC) is defined as

$$\text{AIC} = -2 \log(L) + 2p$$

A model with a smaller value of AIC is deemed better.

AICC The corrected Akaike’s information criterion (AICC) is defined as

$$\text{AICC} = -2 \log(L) + \frac{2Np}{N - p - 1}$$

A model with a smaller value of AICC is deemed better. It corrects the finite-sample bias that AIC has when N is small compared to p . AICC is related to AIC as

$$\text{AICC} = \text{AIC} + \frac{2p(p + 1)}{N - p - 1}$$

As N becomes large compared to p , AICC converges to AIC. AICC is usually recommended over AIC as a model selection criterion.

BIC The Schwarz Bayesian information criterion (BIC) is defined as

$$\text{BIC} = -2 \log(L) + p \log(N)$$

A model with a smaller value of BIC is deemed better.

EDF-Based Statistics

This class of statistics is based on the difference between the estimate of the cumulative distribution function (CDF) and the estimate of the empirical distribution function (EDF). Let $y_i, i = 1, \dots, N$ denote the sample of N values of the response variable. Let $r_i = \sum_{j=1}^N I[y_j \leq y_i]$ denote the number of observations with a value less than or equal to y_i , where I is an indicator function. Let $F_n(y_i)$ denote the EDF estimate that is computed by using the method that you specify in the **EMPIRICALCDF=** option. Let $Z_i = \hat{F}(y_i)$ denote the estimate of the CDF. Let $F_n(Z_i)$ denote the EDF estimate of Z_i values that are computed using the same method that is used to compute the EDF of y_i values. Using the probability integral transformation, if $F(y)$ is the true distribution of the random variable Y , then the random variable $Z = F(y)$ is uniformly distributed between 0 and 1 (D'Agostino and Stephens 1986, Ch. 4). Thus, comparing $F_n(y_i)$ with $\hat{F}(y_i)$ is equivalent to comparing $F_n(Z_i)$ with $\hat{F}(Z_i) = Z_i$ (uniform distribution).

Note the following two points regarding which CDF estimates are used for computing the test statistics:

- If you specify regressor variables, then the CDF estimates Z_i that are used for computing the EDF test statistics are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1667 for more information.
- If the EDF estimates are conditional because of the truncation information, then each unconditional estimate Z_i is converted to a conditional estimate using the method described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1660.

In the following, it is assumed that Z_i denotes an appropriate estimate of the CDF if you specify any truncation or regression effects. Given this, the EDF-based statistics of fit are defined as follows:

KS The Kolmogorov-Smirnov (KS) statistic computes the largest vertical distance between the CDF and the EDF. It is formally defined as follows:

$$KS = \sup_y |F_n(y) - F(y)|$$

If the STANDARD method is used to compute the EDF, then the following formula is used:

$$\begin{aligned} D^+ &= \max_i \left(\frac{r_i}{N} - Z_i \right) \\ D^- &= \max_i \left(Z_i - \frac{r_{i-1}}{N} \right) \\ KS &= \sqrt{N} \max(D^+, D^-) + \frac{0.19}{\sqrt{N}} \end{aligned}$$

Note that r_0 is assumed to be 0.

If the method used to compute the EDF is any method other than the STANDARD method, then the following formula is used:

$$\begin{aligned} D^+ &= \max_i (F_n(Z_i) - Z_i), \text{ if } F_n(Z_i) \geq Z_i \\ D^- &= \max_i (Z_i - F_n(Z_i)), \text{ if } F_n(Z_i) < Z_i \\ KS &= \sqrt{N} \max(D^+, D^-) + \frac{0.19}{\sqrt{N}} \end{aligned}$$

AD The Anderson-Darling (AD) statistic is a quadratic EDF statistic that is proportional to the expected value of the weighted squared difference between the EDF and CDF. It is formally defined as follows:

$$AD = N \int_{-\infty}^{\infty} \frac{(F_n(y) - F(y))^2}{F(y)(1 - F(y))} dF(y)$$

If the STANDARD method is used to compute the EDF, then the following formula is used:

$$AD = -N - \frac{1}{N} \sum_{i=1}^N [(2r_i - 1) \log(Z_i) + (2N + 1 - 2r_i) \log(1 - Z_i)]$$

If the method used to compute the EDF is any method other than the STANDARD method, then the statistic can be computed by using the following two pieces of information:

- If the EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM methods, then EDF is a step function such that the estimate $F_n(z)$ is a constant equal to $F_n(Z_{i-1})$ in interval $[Z_{i-1}, Z_i]$. If the EDF estimates are computed using the TURNBULL method, then there are two types of intervals: one in which the EDF curve is constant and the other in which the EDF curve is theoretically undefined. For computational purposes, it is assumed that the EDF curve is linear for the latter type of the interval. For each method, the EDF estimate $F_n(y)$ at y can be written as

$$F_n(z) = F_n(Z_{i-1}) + S_i(z - Z_{i-1}), \text{ for } z \in [Z_{i-1}, Z_i]$$

where S_i is the slope of the line defined as

$$S_i = \frac{F_n(Z_i) - F_n(Z_{i-1})}{Z_i - Z_{i-1}}$$

For the KAPLANMEIER or MODIFIEDKM method, $S_i = 0$ in each interval.

- Using the probability integral transform $z = F(y)$, the formula simplifies to

$$AD = N \int_{-\infty}^{\infty} \frac{(F_n(z) - z)^2}{z(1 - z)} dz$$

The computation formula can then be derived from the following approximation:

$$\begin{aligned} AD &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(F_n(z) - z)^2}{z(1 - z)} dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(F_n(Z_{i-1}) + S_i(z - Z_{i-1}) - z)^2}{z(1 - z)} dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(P_i - Q_i z)^2}{z(1 - z)} dz \end{aligned}$$

where $P_i = F_n(Z_{i-1}) - S_i Z_{i-1}$, $Q_i = 1 - S_i$, and K is the number of points at which the EDF estimate are computed. For the TURNBULL method, $K = 2k$ for some k .

Assuming $Z_0 = 0$, $Z_{K+1} = 1$, $F_n(0) = 0$, and $F_n(Z_K) = 1$ yields the following computation formula:

$$\begin{aligned} \text{AD} = & -N(Z_1 + \log(1 - Z_1) + \log(Z_K) + (1 - Z_K)) \\ & + N \sum_{i=2}^K [P_i^2 A_i - (Q_i - P_i)^2 B_i - Q_i^2 C_i] \end{aligned}$$

where $A_i = \log(Z_i) - \log(Z_{i-1})$, $B_i = \log(1 - Z_i) - \log(1 - Z_{i-1})$, and $C_i = Z_i - Z_{i-1}$.

If EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM method, then $P_i = F_n(Z_{i-1})$ and $Q_i = 1$, which simplifies the formula as

$$\begin{aligned} \text{AD} = & -N(1 + \log(1 - Z_1) + \log(Z_K)) \\ & + N \sum_{i=2}^K [F_n(Z_{i-1})^2 A_i - (1 - F_n(Z_{i-1}))^2 B_i] \end{aligned}$$

CvM The Cramér-von Mises (CvM) statistic is a quadratic EDF statistic that is proportional to the expected value of the squared difference between the EDF and CDF. It is formally defined as follows:

$$\text{CvM} = N \int_{-\infty}^{\infty} (F_n(y) - F(y))^2 dF(y)$$

If the STANDARD method is used to compute the EDF, then the following formula is used:

$$\text{CvM} = \frac{1}{12N} + \sum_{i=1}^N \left(Z_i - \frac{(2r_i - 1)}{2N} \right)^2$$

If the method used to compute the EDF is any method other than the STANDARD method, then the statistic can be computed by using the following two pieces of information:

- As described previously for the AD statistic, the EDF estimates are assumed to be piecewise linear such that the estimate $F_n(y)$ at y is

$$F_n(z) = F_n(Z_{i-1}) + S_i(z - Z_{i-1}), \text{ for } z \in [Z_{i-1}, Z_i]$$

where S_i is the slope of the line defined as

$$S_i = \frac{F_n(Z_i) - F_n(Z_{i-1})}{Z_i - Z_{i-1}}$$

For the KAPLANMEIER or MODIFIEDKM method, $S_i = 0$ in each interval.

- Using the probability integral transform $z = F(y)$, the formula simplifies to:

$$\text{CvM} = N \int_{-\infty}^{\infty} (F_n(z) - z)^2 dz$$

The computation formula can then be derived from the following approximation:

$$\begin{aligned}\text{CvM} &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} (F_n(z) - z)^2 dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} (F_n(Z_{i-1}) + S_i(z - Z_{i-1}) - z)^2 dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} (P_i - Q_i z)^2 dz\end{aligned}$$

where $P_i = F_n(Z_{i-1}) - S_i Z_{i-1}$, $Q_i = 1 - S_i$, and K is the number of points at which the EDF estimate are computed. For the TURNBULL method, $K = 2k$ for some k .

Assuming $Z_0 = 0$, $Z_{K+1} = 1$, and $F_n(0) = 0$ yields the following computation formula:

$$\text{CvM} = N \frac{Z_1^3}{3} + N \sum_{i=2}^{K+1} \left[P_i^2 A_i - P_i Q_i B_i - \frac{Q_i^2}{3} C_i \right]$$

where $A_i = Z_i - Z_{i-1}$, $B_i = Z_i^2 - Z_{i-1}^2$, and $C_i = Z_i^3 - Z_{i-1}^3$.

If EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM method, then $P_i = F_n(Z_{i-1})$ and $Q_i = 1$, which simplifies the formula as

$$\text{CvM} = \frac{N}{3} + N \sum_{i=2}^{K+1} [F_n(Z_{i-1})^2 (Z_i - Z_{i-1}) - F_n(Z_{i-1}) (Z_i^2 - Z_{i-1}^2)]$$

which is similar to the formula proposed by Koziol and Green (1976).

Defining a Distribution Model with the FCMP Procedure

A severity *distribution model* consists of a set of functions and subroutines that are defined using the FCMP procedure. The FCMP procedure is part of Base SAS software. Each function or subroutine must be named as `<distribution-name>_<keyword>`, where *distribution-name* is the identifying short name of the distribution and *keyword* identifies one of the functions or subroutines. The total length of the name should not exceed 32. Each function or subroutine must have a specific signature, which consists of the number of arguments, sequence and types of arguments, and return value type. The summary of all the recognized function and subroutine names and their expected behavior is given in [Table 23.4](#).

Consider following points when you define a distribution model:

- When you define a function or subroutine requiring parameter arguments, the names and order of those arguments must be the same. Arguments other than the parameter arguments can have any name, but they must satisfy the requirements on their type and order.
- When the SEVERITY procedure invokes any function or subroutine, it provides the necessary input values according to the specified signature, and expects the function or subroutine to prepare the output and return it according to the specification of the return values in the signature.

- You can typically use most of the SAS programming statements and SAS functions that you can use in a DATA step for defining the FCMP functions and subroutines. However, there are a few differences in the capabilities of the DATA step and the FCMP procedure. Refer to the documentation of the FCMP procedure to learn more.
- You must specify either the PDF or the LOGPDF function. Similarly, you must specify either the CDF or the LOGCDF function. All other functions are optional, except when necessary for correct definition of the distribution. It is strongly recommended that you define the PARMINIT subroutine to provide a good set of initial values for the parameters. The information provided by PROC SEVERITY to the PARMINIT subroutine enables you to use popular initialization approaches based on the method of moments and the method of percentile matching, but you can implement any algorithm to initialize the parameters by using the values of the response variable and the estimate of its empirical distribution function.
- The LOWERBOUNDS subroutines should be defined if the lower bound on at least one distribution parameter is different from the default lower bound of 0. If you define a LOWERBOUNDS subroutine but do not set a lower bound for some parameter inside the subroutine, then that parameter is assumed to have no lower bound (or a lower bound of $-\infty$). Hence, it is recommended that you explicitly return the lower bound for each parameter when you define the LOWERBOUNDS subroutine.
- The UPPERBOUNDS subroutines should be defined if the upper bound on at least one distribution parameter is different from the default upper bound of ∞ . If you define an UPPERBOUNDS subroutine but do not set an upper bound for some parameter inside the subroutine, then that parameter is assumed to have no upper bound (or a upper bound of ∞). Hence, it is recommended that you explicitly return the upper bound for each parameter when you define the UPPERBOUNDS subroutine.
- If you want to use the distribution in a model with regression effects, then make sure that the first parameter of the distribution is the scale parameter itself or a log-transformed scale parameter. If the first parameter is a log-transformed scale parameter, then you must define the SCALETRANSFORM function.
- In general, it is not necessary to define the gradient and Hessian functions, because PROC SEVERITY uses an internal system to evaluate the required derivatives. The internal system typically computes the derivatives analytically. But it might not be able to do so if your function definitions use other functions that it cannot differentiate analytically. In such cases, derivatives are approximated using a finite difference method and a note is written to the SAS log to indicate the components that are differentiated using such approximations. PROC SEVERITY does reasonably well with these finite difference approximations. But, if you know of a way to compute the derivatives of such components analytically, then you should define the gradient and Hessian functions.

In order to use your distribution with PROC SEVERITY, you need to record the FCMP library that contains the functions and subroutines for your distribution and other FCMP libraries that contain FCMP functions or subroutines used within your distribution's functions and subroutines. Specify all those libraries in the CMPLIB= system option by using the OPTIONS global statement. For more information about the OPTIONS statement, see the *SAS Statements: Reference*. For more information about the CMPLIB= system option, see the *SAS System Options: Reference*.

Each predefined distribution mentioned in the section “[Predefined Distributions](#)” on page 1649 has a distribution model associated with it. The functions and subroutines of all those models are available in the Sashelp.Svrtldist library. The order of the parameters in the signatures of the functions and subroutines is

the same as listed in Table 23.2. You do not need to use the CMPLIB= option in order to use the predefined distributions with PROC SEVERITY. However, if you need to use the functions or subroutines of the predefined distributions in SAS statements other than the PROC SEVERITY step (such as in a DATA step), then specify the Sashelp.Svrtdist library in the CMPLIB= system option by using the OPTIONS global statement prior to using them.

Table 23.4 shows functions and subroutines that define a distribution model, and subsections after the table provide more detail. The functions are listed in alphabetical order of the keyword suffix.

Table 23.4 List of Functions and Subroutines That Define a Distribution Model

Name	Type	Required	Expected to Return
<i>dist_CDF</i>	Function	YES ¹	Cumulative distribution function value
<i>dist_CDFGRADIENT</i>	Subroutine	NO	Gradient of the CDF
<i>dist_CDFHESSIAN</i>	Subroutine	NO	Hessian of the CDF
<i>dist_CONSTANTPARM</i>	Subroutine	NO	Constant parameters
<i>dist_DESCRIPTION</i>	Function	NO	Description of the distribution
<i>dist_LOGCDF</i>	Function	YES ¹	Log of cumulative distribution function value
<i>dist_LOGCDFGRADIENT</i>	Subroutine	NO	Gradient of the LOGCDF
<i>dist_LOGCDFHESSIAN</i>	Subroutine	NO	Hessian of the LOGCDF
<i>dist_LOGPDF</i>	Function	YES ²	Log of probability density function value
<i>dist_LOGPDFGRADIENT</i>	Subroutine	NO	Gradient of the LOGPDF
<i>dist_LOGPDFHESSIAN</i>	Subroutine	NO	Hessian of the LOGPDF
<i>dist_LOGSDF</i>	Function	NO	Log of survival function value
<i>dist_LOGSDFGRADIENT</i>	Subroutine	NO	Gradient of the LOGSDF
<i>dist_LOGSDFHESSIAN</i>	Subroutine	NO	Hessian of the LOGSDF
<i>dist_LOWERBOUNDS</i>	Subroutine	NO	Lower bounds on parameters
<i>dist_PARMINIT</i>	Subroutine	NO	Initial values for parameters
<i>dist_PDF</i>	Function	YES ²	Probability density function value
<i>dist_PDFGRADIENT</i>	Subroutine	NO	Gradient of the PDF
<i>dist_PDFHESSIAN</i>	Subroutine	NO	Hessian of the PDF
<i>dist_QUANTILE</i>	Function	NO	Quantile for a given CDF value
<i>dist_SCALETRANSFORM</i>	Function	NO	Type of relationship between the first distribution parameter and the scale parameter
<i>dist_SDF</i>	Function	NO	Survival function value
<i>dist_SDFGRADIENT</i>	Subroutine	NO	Gradient of the SDF
<i>dist_SDFHESSIAN</i>	Subroutine	NO	Hessian of the SDF
<i>dist_UPPERBOUNDS</i>	Subroutine	NO	Upper bounds on parameters

Notes:

1. Either the *dist_CDF* or the *dist_LOGCDF* function must be defined.
2. Either the *dist_PDF* or the *dist_LOGPDF* function must be defined.

The signature syntax and semantics of each function or subroutine are as follows:

dist_CDF

defines a function that returns the value of the cumulative distribution function (CDF) of the distribution at the specified values of the random variable and distribution parameters.

- *Type*: Function
- *Required*: YES
- *Number of arguments*: $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments*:

x Numeric value of the random variable at which the CDF value should be evaluated

p_1 Numeric value of the first parameter

p_2 Numeric value of the second parameter

.....

p_m Numeric value of the m th parameter

- *Return value*: Numeric value that contains the CDF value $F(x; p_1, p_2, \dots, p_m)$

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

$$F(x; p_1, p_2, \dots, p_m) = F\left(\frac{x}{p_1}; 1, p_2, \dots, p_m\right)$$

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

$$F(x; p_1, p_2, \dots, p_m) = F\left(\frac{x}{\exp(p_1)}; 0, p_2, \dots, p_m\right)$$

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_CDF(x, P1, P2);
  /* Code to compute CDF by using x, P1, and P2 */

  F = <computed CDF>;
  return (F);
endsub;
```

dist_CONSTANTPARM

defines a subroutine that specifies constant parameters. A parameter is *constant* if it is required for defining a distribution but is not subject to optimization in PROC SEVERITY. Constant parameters are required to be part of the model in order to compute the PDF or the CDF of the distribution. Typically, values of these parameters are known a priori or estimated using some means other than the maximum likelihood method used by PROC SEVERITY. You can estimate them inside the *dist_PARMINIT* subroutine. Once initialized, the parameters remain constant in the context of PROC SEVERITY; that is, they retain their initial value. PROC SEVERITY estimates only the nonconstant parameters.

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: k , where k is the number of constant parameters
- *Sequence and type of arguments*:

constant parameter 1 Name of the first constant parameter

.....

constant parameter k Name of the k th constant parameter

- *Return value*: None

Here is a sample structure of the subroutine for a distribution named 'FOO' that has P3 and P5 as its constant parameters, assuming that distribution has at least three parameters:

```
subroutine FOO_CONSTANTPARM(p5, p3);
endsub;
```

The following points should be noted while specifying the constant parameters:

- At least one distribution parameter must be free to be optimized; that is, if a distribution has total m parameters, then k must be strictly less than m .
- If you want to use this distribution for modeling regression effects, then the first parameter must not be a constant parameter.
- The order of arguments in the signature of this subroutine does not matter as long as each argument's name matches the name of one of the parameters that are defined in the signature of the *dist_PDF* function.
- The constant parameters must be specified in signatures of all the functions and subroutines that accept distribution parameters as their arguments.
- You must provide a nonmissing initial value for each constant parameter by using one of the supported parameter initialization methods.

*dist_***DESCRIPTION**

defines a function that returns a description of the distribution.

- *Type*: Function
- *Required*: NO
- *Number of arguments*: None
- *Sequence and type of arguments*: Not applicable
- *Return value*: Character value containing a description of the distribution

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_DESCRIPTION() $48;
  length desc $48;
  desc = "A model for a continuous distribution named foo";
  return (desc);
endsub;
```

There is no restriction on the length of the description (the length of 48 used in the previous example is for illustration purposes only). However, if the length is greater than 256, then only the first 256 characters appear in the displayed output and in the `_DESCRIPTION_` variable of the `OUTMODELINFO=` data set. Hence, the recommended length of the description is less than or equal to 256.

`dist_`**LOGcore**

defines a function that returns natural logarithm of the specified *core* function of the distribution at the specified values of the random variable and distribution parameters. The *core* keyword can be PDF, CDF, or SDF.

- *Type*: Function
- *Required*: YES only if *core* is PDF or CDF and you have not defined that *core* function; otherwise, NO
- *Number of arguments*: $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments*:
 - x Numeric value of the random variable at which the natural logarithm of the *core* function should be evaluated
 - p1 Numeric value of the first parameter
 - p2 Numeric value of the second parameter
 -
 - pm Numeric value of the m th parameter
- *Return value*: Numeric value that contains the natural logarithm of the *core* function

Here is a sample structure of the function for the core function PDF of a distribution named 'FOO':

```
function FOO_LOGPDF(x, P1, P2);
  /* Code to compute LOGPDF by using x, P1, and P2 */

  l = <computed LOGPDF>;
  return (l);
endsub;
```

`dist_`**LOWERBOUNDS**

defines a subroutine that returns lower bounds for the parameters of the distribution. If this subroutine is not defined for a given distribution, then the SEVERITY procedure assumes a lower bound of 0 for each parameter. If a lower bound of l_i is returned for a parameter p_i , then the SEVERITY procedure assumes that $l_i < p_i$ (strict inequality). If a missing value is returned for some parameter, then the SEVERITY procedure assumes that there is no lower bound for that parameter (equivalent to a lower bound of $-\infty$).

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: m , where m is the number of distribution parameters

- *Sequence and type of arguments:*

- | | |
|-------|---|
| p1 | Output argument that returns the lower bound on the first parameter. You must specify this in the OUTARGS statement inside the subroutine's definition. |
| p2 | Output argument that returns the lower bound on the second parameter. You must specify this in the OUTARGS statement inside the subroutine's definition. |
| | |
| pm | Output argument that returns the lower bound on the <i>m</i> th parameter. You must specify this in the OUTARGS statement inside the subroutine's definition. |
- *Return value:* The results, lower bounds on parameter values, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named 'FOO':

```
subroutine FOO_LOWERBOUNDS(p1, p2);
  outargs p1, p2;

  p1 = <lower bound for P1>;
  p2 = <lower bound for P2>;
endsub;
```

*dist_***PARMINIT**

defines a subroutine that returns the initial values for the distribution's parameters given an empirical distribution function (EDF) estimate.

- *Type:* Subroutine
- *Required:* NO
- *Number of arguments:* $m + 4$, where *m* is the number of distribution parameters
- *Sequence and type of arguments:*

- | | |
|-------|---|
| dim | Input numeric value that contains the dimension of the x, nx, and F array arguments. |
| x{*} | Input numeric array of dimension <i>dim</i> that contains values of the random variables at which the EDF estimate is available. It can be assumed that x contains values in an increasing order. In other words, if $i < j$, then $x[i] < x[j]$. |
| nx{*} | Input numeric array of dimension <i>dim</i> . Each $nx[i]$ contains the number of observations in the original data that have the value $x[i]$. |
| F{*} | Input numeric array of dimension <i>dim</i> . Each $F[i]$ contains the EDF estimate for $x[i]$. This estimate is computed by the SEVERITY procedure based on the EMPIRICAL-CDF= option. |
| Ftype | Input numeric value that contains the type of the EDF estimate that is stored in x and F. See the section “ Supplying EDF Estimates to Functions and Subroutines ” on page 1674 for definition of types. |
| p1 | Output argument that returns the initial value of the first parameter. You must specify this in the OUTARGS statement inside the subroutine's definition. |

p2 Output argument that returns the initial value of the second parameter. You must specify this in the OUTARGS statement inside the subroutine's definition.

pm Output argument that returns the initial value of the *m*th parameter. You must specify this in the OUTARGS statement inside the subroutine's definition.

- *Return value*: The results, initial values of the parameters, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named 'FOO':

```
subroutine FOO_PARMINIT(dim, x{*}, nx{*}, F{*}, Ftype, p1, p2);
  outargs p1, p2;

  /* Code to initialize values of P1 and P2 by using
     dim, x, nx, and F */

  p1 = <initial value for p1>;
  p2 = <initial value for p2>;
endsub;
```

dist_PDF

defines a function that returns the value of the probability density function (PDF) of the distribution at the specified values of the random variable and distribution parameters.

- *Type*: Function
- *Required*: YES
- *Number of arguments*: $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments*:

x Numeric value of the random variable at which the PDF value should be evaluated

p1 Numeric value of the first parameter

p2 Numeric value of the second parameter

....

pm Numeric value of the *m*th parameter

- *Return value*: Numeric value that contains the PDF value $f(x; p_1, p_2, \dots, p_m)$

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

$$f(x; p_1, p_2, \dots, p_m) = \frac{1}{p_1} f\left(\frac{x}{p_1}; 1, p_2, \dots, p_m\right)$$

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

$$f(x; p_1, p_2, \dots, p_m) = \frac{1}{\exp(p_1)} f\left(\frac{x}{\exp(p_1)}; 0, p_2, \dots, p_m\right)$$

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_PDF(x, P1, P2);
  /* Code to compute PDF by using x, P1, and P2 */

  f = <computed PDF>;
  return (f);
endsub;
```

dist_QUANTILE

defines a function that returns the quantile of the distribution at the specified value of the CDF for the specified values of distribution parameters.

- *Type:* Function
- *Required:* NO
- *Number of arguments:* $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments:*
 - cdf Numeric value of the cumulative distribution function (CDF) for which the quantile should be evaluated
 - p1 Numeric value of the first parameter
 - p2 Numeric value of the second parameter
 -
 - pm Numeric value of the m th parameter
- *Return value:* Numeric value that contains the quantile $F^{-1}(\text{cdf}; p_1, p_2, \dots, p_m)$

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_QUANTILE(c, P1, P2);
  /* Code to compute Quantile by using c, P1, and P2 */

  Q = <computed quantile>;
  return (Q);
endsub;
```

dist_SCALETRANSFORM

defines a function that returns a keyword to identify the transform that needs to be applied to the scale parameter to convert it to the first parameter of the distribution.

If you want to use this distribution for modeling regression effects, then the first parameter of this distribution must be a scale parameter. However, for some distributions, a typical or convenient parameterization might not have a scale parameter, but one of the parameters can be a simple transform of the scale parameter. As an example, consider a typical parameterization of the lognormal distribution with two parameters, location μ and shape σ , for which the PDF is defined as follows:

$$f(x; \mu, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2}$$

You can reparameterize this distribution to contain a parameter θ instead of the parameter μ such that $\mu = \log(\theta)$. The parameter θ would then be a scale parameter. However, if you want to specify the distribution in terms of μ and σ (which is a more recognized form of the lognormal distribution) and still allow it as a candidate distribution for estimating regression effects, then instead of writing another distribution with parameters θ and σ , you can simply define the distribution with μ as the first parameter and specify that it is the logarithm of the scale parameter.

- *Type:* Function
- *Required:* NO
- *Number of arguments:* None
- *Sequence and type of arguments:* Not applicable
- *Return value:* Character value that contains one of the following keywords:

LOG specifies that the first parameter is the logarithm of the scale parameter.

IDENTITY specifies that the first parameter is a scale parameter without any transformation.

If you do not specify this function, then the IDENTITY transform is assumed.

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_SCALETRANSFORM() $8;
    length xform $8;
    xform = "IDENTITY";
    return (xform);
endsub;
```

dist_SDF

defines a function that returns the value of the survival distribution function (SDF) of the distribution at the specified values of the random variable and distribution parameters.

- *Type:* Function
- *Required:* NO
- *Number of arguments:* $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments:*

x Numeric value of the random variable at which the SDF value should be evaluated

p1 Numeric value of the first parameter

p2 Numeric value of the second parameter

.....

pm Numeric value of the m th parameter

- *Return value:* Numeric value that contains the SDF value $S(x; p_1, p_2, \dots, p_m)$

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter

or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

$$S(x; p_1, p_2, \dots, p_m) = S\left(\frac{x}{p_1}; 1, p_2, \dots, p_m\right)$$

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

$$S(x; p_1, p_2, \dots, p_m) = S\left(\frac{x}{\exp(p_1)}; 0, p_2, \dots, p_m\right)$$

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_SDF(x, P1, P2);
  /* Code to compute SDF by using x, P1, and P2 */

  S = <computed SDF>;
  return (S);
endsub;
```

*dist_***UPPERBOUNDS**

defines a subroutine that returns upper bounds for the parameters of the distribution. If this subroutine is not defined for a given distribution, then the SEVERITY procedure assumes that there is no upper bound for any of the parameters. If an upper bound of u_i is returned for a parameter p_i , then the SEVERITY procedure assumes that $p_i < u_i$ (strict inequality). If a missing value is returned for some parameter, then the SEVERITY procedure assumes that there is no upper bound for that parameter (equivalent to an upper bound of ∞).

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: m , where m is the number of distribution parameters
- *Sequence and type of arguments*:

$p1$	Output argument that returns the upper bound on the first parameter. You must specify this in the OUTARGS statement inside the subroutine's definition.
$p2$	Output argument that returns the upper bound on the second parameter. You must specify this in the OUTARGS statement inside the subroutine's definition.
.....	
pm	Output argument that returns the upper bound on the m th parameter. You must specify this in the OUTARGS statement inside the subroutine's definition.
- *Return value*: The results, upper bounds on parameter values, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named 'FOO':

```
subroutine FOO_UPPERBOUNDS(p1, p2);
  outargs p1, p2;

  p1 = <upper bound for P1>;
  p2 = <upper bound for P2>;
endsub;
```

dist_coreGRADIENT

defines a subroutine that returns the gradient vector of the specified *core* function of the distribution at the specified values of the random variable and distribution parameters. The *core* keyword can be PDF, CDF, SDF, LOGPDF, LOGCDF, or LOGSDF.

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: $m + 2$, where m is the number of distribution parameters
- *Sequence and type of arguments*:

x	Numeric value of the random variable at which the gradient should be evaluated
p1	Numeric value of the first parameter
p2	Numeric value of the second parameter
....	
pm	Numeric value of the m th parameter
grad{*}	Output numeric array of size m that contains the gradient vector evaluated at the specified values. If h denotes the value of the <i>core</i> function, then the expected order of the values in the array is as follows: $\frac{\partial h}{\partial p_1} \frac{\partial h}{\partial p_2} \dots \frac{\partial h}{\partial p_m}$
- *Return value*: Numeric array that contains the gradient evaluated at x for the parameter values (p_1, p_2, \dots, p_m)

Here is a sample structure of the function for the core function CDF of a distribution named 'FOO':

```
subroutine FOO_CDFGRADIENT(x, P1, P2, grad{*});
  outargs grad;

  /* Code to compute gradient by using x, P1, and P2 */
  grad[1] = <partial derivative of CDF w.r.t. P1
             evaluated at x, P1, P2>;
  grad[2] = <partial derivative of CDF w.r.t. P2
             evaluated at x, P1, P2>;
endsub;
```

dist_coreHESSIAN

defines a subroutine that returns the Hessian matrix of the specified *core* function of the distribution at the specified values of the random variable and distribution parameters. The *core* keyword can be PDF, CDF, SDF, LOGPDF, LOGCDF, or LOGSDF.

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: $m + 2$, where m is the number of distribution parameters
- *Sequence and type of arguments*:

x	Numeric value of the random variable at which the Hessian matrix should be evaluated
p1	Numeric value of the first parameter

- `p2` Numeric value of the second parameter

`pm` Numeric value of the m th parameter
`hess{*}` Output numeric array of size $m(m + 1)/2$ that contains the lower triangular portion of the Hessian matrix in a packed vector form, evaluated at the specified values. If h denotes the value of the *core* function, then the expected order of the values in the array is as follows: $\frac{\partial^2 h}{\partial p_1^2} \mid \frac{\partial^2 h}{\partial p_1 \partial p_2} \mid \frac{\partial^2 h}{\partial p_2^2} \mid \dots \mid \frac{\partial^2 h}{\partial p_1 \partial p_m} \mid \frac{\partial^2 h}{\partial p_2 \partial p_m} \dots \frac{\partial^2 h}{\partial p_m^2}$
- *Return value:* Numeric array that contains the lower triangular portion of the Hessian matrix evaluated at x for the parameter values (p_1, p_2, \dots, p_m)

Here is a sample structure of the subroutine for the core function LOGSDF of a distribution named 'FOO':

```
subroutine FOO_LOGSDFHESSIAN(x, P1, P2, hess{*});
  outargs hess;

  /* Code to compute Hessian by using x, P1, and P2 */
  hess[1] = <second order partial derivative of LOGSDF
             w.r.t. P1 evaluated at x, P1, P2>;
  hess[2] = <second order partial derivative of LOGSDF
             w.r.t. P1 and P2 evaluated at x, P1, P2>;
  hess[3] = <second order partial derivative of LOGSDF
             w.r.t. P2 evaluated at x, P1, P2>;
endsub;
```

Predefined Utility Functions

The following predefined utility functions are provided with the SEVERITY procedure and are available in the Sashelp.Svrtutil library:

SVRTUTIL_EDF:

This function computes the empirical distribution function (EDF) estimate at the specified value of the random variable given the EDF estimate for a sample.

- *Type:* Function
- *Signature:* SVRTUTIL_EDF(y, n, x{*}, F{*}, Ftype)
- *Argument Description:*

- `y` Value of the random variable at which the EDF estimate is desired.
- `n` Dimension of the x and F input arrays.
- `x{*}` Input numeric array of dimension n that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.
- `F{*}` Input numeric array of dimension n in which each $F[i]$ contains the EDF estimate for $x[i]$. These values must be sorted in nondecreasing order.

Ftype Type of the empirical estimate that is stored in the x and F arrays. See the section “[Supplying EDF Estimates to Functions and Subroutines](#)” on page 1674 for definition of types.

- *Return value:* The EDF estimate at y .

The type of the sample EDF estimate determines how the EDF estimate at y is computed. See the section “[Supplying EDF Estimates to Functions and Subroutines](#)” on page 1674 for more information.

SVRTUTIL_EMPLIMMOMENT:

This function computes the empirical estimate of the limited moment of specified order for the specified upper limit, given the EDF estimate for a sample.

- *Type:* Function
- *Signature:* SVRTUTIL_EMPLIMMOMENT($k, u, n, x\{*\}, F\{*\}, Ftype$)
- *Argument Description:*

k Order of the desired empirical limited moment.

u Upper limit on the value of the random variable to be used in the computation of the desired empirical limited moment.

n Dimension of the x and F input arrays.

$x\{*\}$ Input numeric array of dimension n that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.

$F\{*\}$ Input numeric array of dimension n in which each $F[i]$ contains the EDF estimate for $x[i]$. These values must be sorted in nondecreasing order.

Ftype Type of the empirical estimate that is stored in the x and F arrays. See the section “[Supplying EDF Estimates to Functions and Subroutines](#)” on page 1674 for definition of types.

- *Return value:* The desired empirical limited moment.

The empirical limited moment is computed by using the empirical estimate of the CDF. If $F_n(x)$ denotes the EDF at x , then the empirical limited moment of order k with upper limit u is defined as

$$E_n[(X \wedge u)^k] = k \int_0^u (1 - F_n(x))x^{k-1} dx$$

The SVRTUTIL_EMPLIMMOMENT function uses the piecewise linear nature of $F_n(x)$ as described in the section “[Supplying EDF Estimates to Functions and Subroutines](#)” on page 1674 to compute the integration.

SVRTUTIL_HILLCUTOFF:

This function computes an estimate of the value where the right tail of a distribution is expected to begin. The function implements the algorithm described in Danielsson et al. 2001. The description of the algorithm uses the following notation:

n number of observations in the original sample

B number of bootstrap samples to draw

m_1 size of the bootstrap sample in the first step of the algorithm ($m_1 < n$)

$x_{(i)}^{j,m}$ i th order statistic of j th bootstrap sample of size m ($1 \leq i \leq m, 1 \leq j \leq B$)
 $x_{(i)}$ i th order statistic of the original sample ($1 \leq i \leq n$)

Given the input sample x and values of B and m_1 , the steps of the algorithm are as follows:

1. Take B bootstrap samples of size m_1 from the original sample.
2. Find the integer k_1 that minimizes the bootstrap estimate of the mean squared error:

$$k_1 = \arg \min_{1 \leq k < m_1} Q(m_1, k)$$

3. Take B bootstrap samples of size $m_2 = m_1^2/n$ from the original sample.
4. Find the integer k_2 that minimizes the bootstrap estimate of the mean squared error:

$$k_2 = \arg \min_{1 \leq k < m_2} Q(m_2, k)$$

5. Compute the integer k_{opt} , which is used for computing the cutoff point:

$$k_{\text{opt}} = \frac{k_1^2}{k_2} \left(\frac{\log(k_1)}{2 \log(m_1) - \log(k_1)} \right)^{2 - 2 \log(k_1) / \log(m_1)}$$

6. Set the cutoff point equal to $x_{(k_{\text{opt}}+1)}$.

The bootstrap estimate of the mean squared error is computed as

$$Q(m, k) = \frac{1}{B} \sum_{j=1}^B \text{MSE}_j(m, k)$$

The mean squared error of j th bootstrap sample is computed as

$$\text{MSE}_j(m, k) = (M_j(m, k) - 2(\gamma_j(m, k))^2)^2$$

where $M_j(m, k)$ is a control variate proposed by Danielsson et al. 2001,

$$M_j(m, k) = \frac{1}{k} \sum_{i=1}^k \left(\log(x_{(m-i+1)}^{j,m}) - \log(x_{(m-k)}^{j,m}) \right)^2$$

and $\gamma_j(m, k)$ is the Hill's estimator of the tail index (Hill 1975),

$$\gamma_j(m, k) = \frac{1}{k} \sum_{i=1}^k \log(x_{(m-i+1)}^{j,m}) - \log(x_{(m-k)}^{j,m})$$

This algorithm has two tuning parameters, B and m_1 . The number of bootstrap samples B is chosen based on the availability of computational resources. The optimal value of m_1 is chosen such that the following ratio, $R(m_1)$, is minimized:

$$R(m_1) = \frac{(Q(m_1, k_1))^2}{Q(m_2, k_2)}$$

The SVRTUTIL_HILLCUTOFF utility function implements the preceding algorithm. It uses the grid search method to compute the optimal value of m_1 .

- *Type:* Function
- *Signature:* SVRTUTIL_HILLCUTOFF(n, x{*}, b, s, status)

- *Argument Description:*

n	Dimension of the array x .
$x\{*\}$	Input numeric array of dimension n that contains the sample.
b	Number of bootstrap samples used to estimate the mean squared error. If b is less than 10, then a default value of 50 is used.
s	Approximate number of steps used to search the optimal value of m_1 in the range $[n^{0.75}, n - 1]$. If s is less than or equal to 1, then a default value of 10 is used.
<i>status</i>	Output argument that contains the status of the algorithm. If the algorithm succeeds in computing a valid cutoff point, then <i>status</i> is set to 0. If the algorithm fails, then <i>status</i> is set to 1.

- *Return value:* The cutoff value where the right tail is estimated to start. If the size of the input sample is inadequate ($n \leq 5$), then a missing value is returned and *status* is set to a missing value. If the algorithm fails to estimate a valid cutoff value (*status* = 1), then the fifth largest value in the input sample is returned.

SVRTUTIL_PERCENTILE:

This function computes the specified empirical percentile given the EDF estimates.

- *Type:* Function

- *Signature:* SVRTUTIL_PERCENTILE(p , n , $x\{*\}$, $F\{*\}$, $Ftype$)

- *Argument Description:*

p	Desired percentile. The value must be in the interval (0,1). The function returns the 100 p th percentile.
n	Dimension of the x and F input arrays.
$x\{*\}$	Input numeric array of dimension n that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.
$F\{*\}$	Input numeric array of dimension n in which each $F[i]$ contains the EDF estimate for $x[i]$. These values must be sorted in nondecreasing order.
$Ftype$	Type of the empirical estimate that is stored in the x and F arrays. See the section “ Supplying EDF Estimates to Functions and Subroutines ” on page 1674 for definition of types.

- *Return value:* The 100 p th percentile of the input sample.

The method used to compute the percentile depends on the type of the EDF estimate ($Ftype$ argument).

$Ftype = 1$ Smoothed empirical estimates are computed using the method described in Klugman, Panjer, and Willmot (1998). Let $\lfloor x \rfloor$ denote the greatest integer less than or equal to x . Define $g = \lfloor p(n + 1) \rfloor$ and $h = p(n + 1) - g$. Then the empirical percentile $\hat{\pi}_p$ is defined as

$$\hat{\pi}_p = (1 - h)x[g] + hx[g + 1]$$

This method does not work if $p < 1/(n + 1)$ or $p > n/(n + 1)$. If $p < 1/(n + 1)$, then the function returns $\hat{\pi}_p = x[1]/2$, which assumes that the EDF is 0 in the interval $[0, x[1]]$. If $p > n/(n + 1)$, then $\hat{\pi}_p = x[n]$.

Ftype = 2 If $p < F[1]$, then $\hat{\pi}_p = x[1]/2$, which assumes that the EDF is 0 in the interval $[0, x[1])$. If $|p - F[i]| < \epsilon$ for some value of i and $i < n$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = \frac{x[i] + x[i + 1]}{2}$$

where ϵ is a machine-precision constant as returned by the SAS function CONSTANT('MACEPS'). If $F[i - 1] < p < F[i]$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = x[i]$$

If $p \geq F[n]$, then $\hat{\pi}_p = x[n]$.

Ftype = 3 If $p < F[1]$, then $\hat{\pi}_p = x[1]/2$, which assumes that the EDF is 0 in the interval $[0, x[1])$. If $|p - F[i]| < \epsilon$ for some value of i and $i < n$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = \frac{x[i] + x[i + 1]}{2}$$

where ϵ is a machine-precision constant as returned by the SAS function CONSTANT('MACEPS'). If $F[i - 1] < p < F[i]$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = x[i - 1] + (p - F[i - 1]) \frac{x[i] - x[i - 1]}{F[i] - F[i - 1]}$$

If $p \geq F[n]$, then $\hat{\pi}_p = x[n]$.

SVRTUTIL_RAWMOMENTS:

This subroutine computes the raw moments of a sample.

- *Type:* Subroutine
- *Signature:* SVRTUTIL_RAWMOMENTS(n , $x\{*\}$, $nx\{*\}$, $nRaw$, $raw\{*\}$)
- *Argument Description:*

n	Dimension of the x and nx input arrays.
$x\{*\}$	Input numeric array of dimension n that contains distinct values of the random variable that are observed in the sample.
$nx\{*\}$	Input numeric array of dimension n in which each $nx[i]$ contains the number of observations in the sample that have the value $x[i]$.
$nRaw$	Desired number of raw moments. The output array <i>raw</i> contains the first $nRaw$ raw moments.
$raw\{*\}$	Output array of raw moments. The k th element in the array ($raw\{k\}$) contains the k th raw moment, where $1 \leq k \leq nRaw$.
- *Return value:* Numeric array *raw* that contains the first $nRaw$ raw moments. The array contains missing values if the sample has no observations (that is, if all the values in the nx array add up to zero).

SVRTUTIL_SORT:

This function sorts the given array of numeric values in an ascending or descending order.

- *Type:* Subroutine
- *Signature:* SVRTUTIL_SORT(n , $x\{*\}$, *flag*)

- *Argument Description:*

- | | |
|----------|---|
| n | Dimension of the input array x . |
| $x\{*\}$ | Numeric array that contains the values to be sorted at input. The subroutine uses the same array to return the sorted values. |
| flag | A numeric value that controls the sort order. If <i>flag</i> is 0, then the values are sorted in an ascending order. If <i>flag</i> has any value other than 0, then the values are sorted in descending order. |
- *Return value:* Numeric array x , which is sorted in place (that is, the sorted array is stored in the same storage area occupied by the input array x).

You can use the following predefined functions when you define functions and subroutines using the FCMP procedure. They are summarized here for your information. See the FCMP procedure documentation in *Base SAS Procedures Guide* for more information.

INVCDF:

This function computes the quantile from any continuous probability distribution by numerically inverting the CDF of that distribution. You need to specify the CDF function of the distribution, the values of its parameters, and the cumulative probability to compute the quantile.

LIMMOMENT:

This function computes the limited moment of order k with upper limit u for any continuous probability distribution. The limited moment is defined as

$$\begin{aligned} E[(X \wedge u)^k] &= \int_0^u x^k f(x) dx + \int_u^\infty u^k f(x) dx \\ &= \int_0^u x^k f(x) dx + u^k (1 - F(u)) \end{aligned}$$

where $f(x)$ and $F(x)$ denote the PDF and the CDF of the distribution, respectively. The LIMMOMENT function uses the following alternate definition, which can be derived using integration-by-parts:

$$E[(X \wedge u)^k] = k \int_0^u (1 - F(x)) x^{k-1} dx$$

You need to specify the CDF function of the distribution, the values of its parameters, and the values of k and u to compute the limited moment.

Scoring Functions (Experimental)

Scoring refers to the act of evaluating a distribution function, such as LOGPDF, SDF, or QUANTILE, on an observation by using the fitted parameter estimates of that distribution. You can do scoring in a DATA step by using the OUTEST= data set that you create with PROC SEVERITY. However, that approach requires some cumbersome programming. In order to simplify the scoring process, you can specify that PROC SEVERITY create scoring functions for each fitted distribution.

As an example, assume that you have fitted the Pareto distribution by using PROC SEVERITY and that it converges. Further assume that you want to use the fitted distribution to evaluate the probability of observing

a loss value greater than some set of regulatory limits {L} that are encoded in a data set. You can simplify this scoring process as follows. First, in the PROC SEVERITY step that fits your distributions, you create the scoring functions library by specifying the **OUTSCORELIB** statement as illustrated in the following steps:

```
proc severity data=input;
  loss lossclaim;
  dist pareto;
  outscorelib outlib=sasuser.fitdist;
run;
```

Upon successful completion, if the Pareto distribution model has converged, then the Sasuser.Fitdist library contains the *SEV_SDF* scoring function in addition to other scoring functions, such as *SEV_PDF*, *SEV_LOGPDF*, and so on. Further, PROC SEVERITY also sets the CMPLIB system option to include the Sasuser.Fitdist library. If the set of limits {L} is recorded in the variable Limit in the scoring data set Work.Limits, then you can submit the following DATA step to compute the probability of seeing a loss greater than each limit:

```
data prob;
  set work.limits;
  exceedance_probability = sev_sdf(limit);
run;
```

Without the use of scoring functions, you can still perform this scoring task, but the DATA step that you need to write to accomplish it becomes more complicated and less flexible. For example, you would need to read the parameter estimates from some output created by PROC SEVERITY. To do that, you would need to know the parameter names, which are different for different distributions; this in turn would require you to write a specific DATA step for each distribution or to write a SAS macro. With the use of scoring functions, you can accomplish that task much more easily.

If you fit multiple distributions, then you can specify the COMMONPACKAGE option in the OUTSCORELIB statement as follows:

```
proc severity data=input;
  loss lossclaim;
  dist exp pareto weibull;
  outscorelib outlib=sasuser.fitdist commonpackage;
run;
```

The preceding step creates scoring functions such as *SEV_SDF_Exp*, *SEV_SDF_Pareto*, and *SEV_SDF_Weibull*. You can use them to compare the probabilities of exceeding the limit for different distributions by using the following DATA step:

```
data prob;
  set work.limits;
  exceedance_exp = sev_sdf_exp(limit);
  exceedance_pareto = sev_sdf_pareto(limit);
  exceedance_weibull = sev_sdf_weibull(limit);
run;
```

Formal Description

PROC SEVERITY creates a scoring function for each distribution function. A distribution function is defined as any function named *dist_suffix*, where *dist* is the name of a distribution that you specify in the DIST

statement and the function's signature is identical to the signature of the required distribution function such as *dist_CDF* or *dist_LOGCDF*. For example, for the function 'FOO_BAR' to be a distribution function, you must specify the distribution 'FOO' in the DIST statement and you must define 'FOO_BAR' in the following manner if the distribution 'FOO' has parameters named 'P1' and 'P2':

```
function FOO_BAR(y, P1, P2);
  /* Code to compute BAR by using y, P1, and P2 */
  R = <computed BAR>;
  return (R);
endsub;
```

For more information about the signature that defines a distribution function, see the description of the *dist_CDF* function in the section “Defining a Distribution Model with the FCMP Procedure” on page 1679.

The name and package of the scoring function of a distribution function depend on whether you specify the COMMONPACKAGE option in the OUTSCORELIB statement.

When you do not specify the COMMONPACKAGE option, the scoring function that corresponds to the distribution function *dist_suffix* is named *SEV_suffix*, where *SEV_* is the standard prefix of all scoring functions. The scoring function is created in a package named *dist*. Each scoring function accepts only one argument, the value of the loss variable, and returns the same value as the value returned by the corresponding distribution function for the final estimates of the distribution's parameters. For example, for the preceding 'FOO_BAR' distribution function, the scoring function named 'SEV_BAR' is created in the package named 'FOO' and 'SEV_BAR' has the following signature:

```
function SEV_BAR(y);
  /* returns value of FOO_BAR for the supplied value
    of y and fitted values of P1, P2 */
endsub;
```

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, then the scoring function that corresponds to the distribution function *dist_suffix* is named *SEV_suffix_dist*, where *SEV_* is the standard prefix of all scoring functions. The scoring function is created in a package named *sevfit*. For example, for the preceding 'FOO_BAR' distribution function, if you specify the COMMONPACKAGE option, the scoring function named 'SEV_BAR_FOO' is created in the *sevfit* package and 'SEV_BAR_FOO' has the following signature:

```
function SEV_BAR_FOO(y);
  /* returns value of FOO_BAR for the supplied value
    of y and fitted values of P1, P2 */
endsub;
```

Scoring Functions for the Scale Regression Model

If you use the SCALEMODEL statement to specify a scale regression model, then the estimate of the scale parameter or the log-transformed scale parameter of the distribution depends on the values of the regressors. So PROC SEVERITY creates a scoring function that has the following signature, where *x{}* represents the array of regressors:

```
function SEV_BAR(y, x{*});
  /* returns value of FOO_BAR for the supplied value of x and fitted values of P1, P2 */
endsub;
```

As an illustration of using this form, assume that you submit the following PROC SEVERITY step to create the scoring library Sasuser.Scalescore:

```
proc severity data=input;
  loss lossclaim;
  scalemodel x1-x3;
  dist pareto;
  outscorelib outlib=sasuser.scalescore;
run;
```

Your scoring data set must contain all the regressors that you specify in the SCALEMODEL statement. You can submit the following DATA step to score observations by using the scale regression model:

```
data prob;
  array regvals{*} x1-x3;
  set work.limits;
  exceedance_probability = sev_sdf(limit, regvals);
run;
```

PROC SEVERITY creates two utility functions, SEV_NUMREG and SEV_REGNAME, in the OUTLIB= library that return the number of regressors and name of a given regressor, respectively. They are described in detail in the next section. These utility functions are useful when you do not have easy access to the regressor names in the SCALEMODEL statement. You can use the utility functions as follows:

```
data prob;
  array regvals{10} _temporary_;
  set work.limits;
  do i = 1 to sev_numreg();
    regvals(i) = input(vvaluex(sev_regname(i)), best12.);
  end;
  exceedance_probability = sev_sdf(limit, regvals);
run;
```

The dimension of the regressor values array that you supply to the scoring function must be equal to $K + L$, where K is the number of regressors that you specify in the SCALEMODEL statement irrespective of whether PROC SEVERITY deems any of those regressors to be redundant. L is 1 if you specify an **OFFSET=** variable in the SCALEMODEL statement, and 0 otherwise.

Utility Functions and Subroutines in the OUTLIB= Library

In addition to creating the scoring functions for all distribution functions, PROC SEVERITY creates the following utility functions and subroutines in the OUTLIB= library.

SEV_NUMPARM | SEV_NUMPARM_dist

is a function that returns the number of distribution parameters and has the following signature:

- *Type:* Function
- *Number of arguments:* 0
- *Sequence and type of arguments:* Not applicable
- *Return value:* Numeric value that contains the number of distribution parameters

If you do not specify the COMMONPACKAGE option in the OUTSCORELIB statement, then a function named SEV_NUMPARM is created in the package of each distribution. Here is a sample structure of the code that PROC SEVERITY uses to define the function:

```
function SEV_NUMPARM();
  n = <number of distribution parameters>;
  return (n);
endsub;
```

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, then for each distribution *dist*, the function named SEV_NUMPARM_*dist* is created in the *sevfit* package. SEV_NUMPARM_*dist* has the same structure as the SEV_NUMPARM function that is described previously.

SEV_PARMEST | SEV_PARMEST_*dist*

is a subroutine that returns the estimate and standard error of a specified distribution parameter and has the following signature:

- *Type*: Subroutine
- *Number of arguments*: 3
- *Sequence and type of arguments*:
 - index* specifies the numeric value of the index of the distribution parameter for which you want the information. The value of *index* must be in the interval $[1, m]$, where m is the number of parameters in the distribution to which this subroutine belongs.
 - est* specifies the output argument that returns the estimate of the requested parameter.
 - stderr* specifies the output argument that returns the standard error of the requested parameter.
- *Return value*: Estimate and standard error of the requested distribution parameter that are returned in the output arguments *est* and *stderr*, respectively

If you do not specify the COMMONPACKAGE option in the OUTSCORELIB statement, then a subroutine named SEV_PARMEST is created in the package of each distribution. Here is a sample structure of the code that PROC SEVERITY uses to define the subroutine:

```
subroutine SEV_PARMEST(index, est, stderr);
  outargs est, stderr;
  est = <value of the estimate for the distribution parameter
        at position 'index'>;
  stderr = <value of the standard error for distribution parameter
           at position 'index'>;
endsub;
```

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, then for each distribution *dist*, the subroutine named SEV_PARMEST_*dist* is created in the *sevfit* package. SEV_PARMEST_*dist* has the same structure as the SEV_PARMEST subroutine that is described previously.

If you use the SCALEMODEL statement to specify a scale regression model, then for *index*=1, the returned estimates are of θ_0 , the base value of the scale parameter, or $\log(\theta_0)$ if the distribution has a log-scale parameter. For more information about θ_0 , see the section “[Estimating Regression Effects](#)” on page 1664.

SEV_PARMNAME | SEV_PARMNAME_*dist*

is a function that returns the name of a specified distribution parameter and has the following signature:

- *Type*: Function
- *Number of arguments*: 1
- *Sequence and type of arguments*:
 - index* specifies the numeric value of the index of the distribution parameter for which you want the information. The value of *index* must be in the interval $[1,m]$, where m is the number of parameters in the distribution to which this function belongs.
- *Return value*: Character value that contains the name of the distribution parameter that appears at the position *index* in the distribution's definition

If you do not specify the COMMONPACKAGE option in the OUTSCORELIB statement, then a function named SEV_PARMNAME is created in the package of each distribution. Here is a sample structure of the code that PROC SEVERITY uses to define the function:

```
function SEV_PARMNAME(index) $32;
    name = <name of the distribution parameter at position 'index'>;
    return (name);
endsub;
```

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, then for each distribution *dist*, a function named SEV_PARMNAME_*dist* is created in the *sevfit* package. SEV_PARMNAME_*dist* has the same structure as the SEV_PARMNAME function that is described previously.

If you use the SCALEMODEL statement to specify a scale regression model, then the following helper functions and subroutines are also created in the OUTLIB= library.

SEV_NUMREG

is a function that returns the number of regressors and has the following signature:

- *Type*: Function
- *Number of arguments*: 0
- *Sequence and type of arguments*: Not applicable
- *Return value*: Numeric value that contains the number of regressors that you specify in the SCALEMODEL statement. If you specify an OFFSET= variable in the SCALEMODEL statement, then the returned value is equal to 1 plus the number of regressors that you specify in the SCALEMODEL statement.

Here is a sample structure of the code that PROC SEVERITY uses to define the function:

```
function SEV_NUMREG();
    m = <number of regressors>;
    if (<offset variable is specified>) then m = m + 1;
    return (m);
endsub;
```

This function does not depend on any distribution, so it is always created in the *sevfit* package.

SEV_REGEST | SEV_REGEST_*dist*

is a subroutine that returns the estimate and standard error of a specified regression parameter and has the following signature:

- *Type:* Subroutine
- *Number of arguments:* 3
- *Sequence and type of arguments:*
 - index* specifies the numeric value of the index of the regression parameter for which you want the information. The value of *index* must be in the interval $[1, K]$, where K is the number of regressors as returned by the SEV_NUMREG function. If you specify an OFFSET= variable in the SCALEMODEL statement, then an *index* value of K corresponds to the offset variable.
 - est* specifies the output argument that returns the estimate of the requested regression parameter.
 - stderr* specifies the output argument that returns the standard error of the requested regression parameter.
- *Return value:* Estimate and standard error of the requested regression parameter that are returned in the output arguments *est* and *stderr*, respectively

If you do not specify the COMMONPACKAGE option in the OUTSCORELIB statement, then a subroutine named SEV_REGEST is created in the package of each distribution. Here is a sample structure of the code that PROC SEVERITY uses to define the subroutine:

```
subroutine SEV_REGEST(index, est, stderr);
  outargs est, stderr;
  est = <value of the estimate for the regression parameter
        at position 'index'>;
  stderr = <value of the standard error for regression parameter
           at position 'index'>;
endsub;
```

If you specify the COMMONPACKAGE option in the OUTSCORELIB statement, then for each distribution *dist*, the subroutine named SEV_REGEST_dist is created in the *sevfit* package. SEV_REGEST_dist has the same structure as the SEV_REGEST subroutine that is described previously.

If the regressor that corresponds to the specified *index* value is a redundant regressor, the returned values of both *est* and *stderr* are equal to the special missing value of .R. If you specify an OFFSET= variable in the SCALEMODEL statement and if the *index* value corresponds to the offset variable — that is, it is equal to the value that the SEV_NUMREG function returns — then the returned value of *est* is equal to 1 and the returned value of *stderr* is equal to the special missing value of .F.

SEV_REGNAME

is a function that returns the name of a specified regressor and has the following signature:

- *Type:* Function
- *Number of arguments:* 1

- *Sequence and type of arguments:*

index specifies the numeric value of the index of the regressor for which you want the name. The value of *index* must be in the interval $[1, K]$, where K is the number of regressors as returned by the SEV_NUMREG function. If you specify an OFFSET= variable in the SCALEMODEL statement, then an *index* value of K corresponds to the offset variable.

- *Return value:* Character value that contains the name of the regressor that appears at the position *index* in the SCALEMODEL statement. If you specify an OFFSET= variable in the SCALEMODEL statement, then for an *index* value of K , the returned value contains the name of the offset variable.

Here is a sample structure of the code that PROC SEVERITY uses to define the function:

```
function SEV_REGNAME(index) $32;
    name = <name of regressor at position 'index'>;
    return (name);
endsub;
```

This function does not depend on any distribution, so it is always created in the *sevfit* package.

Custom Objective Functions

You can use a series of programming statements that use variables in the DATA= data set to assign a value to an objective function symbol. You must specify the objective function symbol by using the **OBJECTIVE=** option in the PROC SEVERITY statement.

The objective function can be programmed such that it is applicable to any distribution that is used in the model. For that purpose, PROC SEVERITY recognizes the following *keyword* functions in the programming statements:

<code>_PDF_(x)</code>	returns the probability density function (PDF) of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_CDF_(x)</code>	returns the cumulative distribution function (CDF) of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_SDF_(x)</code>	returns the survival distribution function (SDF) of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_LOGPDF_(x)</code>	returns the natural logarithm of the PDF of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_LOGCDF_(x)</code>	returns the natural logarithm of the CDF of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_LOGSDF_(x)</code>	returns the natural logarithm of the SDF of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_EDF_(x)</code>	returns the empirical distribution function (EDF) estimate evaluated at the current value of a data set variable <i>x</i> . Internally, PROC SEVERITY computes the estimate using the SVRTUTIL_EDF function as described in the section “ Predefined Utility Functions ”

on page 1691. The EDF estimate that is required by the SVRTUTIL_EDF function is computed by using the response variable values in the current BY group or in the entire input data set if you do not specify the BY statement.

`_EMPLIMMOMENT_(k, u)`

returns the empirical limited moment of order k evaluated at the current value of a data set variable u that represents the upper limit of the limited moment. The order k can also be a data set variable. Internally, PROC SEVERITY computes the moment using the SVRTUTIL_EMPLIMMOMENT function as described in the section “[Predefined Utility Functions](#)” on page 1691. The EDF estimate that is required by the SVRTUTIL_EMPLIMMOMENT function is computed by using the response variable values in the current BY group or in the entire input data set if you do not specify the BY statement.

`_LIMMOMENT_(k, u)`

returns the limited moment of order k evaluated at the current value of a data set variable u that represents the upper limit of the limited moment. The order k can be a data set variable or a constant. Internally, for each candidate distribution, PROC SEVERITY computes the moment using the LIMMOMENT function as described in the section “[Predefined Utility Functions](#)” on page 1691.

All the preceding functions are right-hand side functions. They act as placeholders for distribution-specific functions, with the exception of `_EDF_` and `_EMPLIMMOMENT_` functions. As an example, let the data set `Work.Test` contain a response variable Y and a left-truncation threshold variable T . The following statements use the values in this data set to fit a model with distribution D such that the parameters of the model minimize the value of the objective function symbol `MYOBJ`:

```
options cmplib=(work.mydist);
proc severity data=work.test objective=myobj;
    loss y / lt=t;

    myobj = -_LOGPDF_(y);
    if (not(missing(t))) then
        myobj = myobj + log(1-_CDF_(t));

    dist d;
run;
```

The symbol `MYOBJ` is designated as an objective function symbol by using the `OBJECTIVE=` option in the PROC SEVERITY statement. The response variable Y and left-truncation variable T are specified in the `LOSS` statement. The distribution D is specified in the `DIST` statement. The remaining statements constitute a program that computes the value of the `MYOBJ` symbol.

Let the distribution D have parameters $P1$ and $P2$. In order to estimate the model for this distribution, PROC SEVERITY internally converts the generic program to the following program specific to distribution D :

```
myobj = -D_LOGPDF(y, p1, p2);
if (not(missing(t))) then
    myobj = myobj + log(1-D_CDF(t, p1, p2));
```

Note that the generic keyword functions `_LOGPDF_` and `_CDF_` have been replaced with distribution-specific functions `D_LOGPDF` and `D_CDF`, respectively, with appropriate distribution parameters. The `D_LOGPDF`

and D_CDF functions must have been defined previously and are assumed to be available in the Work.Mydist library that you specify in the CMPLIB= option.

The program is executed for each observation in Work.Test to compute the value of MYOBJ by using the values of variables Y and T in that observation and internally computed values of the model parameters P1 and P2. The values of MYOBJ are then added over all the observations of the data set or over all the observations of the current BY group if you specify the BY statement. The resulting aggregate value is the value of the objective function, and it is supplied to the optimizer. If the optimizer requires derivatives of the objective function, then PROC SEVERITY automatically differentiates MYOBJ with respect to the parameters P1 and P2. The optimizer iterates over various combinations of the values of parameters P1 and P2, each time computing a new value of the objective function and the needed derivatives of it, until it finds a combination that minimizes the objective function.

Note the following points when you define your own program to compute the custom objective function:

- The value of the objective function is always minimized by PROC SEVERITY. If you want to maximize the value of a certain objective, then add a statement that assigns the negated value of the maximization objective to the objective function symbol that you specify in the **OBJECTIVE=** option. Minimization of the negated objective is equivalent to the maximization of the original objective.
- The contributions of individual observations are always added to compute the overall objective function in a given iteration of the optimizer. If you specify the WEIGHT statement, then the contribution of each observation is weighted by multiplying it with the normalized value of the weight variable for that observation.
- If you are fitting multiple distributions in one PROC SEVERITY step and use any of the keyword functions in your program, then it is recommended that you do not explicitly use the parameters of any of the specified distributions in your programming statements.
- If you use a specific keyword function in your programming statements, then the corresponding distribution functions must be defined in a library that you specify in the CMPLIB= system option or in Sashelp.Svrtdist, the predefined functions library. In the preceding example, it is assumed that the functions D_LOGPDF and D_CDF are defined in the Work.Mydist library that is specified in the CMPLIB= option.
- You can use most DATA step statements and functions in your program. The DATA step file and the data set I/O statements (for example, INPUT, FILE, SET, and MERGE) are not available. However, some functionality of the PUT statement is supported. See the section “PROC FCMP and DATA Step Differences” in *Base SAS Procedures Guide* for more information. In addition to the differences listed in that section, the following differences exist:
 - Only numeric-valued variables can be used in PROC SEVERITY programming statements. This restriction also implies that you cannot use SAS functions or call routines that require character-valued arguments, unless you pass those arguments as constant (literal) strings or characters.
 - You cannot use functions that create lagged versions of a variable in PROC SEVERITY programming statements. If you need lagged versions, then you can use a DATA step prior to the PROC SEVERITY step to add those versions to the input data set.
- When coding your programming statements, avoid defining variables that begin with an underscore (_), because they might conflict with internal variables created by PROC SEVERITY.

Custom Objective Functions and Regression Effects

If you specify regressors by using the SCALEMODEL statement, then PROC SEVERITY automatically adds a statement prior to your programming statements to compute the value of the scale parameter or the log-transformed scale parameter of the distribution using the values of the regression variables and internally created regression parameters. For example, if you specify three regressors x_1 , x_2 , and x_3 in the SCALEMODEL statement, then for a model that contains the distribution D with scale parameter S, PROC SEVERITY prepends your program with a statement that is equivalent to the following statement:

```
S = _SEVTHETA0 * exp(_SEVBETA1 * x1 + _SEVBETA2 * x2 + _SEVBETA3 * x3);
```

If a model contains a distribution D1 with a log-transformed scale parameter M, PROC SEVERITY prepends your program with a statement that is equivalent to the following statement:

```
M = _SEVTHETA0 + _SEVBETA1 * x1 + _SEVBETA2 * x2 + _SEVBETA3 * x3;
```

The `_SEVTHETA0`, `_SEVBETA1`, `_SEVBETA2`, and `_SEVBETA3` are the internal regression parameters associated with the intercept and the regressors x_1 , x_2 , and x_3 , respectively.

Since the names of the internal regression parameters start with a prefix `_SEV`, if you use a variable in your program with a name that begins with `_SEV`, then PROC SEVERITY writes an error message to the SAS log and stops processing.

Multithreaded Computation

PROC SEVERITY attempts to use all the computational resources of the machine where SAS is running in order to complete the estimation tasks as fast as possible. This section describes the options that control the use of multithreading by PROC SEVERITY.

Threading refers to the organization of computational work into multiple tasks (processing units that can be scheduled by the operating system). A task is associated with a thread. Multithreading refers to the concurrent execution of threads. When multithreading is possible, substantial performance gains can be realized compared to sequential (single-threaded) execution.

The number of threads spawned by the SEVERITY procedure is determined by the number of CPUs on a machine. You can control the number of threads by specifying either the `CPUCOUNT=` or the `NOTHREADS` SAS system option.

- You can specify the CPU count with the `CPUCOUNT=` SAS system option. For example, if you specify the following statement, then PROC SEVERITY schedules threads as if it executed on a system with four CPUs, regardless of the actual CPU count:

```
options cpucount=4;
```

On most systems, the default value of the `CPUCOUNT=` system option is set to the number of actual CPU cores available for processing.

- If you do not want PROC SEVERITY to use multithreading, then you can turn off the THREADS SAS system option by specifying the following statement:

```
options nothreads;
```

On most systems, the THREADS option is turned on by default.

You can examine the current settings of these system options in the SAS log by submitting the following PROC OPTIONS step:

```
proc options option=(threads cpucount);
run;
```

Input Data Sets

PROC SEVERITY accepts DATA= and INEST= data sets as input data sets. This section details the information they are expected to contain.

DATA= Data Set

The DATA= data set is expected to contain the values of the analysis variables that you specify in the [LOSS statement](#) and the [SCALEMODEL statement](#).

If you specify the BY statement, then the DATA= data set must contain all the BY variables that you specify in the BY statement and the data set must be sorted by the BY variables unless you specify the NOTSORTED option in the BY statement.

INEST= Data Set

The INEST= data set is expected to contain the initial values of the parameters for the parameter estimation process.

If you specify the BY statement, then the INEST= data set must contain all the BY variables that you specify in the BY statement. If you do not specify the NOTSORTED option in the BY statement, then the INEST= data set must be sorted by the BY variables. However, it is not required to contain all the BY groups present in the DATA= data set. For the BY groups that are not present in the INEST= data set, the default parameter initialization method is used. If you specify the NOTSORTED option in the BY statement, then the INEST= data set must contain all the BY groups that are present in the DATA= data set and they must appear in the same order as they appear in the DATA= data set.

In addition to any variables that you specify in the BY statement, the data set must contain the following variables:

<code>_MODEL_</code>	identifying name of the distribution for which the estimates are provided.
<code>_TYPE_</code>	type of the estimate. The value of this variable must be EST for an observation to be valid.
<code><Parameter 1> ... <Parameter M></code>	M variables, named after the parameters of all candidate distributions, that contain initial values of the respective parameters. M is the cardinality of the union of parameter

name sets from all candidate distributions. In an observation, estimates are read only from variables for parameters that correspond to the distribution that is indicated by the `_MODEL_` variable.

If you specify a missing value for some parameters, then default initial values are used unless the parameter is initialized by using the `INIT=` option in the `DIST` statement. If you want to use the `dist_PARMINIT` subroutine for initializing the parameters of a model, then you should either not specify the model in the `INEST=` data set or specify missing values for all the distribution parameters in the `INEST=` data set and not use the `INIT=` option in the `DIST` statement.

If you specify regressors, then the initial value that you provide for the first parameter of each distribution must be the base value of the scale or log-transformed scale parameter. See the section “[Estimating Regression Effects](#)” on page 1664 for more information.

<Regressor 1> ... <Regressor K>

If you specify K regressors in the [SCALEMODEL statement](#), then the `INEST=` data set must contain K variables that are named for each regressor. The variables contain initial values of the respective regression coefficients. If a regressor is linearly dependent on other regressors for a given BY group, then you can indicate this by providing a special missing value of `.R` for the respective variable. In a given BY group, if you mark a variable as linearly dependent for one model, then you must mark that variable as linearly dependent for all the models. Similarly, in a given BY group, if you do not mark a variable as linearly dependent for one model, then you must not mark that variable as linearly dependent for all the models.

Output Data Sets

PROC SEVERITY writes `OUTCDF=`, `OUTEST=`, `OUTMODELINFO=`, and `OUTSTAT=` data sets when requested with respective options. The data sets and their contents are described in the following sections.

OUTCDF= Data Set

The `OUTCDF=` data set records the estimates of the cumulative distribution function (CDF) of each of the specified model distributions and an estimate of the empirical distribution function (EDF).

If you specify BY variables, then the data are organized in BY groups and the data set contains variables that you specify in the BY statement. In addition, it contains the following variables:

<response variable>

value of the response variable. The values are sorted. If there are multiple BY groups, the values are sorted within each BY group.

`_OBSNUM_` observation number in the `DATA=` data set.

`_EDF_` estimate of the empirical distribution function (EDF). This estimate is computed by using the [EMPIRICALCDF=](#) option that you specify in the PROC SEVERITY statement.

`_EDF_STD` estimate of the standard error of EDF. This estimate is computed by using a method that is appropriate for the [EMPIRICALCDF=](#) option that you specify in the PROC SEVERITY statement.

- _EDF_LOWER** estimate of the lower confidence limit of EDF for a pointwise $100(1 - \alpha)\%$ confidence interval, where α is the value of the **EDFALPHA=** option that you specify in the PROC SEVERITY statement (default is $\alpha = 0.05$). For an EDF estimate F_n with standard error σ_n , it is computed as $\text{MAX}(0, F_n - z_{(1-\alpha/2)}\sigma_n)$, where z_p is the p th quantile from the standard normal distribution.
- _EDF_UPPER** estimate of the upper confidence limit of EDF for a pointwise $100(1 - \alpha)\%$ confidence interval, where α is the value of the **EDFALPHA=** option that you specify in the PROC SEVERITY statement (default is $\alpha = 0.05$). For an EDF estimate F_n with standard error σ_n , it is computed as $\text{MIN}(1, F_n + z_{(1-\alpha/2)}\sigma_n)$, where z_p is the p th quantile from the standard normal distribution.
- <distribution1>_CDF ... <distributionD>_CDF**
estimate of the cumulative distribution function (CDF) for each of the D candidate distributions, computed by using the final parameter estimates for that distribution. This value is missing if parameter estimation process does not converge for the given distribution.
- If you specify regressor variables, then the reported estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1667 for more information.

If you specify truncation, then the data set contains the following additional variables:

- <distribution1>_COND_CDF ... <distributionD>_COND_CDF**
estimate of the conditional CDF for each of the D candidate distributions, computed by using the final parameter estimates for that distribution. This value is missing if parameter estimation process does not converge for the distribution. The conditional estimates are computed using the method described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1660.

OUTEST= Data Set

The OUTEST= data set records the estimates of the model parameters. It also contains estimates of their standard errors and optionally, their covariance structure. If you specify BY variables, then the data are organized in BY groups and the data set contains variables that you specify in the BY statement.

If you do not specify the COVOUT option, then the data set contains the following variables:

- _MODEL_** identifying name of the distribution model. The observation contains information about this distribution.
- _TYPE_** type of the estimates reported in this observation. It can take one of the following two values:
- | | |
|--------|--|
| EST | point estimates of model parameters |
| STDERR | standard error estimates of model parameters |
- _STATUS_** status of the reported estimates. The possible values are listed in the section “[_STATUS_ Variable Values](#)” on page 1712.

<Parameter 1> ... <Parameter M>

M variables, named after the parameters of all candidate distributions, containing estimates of the respective parameters. M is the cardinality of the union of parameter name sets from all candidate distributions. In an observation, estimates are populated only for parameters that correspond to the distribution that is indicated by the `_MODEL_` variable. If `_TYPE_` is EST, then the estimates are missing if the model does not converge. If `_TYPE_` is STDERR, then the estimates are missing if covariance estimates cannot be obtained.

If you specify regressors, then the estimate that is reported for the first parameter of each distribution is the estimate of the base value of the scale or log-transformed scale parameter. See the section “[Estimating Regression Effects](#)” on page 1664 for more information.

<Regressor 1> ... <Regressor K>

If you specify K regressors in the `SCALEMODEL` statement, then the `OUTEST=` data set contains K variables that are named for each regressor. The variables contain estimates for their respective regression coefficients. If a regressor is deemed to be linearly dependent on other regressors for a given BY group, then a warning is written to the SAS log and a special missing value of `.R` is written in the respective variable. If `_TYPE_` is EST, then the estimates are missing if the model does not converge. If `_TYPE_` is STDERR, then the estimates are missing if covariance estimates cannot be obtained.

<Offset Variable>

If you specify an `OFFSET=` variable in the `SCALEMODEL` statement, then the `OUTEST=` data set contains a variable that is named after the offset variable. If `_TYPE_` is EST, then the value of this variable is 1. If `_TYPE_` is STDERR, then the value of this variable is a special missing value of `.F`.

If you specify the `COVOUT` option in the `PROC SEVERITY` statement, then the `OUTEST=` data set contains additional observations that contain the estimates of the covariance structure. Given the symmetric nature of the covariance structure, only the lower triangular portion is reported. In addition to the variables listed and described previously, the data set contains the following variables that are either new or have a modified description:

<code>_TYPE_</code>	type of the estimates reported in this observation. For observations that contain rows of the covariance structure, the value is COV.
<code>_STATUS_</code>	status of the reported estimates. For observations that contain rows of the covariance structure, the status is 0 if covariance estimation was successful. If estimation fails, the status is 1 and a single observation is reported with <code>_TYPE_=COV</code> and missing values for all the parameter variables.
<code>_NAME_</code>	Name of the parameter for the row of covariance matrix reported in the current observation.

OUTMODELINFO= Data Set

The `OUTMODELINFO=` data set records the information about each candidate distribution that you specify in the `DIST` statement. It contains the following variables:

<code>_MODEL_</code>	identifying name of the distribution model. The observation contains information about this distribution.
<code>_DEPVAR_</code>	name of the loss variable.
<code>_DESCRIPTION_</code>	descriptive name of the model. This has a nonmissing value only if the <code>DESCRIPTION</code> function has been defined for this model.
<code>_VALID_</code>	validity of the distribution definition. This has a value of 1 for valid definitions and a value of 0 for invalid definitions. If the definition is invalid, then <code>PROC SEVERITY</code> writes the reason for invalidity to the SAS log.
<code>_PARMNAME1 ... _PARMNAMEM</code>	M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables <code>_PARMNAMEj</code> ($j > m$) are missing.

OUTSTAT= Data Set

The `OUTSTAT=` data set records statistics of fit and model selection information. If you specify `BY` variables, then the data are organized in `BY` groups and the data set contains variables that you specify in the `BY` statement. The data set contains the following variables:

<code>_MODEL_</code>	identifying name of the distribution model. The observation contains information about this distribution.
<code>_NMODELPRM_</code>	number of parameters in the distribution.
<code>_NESTPRM_</code>	number of estimated parameters. This includes the regression parameters, if you specify any regressors.
<code>_NOBS_</code>	number of nonmissing observations used for parameter estimation.
<code>_STATUS_</code>	status of the parameter estimation process for this model. The possible values are listed in the section “ _STATUS_ Variable Values ” on page 1712.
<code>_SELECTED_</code>	indicator of the best distribution model. If the value is 1, then this model is the best model for the current <code>BY</code> group according to the specified model selection criterion. This value is missing if parameter estimation process does not converge for this model.
Neg2LogLike	value of the log likelihood, multiplied by -2 , that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
AIC	value of the Akaike’s information criterion (AIC) that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
AICC	value of the corrected Akaike’s information criterion (AICC) that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
BIC	value of the Schwarz Bayesian information criterion (BIC) that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.

KS	value of the Kolmogorov-Smirnov (KS) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
AD	value of the Anderson-Darling (AD) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
CVM	value of the Cramér-von Mises (CvM) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.

STATUS Variable Values

The `_STATUS_` variable in the `OUTEST=` and `OUTSTAT=` data sets contains a value that indicates the status of the parameter estimation process for the respective distribution model. The variable can take the following values in the `OUTEST=` data set for `_TYPE_=EST` observations and in the `OUTSTAT=` data set:

- 0 The parameter estimation process converged for this model.
- 301 The parameter estimation process might not have converged for this model because there is no improvement in the objective function value. This might indicate that the initial values of the parameters are optimal, or you can try different convergence criteria in the `NLOPTIONS` statement.
- 302 The parameter estimation process might not have converged for this model because the number of iterations exceeded the maximum allowed value. You can try setting a larger value for the `MAXITER=` options in the `NLOPTIONS` statement.
- 303 The parameter estimation process might not have converged for this model because the number of objective function evaluations exceeded the maximum allowed value. You can try setting a larger value for the `MAXFUNC=` options in the `NLOPTIONS` statement.
- 304 The parameter estimation process might not have converged for this model because the time taken by the process exceeded the maximum allowed value. You can try setting a larger value for the `MAXTIME=` option in the `NLOPTIONS` statement.
- 400 The parameter estimation process did not converge for this model.

The `_STATUS_` variable can take the following values in the `OUTEST=` data set for `_TYPE_=STDERR` and `_TYPE_=COV` observations:

- 0 The covariance and standard error estimates are available and valid.
- 1 The covariance and standard error estimates are not available, because the process of computing covariance estimates failed.

Displayed Output

The SEVERITY procedure optionally produces displayed output by using the Output Delivery System (ODS). All output is controlled by the `PRINT=` option in the `PROC SEVERITY` statement. Table 23.5 relates the `PRINT=` options to ODS tables.

Table 23.5 ODS Tables Produced in PROC SEVERITY

ODS Table Name	Description	Option
AllFitStatistics	Statistics of fit for all the distribution models	PRINT=ALLFITSTATS
ConvergenceStatus	Convergence status of parameter estimation process	PRINT=CONVSTATUS
DescStats	Descriptive statistics for the response variable	PRINT=DESCSTATS
DistributionInfo	Distribution information	PRINT=DISTINFO
InitialValues	Initial parameter values and bounds	PRINT=INITIALVALUES
IterationHistory	Optimization iteration history	PRINT=NLOHISTORY
ModelSelection	Model selection summary	PRINT=SELECTION
OptimizationSummary	Optimization summary	PRINT=NLOSUMMARY
ParameterEstimates	Final parameter estimates	PRINT=ESTIMATES
RegDescStats	Descriptive statistics for the regressor variables	PRINT=DESCSTATS
StatisticsOfFit	Statistics of fit	PRINT=STATISTICS
TurnbullSummary	Turnbull EDF estimation summary	PRINT=ALL

If you do not specify the PRINT= option, then by default PROC SEVERITY produces ModelSelection, ConvergenceStatus, OptimizationSummary, StatisticsOfFit, and ParameterEstimates ODS tables.

The TurnbullSummary table is produced only if you specify PRINT=ALL and Turnbull's method is used for computing EDF estimates.

AllFitStatistics (PRINT=ALLFITSTATS)

displays the comparison of all the statistics of fit for all the models in one table. The table does not include the models whose parameter estimation process does not converge. If all the models fail to converge, then this table is not produced. If the table contains more than one model, then the best model according to each statistic is indicated with an asterisk (*) in that statistic's column.

ConvergenceStatus (PRINT=CONVSTATUS)

displays the convergence status of the parameter estimation process.

DescStats (PRINT=DESCSTATS)

displays the descriptive statistics for the response variable.

DistributionInfo (PRINT=DISTINFO)

displays the information about all the candidate distribution. It includes the name, the description, the number of distribution parameters, and whether the distribution is valid for the specified modeling task.

InitialValues (PRINT=INITIALVALUES)

displays the initial values and bounds used for estimating each model.

IterationHistory (PRINT=NLOHISTORY)

displays the iteration history of the nonlinear optimization process used for estimating the parameters.

ModelSelection (PRINT=SELECTION)

displays the model selection table. The table shows the convergence status of each candidate model, and the value of the selection criterion along with an indication of the selected model.

OptimizationSummary (PRINT=NLOSUMMARY)

displays the summary of the nonlinear optimization process used for estimating the parameters.

ParameterEstimates (PRINT=ESTIMATES)

displays the final estimates of parameters. The estimates are not displayed for models whose parameter estimation process does not converge.

RegDescStats (PRINT=DESCSTATS)

displays the descriptive statistics for the regressor variables, if you specify the SCALEMODEL statement.

StatisticsOfFit (PRINT=STATISTICS)

displays the statistics of fit for each model. The statistics of fit are not displayed for models whose parameter estimation process does not converge.

TurnbullSummary (PRINT=ALL)

displays the summary of Turnbull's estimation process if Turnbull's method is used for computing EDF estimates. The summary includes whether the nonlinear optimization converged, the number of iterations, the maximum absolute relative error, the maximum absolute reduced gradient, and whether the final estimates are maximum likelihood estimates.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User's Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the SEVERITY procedure.

ODS Graph Names

PROC SEVERITY assigns a name to each graph it creates by using ODS. You can use these names to selectively reference the graphs. The names are listed in [Table 23.6](#).

Table 23.6 ODS Graphics Produced by PROC SEVERITY

ODS Graph Name	Plot Description	PLOTS= Option
CDFPlot	Comparative CDF Plot	CDF
CDFDistPlot	CDF Plot per Distribution	CDFPERDIST
PDFPlot	Comparative PDF Plot	PDF
PDFDistPlot	PDF Plot per Distribution	PDFPERDIST
PPPlot	P-P Plot of CDF and EDF	PP
QQPlot	Q-Q Plot	QQ

Comparative CDF Plot

The comparative CDF plot helps you visually compare the cumulative distribution function (CDF) estimates of all the candidate distribution models and the empirical distribution function (EDF) estimate. The plot does not contain CDF estimates for models whose parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the CDF or EDF estimates.

If you specify truncation, then conditional CDF estimates are plotted. Otherwise, unconditional CDF estimates are plotted. The conditional estimates are computed using the method described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1660.

If you specify regressor variables, then the plotted CDF estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1667 for more information.

CDF Plot per Distribution

The CDF plot per distribution shows the CDF estimates of each candidate distribution model unless that model’s parameter estimation process does not converge. The plot also contains estimates of the EDF. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the CDF or EDF estimates.

This plot shows the lower and upper pointwise confidence limits for the EDF estimates. For an EDF estimate F_n with standard error σ_n , they are computed as $\text{MAX}(0, F_n - z_{(1-\alpha/2)}\sigma_n)$ and $\text{MIN}(1, F_n + z_{(1-\alpha/2)}\sigma_n)$ respectively, where z_p is the p th quantile from the standard normal distribution and α denotes the confidence level that you specify in the [EDFALPHA=](#) option (the default is $\alpha = 0.05$).

If you specify truncation, then conditional CDF estimates are plotted. Otherwise unconditional CDF estimates are plotted. The conditional estimates are computed using the method described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1660.

If you specify regressor variables, then the plotted CDF estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1667 for more information.

Comparative PDF Plot

The comparative PDF plot helps you visually compare the probability density function (PDF) estimates of all the candidate distribution models. The plot does not contain PDF estimates for models whose parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the PDF estimates.

If you specify the HISTOGRAM option, then the plot also contains the histogram of response variable values. If you specify the KERNEL option, then the plot also contains the kernel density estimate for the response variable values.

If you specify regressor variables, then the plotted PDF estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1667 for more information.

PDF Plot per Distribution

The PDF plot per distribution shows the PDF estimates of each candidate distribution model unless that model’s parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the PDF estimates.

If you specify the HISTOGRAM option, then the plot also contains the histogram of response variable values. If you specify the KERNEL option, then the plot also contains the kernel density estimate for the response variable values.

If you specify regressor variables, then the plotted PDF estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1667 for more information.

P-P Plot of CDF and EDF

The P-P plot of CDF and EDF is the probability-probability plot that compares the CDF estimates of a distribution with the EDF estimates. A plot is not prepared for models whose parameter estimation process does not converge. The horizontal axis represents the CDF estimates of a candidate distribution and the vertical axis represents the EDF estimates.

This plot can be interpreted as displaying the data that are used for computing the EDF-based statistics of fit for the given candidate distribution. As described in the section “[EDF-Based Statistics](#)” on page 1676, these statistics are computed by comparing the EDF, denoted by $F_n(y)$, and the CDF, denoted by $F(y)$, at each of the response variable values y . Using the probability inverse transform $z = F(y)$, this is equivalent to comparing the EDF of the z , denoted by $F_n(z)$, and the CDF of z , denoted by $F(z)$ (D’Agostino and Stephens 1986, Ch. 4). Given that the CDF of z is a uniform distribution ($F(z) = z$), the EDF-based statistics can be computed by comparing the EDF estimate of z with the estimate of z . The horizontal axis of the plot represents the estimated CDF $\hat{z} = \hat{F}(y)$. The vertical axis represents the estimated EDF of z , $\hat{F}_n(z)$. The plot contains a scatter plot of $(\hat{z}, \hat{F}_n(z))$ points and a reference line $F_n(z) = z$ that represents the expected uniform distribution of z . Points scattered closer to the reference line indicate a better fit than the points scattered away from the reference line.

If you specify truncation, then the EDF estimates are conditional as described in the section “[EDF Estimates and Truncation](#)” on page 1673. So, conditional estimates of CDF are displayed, which are computed using the method described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1660.

If you specify regressor variables, then the displayed CDF estimates, both unconditional and conditional, are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1667 for more information.

Q-Q Plot

The Q-Q plot is a quantile-quantile scatter plot that compares the empirical quantiles with the quantiles from a candidate distribution. A plot is not prepared for models whose parameter estimation process does not converge. The horizontal axis represents the quantiles from a candidate distribution, and the vertical axis represents the empirical quantiles.

Each point in the plot corresponds to a specific value of EDF estimate, F_n . The Y coordinate is the value of the response variable for which F_n is computed. The X coordinate is computed by using one of two following methods for a candidate distribution named *dist*:

- If you have defined the *dist_QUANTILE* function that satisfies the requirements listed in the section “*dist_QUANTILE*” on page 1687, then that function is invoked with F_n and estimated distribution parameters as arguments. The *QUANTILE* function is defined in the Sashelp.Svrtldist library for all the predefined distributions except for the Burr distribution.
- If the *dist_QUANTILE* function is not defined, then PROC SEVERITY numerically inverts the *dist_CDF* function at the CDF value of F_n for the estimated distribution parameters. If the *dist_CDF* function is not defined, then the *exp(dist_LOGCDF)* function is inverted. If the inversion fails, the corresponding point is not plotted in the Q-Q plot.

If you specify truncation, then the EDF estimates are conditional as described in the section “*EDF Estimates and Truncation*” on page 1673. The CDF inversion process, whether done numerically or by evaluating the *dist_QUANTILE* function, needs to accept an unconditional CDF value. So, the F_n value is first transformed to an unconditional estimate F_n^u as

$$F_n^u = F_n \cdot (\hat{F}(t_{\max}^r) - \hat{F}(t_{\min}^l)) + \hat{F}(t_{\min}^l)$$

where $\hat{F}(t_{\max}^r)$ and $\hat{F}(t_{\min}^l)$ are as defined in the section “*Truncation and Conditional CDF Estimates*” on page 1660.

If you specify regressor variables, then the value of the first distribution parameter is the mean of the scale values that are implied by all the observations in the current BY group (or in the entire DATA= data set if you do not specify the BY statement).

Examples: SEVERITY Procedure

Example 23.1: Defining a Model for Gaussian Distribution

Suppose you want to fit a distribution model other than one of the predefined ones available to you. Suppose you want to define a model for the Gaussian distribution with the following typical parameterization of the PDF (f) and CDF (F):

$$f(x; \mu, \sigma) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(x - \mu)^2}{2\sigma^2}\right)$$

$$F(x; \mu, \sigma) = \frac{1}{2} \left(1 + \operatorname{erf}\left(\frac{x - \mu}{\sigma\sqrt{2}}\right)\right)$$

For PROC SEVERITY, a *distribution model* consists of a set of functions and subroutines that are defined with the FCMP procedure. Each function and subroutine should be written following certain rules. For more information, see the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1679.

NOTE: The Gaussian distribution is not a commonly used severity distribution. It is used in this example primarily to illustrate the process of defining your own distribution models. Although the distribution has a support over the entire real line, you can fit the distribution with PROC SEVERITY only if the input sample contains nonnegative values.

The following SAS statements define a distribution model named NORMAL for the Gaussian distribution. The OUTLIB= option in the PROC FCMP statement stores the compiled versions of the functions and subroutines in the ‘models’ package of the Work.Sevexmpl library. The LIBRARY= option in the PROC FCMP statement enables this PROC FCMP step to use the SVRTUTIL_RAWMOMENTS utility subroutine that is available in the Sashelp.Svrtldist library. The subroutine is described in the section “[Predefined Utility Functions](#)” on page 1691.

```

/*----- Define Normal Distribution with PROC FCMP -----*/
proc fcmp library=sashelp.svrtldist outlib=work.sevexmpl.models;
  function normal_pdf(x,Mu,Sigma);
    /* Mu      : Location */
    /* Sigma   : Standard Deviation */
    return ( exp(-(x-Mu)**2/(2 * Sigma**2)) /
              (Sigma * sqrt(2*constant('PI')))) );
  endsub;

  function normal_cdf(x,Mu,Sigma);
    /* Mu      : Location */
    /* Sigma   : Standard Deviation */
    z = (x-Mu)/Sigma;
    return (0.5 + 0.5*erf(z/sqrt(2)));
  endsub;

  subroutine normal_parminit(dim, x[*], nx[*], F[*], Ftype, Mu, Sigma);
    outargs Mu, Sigma;
    array m[2] / nosymbols;

    /* Compute estimates by using method of moments */
    call svrtutil_rawmoments(dim, x, nx, 2, m);
    Mu    = m[1];
    Sigma = sqrt(m[2] - m[1]**2);
  endsub;

  subroutine normal_lowerbounds(Mu, Sigma);
    outargs Mu, Sigma;
    Mu = .; /* Mu has no lower bound */
    Sigma = 0; /* Sigma > 0 */
  endsub;
quit;

```

The statements define the two functions required of any distribution model (NORMAL_PDF and NORMAL_CDF) and two optional subroutines (NORMAL_PARMINIT and NORMAL_LOWERBOUNDS). The name of each function or subroutine must follow a specific structure. It should start with the model’s

short or identifying name, which is 'NORMAL' in this case, followed by an underscore '_', followed by a keyword suffix such as 'PDF'. Each function or subroutine has a specific purpose. For more information about all the functions and subroutines that you can define for a distribution model, see the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1679. Following is the description of each function and subroutine defined in this example:

- The PDF and CDF suffixes define functions that return the probability density function and cumulative distribution function values, respectively, given the values of the random variable and the distribution parameters.
- The PARMINIT suffix defines a subroutine that returns the initial values for the parameters by using the sample data or the empirical distribution function (EDF) estimate computed from it. In this example, the parameters are initialized by using the method of moments. Hence, you do not need to use the EDF estimates, which are available in the F array. The first two raw moments of the Gaussian distribution are as follows:

$$E[x] = \mu, E[x^2] = \mu^2 + \sigma^2$$

Given the sample estimates, m_1 and m_2 , of these two raw moments, you can solve the equations $E[x] = m_1$ and $E[x^2] = m_2$ to get the following estimates for the parameters: $\hat{\mu} = m_1$ and $\hat{\sigma} = \sqrt{m_2 - m_1^2}$. The NORMAL_PARMINIT subroutine implements this solution. It uses the SVRTUTIL_RAWMOMENTS utility subroutine to compute the first two raw moments.

- The LOWERBOUNDS suffix defines a subroutine that returns the lower bounds on the parameters. PROC SEVERITY assumes a default lower bound of 0 for all the parameters when a LOWERBOUNDS subroutine is not defined. For the parameter μ (Mu), there is no lower bound, so you need to define the NORMAL_LOWERBOUNDS subroutine. It is recommended that you assign bounds for all the parameters when you define the LOWERBOUNDS subroutine or its counterpart, the UPPERBOUNDS subroutine. Any unassigned value is returned as a missing value, which is interpreted by PROC SEVERITY to mean that the parameter is unbounded, and that might not be what you want.

You can now use this distribution model with PROC SEVERITY. Let the following DATA step statements simulate a normal sample with $\mu = 10$ and $\sigma = 2.5$.

```
/*----- Simulate a Normal sample -----*/
data testnorm(keep=y);
  call streaminit(12345);
  do i=1 to 100;
    y = rand('NORMAL', 10, 2.5);
    output;
  end;
run;
```

Prior to using your distribution with PROC SEVERITY, you must communicate the location of the library that contains the definition of the distribution and the locations of libraries that contain any functions and subroutines used by your distribution model. The following OPTIONS statement sets the CMPLIB= system option to include the FCMP library Work.Sevexmpl in the search path used by PROC SEVERITY to find FCMP functions and subroutines.

```
/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);
```

Now, you are ready to fit the NORMAL distribution model with PROC SEVERITY. The following statements fit the model to the values of Y in the Work.Testnorm data set:

```
/*--- Fit models with PROC SEVERITY ---*/
proc severity data=testnorm print=all;
  loss y;
  dist Normal;
run;
```

The DIST statement specifies the identifying name of the distribution model, which is 'NORMAL'. Neither is the INEST= option specified in the PROC SEVERITY statement nor is the INIT= option specified in the DIST statement. So, PROC SEVERITY initializes the parameters by invoking the NORMAL_PARMINIT subroutine.

Some of the results prepared by the preceding PROC SEVERITY step are shown in [Output 23.1.1](#) and [Output 23.1.2](#). The descriptive statistics of variable Y and the “Model Selection Table”, which includes just the normal distribution, are shown in [Output 23.1.1](#).

Output 23.1.1 Summary of Results for Fitting the Normal Distribution

The SEVERITY Procedure			
Input Data Set			
Name	WORK.TESTNORM		
Descriptive Statistics for y			
Observations			100
Observations Used for Estimation			100
Minimum			3.88249
Maximum			16.00864
Mean			10.02059
Standard Deviation			2.37730
Model Selection			
Distribution	Converged	-2 Log Likelihood	Selected
Normal	Yes	455.97541	Yes

The initial values for the parameters, the optimization summary, and the final parameter estimates are shown in [Output 23.1.2](#). No iterations are required to arrive at the final parameter estimates, which are identical to the initial values. This confirms the fact that the maximum likelihood estimates for the Gaussian distribution are identical to the estimates obtained by the method of moments that was used to initialize the parameters in the NORMAL_PARMINIT subroutine.

Output 23.1.2 Details of the Fitted Normal Distribution Model

The SEVERITY Procedure				
Normal Distribution				
Distribution Information				
Name	Normal			
Distribution Parameters	2			
Initial Parameter Values and Bounds				
Parameter	Initial Value	Lower Bound	Upper Bound	
Mu	10.02059	-Infty	Infty	
Sigma	2.36538	1.05367E-8	Infty	
Optimization Summary				
Optimization Technique	Trust Region			
Iterations	0			
Function Calls	4			
Log Likelihood	-227.98770			
Parameter Estimates				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Mu	10.02059	0.23894	41.94	<.0001
Sigma	2.36538	0.16896	14.00	<.0001

The NORMAL distribution defined and illustrated here has no scale parameter, because all the following inequalities are true:

$$f(x; \mu, \sigma) \neq \frac{1}{\mu} f\left(\frac{x}{\mu}; 1, \sigma\right)$$

$$f(x; \mu, \sigma) \neq \frac{1}{\sigma} f\left(\frac{x}{\sigma}; \mu, 1\right)$$

$$F(x; \mu, \sigma) \neq F\left(\frac{x}{\mu}; 1, \sigma\right)$$

$$F(x; \mu, \sigma) \neq F\left(\frac{x}{\sigma}; \mu, 1\right)$$

This implies that you cannot estimate the effect of regressors on a model for the response variable based on this distribution.

Example 23.2: Defining a Model for Gaussian Distribution with a Scale Parameter

If you want to estimate the effects of regressors, then the model needs to be parameterized to have a scale parameter. While this might not be always possible, for the case of the Gaussian distribution it is possible by replacing the location parameter μ with another parameter, $\alpha = \mu/\sigma$, and defining the PDF (f) and the CDF (F) as follows:

$$f(x; \sigma, \alpha) = \frac{1}{\sigma \sqrt{2\pi}} \exp \left(-\frac{1}{2} \left(\frac{x}{\sigma} - \alpha \right)^2 \right)$$

$$F(x; \sigma, \alpha) = \frac{1}{2} \left(1 + \operatorname{erf} \left(\frac{1}{\sqrt{2}} \left(\frac{x}{\sigma} - \alpha \right) \right) \right)$$

It can be verified that σ is the scale parameter, because both of the following equalities are true:

$$f(x; \sigma, \alpha) = \frac{1}{\sigma} f\left(\frac{x}{\sigma}; 1, \alpha\right)$$

$$F(x; \sigma, \alpha) = F\left(\frac{x}{\sigma}; 1, \alpha\right)$$

NOTE: The Gaussian distribution is not a commonly used severity distribution. It is used in this example primarily to illustrate the concept of parameterizing a distribution such that it has a scale parameter. Although the distribution has a support over the entire real line, you can fit the distribution with PROC SEVERITY only if the input sample contains nonnegative values.

The following statements use the alternate parameterization to define a new model named NORMAL_S. The definition is stored in the Work.Sevexmpl library.

```
/*----- Define Normal Distribution With Scale Parameter -----*/
proc fcmp library=sashelp.svrtldist outlib=work.sevexmpl.models;
  function normal_s_pdf(x, Sigma, Alpha);
    /* Sigma : Scale & Standard Deviation */
    /* Alpha : Scaled mean */
    return ( exp(-(x/Sigma - Alpha)**2/2) /
              (Sigma * sqrt(2*constant('PI'))) );
  endsub;

  function normal_s_cdf(x, Sigma, Alpha);
    /* Sigma : Scale & Standard Deviation */
    /* Alpha : Scaled mean */
    z = x/Sigma - Alpha;
    return (0.5 + 0.5*erf(z/sqrt(2)));
  endsub;

  subroutine normal_s_parinit(dim, x[*], nx[*], F[*], Ftype, Sigma, Alpha);
    outargs Sigma, Alpha;
    array m[2] / nosymbols;

    /* Compute estimates by using method of moments */
```

```

    call svrtutil_rawmoments(dim, x, nx, 2, m);
    Sigma = sqrt(m[2] - m[1]**2);
    Alpha = m[1]/Sigma;
endsub;

subroutine normal_s_lowerbounds(Sigma, Alpha);
    outargs Sigma, Alpha;
    Alpha = .; /* Alpha has no lower bound */
    Sigma = 0; /* Sigma > 0 */
endsub;
quit;

```

An important point to note is that the scale parameter *Sigma* is the first distribution parameter (after the 'x' argument) listed in the signatures of NORMAL_S_PDF and NORMAL_S_CDF functions. *Sigma* is also the first distribution parameter listed in the signatures of other subroutines. This is required by PROC SEVERITY, so that it can identify which is the scale parameter. When you specify regressor variables, PROC SEVERITY checks whether the first parameter of each candidate distribution is a scale parameter (or a log-transformed scale parameter if [dist_SCALETRANSFORM](#) subroutine is defined for the distribution with LOG as the transform). If it is not, then an appropriate message is written the SAS log and that distribution is not fitted.

Let the following DATA step statements simulate a sample from the normal distribution where the parameter σ is affected by the regressors as follows:

$$\sigma = \exp(1 + 0.5 X_1 + 0.75 X_3 - 2 X_4 + X_5)$$

The sample is simulated such that the regressor X2 is linearly dependent on regressors X1 and X3.

```

/*--- Simulate a Normal sample affected by Regressors ---*/
data testnorm_reg(keep=y x1-x5 Sigma);
    array x{*} x1-x5;
    array b{6} _TEMPORARY_ (1 0.5 . 0.75 -2 1);
    call streaminit(34567);
    label y='Normal Response Influenced by Regressors';

    do n = 1 to 100;
        /* simulate regressors */
        do i = 1 to dim(x);
            x(i) = rand('UNIFORM');
        end;
        /* make x2 linearly dependent on x1 and x3 */
        x(2) = x(1) + 5 * x(3);

        /* compute log of the scale parameter */
        logSigma = b(1);
        do i = 1 to dim(x);
            if (i ne 2) then
                logSigma = logSigma + b(i+1) * x(i);
        end;

        Sigma = exp(logSigma);
        y = rand('NORMAL', 25, Sigma);
        output;
    end;
run;

```

The following statements use PROC SEVERITY to fit the NORMAL_S distribution model along with some of the predefined distributions to the simulated sample:

```

/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);

/*----- Fit models with PROC SEVERITY -----*/
proc severity data=testnorm_reg print=all plots=none;
  loss y;
  scalemodel x1-x5;
  dist Normal_s burr logn pareto weibull;
run;

```

The “Model Selection Table” in [Output 23.2.1](#) indicates that all the models, except the Burr distribution model, have converged. Also, only three models, Normal_s, Burr, and Weibull, seem to have a good fit for the data. The table that compares all the fit statistics indicates that Normal_s model is the best according to the likelihood-based statistics; however, the Burr model is the best according to the EDF-based statistics.

Output 23.2.1 Summary of Results for Fitting the Normal Distribution with Regressors

Logn	16.20558	3.04825
Pareto	31.60568	6.84046
Weibull	3.90559	0.63458

Note: The asterisk (*) marks the best model according to each column's criterion.

This prompts for further evaluation of why the model with Burr distribution has not converged. The initial values, convergence status, and the optimization summary for the Burr distribution are shown in [Output 23.2.2](#). The initial values table indicates that the regressor X2 is redundant, which is expected. More importantly, the convergence status indicates that it requires more than 50 iterations. PROC SEVERITY enables you to change several settings of the optimizer by using the [NLOPTIONS](#) statement. In this case, you can increase the limit of 50 on the iterations, change the convergence criterion, or change the technique to something other than the default trust-region technique.

Output 23.2.2 Details of the Fitted Burr Distribution Model

The SEVERITY Procedure	
Burr Distribution	
Distribution Information	
Name	Burr
Description	Burr Distribution
Distribution Parameters	3
Regression Parameters	4

Output 23.2.2 *continued*

Initial Parameter Values and Bounds			
Parameter	Initial Value	Lower Bound	Upper Bound
Theta	25.75198	1.05367E-8	Infty

Convergence Status	
Needs more than 50 iterations.	

Optimization Summary	
Optimization Technique	Trust Region
Iterations	50
Function Calls	137
Log Likelihood	-306.40842

The following PROC SEVERITY step uses the NLOPTIONS statement to change the convergence criterion and the limits on the iterations and function evaluations, exclude the lognormal and Pareto distributions that have been confirmed previously to fit the data poorly, and exclude the redundant regressor X2 from the model:

```

/*--- Refit and compare models with higher limit on iterations ---*/
proc severity data=testnorm_reg print=all plots=pp;
  loss y;
  scalemodel x1 x3-x5;
  dist Normal_s burr weibull;
  nloptions absfconv=2.0e-5 maxiter=100 maxfunc=500;
run;

```

The results shown in [Output 23.2.3](#) indicate that the Burr distribution has now converged and that the Burr and Weibull distributions have an almost identical fit for the data. The NORMAL_S distribution is still the best distribution according to the likelihood-based criteria.

Output 23.2.3 Summary of Results after Changing Maximum Number of Iterations

The SEVERITY Procedure	
Input Data Set	
Name	WORK.TESTNORM_REG

Output 23.2.3 *continued*

Note: The asterisk (*) marks the best model according to each column's criterion.

The comparison of the PDF estimates of all the candidates is shown in [Output 23.2.4](#). Each plotted PDF estimate is an average computed over the N PDF estimates that are obtained with the scale parameter determined by each of the N observations in the input data set. The PDF plot shows that the Burr and Weibull models result in almost identical estimates. All the estimates have a slight left skew with the mode closer to $Y=25$, which is the mean of the simulated sample.

Output 23.2.4 Comparison of EDF and CDF Estimates of the Fitted Models

The P-P plots for the Normal_s and Burr distributions are shown in [Output 23.2.5](#). These plots show how the EDF estimates compare against the CDF estimates. Each plotted CDF estimate is an average computed over the N CDF estimates that are obtained with the scale parameter determined by each of the N observations in the input data set. Comparing the P-P plots of Normal_s and Burr distributions indicates that both fit the data almost similarly, but the Burr distribution fits the right tail slightly better, which explains why the EDF-based statistics prefer it over the Normal_s distribution.

Output 23.2.5 Comparison of EDF and CDF Estimates of NORMAL_S and BURR Models**Example 23.3: Defining a Model for Mixed-Tail Distributions**

In some applications, a few severity values tend to be extreme as compared to the typical values. The extreme values represent the worst case scenarios and cannot be discarded as outliers. Instead, their distribution must be modeled to prepare for their occurrences. In such cases, it is often useful to fit one distribution to the non-extreme values and another distribution to the extreme values. The *mixed-tail* distribution mixes two distributions: one for the *body* region, which contains the non-extreme values, and another for the *tail* region, which contains the extreme values. The tail distribution is typically a generalized Pareto distribution (GPD), because it is usually good for modeling the conditional excess severity above a threshold. The body distribution can be any distribution. The following definitions are used in describing a generic formulation of a mixed-tail distribution:

$g(x)$	PDF of the body distribution
$G(x)$	CDF of the body distribution
$h(x)$	PDF of the tail distribution
$H(x)$	CDF of the tail distribution
θ	scale parameter for the body distribution
Ω	set of nonscale parameters for the body distribution
ξ	shape parameter for the GPD tail distribution
x_r	normalized value of the response variable at which the tail starts
p_n	mixing probability

Given these notations, the PDF $f(x)$ and the CDF $F(x)$ of the mixed-tail distribution are defined as

$$f(x) = \begin{cases} \frac{p_n}{G(x_b)} g(x) & \text{if } x \leq x_b \\ (1 - p_n)h(x - x_b) & \text{if } x > x_b \end{cases}$$

$$F(x) = \begin{cases} \frac{p_n}{G(x_b)} G(x) & \text{if } x \leq x_b \\ p_n + (1 - p_n)H(x - x_b) & \text{if } x > x_b \end{cases}$$

where $x_b = \theta x_r$ is the value of the response variable at which the tail starts.

These definitions indicate the following:

- The body distribution is conditional on $X \leq x_b$, where X denotes the random response variable.
- The tail distribution is the generalized Pareto distribution of the $(X - x_b)$ values.
- The probability that a response variable value belongs to the body is p_n . Consequently the probability that the value belongs to the tail is $(1 - p_n)$.

The parameters of this distribution are θ , Ω , ξ , x_r , and p_n . The scale of the GPD tail distribution θ_t is computed as

$$\theta_t = \frac{G(x_b; \theta, \Omega) (1 - p_n)}{g(x_b; \theta, \Omega) p_n} = \theta \frac{G(x_r; \theta = 1, \Omega) (1 - p_n)}{g(x_r; \theta = 1, \Omega) p_n}$$

The parameter x_r is typically estimated using a tail index estimation algorithm. One such algorithm is the Hill's algorithm (Danielsson et al. 2001), which is implemented by the predefined utility function SVRTUTIL_HILLCUTOFF available to you in the Sashelp.Svrtldist library. The algorithm and the utility function are described in detail in the section “[Predefined Utility Functions](#)” on page 1691. The function computes an estimate of x_b , which can be used to compute an estimate of x_r because $x_r = x_b / \hat{\theta}$, where $\hat{\theta}$ is the estimate of the scale parameter of the body distribution.

The parameter p_n is typically determined by the domain expert based on the fraction of losses that are expected to belong to the tail.

The following SAS statements define the LOGNGPD distribution model for a mixed-tail distribution with the lognormal distribution as the body distribution and GPD as the tail distribution:

```
/*----- Define Lognormal Body-GPD Tail Mixed Distribution -----*/
proc fcmp library=sashelp.svrtldist outlib=work.sevexmpl.models;
  function LOGNGPD_DESCRIPTION() $256;
    length desc $256;
    desc1 = "Lognormal Body-GPD Tail Distribution.";
    desc2 = " Mu, Sigma, and Xi are free parameters.";
    desc3 = " Xr and Pn are constant parameters.";
    desc = desc1 || desc2 || desc3;
    return(desc);
  endsub;

  function LOGNGPD_SCALETRANSFORM() $3;
    length xform $3;
    xform = "LOG";
    return (xform);
  endsub;
```

```

endsub;

subroutine LOGNGPD_CONSTANTPARM(Xr,Pn);
endsub;

function LOGNGPD_PDF(x, Mu,Sigma,Xi,Xr,Pn);
  cutoff = exp(Mu) * Xr;
  p = CDF('LOGN',cutoff, Mu, Sigma);
  if (x < cutoff + constant('MACEPS')) then do;
    return ((Pn/p)*PDF('LOGN', x, Mu, Sigma));
  end;
  else do;
    gpd_scale = p*((1-Pn)/Pn)/PDF('LOGN', cutoff, Mu, Sigma);
    h = (1+Xi*(x-cutoff)/gpd_scale)**(-1-(1/Xi))/gpd_scale;
    return ((1-Pn)*h);
  end;
endsub;

function LOGNGPD_CDF(x, Mu,Sigma,Xi,Xr,Pn);
  cutoff = exp(Mu) * Xr;
  p = CDF('LOGN',cutoff, Mu, Sigma);
  if (x < cutoff + constant('MACEPS')) then do;
    return ((Pn/p)*CDF('LOGN', x, Mu, Sigma));
  end;
  else do;
    gpd_scale = p*((1-Pn)/Pn)/PDF('LOGN', cutoff, Mu, Sigma);
    H = 1 - (1 + Xi*((x-cutoff)/gpd_scale))**(-1/Xi);
    return (Pn + (1-Pn)*H);
  end;
endsub;

subroutine LOGNGPD_PARMINIT(dim,x[*],nx[*],F[*],Ftype,
                          Mu,Sigma,Xi,Xr,Pn);
  outargs Mu,Sigma,Xi,Xr,Pn;
  array xe[1] / nosymbols;
  array nxe[1] / nosymbols;

  eps = constant('MACEPS');

  Pn = 0.8; /* Set mixing probability */
  _status_ = .;
  call streaminit(56789);
  Xb = svrtutil_hillcutoff(dim, x, 100, 25, _status_);
  if (missing(_status_) or _status_ = 1) then
    Xb = svrtutil_percentile(Pn, dim, x, F, Ftype);

  /* prepare arrays for excess values */
  i = 1;
  do while (i <= dim and x[i] < Xb+eps);
    i = i + 1;
  end;
  dime = dim-i+1;
  call dynamic_array(xe, dime);
  call dynamic_array(nxe, dime);

```

```

j = 1;
do while(i <= dim);
    xe[j] = x[i] - Xb;
    nxe[j] = nx[i];
    i = i + 1;
    j = j + 1;
end;

/* Initialize lognormal parameters */
call logn_parminit(dim, x, nx, F, Ftype, Mu, Sigma);
if (not(missing(Mu))) then
    Xr = Xb/exp(Mu);
else
    Xr = .;

/* Initialize GPD's shape parameter using excess values */
call gpd_parminit(dime, xe, nxe, F, Ftype, theta_gpd, Xi);
endsub;

subroutine LOGNGPD_LOWERBOUNDS(Mu, Sigma, Xi, Xr, Pn);
    outargs Mu, Sigma, Xi, Xr, Pn;

    Mu = .; /* Mu has no lower bound */
    Sigma = 0; /* Sigma > 0 */
    Xi = 0; /* Xi > 0 */
endsub;
quit;

```

The following points should be noted regarding the LOGNGPD definition:

- The parameters x_r and p_n are not estimated with the maximum likelihood method used by PROC SEVERITY, so you need to specify them as *constant* parameters by defining the [dist_CONSTANTPARM](#) subroutine. The signature of LOGNGPD_CONSTANTPARM subroutine lists only the constant parameters Xr and Pn .
- The parameter x_r is estimated by first using the SVRTUTIL_HILLCUTOFF utility function to compute an estimate of the cutoff point \hat{x}_b and then computing $x_r = \hat{x}_b / e^{\hat{\mu}}$. If SVRTUTIL_HILLCUTOFF fails to compute a valid estimate, then the SVRTUTIL_PERCENTILE utility function is used to set \hat{x}_b to the p_n th percentile of the data. The parameter p_n is fixed to 0.8.
- The Sashelp.Svrtdist library is specified with the LIBRARY= option in the PROC FCMP statement to enable the LOGNGPD_PARMINIT subroutine to use the predefined utility functions (SVRTUTIL_HILLCUTOFF and SVRTUTIL_PERCENTILE) and parameter initialization subroutines (LOGN_PARMINIT and GPD_PARMINIT).
- The LOGNGPD_LOWERBOUNDS subroutine defines the lower bounds for all parameters. This subroutine is required because the parameter Mu has a non-default lower bound. The bounds for $Sigma$ and Xi must be specified. If they are not specified, they are returned as missing values, which get interpreted as having no lower bound by PROC SEVERITY. You need not specify any bounds for the constant parameters Xr and Pn , because they are not subject to optimization.

The following DATA step statements simulate a sample from a mixed-tail distribution with a lognormal body and GPD tail. The parameter p_n is fixed to 0.8, the same value used in the LOGNGPD_PARMINIT subroutine defined previously:

```

/*----- Simulate a sample for the mixed-tail distribution -----*/
data testmixdist(keep=y label='Lognormal Body-GPD Tail Sample');
  call streaminit(45678);
  label y='Response Variable';
  N = 100;
  Mu = 1.5;
  Sigma = 0.25;
  Xi = 1.5;
  Pn = 0.8;

  /* Generate data comprising the lognormal body */
  Nbody = N*Pn;
  do i=1 to Nbody;
    y = exp(Mu) * rand('LOGNORMAL')**Sigma;
    output;
  end;

  /* Generate data comprising the GPD tail */
  cutoff = quantile('LOGNORMAL', Pn, Mu, Sigma);
  gpd_scale = (1-Pn) / pdf('LOGNORMAL', cutoff, Mu, Sigma);
  do i=Nbody+1 to N;
    y = cutoff + ((1-rand('UNIFORM'))**(-Xi) - 1)*gpd_scale/Xi;
    output;
  end;
run;

```

The following statements use PROC SEVERITY to fit the LOGNGPD distribution model to the simulated sample. They also fit three other predefined distributions (BURR, LOGN, and GPD). The final parameter estimates are written to the Work.Parmest data set.

```

/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);

/*----- Fit LOGNGPD model with PROC SEVERITY -----*/
proc severity data=testmixdist print=all plots(histogram kernel)=all
  outest=parmest;
  loss y;
  dist logngpd burr logn gpd;
run;

```

Some of the results prepared by PROC SEVERITY are shown in [Output 23.3.1](#) through [Output 23.3.4](#). The “Model Selection Table” in [Output 23.3.1](#) indicates that all models converged. The last table in [Output 23.3.1](#) shows that the model with LOGNGPD distribution has the best fit according to almost all the statistics of fit. The Burr distribution model is the closest contender to the LOGNGPD model, but the GPD distribution model fits the data very poorly.

Output 23.3.1 Summary of Fitting Mixed-Tail Distribution

The SEVERITY Procedure					
Input Data Set					
Name	WORK.TESTMIXDIST				
Label	Lognormal Body-GPD Tail Sample

The following SAS statements use the parameter estimates to compute the value where the tail region is estimated to start ($x_b = e^{\hat{\mu}} \hat{x}_r$) and the scale of the GPD tail distribution ($\theta_t = \frac{G(x_b)}{g(x_b)} \frac{(1-p_n)}{p_n}$):

```

/*----- Compute tail cutoff and tail distribution's scale -----*/
data xb_thetat(keep=x_b theta_t);
  set parmesest(where=(_MODEL_='logngpd' and _TYPE_='EST'));
  x_b = exp(Mu) * Xr;
  theta_t = (CDF('LOGN',x_b,Mu,Sigma)/PDF('LOGN',x_b,Mu,Sigma)) *
            ((1-Pn)/Pn);
run;

proc print data=xb_thetat noobs;
run;

```

Output 23.3.5 Start of the Tail and Scale of the GPD Tail Distribution

x_b	theta_t
6.18005	1.27865

The computed values of x_b and θ_t are shown as `x_b` and `theta_t` in [Output 23.3.5](#). Equipped with this additional derived information, you can now interpret the results of fitting the mixed-tail distribution as follows:

- The tail starts at $y \approx 6.18$. The primary benefit of using the scale-normalized cutoff (x_r) as the constant parameter instead of using the actual cutoff (x_b) is that the absolute cutoff gets optimized by virtue of optimizing the scale of the body region ($\theta = e^\mu$).
- The values $y \leq 6.18$ follow the lognormal distribution with parameters $\mu \approx 1.58$ and $\sigma \approx 0.32$. These parameter estimates are reasonably close to the parameters used for simulating the sample.
- The values $y_t = y - 6.18$ ($y_t > 0$) follow the GPD distribution with scale $\theta_t \approx 1.28$ and shape $\xi \approx 1.04$.

Example 23.4: Estimating Parameters Using Cramér-von Mises Estimator

PROC SEVERITY enables you to estimate model parameters by minimizing your own objective function. This example illustrates how you can use PROC SEVERITY to implement the Cramér-von Mises estimator. Let $F(y_i; \Theta)$ denote the estimate of CDF at y_i for a distribution with parameters Θ , and let $F_n(y_i)$ denote the empirical estimate of CDF (EDF) at y_i that is computed from a sample y_i , $1 \leq i \leq N$. Then, the Cramér-von Mises estimator of the parameters is defined as

$$\hat{\Theta} = \arg \min_{\Theta} \sum_{i=1}^N (F(y_i; \Theta) - F_n(y_i))^2$$

This estimator belongs to the class of minimum distance estimators. It attempts to estimate the parameters such that the squared distance between the CDF and EDF estimates is minimized.

The following PROC SEVERITY step uses the Cramér-von Mises estimator to fit four candidate distribution models, including the LOGNGPD mixed-tail distribution model that was defined in “[Example 23.3: Defining a Model for Mixed-Tail Distributions](#)” on page 1729. The input sample is the same as is used in that example.

```

/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);

/*----- Fit LOGNGPD model with PROC HPSEVERITY by using -----
----- the Cramer-von Mises minimum distance estimator -----*/
proc severity data=testmixdist obj=cvmobj print=all plots=pp;
  loss y;
  dist logngpd burr logn gpd;

  * Cramer-von Mises estimator (minimizes the distance *
  * between parametric and nonparametric estimates)    *;
  cvmobj = _cdf_(y);
  cvmobj = (cvmobj - _edf_(y))**2;
run;

```

The OBJ= option in the PROC SEVERITY statement specifies that the objective function cvmobj should be minimized. The programming statements compute the contribution of each observation in the input data set to the objective function cvmobj. The use of keyword functions _CDF_ and _EDF_ makes the program applicable to all the distributions.

Some of the key results prepared by PROC SEVERITY are shown in [Output 23.4.1](#). The “Model Selection Table” indicates that all models converged. When you specify a custom objective function, the default selection criterion is the value of the custom objective function. The “All Fit Statistics Table” indicates that LOGNGPD is the best distribution according to all the statistics of fit. Comparing the fit statistics of [Output 23.4.1](#) with those of [Output 23.3.1](#) indicates that the use of the Cramér-von Mises estimator has resulted in smaller values for all the EDF-based statistics of fit for all the models, which is expected from a minimum distance estimator.

Output 23.4.1 Summary of Cramér-von Mises Estimation

Example 23.5: Fitting a Scaled Tweedie Model with Regressors

The Tweedie distribution is often used in the insurance industry to explain the effect of independent variables (regressors) on the distribution of losses. PROC SEVERITY provides a predefined scaled Tweedie distribution (STWEEDIE) that enables you to model the regression effects on the scale parameter. The scale regression model has its own advantages such as the ability to easily account for inflation effects. This example illustrates how that model can be used to evaluate the effect of regressors on the *mean* of the Tweedie distribution, which is useful in problems such rate-making and pure premium modeling.

Assume a Tweedie process, whose mean μ is affected by k regressors x_j , $j = 1, \dots, k$ as follows:

$$\mu = \mu_0 \exp \left(\sum_{j=1}^k \beta_j x_j \right)$$

where μ_0 represents the base value of the mean (you can think of μ_0 as $\exp(\beta_0)$, where β_0 is the intercept). This model for the mean is identical to the popular generalized linear model for the mean with a logarithmic link function. More interestingly, it parallels the model used by PROC SEVERITY for the scale parameter θ , which is as follows

$$\theta = \theta_0 \exp \left(\sum_{j=1}^k \beta_j x_j \right)$$

where θ_0 represents the base value of the scale parameter. As described in the section “[Tweedie Distributions](#)” on page 1651, for the parameter range $p \in (1, 2)$, the mean of the Tweedie distribution is given by

$$\mu = \theta \lambda \frac{2-p}{p-1}$$

where λ is the Poisson mean parameter of the scaled Tweedie distribution. This relationship enables you to use the scale regression model to infer the effect of regressors on the mean of the distribution.

Let the data set `Work.Test_Sevtw` contain a sample generated from a Tweedie distribution with dispersion parameter $\phi = 0.5$, index parameter $p = 1.75$, and the mean parameter that is affected by three regression variables `x1`, `x2`, and `x3` as follows:

$$\mu = 5 \exp(0.25 x_1 - x_2 + 3 x_3)$$

Thus, the population values of regression parameters are $\mu_0 = 5$, $\beta_1 = 0.25$, $\beta_2 = -1$, and $\beta_3 = 3$. You can find the code used to generate the sample in the PROC SEVERITY sample program `sevex05.sas`.

The following PROC SEVERITY step uses the sample in `Work.Test_Sevtw` data set to estimate the parameters of the scale regression model for the predefined scaled Tweedie distribution (STWEEDIE) with the dual quasi-Newton (QUANEW) optimization technique:

```
/*--- Fit the scale parameter version of the Tweedie distribution ---*/
proc severity data=test_sevtw outest=estw covout print=all plots=none;
  loss y;
  scalemodel x1-x3;

  dist stweedie;
  nloptions tech=quanew;
run;
```

The dual quasi-Newton technique is used because it requires only the first-order derivatives of the objective function, and it is harder to compute reasonably accurate estimates of the second-order derivatives of Tweedie distribution's PDF with respect to the parameters.

Some of the key results prepared by PROC SEVERITY are shown in [Output 23.5.1](#) and [Output 23.5.2](#). The distribution information and the convergence results are shown in [Output 23.5.1](#).

Output 23.5.1 Convergence Results for the STWEEDIE Model with Regressors

The SEVERITY Procedure

The final parameter estimates of the STWEEDIE regression model are shown in [Output 23.5.2](#). The estimate that is reported for the parameter Theta is the estimate of the base value θ_0 . The estimates of regression coefficients β_1 , β_2 , and β_3 are indicated by the rows of x1, x2, and x3, respectively.

Output 23.5.2 Parameter Estimates for the STWEEDIE Model with Regressors

Parameter Estimates				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Theta	0.82345	0.29281	2.81	0.0053
Lambda	16.24203	14.02459	1.16	0.2478
P	1.74930	0.22497	7.78	<.0001
x1	0.27930	0.09879	2.83	0.0050
x2	-0.76730	0.10318	-7.44	<.0001
x3	3.03183	0.10143	29.89	<.0001

If your goal is to explain the effect of regressors on the scale parameter, then the output displayed in [Output 23.5.2](#) is sufficient. But, if you want to compute the effect of regressors on the mean of the distribution,

then some postprocessing needs to be done. Using the relationship between μ and θ , μ can be written in terms of the parameters of the STWEEDIE model as

$$\mu = \theta_0 \exp \left(\sum_{j=1}^k \beta_j x_j \right) \lambda \frac{2-p}{p-1}$$

This shows that the parameters β_j are identical for the mean and the scale model, and the base value μ_0 of the mean model is

$$\mu_0 = \theta_0 \lambda \frac{2-p}{p-1}$$

The estimate of μ_0 and the standard error associated with it can be computed by using the property of the functions of maximum likelihood estimators (MLE). If $g(\Omega)$ represents a totally differentiable function of parameters Ω , then the MLE of g has an asymptotic normal distribution with mean $g(\hat{\Omega})$ and covariance $C = (\partial g)' \Sigma (\partial g)$, where $\hat{\Omega}$ is the MLE of Ω , Σ is the estimate of covariance matrix of Ω , and ∂g is the gradient vector of g with respect to Ω evaluated at $\hat{\Omega}$. For μ_0 , the function is $g(\Omega) = \theta_0 \lambda (2-p)/(p-1)$. The gradient vector is

$$\begin{aligned} \partial g &= \left(\frac{\partial g}{\partial \theta_0} \quad \frac{\partial g}{\partial \lambda} \quad \frac{\partial g}{\partial p} \quad \frac{\partial g}{\partial \beta_1} \cdots \frac{\partial g}{\partial \beta_k} \right) \\ &= \left(\frac{\mu_0}{\theta_0} \quad \frac{\mu_0}{\lambda} \quad \frac{-\mu_0}{(p-1)(2-p)} \quad 0 \dots 0 \right) \end{aligned}$$

You can write a DATA step that implements these computations by using the parameter and covariance estimates prepared by PROC SEVERITY step. The DATA step program is available in the sample program *sevex05.sas*. The estimates of μ_0 prepared by that program are shown in [Output 23.5.3](#). These estimates and the estimates of β_j as shown in [Output 23.5.2](#) are reasonably close (that is, within one or two standard errors) to the parameters of the population from which the sample in *Work.Test_Sevtw* data set was drawn.

Output 23.5.3 Estimate of the Base Value Mu0 of the Mean Parameter

Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Mu0	4.47472	0.42271	10.5858	0

Another effect of using the scaled Tweedie distribution to model the regression effects is that the regressors also affect the variance V of the Tweedie distribution. The variance is related to the mean as $V = \phi \mu^p$, where ϕ is the dispersion parameter. Using the relationship between the parameters TWEEDIE and STWEEDIE distributions as described in the section “[Tweedie Distributions](#)” on page 1651, the regression model for the dispersion parameter is

$$\begin{aligned} \log(\phi) &= (2-p) \log(\mu) - \log(\lambda(2-p)) \\ &= ((2-p) \log(\mu_0) - \log(\lambda(2-p))) + (2-p) \sum_{j=1}^k \beta_j x_j \end{aligned}$$

Subsequently, the regression model for the variance is

$$\begin{aligned}\log(V) &= 2\log(\mu) - \log(\lambda(2 - p)) \\ &= (2\log(\mu_0) - \log(\lambda(2 - p))) + 2 \sum_{j=1}^k \beta_j x_j\end{aligned}$$

In summary, PROC SEVERITY enables you to estimate regression effects on various parameters and statistics of the Tweedie model.

Example 23.6: Fitting Distributions to Interval-Censored Data

In some applications, the data available for modeling might not be exact. A commonly encountered scenario is the use of grouped data from an external agency, which for several reasons, including privacy, does not provide information about individual loss events. The losses are grouped into disjoint bins, and you know only the range and number of values in each bin. Each group is essentially interval-censored, because you know that a loss magnitude is in certain interval, but you do not know the exact magnitude. This example illustrates how you can use PROC SEVERITY to model such data.

The following DATA step generates sample grouped data for dental insurance claims, which is taken from Klugman, Panjer, and Willmot (1998).

```
/* Grouped dental insurance claims data
   (Klugman, Panjer, and Willmot, 1998) */
data gdental;
    input lowerbd upperbd count @@;
    datalines;
0 25 30 25 50 31 50 100 57 100 150 42 150 250 65 250 500 84
500 1000 45 1000 1500 10 1500 2500 11 2500 4000 3
;
run;
```

Often, when you do not know the nature of the data, it is recommended that you first explore the nature of the sample distribution by examining the nonparametric estimates of PDF and CDF. The following PROC SEVERITY step prepares the nonparametric estimates, but it does not fit any distribution because there is no DIST statement specified:

```
/* Prepare nonparametric estimates */
proc severity data=gdental print=all plots(histogram kernel)=all;
    loss / rc=lowerbd lc=upperbd;
    weight count;
run;
```

The LOSS statement specifies the left and right boundary of each group as the right-censoring and left-censoring limits, respectively. The variable count records the number of losses in each group and is specified in the WEIGHT statement. Note that there is no response or loss variable specified in the LOSS statement, which is allowed as long as each observation in the input data set is censored. The nonparametric estimates prepared by this step are shown in [Output 23.6.1](#). The histogram, kernel density, and EDF plots all indicate

that the data is heavy-tailed. For interval-censored data, PROC SEVERITY uses Turnbull’s algorithm to compute the EDF estimates. The plot of Turnbull’s EDF estimates is shown to be linear between the endpoints of a censored group. The linear relationship is chosen for convenient visualization and ease of computation of EDF-based statistics, but you should note that theoretically the behavior of Turnbull’s EDF estimates is undefined within a group.

Output 23.6.1 Nonparametric Distribution Estimates for Interval-Censored Data

With the PRINT=ALL option, PROC SEVERITY prints the summary of the Turnbull EDF estimation process as shown in [Output 23.6.2](#). It indicates that the final EDF estimates have converged and are in fact maximum likelihood (ML) estimates. If they were not ML estimates, then you could have used the [ENSUREMLE](#) option to force the algorithm to search for ML estimates.

Output 23.6.2 Turnbull EDF Estimation Summary for Interval-Censored Data

Turnbull EDF Estimation Summary	
Technique	EM with Maximum Likelihood Check
Convergence Status	Converged
Iterations	2
Maximum Absolute Relative Error	1.8406E-16
Maximum Absolute Reduced Gradient	1.7764E-15
Estimates	Maximum Likelihood

After exploring the nature of the data, you can now fit a set of heavy-tailed distributions to this data. The following PROC SEVERITY step fits all the predefined distributions to the data in Work.Gdental data set:

```
/* Fit all predefined distributions */
proc severity data=gdental print=all plots(histogram kernel)=all
    criterion=ad;
    loss / rc=lowerbd lc=upperbd;
    weight count;
    dist _predef_;
run;
```

Some of the key results prepared by PROC SEVERITY are shown in [Output 23.6.3](#) through [Output 23.6.4](#). According to the “Model Selection Table” in [Output 23.6.3](#), all distribution models have converged. The “All Fit Statistics Table” in [Output 23.6.3](#) indicates that the generalized Pareto distribution (GPD) has the best fit for data according to a majority of the likelihood-based statistics and that the Burr distribution (BURR) has the best fit according to all the EDF-based statistics.

The P-P plots of [Output 23.6.4](#) show that both GPD and BURR have a close fit between EDF and CDF estimates, although BURR has slightly better fit, which is also indicated by the EDF-based statistics. Given that BURR is a generalization of the GPD and that the plots do not offer strong evidence in support of the more complex distribution, GPD seems like a good choice for this data.

Output 23.6.4 P-P Plots of Burr and GPD for Interval-Censored Data

Example 23.7: Defining a Finite Mixture Model That Has a Scale Parameter

A finite mixture model is a stochastic model that postulates that the probability distribution of the data generation process is a mixture of a finite number of probability distributions. For example, when an insurance company analyzes loss data from multiple policies that are underwritten in different geographic regions, some regions might behave similarly, but the distribution that governs some regions might be different from the distribution that governs other regions. Further, it might not be known which regions behave similarly. Also, the larger amounts of losses might follow a different stochastic process from the stochastic process that governs the smaller amounts of losses. It helps to model all policies together in order to pool the data together and exploit any commonalities among the regions, and the use of a finite mixture model can help capture the differences in distributions across regions and ranges of loss amounts.

Formally, if f_i and F_i denote the PDF and CDF, respectively, of component distribution i and p_i represents the mixing probability that is associated with component i , then the PDF and CDF of the finite mixture of K distribution components are

$$f(x; \Theta, \mathbf{p}) = \sum_{i=1}^K p_i f_i(x; \Theta_i)$$

$$F(x; \Theta, \mathbf{p}) = \sum_{i=1}^K p_i F_i(x; \Theta_i)$$

where Θ_i denotes the parameters of component distribution i and Θ denotes the parameters of the mixture distribution, which is a union of all the Θ_i parameters. \mathbf{p} denotes the set of mixing probabilities. All mixing probabilities must add up to 1 ($\sum_{i=1}^K p_i = 1$).

You can define the finite mixture of a specific number of components and specific distributions for each of the components by defining the FCMP functions for the PDF and CDF. However, in general, it is not possible to fit a scale regression model by using any finite mixture distribution unless you take special care to ensure

that the mixture distribution has a scale parameter. This example provides a formulation of a two-component finite mixture model that has a scale parameter.

To start with, each component distribution must have either a scale parameter or a log-transformed scale parameter. Let θ_1 and θ_2 denote the scale parameters of the first and second components, respectively. Let $p_1 = p$ be the mixing probability, which makes $p_2 = 1 - p$ by using the constraint on \mathbf{p} . The PDF of the mixture of these two distributions can be written as

$$f(x; \theta_1, \theta_2, \Phi, p) = \frac{p}{\theta_1} f_1\left(\frac{x}{\theta_1}; \Phi_1\right) + \frac{1-p}{\theta_2} f_2\left(\frac{x}{\theta_2}; \Phi_2\right)$$

where Φ_1 and Φ_2 denote the sets of nonscale parameters of the first and second components, respectively, and Φ denotes a union of Φ_1 and Φ_2 . For the mixture to have the scale parameter θ , the PDF must be of the form

$$f(x; \theta, \Phi', p) = \frac{1}{\theta} \left(p f_1\left(\frac{x}{\theta}; \Phi'_1\right) + (1-p) f_2\left(\frac{x}{\theta}; \Phi'_2\right) \right)$$

where Φ' , Φ'_1 , and Φ'_2 denote the modified sets of nonscale parameters. One simple way to achieve this is to make $\theta_1 = \theta_2 = \theta$ and $\Phi' = \Phi$; that is, you simply equate the scale parameters of both components and keep the set of nonscale parameters unchanged. However, forcing the scale parameters to be equal in both components is restrictive, because the mixture cannot model potential differences in the scales of the two components. A better approach is to tie the scale parameters of the two components by a ratio such that $\theta_1 = \theta$ and $\theta_2 = \rho\theta$. If the ratio parameter ρ is estimated along with the other parameters, then the mixture distribution becomes flexible enough to model the variations across the scale parameters of individual components.

To summarize, the PDF and CDF are of the following form for the two-component mixture that has a scale parameter:

$$f(x; \theta, \rho, \Phi, p) = \frac{1}{\theta} \left(p f_1\left(\frac{x}{\theta}; \Phi_1\right) + (1-p) f_2\left(\frac{x}{\rho\theta}; \Phi_2\right) \right)$$

$$F(x; \theta, \rho, \Phi, p) = p F_1\left(\frac{x}{\theta}; \Phi_1\right) + (1-p) F_2\left(\frac{x}{\rho\theta}; \Phi_2\right)$$

This can be generalized to a mixture of K components by introducing the $K - 1$ ratio parameters ρ_i that relate the scale parameters of each of the K components to the scale parameter θ of the mixture distribution as follows:

$$\theta_1 = \theta$$

$$\theta_i = \rho_i \theta; i \in [2, K]$$

In order to illustrate this approach, define a mixture of two lognormal distributions by using the following PDF function:

$$f(x; \mu, \sigma_1, p_2, \rho_2, \sigma_2) = \frac{(1-p_2)}{\sigma_1 x \sqrt{2\pi}} \exp\left(-\frac{(\log(x) - \mu)^2}{2\sigma_1^2}\right) +$$

$$\frac{p_2}{\sigma_2 x \sqrt{2\pi}} \exp\left(-\frac{(\log(x) - \mu - \log(\rho_2))^2}{2\sigma_2^2}\right)$$

You can verify that μ serves as the log of the scale parameter θ ($\mu = \log(\theta)$). The following PROC FCMP steps encode this formulation in a distribution named SLOGNMIX2 for use with PROC SEVERITY:

```

/*- Define Mixture of 2 Lognormal Distributions with a Log-Scale Parameter -*/
proc fcmp library=sashelp.svrtldist outlib=work.sevexmpl.models;
  function slognmix2_description() $128;
    return ("Mixture of two lognormals with a log-scale parameter Mu");
  endsub;

  p2 = 1; /* p2 < 1 */
  Rho2 = 1; /* Rho2 < 1 */
  Sigma2 = .; /* Sigma2 has no upper bound */
endsub;
quit;

```

As shown in previous examples, an important aspect of defining a distribution for use with PROC SEVERITY is the definition of the PARMINIT subroutine that initializes the parameters. For mixture distributions, in general, the parameter initialization is a nontrivial task. For a two-component mixture, some simplifying assumptions make the problem easier to handle. For the initialization of SLOGNMIX2, the initial values of p_1 and p_2 are fixed at 0.5, and the following two simplifying assumptions are made:

- The median of the mixture is the average of the medians of the two components:

$$F^{-1}(0.5) = (\exp(\mu_1) + \exp(\mu_2))/2 = \exp(\mu)(1 + \rho_2)/2$$

Solution of this equation yields the value of μ in terms of p_2 and the sample median.

- Each component has the same mean, which implies the following:

$$\exp(\mu + \sigma_1^2/2) = \exp(\mu + \log(\rho_2) + \sigma_2^2/2)$$

If X_i represents the random variable of component distribution i and X represents the random variable of the mixture distribution, then the following equation holds for the raw moment of any order k :

$$E[X^k] = \sum_{i=1}^K p_i E[X_i^k]$$

This, in conjunction with the assumption on component means, leads to the equations

$$\log(m_1) = \mu + \frac{\sigma_1^2}{2} \qquad \log(m_1) = \mu + \log(\rho_2) + \frac{\sigma_2^2}{2}$$

where m_1 denotes the first raw moment of the sample. Solving these equations leads to the following values of σ_1 and σ_2 :

$$\sigma_1^2 = 2(\log(m_1) - \mu) \qquad \sigma_2^2 = 2(\log(m_1) - \mu - \log(\rho_2))$$

Note that σ_1 has a valid value only if $\log(m_1) > \mu$. Among the many possible methods of ensuring this condition, the SLOGNMIX2_PARMINIT subroutine uses the method of doing a linear search over ρ_2 .

Even when the preceding assumptions are not true for a given problem, they produce reasonable initial values to help guide the nonlinear optimizer to an acceptable optimum if the mixture of two lognormal distributions is indeed a good fit for your input data. This is illustrated by the results of the following steps that fit the SLOGNMIX2 distribution to simulated data, which have different means for the two components (12.18 and 22.76, respectively), and the median of the sample (15.94) is not equal to the average of the medians of the two components (7.39 and 20.09, respectively):

```
/*----- Simulate a lognormal mixture sample -----*/
data testlognmix(keep=y);
  call streaminit(12345);
  Mu1 = 2;
  Sigma1 = 1;
  i = 0;
  do j=1 to 2000;
    y = exp(Mu1) * rand('LOGNORMAL')**Sigma1;
    output;
  end;
  Mu2 = 3;
  Sigma2 = 0.5;
  do j=1 to 3000;
    y = exp(Mu2) * rand('LOGNORMAL')**Sigma2;
    output;
  end;
run;

/*-- Fit and compare scale regression models with 2-component --*/
/*-- lognormal mixture and the standard lognormal distribution --*/
options cmplib=(work.sevexmpl);

proc severity data=testlognmix print=all plots(histogram kernel)=all;
  loss y;
  dist slognmix2 logn;
run;
```

The comparison of the fit statistics of SLOGNMIX2 and LOGN, as shown in [Output 23.7.1](#), confirms that the two-component mixture is certainly a better fit to these data than the single lognormal distribution.

Output 23.7.1 Comparison of Fitting One versus Two Lognormal Components to Mixture Data

All Fit Statistics					
Distribution	-2 Log Likelihood	AIC	AICC	BIC	KS
slognmix2	38343*	38353*	38353*	38386*	0.52221*
Logn	39073	39077	39077	39090	5.86522
Note: The asterisk (*) marks the best model according to each column's criterion.					

All Fit Statistics		
Distribution	AD	CvM
slognmix2	0.19843*	0.02728*
Logn	66.93414	11.72703
Note: The asterisk (*) marks the best model according to each column's criterion.		

The comparative plot of probability densities in [Output 23.7.2](#) shows that the density function of the mixture distribution is bimodal. In fact, one of the key motivations for using mixture distributions is to find better-fitting models for multimodal data.

Output 23.7.2 Comparison of PDF Estimates of the Fitted Models

The P-P and Q-Q plots in [Output 23.7.3](#) visually confirm that SLOGNMIX2 fits the data very well.

Output 23.7.3 P-P and Q-Q Plots to Evaluate SLOGNMIX2 Fit

The detailed results for the SLOGNMIX2 distribution are shown in [Output 23.7.4](#). According to the “Initial Parameter Values and Bounds” table, the initial value of ρ_2 is not 0.5, indicating that a linear search was conducted to ensure $\log(m_1) > \mu$.

Output 23.7.4 Detailed Estimation Results for the SLOGNMIX2 Distribution

The SEVERITY Procedure			
slognmix2 Distribution			
Distribution Information			
Name	slognmix2		
Description	Mixture of two lognormals with a log-scale parameter Mu		
Distribution Parameters	5		
Initial Parameter Values and Bounds			
Parameter	Initial Value	Lower Bound	Upper Bound
Mu	2.92006	-Infty	Infty
Sigma1	0.10455	1.05367E-8	Infty
P2	0.50000	1.05367E-8	1.00000
Rho2	0.72000	1.05367E-8	1.00000
Sigma2	0.81728	1.05367E-8	Infty
Convergence Status			
Convergence criterion (GCONV=1E-8) satisfied.			

Output 23.7.4 *continued*

Optimization Summary				
Optimization Technique	Trust Region			
Iterations	7			
Function Calls	18			
Log Likelihood	-19171.5			
Parameter Estimates				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Mu	3.00922	0.01554	193.68	<.0001
Sigma1	0.49516	0.01451	34.13	<.0001
P2	0.40619	0.02600	15.62	<.0001
Rho2	0.37212	0.02038	18.26	<.0001
Sigma2	1.00019	0.02124	47.09	<.0001

By using the relationship that $\mu_2 = \mu + \log(\rho_2)$, you can see that the final parameter estimates are indeed close to the true parameter values that were used to simulate the input sample.

Example 23.8: Predicting Mean and Value-at-Risk by Using Scoring Functions

If you work in the risk management department of an insurance company or a bank, then one of your primary applications of severity loss distribution models is to predict the value-at-risk (VaR), such that the probability of experiencing a loss value greater than the VaR is very low. The probability level at which VaR is measured is prescribed by industry regulations such as Basel III and Solvency II. The VaR level is usually specified in terms of $(1 - \alpha)$, where $\alpha \in (0, 1)$ is the probability that a loss value exceeds the VaR. Typical VaR levels are 0.95, 0.975, and 0.995.

In addition to predicting VaR, which is regarded as an estimate of the worst-case loss, businesses are often interested in predicting the average loss by estimating either the mean or median of the distribution.

The estimation of the mean and VaR combined with the scale regression model is very potent tool for analyzing worst-case and average losses for various scenarios. For example, if the regressors that are used in a scale regression model represent some key macroeconomic and operational indicators, which are widely referred to as key risk indicators (KRIs), then you can analyze the VaR and mean loss estimates over various values for the KRIs to get a more comprehensive picture of the risk profile of your organization across various market and internal conditions.

This example illustrates the use of scoring functions to simplify the process of predicting the mean and VaR of scale regression models.

First, the following PROC FCMP steps define the functions to compute the mean for each of the 10 predefined distributions that are available in the Sashelp.Svrtldist library:

```

/*----- Define distribution functions that compute the mean -----*/
proc fcmp library=sashelp.svrtldist outlib=work.means.scalemod;
  function BURR_MEAN(x, Theta, Alpha, Gamma);
    if not(Alpha * Gamma > 1) then
      return (.); /* first moment does not exist */
    return (Theta*gamma(1 + 1/Gamma)*gamma(Alpha - 1/Gamma)/gamma(Alpha));
  endsub;
  function EXP_MEAN(x, Theta);
    return (Theta);
  endsub;
  function GAMMA_MEAN(x, Theta, Alpha);
    return (Theta*Alpha);
  endsub;
  function GPD_MEAN(x, Theta, Xi);
    if not(Xi < 1) then
      return (.); /* first moment does not exist */
    return (Theta/(1 - Xi));
  endsub;
  function IGAUSS_MEAN(x, Theta, Alpha);
    return (Theta);
  endsub;
  function LOGN_MEAN(x, Mu, Sigma);
    return (exp(Mu + Sigma*Sigma/2.0));
  endsub;
  function PARETO_MEAN(x, Theta, Alpha);
    if not(Alpha > 1) then
      return (.); /* first moment does not exist */
    return (Theta/(Alpha - 1));
  endsub;
  function STWEEDIE_MEAN(x, Theta, Lambda, P);
    return (Theta* Lambda * (2 - P) / (P - 1));
  endsub;
  function TWEEDIE_MEAN(x, P, Mu, Phi);
    return (Mu);
  endsub;
  function WEIBULL_MEAN(x, Theta, Tau);
    return (Theta*gamma(1 + 1/Tau));
  endsub;
quit;

```

The following statements include the Work.Means library in the CMPLIB= system option and submit a PROC SEVERITY step to estimate the scale regression models for various distributions by using a lognormal sample in the Work.Test_sev8 data set:

```

/*----- Fit all distributions and generate scoring functions -----*/
options cmplib=work.means;
proc severity data=test_sev8 outest=est print=all plots=none;
  loss y;
  scalemodel x1-x5;
  dist _predefined_ stweedie;
  outscorelib outlib=scorefuncs commonpackage;
run;

```

The SAS statements that simulate the sample in the `Work.Test_sev8` data set are available in the PROC SEVERITY sample program `sevex08.sas`. The `OUTLIB=` option in the `OUTSCORELIB` statement requests that the scoring functions be written to the `Work.Scorefuncs` library, and the `COMMONPACKAGE` option in the `OUTSCORELIB` statement requests that all the functions be written to the same package. Upon completion, PROC SEVERITY sets the `CMPLIB` system option to the following value:

```
(work.means sashelp.svrtdist work.scorefuncs)
```

The “All Fit Statistics” table in [Output 23.8.1](#) shows that the lognormal distribution’s scale model is the best and the inverse Gaussian’s scale model is a close second according to the likelihood-based statistics.

Output 23.8.1 Comparison of Fitted Scale Models for Mean and VaR Illustration

You can examine the scoring functions that are written to the Work.Scorefuncs library by using the FCMP Function Editor that is available in the Display Manager session of Base SAS when you select **Solutions**→**Analysis** from the main menu. For example, PROC SEVERITY automatically generates and submits the following PROC FCMP statements to define the scoring functions ‘SEV_MEAN_LOGN’ and ‘SEV_QUANTILE_IGAUSS’:

```
proc fcmp library=(work.means sashelp.svrtldist) outlib=work.scorefuncs.sevfit;
  function SEV_MEAN_LOGN(y, x{*});
    _logscale_=0;
    _logscale_ = _logscale_ + ( 7.64722278930350E-01 * x{1});
    _logscale_ = _logscale_ + ( 2.99209540369860E+00 * x{2});
    _logscale_ = _logscale_ + (-1.00788916253430E+00 * x{3});
    _logscale_ = _logscale_ + ( 2.58883602184890E-01 * x{4});
    _logscale_ = _logscale_ + ( 5.00927479793970E+00 * x{5});
    _logscale_ = _logscale_ + ( 9.95078833050690E-01);
    return (LOGN_MEAN(y, _logscale_, 2.31592981635590E-01));
  endsub;

  function SEV_QUANTILE_IGAUSS(y, x{*});
    _logscale_=0;
    _logscale_ = _logscale_ + ( 7.64581738373520E-01 * x{1});
    _logscale_ = _logscale_ + ( 2.99159055015310E+00 * x{2});
    _logscale_ = _logscale_ + (-1.00793496641510E+00 * x{3});
    _logscale_ = _logscale_ + ( 2.58870460543840E-01 * x{4});
    _logscale_ = _logscale_ + ( 5.00996884646730E+00 * x{5});
    _scale_ = 2.77854870591020E+00 * exp(_logscale_);
    return (IGAUSS_QUANTILE(y, _scale_, 1.81511227238720E+01));
  endsub;
quit;
```

An important point to note is that the *dist*_MEAN distribution functions are not available in the original definition of any of the distributions in the Sashelp.Svrtldist library. PROC SEVERITY detects the availability of those functions in the Work.Means library that is included in the value of the CMPLIB= system option just before submitting the PROC SEVERITY step. Each *dist*_MEAN distribution function has a signature that matches the signature of a distribution function of the respective distribution, so PROC SEVERITY creates the corresponding scoring functions. Specifying the COMMONPACKAGE option in the OUTSCORELIB statement causes the name of the scoring function to take the form SEV_MEAN_*dist*. You can define any distribution function that has the desired signature to compute an estimate of your choice, include its library in the CMPLIB= system option, and then specify the OUTSCORELIB statement to generate the corresponding scoring functions.

To illustrate the use of scoring functions, let Work.Reginput contain the scoring data, where the values of regressors in each observation define one scenario. Scoring functions make it very easy to compute the mean and VaR of each distribution’s scale model for each of the scenarios, as the following steps illustrate for the lognormal and inverse Gaussian distributions:

```
/*--- Set VaR level ---*/
%let varLevel=0.975;

/*--- Compute scores (mean and var) for the ---
   --- scoring data by using the scoring functions ---*/
data scores;
  array x{*} x1-x5;
  set reginput;
```

```

    igauss_mean = sev_mean_igauss(., x);
    igauss_var  = sev_quantile_igauss(&varLevel, x);
    logn_mean   = sev_mean_logn(., x);
    logn_var    = sev_quantile_logn(&varLevel, x);
run;

```

The preceding steps use a VaR level of 97.5%.

The following DATA step accomplishes the same task by reading the parameter estimates that were written to the Work.Est data set by the previous PROC SEVERITY step:

```

/*--- Compute scores (mean and var) for the      ---
--- scoring data by using the OUTEST= data set ---*/
data scoresWithoutest(keep=x1-x5 igauss_mean igauss_var logn_mean logn_var);
    array _x_{*} x1-x5;
    array _xparmIgauss_{5} _temporary_;
    array _xparmLogn_{5} _temporary_;
    retain _Theta0_ Alpha0;
    retain _Mu0_ Sigma0;
    *--- read parameter estimates for igauss and logn models ---*;
    if (_n_ = 1) then do;
        set est(where=(upcase(_MODEL_)='IGAUSS' and _TYPE_='EST'));
        _Theta0_ = Theta; Alpha0 = Alpha;
        do _i_=1 to dim(_x_);
            if (_x_(_i_) = .R) then _xparmIgauss_(_i_) = 0;
            else _xparmIgauss_(_i_) = _x_(_i_);
        end;
        set est(where=(upcase(_MODEL_)='LOGN' and _TYPE_='EST'));
        _Mu0_ = Mu; Sigma0 = Sigma;
        do _i_=1 to dim(_x_);
            if (_x_(_i_) = .R) then _xparmLogn_(_i_) = 0;
            else _xparmLogn_(_i_) = _x_(_i_);
        end;
    end;
    set reginput;

    *--- predict mean and VaR for inverse Gaussian ---*;
    * first compute X'*beta for inverse Gaussian *;
    _xbeta_ = 0.0;
    do _i_ = 1 to dim(_x_);
        _xbeta_ = _xbeta_ + _xparmIgauss_(_i_) * _x_(_i_);
    end;
    * now compute scale for inverse Gaussian *;
    _SCALE_ = _Theta0_ * exp(_xbeta_);
    igauss_mean = igauss_mean(., _SCALE_, Alpha0);
    igauss_var = igauss_quantile(&varLevel, _SCALE_, Alpha0);
    *--- predict mean and VaR for lognormal ---*;
    * first compute X'*beta for lognormal*;
    _xbeta_ = 0.0;
    do _i_ = 1 to dim(_x_);
        _xbeta_ = _xbeta_ + _xparmLogn_(_i_) * _x_(_i_);
    end;
    * now compute Mu=log(scale) for lognormal *;
    _MU_ = _Mu0_ + _xbeta_;
    logn_mean = logn_mean(., _MU_, Sigma0);
    logn_var = logn_quantile(&varLevel, _MU_, Sigma0);
run;

```

The “Values Comparison Summary” table in [Output 23.8.2](#) shows that the difference between the estimates that are produced by both methods is within the acceptable machine precision. However, the comparison of the DATA step complexity of each method clearly shows that the method that uses the scoring functions is much easier because it saves a lot of programming effort. Further, new distribution functions, such as the *dist_MEAN* functions that are illustrated here, are automatically discovered and converted to scoring functions by PROC SEVERITY. That enables you to focus your efforts on writing the distribution function that computes your desired score, which needs to be done only once. Then, you can create and use the corresponding scoring functions multiple times with much less effort.

Output 23.8.2 Comparison of Mean and VaR Estimates of Two Scoring Methods

Observation Summary		
Observation	Base	Compare
First Obs	1	1
Last Obs	10	10
Number of Observations in Common: 10.

Overview: SIMILARITY Procedure

The SIMILARITY procedure computes similarity measures associated with time-stamped data, time series, and other sequentially ordered numeric data. PROC SIMILARITY computes similarity measures for time-stamped transactional data (transactions) with respect to time by accumulating the data into a time series format, and it computes similarity measures for sequentially ordered numeric data (sequences) by respecting the ordering of the data.

Given two ordered numeric sequences (input and target), a similarity measure is a metric that measures the distance between the input and target sequences while taking into account the ordering of the data. The SIMILARITY procedure computes similarity measures between an input sequence and a target sequence, in addition to similarity measures that “slide” the target sequence with respect to the input sequence. The “slides” can be by observation index (sliding-sequence similarity measures) or by seasonal index (seasonal-sliding-sequence similarity measures).

In order to compare the raw input and the raw target time-stamped data, the raw data must be accumulated to a time series format. After the input and target time series are formed, the two accumulated time series can be compared as two ordered numeric sequences.

For raw time-stamped data, after the transactional data are accumulated to form time series and any missing values are interpreted, each accumulated time series can be functionally transformed, if desired. Transformations are useful when you want to stabilize the time series before computing the similarity measures. Transformations performed by the SIMILARITY procedure include the following:

- log (LOG)
- square-root (SQRT)
- logistic (LOGISTIC)
- Box-Cox (BOXCOX)
- user-defined transformations

Each time series can be transformed further by using simple differencing or seasonal differencing or both. Additional time series transformations can be performed by using various time series transformation and analysis techniques provided by this procedure or other SAS/ETS procedures.

After optionally transforming each time series, the accumulated and transformed time series can be stored in an output data set (OUT= data set).

After optional accumulation and transformation, each of these time series are the “working series,” which can now be analyzed as sequences of numeric data. Each of these sequences can be a target sequence, an input sequence, or both a target and an input sequence. Throughout the remainder of this chapter, the term “original sequence” applies to both the original input and target sequence. The term “working sequence” applies to a version of both the original input and target sequence under investigation.

Each original sequence can be normalized prior to similarity analysis. Normalizations are useful when you want to compare the “shape” or “profile” of the time series. Normalizations performed by the SIMILARITY procedure include the following:

- standard (STANDARD)
- absolute (ABSOLUTE)
- user-defined normalizations

After each original sequence is optionally normalized, each working input sequence can be scaled to the target sequence prior to similarity analysis. Scaling is useful when you want to compare the input sequence to the target sequence while discounting the variation of the target sequence. Input sequence scaling performed by the SIMILARITY procedure include the following:

- standard (STANDARD)
- absolute (ABSOLUTE)
- user-defined scaling

After the working input sequence is optionally scaled to the target sequence, similarity measures can be computed. Similarity measures computed by the SIMILARITY procedure include:

- squared deviation (SQRDEV)
- absolute deviation (ABSDEV)
- mean square deviation (MSQRDEV)
- mean absolute deviation (MABSDEV)
- user-defined similarity measures

In computing the similarity measure between two time series, tasks are needed for transforming time series, normalizing sequences, scaling sequences, and computing metrics or measures. The SIMILARITY procedure provides built-in routines to perform these tasks. The SIMILARITY procedure also enables you to extend the procedure with user-defined routines.

All results of the similarity analysis can be stored in output data sets, printed, or graphed using the Output Delivery System (ODS).

The SIMILARITY procedure can process large amounts of time-stamped transactional data, time series, or sequential data. Therefore, the analysis results are useful for large-scale time series analysis, analogous time series forecasting, new product forecasting, or time series (temporal) data mining.

The SAS/ETS EXPAND procedure can be used for frequency conversion and transformations of time series. The TIMESERIES procedure can be used for large-scale time series analysis. The SAS/STAT DISTANCE procedure can be used to compute various measures of distance, dissimilarity, or similarity between observations (rows) of a SAS data set.

Getting Started: SIMILARITY Procedure

This section outlines the use of the SIMILARITY procedure and gives a cursory description of some of the analysis techniques that can be performed on time-stamped transactional data, time series, or sequentially ordered numeric data.

Given an input data set that contains numerous transaction variables recorded over time at no specific frequency, the SIMILARITY procedure can form equally spaced input and target time series as follows:

```
PROC SIMILARITY DATA=<input-data-set>
                OUT=<output-data-set>
                OUTSUM=<summary-data-set>;
  ID <time-ID-variable> INTERVAL=<frequency>
                ACCUMULATE=<statistic>;
  INPUT <input-time-stamp-variables>;
  TARGET <target-time-stamp-variables>;
RUN;
```

The SIMILARITY procedure forms time series from the input time-stamped transactional data. It can provide results in output data sets or in other output formats using the Output Delivery System (ODS). The examples in this section are more fully illustrated in the section “[Examples: SIMILARITY Procedure](#)” on page 1807.

Time-stamped transactional data are often recorded at no fixed interval. Analysts often want to use time series analysis techniques that require fixed-time intervals. Therefore, the transactional data must be accumulated to form a fixed-interval time series.

Suppose that a bank wants to analyze the transactions that are associated with each of its customers over time. Further, suppose that the data set WORK.TRANSACTIONS contains three variables that are related to the customer transactions (CUSTOMER, DATE, and WITHDRAWAL) and one variable that contains an example fraudulent behavior (FRAUD).

The following statements illustrate how to use the SIMILARITY procedure to accumulate time-stamped transactional data to form a daily time series based on the accumulated daily totals of each type of transaction (WITHDRAWALS and FRAUD):

```
proc similarity data=transactions out=timedata;
  by customer;
  id date interval=day accumulate=total;
  input withdrawals;
  target fraud;
run;
```

The OUT=TIMEDATA option specifies that the resulting time series data for each customer are to be stored in the data set WORK.TIMEDATA. The INTERVAL=DAY option specifies that the transactions are to be

accumulated on a daily basis. The ACCUMULATE=TOTAL option specifies that the sum of the transactions are to be accumulated. After the transactional data are accumulated into a time series format, the time series data can be normalized so that the “shape” or “profile” is analyzed.

For example, the following statements build on the previous statements and demonstrate normalization of the accumulated time series:

```
proc similarity data=transactions out=timedata;
  by customer;
  id date interval=day accumulate=total;
  input withdrawals / NORMALIZE=STANDARD;
  target fraud      / NORMALIZE=STANDARD;
run;
```

The NORMALIZE=STANDARD option specifies that each accumulated time series observation is normalized by subtracting the mean and then dividing by the standard deviation of the accumulated time series. The WORK.TIMEDATA data set now contains the accumulated and normalized time series data for each customer.

After the transactional data are accumulated into a time series format and normalized to a mean of zero and standard deviation of one, similarity analysis can be performed on the accumulated and normalized time series.

For example, the following statements build on the previous statements and demonstrate similarity analysis of the accumulated and normalized time series:

```
proc similarity data=transactions
  out=timedata OUTSUM=SUMMARY;
  by customer;
  id date interval=day accumulate=total;
  input withdrawals / normalize=standard;
  target fraud      / normalize=standard MEASURE=MABSDEV;
run;
```

The MEASURE=MABSDEV option specifies the accumulated and normalized time series data that are associated with the variables WITHDRAWALS and FRAUD are to be compared by using mean absolute deviation. The OUTSUM=SUMMARY option specifies that the similarity analysis summary for each customer is to be stored in the data set WORK.SUMMARY.

Syntax: SIMILARITY Procedure

The following statements are used with the SIMILARITY procedure.

```
PROC SIMILARITY options ;  
  BY variables ;  
  ID variable INTERVAL= interval options ;  
  FCMPOPT options ;  
  INPUT variable-list / options ;  
  TARGET variable-list / options ;
```

Functional Summary

The statements and options that control the SIMILARITY procedure are summarized in the following table.

Table 24.1 SIMILARITY Functional Summary

Description	Statement	Option
Statements		
Specifies BY-group processing	BY	
Specifies the time ID variable	ID	
Specifies the FCMP options	FCMPOPT	
Specifies input variables to analyze	INPUT	
Specifies target variables to analyze	TARGET	
Data Set Options		
Specifies the input data set	PROC SIMILARITY	DATA=
Specifies the time series output data set	PROC SIMILARITY	OUT=
Specifies the measure summary output data set	PROC SIMILARITY	OUTMEASURE=
Specifies the path output data set	PROC SIMILARITY	OUTPATH=
Specifies the sequence output data set	PROC SIMILARITY	OUTSEQUENCE=
Specifies the summary output data set	PROC SIMILARITY	OUTSUM=
User-Defined Functions and Subroutine Options		
Specifies FCMP quiet mode	FCMPOPT	QUIET=
Specifies FCMP trace mode	FCMPOPT	TRACE=

Description	Statement	Option
Accumulation and Seasonality Options		
Specifies the accumulation frequency	ID	INTERVAL=
Specifies the length of seasonal cycle	PROC SIMILARITY	SEASONALITY=
Specifies the interval alignment	ID	ALIGN=
Specifies that the time ID variable values are not sorted	ID	NOTSORTED
Specifies the starting time ID value	ID	START=
Specifies the ending time ID value	ID	END=
Specifies the accumulation statistic	ID, INPUT, TARGET	ACCUMULATE=
Specifies the missing value interpretation	ID, INPUT, TARGET	SETMISS=
Specifies the zero value interpretation	ID, INPUT, TARGET	ZEROMISS=
Specifies the type of missing value trimming	INPUT, TARGET	TRIMMISS=
Time Series Transformation Options		
Specifies simple differencing	INPUT, TARGET	DIF=
Specifies seasonal differencing	INPUT, TARGET	SDIF=
Specifies the transformation	INPUT, TARGET	TRANSFORM=
Input Sequence Options		
Specifies normalization	INPUT	NORMALIZE=
Specifies scaling	INPUT	SCALE=
Target Sequence Options		
Specifies normalization	TARGET	NORMALIZE=
Similarity Measure Options		
Specifies the compression limits	TARGET	COMPRESS=
Specifies the expansion limits	TARGET	EXPAND=
Specifies the similarity measure	TARGET	MEASURE=
Specifies the similarity measure and path	TARGET	PATH=
Specifies the sequence slide	TARGET	SLIDE=
Printing and Graphical Control Options		
Specifies the time ID format	ID	FORMAT=
Specifies printed output	PROC SIMILARITY	PRINT=
Specifies detailed printed output	PROC SIMILARITY	PRINTDETAILS
Specifies graphical output	PROC SIMILARITY	PLOTS=
Miscellaneous Options		
Specifies that analysis variables are processed in ascending order	PROC SIMILARITY	SORTNAMES
Specifies the ordering of the processing of the input and target variables	PROC SIMILARITY	ORDER=

PROC SIMILARITY Statement

PROC SIMILARITY *options* ;

The following options can be used in the PROC SIMILARITY statement.

DATA=SAS-data-set

names the SAS data set that contains the time series, transactional, or sequence input data for the procedure. If the DATA= option is not specified, the most recently created SAS data set is used.

ORDER=order-option

specifies the order in which the variables listed in the INPUT and TARGET statements are to be processed. This ordering affects the OUTSEQUENCE=, OUTPATH=, OUTMEASURE=, and OUTSUM= data sets, in addition to the printed and graphical output. The SORTNAMES option also affects the ordering of the analysis. You must specify one of the following *order-options*:

INPUT	specifies that each INPUT variable be processed and then the TARGET variables be processed. The results are stored and printed based only on the INPUT variables.
INPUTTARGET	specifies that each INPUT variable be processed and then the TARGET variables be processed. The results are stored and printed based on both the INPUT and TARGET variables. This is the default.
TARGET	specifies that each TARGET variable be processed and then the INPUT variables be processed. The results are stored and printed based only on the TARGET variables.
TARGETINPUT	specifies that each TARGET variable be processed and then the INPUT variables be processed. The results are stored and printed based on both the TARGET and INPUT variables.

OUT=SAS-data-set

names the output data set to contain the time series variables specified in the subsequent INPUT and TARGET statements. If an ID variable is specified in the ID statement, it is also included in the OUT= data set. The values are accumulated based on the ID statement INTERVAL= option or the ACCUMULATE= options or both. The values are transformed based on the INPUT or TARGET statement TRANSFORM=, DIF=, and SDIF= options in this order. The OUT= data set is particularly useful when you want to further analyze, model, or forecast the resulting time series with other SAS/ETS procedures.

OUTMEASURE=SAS-data-set

names the output data set to contain the detailed similarity measures by time ID value. The form of the OUTMEASURE= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

OUTPATH=SAS-data-set

names the output data set to contain the path used to compute the similarity measures for each slide and warp. The form of the OUTPATH= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options. If a user-defined similarity measure is specified, the path cannot be determined; therefore, the OUTPATH= data set does not contain information related to this measure.

OUTSEQUENCE=SAS-data-set

names the output data set to contain the sequences used to compute the similarity measures for each slide and warp. The form of the OUTSEQUENCE= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

OUTSUM=SAS-data-set

names the output data set to contain the similarity measure summary. The OUTSUM= data set is particularly useful when analyzing large numbers of series and only the summary of the results are needed. The form of the OUTSUM= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

PLOTS=option**PLOTS=(options ...)**

specifies the graphical output desired. To specify multiple *options*, separate them by spaces and enclose the group in parentheses. By default, the SIMILARITY procedure produces no graphical output. The following graphical *options* are available:

COSTS	plots graphics for time warp costs.
DISTANCES	plots graphics for similarity absolute and relative distances (OUTPATH= data set).
INPUTS	plots graphics for input variable time series (OUT= data set).
MAPS	plots graphics for time warp maps (OUTPATH= data set).
MEASURES	plots graphics for similarity measures (OUTMEASURE= data set).
NORMALIZED	plots graphics for both the input and target variable normalized sequence. These plots are displayed only when the INPUT or TARGET statement NORMALIZE= option is specified.
PATHS	plots time warp paths graphics (OUTPATH= data set).
SCALED	plots graphics for both the input variable scaled sequence. These plots are displayed only when the INPUT statement SCALE= option is specified.
SEQUENCES	plots graphics for both the input and target variable sequence (OUTSEQUENCE= data set).
TARGETS	plots graphics for the target variable time series (OUT= data set).
WARPS	plots graphics for time warps (OUTPATH= data set).
ALL	is the same as PLOTS=(INPUTS TARGETS SEQUENCES NORMALIZED SCALED DISTANCES PATHS MAPS WARPS COST MEASURES).

PRINT=option**PRINT=(options ...)**

specifies the printed output desired. To specify multiple *options*, separate them by spaces and enclose the group in parentheses. By default, the SIMILARITY procedure produces no printed output. The following printing options are available:

DESCSTATS	prints the descriptive statistics for the working time series.
PATHS	prints the path statistics table. If a user-defined similarity measure is specified, the path cannot be determined; therefore, the PRINT=PATHS table is not printed for this measure.

COSTS	prints the cost statistics table.
WARPS	prints the warp summary table.
SLIDES	prints the slides summary table.
SUMMARY	prints the similarity measure summary table.
ALL	is the same as PRINT=(DESCSTATS PATHS COSTS WARPS SLIDES SUMMARY).

PRINTDETAILS

specifies that the output requested with the PRINT= option be printed in greater detail.

SEASONALITY=integer

specifies the length of the seasonal cycle where *integer* ranges from one to 10,000. For example, SEASONALITY=3 means that every group of three time periods forms a seasonal cycle. By default, the length of the seasonal cycle is 1 (no seasonality) or the length implied by the INTERVAL= option specified in the ID statement. For example, INTERVAL=MONTH implies that the length of the seasonal cycle is 12.

SORTNAMES

specifies that the variables specified in the INPUT and TARGET statements be processed in alphabetical order of the variable names. By default, the SIMILARITY procedure processes the variables in the order in which they are listed. The ORDER= option also affects the ordering in which the analysis is performed.

BY Statement

A BY statement can be used with PROC SIMILARITY to obtain separate dummy variable definitions for groups of observations defined by the BY variables.

When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the option NOTSORTED or DESCENDING in the BY statement for the SIMILARITY procedure. The NOTSORTED option does not mean that the data are unsorted, but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY-group processing, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

FCMPOPT Statement

FCMPOPT *options* ;

The FCMPOPT statement specifies the following *options* that are related to user-defined functions and subroutines:

QUIET=ON | OFF

specifies whether the nonfatal errors and warnings that are generated by the user-defined SAS language functions and subroutines are printed to the log. Nonfatal errors are usually associated with operations with missing values. The default is QUIET=ON.

TRACE=ON | OFF

specifies whether the user-defined SAS language functions and subroutines tracings are printed to the log. Tracings are the results of every operation executed. This option is generally used for debugging. The default is TRACE=OFF.

ID Statement

ID *variable* **INTERVAL=** *interval options* ;

The ID statement names a numeric variable that identifies observations in the input and output data sets. The ID variable's values are assumed to be SAS date, time, or datetime values. In addition, the ID statement specifies the (desired) frequency associated with the time series. The ID statement options also specify how the observations are accumulated and how the time ID values are aligned to form the time series. The options specified affect all variables listed in subsequent INPUT and TARGET statements. If an ID statement is specified, the INTERVAL= option must also be specified. The other ID statement options are optional. If an ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID.

The following options can be used with the ID statement:

ACCUMULATE=*option*

specifies how the data set observations are accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option. The ID variable contains the time ID values. Each time ID variable value corresponds to a specific time period. The accumulated values form the time series, which is used in subsequent analysis.

The ACCUMULATE= option is particularly useful when there are zero or more than one input observations that coincide with a particular time period (for example, time-stamped transactional data). The EXPAND procedure offers additional frequency conversions and transformations that can also be useful in creating a time series.

The following *options* determine how the observations are accumulated within each time period based on the ID variable and the frequency specified by the INTERVAL= option:

NONE	No accumulation occurs; the ID variable values must be equally spaced with respect to the frequency. This is the default option.
TOTAL	Observations are accumulated based on the total sum of their values.

AVERAGE AVG	Observations are accumulated based on the average of their values.
MINIMUM MIN	Observations are accumulated based on the minimum of their values.
MEDIAN MED	Observations are accumulated based on the median of their values.
MAXIMUM MAX	Observations are accumulated based on the maximum of their values.
N	Observations are accumulated based on the number of nonmissing observations.
NMISS	Observations are accumulated based on the number of missing observations.
NOBS	Observations are accumulated based on the number of observations.
FIRST	Observations are accumulated based on the first of their values.
LAST	Observations are accumulated based on the last of their values.
STDDEV STD	Observations are accumulated based on the standard deviation of their values.
CSS	Observations are accumulated based on the corrected sum of squares of their values.
USS	Observations are accumulated based on the uncorrected sum of squares of their values.

If the `ACCUMULATE=` option is specified, the `SETMISSING=` option is useful for specifying how accumulated missing values are treated. If missing values should be interpreted as zero, then `SETMISSING=0` should be used. The section “[Details: SIMILARITY Procedure](#)” on page 1785 describes accumulation in greater detail.

ALIGN=option

controls the alignment of SAS dates that are used to identify output observations. The `ALIGN=` option accepts the following values: `BEGINNING` | `BEG` | `B`, `MIDDLE` | `MID` | `M`, and `ENDING` | `END` | `E`. `ALIGN=BEGINNING` is the default.

END=option

specifies a SAS date, datetime, or time value that represents the end of the data. If the last time ID variable value is less than the `END=` value, the series is extended with missing values. If the last time ID variable value is greater than the `END=` value, the series is truncated. For example, `END=&sysdate` uses the automatic macro variable `SYSDATE` to extend or truncate the series to the current date. The `START=` and `END=` options can be used to ensure that data that are associated within each `BY` group contain the same number of observations.

FORMAT=format

specifies the SAS format for the time ID values. If the `FORMAT=` option is not specified, the default format is implied by the `INTERVAL=` option. For example, `FORMAT=DATE9.` specifies that the `DATE9.` SAS format be used. Notice that the terminating “.” is required when specifying a SAS format.

INTERVAL= *interval*

specifies the frequency of the accumulated time series. For example, if the input data set consists of quarterly observations, then INTERVAL=QTR should be used. If the SEASONALITY= option is not specified, the length of the seasonal cycle is implied from the INTERVAL= option. For example, INTERVAL=QTR implies a seasonal cycle of length 4. If the ACCUMULATE= option is also specified, the INTERVAL= option determines the time periods for the accumulation of observations.

NOTSORTED

specifies that the time ID values are not in sorted order. The SIMILARITY procedure sorts the data with respect to the time ID prior to analysis if the NOTSORTED option is specified.

SETMISSING= *option* | *number*

specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series. If a *number* is specified, missing values are set to that number. If a missing value indicates an unknown value, the SETMISSING= option should not be used. If a missing value indicates no value, then SETMISSING=0 should be used. You typically use SETMISSING=0 for transactional data, because no recorded data usually implies no activity. The following *options* can also be used to determine how missing values are assigned:

MISSING	Missing values are set to missing. This is the default option.
AVERAGE AVG	Missing values are set to the accumulated average value.
MINIMUM MIN	Missing values are set to the accumulated minimum value.
MEDIAN MED	Missing values are set to the accumulated median value.
MAXIMUM MAX	Missing values are set to the accumulated maximum value.
FIRST	Missing values are set to the accumulated first nonmissing value.
LAST	Missing values are set to the accumulated last nonmissing value.
PREVIOUS PREV	Missing values are set to the previous period's accumulated nonmissing value. Missing values at the beginning of the accumulated series remain missing.
NEXT	Missing values are set to the next period's accumulated nonmissing value. Missing values at the end of the accumulated series remain missing.

START= *option*

specifies a SAS date, datetime, or time value that represents the beginning of the data. If the first time ID variable value is greater than the START= value, the series is prepended with missing values. If the first time ID variable value is less than the START= value, the series is truncated. The START= and END= options can be used to ensure that data that are associated with each BY group contain the same number of observations.

ZEROMISS= *option*

specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series. The following *options* can also be used to determine how beginning and ending zero values are assigned:

NONE	Beginning and ending zeros are unchanged. This is the default.
LEFT	Beginning zeros are set to missing.
RIGHT	Ending zeros are set to missing.
BOTH	Both beginning and ending zeros are set to missing.

If the accumulated series is all missing or zero, the series is not changed.

INPUT Statement

INPUT *variable-list* < / *options* > ;

The INPUT statement lists the input numeric variables in the DATA= data set whose values are to be accumulated to form the time series or represent ordered numeric sequences (when no ID statement is specified).

An input data set variable can be specified in only one INPUT or TARGET statement. Any number of INPUT statements can be used. The following *options* can be used with an INPUT statement:

ACCUMULATE=*option*

specifies how the data set observations are accumulated within each time period for the variables listed in the INPUT statement. If the ACCUMULATE= option is not specified in the INPUT statement, accumulation is determined by the ACCUMULATE= option of the ID statement. If the ACCUMULATE= option is not specified in the ID statement or the INPUT statement, no accumulation is performed. See the ID statement ACCUMULATE= option for more details.

DIF=(*numlist*)

specifies the differencing to be applied to the accumulated time series. The list of differencing orders must be separated by spaces or commas. For example, DIF=(1,3) specifies first, then third order, differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the DIF= option. Simple differencing is useful when you want to detrend the time series before computing the similarity measures.

NORMALIZE=*option*

specifies the sequence normalization to be applied to the working input sequence. The following normalization *options* are provided:

NONE	No normalization is applied. This option is the default.
ABSOLUTE	Absolute normalization is applied.
STANDARD	Standard normalization is applied.
<i>User-Defined</i>	Normalization is computed by a user-defined subroutine that is created using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

Normalization is applied to the working input sequence, which can be a subset of the working input time series if the SLIDE=INDEX or SLIDE=SEASON option is specified.

SCALE=option

specifies the scaling of the working input sequence with respect to the working target sequence. Scaling is performed after normalization. The following scaling *options* are provided:

NONE	No scaling is applied. This option is the default.
ABSOLUTE	Absolute scaling is applied.
STANDARD	Standard scaling is applied.
<i>User-Defined</i>	Scaling is computed by a user-defined subroutine that is created using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

Scaling is applied to the working input sequence, which can be a subset of the working input time series if the SLIDE=INDEX or SLIDE=SEASON option is specified.

SDIF=(numlist)

specifies the seasonal differencing to be applied to the accumulated time series. The list of seasonal differencing orders must be separated by spaces or commas. For example, SDIF=(1,3) specifies first, then third, order seasonal differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the SDIF= option. Seasonal differencing is useful when you want to deseasonalize the time series before computing the similarity measures.

SETMISSING=option | number**SETMISS=option | number**

specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the INPUT statement. If the SETMISSING= option is not specified in the INPUT statement, missing values are set based on the SETMISSING= option in the ID statement. If the SETMISSING= option is not specified in the ID statement or the INPUT statement, no missing value interpretation is performed. See the ID statement SETMISSING= option for more details.

TRANSFORM=option

specifies the time series transformation to be applied to the accumulated time series. The following transformations are provided:

NONE	No transformation is applied. This option is the default.
LOG	Logarithmic transformation is applied.
SQRT	Square-root transformation is applied.
LOGISTIC	Logistic transformation is applied.
BOXCOX(<i>number</i>)	Box-Cox transformation with parameter is applied, where the real <i>number</i> is between -5 and 5.
<i>User-Defined</i>	Transformation is computed by a user-defined subroutine that is created using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

When the TRANSFORM= option is specified, the time series must be strictly positive unless a user-defined function is used.

TRIMMISSING=option**TRIMMISSING=option**

specifies how missing values (either actual or accumulated) are trimmed from the accumulated time series or ordered sequence for variables that are listed in the INPUT statement. The following trimming options are provided:

NONE	No missing value trimming is applied.
LEFT	Beginning missing values are trimmed.
RIGHT	Ending missing values are trimmed.
BOTH	Both beginning and ending missing value are trimmed. This is the default.

ZEROMISS=option

specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the INPUT statement. If the ZEROMISS= option is not specified in the INPUT statement, beginning and ending zero values are set based on the ZEROMISS= option of the ID statement. If the ZERO= option is not specified in the ID statement or the INPUT statement, no zero value interpretation is performed. See the ID statement ZEROMISS= option for more details.

TARGET Statement

TARGET *variable-list* < / *options* > ;

The TARGET statement lists the numeric target variables in the DATA= data set whose values are to be accumulated to form the time series or represent ordered numeric sequences (when no ID statement is specified).

An input data set variable can be specified in only one INPUT or TARGET statement. Any number of TARGET statements can be used. The following *options* can be used with a TARGET statement:

ACCUMULATE=option

specifies how the data set observations are accumulated within each time period for the variables listed in the TARGET statement. If the ACCUMULATE= option is not specified in the TARGET statement, accumulation is determined by the ACCUMULATE= option in the ID statement. If the ACCUMULATE= option is not specified in the ID statement or the TARGET statement, no accumulation is performed. See the ID statement ACCUMULATE= option for more details.

COMPRESS=option | (options)

specifies the sliding sequence (global) and warping (local) compression range of the target sequence with respect to the input sequence. Compression of the target sequence is the same as expansion of the input sequence and vice versa. The compression limits are defined based on the length of the target sequence and are imposed on the target sequence. The following compression options are provided:

GLOBALABS=integer specifies the absolute global compression, where *integer* ranges from zero to 10,000. GLOBALABS=0 implies no global compression, which is the default unless the GLOBALPCT= option is specified.

GLOBALPCT=number specifies global compression as a percentage of the length of the target sequence, where *number* ranges from zero to 100. GLOBALPCT=0 implies no global compression, which is the default. GLOBALPCT=100 implies maximum allowable compression.

LOCALABS=integer specifies the absolute local compression, where *integer* ranges from zero to 10,000. The default is maximum allowable absolute local compression unless the LOCALPCT= option is specified.

LOCALPCT=number specifies local compression as a percentage of the length of the target sequence, where *number* ranges from zero to 100. The percentage specified by the LOCALPCT= option must be less than the GLOBALPCT= option. LOCALPCT=0 implies no local compression. LOCALPCT=100 implies maximum allowable local compression. The default is LOCALPCT=100.

If the SLIDE=NONE or the SLIDE=SEASON option is specified in the TARGET statement, the global compression options are ignored. To disallow local compression, use the option COMPRESS=(LOCALPCT=0 LOCALABS=0).

If the SLIDE=INDEX option is specified, the global compression options are not ignored. To completely disallow both global and local compression, use the option COMPRESS=(GLOBALPCT=0 LOCALPCT=0) or COMPRESS=(GLOBALABS=0 LOCALABS=0). To allow only local compression, use the option COMPRESS=(GLOBALPCT=0 GLOBALABS=0). These are the default compression options.

The preceding options can be used in combination to specify the desired amount of global and local compression as the following examples illustrate, where L_c denotes the global compression limit and l_c denotes the local compression limit:

- COMPRESS=(GLOBALPCT=20) allows the global and local compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$.
- COMPRESS=(GLOBALPCT=20 GLOBALABS=10) allows the global and local compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$.
- COMPRESS=(LOCALPCT=10) allows the local compression to range from zero to $l_c = \min(\lfloor 0.1N_y \rfloor, (N_y - 1))$.
- COMPRESS=(LOCALPCT=20 LOCALABS=5) allows the local compression to range from zero to $l_c = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 5))$.
- COMPRESS=(GLOBALPCT=20 LOCALPCT=20) allows the global compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$ and allows the local compression to range from zero to $l_c = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$.
- COMPRESS=(GLOBALPCT=20 GLOBALABS=10 LOCALPCT=10 LOCALABS=5) allows the global compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$ and allows the local compression to range from zero to $l_c = \min(\lfloor 0.1N_y \rfloor, \min((N_y - 1), 5))$.

Suppose T_z is the length of the input time series and N_y is the length of the target sequence. The *valid* global compression limit, L_c , is always limited by the length of the target sequence: $0 \leq L_c < N_y$.

Suppose N_x is the length of the input sequence and N_y is the length of the target sequence. The *valid* local compression limit, l_c , is always limited by the lengths of the input and target sequence: $\max(0, (N_y - N_x)) \leq l_c < N_y$.

DIF=(numlist)

specifies the differencing to be applied to the accumulated time series. The list of differencing orders must be separated by spaces or commas. For example, DIF=(1,3) specifies first, then third, order differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the DIF= option. Simple differencing is useful when you want to detrend the time series before computing the similarity measures.

EXPAND=option | (options)

specifies the sliding sequence (global) and warping (local) expansion range of the target sequence with respect to the input sequence. Expansion of the target sequence is the same as compression of the input sequence and vice versa. The expansion limits are defined based on the length of the input sequence, but are imposed on the target sequence. The following expansion options are provided:

GLOBALABS=integer specifies the absolute global expansion, where *integer* ranges from zero to 10,000. GLOBALABS=0 implies no global expansion, which is the default unless the GLOBALPCT= option is specified.

GLOBALPCT=number specifies global expansion as a percentage of the length of the target sequence, where *number* ranges from zero to 100. GLOBALPCT=0 implies no global expansion, which is the default unless the GLOBALABS= option is specified. GLOBALPCT=100 implies maximum allowable global expansion.

LOCALABS=integer specifies the absolute local expansion, where *integer* ranges from zero to 10,000. The default is the maximum allowable absolute local expansion unless the LOCALPCT= option is specified.

LOCALPCT=number specifies local expansion as a percentage of the length of the target sequence, where *number* ranges from zero to 100. LOCALPCT=0 implies no local expansion. LOCALPCT=100 implies maximum allowable local expansion. The default is LOCALPCT=100.

If the SLIDE=NONE or the SLIDE=SEASON option is specified in the TARGET statement, the global expansion options are ignored. To disallow local expansion, use the option EXPAND=(LOCALPCT=0 LOCALABS=0).

If the SLIDE=INDEX option is specified, the global expansion options are not ignored. To completely disallow both global and local expansion, use the option EXPAND=(GLOBALPCT=0 LOCALPCT=0) or EXPAND=(GLOBALABS=0 LOCALABS=0). To allow only local expansion, use the option EXPAND=(GLOBALPCT=0 GLOBALABS=0). These are the default expansion options.

The preceding options can be used in combination to specify the desired amount of global and local expansion as the following examples illustrate, where L_e denotes the global expansion limit and l_e denotes the local expansion limit:

- EXPAND=(GLOBALPCT=20) allows the global and local expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$.
- EXPAND=(GLOBALPCT=20 GLOBALABS=10) allows the global and local expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$.
- EXPAND=(LOCALPCT=10) allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, (N_y - 1))$.

- EXPAND=(LOCALPCT=10 LOCALABS=5) allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, \min((N_y - 1), 5))$.
- EXPAND=(GLOBALPCT=20 LOCALPCT=10) allows the global expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$ and allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, (N_y - 1))$.
- EXPAND=(GLOBALPCT=20 GLOBALABS=10 LOCALPCT=10 LOCALABS=5) allows the global expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$ and allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, \min((N_y - 1), 5))$.

Suppose T_z is the length of the input time series and N_y is the length of the target sequence. The *valid* global expansion limit, L_e , is always limited by the length of the input time series: $0 \leq L_e < T_z$.

Suppose N_x is the length of the input sequence and N_y is the length of the target sequence. The *valid* local expansion limit, l_e , is always limited by the lengths of the input and target sequence: $\max(0, (N_x - N_y)) \leq l_e < N_x$.

MEASURE=option

specifies the similarity measure to be computed by using the working input and target sequences. The following similarity measures are provided:

SQRDEV	squared deviation. This option is the default.
ABSDEV	absolute deviation
MSQRDEV	mean squared deviation
MSQRDEVINP	mean squared deviation relative to the length of the input sequence
MSQRDEVTAR	mean squared deviation relative to the length of the target sequence
MSQRDEVMIN	mean squared deviation relative to the minimum valid path length
MSQRDEVMAX	mean squared deviation relative to the maximum valid path length
MABSDEV	mean absolute deviation
MABSDEVINP	mean absolute deviation relative to the length of the input sequence
MABSDEVTAR	mean absolute deviation relative to the length of the target sequence
MABSDEVMIN	mean absolute deviation relative to the minimum valid path length
MABSDEVMAX	mean absolute deviation relative to the maximum valid path length
<i>User-Defined</i>	The measure is computed by a user-defined function created by using the FCMP procedure, where <i>User-Defined</i> is the function name.

NORMALIZE=option

specifies the sequence normalization to be applied to the working target sequence. The following normalization options are provided:

NONE	No normalization is applied. This option is the default.
ABSOLUTE	Absolute normalization is applied.
STANDARD	Standard normalization is applied.
<i>User-Defined</i>	Normalization is computed by a user-defined subroutine that is created by using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

PATH=option

specifies the similarity measure and warping path information to be computed using the working input and target sequences. The following similarity measures and warping path are provided:

User-Defined The measure and path are computed by a user-defined subroutine that is created by using the FCMP procedure, where *User-Defined* is the subroutine name

For computational efficiency, the PATH= option should be only used when you want to compute both the similarity measure and the warping path information. If only the similarity measure is needed, use the MEASURE= option. If you specify both the MEASURE= and PATH= option in the TARGET statement, the PATH= option takes precedence.

SDIF=(numlist)

specifies the seasonal differencing to be applied to the accumulated time series. The list of seasonal differencing orders must be separated by spaces or commas. For example, SDIF=(1,3) specifies first, then third, order seasonal differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the SDIF= option. Seasonal differencing is useful when you want to deseasonalize the time series before computing the similarity measures.

SETMISSING=option | number**SETMISS=option | number**

option specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series for variables that are listed in the TARGET statement. If the SETMISSING= option is not specified in the TARGET statement, missing values are set based on the SETMISSING= option in the ID statement. If the SETMISSING= option is not specified in the ID statement or the TARGET statement, no missing value interpretation is performed. See the ID statement SETMISSING= option for more details.

SLIDE=option

specifies the sliding of the target sequence with respect to the input sequence. The following slides are provided:

NONE	No sequence sliding. The input time series is compared with the target sequence directly with no sliding. This option is the default.
INDEX	Slide by time index. The input time series is compared with the target sequence by observation index.
SEASON	Slide by seasonal index. The input time series is compared with the target sequence by seasonal index.

The SLIDE= option takes precedence over the COMPRESS= and EXPAND= options.

TRANSFORM=option

specifies the time series transformation to be applied to the accumulated time series. The following transformations are provided:

NONE	No transformation is applied. This option is the default.
LOG	Logarithmic transformation is applied.
SQRT	Square-root transformation is applied.

LOGISTIC	Logistic transformation is applied.
BOXCOX(<i>number</i>)	Box-Cox transformation with parameter is applied, where the real <i>number</i> is between -5 and 5
<i>User-Defined</i>	Transformation is computed by a user-defined subroutine that is created by using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

When the TRANSFORM= option is specified, the time series must be strictly positive unless a user-defined function is used.

TRIMMISSING=option

TRIMMISS= option

specifies how missing values (either actual or accumulated) are trimmed from the accumulated time series or ordered sequence for variables that are listed in the TARGET statement. The following trimming options are provided:

NONE	No missing value trimming is applied.
LEFT	Beginning missing values are trimmed.
RIGHT	Ending missing values are trimmed.
BOTH	Both beginning and ending missing values are trimmed. This is the default.

ZEROMISS=option

specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the TARGET statement. If the ZEROMISS= option is not specified in the TARGET statement, beginning and ending values are set based on the ZEROMISS= option in the ID statement. See the ID statement ZEROMISS= option for more details.

Details: SIMILARITY Procedure

You can use the SIMILARITY procedure to do the following functions, which are done in the order shown. First, you can form time series data from transactional data with the options shown:

1. accumulation ACCUMULATE= option
2. missing value interpretation SETMISSING= option
3. zero value interpretation ZEROMISS= option

Next, you can transform the accumulated time series to form the working time series with the following options. Transformations are useful when you want to stabilize the time series before computing the similarity measures. Simple and seasonal differencing are useful when you want to detrend or deseasonalize the time series before computing the similarity measures. Often, but not always, the TRANSFORM=, DIF=, and SDIF= options should be specified in the same way for both the target and input variables.

- 4. time series transformation TRANSFORM= option
- 5. time series differencing DIF= and SDIF= option
- 6. time series missing value trimming TRIMMISSING= option
- 7. time series descriptive statistics PRINT=DESCSTATS option

After the working series is formed, you can treat it as an ordered sequence that can be normalized or scaled. Normalizations are useful when you want to compare the “shape” or “profile” of the time series. Scaling is useful when you want to compare the input sequence to the target sequence while discounting the variation of the target sequence.

- 8. normalization NORMALIZE= option
- 9. scaling SCALE= option

After the working sequences are formed, you can compute similarity measures between input and target sequences:

- 10. sliding SLIDE= option
- 11. warping COMPRESS= and EXPAND= option
- 12. similarity measure MEASURE= and PATH= option

The SLIDE= option specifies observation-index sliding, seasonal-index sliding, or no sliding. The COMPRESS= and EXPAND= options specify the warping limits. The MEASURE= and PATH= options specify how the similarity measures are computed.

Accumulation

If the ACCUMULATE= option is specified in the ID, INPUT, or TARGET statement, data set observations are accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option in the ID statement. The ID variable contains the time ID values. Each time ID value corresponds to a specific time period. Accumulation is particularly useful when the input data set contains transactional data, whose observations are not spaced with respect to any particular time interval. The accumulated values form the time series, which is used in subsequent analyses.

For example, suppose a data set contains the following observations:

```
19MAR1999    10
19MAR1999    30
11MAY1999    50
12MAY1999    20
23MAY1999    20
```

If the INTERVAL=MONTH is specified, all of the preceding observations fall within three time periods of March 1999, April 1999, and May 1999. The observations are accumulated within each time period as follows:

If the ACCUMULATE=NONE option is specified, an error is generated because the ID variable values are not equally spaced with respect to the specified frequency (MONTH).

If the ACCUMULATE=TOTAL option is specified, the data are accumulated as follows:

O1MAR1999	40
O1APR1999	.
O1MAY1999	90

If the ACCUMULATE=AVERAGE option is specified, the data are accumulated as follows:

O1MAR1999	20
O1APR1999	.
O1MAY1999	30

If the ACCUMULATE=MINIMUM option is specified, the data are accumulated as follows:

O1MAR1999	10
O1APR1999	.
O1MAY1999	20

If the ACCUMULATE=MEDIAN option is specified, the data are accumulated as follows:

O1MAR1999	20
O1APR1999	.
O1MAY1999	20

If the ACCUMULATE=MAXIMUM option is specified, the data are accumulated as follows:

O1MAR1999	30
O1APR1999	.
O1MAY1999	50

If the ACCUMULATE=FIRST option is specified, the data are accumulated as follows:

O1MAR1999	10
O1APR1999	.
O1MAY1999	50

If the ACCUMULATE=LAST option is specified, the data are accumulated as follows:

O1MAR1999	30
O1APR1999	.
O1MAY1999	20

If the ACCUMULATE=STDDEV option is specified, the data are accumulated as follows:

```
01MAR1999    14.14
01APR1999    .
01MAY1999    17.32
```

As can be seen from the preceding examples, even though the data set observations contain no missing values, the accumulated time series can have missing values.

Missing Value Interpretation

Sometimes missing values should be interpreted as unknown values. But sometimes missing values are known, such as when missing values are created from accumulation and no observations should be interpreted as no (zero) value. In the former case, the SETMISSING= option in the ID, INPUT, or TARGET statement can be used to interpret how missing values are treated. The SETMISSING=0 option should be used when missing observations are to be treated as no (zero) values. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and interpreted time series is used in subsequent analyses.

The SETMISSING=0 option should be used with missing observations are to be treated as a zero value. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and interpreted time series is then used in subsequent analyses.

Zero Value Interpretation

When querying certain databases for time-stamped data based on a particular time range, time periods that contain no data are sometimes assigned zero values. For certain analyses, it is more desirable to assign these values to missing. Often, these beginning or ending zero values need to be interpreted as missing values. The ZEROMISS= option in the ID, INPUT, or TARGET statement specifies that the beginning, ending, or both the beginning and ending values are to be interpreted as zero values.

Time Series Transformation

Transformations are useful when you want to stabilize the time series before computing the similarity measures. There are four transformations available, for strictly positive series only. Let $y_t > 0$ be the original time series, and let w_t be the transformed series. The transformations are defined as follows:

Log is the logarithmic transformation,

$$w_t = \ln(y_t)$$

Logistic is the logistic transformation,

$$w_t = \ln(cy_t/(1 - cy_t))$$

where the scaling factor c is

$$c = (1 - e^{-6})10^{-\text{ceil}(\log_{10}(\max(y_t)))}$$

and $\text{ceil}(x)$ is the smallest integer greater than or equal to x .

Square root is the square root transformation,

$$w_t = \sqrt{y_t}$$

Box-Cox is the Box-Cox transformation,

$$w_t = \begin{cases} \frac{y_t^\lambda - 1}{\lambda} & \lambda \neq 0 \\ \ln(y_t) & \lambda = 0 \end{cases}$$

User-Defined is the transformation computed by a user-defined subroutine that is created by using the FCMP procedure, where *User-Defined* is the subroutine name.

Other time series transformations can be performed prior to invoking the SIMILARITY procedure by using the SAS/ETS EXPAND procedure or the DATA step.

Time Series Differencing

After optionally transforming the series, the accumulated series can be simply or seasonally differenced using the INPUT or TARGET statement DIF= and SDIF= options. Simple and seasonal differencing are useful when you want to detrend or deseasonalize the time series before computing the similarity measures.

For example, suppose y_t is a monthly time series. The following examples of the DIF= and SDIF= options demonstrate how to simply and seasonally difference the time series: DIF=(1,3) specifies first, then third, order differencing; SDIF=(1,3) specifies first, then third, order seasonal differencing.

Additionally, assuming that y_t is strictly positive, the INPUT or TARGET statement TRANSFORM= option and the DIF= and SDIF= options can be combined.

Time Series Missing Value Trimming

In some instances, missing values should be interpreted as an unknown observation, but other times, missing values are known and should be interpreted as a zero value. This is the case when missing values are created from accumulation, and a missing observation should be interpreted as having no value (meaning a value of zero). In the former case, the SETMISSING=option in the ID, INPUT, or TARGET, statement can be used to interpret how missing observations should be treated. By default, missing values, at the beginning and ending of the data set, are trimmed from the data set prior to analysis. This can be performed using TRIMMISS=both.

Time Series Descriptive Statistics

After a series has been optionally accumulated and transformed with missing values interpreted, descriptive statistics can be computed for the resulting working series by specifying the PRINT=DESCSTATS option. This option produces an ODS table that contains the sum, mean, minimum, maximum, and standard deviation of the working series.

Input and Target Sequences

After the input and target working series are formed, they can be treated as two ordered sequences. Given an input time sequence, x_i , for $i = 1$ to N_x , where i is the input sequence index, and a target time sequence, y_j , for $j = 1$ to N_y , where j is the target sequence index, these sequences are analyzed for similarity.

Sliding Sequences

Similarity measures can be computed between the target sequence and any contiguous subsequences of the input time series.

There are three types of sequence sliding:

- no sliding
- slide by time index
- slide by season index

For more information, see Leonard, Elsheimer, and Sloan (2008).

Time Warping

Time warping allows for the comparison between target and input sequences of differing lengths by compressing or expanding the input sequence with respect to the target sequence while respecting the order of the sequence elements.

For more information, see Leonard, Elsheimer, and Sloan (2008).

Sequence Normalization

The working (input or target) sequence can be normalized prior to further analysis. Let q_i be the original sequence with mean μ_q and standard deviation σ_q , and let r_t be the normalized sequence. The normalizations are defined as follows:

- Standard is the standard normalization

$$r_i = (q_i - \mu_q) / \sigma_q$$

- Absolute is the absolute normalization

$$r_i = (q_i - \min(q_i)) / (\max(q_i) - \min(q_i))$$

- User-defined is a user-defined normalization created by the FCMP procedure.

Sequence Scaling

The working input sequence can be scaled to the working target sequence. Sequence scaling is applied after normalization. Let y_j be the working target sequence with mean μ_y and standard deviation σ_y . Let x_i be the working input sequence and let q_i be the scaled sequence. The scaling is defined as follows:

- Standard is the standard normalization

$$q_i = (x_i - \mu_y) / \sigma_y$$

- Absolute is the absolute scaling

$$q_i = (x_i - \min(y_j)) / (\max(y_j) - \min(y_j))$$

- User-defined is a user-defined scaling created by the FCMP procedure.

Similarity Measures

The working input sequence can be compared to the working target sequence to create a similarity.

For more information, see Leonard, Elsheimer, and Sloan (2008).

User-Defined Functions and Subroutines

A user-defined routine can be written in the SAS language by using the FCMP procedure or in the C language by using both the FCMP procedure and the PROTO procedure, respectively. The SIMILARITY procedure cannot use C language routines directly. The procedure can use only SAS language routines that might or might not call C language routines. Creating user-defined routines is more completely described in the FCMP procedure and the PROTO procedure documentation. The FCMP and PROTO procedures are part of Base SAS software.

The SAS language provides integrated memory management and exception handling such as operations on missing values. The C language provides flexibility and allows the integration of existing C language libraries. However, proper memory management and exception handling are solely the responsibility of

the user. Additionally, the support for standard C libraries is restricted. If you have a choice, it is highly recommended that you write user-defined functions and subroutines in the SAS language using the FCMP procedure.

For each of the tasks previously described, the following sections describe the required subroutine or function signature and provide examples of using a user-defined routine with the SIMILARITY procedure.

Time Series Transformations

A user-defined transformation subroutine has the following subroutine signature:

```
SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*] );
```

where the array-name is the time series to be transformed.

For example, to duplicate the functionality of the built-in TRANSFORM=LOG option in the INPUT and TARGET statement, the following SAS statements create a user-defined version of this transformation called MYTRANSFORM and store this subroutine in the catalog SASUSER.MYSIMILAR.

```
proc fcmp outlib=sasuser.mysimilar.package;

  subroutine mytransform( series[*] );

    outargs series;

    length = DIM(series);

    do i = 1 to length;
      value = series[i];
      if value > 0 then do;
        series[i] = log( value );
      end;
      else do;
        series[i] = .;
      end;
    end;

  endsub;

run;
```

This user-defined subroutine can be specified in the TRANSFORM= option in the INPUT or TARGET statement as follows:

```
options cmplib = sasuser.mysimilar;

proc similarity ...;
...
input myinput / transform=mytransform;
target mytarget / transform=mytransform;
...
run;
```

Sequence Normalizations

A user-defined normalization subroutine has the following signature:

```
SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*] );
```

where the array-name is the sequence to be normalized.

For example, to duplicate the functionality of the built-in NORMALIZE=ABSOLUTE option in the INPUT and TARGET statement, the following SAS statements create a user-defined version of this normalization called MYNORMALIZE and store this subroutine in the catalog SASUSER.MYSIMILAR.

```
proc fcmp outlib=sasuser.mysimilar.package;

  subroutine mynormalize( sequence[*] );

    outargs sequence;

    length = DIM(sequence);
    minimum = .; maximum = .;

    do i = 1 to length;
      value = sequence[i];
      if nmiss(minimum) | nmiss(maximum) then do;
        minimum = value;
        maximum = value;
      end;
      if nmiss(value) = 0 then do;
        if value < minimum then minimum = value;
        if value > maximum then maximum = value;
      end;
    end;

    do i = 1 to length;
      value = sequence[i];
      if nmiss( value ) | minimum > maximum then do;
        sequence[i] = .;
      end;
      else do;
        sequence[i] = (value - minimum) / (maximum - minimum);
      end;
    end;

  endsub;

run;
```

This user-defined subroutine can be specified in the NORMALIZE= option in the INPUT or TARGET statement as follows:

```
options cmplib = sasuser.mysimilar;

proc similarity ...;
  ...
  input myinput / normalize=mynormalize;
```

```

    target mytarget / normalize=mynormalize;
    ...
run;

```

Sequence Scaling

A user-defined scaling subroutine has the following signature:

```
SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*], <ARRAY-NAME>[*] );
```

where the first array-name is the target sequence and the second array-name is the input sequence to be scaled.

For example, to duplicate the functionality of the built-in SCALE=ABSOLUTE option in the INPUT statement, the following SAS statements create a user-defined version of this scaling called MYSCALE and store this subroutine in the catalog SASUSER.MYSIMILAR.

```

proc fcmp outlib=sasuser.mysimilar.package;

  subroutine myscale( target[*], input[*] );

    outargs input;

    length = DIM(target);
    minimum = .; maximum = .;

    do i = 1 to length;
      value = target[i];
      if nmiss(minimum) | nmiss(maximum) then do;
        minimum = value;
        maximum = value;
      end;
      if nmiss(value) = 0 then do;
        if value < minimum then minimum = value;
        if value > maximum then maximum = value;
      end;
    end;

    do i = 1 to length;
      value = input[i];
      if nmiss( value ) | minimum > maximum then do;
        input[i] = .;
      end;
      else do;
        input[i] = (value - minimum) / (maximum - minimum);
      end;
    end;

  endsub;

run;

```

This user-defined subroutine can be specified in the SCALE= option in the INPUT statement as follows:

```

options cmplib=sasuser.mysimilar;

proc similarity ...;
  ...
  input myinput / scale=myscale;
  ...
run;

```

Similarity Measures

A user-defined similarity measure function has the following signature:

```
FUNCTION <FUNCTION-NAME> ( <ARRAY-NAME>[*], <ARRAY-NAME>[*] );
```

where the first array-name is the target sequence and the second array-name is the input sequence. The return value of the function is the similarity measure associated with the target sequence and the input sequence.

For example, to duplicate the functionality of the built-in MEASURE=ABSDEV option in the TARGET statement with no warping, the following SAS statements create a user-defined version of this measure called MYMEASURE and store this subroutine in the catalog SASUSER.MYSIMILAR.

```

proc fcmp outlib=sasuser.mysimilar.package;

  function mymeasure( target[*], input[*] );

    length = min(DIM(target), DIM(input));
    sum = 0; num = 0;

    do i = 1 to length;
      x = input[i];
      w = target[i];
      if nmiss(x) = 0 & nmiss(w) = 0 then do;
        d = x - w;
        sum = sum + abs(d);
        num = num + 1;
      end;
    end;

    if num <= 0 then return(.);

    return(sum);

  endsub;

run;

```

This user-defined function can be specified in the MEASURE= option in the TARGET statement as follows:

```

options cmplib=sasuser.mysimilar;

proc similarity ...;
  ...
  target mytarget / measure=mymmeasure;
  ...
run;

```

For another example, to duplicate the functionality of the built-in MEASURE=SQRDEV and MEASURE=ABSDEV options by using the C language, the following SAS statements create a user-defined C language version of these measures called DTW_SQRDEV_C and DTW_ABSDEV_C and store these functions in the catalog SASUSER.CSIMIL.CFUNCS. DTW refers to dynamic time warping. These C language functions can be then called by SAS language functions and subroutines.

```
proc proto package=sasuser.csimil.cfuncs;

mapmiss double = 999999999;

double dtw_sqrdev_c( double * target / iotype=input,
                    int      targetLength,
                    double * input / iotype=input,
                    int      inputLength );

externc dtw_sqrdev_c;
double dtw_sqrdev_c( double * target,
                    int      targetLength,
                    double * input,
                    int      inputLength )
{
    int      i,j;
    double   x,w,d;
    double * prev = (double *)malloc( sizeof(double)*targetLength);
    double * curr = (double *)malloc( sizeof(double)*inputLength);
    if ( prev == 0 || curr == 0 ) return 999999999;

    x = input[0];
    for ( j=0; j<targetLength; j++ ) {
        w = target[j];
        d = x - w;
        d = d*d;
        if ( j == 0 ) prev[j] = d;
        else          prev[j] = d + prev[j-1];
    }

    for (i=1; i<inputLength; i++ ) {
        x = input[i];

        j = 0;
        w = target[j];
        d = x - w;
        d = d*d;
        curr[j] = d + prev[j];

        for (j=1; j<targetLength; j++ ) {
            w = target[j];
            d = x - w;
            d = d*d;
            curr[j] = d + fmin( prev[j],
                               fmin( prev[j-1], curr[j])));
        }

        if ( i < targetLength ) {
            for( j=0; j<inputLength; j++ )
                prev[j] = curr[j];
        }
    }
}
```

```

    }

    d = curr[inputLength-1];
    free( (char*) prev);
    free( (char*) curr);
    return( d );
}

    }
externcend;

run;

```

The preceding SAS statements create two C language functions which can then be used in SAS language functions or subroutines or both. However, these functions cannot be directly used by the SIMILARITY procedure. In order to use these C language functions in the SIMILARITY procedure, two SAS language functions must be created that call these two C language functions. The following SAS statements create two user-defined SAS language versions of these measures called DTW_SQRDEV and DTW_ABSDEV and stores these functions in the catalog SASUSER.MYSIMILAR.FUNCS. These SAS language functions use the previously created C language function; the SAS language functions can then be used by the SIMILARITY procedure.

```

proc fcmp outlib=sasuser.mysimilar.funcs
    inlib=sasuser.cfuncs;

    function dtw_sqrdev( target[*], input[*] );
        dev = dtw_sqrdev_c(target,DIM(target),input,DIM(input));
        return( dev );
    endsub;

    function dtw_absdev( target[*], input[*] );
        dev = dtw_absdev_c(target,DIM(target),input,DIM(input));
        return( dev );
    endsub;

run;

```

This user-defined function can be specified in the MEASURE= option in the TARGET statement as follows:

```

options cmplib=sasuser.mysimilar;

proc similarity ...;
    ...
    target  mytarget    / measure=dtw_sqrdev;
    target  yourtarget  / measure=dtw_absdev;
    ...
run;

```

Similarity Measures and Warping Path

A user-defined similarity measure and warping path information function has the following signature:

```

FUNCTION <FUNCTION-NAME> ( <ARRAY-NAME>[*], <ARRAY-NAME>[*],
                           <ARRAY-NAME>[*], <ARRAY-NAME>[*],
                           <ARRAY-NAME>[*] );

```

where the first array-name is the target sequence, the second array-name is the input sequence, the third array-name is the returned target sequence indices, the fourth array-name is the returned input sequence indices, the fifth array-name is the returned path distances. The returned value of the function is the similarity measure. The last three returned arrays are used to compute the path and cost statistics.

The returned sequence indices must represent a valid warping path; that is, integers greater than zero and less than or equal to the sequence length and recorded in ascending order. The returned path distances must be nonnegative numbers.

Output Data Sets

The SIMILARITY procedure can create the OUT=, OUTMEASURE=, OUTPATH=, OUTSEQUENCE=, and OUTSUM= data sets. In general, these data sets contain the variables listed in the BY statement. The ID statement time ID variable is also included in the data sets when the time dimension is important. If an analysis step related to an output data step fails, then the values of this step are not recorded or are set to missing in the related output data set, and appropriate error and warning messages are recorded in the SAS log.

OUT= Data Set

The OUT= data set contains the variables that are specified in the BY, ID, INPUT, and TARGET statements. If the ID statement is specified, the ID variable values are aligned and extended based on the ALIGN=, INTERVAL=, START=, and END= options. The values of the variables specified in the INPUT and TARGET statements are accumulated based on the ACCUMULATE= option, missing values are interpreted based on the SETMISSING= option, and zero values are interpreted using the ZEROMISS= option. The accumulated time series is transformed based on the TRANSFORM=, DIF=, and SDIF= options.

OUTMEASURE= Data Set

The OUTMEASURE= data set records the similarity measures between each INPUT and TARGET statement variable with respect to each time ID value. The form of the OUTMEASURE= data set depends on the SORTNAMES and ORDER= options. The OUTMEASURE= data set contains the variables specified in the BY statement in addition to the variables listed below.

For ORDER=INPUTTARGET and ORDER=TARGETINPUT, the OUTMEASURE= data set has the following form:

<code>_INPUT_</code>	input variable name
<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_INPSEQ_</code>	input sequence values
<code>_TARSEQ_</code>	target sequence values
<code>_SIM_</code>	similarity measures

The OUTMEASURE= data set is ordered by the variables `_INPUT_`, then `_TARGET_`, then `_TIMEID_` when `ORDER=INPUTTARGET`. The OUTMEASURE= data set is ordered by the variables `_TARGET_`, then `_INPUT_`, then `_TIMEID_` when `ORDER=TARGETINPUT`.

For `ORDER=INPUT`, the OUTMEASURE= data set has the following form:

<code>_INPUT_</code>	input variable name
<code>_TIMEID_</code>	time ID values
<code>_INPSEQ_</code>	input sequence values
<i>target-names</i>	similarity measures that are associated with each TARGET statement variable name

The OUTMEASURE= data set is ordered by the variables `_INPUT_`, then `_TIMEID_`.

For `ORDER=TARGET`, the OUTMEASURE= data set has the following form:

<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_TARSEQ_</code>	target sequence values
<i>input-names</i>	similarity measures that are associated with each INPUT statement variable name

The OUTMEASURE= data set is ordered by the variables `_TARGET_`, then `_TIMEID_`.

OUTPATH= Data Set

The OUTPATH= data set records the path analysis between each INPUT and TARGET statement variable. This data set records the path sequences for each slide index and for each warp index associated with the slide index. The sequence values recorded are normalized and scaled based on the `NORMALIZE=` and `SCALE=` options.

The OUTPATH= data set contains the variables specified in the BY statement and the following variables:

<code>_INPUT_</code>	input variable name
<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_SLIDE_</code>	slide index
<code>_WARP_</code>	warp index
<code>_INPSEQ_</code>	input sequence values
<code>_TARSEQ_</code>	target sequence values
<code>_INPPTH_</code>	input path index
<code>_TARPTH_</code>	target path index
<code>_METRIC_</code>	distance metric values

The Warp Index indicates the total amount of warping for each slide. A negative number represents compression of the target sequence. A positive number represents expansion of the target sequence. The Warp Index is always zero for SLIDE=NONE and SLIDE=SEASON.

The sorting of the OUTPATH= data set depends on the SORTNAMES and the ORDER= option.

The OUTPATH= data set is ordered by the variables `_INPUT_`, then `_TARGET_`, then `_TIMEID_` when ORDER=INPUTTARGET or ORDER=INPUT. The OUTPATH= data set is ordered by the variables `_TARGET_`, then `_INPUT_`, then `_TIMEID_` when ORDER=TARGETINPUT or ORDER=TARGET.

If there are a large number of slides or warps or both, this data set might be large.

OUTSEQUENCE= Data Set

The OUTSEQUENCE= data set records the input and target sequences that are associated with each INPUT and TARGET statement variable. This data set records the input and target sequence values for each slide index and for each warp index that is associated with the slide index. The sequence values that are recorded are normalized and scaled based on the NORMALIZE= and SCALE= options. This data set also contains the similarity measure associated with the two sequences.

The OUTSEQUENCE= data set contains the variables specified in the BY statement in addition to the following variables:

<code>_INPUT_</code>	input variable name
<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_SLIDE_</code>	slide index
<code>_WARP_</code>	warp index
<code>_INPSEQ_</code>	input sequence values
<code>_TARSEQ_</code>	target sequence values
<code>_SIM_</code>	similarity measure
<code>_STATUS_</code>	sequence status

The sorting of the OUTSEQUENCE= data set depends on the SORTNAMES and the ORDER= option.

The OUTSEQUENCE= data set is ordered by the variables `_INPUT_`, then `_TARGET_`, then `_TIMEID_` when ORDER=INPUTTARGET or ORDER=INPUT. The OUTSEQUENCE= data set is ordered by the variables `_TARGET_`, then `_INPUT_`, then `_TIMEID_` when ORDER=TARGETINPUT or ORDER=TARGET.

If there are a large number of slides or warps or both, this data set might be large.

OUTSUM= Data Set

The OUTSUM= data set summarizes the similarity measures between each INPUT and TARGET statement variable. The form of the OUTSUM= data set depends on the SORTNAMES and ORDER= option. If the SORTNAMES option is specified, each variable (INPUT or TARGET) is analyzed in ascending order. The

OUTSUM= data set contains the variables specified in the BY statement in addition to the variables listed below.

For ORDER=INPUTTARGET and ORDER=TARGETINPUT, the OUTSUM= data set has the following form:

<code>_INPUT_</code>	input variable name
<code>_TARGET_</code>	target variable name
<code>_STATUS_</code>	status flag that indicates whether the requested analyses were successful
<code>_TIMEID_</code>	time ID values
<code>_SIM_</code>	similarity measure summary

The OUTSUM= data set is ordered by the variables `_INPUT_`, then `_TARGET_` when ORDER=INPUTTARGET. The OUTSUM= data set is ordered by the variables `_TARGET_`, then `_INPUT_` when ORDER=TARGETINPUT.

For ORDER=INPUT, the OUTSUM= data set has the following form:

<code>_INPUT_</code>	input variable name
<code>_STATUS_</code>	status flag that indicates whether the requested analyses were successful
<i>target-names</i>	similarity measure summary that is associated with each TARGET statement variable name

The OUTSUM= data set is ordered by the variable `_INPUT_`.

For ORDER=TARGET, the OUTSUM= data set has the following form:

<code>_TARGET_</code>	target variable name
<code>_STATUS_</code>	status flag that indicates whether the requested analyses were successful
<i>input-names</i>	similarity measure summary that is associated with each INPUT statement variable name

The OUTSUM= data set is ordered by the variable `_TARGET_`.

`_STATUS_` Variable Values

The `_STATUS_` variable contains a code that specifies whether the similarity analysis has been successful or not. The `_STATUS_` variable can take the following values:

0	Success
3000	Accumulation failure
4000	Missing value interpretation failure
6000	Series is all missing
7000	Transformation failure
8000	Differencing failure

9000	Unable to compute descriptive statistics
10000	Normalization failure
11000	Input contains imbedded missing values
12000	Target contains imbedded missing values
13000	Scaling failure
14000	Measure failure
15000	Path failure
16000	Slide summarization failure

Printed Output

The SIMILARITY procedure optionally produces printed output by using the Output Delivery System (ODS). By default, the procedure produces no printed output. All output is controlled by the PRINT= and PRINTDETAILS options in the PROC SIMILARITY statement.

The sort, order, and form of the printed output depends on both the SORTNAMES option and the ORDER= option. If the SORTNAMES option is specified, each variable (INPUT or TARGET) is analyzed in ascending order. For ORDER=INPUTTARGET, the printed output is ordered by the INPUT statement variables (row) and then by the TARGET statement variables (row). For ORDER=TARGETINPUT, the printed output is ordered by the TARGET statement variables (row) and then by the INPUT statement variables (row). For ORDER=INPUT, the printed output is ordered by the INPUT statement variables (row) and then by the TARGET statement variables (column). For ORDER=TARGET, the printed output is ordered by the TARGET statement variables (row) and then by the INPUT statement variables (column).

In general, if an analysis step related to printed output fails, the values of that step are not printed and appropriate error and warning messages are recorded in the SAS log. The printed output is similar to the output data set; these similarities are described as follows:

PRINT=COSTS

prints the costs statistics.

PRINT=DESCSTATS

prints the descriptive statistics.

PRINT=PATHS

prints the path statistics.

PRINT=SLIDES

prints the sliding sequence summary.

PRINT=SUMMARY

prints the summary of similarity measures similar to the OUTSUM= data set.

PRINT=WARPS

prints the warp summary.

PRINTDETAILS

prints each table with greater detail.

ODS Table Names

The following table relates the PRINT= options to ODS tables.

Table 24.2 ODS Tables Produced in PROC SIMILARITY

ODS Table Name	Description	Option
CostStatistics	Cost statistics	PRINT=COSTS
DescStats	Descriptive statistics	PRINT=DESCSTATS
PathLimits	Path limits	PRINT=PATHS
PathStatistics	Path statistics	PRINT=PATHS
SlideMeasuresSummary	Summary of measure per slide	PRINT=SLIDES
MeasuresSummary	Measures summary	PRINT=SUMMARY
InputMeasuresSummary	Measures summary	PRINT=SUMMARY
TargetMeasuresSummary	Measures summary	PRINT=SUMMARY
WarpMeasuresSummary	Summary of measure per warp	PRINT=WARPS

The tables are related to a single series within a BY group.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the SIMILARITY procedure.

ODS Graph Names

PROC SIMILARITY assigns a name to each graph it creates by using ODS. You can use these names to selectively reference the graphs. The names are listed in [Table 24.3](#).

Table 24.3 ODS Graphics Produced by PROC SIMILARITY

ODS Graph Name	Plot Description	Statement	PLOTS= Option
CostsPlot	Costs plot	SIMILARITY	PLOTS=COSTS
NormalizedSequencePlot	Normalized Sequence Plot	SIMILARITY	PLOTS=NORMALIZED
PathDistancePlot	Path distances plot	SIMILARITY	PLOTS=DISTANCES
PathDistanceHistogram	Path distances histogram	SIMILARITY	PLOTS=DISTANCES
PathRelativeDistancePlot	Path relative distances plot	SIMILARITY	PLOTS=DISTANCES
PathRelativeDistanceHistogram	Path relative distances histogram	SIMILARITY	PLOTS=DISTANCES
PathPlot	Path plot	SIMILARITY	PLOTS=PATHS
PathSequencesPlot	Path sequences plot	SIMILARITY	PLOTS=MAPS
PathSequencesScaledPlot	Scaled path sequences map plot	SIMILARITY	PLOTS=MAPS
ScaledSequencePlot	Scaled Sequence plot	SIMILARITY	PLOTS=SCALED
SequencePlot	Sequence plot	SIMILARITY	PLOTS=SEQUENCES
SeriesPlot	Input time series plot	SIMILARITY	PLOTS=INPUTS
SimilarityPlot	Similarity measures plot	SIMILARITY	PLOTS=MEASURES
TargetSequencePlot	Target sequence plot	SIMILARITY	PLOTS=TARGETS
WarpPlot	Warping plot	SIMILARITY	PLOTS=WARPS
WarpScaledPlot	Scaled warping plot	SIMILARITY	PLOTS=WARPS

Time Series Plots

The time series plots (SeriesPlot) illustrate the input time series to be compared. The horizontal axis represents the input series time ID values, and the vertical axis represents the input series values.

Sequence Plots

The sequence plots (SequencePlot) illustrate the target and input sequences to be compared. The horizontal axis represents the (target or input) sequence index, and the vertical axis represents the (target or input) sequence values.

Path Plots

The path plot (PathPlot) and path limits plot (PathLimitsPlot) illustrate the path through the distance matrix. The horizontal axis represents the input sequence index, and the vertical axis represents the target sequence index. The dots represent the path coordinates. The upper parallel line represents the compression limit, and the lower parallel line represents the expansion limit. These plots visualize the path through the distance matrix. Vertical movements indicate compression, and horizontal movements represent expansion of the

target sequence with respect to the input sequence. These plots are useful for visualizing the amount of expansion and compression along the path.

Time Warp Plots

The time warp plot (`WarpPlot`) and scaled time warp plot (`WarpScaledPlot`) illustrate the time warping. The horizontal axis represents the (input and target) sequence index. The upper line plot represents the target sequence. The lower line plot represents the input sequence. The lines that connect the input and target sequence values represent the mapping between the input and target sequence indices along the optimal path. These plots visualize the warping of the time index with respect to the input and target sequence values. Expansion of a single target sequence value occurs when it is mapped to more than one input sequence value. Expansion of a single input sequence value occurs when it is mapped to more than one target sequence value. The plots are useful for visualizing the mapping between the input and target sequence values along the path. The plots are useful for comparing the path sequences or input and target sequence after time warping.

Path Sequence Plots

The path sequence plot (`PathSequencesPlot`) and scaled path sequence plot (`PathSequencesScaledPlot`) illustrate the sequence mapping along the optimal path. The horizontal axis represents the path index. The dashed line represents the time warped input sequence. The solid line represents the time warped target sequence. These plots visualize the mapping between the input and target sequence values with respect to the path index. The scaled plot with the input and target sequence values are scaled and evenly separated for visual convenience.

Path Distance Plots

The path distance plots (`PathDistancePlot`) and path relative distance plots (`PathRelativeDistancePlot`) illustrate the path (relative) distances. The horizontal axis represents the path index. The vertical needles represent the (relative) distances. The horizontal reference lines indicate one and two standard deviations.

The path distance histogram (`PathDistanceHistogram`) and path relative distance histogram (`PathDistanceRelativeHistogram`) illustrate the distribution of the path (relative) distances. The bars represent the histogram, and the solid line represents a normal distribution with the same mean and variance.

Cost Plots

The cost plot (`CostPlot`) and cost limits plot (`CostPlot`) illustrate the cost of traversing the distance matrix. The horizontal axis represents the input sequence index, and the vertical axis represents the target sequence index. The colors and shading within the plot illustrate the incremental cost of traversing the distance matrix. The upper parallel line represents the compression limit, and the lower parallel line represents the expansion limit.

Examples: SIMILARITY Procedure

Example 24.1: Accumulating Transactional Data into Time Series Data

This example uses the SIMILARITY procedure to illustrate the accumulation of time-stamped transactional data that has been recorded at no particular frequency into time series data at a specific frequency. After the time series is created, the various SAS/ETS procedures related to time series analysis, similarity analysis, seasonal adjustment and decomposition, modeling, and forecasting can be used to further analyze the time series data.

Suppose that the input data set WORK.RETAIL contains variables STORE and TIMESTAMP and numerous other numeric transaction variables. The BY variable STORE contains values that break up the transactions into groups (BY groups). The time ID variable TIMESTAMP contains SAS date values recorded at no particular frequency. The other data set variables contain the numeric transaction values to be analyzed. It is further assumed that the input data set is sorted by the variables STORE and TIMESTAMP.

The following statements form monthly time series from the transactional data based on the median value (ACCUMULATE=MEDIAN) of the transactions recorded with each time period. The accumulated time series values for time periods with no transactions are set to zero instead of missing (SETMISS=0). Only transactions recorded between the first day of 1998 (START='01JAN1998'D) and last day of 2000 (END='31JAN2000'D) are considered and if needed are extended to include this range.

```
proc similarity data=work.retail out=mseries;
  by store;
  id timestamp interval=month
              accumulate=median
              setmiss=0
              start='01jan1998'd
              end  ='31dec2000'd;
  target _NUMERIC_;
run;
```

The monthly time series data are stored in the data WORK.MSERIES. Each BY group associated with the BY variable STORE contains an observation for each of the 36 months associated with the years 1998, 1999, and 2000. Each observation contains the variable STORE, TIMESTAMP, and each of the analysis variables in the input DATA= data set.

After each set of transactions has been accumulated to form the corresponding time series, the accumulated time series can be analyzed by using various time series analysis techniques. For example, exponentially weighted moving averages can be used to smooth each series. The following statements use the EXPAND procedure to smooth the analysis variable named STOREITEM.

```
proc expand data=mseries
           out=smoothed
           from=month;
  by store;
  id timestamp;
  convert storeitem=smooth / transform=(ewma 0.1);
run;
```

The smoothed series is stored in the data set WORK.SMOOTHED. The variable SMOOTH contains the smoothed series.

If the time ID variable TIMESTAMP contains SAS datetime values instead of SAS date values, the INTERVAL=, START=, and END= options in the SIMILARITY procedure must be changed accordingly, and the following statements could be used to accumulate the datetime transactions to a monthly interval:

```
proc similarity data=work.retail
    out=tseries;
    by store;
    id timestamp interval=dtmonth
        accumulate=median
        setmiss=0
        start='01jan1998:00:00:00'dt
        end   ='31dec2000:00:00:00'dt;
    target _NUMERIC_;
run;
```

The monthly time series data are stored in the data WORK.TSERIES, and the time ID values use a SAS datetime representation.

Example 24.2: Similarity Analysis

This simple example illustrates how to use similarity analysis to compare two time sequences. The following statements create an example data set that contains two time sequences of differing lengths:

```
data test;
input i y x;
datalines;
1 2 3
2 4 5
3 6 3
4 7 3
5 3 3
6 8 6
7 9 3
8 3 8
9 10 .
10 11 .
;
run;
```

The following statements perform similarity analysis on the example data set:

```
proc similarity data=test out=_null_
    print=all plot=all;
    input x;
    target y / measure=absdev;
run;
```

The DATA=TEST option specifies that the input data set WORK.TEST is to be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The PRINT=ALL and

PLOTS=ALL options specify that all ODS tables and graphs are to be produced. The INPUT statement specifies that the input variable is X. The TARGET statement specifies that the target variable is Y and that the similarity measure is computed using absolute deviation (MEASURE=ABSDEV).

Output 24.2.1 Description Statistics of the Input Variable, x

Relative Costs based on Target Sequence values						

Output 24.2.16 Time Warp Plot

Output 24.2.17 Time Warp Scaled Plot

The following statements repeat the preceding similarity analysis on the example data set with warping limits:

```
proc similarity data=test out=_null_
  print=all plot=all;
  input x;
  target y / measure=absdev
             compress=(localabs=2)
             expand=(localabs=2);
run;
```

The COMPRESS=(LOCALABS=2) option limits local absolute compression to 2. The EXPAND=(LOCALABS=2) option limits local absolute expansion to 2.

Output 24.2.18 Path Plot with Warping Limits

Output 24.2.19 Warped Path Limits

Path Limits					
Limit	Specified Absolute	Specified Percentage	Minimum Allowed	Maximum Allowed	Applied
Compression	2	None	2	9	2
Expansion	2	None	0	7	2

Output 24.2.20 Cost Plot with Warping Limits

The following statements repeat the preceding similarity analysis on the example data set but store the results in output data sets:

```
proc similarity data=test out=series
  outsequence=sequences outpath=path outsum=summary;
  input x;
  target y / measure=absdev
             compress=(localabs=2)
             expand=(localabs=2);
run;
```

The OUT=SERIES, OUTSEQUENCE=SEQUENCES, OUTPATH=PATH, and OUTSUM=SUMMARY options specify that the output time series, time sequences, path analysis, and summary data sets be created, respectively.

Example 24.3: Sliding Similarity Analysis

This example illustrates how to use sliding similarity analysis to compare two time sequences. The SASHELP.WORKERS data set contains two similar time series variables (ELECTRIC and MASONRY), which represent employment over time. The following statements create an example data set that contains two time series of differing lengths, where the variable MASONRY has the first 12 and last 7 observations set to missing to simulate the lack of data associated with the target series:

```
data workers; set sashelp.workers;
  if '01JAN1978'D <= date < '01JAN1982'D then masonry = masonry;
  else masonry = .;
run;
```

The goal of sliding similarity measures analysis is find the slide index that corresponds to the most similar subsequence of the input series when compared to the target sequence. The following statements perform sliding similarity analysis on the example data set:

```
proc similarity data=workers out=_NULL_ print=(slides summary);
  id date interval=month;
  input electric;
  target masonry / slide=index measure=msqrdev
                  expand=(localabs=3 globalabs=3)
                  compress=(localabs=3 globalabs=3);
run;
```

The DATA=WORKERS option specifies that the input data set WORK.WORKERS is to be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The PRINT=(SLIDES SUMMARY) option specifies that the ODS tables related to the sliding similarity measures and their summary be produced. The INPUT statement specifies that the input variable is ELECTRIC. The TARGET statement specifies that the target variable is MASONRY and that the similarity measure be computed using mean squared deviation (MEASURE=MSQRDEV). The SLIDE=INDEX option specifies observation index sliding. The COMPRESS=(LOCALABS=3 GLOBALABS=3) option limits local and global absolute compression to 3. The EXPAND=(LOCALABS=3 GLOBALABS=3) option limits local and global absolute expansion to 3.

Output 24.3.1 Summary of the Slide Measures

The SIMILARITY Procedure					
Slide Measures Summary for Input=ELECTRIC and Target=MASONRY					
Slide Index	DATE	Slide Target Sequence Length	Slide Input Sequence Length	Slide Warping Amount	Slide Minimum Measure
0	JAN1977	48	51	3	497.6737
1	FEB1977	48	51	1	482.6777
2	MAR1977	48	51	0	474.1251
3	APR1977	48	51	0	490.7792
4	MAY1977	48	51	-2	533.0788
5	JUN1977	48	51	-3	605.8198
6	JUL1977	48	51	-3	701.7138
7	AUG1977	48	51	3	646.5918
8	SEP1977	48	51	3	616.3258
9	OCT1977	48	51	3	510.9836
10	NOV1977	48	51	3	382.1434
11	DEC1977	48	51	3	340.4702
12	JAN1978	48	51	2	327.0572
13	FEB1978	48	51	1	322.5460
14	MAR1978	48	51	0	325.2689
15	APR1978	48	51	-1	351.4161
16	MAY1978	48	51	-2	398.0490
17	JUN1978	48	50	-3	471.6931
18	JUL1978	48	49	-3	590.8089
19	AUG1978	48	48	0	595.2538
20	SEP1978	48	47	-1	689.2233
21	OCT1978	48	46	-2	745.8891
22	NOV1978	48	45	-3	679.1907

Output 24.3.2 Minimum Measure

Minimum Measure Summary	
Input Variable	MASONRY
ELECTRIC	322.5460

This analysis results in 23 slides based on the observation index. The minimum measure (322.5460) occurs at slide index 13 which corresponds to the time value FEB1978. Note that the original data set SASHELP.WORKERS was modified beginning at the time value JAN1978. This similarity analysis justifies the belief the ELECTRIC lags MASONRY by one month based on the time series cross-correlation analysis despite the lack of target data (MASONRY).

The goal of seasonal sliding similarity measures is to find the seasonal slide index that corresponds to the most similar seasonal subsequence of the input series when compared to the target sequence. The following statements repeat the preceding similarity analysis on the example data set with seasonal sliding:

```
proc similarity data=workers out=_NULL_ print=(slides summary);
  id date interval=month;
  input electric;
  target masonry / slide=season measure=msqrdev;
run;
```

Output 24.3.3 Summary of the Seasonal Slide Measures

The SIMILARITY Procedure					
Slide Measures Summary for Input=ELECTRIC and Target=MASONRY					
Slide Index	DATE	Slide Target Sequence Length	Slide Input Sequence Length	Slide Warping Amount	Slide Minimum Measure
0	JAN1977	48	48	0	1040.086
12	JAN1978	48	48	0	641.927

Output 24.3.4 Seasonal Minimum Measure

Minimum Measure Summary	
Input Variable	MASONRY
ELECTRIC	641.9273

The analysis differs from the previous analysis in that the slides are performed based on the seasonal index (SLIDE=SEASON) with no warping. With a seasonality of 12, two seasonal slides are considered at slide indices 0 and 12 with the minimum measure (641.9273) occurring at slide index 12 which corresponds to the time value JAN1978. Note that the original data set SASHELP.WORKERS was modified beginning at the time value JAN1978. This similarity analysis justifies the belief that ELECTRIC and MASONRY have similar seasonal properties based on seasonal decomposition analysis despite the lack of target data (MASONRY).

Example 24.4: Searching for Historical Analogies

This example illustrates how to search for historical analogies by using seasonal sliding similarity analysis of transactional time-stamped data. The SASHELP.TIMEDATA data set contains the variable (VOLUME), which represents activity over time. The following statements create an example data set that contains two time series of differing lengths, where the variable HISTORY represents the historical activity and RECENT represents the more recent activity:

```
data timedata; set sashelp.timedata;
  drop volume;
  recent = .;
  history = volume;
  if datetime >= '20AUG2000:00:00:00'DT then do;
    recent = volume;
    history = .;
  end;
run;
```

The goal of seasonal sliding similarity measures is to find the seasonal slide index that corresponds to the most similar seasonal subsequence of the input series when compared to the target sequence. The following statements perform similarity analysis on the example data set with seasonal sliding:

```
proc similarity data=timedata out=_NULL_ outsequence=sequences
  outsum=summary;
  id datetime interval=dtday accumulate=total
  start='27JUL1997:00:00:00'dt
  end='21OCT2000:11:59:59'DT;
  input history / normalize=absolute;
  target recent / slide=season normalize=absolute measure=mabsdev;
run;
```

The DATA=TIMEDATA option specifies that the input data set WORK.TIMEDATA be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The OUTSEQUENCE=SEQUENCES and OUTSUM=SUMMARY options specify the output sequences and summary data sets, respectively. The ID statement specifies that the time ID variable is DATETIME, which is to be accumulated on a daily basis (INTERVAL=DTDAY) by summing the transactions (ACCUMULATE=TOTAL). The ID statement also specifies that the data is accumulated on the weekly boundaries starting on the week of 27JUL1997 and ending on the week of 15OCT2000 (START='27JUL1997:00:00:00'DT END='21OCT2000:11:59:59'DT). The INPUT statement specifies that the input variable is HISTORY, which is to be normalized using absolute normalization (NORMALIZE=ABSOLUTE). The TARGET statement specifies that the target variable is RECENT, which is to be normalized by using absolute normalization (NORMALIZE=ABSOLUTE) and that the similarity measure be computed by using mean absolute deviation (MEASURE=MABSDEV). The SLIDE=SEASON options specifies season index sliding.

To illustrate the results of the similarity analysis, the output sequence data set must be subset by using the output summary data set.

```
data _NULL_; set summary;
  call symput('MEASURE', left(trim(putn(recent, 'BEST20.'))));
run;

data result; set sequences;
```

```

by _SLIDE_;
retain flag 0;
if first._SLIDE_ then do;
    if (&measure - 0.00001 < _SIM_ < &measure + 0.00001)
        then flag = 1;
end;
if flag then output;
if last._SLIDE_ then flag = 0;
run;

```

The following statements generate a cross series plot of the results:

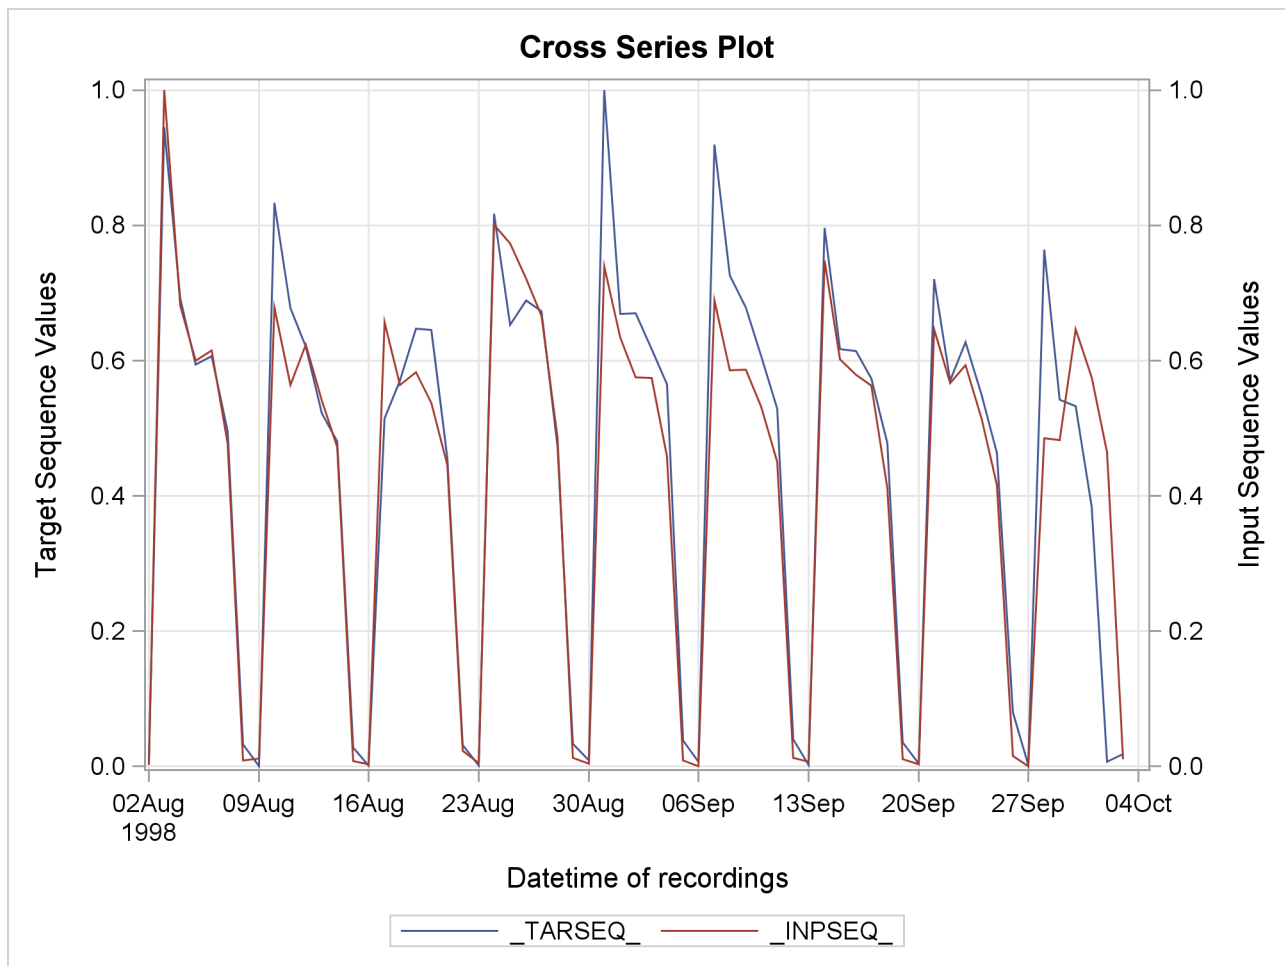

```

proc timeseries data=result out=_NULL_ crossplot=series;
    id datetime interval=dtday;
    var _TARSEQ_;
    crossvar _INPSEQ_;
run;

```

The cross series plot illustrates that the historical time series analogy most similar to the most recent time series data that started on 20AUG2000 occurred on 02AUG1998.

Output 24.4.1 Cross Series Plot of the Historical Time Series

Example 24.5: Clustering Time Series

This example illustrates how to cluster time series using a similarity matrix. The WORK.APPLIANCE data set contains 24 variables that record sales histories. The following statements create a similarity matrix and store the matrix in the WORK.SIMMATRIX data set:

```
proc similarity data=sashelp.applianc out=_null_ outsum=simmatrix;  
  target units_1--units_24 / measure=mabsdev normalize=absolute;  
run;
```

The following statements cluster the rows of the similarity matrix.

```
proc cluster data=simmatrix(drop=_status_) outtree=tree method=ward noprint;  
  id _input_;  
run;
```

The following statements plot the dendrogram:

```
proc tree data=tree horizontal;  
run;
```

Overview: SIMLIN Procedure

The SIMLIN procedure reads the coefficients for a set of linear structural equations, which are usually produced by the SYSLIN procedure. PROC SIMLIN then computes the reduced form and, if input data are given, uses the reduced form equations to generate predicted values. PROC SIMLIN is especially useful

when dealing with sets of structural difference equations. The SIMLIN procedure can perform simulation or forecasting of the endogenous variables.

The SIMLIN procedure can be applied only to models that are:

- linear with respect to the parameters
- linear with respect to the variables
- square (as many equations as endogenous variables)
- nonsingular (the coefficients of the endogenous variables form an invertible matrix)

Getting Started: SIMLIN Procedure

The SIMLIN procedure processes the coefficients in a data set created by the SYSLIN procedure using the OUTEST= option or by another regression procedure such as PROC REG. To use PROC SIMLIN you must first produce the coefficient data set and then specify this data set on the EST= option of the PROC SIMLIN statement. You must also tell PROC SIMLIN which variables are endogenous and which variables are exogenous. List the endogenous variables in an ENDOGENOUS statement, and list the exogenous variables in an EXOGENOUS statement.

The following example illustrates the creation of an OUTEST= data set with PROC SYSLIN and the computation and printing of the reduced form coefficients for the model with PROC SIMLIN.

```
proc syslin data=in outest=e;
  model y1 = y2 x1;
  model y2 = y1 x2;
run;

proc simlin est=e;
  endogenous y1 y2;
  exogenous x1 x2;
run;
```

If the model contains lagged endogenous variables you must also use a LAGGED statement to tell PROC SIMLIN which variables contain lagged values, which endogenous variables they are lags of, and the number of periods of lagging. For dynamic models, the TOTAL and INTERIM= options can be used on the PROC SIMLIN statement to compute and print total and impact multipliers. (See "Dynamic Multipliers" later in this section for an explanation of multipliers.)

In the following example the variables Y1LAG1, Y2LAG1, and Y2LAG2 contain lagged values of the endogenous variables Y1 and Y2. Y1LAG1 and Y2LAG1 contain values of Y1 and Y2 for the previous observation, while Y2LAG2 contains 2 period lags of Y2. The LAGGED statement specifies the lagged relationships, and the TOTAL and INTERIM= options request multiplier analysis. The INTERIM=2 option prints matrices showing the impact that changes to the exogenous variables have on the endogenous variables after 1 and 2 periods.

```

data in; set in;
  y1lag1 = lag(y1);
  y2lag1 = lag(y2);
  y2lag2 = lag2(y2);
run;

proc syslin data=in outest=e;
  model y1 = y2 y1lag1 y2lag2 x1;
  model y2 = y1 y2lag1 x2;
run;

proc simlin est=e total interim=2;
  endogenous y1 y2;
  exogenous x1 x2;
  lagged y1lag1 y1 1 y2lag1 y2 1 y2lag2 y2 2;
run;

```

After the reduced form of the model is computed, the model can be simulated by specifying an input data set on the PROC SIMLIN statement and using an OUTPUT statement to write the simulation results to an output data set. The following example modifies the PROC SIMLIN step from the preceding example to simulate the model and stores the results in an output data set.

```

proc simlin est=e total interim=2 data=in;
  endogenous y1 y2;
  exogenous x1 x2;
  lagged y1lag1 y1 1 y2lag1 y2 1 y2lag2 y2 2;
  output out=sim predicted=y1hat y2hat
         residual=y1resid y2resid;
run;

```

Prediction and Simulation

If an input data set is specified with the DATA= option in the PROC SIMLIN statement, the procedure reads the data and uses the reduced form equations to compute predicted and residual values for each of the endogenous variables. (If no data set is specified with the DATA= option, no simulation of the system is performed, and only the reduced form and multipliers are computed.)

The character of the prediction is based on the START= value. Until PROC SIMLIN encounters the START= observation, actual endogenous values are found and fed into the lagged endogenous terms. Once the START= observation is reached, dynamic simulation begins, where predicted values are fed into lagged endogenous terms until the end of the data set is reached.

The predicted and residual values generated here are different from those produced by the SYSLIN procedure since PROC SYSLIN uses the structural form with actual endogenous values. The predicted values computed by the SIMLIN procedure solve the simultaneous equation system. These reduced-form predicted values are functions only of the exogenous and lagged endogenous variables and do not depend on actual values of current period endogenous variables.

Syntax: SIMLIN Procedure

The following statements can be used with PROC SIMLIN:

```
PROC SIMLIN options ;
  BY variables ;
  ENDOGENOUS variables ;
  EXOGENOUS variables ;
  ID variables ;
  LAGGED lag-var endogenous-var number ellipsis ;
  OUTPUT OUT=SAS-data-set options ;
```

Functional Summary

The statements and options controlling the SIMLIN procedure are summarized in the following table.

Description	Statement	Option
Data Set Options		
specify input data set containing structural coefficients	PROC SIMLIN	EST=
specify type of estimates read from EST= data set	PROC SIMLIN	TYPE=
write reduced form coefficients and multipliers to an output data set	PROC SIMLIN	OUTEST=
specify the input data set for simulation	PROC SIMLIN	DATA=
write predicted and residual values to an output data set	OUTPUT	
Printing Control Options		
print the structural coefficients	PROC SIMLIN	ESTPRINT
suppress printing of reduced form coefficients	PROC SIMLIN	NORED
suppress all printed output	PROC SIMLIN	NOPRINT
Dynamic Multipliers		
compute interim multipliers	PROC SIMLIN	INTERIM=
compute total multipliers	PROC SIMLIN	TOTAL
Declaring the Role of Variables		
specify BY-group processing	BY	
specify the endogenous variables	ENDOGENOUS	
specify the exogenous variables	EXOGENOUS	
specify identifying variables	ID	
specify lagged endogenous variables	LAGGED	

Description	Statement	Option
Controlling the Simulation		
specify the starting observation for dynamic simulation	PROC SIMLIN	START=

PROC SIMLIN Statement

PROC SIMLIN *options* ;

The following options can be used in the PROC SIMLIN statement:

DATA= *SAS-data-set*

specifies the SAS data set containing input data for the simulation. If the DATA= option is used, the data set specified must supply values for all exogenous variables throughout the simulation. If the DATA= option is not specified, no simulation of the system is performed, and only the reduced form and multipliers are computed.

EST= *SAS-data-set*

specifies the input data set containing the structural coefficients of the system. If EST= is omitted the most recently created SAS data set is used. The EST= data set is normally a "TYPE=EST" data set produced by the OUTEST= option of PROC SYSLIN. However, you can also build the EST= data set with a SAS DATA step. See "The EST= Data Set" later in this chapter for details.

ESTPRINT

prints the structural coefficients read from the EST= data set.

INTERIM= *n*

requests that interim multipliers be computed for interims 1 through *n*. If not specified, no interim multipliers are computed. This feature is available only if there are no lags greater than 1.

NOPRINT

suppresses all printed output.

NORED

suppresses the printing of the reduced form coefficients.

OUTEST= *SAS-data-set*

specifies an output SAS data set to contain the reduced form coefficients and multipliers, in addition to the structural coefficients read from the EST= data set. The OUTEST= data set has the same form as the EST= data set. If the OUTEST= option is not specified, the reduced form coefficients and multipliers are not written to a data set.

START= *n*

specifies the observation number in the DATA= data set where the dynamic simulation is to be started. By default, the dynamic simulation starts with the first observation in the DATA= data set for which all variables (including lags) are not missing.

TOTAL

requests that the total multipliers be computed. This feature is available only if there are no lags greater than 1.

TYPE= value

specifies the type of estimates to be read from the EST= data set. The TYPE= value must match the value of the `_TYPE_` variable for the observations that you want to select from the EST= data set (TYPE=2SLS, for example).

BY Statement

BY variables ;

A BY statement can be used with PROC SIMLIN to obtain separate analyses for groups of observations defined by the BY variables.

The BY statement can be applied to one or both of the EST= and the DATA= input data set. When a BY statement is used and both an EST= and a DATA= input data set are specified, PROC SIMLIN checks to see if one or both of the data sets contain the BY variables.

Thus, there are three ways of using the BY statement with PROC SIMLIN:

1. If the BY variables are found in the EST= data set only, PROC SIMLIN simulates over the entire DATA= data set once for each set of coefficients read from the BY groups in the EST= data set.
2. If the BY variables are found in the DATA= data set only, PROC SIMLIN performs separate simulations over each BY group in the DATA= data set, using the single set of coefficients in the EST= data set.
3. If the BY variables are found in both the EST= and the DATA= data sets, PROC SIMLIN performs separate simulations over each BY group in the DATA= data set using the coefficients from the corresponding BY group in the EST= data set.

ENDOGENOUS Statement

ENDOGENOUS variables ;

List the names of the endogenous (jointly dependent) variables in the ENDOGENOUS statement. The ENDOGENOUS statement can be abbreviated as ENDOG or ENDO.

EXOGENOUS Statement

EXOGENOUS variables ;

List the names of the exogenous (independent) variables in the EXOGENOUS statement. The EXOGENOUS statement can be abbreviated as EXOG or EXO.

ID Statement

ID *variables ;*

The ID statement can be used to restrict the variables copied from the DATA= data set to the OUT= data set. Use the ID statement to list the variables you want copied to the OUT= data set besides the exogenous, endogenous, lagged endogenous, and BY variables. If the ID statement is omitted, all the variables in the DATA= data set are copied to the OUT= data set.

LAGGED Statement

LAGGED *lag-var endogenous-var number ellipsis ;*

For each lagged endogenous variable, specify the name of the lagged variable, the name of the endogenous variable that was lagged, and the degree of the lag. Only one LAGGED statement is allowed.

The following is an example of the use of the LAGGED statement:

```
proc simlin est=e;
  endog y1 y2;
  lagged y1lag1 y1 1  y2lag1 y2 1  y2lag3 y2 3;
run;
```

This statement specifies that the variable Y1LAG1 contains the values of the endogenous variable Y1 lagged one period; the variable Y2LAG1 refers to the values of Y2 lagged one period; and the variable Y2LAG3 refers to the values of Y2 lagged three periods.

OUTPUT Statement

OUTPUT *OUT= SAS-data-set options ;*

The OUTPUT statement specifies that predicted and residual values be put in an output data set. A DATA= input data set must be supplied if the OUTPUT statement is used, and only one OUTPUT statement is allowed. The following options can be used in the OUTPUT statement:

OUT= *SAS-data-set*

names the output SAS data set to contain the predicted values and residuals. If OUT= is not specified, the output data set is named using the DATA*n* convention.

PREDICTED= *names*

P= *names*

names the variables in the output data set that contain the predicted values of the simulation. These variables correspond to the endogenous variables in the order in which they are specified in the ENDOGENOUS statement. Specify up to as many names as there are endogenous variables. If you specify names on the PREDICTED= option for only some of the endogenous variables, predicted values for the remaining variables are not output. The names must not match any variable name in the input data set.

RESIDUAL= *names*

R= *names*

names names the variables in the output data set that contain the residual values from the simulation. The residuals are the differences between the actual values of the endogenous variables from the DATA= data set and the predicted values from the simulation. These variables correspond to the endogenous variables in the order in which they are specified in the ENDOGENOUS statement. Specify up to as many names as there are endogenous variables. The names must not match any variable name in the input data set.

The following is an example of the use of the OUTPUT statement. This example outputs predicted values for Y1 and Y2 and outputs residuals for Y1.

```
proc simlin est=e;
  endog y1 y2;
  output out=b predicted=y1hat y2hat
           residual=y1resid;
run;
```

Details: SIMLIN Procedure

The following sections explain the structural and reduced forms, dynamic multipliers, input data sets, and the model simulation process in more detail.

Defining the Structural Form

An EST= input data set supplies the coefficients of the equation system. The data set containing the coefficients is normally a "TYPE=EST" data set created by the OUTEST= option of PROC SYSLIN or another regression procedure. The data set contains the special variables _TYPE_, _DEPVAR_, and INTERCEPT. You can also supply the structural coefficients of the system to PROC SIMLIN in a data set produced by a SAS DATA step as long as the data set is of the form TYPE=EST. Refer to SAS/STAT software documentation for a discussion of the special TYPE=EST type of SAS data set.

Suppose that there is a $g \times 1$ vector of endogenous variables \mathbf{y}_t , an $l \times 1$ vector of lagged endogenous variables \mathbf{y}_t^L , and a $k \times 1$ vector of exogenous variables \mathbf{x}_t , including the intercept. Then, there are g structural equations in the simultaneous system that can be written

$$\mathbf{G}\mathbf{y}_t = \mathbf{C}\mathbf{y}_t^L + \mathbf{B}\mathbf{x}_t$$

where \mathbf{G} is the matrix of coefficients of current period endogenous variables, \mathbf{C} is the matrix of coefficients of lagged endogenous variables, and \mathbf{B} is the matrix of coefficients of exogenous variables. \mathbf{G} is assumed to be nonsingular.

Computing the Reduced Form

First, the SIMLIN procedure computes reduced form coefficients by premultiplying by \mathbf{G}^{-1} :

$$\mathbf{y}_t = \mathbf{G}^{-1}\mathbf{C}\mathbf{y}_t^L + \mathbf{G}^{-1}\mathbf{B}\mathbf{x}_t$$

This can be written as

$$\mathbf{y}_t = \Pi_1\mathbf{y}_t^L + \Pi_2\mathbf{x}_t$$

where $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$ and $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$ are the reduced form coefficient matrices.

The reduced form matrices $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$ and $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$ are printed unless the NORED option is specified in the PROC SIMLIN statement. The structural coefficient matrices \mathbf{G} , \mathbf{C} , and \mathbf{B} are printed when the ESTPRINT option is specified.

Dynamic Multipliers

For models that have only first-order lags, the equation of the reduced form of the system can be rewritten

$$\mathbf{y}_t = \mathbf{D}\mathbf{y}_{t-1} + \Pi_2\mathbf{x}_t$$

\mathbf{D} is a matrix formed from the columns of Π_1 plus some columns of zeros, arranged in the order in which the variables meet the lags. The elements of Π_2 are called *impact multipliers* because they show the immediate effect of changes in each exogenous variable on the values of the endogenous variables. This equation can be rewritten as

$$\mathbf{y}_t = \mathbf{D}^2\mathbf{y}_{t-2} + \mathbf{D}\Pi_2\mathbf{x}_{t-1} + \Pi_2\mathbf{x}_t$$

The matrix formed by the product $\mathbf{D}\Pi_2$ shows the effect of the exogenous variables one lag back; the elements in this matrix are called *interim multipliers* and are computed and printed when the INTERIM= option is specified in the PROC SIMLIN statement. The i th period interim multipliers are formed by $\mathbf{D}^i\Pi_2$.

The series can be expanded as

$$\mathbf{y}_t = \mathbf{D}^\infty\mathbf{y}_{t-\infty} + \sum_{i=0}^{\infty} \mathbf{D}^i\Pi_2\mathbf{x}_{t-i}$$

A permanent and constant setting of a value for x has the following cumulative effect:

$$\left(\sum_{i=0}^{\infty} \mathbf{D}^i\right)\Pi_2\mathbf{x} = (\mathbf{I} - \mathbf{D})^{-1}\Pi_2\mathbf{x}$$

The elements of $(\mathbf{I} - \mathbf{D})^{-1}\Pi_2$ are called the *total multipliers*. Assuming that the sum converges and that $(\mathbf{I} - \mathbf{D})$ is invertible, PROC SIMLIN computes the total multipliers when the TOTAL option is specified in the PROC SIMLIN statement.

Multipliers for Higher Order Lags

The dynamic multiplier options require the system to have no lags of order greater than one. This limitation can be circumvented, since any system with lags greater than one can be rewritten as a system where no lag is greater than one by forming new endogenous variables that are single-period lags.

For example, suppose you have the third-order single equation

$$y_t = ay_{t-3} + b\mathbf{x}_t$$

This can be converted to a first-order three-equation system by introducing two additional endogenous variables, $y_{1,t}$ and $y_{2,t}$, and computing corresponding first-order lagged variables for each endogenous variable: y_{t-1} , $y_{1,t-1}$, and $y_{2,t-1}$. The higher order lag relations are then produced by adding identities to link the endogenous and identical lagged endogenous variables:

$$y_{1,t} = y_{t-1}$$

$$y_{2,t} = y_{1,t-1}$$

$$y_t = ay_{2,t-1} + b\mathbf{X}_t$$

This conversion using the SYSLIN and SIMLIN procedures requires three steps:

1. Add the extra endogenous and lagged endogenous variables to the input data set using a DATA step. Note that two copies of each lagged endogenous variable are needed for each lag reduced, one to serve as an endogenous variable and one to serve as a lagged endogenous variable in the reduced system.
2. Add IDENTITY statements to the PROC SYSLIN step to equate each added endogenous variable to its lagged endogenous variable copy.
3. In the PROC SIMLIN step, declare the added endogenous variables in the ENDOGENOUS statement and define the lag relations in the LAGGED statement.

See [Example 25.2](#) for an illustration of how to convert an equation system with higher-order lags into a larger system with only first-order lags.

EST= Data Set

Normally, PROC SIMLIN uses an EST= data set produced by PROC SYSLIN with the OUTEST= option. This data set is in the form expected by PROC SIMLIN. If there is more than one set of estimates produced by PROC SYSLIN, you must use the TYPE= option in the PROC SIMLIN statement to select the set to be simulated. Then PROC SIMLIN reads from the EST= data set only those observations with a _TYPE_ value corresponding to the TYPE= option (for example, TYPE=2SLS) or with a _TYPE_ value of IDENTITY.

The SIMLIN procedure can only solve square, nonsingular systems. If you have fewer equations than endogenous variables, you must specify IDENTITY statements in the PROC SYSLIN step to bring the system up to full rank. If there are g endogenous variables and $m < g$ stochastic equations with unknown

parameters, then you use m MODEL statements to specify the equations with parameters to be estimated and you must use g - m IDENTITY statements to complete the system.

You can build your own EST= data set with a DATA step rather than use PROC SYSLIN. The EST= data set must contain the endogenous variables, the lagged endogenous variables (if any), and the exogenous variables in the system (if any). If any of the equations have intercept terms, the variable INTERCEPT must supply these coefficients. The EST= data set should also contain the special character variable comp _DEPVAR_ to label the equations.

The EST= data set must contain one observation for each equation in the system. The values of the lagged endogenous variables must contain the **C** coefficients. The values of the exogenous variables and the INTERCEPT variable must contain the **B** coefficients. The values of the endogenous variables, however, must contain the negatives of the **G** coefficients. This is because the SYSLIN procedure writes the coefficients to the OUTEST= data set in the form

$$0 = \mathbf{H}\mathbf{y}_t + \mathbf{C}\mathbf{y}_t^L + \mathbf{B}\mathbf{x}_t$$

where $\mathbf{H} = -\mathbf{G}$.

See "Multipliers for Higher Order Lags" and [Example 25.2](#) later in this chapter for more information on building the EST= data set.

DATA= Data Set

The DATA= data set must contain all of the exogenous variables. Values for all of the exogenous variables are required for each observation for which predicted endogenous values are desired. To forecast past the end of the historical data, the DATA= data set should contain nonmissing values for all of the exogenous variables and missing values for the endogenous variables for the forecast periods, in addition to the historical data. (See [Example 25.1](#) for an illustration.)

In order for PROC SIMLIN to output residuals and compute statistics of fit, the DATA= data set must also contain the endogenous variables with nonmissing actual values for each observation for which residuals and statistics are to be computed.

If the system contains lags, initial values must be supplied for the lagged variables. This can be done by including either the lagged variables or the endogenous variables, or both, in the DATA= data set. If the lagged variables are not in the DATA= data set or if they have missing values in the early observations, PROC SIMLIN prints a warning and uses the endogenous variable values from the early observations to initialize the lags.

OUTEST= Data Set

The OUTEST= data set contains all the variables read from the EST= data set. The variables in the OUTEST= data set are as follows.

- the BY statement variables, if any
- _TYPE_, a character variable that identifies the type of observation

- `_DEPVAR_`, a character variable containing the name of the dependent variable for the observation
- the endogenous variables
- the lagged endogenous variables
- the exogenous variables
- INTERCEPT, a numeric variable containing the intercept values
- `_MODEL_`, a character variable containing the name of the equation
- `_SIGMA_`, a numeric variable containing the estimated error variance of the equation (output only if present in the EST= data set)

The observations read from the EST= data set that supply the structural coefficients are copied to the OUTEST= data set, except that the signs of endogenous coefficients are reversed. For these observations, the `_TYPE_` variable values are the same as in the EST= data set.

In addition, the OUTEST= data set contains observations with the following `_TYPE_` values:

REDUCED	the reduced form coefficients. The endogenous variables for this group of observations contain the inverse of the endogenous coefficient matrix \mathbf{G} . The lagged endogenous variables contain the matrix $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$. The exogenous variables contain the matrix $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$.
IMULT <i>i</i>	the interim multipliers, if the INTERIM= option is specified. There are gn observations for the interim multipliers, where g is the number of endogenous variables and n is the value of the INTERIM= n option. For these observations the <code>_TYPE_</code> variable has the value IMULT <i>i</i> , where the interim number i ranges from 1 to n . The exogenous variables in groups of g observations that have a <code>_TYPE_</code> value of IMULT <i>i</i> contain the matrix $\mathbf{D}^i \Pi_2$ of multipliers at interim i . The endogenous and lagged endogenous variables for this group of observations are set to missing.
TOTAL	the total multipliers, if the TOTAL option is specified. The exogenous variables in this group of observations contain the matrix $(\mathbf{I} - \mathbf{D})^{-1} \Pi_2$. The endogenous and lagged endogenous variables for this group of observations are set to missing.

OUT= Data Set

The OUT= data set normally contains all of the variables in the input DATA= data set, plus the variables named in the PREDICTED= and RESIDUAL= options in the OUTPUT statement.

You can use an ID statement to restrict the variables that are copied from the input data set. If an ID statement is used, the OUT= data set contains only the BY variables (if any), the ID variables, the endogenous and lagged endogenous variables (if any), the exogenous variables, plus the PREDICTED= and RESIDUAL= variables.

The OUT= data set contains an observation for each observation in the DATA= data set. When the actual value of an endogenous variable is missing in the DATA= data set, or when the DATA= data set does not contain the endogenous variable, the corresponding residual is missing.

Printed Output

Structural Form

The following items are printed as they are read from the EST= input data set. Structural zeros are printed as dots in the listing of these matrices.

1. Structural Coefficients for Endogenous Variables. This is the **G** matrix, with g rows and g columns.
2. Structural Coefficients for Lagged Endogenous Variables. These coefficients make up the **C** matrix, with g rows and l columns.
3. Structural Coefficients for Exogenous Variables. These coefficients make up the **B** matrix, with g rows and k columns.

Reduced Form

1. The reduced form coefficients are obtained by inverting **G** so that the endogenous variables can be directly expressed as functions of only lagged endogenous and exogenous variables.
2. Inverse Coefficient Matrix for Endogenous Variables. This is the inverse of the **G** matrix.
3. Reduced Form for Lagged Endogenous Variables. This is $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$, with g rows and l columns. Each value is a dynamic multiplier that shows how past values of lagged endogenous variables affect values of each of the endogenous variables.
4. Reduced Form for Exogenous Variables. This is $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$, with g rows and k columns. Its values are called *impact multipliers* because they show the immediate effect of each exogenous variable on the value of the endogenous variables.

Multipliers

Interim and total multipliers show the effect of a change in an exogenous variable over time.

1. Interim Multipliers. These are the interim multiplier matrices. They are formed by multiplying Π_2 by powers of **D**. The d th interim multiplier is $\mathbf{D}^d \Pi_2$. The interim multiplier of order d shows the effects of a change in the exogenous variables after d periods. Interim multipliers are only available if the maximum lag of the endogenous variables is 1.
2. Total Multipliers. This is the matrix of total multipliers, $\mathbf{T} = (\mathbf{I} - \mathbf{D})^{-1} \Pi_2$. This matrix shows the cumulative effect of changes in the exogenous variables. Total multipliers are only available if the maximum lag is one.

Statistics of Fit

If the DATA= option is used and the DATA= data set contains endogenous variables, PROC SIMLIN prints a statistics-of-fit report for the simulation. The statistics printed include the following. (Summations are over the observations for which both y_t and \hat{y}_t are nonmissing.)

1. the number of nonmissing errors. (Number of observations for which both y_t and \hat{y}_t are nonmissing.)
2. the mean error: $\frac{1}{n} \sum (y_t - \hat{y}_t)$
3. the mean percent error: $\frac{100}{n} \sum \frac{(y_t - \hat{y}_t)}{y_t}$
4. the mean absolute error: $\frac{1}{n} \sum |y_t - \hat{y}_t|$
5. the mean absolute percent error $\frac{100}{n} \sum \frac{|y_t - \hat{y}_t|}{y_t}$
6. the root mean square error: $\sqrt{\frac{1}{n} \sum (y_t - \hat{y}_t)^2}$
7. the root mean square percent error: $\sqrt{\frac{100}{n} \sum \left(\frac{(y_t - \hat{y}_t)}{y_t}\right)^2}$

ODS Table Names

PROC SIMLIN assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 25.2 ODS Tables Produced in PROC SIMLIN

ODS Table Name	Description	Option
Endogenous	Structural Coefficients for Endogenous Variables	default
LaggedEndogenous	Structural Coefficients for Lagged Endogenous Variables	default
Exogenous	Structural Coefficients for Exogenous Variables	default
InverseCoeff	Inverse Coefficient Matrix for Endogenous Variables	default
RedFormLagEndo	Reduced Form for Lagged Endogenous Variables	default
RedFormExog	Reduced Form for Exogenous Variables	default
InterimMult	Interim Multipliers	INTERIM= option
TotalMult	Total Multipliers	TOTAL= option
FitStatistics	Fit statistics	default

Examples: SIMLIN Procedure

Example 25.1: Simulating Klein's Model I

In this example, the SIMLIN procedure simulates a model of the U.S. economy called Klein's Model I. The SAS data set KLEIN is used as input to the SYSLIN and SIMLIN procedures.

```
data klein;
  input year c p w i x wp g t k wsum;
  date=mdy(1,1,year);
  format date year.;
  y  = c + i + g - t;
  yr = year - 1931;
  klag = lag( k );
  plag = lag( p );
  xlag = lag( x );
  if year >= 1921;
  label c    ='consumption'
        p    ='profits'
        w    ='private wage bill'
        i    ='investment'
        k    ='capital stock'
        y    ='national income'
        x    ='private production'
        wsum ='total wage bill'
        wp   ='govt wage bill'
        g    ='govt demand'
        t    ='taxes'
        klag ='capital stock lagged'
        plag ='profits lagged'
        xlag ='private product lagged'
        yr   ='year-1931';
datalines;
1920      .  12.7      .      .  44.9      .      .      .  182.8      .
1921  41.9  12.4  25.5 -0.2  45.6  2.7    3.9    7.7  182.6  28.2

... more lines ...
```

First, the model is specified and estimated using the SYSLIN procedure, and the parameter estimates are written to an OUTEST= data set. The printed output produced by the SYSLIN procedure is not shown here; see [Example 29.1](#) in [Chapter 29](#) for the printed output of the PROC SYSLIN step.

```

title1 'Simulation of Klein''s Model I using SIMLIN';
proc syslin 3sls data=klein outest=a;

    instruments klag plag xlag wp g t yr;
    endogenous c p w i x wsum k y;

    consume: model    c = p plag wsum;
    invest:  model    i = p plag klag;
    labor:   model    w = x xlag yr;

    product: identity x = c + i + g;
    income:  identity y = c + i + g - t;
    profit:  identity p = x - w - t;
    stock:   identity k = klag + i;
    wage:    identity wsum = w + wp;
run;

```

The OUTEST= data set A created by the SYSLIN procedure contains parameter estimates to be used by the SIMLIN procedure. The OUTEST= data set is shown in [Output 25.1.1](#).

Output 25.1.1 The OUTEST= Data Set Created by PROC SYSLIN

Using the OUTEST= data set A produced by the SYSLIN procedure, the SIMLIN procedure can now compute the reduced form and simulate the model. The following statements perform the simulation.

```

title1 'Simulation of Klein''s Model I using SIMLIN';
proc simlin data=klein
    est=a type=3sls
    estprint
    total interim=2
    outest=b;
    endogenous c p w i x wsum k y;
    exogenous wp g t yr;
    lagged klag k 1   plag p 1   xlag x 1;
    id year;
    output out=c p=chat phat what ihat xhat wsumhat khat yhat
           r=cres pres wres ires xres wsumres kres yres;
run;

```

The reduced form coefficients and multipliers are added to the information read from EST= data set A and written to the OUTEST= data set B. The predicted and residual values from the simulation are written to the OUT= data set C specified in the OUTPUT statement.

The SIMLIN procedure first prints the structural coefficient matrices read from the EST= data set, as shown in [Output 25.1.2](#) through [Output 25.1.4](#).

Output 25.1.2 SIMLIN Procedure Output – Endogenous Structural Coefficients

Simulation of Klein's Model I using SIMLIN

Example 25.2: Multipliers for a Third-Order System

This example shows how to fit and simulate a single equation dynamic model with third-order lags. It then shows how to convert the third-order equation into a three equation system with only first-order lags, so that the SIMLIN procedure can compute multipliers. (See the section "Multipliers for Higher Order Lags" earlier in this chapter for more information.)

The input data set TEST is created from simulated data. A partial listing of the data set TEST produced by PROC PRINT is shown in [Output 25.2.1](#).

Overview: SPECTRA Procedure

The SPECTRA procedure performs spectral and cross-spectral analysis of time series. You can use spectral analysis techniques to look for periodicities or cyclical patterns in data.

The SPECTRA procedure produces estimates of the spectral and cross-spectral densities of a multivariate time series. Estimates of the spectral and cross-spectral densities of a multivariate time series are produced using a finite Fourier transform to obtain periodograms and cross-periodograms. The periodogram ordinates are smoothed by a moving average to produce estimated spectral and cross-spectral densities. PROC SPECTRA can also test whether or not the data are white noise.

PROC SPECTRA uses the finite Fourier transform to decompose data series into a sum of sine and cosine waves of different amplitudes and wavelengths. The finite Fourier transform decomposition of the series x_t is

$$x_t = \frac{a_0}{2} + \sum_{k=1}^{m-1} f_k (a_k \cos \omega_k t + b_k \sin \omega_k t)$$

$$f_k = \begin{cases} 1/2 & \text{if } n \text{ is even and } k = m - 1 \\ 1 & \text{otherwise} \end{cases}$$

where

t	is the time subscript, $t = 0, 1, 2, \dots, n - 1$
x_t	are the equally spaced time series data
n	is the number of observations in the time series
m	is the number of frequencies in the Fourier decomposition: $m = \frac{n+2}{2}$ if n is even, $m = \frac{n+1}{2}$ if n is odd
k	is the frequency subscript, $k = 0, 1, 2, \dots, m - 1$
a_0	is the mean term: $a_0 = 2\bar{x}$
a_k	are the cosine coefficients
b_k	are the sine coefficients
ω_k	are the Fourier frequencies: $\omega_k = \frac{2\pi k}{n}$

Functions of the Fourier coefficients a_k and b_k can be plotted against frequency or against wave length to form *periodograms*. The amplitude periodogram J_k is defined as follows:

$$J_k = \frac{n}{2}(a_k^2 + b_k^2)$$

Several definitions of the term periodogram are used in the spectral analysis literature. The following discussion refers to the J_k sequence as the periodogram.

The periodogram can be interpreted as the contribution of the k th harmonic ω_k to the total sum of squares (in an analysis of variance sense) in the decomposition of the process into two-degree-of-freedom components for each of the m frequencies. When n is even, $\sin(\omega_{\frac{n}{2}})$ is zero, and thus the last periodogram value is a one-degree-of-freedom component.

The periodogram is a volatile and inconsistent estimator of the spectrum. The spectral density estimate is produced by smoothing the periodogram. Smoothing reduces the variance of the estimator but introduces a bias. The weight function used for the smoothing process, $W()$, often called the kernel or spectral window, is specified with the WEIGHTS statement. It is related to another weight function, $w()$, the lag window, that is used in other methods to taper the correlogram rather than to smooth the periodogram. Many specific weighting functions have been suggested in the literature (Fuller 1976; Jenkins and Watts 1968; Priestley 1981). Table 26.3 later in this chapter gives the relevant formulas when the WEIGHTS statement is used.

Letting i represent the imaginary unit $\sqrt{-1}$, the cross-periodogram is defined as follows:

$$J_k^{xy} = \frac{n}{2}(a_k^x a_k^y + b_k^x b_k^y) + i \frac{n}{2}(a_k^x b_k^y - b_k^x a_k^y)$$

The cross-spectral density estimate is produced by smoothing the cross-periodogram in the same way as the periodograms are smoothed using the spectral window specified by the WEIGHTS statement.

The SPECTRA procedure creates an output SAS data set whose variables contain values of the periodograms, cross-periodograms, estimates of spectral densities, and estimates of cross-spectral densities. The form of the output data set is described in the section “OUT= Data Set” on page 1871.

Getting Started: SPECTRA Procedure

To use the SPECTRA procedure, specify the input and output data sets and options for the analysis you want in the PROC SPECTRA statement, and list the variables to analyze in the VAR statement. The procedure produces no printed output unless the WHITESTEST option is specified in the PROC SPECTRA statement. The periodogram, spectral density, and other results are written to the OUT= data set, depending on the options used.

For example, to compute the Fourier transform of a variable X in a data set A, use the following statements:

```
proc spectra data=a out=b coef;
  var x;
run;
```

This PROC SPECTRA step writes the Fourier coefficients a_k and b_k to the variables COS_01 and SIN_01 in the output data set B.

When a WEIGHTS statement is specified, the periodogram is smoothed by a weighted moving average to produce an estimate of the spectral density of the series. The following statements write a spectral density estimate for X to the variable S_01 in the output data set B.

```
proc spectra data=a out=b s;
  var x;
  weights 1 2 3 4 3 2 1;
run;
```

When the VAR statement specifies more than one variable, you can perform cross-spectral analysis by specifying the CROSS option in the PROC SPECTRA statement. The CROSS option by itself produces the cross-periodograms for all two-way combinations of the variables listed in the VAR statement. For example, the following statements write the real and imaginary parts of the cross-periodogram of X and Y to the variables RP_01_02 and IP_01_02 in the output data set B.

```
proc spectra data=a out=b cross;
  var x y;
run;
```

To produce cross-spectral density estimates, specify both the CROSS option and the S option. The cross-periodogram is smoothed using the weights specified by the WEIGHTS statement in the same way as the spectral density. The squared coherency and phase estimates of the cross-spectrum are computed when the K and PH options are used.

The following example computes cross-spectral density estimates for the variables X and Y.

```
proc spectra data=a out=b cross s;
  var x y;
  weights 1 2 3 4 3 2 1;
run;
```

The real part and imaginary part of the cross-spectral density estimates are written to the variables CS_01_02 and QS_01_02, respectively.

Syntax: SPECTRA Procedure

The following statements are used with the SPECTRA procedure:

```
PROC SPECTRA options ;
  BY variables ;
  VAR variables ;
  WEIGHTS < weights> < kernel> ;
```

Functional Summary

Table 26.1 summarizes the statements and options that control the SPECTRA procedure.

Table 26.1 SPECTRA Functional Summary

Description	Statement	Option
Statements		
specify BY-group processing	BY

ADJMEAN

CENTER

subtracts the series mean before performing the Fourier decomposition. This sets the first periodogram ordinate to 0 rather than $2n$ times the squared mean. This option is commonly used when the periodograms are to be plotted to prevent a large first periodogram ordinate from distorting the scale of the plot.

ALTW

specifies that the quadrature spectrum estimate is computed at the boundaries in the same way as the spectral density estimate and the cospectrum estimate are computed.

COEF

outputs the Fourier cosine and sine coefficients of each series.

CROSS

is used with the P and S options to output cross-periodograms and cross-spectral densities when more than one variable is listed in the VAR statement.

DATA=SAS-data-set

names the SAS data set that contains the input data. If the DATA= option is omitted, the most recently created SAS data set is used.

K

outputs the squared coherency variables (K_{nn_mm}) of the cross-spectrum. The K_{nn_mm} variables are identically 1 unless weights are given in the WEIGHTS statement and the S option is specified.

OUT=SAS-data-set

names the output data set created by PROC SPECTRA to store the results. If the OUT= option is omitted, the output data set is named by using the DATA n convention.

P

outputs the periodogram variables. The variables are named P_{nn} , where nn is an index of the original variable with which the periodogram variable is associated. When both the P and CROSS options are specified, the cross-periodogram variables RP_{nn_mm} and IP_{nn_mm} are also output.

PH

outputs the phase variables (PH_{nn_mm}) of the cross-spectrum.

S

outputs the spectral density estimates. The variables are named S_{nn} , where nn is an index of the original variable with which the estimate variable is associated. When both the S and CROSS options are specified, the cross-spectral variables CS_{nn_mm} and QS_{nn_mm} are also output.

WHITETEST

prints two tests of the hypothesis that the data are white noise. See the section “[White Noise Test](#)” on page 1871 for details.

Note that the CROSS, A, K, and PH options are meaningful only if more than one variable is listed in the VAR statement.

BY Statement

BY *variables* ;

A BY statement can be used with PROC SPECTRA to obtain separate analyses for groups of observations defined by the BY variables.

VAR Statement

VAR *variables* ;

The VAR statement specifies one or more numeric variables that contain the time series to analyze. The order of the variables in the VAR statement list determines the index, nn , used to name the output variables. The VAR statement is required.

WEIGHTS Statement

WEIGHTS *weight-constants / kernel-specification* ;

The WEIGHTS statement specifies the relative weights used in the moving average applied to the periodogram ordinates to form the spectral density estimates. A WEIGHTS statement must be used to produce smoothed spectral density estimates. You can specify the relative weights in two ways: you can specify them explicitly as explained in the section “[Using Weight Constants Specification](#)” on page 1867, or you can specify them implicitly by using the kernel specification as explained in the section “[Using Kernel Specifications](#)” on page 1867. If the WEIGHTS statement is not used, only the periodogram is produced.

Using Weight Constants Specification

Any number of weighting constants can be specified. The constants should be positive and symmetric about the middle weight. The middle constant (or the constant to the right of the middle if an even number of weight constants are specified) is the relative weight of the current periodogram ordinate. The constant immediately following the middle one is the relative weight of the next periodogram ordinate, and so on. The actual weights used in the smoothing process are the weights specified in the WEIGHTS statement scaled so that they sum to $\frac{1}{4\pi}$.

The moving average reflects at each end of the periodogram. The first periodogram ordinate is not used; the second periodogram ordinate is used in its place.

For example, a simple triangular weighting can be specified using the following WEIGHTS statement:

```
weights 1 2 3 2 1;
```

Using Kernel Specifications

You can specify five different kernels in the WEIGHTS statement. The syntax for the statement is

```
WEIGHTS [PARZEN][BART][TUKEY][TRUNCAT][QS] [c e] ;
```

where $c \geq 0$ and $e \geq 0$ are used to compute the bandwidth parameter as

$$l(q) = cq^e$$

and q is the number of periodogram ordinates + 1:

$$q = \text{floor}(n/2) + 1$$

To specify the bandwidth explicitly, set $c =$ to the desired bandwidth and $e = 0$.

For example, a Parzen kernel can be specified using the following WEIGHTS statement:

```
weights parzen 0.5 0;
```

For details, see the section “[Kernels](#)” on page 1868.

Details: SPECTRA Procedure

Input Data

Observations in the data set analyzed by the SPECTRA procedure should form ordered, equally spaced time series. No more than 99 variables can be included in the analysis.

Data are often detrended before analysis by the SPECTRA procedure. This can be done by using the residuals output by a SAS regression procedure. Optionally, the data can be centered using the ADJMEAN option in the PROC SPECTRA statement, since the zero periodogram ordinate corresponding to the mean is of little interest from the point of view of spectral analysis.

Missing Values

Missing values are excluded from the analysis by the SPECTRA procedure. If the SPECTRA procedure encounters missing values for any variable listed in the VAR statement, the procedure determines the longest contiguous span of data that has no missing values for the variables listed in the VAR statement and uses that span for the analysis.

Computational Method

If the number of observations n factors into prime integers that are less than or equal to 23, and the product of the square-free factors of n is less than 210, then PROC SPECTRA uses the fast Fourier transform developed by Cooley and Tukey and implemented by Singleton (1969). If n cannot be factored in this way, then PROC SPECTRA uses a Chirp-Z algorithm similar to that proposed by Monro and Branch (1977). To reduce memory requirements, when n is small, the Fourier coefficients are computed directly using the defining formulas.

Kernels

Kernels are used to smooth the periodogram by using a weighted moving average of nearby points. A smoothed periodogram is defined by the following equation.

$$\hat{J}_i(l(q)) = \sum_{\tau=-l(q)}^{l(q)} w\left(\frac{\tau}{l(q)}\right) \tilde{J}_{i+\tau}$$

where $w(x)$ is the kernel or weight function. At the endpoints, the moving average is computed cyclically; that is,

$$\tilde{J}_{i+\tau} = \begin{cases} J_{i+\tau} & 0 \leq i + \tau \leq q \\ J_{-(i+\tau)} & i + \tau < 0 \\ J_{q-(i+\tau)} & i + \tau > q \end{cases}$$

The SPECTRA procedure supports the following kernels. They are listed with their default bandwidth functions.

Bartlett: KERNEL BART

$$\begin{aligned} w(x) &= \begin{cases} 1 - |x| & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(q) &= \frac{1}{2}q^{1/3} \end{aligned}$$

Parzen: KERNEL PARZEN

$$\begin{aligned} w(x) &= \begin{cases} 1 - 6|x|^2 + 6|x|^3 & 0 \leq |x| \leq \frac{1}{2} \\ 2(1 - |x|)^3 & \frac{1}{2} \leq |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(q) &= q^{1/5} \end{aligned}$$

Quadratic spectral: KERNEL QS

$$\begin{aligned} w(x) &= \frac{25}{12\pi^2 x^2} \left(\frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right) \\ l(q) &= \frac{1}{2}q^{1/5} \end{aligned}$$

Tukey-Hanning: KERNEL TUKEY

$$\begin{aligned} w(x) &= \begin{cases} (1 + \cos(\pi x))/2 & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(q) &= \frac{2}{3}q^{1/5} \end{aligned}$$

Truncated: KERNEL TRUNCAT

$$\begin{aligned} w(x) &= \begin{cases} 1 & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(q) &= \frac{1}{4}q^{1/5} \end{aligned}$$

A summary of the default values of the bandwidth parameters, c and e , associated with the kernel smoothers in PROC SPECTRA are listed below in Table 26.2:

Table 26.2 Bandwidth Parameters

Kernel	c	e
Bartlett	$1/2$	$1/3$
Parzen	1	$1/5$
quadratic	$1/2$	$1/5$
Tukey-Hanning	$2/3$	$1/5$
truncated	$1/4$	$1/5$

Figure 26.1 Kernels for Smoothing

See Andrews (1991) for details about the properties of these kernels.

White Noise Test

PROC SPECTRA prints two test statistics for white noise when the WHITEST option is specified: Fisher's Kappa (Davis 1941; Fuller 1976) and Bartlett's Kolmogorov-Smirnov statistic (Bartlett 1966; Fuller 1976; Durbin 1967).

If the time series is a sequence of independent random variables with mean 0 and variance σ^2 , then the periodogram, J_k , will have the same expected value for all k . For a time series with nonzero autocorrelation, each ordinate of the periodogram, J_k , will have different expected values. The Fisher's Kappa statistic tests whether the largest J_k can be considered different from the mean of the J_k . Critical values for the Fisher's Kappa test can be found in Fuller 1976.

The Kolmogorov-Smirnov statistic reported by PROC SPECTRA has the same asymptotic distribution as Bartlett's test (Durbin 1967). The Kolmogorov-Smirnov statistic compares the normalized cumulative periodogram with the cumulative distribution function of a uniform(0,1) random variable. The normalized cumulative periodogram, F_j , of the series is

$$F_j = \frac{\sum_{k=1}^j J_k}{\sum_{k=1}^m J_k}, j = 1, 2, \dots, m-1$$

where $m = \frac{n}{2}$ if n is even or $m = \frac{n-1}{2}$ if n is odd. The test statistic is the maximum absolute difference of the normalized cumulative periodogram and the uniform cumulative distribution function. Approximate p -values for Bartlett's Kolmogorov-Smirnov test statistics are provided with the test statistics. Small p -values cause you to reject the null-hypothesis that the series is white noise.

Transforming Frequencies

The variable FREQ in the data set created by the SPECTRA procedure ranges from 0 to π . Sometimes it is preferable to express frequencies in cycles per observation period, which is equal to $\frac{1}{2\pi}$ FREQ.

To express frequencies in cycles per unit time (for example, in cycles per year), multiply FREQ by $\frac{d}{2\pi}$, where d is the number of observations per unit of time. For example, for monthly data, if the desired time unit is years then d is 12. The period of the cycle is $\frac{2\pi}{d \times \text{FREQ}}$, which ranges from $\frac{2}{d}$ to infinity.

OUT= Data Set

The OUT= data set contains $\frac{n}{2} + 1$ observations, if n is even, or $\frac{n+1}{2}$ observations, if n is odd, where n is the number of observations in the time series or the span of data being analyzed if missing values are present in the data. See the section "Missing Values" on page 1868 for details.

The variables in the new data set are named according to the following conventions. Each variable to be analyzed is associated with an index. The first variable listed in the VAR statement is indexed as 01, the second variable as 02, and so on. Output variables are named by combining indexes with prefixes. The prefix always identifies the nature of the new variable, and the indices identify the original variables from which the statistics were obtained.

Variables that contain spectral analysis results have names that consist of a prefix, an underscore, and the index of the variable analyzed. For example, the variable S_01 contains spectral density estimates for the

first variable in the VAR statement. Variables that contain cross-spectral analysis results have names that consist of a prefix, an underscore, the index of the first variable, another underscore, and the index of the second variable. For example, the variable A_01_02 contains the amplitude of the cross-spectral density estimate for the first and second variables in the VAR statement.

Table 26.3 shows the formulas and naming conventions used for the variables in the OUT= data set. Let X be variable number *nn* in the VAR statement list and let Y be variable number *mm* in the VAR statement list. Table 26.3 shows the output variables that contain the results of the spectral and cross-spectral analysis of X and Y.

In Table 26.3 the following notation is used. Let W_j be the vector of $2p + 1$ smoothing weights given by the WEIGHTS statement, normalized to sum to $\frac{1}{4\pi}$. Note that the weights are either explicitly provided using the constant specification or are implicitly determined by the kernel specification in the WEIGHTS statement.

The subscript of W_j runs from W_{-p} to W_p , so that W_0 is the middle weight in the list. Let $\omega_k = \frac{2\pi k}{n}$, where $k = 0, 1, \dots, \text{floor}(\frac{n}{2})$.

Table 26.3 Variables Created by PROC SPECTRA

Variable	Description
FREQ	frequency in radians from 0 to π (Note: Cycles per observation is $\frac{\text{FREQ}}{2\pi}$.)
PERIOD	period or wavelength: $\frac{2\pi}{\text{FREQ}}$ (Note: PERIOD is missing for FREQ=0.)
COS_nn	cosine transform of X: $a_k^x = \frac{2}{n} \sum_{t=1}^n X_t \cos(\omega_k(t-1))$
SIN_nn	sine transform of X: $b_k^x = \frac{2}{n} \sum_{t=1}^n X_t \sin(\omega_k(t-1))$
P_nn	periodogram of X: $J_k^x = \frac{n}{2} [(a_k^x)^2 + (b_k^x)^2]$
S_nn	spectral density estimate of X: $F_k^x = \sum_{j=-p}^p W_j J_{k+j}^x$ (except across endpoints)
RP_nn_mm	real part of cross-periodogram X and Y: $\text{real}(J_k^{xy}) = \frac{n}{2} (a_k^x a_k^y + b_k^x b_k^y)$
IP_nn_mm	imaginary part of cross-periodogram of X and Y: $\text{imag}(J_k^{xy}) = \frac{n}{2} (a_k^x b_k^y - b_k^x a_k^y)$
CS_nn_mm	cospectrum estimate (real part of cross-spectrum) of X and Y: $C_k^{xy} = \sum_{j=-p}^p W_j \text{real}(J_{k+j}^{xy})$ (except across endpoints)
QS_nn_mm	quadrature spectrum estimate (imaginary part of cross-spectrum) of X and Y:

Table 26.3 *continued*

Variable	Variable
	$Q_k^{xy} = \sum_{j=-p}^p W_j \text{imag}(J_{k+j}^{xy})$ (except across end-points)
A_nn_mm	amplitude (modulus) of cross-spectrum of X and Y: $A_k^{xy} = \sqrt{(C_k^{xy})^2 + (Q_k^{xy})^2}$
K_nn_mm	coherency squared of X and Y: $K_k^{xy} = (A_k^{xy})^2 / (F_k^x F_k^y)$
PH_nn_mm	phase spectrum in radians of X and Y: $\Phi_k^{xy} = \arctan(Q_k^{xy} / C_k^{xy})$

Printed Output

By default PROC SPECTRA produces no printed output.

When the WHITETEST option is specified, the SPECTRA procedure prints the following statistics for each variable in the VAR statement:

1. the name of the variable
2. M-1, the number of two-degree-of-freedom periodogram ordinates used in the test
3. MAX(P(*)), the maximum periodogram ordinate
4. SUM(P(*)), the sum of the periodogram ordinates
5. Fisher's Kappa statistic
6. Bartlett's Kolmogorov-Smirnov test statistic
7. Approximate *p*-value for Bartlett's Kolmogorov-Smirnov test statistic

See the section “[White Noise Test](#)” on page 1871 for details.

ODS Table Names: SPECTRA procedure

PROC SPECTRA assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 26.4 ODS Tables Produced in PROC SPECTRA

ODS Table Name	Description	Option
WhiteNoiseTest	white noise test	WHITETEST
Kappa	Fishers Kappa statistic	WHITETEST
Bartlett	Bartlett's Kolmogorov-Smirnov statistic	WHITETEST

Examples: SPECTRA Procedure

Example 26.1: Spectral Analysis of Sunspot Activity

This example analyzes Wolfer's sunspot data (Anderson 1971). The following statements read and plot the data.

```

title "Wolfer's Sunspot Data";
data sunspot;
    input year wolfer @@;
datalines;
1749  809 1750  834 1751  477 1752  478 1753  307 1754  122 1755  96

... more lines ...

proc sgplot data=sunspot;
    series x=year y=wolfer / markers markerattrs=(symbol=circlefilled);
    xaxis values=(1740 to 1930 by 10);
    yaxis values=(0 to 1600 by 200);
run;

```

The plot of the sunspot series is shown in [Output 26.1.1](#).

Output 26.1.1 Plot of Original Sunspot Data

The spectral analysis of the sunspot series is performed by the following statements:

```
proc spectra data=sunspot out=b p s adjmean whitetest;
  var wolfer;
  weights 1 2 3 4 3 2 1;
run;

proc print data=b(obs=12);
run;
```

The PROC SPECTRA statement specifies the P and S options to write the periodogram and spectral density estimates to the OUT= data set B. The WEIGHTS statement specifies a triangular spectral window for smoothing the periodogram to produce the spectral density estimate. The ADJMEAN option zeros the frequency 0 value and avoids the need to exclude that observation from the plots. The WHITETEST option prints tests for white noise.

The Fisher's Kappa test statistic of 16.070 is larger than the 5% critical value of 7.2, so the null hypothesis that the sunspot series is white noise is rejected (see the table of critical values in Fuller (1976)).

The Bartlett's Kolmogorov-Smirnov statistic is 0.6501, and its approximate p -value is < 0.0001 . The small p -value associated with this test leads to the rejection of the null hypothesis that the spectrum represents white noise.

The printed output produced by PROC SPECTRA is shown in [Output 26.1.2](#). The output data set B created by PROC SPECTRA is shown in part in [Output 26.1.3](#).

Output 26.1.2 White Noise Test Results

Wolfer's Sunspot Data	
The SPECTRA Procedure	
Test for White Noise for Variable wolfer	
M-1	87
Max(P(*))	4062267
Sum(P(*))	21156512
Fisher's Kappa: (M-1)*Max(P(*))/Sum(P(*))	
Kappa	16.70489
Bartlett's Kolmogorov-Smirnov Statistic:	
Maximum absolute difference of the standardized	
partial sums of the periodogram and the CDF of a	
uniform(0,1) random variable.	
Test Statistic	0.650055
Approximate P-Value	<.0001

Output 26.1.3 First 12 Observations of the OUT= Data Set

Wolfer's Sunspot Data				
Obs	FREQ	PERIOD	P_01	S_01
1	0.00000	.	0.00	59327.52
2	0.03570	176.000	3178.15	61757.98
3	0.07140	88.000	2435433.22	69528.68
4	0.10710	58.667	1077495.76	66087.57
5	0.14280	44.000	491850.36	53352.02
6	0.17850	35.200	2581.12	36678.14
7	0.21420	29.333	181163.15	20604.52
8	0.24990	25.143	283057.60	15132.81
9	0.28560	22.000	188672.97	13265.89
10	0.32130	19.556	122673.94	14953.32
11	0.35700	17.600	58532.93	16402.84
12	0.39270	16.000	213405.16	18562.13

The following statements plot the periodogram and spectral density estimate by the frequency and period.

```

proc sgplot data=b;
  series x=freq y=p_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
  series x=period y=p_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
  series x=freq y=s_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
  series x=period y=s_01 / markers markerattrs=(symbol=circlefilled);
run;

```

The periodogram is plotted against the frequency in [Output 26.1.4](#) and plotted against the period in [Output 26.1.5](#). The spectral density estimate is plotted against the frequency in [Output 26.1.6](#) and plotted against the period in [Output 26.1.7](#).

Output 26.1.4 Plot of Periodogram by Frequency

Output 26.1.5 Plot of Periodogram by Period

Output 26.1.6 Plot of Spectral Density Estimate by Frequency

Output 26.1.7 Plot of Spectral Density Estimate by Period

Since PERIOD is the reciprocal of frequency, the plot axis for PERIOD is stretched for low frequencies and compressed at high frequencies. One way to correct for this is to use a WHERE statement to restrict the plots and exclude the low frequency components. The following statements plot the spectral density for periods less than 50.

```
proc sgplot data=b;
  where period < 50;
  series x=period y=s_01 / markers markerattrs=(symbol=circlefilled);
  refline 11 / axis=x;
run;
title;
```

The spectral analysis of the sunspot series confirms a strong 11-year cycle of sunspot activity. The plot makes this clear by drawing a reference line at the 11 year period, which highlights the position of the main peak in the spectral density.

Output 26.1.8 shows the plot. Contrast Output 26.1.8 with Output 26.1.7.

Output 26.1.8 Plot of Spectral Density Estimate by Period to 50 Years

Example 26.2: Cross-Spectral Analysis

This example uses simulated data to show cross-spectral analysis for two variables X and Y. X is generated by an AR(1) process; Y is generated as white noise plus an input from X lagged 2 periods. All output options are specified in the PROC SPECTRA statement. PROC CONTENTS shows the contents of the OUT= data set.

```
data a;
  x1 = 0; x11 = 0;
  do i = - 10 to 100;
    x = .4 * x1 + rannor(123);
    y = .5 * x11 + rannor(123);
    if i > 0 then output;
    x11 = x1; x1 = x;
  end;
run;

proc spectra data=a out=b cross coef a k p ph s;
  var x y;
  weights 1 1.5 2 4 8 9 8 4 2 1.5 1;
```

```
run;

proc contents data=b position;
run;
```

The PROC CONTENTS report for the output data set B is shown in [Output 26.2.1](#).

Output 26.2.1 Contents of PROC SPECTRA OUT= Data Set

The CONTENTS Procedure				
Alphabetic List of Variables and Attributes				
#	Variable	Type	Len	Label
16	A_01_02	Num	8	Amplitude of x by y
3	COS_01	Num	8	Cosine Transform of x

11	RP_01_02	Num	8	Real Periodogram of x by y
4	SIN_01	Num	8	Sine Transform of x
6	SIN_02	Num	8	Sine Transform of y
9	S_01	Num	8	Spectral Density of x
10	S_02	Num	8	Spectral Density of y

The following statements plot the amplitude of the cross-spectrum estimate against frequency and against period for periods less than 25.

```
proc sgplot data=b;
  series x=freq y=a_01_02 / markers markerattrs=(symbol=circlefilled);
  xaxis values=(0 to 4 by 1);
run;
```

The plot of the amplitude of the cross-spectrum estimate against frequency is shown in [Output 26.2.2](#).

Output 26.2.2 Plot of Cross-Spectrum Amplitude by Frequency

The plot of the cross-spectrum amplitude against period for periods less than 25 observations is shown in [Output 26.2.3](#).

```
proc sgplot data=b;
  where period < 25;
  series x=period y=a_01_02 / markers markerattrs=(symbol=circlefilled);
  xaxis values=(0 to 30 by 5);
run;
```

Output 26.2.3 Plot of Cross-Spectrum Amplitude by Period

Overview: SSM Procedure

State space models (SSMs) are used for analyzing continuous response variables that are recorded sequentially according to a numeric indexing variable. In many cases, the indexing variable is time and the observations are collected at regular time intervals—for example, hourly, weekly, or monthly. In such cases, the resulting data are called time series data. In other cases, the indexing variable might not be time or the observations might not be equally spaced according to the indexing variable. These more general types of sequential data are called longitudinal data. Because of their sequential nature, these types of data exhibit some characteristic features. For example, chronologically closer measurements tend to be highly correlated while measurements

farther apart are essentially uncorrelated. Data can be trending in a particular direction and can have seasonal or other periodic patterns. SSMs are specially designed to model such sequential data. They apply to both univariate and multivariate response situations and can easily incorporate predictor (independent variable) information when it is available.

The SSM procedure performs state space modeling of univariate and multivariate time series and longitudinal data. You can do the following with the SSM procedure:

- analyze quite general linear state space models.
- use an expressive language to specify an SSM. An SSM specification consists of specifying a variety of matrices—for example, the state transition matrix and the covariance matrices of the state and observation disturbances. The SSM procedure provides language similar to a DATA step for specifying the elements of these matrices. The matrix elements can be user-defined functions of data variables and unknown parameters.
- easily specify several commonly needed univariate and multivariate SSMs by using only a few keywords. These SSMs include the principal univariate and multivariate structural models for regularly spaced data and a variety of trend and cycle models for the longitudinal data.
- estimate unknown model parameters by (restricted) maximum likelihood. The likelihood function is computed by using the (diffuse) Kalman filter algorithm.
- print, or output to a data set, the series forecasts, residuals, and the full-sample estimates of any linear combination of the underlying state variables. These estimates are obtained by using the (diffuse) Kalman filter and smoother algorithm.
- generate residual diagnostic plots and plots useful for detecting structural breaks.

Background

State space models are widely used in a variety of fields such as engineering, statistics, econometrics, and agriculture. There are numerous references that deal with state space modeling, particularly with the state space modeling of time series data. State space modeling of longitudinal data has received a little less attention. The primary reference for the modeling techniques implemented in the SSM procedure is Harvey (1989). It contains treatment of both the time series and longitudinal data. Other useful books about this subject are: Durbin and Koopman (2001); Jones (1993); Anderson and Moore (1979). In addition, informative articles about state space modeling of longitudinal data include Wecker and Ansley (1983); Kohn and Ansley (1991); de Jong and Mazzi (2001); Eubank, Huang, and Wang (2003). For the implementation details of the diffuse Kalman filter and smoother (the main computational tool used by the SSM procedure), the main references are a series of articles (de Jong 1989, 1991; de Jong and Chu-Chun-Lin 2003) and the references therein.

Getting Started: SSM Procedure

This example illustrates how you can use the SSM procedure to analyze a panel of time series. The following data set, Cigar, contains information about yearly per capita cigarette sales for 46 geographic regions in

the United States over the period 1963–1992. The variables *lsales*, *lprice*, *lndi*, and *lpimin* denote the per capita cigarette sales, price per pack of cigarettes, per capita disposable income, and minimum price in adjoining regions per pack of cigarettes, respectively (all in the natural log scale). The variable *year* contains the observation year, and the variable *region* contains an integer between 1 to 46 that serves as the unique identifier for the region. For additional data description see Baltagi and Levin (1992); Baltagi (1995). The data are sorted by year.

```
data cigar;
  input year region lsales lprice lndi lpimin;
  label lsales = 'Log cigarette sales in packs per capita';
  label lprice = 'Log price per pack of cigarettes';
  label lndi = 'Log per capita disposable income';
  label lpimin = 'Log minimum price in adjoining regions
                 per pack of cigarettes';
  year = intnx( 'year', '1jan63'd, year-63 );
  format year year.;
datalines;
63 1 4.54223 3.35341 7.3514 3.26194
63 2 4.82831 3.17388 7.5729 3.21487
63 3 4.63860 3.29584 7.3000 3.25037
63 4 4.95583 3.23080 7.9288 3.17388
63 5 5.05114 3.28840 7.9772 3.26576

... more lines ...
```

The goal of the analysis is to study the impact of the regressors on the smoking behavior and to understand the changes in the smoking patterns in different regions over the years. Consider the following model for *lsales*:

$$lsales_{i,t} = \mu_{i,t} + lprice \beta_1 + lndi \beta_2 + lpimin \beta_3 + \epsilon_{i,t}$$

This model represents *lsales* in a region *i* and in a year *t* as a sum of region-specific trend components $\mu_{i,t}$, the regression effects due to *lprice*, *lndi*, and *lpimin*, and the observation noise $\epsilon_{i,t}$. Different variations of this model are obtained by considering different models for the trend component $\mu_{i,t}$. Proper modeling of the trend component is important because it captures differences between the regions because of unrecorded factors such as demographic changes over time, results of anti-smoking campaigns, and so on. The following statements specify and fit one such model:

```
proc ssm data=Cigar plots=residual;
  id year interval=year;
  array RegionArray{46} region1-region46;
  do i=1 to 46;
    RegionArray[i] = (region=i);
  end;
  trend IrwTrend(11) cross(matchparm)=(RegionArray) levelvar=0;
  irregular wn;
  model lsales = lprice lndi lpimin IrwTrend wn;
  eval TrendPlusReg = IrwTrend + lprice + lndi + lpimin;
  output out=forCigar pdv press;
run;
```

The PROC SSM statement specifies the input data set, *Cigar*, which contains analysis variables such as the response variable, *lsales*, and the predictor variables, *lprice*, *lndi*, and *lpimin*. The PLOTS=RESIDUAL option in the PROC SSM statement produces residual diagnostic plots. The optional ID statement specifies a numeric index variable (often a SAS date or datetime variable), which is *year* in this case. The INTERVAL=YEAR option in the ID statement indicates that the measurements are collected on a yearly basis. The next few statements define a 46-dimensional array of dummy variables, *RegionArray*, such that *RegionArray*[*i*] is 1 if region is *i* and is 0 otherwise. The next three statements, TREND, IRREGULAR, and MODEL, constitute the model specification part of the program:

- **trend IrwTrend(11) cross(matchparm)=(RegionArray) levelvar=0;** defines a trend, named *IrwTrend*, of local linear type (which is signified by the keyword *ll* used within the parenthesis after the name). A local linear trend—a trend with time-varying level and time-varying slope—depends on two parameters: the disturbance variance of the level equation and the disturbance variance of the slope equation (see the section “[Local Linear Trend](#)” on page 1934 for more information). The LEVELVAR=0 specification fixes the disturbance variance of the level equation to 0, which results in a trend model called an *integrated random walk* (IRW). An IRW model tends to produce a smoother trend than a general local linear trend. In the limiting case, if the disturbance variance of the slope equation is also 0, the IRW trend reduces to a straight line (with a fixed intercept and slope). In addition, because of the use of the 46-dimensional array, *RegionArray*, in the CROSS= option (**cross(matchparm)=(RegionArray)**), this trend specification amounts to fitting a separate IRW trend for each region. This is because, as a result of the CROSS= option, *IrwTrend* is treated as a linear combination of 46 (the number of variables in *RegionArray*) stochastically independent, integrated random walks,

$$\text{IrwTrend}_t = \sum_{i=1}^{46} \text{RegionArray}[i] \mu_{i,t}$$

where each $\mu_{i,t}$ is an integrated random walk. Note that since *RegionArray*[*i*] is a binary variable, *IrwTrend* equals $\mu_{i,t}$ when region is *i*. Lastly, the use of MATCHPARM option specifies that the different IRW trends $\mu_{i,t}$ use the same disturbance variance parameter for their slope equation. This is done mainly for parsimony. Based on the model diagnostics shown later, this appears to be a reasonable model simplification.

- **irregular wn;** defines the observation noise $\epsilon_{i,t}$, named *wn*, as a sequence of independent, identically distributed, zero-mean, Gaussian variables—a white noise sequence.
- **model lsales = lprice lndi lpimin IrwTrend wn;** defines the model for *lsales* as a sum of regression effects that involve *lprice*, *lndi*, and *lpimin*, a trend term, *IrwTrend*, and the observation noise *wn*.

The last two statements, EVAL and OUTPUT, control certain aspects of the procedure output. The following EVAL statement defines a linear combination, named *TrendPlusReg*, of selected terms in the MODEL statement.

```
eval TrendPlusReg = IrwTrend + lprice + lndi + lpimin;
```

This EVAL statement causes the SSM procedure to produce an estimate of *TrendPlusReg* (and its standard error), which can then be printed or output to a data set. *TrendPlusReg* contains all the terms in the model

except for the observation noise and thus can be regarded as the *explanatory* part of the model. In the OUTPUT statement, you can specify an output data set that stores all the component estimates that are produced by the procedure. The following OUTPUT statement specifies forCigar as the output data set:

```
output out=forCigar pdv press;
```

The PDV option causes variables such as region1–region46, which are defined by the DATA step statements within the SSM procedure, also to be included in the output data set. The PRESS option causes the printing of fit measures that are based on the delete-one cross validation errors (see the section “Delete-One Cross Validation and Structural Breaks” on page 1930 for more information).

All the models that are specified in the SSM procedure possess a state space representation. See the section “State Space Model and Notation” on page 1919 for more information. The SSM procedure output begins with a table (not shown here) of the input data set that provides the name and other information. Next, the “Model Summary” table, shown in Figure 27.1, provides basic model information, such as the following:

- the dimension of the underlying state equation, 92 (because each of the 46 IRW trends $\mu_{i,t}$ contributes two elements to the state)
- the diffuse dimension of the model, 95 (which is equal to the three regressors plus the 92 diffuse initial states of $\mu_{i,t}$)
- the number of model parameters, 2 (which is the common disturbance variance of the slope equation in lrwTrend and the variance of the noise term wn)

This information is very useful in determining the computational complexity of the model (the larger state size, 92, explains the relatively long computing time—as much as two minutes on some desktops—for this example).

Figure 27.1 Summary of the Underlying State Space Model

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	1
State Dimension	92
Dimension of the Diffuse Initial Condition	95
Number of Parameters	2

The index variable information is shown in Figure 27.2. Among other things, it categorizes the data to be of the type *Regular with Replication*, which implies that the data are regularly spaced with respect to the ID variable and at least some observations have the same ID value. This is clearly true in this example: the data are yearly without any gaps, and there are 46 observations in each year—one per region.

Figure 27.2 Index Variable Information

ID Variable Information				
Name	Start	End	Max Delta	Type
year	1963	1992	1	Regular with Replication

Figure 27.3 provides simple summary information about the response variable. It shows that *lsales* has no missing values and no induced missing values because the predictors in the model, *lprice*, *lndi*, and *lpimin*, do not have any missing values either.

Figure 27.3 Response Variable Summary

Response Variable Information							
Name	--Number of Observations--			Minimum	Maximum	Mean	Std Deviation
	Total	Missing	Induced Missing				
lsales	1380	0	0	3.98	5.7	4.79	0.225

The regression coefficients of *lprice*, *lndi*, and *lpimin* are shown in Figure 27.4. As expected, the coefficient of *lprice* is negative and the coefficients of *lndi* and *lpimin* are positive, all being statistically significant. This is consistent with the expectation that the cigarette sales are adversely affected by the price and are positively correlated with the disposable income. The estimated effect of *lpimin*, called bootlegging effect by Baltagi and Levin (1992), is statistically significant but much smaller than the effects of *lprice* and *lndi*.

Figure 27.4 Estimated Regression Coefficients

Regression Parameter Estimates					
Response Variable	Regression Variable	Estimate	Standard Error	t Value	Pr > t
lsales	lprice	-0.3480	0.0232	-15.01	<.0001
lsales	lndi	0.1425	0.0344	4.15	<.0001
lsales	lpimin	0.0619	0.0269	2.30	0.0214

Figure 27.5 Estimated Model Parameters

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
lrwTrend	LL Trend	Slope Variance	0.000169	0.0000219
wn	Irregular	Variance	0.000592	0.0000342

Figure 27.5 shows the estimates of the disturbance variance of the slope equation in lrwTrend and the variance of the noise term wn. The estimate of the disturbance variance of the slope equation in lrwTrend, 0.00017, is statistically significant (being several times larger than its standard error, 0.000022). This implies that the estimated trends $\mu_{i,t}$ are not simple lines with fixed intercept and slope.

Figure 27.6 shows a panel of residual normality diagnostic plots. These plots show that the residuals are symmetrically distributed but contain slightly larger than expected number of extreme residuals. Figure 27.7 shows the plot of residuals versus time. There the residuals do not exhibit any obvious pattern; however, the plot does show that more extreme residuals appear before 1970 and after 1989. On the whole, however, these plots do not exhibit serious violations of model assumptions.

Figure 27.6 Residual Normality Check

Figure 27.7 Standardized Residuals Plotted against Time

Figure 27.8 shows the details of the likelihood computations such as the number of nonmissing response values used and the likelihood of the fitted model. See the section “Likelihood Computation and Model Fitting Phase” on page 1928 for more information. Figure 27.8 shows the likelihood-based information criteria in lower-is-better format, which are useful for model comparison.

Figure 27.8 Likelihood Computation Details

Likelihood Computation Summary	
Statistic	Value
Nonmissing Response Values Used	1380
Estimated Parameters	2
Initialized Diffuse State Elements	95
Normalized Residual Sum of Squares	1285.0002
Diffuse Log Likelihood	2246.0466
Profile Log Likelihood	2169.6232

Figure 27.9 Information Criteria

Information Criteria		
Statistic	Diffuse Likelihood Based	Profile Likelihood Based
AIC (lower is better)	-4488.093	-4145.246
BIC (lower is better)	-4477.776	-3637.952
AICC (lower is better)	-4488.084	-4130.417
HQIC (lower is better)	-4484.220	-3955.472
CAIC (lower is better)	-4475.776	-3540.952

In addition to the regression estimates, it is useful to analyze the estimates of different model components such as the trend component `lrwTrend` and the linear combination `TrendPlusReg`. These estimates can be printed by using the `PRINT=` option provided in the `TREND` and `EVAL` statements, or they can be output to a data set (as it is done in this illustration). This latter option is particularly useful for graphical exploration of these components by standard graphical procedures such as `SGPLOT` and `SGPANEL` procedures. The following statements produce a panel of plots that shows how well the proposed model fits the observed cigarette sales in the first three regions, which correspond to Alabama, Arizona, and Arkansas. The output data set, `forCigar`, contains all the needed information: `Smoothed_TrendPlusReg` contains the smoothed (full-sample) estimate of `TrendPlusReg`, and `Smoothed_Lower_TrendPlusReg` and `Smoothed_Upper_TrendPlusReg` contain its 95% lower and upper confidence limits. In addition, for easy readability, a user-defined format (`RegionFormat`), which is created by using the `FORMAT` procedure (not shown), is used to associate the region names to region values.

```
proc sgpanel data=forCigar noautolegend;
  where region <= 3;
  format region RegionFormat.;
  title 'Region-Specific Sales Patterns with 95% Confidence Band';
  panelby region / columns=3;
  band x=year lower=Smoothed_Lower_TrendPlusReg
  upper=Smoothed_Upper_TrendPlusReg;
  scatter x=year y=lsales;
  series x=year y= Smoothed_TrendPlusReg;
run;
```

Figure 27.10 Cigarette Sales Patterns for the First Three Regions

Figure 27.10 seems to indicate that the model fits the data reasonably well. It also shows that Arizona differs markedly from Alabama and Arkansas in its cigarette sales pattern over the years. The following statements produce a similar panel of plots that show the estimate of trend without the regression effects:

```
proc sgpanel data=forCigar noautolegend;
  where region <= 3;
  format region RegionFormat.;
  title 'Region-Specific Trend Estimates';
  panelby region / columns=3;
  series x=year y= smoothed_IrwTrend;
run;
```

Figure 27.11 Estimate of lrwTrend for the First Three Regions

The trend patterns, shown in Figure 27.11, seem to suggest that after accounting for the regression effects, per capita cigarette sales were on the rise in Alabama and Arkansas while they were declining in Arizona.

Syntax: SSM Procedure

The following statements are available in the SSM procedure:

```

PROC SSM < options > ;
  BY variables ;
  COMPONENT name = (variables) * state < / options > ;
  EVAL name = expression < / options > ;
  ID variable < option > ;
  IRREGULAR name < options > ;
  MODEL response = variables < / options > ;
  OUTPUT < options > ;
  PARMS variables < / options > ;
  Programming statements ;
  STATE name(dim) < options > ;
  TREND name(type) < options > ;

```

You can specify all statements except the BY, ID, and the OUTPUT statements multiple times. The PROC SSM statement and at least one MODEL statement are required. In addition to these statements, you can use most DATA step programming statements to define new variables that are needed for specifying different parts of the state space model.

NOTE: In the statement options described throughout this section, whenever you use a list to specify the elements of the system matrices, the list elements must all be of the same type: either all of them must be variables or all of them must be numbers. In addition, if the list contains more than one variable, then they cannot be of the array type. These are not serious restrictions. When the list contains mix of variables and numbers, you can redefine the numbers as constant variables. Similarly, you can reformulate a list that contains a mix of variables of array and non-array types as just one array by combining all its elements in a new array.

Functional Summary

Table 27.1 summarizes the statements and options that control the SSM procedure. Most commonly needed scenarios are listed; see the individual statements for additional details.

Table 27.1 Functional Summary

Description	Statement	Option
Data Set Options		
Specifies the input data set	PROC SSM	DATA=
Writes series and component forecasts to an output data set	OUTPUT	OUT=
Model Specification Options		
Specifies the index variable	ID	
Defines variables as model parameters	PARMS	
Specifies a response variable and the associated observation equation	MODEL	
Specifies a state subsection	STATE	
Specifies the transition matrix of a state subsection	STATE	T

Table 27.1 *continued*

Description	Statement	Option
Specifies the disturbance covariance matrix of a state subsection	STATE	COV
Specifies the size of the diffuse initial condition of a state subsection	STATE	A1
Specifies the initial covariance matrix of a state subsection	STATE	COV1
Specifies a state subsection for a predefined structural model	STATE	TYPE=
Specifies the regressors in a state equation	STATE	W
Specifies the input vector in a state equation	STATE	SINPUT=
Specifies a component	COMPONENT	
Specifies a predefined trend component	TREND	
Likelihood Optimization Process Control Options		
Specifies the optimization technique	PROC SSM	OPTIMIZER(TECH=)
Limits the number of iterations	PROC SSM	OPTIMIZER(MAXITER=)
Outlier and Structural Break Detection Options		
Turns on the search for additive outliers (AO)		Default
Turns on the search for structural breaks in a state subsection	STATE	CHECKBREAK
Turns on the search for structural breaks in a state subsection associated with a trend	TREND	CHECKBREAK
Specifies the significance level for additive outlier tests	OUTPUT	AO(ALPHA=)
Limits the reported number of additive outliers	OUTPUT	AO(MAXNUM=)
Limits the reported number of additive outliers to a percentage of the series length	OUTPUT	AO(MAXPCT=)
Specifies the significance level for structural break tests	OUTPUT	BREAK(ALPHA=)
Limits the reported number of structural breaks	OUTPUT	BREAK(MAXNUM=)
Limits the reported number of structural breaks to a percentage of the series length	OUTPUT	BREAK(MAXPCT=)
Turns on the search for maximal state shock	OUTPUT	MAXSHOCK
Graphical Residual and Outlier Analysis Options		
Creates a panel of plots that consists of residual normality plots	PROC SSM	PLOTS=RESIDUAL(NORMAL)
Creates the standardized residual plot against time	PROC SSM	PLOTS=RESIDUAL(STD)
Creates a panel of plots that consists of prediction error normality plots	PROC SSM	PLOTS=AO(NORMAL)
Creates the standardized prediction error plot against time	PROC SSM	PLOTS=AO(STD)

Table 27.1 *continued*

Description	Statement	Option
Creates the plot of maximal state shock chi-square statistics against time	PROC SSM	PLOTS=MAXSHOCK
Output Control Options		
Specifies the significance level of the forecast confidence limits	OUTPUT	ALPHA=
Prints the prediction error sum of squares table	OUTPUT	PRESS
Specifies a linear combination of components to be output	EVAL	
Global Printing and Plotting Options		
Turns off all printing for the procedure	PROC SSM	NOPRINT
Turns on all printing options for the procedure	PROC SSM	PRINTALL
Turns off all plotting for the procedure	PROC SSM	PLOTS=NONE
Turns on all plotting options for the procedure	PROC SSM	PLOTS=ALL
Printing State Equation System Matrix Options		
Prints the transition matrix that is associated with a state subsection	STATE	PRINT=T
Prints the disturbance covariance matrix that is associated with a state subsection	STATE	PRINT=COV
Prints the initial covariance matrix that is associated with a state subsection	STATE	PRINT=COV1
Prints the autoregressive coefficient matrix that is associated with a state subsection	STATE	PRINT=AR
Prints the moving average coefficient matrix that is associated with a state subsection	STATE	PRINT=MA
Printing Component, Series Forecast, and Smoothed Estimate Options		
Prints the series forecasts	MODEL	PRINT=FILTER
Prints the full-sample estimates of missing series values	MODEL	PRINT=SMOOTH
Prints the smoothed trend estimate	TREND	PRINT=SMOOTH
Prints the filtered trend estimate	TREND	PRINT=FILTER
Prints the smoothed component estimate	COMPONENT	PRINT=SMOOTH
Prints the filtered component estimate	COMPONENT	PRINT=FILTER
Prints the smoothed component estimate	EVAL	PRINT=SMOOTH
Prints the filtered component estimate	EVAL	PRINT=FILTER
BY Groups		
Specifies BY-group processing	BY	

PROC SSM Statement

PROC SSM *< options >* ;

The PROC SSM statement is required. You can specify the following *options* in the PROC SSM statement:

DATA=*SAS-data-set*

specifies the name of the SAS data set that contains the variables needed for the analysis. If you do not specify this option, PROC SSM uses the most recently created SAS data set.

NOPRINT

turns off all the printing and plotting for the procedure. Any subsequent print options are ignored.

PLOTS *< (global-plot-options) > = plot-request < (options) >*

PLOTS *< (global-plot-options) > = (plot-request < (options) > < ... plot-request < (options) > >)*

controls the plots produced with ODS Graphics. When you specify only one *plot-request*, you can omit the parentheses around it. Here are some examples:

```
plots=none
plots=all
plots=residual
plots=residual(normal)
plots=(maxshock residual(normal))
plots(unpack)=residual
```

If you do not specify any specific *plot-request*, then by default PROC SSM produces the plot of standardized residuals against time. For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Global Plot Options:

The *global-plot-options* apply to all relevant plots generated by the SSM procedure. The following *global-plot-option* is supported:

UNPACK

displays each graph separately. (By default, some graphs can appear together in a single panel.)

Specific Plot Options:

The following list describes the specific *plot-requests* and their *options*:

ALL

produces all plots appropriate for the particular analysis.

AO *< (prediction-error-plot-options) >*

produces the prediction error plots—one for each response variable. You can specify the following *prediction-error-plot-options*:

NORMAL

produces a summary panel of the prediction error diagnostics, which consist of the following:

- histogram of prediction errors
- normal quantile plot of prediction errors

STD

produces a scatter plot of standardized prediction errors against time.

MAXSHOCK

produces a scatter plot of maximal state shock statistics against time.

NONE

suppresses all plots.

RESIDUAL < (*residual-plot-options*) >

produces the residuals plots—one for each response variable. You can specify the following *residual-plot-options*:

NORMAL

produces a summary panel of the residual diagnostics, which consist of the following:

- histogram of residuals
- normal quantile plot of residuals

STD

produces a scatter plot of standardized residuals against time.

See the section “[Delete-One Cross Validation and Structural Breaks](#)” on page 1930 for more information about the precise meaning of the terms *maximal state shock statistics* and *prediction errors*.

PRINTALL

turns on all the printing options for the procedure. All subsequent NOPRINT options in the procedure are ignored.

STATEINFO

prints two tables that provide information about the composition of the state vector in terms of the components specified in the model. One table describes the composition of state α_t , and the other table describes the diffuse vector δ and the regressors, which are part of the initial condition specification α_1 . See the section “[State Space Model and Notation](#)” on page 1919 for more information about the state space model notation.

OPTIMIZER(< **TECHNIQUE**=*technique* > < **MAXITER**=*integer* >)

specifies options that are associated with the optimizer used in the maximum likelihood parameter estimation. The default settings of the optimization process are adequate in most problems. However, in some cases it might be useful to change the optimization technique or to change the maximum number of iterations. You can specify one of the following *techniques*:

ACTIVESET	corresponds to the active-set method.
DBLDOG	corresponds to the double-dogleg method.
INTERIORPOINT	corresponds to the primal-dual interior point method.
NEWRAP	corresponds to the Newton-Raphson method.
QUANEW	corresponds to the (dual) quasi-Newton method.
TRUREG	corresponds to the trust region method.

The default technique is TRUREG. The INTERIORPOINT and ACTIVESET techniques are documented in Chapter 9, “The Nonlinear Programming Solver” (*SAS/OR User’s Guide: Mathematical Programming*) and the remaining techniques are documented in Chapter 6, “[Nonlinear Optimization Methods](#).” You can alter the maximum number of iterations setting in the nonlinear optimization search by specifying a nonnegative *integer* as the MAXITER= value.

BY Statement

BY *variables* ;

A BY statement can be used in the SSM procedure to process a data set in groups of observations that are defined by the BY variables. The model specified by using the MODEL and other statements is applied to all the groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The BY variables are one or more variables in the input data set. The BY variables cannot be used in the model specification; in particular, they cannot be used as response variables or regressors in a MODEL statement.

COMPONENT Statement

COMPONENT *name* = (*var1 var2 ...*) * *state* </ options> ;

COMPONENT *name* = *state*[*integer*] </ options> ;

COMPONENT *name* = (*Variable* | *Number*) * *state*[*integer*] </ options> ;

The COMPONENT statement specifies a component (a linear combination of state elements), named *name*. You can use *name* later as a term in the right-hand side of the MODEL statement, which defines the observation equation. The estimate of *name* is output to the OUT= data set that is specified in the OUTPUT statement. In addition, you can print the component estimate by using the PRINT= option.

The first form of the COMPONENT statement defines a component as a dot product of a state subsection *state* and a row vector (*var1 var2 ...*). The value of *state* can be the name of a state subsection that is defined by using a [STATE](#) statement elsewhere in the program, or it can be the name of the state that is associated with a trend component defined by using a [TREND](#) statement elsewhere in the program (see the section “[TREND Statement](#)” on page 1914 for more information about the naming of the state that is associated with a trend component). The row vector (*var1 var2 ...*), which can be either a list of numbers or a list of variables, must be of the same dimension as the actual dimension of the state subsection. The dot product form—also called the explicit dot product form—of the component specification is unambiguous; however, it requires detailed knowledge of the state vector underlying the *state* specification. Suppose that mystate is a two-dimensional

state defined by a STATE statement elsewhere in the program and that X1 and X2 are (numeric) predictor variables. The following are valid examples of the dot product form of the COMPONENT statement:

```
component c1 = (x1 x2) * mystate;
component c2 = (1 1) * mystate;
```

The second and the third forms of the COMPONENT statement are a shortened version of the first form. The second form defines the component as a particular element of *state*—for example, *state*[3] defines the component as the third element of *state*. The specified *integer* must lie between 1 and *dim*, the nominal dimension of *state*. The second form of component specification has another important use when the STATE statement that defines *state* uses the TYPE= option to set its type or when *state* is associated with a trend component. In these cases, the second form of the component specification assumes additional meaning when the nominal state dimension and the actual state dimensions differ (specifically the state types LL, SEASON, CYCLE, and VARMA and the states associated with all the trend types). For example, if *state* is a three-dimensional seasonal component, *state*[2] signifies an appropriate linear combination of *state* that results in the second of the three seasonals that constitute the three-dimensional seasonal. Similar interpretation holds for the CYCLE type. See the sections “[Multivariate Season](#)” on page 1940 and “[Predefined Structural Models](#)” on page 1936 for more information. The third form extends the second form by permitting multiplication by a variable or a number.

NOTE: A component that is based on a state associated with a trend component cannot be used as a right-hand side term in any MODEL statement. That is, it is defined purely for output purposes (either printed or output to a data set). However, it can be used as a term in the expression that is specified in an [EVAL](#) statement to build more complex linear combinations for output.

You can specify the following *options* to print the filtered or smoothed estimate of the component:

PRINT=FILTER | SMOOTH

PRINT=(*< FILTER >* *< SMOOTH >*)

requests printing of the filtered or smoothed estimate of the specified component.

EVAL Statement

EVAL *name* = *number1*variable1 + number2*variable2 + ...* *</ options>* ;

The EVAL statement defines a linear combination, named *name*, of the terms used in the right-hand side of a MODEL statement. You can specify any variables (for example, predictor variables and names of components) in the expression of the EVAL statement; however, you cannot specify in this expression any observation disturbances that are specified by the IRREGULAR statement. Suppose C1 and C2 are two components (defined by COMPONENT statements elsewhere in the program), T1 is a trend component, and X1 is a regression variable used in a model. The following are valid examples of the EVAL statement:

```
eval e1 = c1 - c2;
eval e2 = t1 + c1 + x1;
eval e2 = t1 + 2*c1 - 1.5*x1;
```

The estimates of linear combinations defined by the EVAL statement (for example, E1, E2, and E3) are output to the OUT= data set that is specified in the OUTPUT statement.

The components used in a given EVAL expression must correspond to distinct state subsections. This requirement is imposed only to simplify the overall readability of the program and does not limit the type of

linear combinations that can be specified; if two components in the right hand side of an EVAL expression share the same state subsection, a new component that combines the effect of these two components can always be defined.

In addition, you can print these estimates by using the following PRINT= options:

PRINT=FILTER | SMOOTH

PRINT=(< FILTER > < SMOOTH >)

requests printing of the filtered or smoothed estimate of the specified linear combination.

ID Statement

ID *variable* < *option* > ;

The ID statement names a numeric variable to associate a sequence value—usually related to a time stamp—to the observations in the input data set. The observations within a BY group must be ordered in ascending order by the ID variable. Often the ID variable's values are SAS date, time, or datetime values, and each observation within a BY group has a unique ID value. Generally, however, the ID variable can be any numeric variable, and there can be multiple observations with the same ID value. If the ID values are SAS date, time, or datetime values, you can specify the associated unit of time—for example, day, week or month—by using the INTERVAL= option. If an ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID. Whenever an ID variable is specified, a variable, `_ID_DELTA_`, is automatically created that can be used as any input data set variable in the programming statements. `_ID_DELTA_` contains the distance between two successive ID values. The first `_ID_DELTA_` value is arbitrarily taken as one. If the INTERVAL= option is specified, the distance between the ID values is measured in terms of the number of intervals; therefore, for regularly spaced data, `_ID_DELTA_` is identically equal to one. You can specify the following *option* in the ID statement:

INTERVAL=*value*

specifies the unit of time interval that is used for measuring the ID values. INTERVAL=*value* is used in conjunction with the ID variable to check that the input data are in the proper order. For a complete discussion of the supported intervals, see Chapter 4, “Date Intervals, Formats, and Functions.”

IRREGULAR Statement

IRREGULAR *name* < *options* > ;

The IRREGULAR statement specifies a one-dimensional white noise component, which can be used to specify the observation error in a MODEL statement. You can specify the following *options* in the IRREGULAR statement:

PRINT=SMOOTH

requests printing of the smoothed estimate of the specified irregular component.

VARIANCE=*variable* | *number*

specifies the variance of the white noise. Any nonnegative value, including 0, is permissible. If the *variable* contains unknown parameters, they are estimated from the data. Similarly, if the VARIANCE= option is not specified, the variance is estimated from the data.

MODEL Statement

MODEL *response* = *variables* </ *options* > ;

A MODEL statement specifies an observation equation that describes a response variable as a sum of regression effects and components that are defined in the program. The response variable must be a numeric variable from the input data set. The variables used in the right-hand side of the model expression can be numeric variables from the input data set, numeric variables defined by using programming statements, or names of components that are specified in the COMPONENT, TREND, or IRREGULAR statements.

For a multivariate model, a separate MODEL statement is needed for each of the response variables. In this case, the observation errors, which are specified in an IRREGULAR statement, must be different in each MODEL statement.

The components that are specified in a given MODEL statement must correspond to distinct state subsections. This requirement is imposed only to simplify the overall readability of the program and does not limit the type of models that can be specified; if two components on the right-hand side of a MODEL statement share the same state subsection, a new component that combines the effect of these two components can always be defined.

You can specify the following *options* to print the filtered or smoothed estimate of the response variable:

PRINT=FILTER | SMOOTH

PRINT=(< FILTER > < SMOOTH >)

requests printing of the filtered or smoothed estimate of the specified response variable. The filtered estimate is produced during the filtering phase, and the smoothed estimate is produced by the smoothing phase of the Kalman filter and smoother algorithm. The filtered estimate is also called the one-step-ahead forecast of the response variable. The smoothed estimate corresponds to the full-sample prediction of the response variable. Since the full-sample prediction of a nonmissing response value is that value itself, full-sample predictions are printed only for the missing response values.

OUTPUT Statement

OUTPUT < *options* > ;

The OUTPUT statement specifies an output data set to store the estimates of the model components and series forecasts. In addition, it provides options to control certain aspects of the procedure output—for example, you can control the searching of additive outliers and structural breaks by using the suboptions of the AO and BREAK options, respectively.

AO(< ALPHA=number > < MAXNUM=number > < MAXPCT=number >)

controls the additive outlier search (see the section “[Delete-One Cross Validation and the Additive Outlier Detection](#)” on page 1930 for more information). The ALPHA= suboption specifies the significance level for reporting the outliers. The default is ALPHA=0.05. The MAXNUM= suboption limits the number of outliers to search. The default is MAXNUM=5. The MAXPCT= suboption is similar to the MAXNUM= suboption. In the MAXPCT= option you can limit the number of outliers to search for according to a percentage of the series length. The default is MAXPCT=1. When you specify both of these options, the lesser of the two search numbers is used.

ALPHA=number

specifies the significance level of the forecast confidence intervals. For example, ALPHA=0.05, which is the default, results in a 95% confidence interval.

BREAK(< ALPHA=number > < MAXNUM=number > < MAXPCT=number >)

controls the structural break search (for more information, see the section “[Structural Breaks in the State Evolution](#)” on page 1931). In order for this option to have any effect, the CHECKBREAK option in one of the STATE or TREND statements, or the MAXSHOCK option in the OUTPUT statement, must be turned on. The ALPHA= suboption specifies the significance level for reporting the breaks. The default is ALPHA=0.05. The MAXNUM= suboption limits the number of breaks to search. The default is MAXNUM=5. The MAXPCT= suboption is similar to the MAXNUM= suboption. In the MAXPCT= option, you can limit the number of breaks to search for according to a percentage of the number of distinct time points in the data. The default is MAXPCT=1. When you specify both of these options, the lesser of the two search numbers is used.

MAXSHOCK

causes the computation of the maximal state shock chi-square statistic at each distinct time point in the input data set. These statistics are output to the data set that is specified in the OUT= option. A time series plot of these statistics is produced if the PLOTS=MAXSHOCK option is specified in the PROC SSM statement. These statistics are useful for detecting structural breaks in the state evolution process. This option can be computationally expensive for a model with large state size. See the section “[Structural Breaks in the State Evolution](#)” on page 1931 for more information.

OUT=SAS-data-set

specifies an output data set for the forecasts. The output data set contains the ID variable (if specified), the response variables, the one-step-ahead and out-of-sample response variable forecasts, the forecast confidence intervals, the smoothed values of the response series, and the one-step-ahead and smoothed estimates of the model components—including expressions that are defined by using the EVAL statement. See the section “[OUT= Data Set](#)” on page 1948 for more information.

PDV

causes the inclusion of the variables (variables in the program data vector) that are defined by using the programming statements in the SSM procedure in the OUT= data set. The parameters defined by the PARMS statement are also included. The output data set contains the values of these variables evaluated for all the rows in the input data set that is specified in the DATA= option. The parameters in the PARMS statement contain their estimated values.

PRESS

prints the prediction error sum of squares (PRESS) and the generalized cross validation error sum of squares (GCV). The PRESS table also reports the number of summands that are used in these sums of squares. See the section “[Delete-One Cross Validation and the Additive Outlier Detection](#)” on page 1930 for more information.

PARMS Statement

PARMS *variable*< =number> *variable*< =number> < / options> ;

The PARMS statement declares the parameters of a model and optionally sets their initial values. You can also specify the lower and upper limits of their validity range. The parameters declared by using the PARMS

statement are called *named parameters* throughout this chapter. A model can have additional parameters: any unspecified quantity in the model specification becomes part of the parameter vector. You can specify the following *options*:

LOWER=(*number1 number2 . . .*)

LOWER=(*number*)

specifies the lower bounds for the specified parameters. The list can contain exactly one number, which is taken to be the lower bound for all the listed parameters in the statement, or it must contain as many values as the number of parameters specified. A missing value, denoted by ., is a permissible value, which signifies that the parameter has no lower bound.

UPPER=(*number1 number2 . . .*)

UPPER=(*number*)

specifies the upper bounds for the specified parameters. The list can contain exactly one number, which is taken to be the upper bound for all the listed parameters in the statement, or it must contain as many values as the number of parameters specified. A missing value, denoted by ., is a permissible value, which signifies that the parameter has no upper bound.

Programming Statements

To define the model, you can use most of the programming statements that are allowed in the SAS DATA step. See the *SAS Language Reference: Dictionary* for more information. For the most part, the syntax of programming statements used in PROC SSM is identical to that used in the MODEL procedure (see Chapter 19, “[The MODEL Procedure](#)”) and the NLMIXED procedure (see Chapter 68, “[The NLMIXED Procedure](#)” (*SAS/STAT User’s Guide*)). However, there are some restrictions: the DATA step lagging and differencing functions are not allowed, and the use of character variables in the DATA step expressions is not permitted. These are not serious restrictions; usually you can overcome them by adding the variables that are created by such operations to the input data set before its use in the SSM procedure.

STATE Statement

STATE *name (dim) < options >* ;

The STATE statement specifies a subsection of α_t , the overall state vector at time t (for more information, see the section “[State Space Model and Notation](#)” on page 1919). Consider the state equations that define the state space model:

$$\begin{aligned}\alpha_{t+1} &= \mathbf{T}_t \alpha_t + \mathbf{W}_{t+1} \gamma + c_{t+1} + \eta_{t+1} \\ \alpha_1 &= c_1 + \mathbf{A}_1 \delta + \mathbf{W}_1 \gamma + \eta_1\end{aligned}$$

You can specify multiple STATE statements, each specifying a separate subsection. It is assumed that the subsections that are specified by using different STATE statements are mutually independent. This independence assumption implies a block-diagonal structure for the transition matrices \mathbf{T}_t and the disturbance covariances \mathbf{Q}_t for all $t \geq 1$. An appropriate block structure also applies to \mathbf{W}_t and \mathbf{A}_1 . The *options* in the STATE statement provide complete control over the description of the relevant blocks of \mathbf{T}_t , \mathbf{Q}_t , \mathbf{W}_t , and

A_1 . The argument *dim* (a positive integer in *name (dim)*) specifies the nominal dimension of this subsection. In most situations, the nominal dimension and the actual dimension of the state subsection are the same. However, when you specify the **TYPE=** option, the actual dimension of the state subsection can be different from the nominal dimension. The **TYPE=** option simplifies the state specification task for some commonly needed models.

NOTE: The **T**, **COV**, **W**, and **COV1** options, described later in this section, specify the relevant blocks of T_t , Q_t , W_t , and Q_1 , respectively. The structure of these matrix blocks is described in a similar way in the option descriptions. For example, the specification **COV(I)** corresponds to the identity form, **COV(D)** corresponds to the diagonal form, and **COV(G)** corresponds to the general form of the Q_t block.

You can use the following *options* in the **STATE** statement to specify the system matrices T_t , Q_t , W_t , and A_1 and to request printing of their estimates when they contain unknown parameters. You can also request the checking of unexpected changes—structural breaks—in the evolution of this state subsection by using the **CHECKBREAK** option.

A1(nd)

specifies that the last *nd* elements of the state subsection be treated as diffuse. This becomes the dimension of the relevant subsection of the diffuse vector δ . The A_1 block is created by using appropriate columns of the identity matrix. The value of *nd* must lie between 1 and the nominal dimension, *dim*. The absence of this option signifies that this subsection of α_t is nondiffuse. If both the **COV1** and **A1** options are specified, the last *nd* rows and columns of the matrix specified in the **COV1** option are taken to be 0. This option cannot be used together with the **RANK=** option of the **COV1** option.

CHECKBREAK<(ELEMENTWISE | OVERALL)>

turns on the checking of breaks for this state subsection. The **ELEMENTWISE** suboption requests the elementwise checking of any unexpected change in the state subsection as it evolves from one time point to the next. The **OVERALL** suboption requests a similar check for the entire state subsection—that is, in this case the change is measured as a multidimensional change. The **ELEMENTWISE** suboption is the default. Unless the **PRINT=BREAKDETAIL** option is specified, only a summary of the most significant breaks is produced. If the **PRINT=BREAKDETAIL** is specified, tables that contain the break significance statistics at every distinct time point are produced—one for the **ELEMENTWISE** suboption and one for the **OVERALL** suboption. For more information about the structural break detection process, see the section “[Structural Breaks in the State Evolution](#)” on page 1931. For an example of the use of the **CHECKBREAK** option, see [Example 27.8](#).

COV(D) <= (var1 var2 ...) | (number1 number2 ...)>

COV(G) <= (var1 var2 ...) | (number1 number2 ...)>

COV(I) <= (variable) | (number)>

COV(RANK=integer)

specifies the relevant block of the disturbance covariance Q_t (for $t \geq 2$) in the transition equation. As with the **T** option, the absence of this option signifies that this Q -block consists of only zeros. The structure of the Q -block is also similarly specified. However, the following differences exist:

- The list that is specified to form the covariance must result in a symmetric, positive semidefinite matrix. For an example, see [Example 27.5](#).
- You can specify a rank constraint on the Q -block by specifying **COV(RANK=integer)**, where the specified integer must lie between 1 and *dim*. A rank constraint is permissible only for the general form and only when its elements are not specified by using a list.

- The convention of treating unset variables as structural zeros, which is used in specifying sparsity of the T-block, is not used in the Q-block specification. Whenever you explicitly specify the entries of the Q-block by specifying a list of variables in parentheses, all variables in the list must evaluate to nonmissing values.

The following examples illustrate different ways of specifying a Q-block. It is assumed that $dim = 2$.

- COV(G) specifies a general-form Q-block, which contributes $(2 * (2 + 1))/2 = 3$ unspecified elements to the parameter vector θ .
- COV(RANK=1) specifies a rank-one Q-block.

COV1(D) <= (var1 var2 ...) | (number1 number2 ...)>

COV1(G) <= (var1 var2 ...) | (number1 number2 ...)>

COV1(I) <= (variable) | (number)>

COV1(RANK=integer)

specifies the relevant block of the initial state covariance Q_1 . The different options in this case have the same meaning as the options of the **COV** option. However, the following differences exist:

- If the elements of Q_1 are specified by a list of variables in parentheses, then these variables must evaluate to constant values. In particular, they can depend on parameters that are specified by the **PARMS** statements; however, they cannot depend on any of the input data columns.
- If the initial condition is partially diffuse (that is, the diffuse dimension nd specified in the **A1** option is nonzero), the last nd rows and columns of the matrix specified in **COV1** are taken to be zero. Moreover, if the elements of Q_1 are specified by a list, its number of elements must correspond to a matrix of dimension $(dim - nd)$.

PRINT=AR | BREAKDETAIL | COV | COV1 | MA | T

PRINT=(<AR> <BREAKDETAIL> <COV> <COV1> <MA> <T>)

requests printing of the respective system matrices and the printing of the break statistics at each distinct time point. You can specify **PRINT=AR** or **PRINT=MA** only if you specify the **TYPE=VARMA** option. If any of these matrices are time-varying, the matrix that corresponds to the first time instance is printed. For the **BREAKDETAIL** suboption to have any effect, the **CHECKBREAK** option must be turned on.

SINPUT = (var1 var2 ...) | (number1 number2 ...)

specifies the relevant dim -dimensional block of the state input vector c_t . The absence of this option signifies that this block of the c_t vector consists of only zeros. If the elements of c_t are specified by a list of variables in parentheses, then these variables must be independent of unknown parameters. In particular, they cannot be functions of parameters that are defined by the **PARMS** statements.

T(D) <= (var1 var2 ...) | (number1 number2 ...)>

T(G) <= (var1 var2 ...) | (number1 number2 ...)>

T(I) <= (variable) | (number)>

specifies the relevant block of the transition matrix T_t . The absence of this option signifies that this block consists of only zeros. You can specify the structure of the T-block by specifying **T(I)** for the identity form, **T(D)** for the diagonal form, and **T(G)** for a general unstructured form. In addition, you can explicitly specify the entries of the T-block by specifying a list of numbers in parentheses, or by

specifying in parentheses a list of variables that are defined by using the programming statements. The unspecified elements of the T-block are included in the list of parameters to be estimated from the data. If the elements of the T-block are supplied by a list in parentheses, the number of elements in the list depends on its structure. For the diagonal form, the list must contain exactly *dim* elements. In the case of the identity form—T(I)—the block is already fully specified; however, a specification T(I)=(*variable*) is understood to mean that the identity block is scaled by the specified *variable* (or a *number*). In the general case—T(G)—the list must consist of *dim* * *dim* elements, specified in a rowwise fashion. An inappropriate number of elements in the list results in a syntax error.

The following examples illustrate different ways of specifying the transition matrix. It is assumed that *dim* = 2.

- T(I) specifies that the T-block is a two-dimensional identity matrix.
- T(D) specifies that the T-block is a two-dimensional diagonal matrix. The two unspecified diagonal entries become part of the parameter vector θ .
- T(D)=(1.1 2) fully specifies the two-dimensional diagonal T-block.
- T(D)=($X_1 X_2$) specifies a two-dimensional diagonal T-block where the diagonal elements are dynamically calculated based on the values of the variables X_1 and X_2 . In this case the T-block can change with time if X_1 or X_2 changes with time.
- T(G) specifies a general form T-block (with $2^2 = 4$ unspecified elements).
- T(G)=($X_1 X_2 X_3 X_4$) specifies a general form T-block where the first row is formed by X_1 and X_2 , and the second row is formed by X_3 and X_4 .

In practice the transition matrix is often sparse—that is, many of its elements are 0. The algorithms in the SSM procedure exploit this sparsity structure for computational efficiency. Whenever you explicitly specify the entries of the T-block by specifying a list of variables in parentheses, you can leave the variables that correspond to the zero elements *unset*. These unset variables are treated as structural zeros by the SSM procedure. The section “[Sparse Transition Matrix Specification](#)” on page 1924 further explains how to use this sparsity convention.

TYPE=WN

TYPE=RW

TYPE=LL (SLOPECOV(I | D | G) <= (var1, var2, ...) | (number1, number2, ...) >)

TYPE=LL (SLOPECOV(RANK=*integer*)

TYPE=SEASON (LENGTH=*integer* <DROPH=*number-list*> <KEEPPH=*number-list*>)

TYPE=CYCLE <(<CT> <RHO=*variable* | *number*> <PERIOD=*variable* | *number*>)>

TYPE=VARMA (<p <(I | D)> =*integer*> <q<(D)> =*integer*>)

specifies a state subsection that corresponds to the specified type. You can specify either a number or a variable for the RHO= and PERIOD= suboptions. When TYPE=VARMA, the autoregressive and moving average orders can be at most 1 ($0 \leq p \leq 1$ and $0 \leq q \leq 1$). Moreover, by using the D and I flags with the order specification, you can impose additional structure on the autoregressive and moving average coefficient matrices—for example, specifying TYPE=VARMA(P=1) implies a VAR(1) model with general autoregressive coefficient matrix, whereas specifying TYPE=VARMA(P(D)=1) implies a VAR(1) model with diagonal autoregressive coefficient matrix. If you specify the TYPE= option, the T, COV1, SINPUT, and A1 options are not needed. In fact they are ignored, since the transition matrix T_t and the matrices in the initial condition (Q_1 and A_1) are implicitly defined by the

choice of the type. However, the **COV** and **W** options can be useful. In fact, the specification of the **COV** option does play a key role in the eventual form of \mathbf{Q}_t —the covariance of the disturbance term in the transition equation. For the types **LL**, **CYCLE**, **SEASON**, and **VARMA**, the dimension of the resulting state subsection is a certain multiple of *dim*, the nominal dimension in the **STATE** statement. For example, the following specification results in a state subsection, named `cycleState`, of dimension $2 * \text{dim}$:

```
state cycleState(dim) cov(g) type=cycle;
```

The name `cycleState` corresponds to the state underlying a *dim*-dimensional cycle component. All of these special state types require that the data be regular (replication is permissible); the only exception is **TYPE=CYCLE(CT)**, which defines a continuous-time cycle and is applicable to any data type. [Table 27.2](#) summarizes some of this information for easy reference. For more information about these state types, see the section “[Predefined Structural Models](#)” on page 1936.

The **TYPE=LL** specification results in a state that corresponds to a multivariate local linear trend. It is governed by two covariance matrices: the **COV** option specifies the covariance that corresponds to the level equation, and the **SLOPECOV** suboption specifies the covariance used in the slope equation. The form of the **SLOPECOV** suboption is exactly the same as that of the **COV** option.

The **TYPE=CYCLE** option results in a state that corresponds to a (stochastic) cycle. By default, this cycle is assumed to be for the regular data type. If **TYPE=CYCLE(CT)**, the resulting cycle is applicable to any data type. The **CT** option is available only for *dim* = 1; that is, only a univariate cycle is available for the irregular data type. The cycle specification depends on a covariance matrix and two numbers: the damping factor **RHO** and the cycle period **PERIOD**. The covariance can be specified by the **COV** option. The damping factor is specified by the **RHO=** suboption; its value must lie between 0.0 and 1.0. The cycle period can be specified by the **PERIOD=** suboption. If the **CT** suboption is not included, the period value must be larger than 2.0. On the other hand, if the **CT** suboption is included, its value must be strictly positive. If these parameters are not specified, they are estimated from the data.

The **TYPE=SEASON(LENGTH=integer)** specifies a multivariate trigonometric season that contains the full set of harmonics (for more information, see “[Multivariate Season](#)” on page 1940). In some cases, you might want to drop some of the harmonics from this complete set to obtain a more parsimonious trigonometric season specification. You can use the **DROPH=** (to drop) or **KEEPH=** (to keep) suboption to control the harmonics that are included in the season specification as follows:

```
TYPE=SEASON(
  LENGTH=integer
  < DROPH=number-list | n TO m BY p >
  < KEEPH=number-list | n TO m BY p >
)
```

The **DROPH=** and **KEEPH=** lists can include any integer between 1 and $LENGTH/2$ if the season length is even and any integer between 1 and $(LENGTH - 1)/2$ if the season length is odd. For example, the following specification results in a specification of a trigonometric season with a season length 12 that consists of only the first four harmonics ζ_j , $j = 1, 2, 3, 4$:

```
type=season(length=12 DROPH=5 6) ...;
```

The last two *high*-frequency harmonics, ξ_5 and ξ_6 , are dropped. The DROPH= suboption cannot be used with the KEEPH= suboption.

Table 27.2 Summary of Predefined State Types

Type	Description	Parameters	State Dimension
WN	dim -variate white noise	COV	dim
RW	dim -variate random walk	COV	dim
LL	dim -variate local linear	COV, SLOPECOV	$2*dim$
SEASON(LENGTH=length)	dim -variate season	COV	$(length-1)*dim$
CYCLE	dim -variate cycle	COV, RHO, PERIOD	$2*dim$
VARMA(P=p Q=q)	dim -variate VARMA(p, q)	COV, AR, MA	$dim*\max(p, q+1)$

W(D)= (*var1 var2 ...*)

W(G)= (*var1 var2 ...*)

W(I)= (*variable*)

specifies the relevant block of the design matrix W_t in the transition equation. The W-block is of dimension $sdim \times sg$, where $sdim$ denotes the actual dimension of the state subsection (which can be the same as dim , the nominal dimension, or different if the TYPE= option is used) and sg denotes the desired size of the subsection of the overall state regression vector γ . As with the T option, the absence of this option signifies that this W-block consists of only zeros. The structure of the W-block is also similarly specified. The number of variables supplied in the W(G)= list option must be a multiple of $sdim$. For example, if $sdim = 4$ and the W(G)= list contains 8 variables, then the implied size of γ subsection is 2. If the W(D)= or W(I)= option is used, then the W-block is assumed to be an $sdim$ -dimensional diagonal matrix and the W(D)= list must contain exactly $sdim$ variables. For examples of the use of this option, see [Example 27.8](#), [Example 27.10](#), and [Example 27.11](#).

TREND Statement

TREND *name (type) < options >* ;

The TREND statement defines a term in the model that follows a stochastic pattern of a certain predefined type. The *options* in the TREND statement enable you to specify a wide variety of commonly used stochastic patterns. Each TREND statement in effect stands for a special pair of STATE and COMPONENT statements. You can specify more than one TREND statement. Each separate TREND statement defines a component that is assumed to be independent of all other component specifications in the model. Very often the TREND statement is used to specify a component that captures the time-varying level of the data. However, in many cases it is also used to define components of a more general nature; for example, it can be used to define a noise component that follows a stationary ARMA model.

You can refer to the state that is associated with a TREND statement by appending the string “_state_” to the end of its name. For example, *name_state_* is the state that is associated with a trend named *name*. You can use *name_state_* in a COMPONENT statement to define a linear combination of its elements. The estimate of this linear combination can then be printed or output to a data set. The nominal dimension of *name_state_* is taken to be 1, or the number of variables in the list that is specified in the CROSS= option in the TREND

statement that is used to define name (see [Example 27.4](#) for an example of such use of the COMPONENT statement).

Some of these trend specifications are applicable to all the data types—that is, they can be used for both regular data types and irregular data types, whereas the others require that the data be regular or regular with replication. Of course, the trend specification is only part of the overall model specification. Therefore, the other parts of the model can imply additional constraints on the data type.

[Table 27.3](#) lists the available trend models and their data requirements. The *type* column shows the admissible keywords that signify the particular trend type. For brevity, the Data Type column groups the data types regular and regular with replication into one category: regular. For more information about these trend models, see the section “[Predefined Trend Models](#)” on page 1933.

Table 27.3 Summary of Trend Types

<i>type</i>	Data Type	Description	Parameters
ARIMA(<i>P=integer D=integer ...</i>)	Regular	ARIMA model specification	AR and MA coefficients, and the error variance σ^2
DLL	Regular	Damped local linear	Level and slope σ_1^2, σ_2^2 , damping factor ϕ
LL	Regular	Local linear	Level and slope σ_1^2, σ_2^2
RW	Regular	Random walk	Level σ^2
DECAY	Irregular	A type of decay pattern	Level σ^2 , decay rate ϕ
DECAY(OU)	Irregular	Ornstein-Uhlenbeck decay pattern	Level σ^2 , decay rate ϕ
GROWTH	Irregular	A type of growth pattern	Level σ^2 , growth rate ϕ
GROWTH(OU)	Irregular	Ornstein-Uhlenbeck growth pattern	Level σ^2 , growth rate ϕ
PS(<i>order</i>)	Irregular	Polynomial spline of a given order	Level σ^2

The keyword specification of different trend types, except possibly the ARIMA trend, is quite simple. For example, the following statement specifies `polySpline` as a trend of the type second-order polynomial spline:

```
trend polySpline(ps(2));
```

Similarly, the following statement defines `dampedTrend` as a damped local linear trend:

```
trend dampedTrend(dll) slopevar=x;
```

The variance parameter that governs the slope equation of this trend type is given by a variable `x`, which must be defined elsewhere in the program. The other parameters that define `dampedTrend` are left unspecified (and are estimated by using the data).

The ARIMA trend specification permits specification of trends that follow an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model. The specification of ARIMA models requires some notation, which is explained first.

Let B denote the backshift operator—that is, for any sequence ζ_t , $B\zeta_t = \zeta_{t-1}$. The higher powers of B represent larger shifts (for example, $B^3\zeta_t = \zeta_{t-3}$). A random sequence ζ_t follows an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model with nonseasonal autoregressive order p , seasonal autoregressive order P , nonseasonal differencing order d , seasonal differencing order D , nonseasonal moving average order q , and seasonal moving average

order Q if it satisfies the following difference equation, which is specified in terms of the polynomials in the backshift operator, where a_t is a white noise sequence and s is the season length:

$$\phi(B)\Phi(B^s)(1-B)^d(1-B^s)^D\zeta_t = \theta(B)\Theta(B^s)a_t$$

The polynomials ϕ , Φ , θ , and Θ are of orders p , P , q , and Q , respectively, which can be any nonnegative integers. The season length s must be a positive integer. For example, ζ_t satisfies an ARIMA(1,0,1) model (that is, $p = 1$, $d = 0$, $q = 1$, $P = 0$, $D = 0$, and $Q = 0$) if

$$\zeta_t = \phi_1\zeta_{t-1} + a_t - \theta_1a_{t-1}$$

for some coefficients ϕ_1 and θ_1 and a white noise sequence a_t . Similarly, ζ_t satisfies an ARIMA(0,1,1)×(0,1,1)₁₂ model if

$$\zeta_t = \zeta_{t-1} + \zeta_{t-12} - \zeta_{t-13} + a_t - \theta_1a_{t-1} - \Theta_1a_{t-12} + \theta_1\Theta_1a_{t-13}$$

for some coefficients θ_1 and Θ_1 and a white noise sequence a_t . An ARIMA process is zero-mean, stationary, and invertible if $d = 0$, $D = 0$, and the defining polynomials ϕ , Φ , θ , and Θ have all their roots outside the unit circle—that is, their absolute values are strictly larger than 1.0. It is assumed that the coefficients of the polynomials ϕ , Φ , θ , and Θ are constrained so that the stationarity and invertibility conditions are satisfied. The unknown coefficients of these polynomials become part of the model parameter vector that is estimated by using the data. The general form of the ARIMA trend specification is as follows:

ARIMA(<P=integer> <D=integer> <Q=integer> <SP=integer> <SD=integer> <SQ=integer> <S=integer>)

By default, the different orders are equal to 0 and the season length is equal to 1. The following examples illustrate a few different ARIMA trend specifications. The following statement defines `ima` as an integrated moving average trend:

```
trend ima(arima(d=1 q=1));
```

The following statement defines `airTrend` as a trend that satisfies the well-known airline model (ARIMA(0,1,1)(0,1,1)₁₂ model) for monthly seasonal data:

```
trend airTrend(arima(d=1 q=1 sd=1 sq=1 s=12));
```

The following statement defines `arma11` as a zero-mean ARMA(1,1) trend with autoregressive parameter fixed to 0.1:

```
trend arma11(arima(p=1 q=1) ar=0.1;
```

For an example of the use of the ARIMA trend specification, see [Example 27.6](#).

You can use the following *options* in the **TREND** statement to specify the trend parameters and to request printing of the trend estimates. In addition, you can create a custom combination of a given trend type by specifying the **CROSS=** option to create a more general trend. For an example of using the **CROSS=** option, see the section “[Getting Started: SSM Procedure](#)” on page 1889 and the discussion of the second model in [Example 27.4](#). You can also check for the unexpected changes in the trend component by using the **CHECKBREAK** option.

AR= $\phi_1 \phi_2 \dots \phi_p$

lists the values of the coefficients of the nonseasonal autoregressive polynomial

$$\phi(B) = 1 - \phi_1 B - \dots - \phi_p B^p$$

where the order p is specified in the ARIMA trend specification. The coefficients ϕ_i must define a stationary autoregressive polynomial.

CHECKBREAK<(**ELEMENTWISE** | **OVERALL**)>

turns on the checking of breaks for this trend component. The **ELEMENTWISE** suboption requests the elementwise checking of any unexpected change in the state subsection that is associated with the trend component. The **OVERALL** suboption requests a similar check for the entire state subsection—that is, in this case the change is measured as a multidimensional change. The **ELEMENTWISE** suboption is the default. Unless the **PRINT=BREAKDETAIL** option is specified, only a summary of the most significant breaks is produced. If the **PRINT=BREAKDETAIL** is specified, tables that contain the break significance statistics at every distinct time point are produced—one for the **ELEMENTWISE** suboption and one for the **OVERALL** suboption. If the **CROSS=** option is specified and the **CROSS=** list contains more than one variable, the **OVERALL** suboption considers subsections that are associated with each **CROSS=** variable separately. For more information about the structural break detection process, see the section “[Structural Breaks in the State Evolution](#)” on page 1931.

CROSS=(*var1*, *var2*, ...)

CROSS(MATCHPARM)=(*var1*, *var2*, ...)

creates a linear combination of one or more independent trend components that is based on the variables in the list. If the parameters of the trend are specified by options such as the **LEVELVAR=** option or the **PHI=** option, these parameters are shared by these constituent trends. For example, suppose that the **CROSS=** list contains two variables (X_1 and X_2) and the trend specification is of the type **RW**. The effect of **CROSS=(X_1, X_2)** is to create a component $\mu_t = X_1\mu_{1,t} + X_2\mu_{2,t}$, where $\mu_{1,t}$ and $\mu_{2,t}$ are two independent random walk trends. Moreover, if the random walk trend specification uses the **LEVELVAR=** option to specify the variance parameter, $\mu_{1,t}$ and $\mu_{2,t}$ share the same variance parameter; otherwise, two separate variance parameters are assigned to these random walks. If the second form of the **CROSS** option, **CROSS(MATCHPARM)=**, is used, then the constituent trends share all the relevant parameters no matter how they are specified. The **CROSS=** option is useful for a variety of situations. For example, suppose X is an indicator variable that is 1 before a certain time point t_0 and 0 thereafter. Then **CROSS=(X)** has the effect of turning off the trend component after time t_0 . Similarly, suppose G_1 and G_2 are indicators for gender—for example, $G_1 = (\text{GENDER}=1)$ and $G_2 = (\text{GENDER}=0)$ for male and female cases, respectively. Then **CROSS=(G_1, G_2)** results in separate trends according to the gender. The variables in the **CROSS=** list must be free of unknown parameters.

The **CROSS=** option can be computationally expensive; computationally it is equivalent to specifying as many separate trends as the number of variables in the specified list.

LEVELVAR=*variable* | *number*

specifies the disturbance variance parameter for all the trend types. For trend types **LL** and **DLL**, this option specifies σ_1^2 . Any nonnegative value, including 0, is permissible. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the **LEVELVAR=** option is not specified, σ^2 is estimated from the data.

MA= $\theta_1 \theta_2 \dots \theta_q$

lists the values of the coefficients of the nonseasonal moving average polynomial,

$$\theta(B) = 1 - \theta_1 B - \dots - \theta_q B^q$$

where the order q is specified in the ARIMA trend specification. The coefficients θ_i must define an invertible moving average polynomial.

NODIFFUSE

causes the diffuse elements in the initial state of the state subsection underlying the trend component to be treated as nondiffuse. This option is applicable to all trend types except ARIMA. For the ARIMA trend type, this option is ignored even if the nonseasonal or seasonal differencing orders are nonzero. The diffuse elements are assumed to be independent, zero-mean, Gaussian variables. Their variances become part of the parameter vector and are estimated by using the data. This option is useful for creating a trend component that can be interpreted as a deviation from an overall trend component (with diffuse initialization), which is defined separately.

PHI=*variable* | *number*

specifies the value of ϕ for trend types DLL, DECAY, DECAY(OU), GROWTH, and GROWTH(OU). For the type DLL, the specified value must be between 0.0 and 1.0. For types DECAY and DECAY(OU), ϕ must be strictly negative. For types GROWTH and GROWTH(OU), ϕ must be strictly positive. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the PHI= option is not specified, ϕ is estimated from the data.

PRINT=BREAKDETAIL | COV | COV1 | FILTER | SMOOTH | T**PRINT**= (< BREAKDETAIL > < COV > < COV1 > < FILTER > < SMOOTH > < T >)

requests printing of the respective system matrices of the state equation that underlies the specified trend, the printing of its filtered and smoothed estimates, and the printing of the break statistics at each distinct time point. For the BREAKDETAIL suboption to have any effect, the [CHECKBREAK](#) option must be turned on. If any of these matrices are time-varying, the matrix that corresponds to the first time instance is printed.

SAR= $\Phi_1 \Phi_2 \dots \Phi_P$

lists the values of the coefficients of the seasonal autoregressive polynomial

$$\Phi(B^s) = 1 - \Phi_1 B^s - \dots - \Phi_P B^{sP}$$

where the order P is specified by using the SP= option in the ARIMA trend specification and the season length s is specified in the S= option. The coefficients Φ_i must define a stationary autoregressive polynomial.

SMA= $\Theta_1 \Theta_2 \dots \Theta_Q$

lists the values of the coefficients of the seasonal moving average polynomial

$$\Theta(B^s) = 1 - \Theta_1 B^s - \dots - \Theta_Q B^{sQ}$$

where the order Q is specified by using the SQ= option in the ARIMA trend specification and the season length s is specified in the S= option. The coefficients Θ_i must define an invertible moving average polynomial.

SLOPEVAR=*variable* | *number*

specifies the second disturbance variance parameter, σ_2^2 , for trend types LL and DLL. Any nonnegative value, including 0, is permissible. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the SLOPEVAR= option is not specified, σ_2^2 is estimated from the data.

Details

Throughout this section, vectors and matrices are denoted by boldface letters. Generally, Greek letters (such as α , β , and ϵ) denote unobserved or latent quantities—often estimated from the data—that represent model parameters, latent states, or noise variables. Capital letters such as X , Y , and Z are used to denote the observed data variables. Whenever there is no ambiguity, it is assumed that the matrices have appropriate dimensions when they are being multiplied—in particular, the vectors behave as column vectors or row vectors as the need arises. On many occasions, matrices are described inline—that is, they are described as parenthesized lists, in a rowwise fashion, with the rows separated by a comma. The term “dot product” is used to describe the scalar that results from the product of a row vector with a (conforming) column vector.

State Space Model and Notation

The (linear) state space model is described in the literature in a few different ways and with varying degree of generality. The description given in this section loosely follows the description given in Durbin and Koopman (2001, chap. 6, sec. 4). This formulation of SSM is quite general; in particular, it includes nonstationary SSMs with time-varying system matrices and state equations with a diffuse initial condition (these terms are defined later in this subsection).

Suppose that observations are collected in a sequential fashion (indexed by a numeric variable τ) on some variables: the vector $\mathbf{y} = (y_1, y_2, \dots, y_q)$, which denotes the q -variate response values, and the k -dimensional vector \mathbf{x} , which denotes the predictors. Suppose that the observation instances are $\tau_1 < \tau_2 < \dots < \tau_n$. The possibility that multiple observations are taken at a particular instance τ_i is not ruled out, and the successive observation instances do not need to be regularly spaced—that is, $(\tau_2 - \tau_1)$ does not need to equal $(\tau_3 - \tau_2)$. For $t = 1, 2, \dots, n$, suppose $p_t (\geq 1)$ denotes the number of observations recorded at instance τ_t . For notational simplicity, an integer-valued secondary index t is used to index the data so that $t = 1$ corresponds to $\tau = \tau_1$, $t = 2$ corresponds to $\tau = \tau_2$, and so on. Consider the following model:

$$\begin{aligned} \mathbf{Y}_t &= \mathbf{Z}_t \alpha_t + \mathbf{X}_t \beta + \epsilon_t && \text{Observation equation} \\ \alpha_{t+1} &= \mathbf{T}_t \alpha_t + \mathbf{W}_{t+1} \gamma + \mathbf{c}_{t+1} + \eta_{t+1} && \text{State transition equation} \\ \alpha_1 &= \mathbf{c}_1 + \mathbf{A}_1 \delta + \mathbf{W}_1 \gamma + \eta_1 && \text{Initial condition} \end{aligned}$$

The following list describes these equations:

- The *observation equation* describes the relationship between the $(p_t * q)$ -dimensional response vector \mathbf{Y}_t and the unobserved vectors α_t , β , and ϵ_t . The q -variate responses are vertically stacked in a column to form this $(p_t * q)$ -dimensional response vector \mathbf{Y}_t . The m -dimensional vectors α_t are called *states*, the k -dimensional vector β is the regression coefficient vector associated with predictors \mathbf{x} , and the $(p_t * q)$ -dimensional vectors ϵ_t are called the *observation disturbances*. The matrices \mathbf{Z}_t (of dimension

$(q * p_t) \times m$) and \mathbf{X}_t (of dimension $(q * p_t) \times k$) correspond to the *state effect* and the *regression effect*, respectively. The elements of \mathbf{X}_t are assumed to be fully known. The states α_t and the disturbances ϵ_t are *random* sequences. It is assumed that ϵ_t is a sequence of independent, zero-mean, Gaussian random vectors with diagonal covariances, with the diagonal elements denoted by $\sigma_{t,i}^2, i = 1, 2, \dots, q * p_t$.

- The state sequence α_t is assumed to follow a Markovian structure described by the state transition equation and the associated initial condition.
- The *state transition equation* postulates that a new instance of the state, α_{t+1} , is obtained by multiplying its previous instance, α_t , by an m -dimensional square matrix \mathbf{T}_t (called the state transition matrix) and by adding three more terms: a known nonrandom vector \mathbf{c}_{t+1} (called the state input); a regression term $\mathbf{W}_{t+1}\gamma$, where \mathbf{W}_{t+1} is an $m \times g$ -dimensional design matrix with fully known elements and γ is the g -dimensional regression vector; and a random disturbance vector η_{t+1} . The m -dimensional state disturbance vectors η_t are assumed to be independent, zero-mean, Gaussian random vectors with covariances \mathbf{Q}_t (not necessarily diagonal).
- The *initial condition* describes the starting condition of the state evolution equation. The starting state vector α_1 is assumed to be partially diffuse: it is the sum of a known nonrandom vector \mathbf{c}_1 , a mean-zero Gaussian vector η_1 , and the terms $\mathbf{A}_1\delta$ and $\mathbf{W}_1\gamma$. $\mathbf{A}_1\delta$ represents the contribution from a d -dimensional diffuse vector δ (a diffuse vector is a Gaussian vector with infinite covariance). The observation and state regression vectors β and γ are also assumed to be diffuse. The $m \times d$ matrix \mathbf{A}_1 is assumed to be completely known.
- The observation disturbances ϵ_t and the state disturbances η_t (for $t \geq 1$) are assumed to be mutually independent. Either the elements of the matrices \mathbf{Z}_t , \mathbf{T}_t , and \mathbf{Q}_t and the diagonal elements of the observation disturbance covariances $\sigma_{t,i}^2$ are assumed to be completely known, or some of them can be functions of a small set of unknown parameters (to be estimated from the data). Suppose that this unknown set of parameters is denoted by θ .
- The d -dimensional diffuse vector δ from the state initial condition together with the observation and state regression vectors β and γ constitute the overall $(d + k + g)$ -dimensional diffuse initial condition of the model. See the section “[Filtering, Smoothing, Likelihood, and Structural Break Detection](#)” on page 1926 for more information.

Although this description of the state space model might appear involved, it conveniently covers many variants of the SSMs that are encountered in practice and precisely describes the most general case that can be handled by the SSM procedure. An important restriction about the preceding description of the model formulation is that it assumes that the matrices \mathbf{X}_t and \mathbf{W}_t that appear in the observation equation and the state equation respectively are free of unknown parameters and that the covariances of the observation disturbances ϵ_t are diagonal. In most practical situations, the model under consideration can be easily reformulated to a statistically equivalent form that conforms to this restriction.

NOTE: The transition matrix \mathbf{T}_t in the state equation relates the state α_t at time t with the state α_{t+1} at time $t + 1$. In many situations, such as when the observations are taken at irregular time intervals, \mathbf{T}_t depends on information at both t and $t + 1$. Therefore, it is more appropriate to denote the transition matrix as \mathbf{T}_t^{t+1} . However, for simplicity, the former notation is used throughout this chapter. The same comment applies to the covariance matrix \mathbf{Q}_t of the disturbance term η_t .

For easy reference, [Table 27.4](#) summarizes the information contained in the SSM equations.

Table 27.4 State Space Model: Notation

Notation	Description
$\tau_1, \tau_2, \dots, \tau_n$	Distinct index values at which the observations are recorded
n	Number of distinct index instances
p_t	Number of observations recorded at index τ_t , $t = 1, 2, \dots, n$
q	Number of response variables in the model
$\mathbf{Y}_t = (y_{t,1}, y_{t,2}, \dots, y_{t,p_t * q})$	Vertically stacked vector of response values recorded at τ_t
$N = q * \sum_{t=1}^n p_t$	Total number of response values in the data set
k	Number of predictor (regressor) variables in the observation equation
\mathbf{X}_t	$(p_t * q) \times k$ matrix of predictor values recorded at τ_t
$\boldsymbol{\beta}$	k -dimensional regression vector that is associated with the predictors
$\boldsymbol{\epsilon}_t \sim N(0, (\sigma_{t,1}^2, \dots))$	$(q * p_t)$ -dimensional observation disturbance vector with diagonal covariance
m	Dimension of the state vectors $\boldsymbol{\alpha}_t$
$\boldsymbol{\alpha}_t$	m -dimensional state vector
\mathbf{Z}_t	$(q * p_t) \times m$ matrix that is associated with $\boldsymbol{\alpha}_t$ in the observation equation
\mathbf{T}_t	$m \times m$ state transition matrix
\mathbf{c}_t	m -dimensional state input vector
\mathbf{W}_t	$m \times g$ design matrix associated with $\boldsymbol{\gamma}$, the state regression vector
$\boldsymbol{\gamma}$	g -dimensional state regression vector
$\boldsymbol{\eta}_t \sim N(0, \mathbf{Q}_t)$	m -dimensional state disturbance vector
d	Dimension of the diffuse vector $\boldsymbol{\delta}$ in the state initial condition
$\boldsymbol{\delta} \sim N(0, \kappa \boldsymbol{\Sigma}), \kappa \rightarrow \infty$	Diffuse vector in the state initial condition
\mathbf{A}_1	$m \times d$ constant matrix associated with $\boldsymbol{\delta}$
$\boldsymbol{\eta}_1 \sim N(0, \mathbf{Q}_1)$	m -dimensional state disturbance vector in the initial condition
$\boldsymbol{\theta}$	Parameter vector

Types of Sequence Data

The state space model specification in the SSM procedure requires proper understanding of both the data organization and the form of the model. The SSMs that are appropriate for time series data might not be appropriate for irregularly spaced longitudinal data. The SSM procedure distinguishes three types of data organization based on the way the observations are sequenced by the index variable. If an index variable is not specified, it is assumed that the observations are sequenced according to the observation number.

Regular: The observations are recorded at regularly spaced intervals; that is, $\tau_1, \tau_2, \dots, \tau_n$ are regularly spaced. Moreover, at each observation instance τ_i a single observation is recorded; that is, $p_t = 1$ for all t . The standard time series data (both univariate and multivariate) fall in this category.

Regular with Replication: The observations are recorded at regularly spaced intervals, but $p_t > 1$ for at least one t . Here the word replication is used loosely—it does not mean that the multiple observations at τ_t are replications in the precise statistical sense. The panel or cross-sectional data types fall into this category. In the panel data case with p cross-sections, $p_t = p$ for all t .

Irregular: The observations are not recorded at regular intervals, and the number of observations p_t at each index instance can be different. The longitudinal data fall into this category.

It is not always easy to decide whether the specified model is appropriate for the given data type. Whenever possible, the SSM procedure issues a note regarding the possible mismatch between the specified model and the data type being analyzed.

Overview of Model Specification Syntax

An SSM specification involves the description of the terms in the observation equation, the state transition equation, and the initial condition. For example, the response variables, the predictor variables, and the elements of the state transition matrix \mathbf{T}_t must somehow be specified. The SSM procedure syntax is designed so that little effort is needed to specify the more commonly needed models, while a highly flexible language is available for specifying more complex models. Two syntax features help achieve this goal: the ability to build a complex specification by combining simpler subspecifications, and a programming language for creating lists of variables to be used later in the model specification.

The SSM procedure statements can be divided into two classes:

- **programming statements**, which are used to create lists of variables that can be used for a variety of purposes (for example, as the elements of the model system matrices)
- statements specific to the SSM procedure that formulate the state space model and control its other aspects such as the input data specification and the resulting output

Since the matrices involved in the model specification can be specified as lists of variables, which you separately create by using the programming statements, you can finely control all aspects of the model specification. These programming statements permit the use of most DATA step language features such as the conditional logic (IF-THEN-ELSE), array type variables, and all the mathematical functions available in the DATA step. You can also use programming statements to define predictor variables on the fly.

Building a Complex Model Specification

In addition to being able to specify the system matrices in a flexible way, you can also build a complex model specification in a modular way by combining simpler subspecifications. Suppose that the state vector for the model to be specified is composed of subsections that are statistically independent, which is a common scenario in practical modeling situations. For example, suppose that α_t can be divided into two disjoint subsections α_t^a and α_t^b , which are statistically independent. This entails a corresponding block-diagonal structure to the system matrices \mathbf{T}_t , \mathbf{W}_t , and \mathbf{Q}_t that govern the state equations. In this case the term $\mathbf{Z}_t \alpha_t$ that appears in the observation equation also splits into the sum $\mathbf{Z}_t^a \alpha_t^a + \mathbf{Z}_t^b \alpha_t^b$ for appropriately partitioned matrices \mathbf{Z}_t^a and \mathbf{Z}_t^b . The model specification syntax of the SSM procedure makes building an SSM from such smaller pieces easy. Throughout this chapter, the linear combinations of the state subsections (such as $\mathbf{Z}_t^a \alpha_t^a$) that appear in the observation equation are called *components*. An SSM specification in the SSM procedure is created by combining separate component specifications. In general, you specify a component in two steps: first you define a state subsection α_t^a , and then you define a matching linear combination $\mathbf{Z}_t^a \alpha_t^a$. For some special components, such as some commonly needed *trend* components, you can combine these two steps into one keyword specification.

The following list summarizes the (nonprogramming) SSM procedure syntax statements used for model specification:

- The **ID** statement specifies the index variable (τ). It is assumed that the data within each BY group are ordered (in ascending order) according to the ID variable. The SSM procedure automatically creates a variable, `_ID_DELTA_`, which contains the difference between the successive ID values. This variable is available for use by the programming statements to define time-varying system matrices. For example, in the case of SSMs used for modeling the longitudinal data, the T_t and Q_t matrices often depend on `_ID_DELTA_` (see [Example 27.5](#)).
- The **PARMS** statement specifies variables that serve as the parameters of the model. That is, it partially defines the model parameter vector θ . Other elements of θ are implicitly defined if your specification of the system matrices is not fully complete.
- The **STATE** statement specifies a subsection of the model state vector. Multiple STATE statements can be used in the model specification; each one defines a statistically independent subsection of the model state vector. For full customization, T_t , W_t , and Q_t blocks that govern this subsection can be specified as lists of variables that are created by programming statements. However, you can obtain many commonly needed state subsection types simply by using the TYPE= option in this statement. For example, the use of TYPE=SEASON(LENGTH=12) results in a state subsection that can be used to define a monthly seasonal component.
- The **COMPONENT** statement specifies a linear combination that matches a state subsection that is previously defined in a STATE statement. Thus, a matching pair of STATE and COMPONENT statements define a component.
- The **TREND** statement is used for easy specification of some commonly needed components that follow stochastic patterns of certain predefined types.
- The **IRREGULAR** statement specifies the observation disturbance for a particular response variable.
- The **MODEL** statement specifies the observation equation for one of the response variables. A separate MODEL statement is needed for each response variable in the multivariate case. The MODEL statement specifies an equation in which the left-hand side is the response variable and the right-hand side is a list that contains components and regression variables.

Model Specification Steps

To illustrate the model specification steps, suppose y is a response variable and variables x_1 and x_2 are predictors. The following statements specify a model for y that includes two components named `cycle` and `randomWalk`, predictors x_1 and x_2 , and an observation disturbance named `whiteNoise`:

```
parms lambda / lower=(1.e-6) upper=(3.14);
parms cycleVar / lower=(1.e-6);
array cycleT{4} c1-c4;
c1 = cos(lambda);
c2 = sin(lambda);
c3 = -c2;
c4 = c1;
state s_cycle(2) T(g)=(cycleT) cov(I)=(cycleVar) a1(2);
component cycle=(1 0)*s_cycle;
trend randomWalk(rw);
irregular whiteNoise;
model y = x1 x2 randomWalk cycle whiteNoise;
```

The specification begins with a PARMS statement that defines two parameters, `lambda` and `cycleVar`, along with their lower and upper bounds (essentially 0 and π for `lambda`, and 0 and infinity for `cycleVar`). Next, programming statements define an array of variables, `cycleT`, which contains four variables, `c1`–`c4`; these variables are used later for defining the elements of the transition matrix of a state subsection. The STATE statement specifies the two-dimensional subsection `s_cycle`; the dimension appears within the parentheses after the name (`s_cycle(2)`). The T= option specifies the transition matrix for the `s_cycle` ($\mathbf{T}(\mathbf{g}) = (\mathbf{cycleT})$); the `g` in $\mathbf{T}(\mathbf{g})$ signifies that the form of the T matrix is *general*. The COV= option ($\mathbf{cov}(\mathbf{I}) = (\mathbf{cycleVar})$) specifies the covariance of the state disturbance (\mathbf{Q}_t for $t \geq 2$); because of the use of `I` in $\mathbf{cov}(\mathbf{I})$, the covariance is of the form scaled identity, essentially a two-dimensional diagonal matrix with both diagonal elements equal to `cycleVar`. The initial condition for `s_cycle` is completely diffuse because the A1= option, which specifies \mathbf{A}_1 , specifies that the dimension of the diffuse vector $\boldsymbol{\delta}$ is 2: `a1(2)`. In this case there is no need to specify the covariance \mathbf{Q}_1 in the initial condition. The COMPONENT statement specifies the component `cycle`. It specifies `cycle` as a dot product of two vectors—(1 0) and `s_cycle`, which merely selects the first element of `s_cycle`: `component cycle=(1 0)*s_cycle`. The TREND statement defines a component named `randomWalk`; its type is `rw`, which signifies random walk. The IRREGULAR statement defines an observation disturbance named `whiteNoise`. Both the `randomWalk` and `whiteNoise` specifications are only partially complete—for example, the disturbance variance of `whiteNoise` is not specified. These unspecified variances, `trendVar`, which corresponds to `randomWalk`, and `wnVar`, which corresponds to `whiteNoise`, are automatically included in the list of unknown parameters, $\boldsymbol{\theta}$, along with the parameters that are defined by the PARMS statements. Thus, the parameter vector for this model is $\boldsymbol{\theta} = (\text{lambda } \text{cycleVar } \text{trendVar } \text{wnVar})$. Finally, the model specification is completed by the MODEL statement, which specifies the components of the observation equation: the response variable `y`, the predictors `x1` and `x2`, the components `randomWalk` and `cycle`, and the irregular term `whiteNoise`.

The preceding statements result in an SSM with a three-dimensional state vector, which is the result of combining the two-dimensional state subsection, `s_cycle`, and a one-dimensional subsection underlying the trend, `randomWalk`. In this specification, the initial state is completely diffuse with \mathbf{Q}_1 a null matrix, and \mathbf{A}_1 equal to the three-dimensional identity. The other state system matrices \mathbf{T}_t and \mathbf{Q}_t are time-invariant:

$$\mathbf{T} = \begin{bmatrix} \cos(\text{lambda}) & \sin(\text{lambda}) & 0 \\ -\sin(\text{lambda}) & \cos(\text{lambda}) & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad \mathbf{Q} = \begin{bmatrix} \text{cycleVar} & 0 & 0 \\ 0 & \text{cycleVar} & 0 \\ 0 & 0 & \text{trendVar} \end{bmatrix}$$

The observation equation is obvious with $\mathbf{Z} = [1 \ 0 \ 1]$.

Sparse Transition Matrix Specification

It often happens that the transition matrix \mathbf{T} (or \mathbf{T}_t in the time-varying case) specified in a STATE statement is sparse—that is, many of its elements are zero. The algorithms in the SSM procedure exploit this sparsity for computational efficiency. In most cases the sparsity of a T-block can be inferred from the context. However, if the elements of the T-block are supplied by a list of variables in parentheses, it can be difficult to recognize elements that are structurally zero (this is because of the generality of the DATA step language used for defining the variables). To simplify the specification of such sparse transition matrix, SSM procedure has adopted a convention: the variables that correspond to structural zeros can (and should) be left *unset*—that is, these variables are declared, but no value is assigned to them. As an example, suppose that a three-dimensional state subsection has the following form of transition matrix for some variables `X1`, `X2`, and `X3` defined elsewhere in the program:

$$\mathbf{T} = \begin{bmatrix} \text{X1} & 0 & 0 \\ \text{X2} & \text{X1} & 0 \\ \text{X3} & 0 & \text{X1} \end{bmatrix}$$

The following (incomplete) statements show how to specify such a T-block:

```
array tMat{3,3};
do i=1 to 3;
    tMat[i, i] = x1;
end;
tMat[2,1] = x2;
tMat[3,1] = x3;
state foo(3) T(g)=(tMat) ...;
```

In this specification only the nonzero elements of the tMat array, which contains $3 \times 3 = 9$ elements, are assigned a value. On the other hand, the following statements show an alternate way of specifying the same T-block. This specification explicitly sets the zeros in the T-block (the elements above the diagonal and tMat[3,2]) to 0.

```
array tMat{3,3};
do i=1 to 3;
    do j=1 to 3;
        if i=j then tMat[i, j] = x1;
        else if j > i then tMat[i, j] = 0;
    end;
end;
tMat[2,1] = x2;
tMat[3,1] = x3;
tMat[3,2] = 0;
state foo(3) T(g)=(tMat) ...;
```

The first specification is simpler, and is preferred. The second specification is mathematically equivalent (and generates the same output) but is computationally less efficient since its sparsity structure cannot always be reliably inferred due to the generality of the DATA step language. In the first specification, the unset elements are recognized to be *structural* zeros while the set elements are treated as nonzero for sparsity purposes. See [Example 27.5](#) for a simple illustration. Proper sparsity specification can lead to significant computational savings for larger matrices.

Regression Variable Specification in Multivariate Models

Suppose that a regression variable in a multivariate model affects two or more response variables. For example, suppose that response variables y1 and y2 depend on a regression variable x. This dependence can be categorized as one of two types:

- In the more common case, the regression coefficient of x for y1 and the regression coefficient of x for y2 are different. The relationship can be described as follows:

$$\begin{aligned} y1 &= \beta_1 x + \text{other terms} \\ y2 &= \beta_2 x + \text{other terms} \end{aligned}$$

In the SSM procedure you can specify this type of relationship in two equivalent ways:

- You can specify the variable x in the MODEL statement for y1 and specify the variable x_copy (a copy of x) in the MODEL statement for y2 as follows:

```

x_copy = x;           /* create a copy of x */
model y1 = x ...;
model y2 = x_copy ...;

```

- You can specify the variable x in MODEL statements for both $y1$ and $y2$ as follows:

```

model y1 = x ...;
model y2 = x ...;

```

This specification avoids creating x_copy .

Of these two alternate ways, the first is preferred because x and x_copy can then be unambiguously used in an EVAL statement to refer to the terms $\beta_1 x$ and $\beta_2 x$, respectively.

- In the less common case, $y1$ and $y2$ share a common regression coefficient. The relationship can be described as follows:

$$\begin{aligned} y1 &= \beta x + \text{other terms} \\ y2 &= \beta x + \text{other terms} \end{aligned}$$

You can specify this type of relationship by placing the regression coefficient in the model state vector as follows:

```

state beta(1) T(I) A1(1) ;      /* beta is a constant state */
comp xeffect = beta*(x) ;
model y1 = xeffect ...;
model y2 = xeffect ...;

```

Here the STATE statement defines β as a one-dimensional, time-invariant constant (because the transition matrix is identity, the disturbance covariance is 0 and the initial state is diffuse). Next, the COMP statement defines $xeffect$ as the product between β and the variable x . Subsequently, both $y1$ and $y2$ use $xeffect$ in their respective MODEL statements.

Filtering, Smoothing, Likelihood, and Structural Break Detection

The Kalman filter and smoother (KFS) algorithm is the main computational tool for using SSM for data analysis. This subsection briefly describes the basic quantities generated by this algorithm and their relationship to the output generated by the SSM procedure. For proper treatment of SSMs with a diffuse initial condition or when regression variables are present, a modified version of the traditional KFS, called diffuse Kalman filter and smoother (DKFS), is needed. A good discussion of the different variants of the traditional and diffuse KFS can be found in Durbin and Koopman (2001). The DKFS implemented in the SSM procedure closely follows the treatment in de Jong and Chu-Chun-Lin (2003). Additional details can be found in these references.

The state space model equations (see the section “[State Space Model and Notation](#)” on page 1919) imply that the combined response data vector $\mathbf{Y} = (\mathbf{Y}_1, \mathbf{Y}_2, \dots, \mathbf{Y}_n)$ has a Gaussian probability distribution. This probability distribution is *proper* if d , the dimension of the diffuse vector $\boldsymbol{\delta}$ in the initial condition, is 0 and if $(k + g)$, the total number of regression variables in the observation and state equations, is also 0 (the regression vectors $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ are also treated as a diffuse vectors). Otherwise, this probability distribution is *improper*. The KFS algorithm is a combination of two iterative phases: a forward pass through the data, called *filtering*, and a backward pass through the data, called *smoothing*, that uses the quantities generated

during filtering. One of the advantages of using the SSM formulation to analyze the time series data is its ability to handle the missing values in the response variables. The KFS algorithm appropriately handles the missing values in \mathbf{Y} . For additional information about how PROC SSM handles missing values, see the section “Missing Values” on page 1943.

Filtering Pass

The filtering pass sequentially computes the quantities shown in Table 27.5 for $t = 1, 2, \dots, n$ and $i = 1, 2, \dots, q * p_t$.

Table 27.5 KFS: Filtering Phase

Quantity	Description
$\hat{y}_{t,i} = E(y_{t,i} y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	One-step-ahead prediction of the response values
$v_{t,i} = y_{t,i} - \hat{y}_{t,i}$	One-step-ahead prediction residuals
$F_{t,i} = \text{Var}(y_{t,i} y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	Variance of the one-step-ahead prediction
$\hat{\alpha}_{t,i} = E(\alpha_t y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	One-step-ahead prediction of the state vector
$\mathbf{P}_{t,i} = \text{Cov}(\alpha_t y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	Covariance of $\hat{\alpha}_{t,i}$
$\mathbf{b}_{t,i}$	$(d + k + g)$ -dimensional vector
$\mathbf{S}_{t,i}$	$(d + k + g)$ -dimensional symmetric matrix
$(\hat{\delta} \ \hat{\beta} \ \hat{\gamma})'_{t,i} = \mathbf{S}_{t,i}^{-1} \mathbf{b}_{t,i}$	Estimates of δ , β , and γ by using the data up to (t, i)
$\mathbf{S}_{t,i}^{-1}$	Covariance of $(\hat{\delta} \ \hat{\beta} \ \hat{\gamma})'_{t,i}$

Here the notation $E(y_{t,i} | y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$ denotes the *conditional expectation* of $y_{t,i}$ given the history up to the index $(t, i - 1)$: $(y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$. Similarly $\text{Var}(y_{t,i} | y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$ denotes the corresponding conditional variance. The quantity $v_{t,i} = y_{t,i} - \hat{y}_{t,i}$ is set to missing whenever $y_{t,i}$ is missing. Note that $\hat{y}_{t,i}$ are *one-step-ahead* forecasts only when the model has only one response variable and the data are a time series; in all other cases it is more appropriate to call them *one-measurement-ahead* forecasts (since the next measurement might be at the same time point). Despite this, $\hat{y}_{t,i}$ are called one-step-ahead predictions (and $v_{t,i}$ are called one-step-ahead residuals) throughout this document. In the diffuse case, the conditional expectations must be appropriately interpreted. The vector $\mathbf{b}_{t,i}$ and the matrix $\mathbf{S}_{t,i}$ contain some accumulated quantities that are needed for the estimation of δ , β , and γ . Of course, when $(d + k + g) = 0$ (the nondiffuse case), these quantities are not needed. In the diffuse case, because the matrix $\mathbf{S}_{t,i}$ is sequentially accumulated (starting at $t = 1, i = 1$), it might not be invertible until some $t = t_*, i = i_*$. The filtering process is called *initialized* after $t = t_*, i = i_*$. In some situations, this initialization might not happen even after the entire sample is processed—that is, the filtering process remains *uninitialized*. This can happen if the regression variables are collinear or if the data are not sufficient to estimate the initial condition δ for some other reason.

The filtering process is used for a variety of purposes. One important use of filtering is to compute the likelihood of the data. In the model-fitting phase, the unknown model parameters θ are estimated by maximum likelihood. This requires repeated evaluation of the likelihood at different trial values of θ . After θ is estimated, it is treated as a known vector. The filtering process is used again with the fitted model in the forecasting phase, when the one-step-ahead forecasts and residuals based on the fitted model are provided. In addition, this filtering output is needed by the smoothing phase to produce the full-sample component estimates and for the structural break analysis.

Likelihood Computation and Model Fitting Phase

In view of the Gaussian nature of the response vector, the likelihood of \mathbf{Y} can be computed by using the prediction-error decomposition. In the diffuse case the definition of the likelihood depends on the treatment of the diffuse quantities— δ , β , and γ . In the SSM procedure a likelihood called the *diffuse*-likelihood, $\mathbf{L}_d(\mathbf{Y}, \theta)$, is used for parameter estimation. In the literature the diffuse likelihood is also called the *restricted*-likelihood. The diffuse likelihood is computed by treating the diffuse quantities as zero-mean, Gaussian, random variables with infinite variance (that is, they have diffuse distribution). In terms of the quantities described in Table 27.5 the diffuse likelihood is defined as follows:

$$-2 \log \mathbf{L}_d(\mathbf{Y}, \theta) = N_0 \log 2\pi + \sum_{t=1}^n \sum_{i=1}^{q \cdot p_t} \left(\log F_{t,i} + \frac{v_{t,i}^2}{F_{t,i}} \right) - \log(|\mathbf{S}_{n,p_n}^{-1}|) - \mathbf{b}_{n,p_n}' \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n}$$

where $N_0 = (N - k - g - d)$, $|\mathbf{S}_{n,p_n}^{-1}|$ denotes the determinant of \mathbf{S}_{n,p_n}^{-1} , and \mathbf{b}_{n,p_n}' denotes the transpose of the column vector \mathbf{b}_{n,p_n} . In the preceding formula, the terms that are associated with the missing response values $y_{t,i}$ are excluded and N denotes the total number of nonmissing response values in the sample. If \mathbf{S}_{n,p_n} is not invertible, then a generalized inverse is used in place of \mathbf{S}_{n,p_n}^{-1} , and $|\mathbf{S}_{n,p_n}^{-1}|$ is computed based on the nonzero eigenvalues of \mathbf{S}_{n,p_n} . Moreover, in this case $N_0 = N - \text{Rank}(\mathbf{S}_{n,p_n})$. When $(d + k + g) = 0$, the terms that involve \mathbf{S}_{n,p_n} and \mathbf{b}_{n,p_n} are absent.

In addition to reporting the diffuse likelihood, the SSM procedure reports a variant of the likelihood called the *profile* likelihood. The profile likelihood is computed by treating the diffuse quantities— δ , β , and γ —as unknown parameters (similar to θ). Interestingly, the quantities that are described in Table 27.5 play a key role in the computation of this variant of the likelihood also. It turns out that the filtering process yields the maximum likelihood (ML) estimates of δ , β , and γ conditional on the remaining parameters of the model— θ . Moreover, the likelihood that is evaluated at the ML estimates of δ , β , and γ —that is, the likelihood from which these parameters are *profiled* out—has the following expression:

$$-2 \log \mathbf{L}_p(\mathbf{Y}, \theta) = N \log 2\pi + \sum_{t=1}^n \sum_{i=1}^{q \cdot p_t} \left(\log F_{t,i} + \frac{v_{t,i}^2}{F_{t,i}} \right) - \mathbf{b}_{n,p_n}' \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n}$$

Note that, computationally, the profile likelihood differs from the diffuse likelihood in only two respects: the constant term involves N —the total number of nonmissing response values—rather than N_0 , and the log-determinant term $\log(|\mathbf{S}_{n,p_n}^{-1}|)$ is absent. However, in terms of theoretical considerations, the diffuse likelihood and the profile likelihood differ in an important way. It can be shown that the diffuse likelihood corresponds to the (nondiffuse) likelihood of a suitable transformation of \mathbf{Y} . The transformation is chosen in such a way that the distribution of the transformed data no longer depends on the initial condition δ and the regression vectors β and γ . In this sense, the diffuse likelihood is a pseudo-likelihood of the original data \mathbf{Y} . The profile likelihood, on the other hand, does not involve any data transformation and can be considered as the likelihood of the original data \mathbf{Y} . Of course, if the state space model for \mathbf{Y} does not involve any diffuse quantities, then the two likelihoods are the same.

As noted earlier, the SSM procedure does not use the profile likelihood for parameter estimation. When the model specification contains any unknown parameters θ , they are estimated by maximizing the diffuse likelihood function. This is done by using a nonlinear optimization process that involves repeated evaluations of $\mathbf{L}_d(\mathbf{Y}, \theta)$ at different values of θ . The maximum likelihood (ML) estimate of θ is denoted by $\hat{\theta}$. Because the diffuse likelihood is also called the restricted likelihood, $\hat{\theta}$ is sometimes called the restricted maximum likelihood (REML) estimate. Approximate standard errors of $\hat{\theta}$ are computed by taking the square root of the diagonal elements of its (approximate) covariance matrix. This covariance is computed as $-\mathbf{H}^{-1}$, where \mathbf{H} is the Hessian (the matrix of the second-order partials) of $\log \mathbf{L}_d(\mathbf{Y}, \theta)$ evaluated at the optimum $\hat{\theta}$. It is known

that the ML (or REML) estimate of θ based on the diffuse likelihood as well as the profile likelihood is consistent and efficient under mild regularity assumptions (as the number of distinct time points tend toward infinity). In addition, it is known that the estimate based on the diffuse likelihood is better in terms of having smaller bias.

Let $\dim(\theta)$ denote the dimension of the parameter vector θ . After the parameter estimation is completed, PROC SSM prints the “Likelihood Computation Summary” table, which summarizes the likelihood calculations at $\hat{\theta}$, as shown in Table 27.6.

Table 27.6 Likelihood Computation Summary

Quantity	Formula
Nonmissing response values used	N
Estimated parameters	$\dim(\theta)$
Initialized diffuse state elements	$\text{rank}(\mathbf{S}_{n,p_n})$
Normalized residual sum of squares	$\sum_{t=1}^n \sum_{i=1}^{q \cdot p_t} \left(\frac{v_{t,i}^2}{F_{t,i}} \right) - \mathbf{b}'_{n,p_n} \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n}$
Diffuse log likelihood	$\log \mathbf{L}_d(\mathbf{Y}, \hat{\theta})$
Profile log likelihood	$\log \mathbf{L}_p(\mathbf{Y}, \hat{\theta})$

In addition, the information criteria based on the diffuse likelihood and the profile likelihood are also reported. A variety of information criteria are reported. All these criteria are functions of twice the negative likelihood, $-2 \log \mathbf{L}$ (the likelihood can be either diffuse or profile); N_* , the effective sample size; and $nparm$, the effective number of model parameters. For the information criteria based on the diffuse likelihood, the effective sample size $N_* = N_0$ and the effective number of model parameters $nparm = \dim(\theta)$. For the information criteria based on the profile likelihood, the effective sample size $N_* = N$ and the effective number of model parameters $nparm = \dim(\theta) + d + k + g$. Table 27.7 summarizes the reported information criteria in smaller-is-better form.

Table 27.7 Information Criteria

Criterion	Formula	Reference
AIC	$-2 \log \mathbf{L} + 2nparm$	Akaike (1974)
AICC	$-2 \log \mathbf{L} + 2nparm N_*/(N_* - nparm - 1)$	Hurvich and Tsai (1989)
HQIC	$-2 \log \mathbf{L} + 2nparm \log \log(N_*)$	Burnham and Anderson (1998)
BIC	$-2 \log \mathbf{L} + nparm \log(N_*)$	Hannan and Quinn (1979)
CAIC	$-2 \log \mathbf{L} + nparm(\log(N_*) + 1)$	Schwarz (1978)
		Bozdogan (1987)

Forecasting Phase

After the model-fitting phase, the filtering process is repeated again to produce the model-based one-step-ahead response variable forecasts ($\hat{y}_{t,i}$), residuals ($v_{t,i}$), and their standard errors ($\sqrt{F_{t,i}}$). In addition, one-step-ahead forecasts of the components that are specified in the MODEL statements, and any other user-defined linear combinations of α_t , are also produced. These forecasts are set to missing as long as the index $t < t_*$ (that is, until the filtering process is initialized). If the filtering process remains uninitialized, then all the quantities that are related to the one-step-ahead forecast (such as $\hat{y}_{t,i}$ and $v_{t,i}$) are reported

as missing. When the fitted model is appropriate, the one-step-ahead residuals $v_{t,i}$ form a sequence of uncorrelated normal variates. This fact can be used during model diagnostic process.

Smoothing Phase

After the filtering phase of KFS produces the one-step-ahead predictions of the response variables and the underlying state vectors, the smoothing phase of KFS produces the full-sample versions of these quantities—that is, rather than using the history up to $(t, i - 1)$, the entire sample \mathbf{Y} is used. The smoothing phase of KFS is a backward algorithm, which begins at $t = n$ and $i = q * p_n$ and goes back toward $t = 1$ and $i = 1$. It produces the following quantities:

Table 27.8 KFS: Smoothing Phase

Quantity	Description
$\tilde{y}_{t,i} = E(y_{t,i} \mathbf{Y})$	Interpolated response value
$\tilde{F}_{t,i} = \text{Var}(y_{t,i} \mathbf{Y})$	Variance of the interpolated response value
$\tilde{\alpha}_t = E(\alpha_t \mathbf{Y})$	Full-sample estimate of the state vector
$\tilde{\mathbf{P}}_t = \text{Cov}(\alpha_t \mathbf{Y})$	Covariance of $\tilde{\alpha}_t$
$\begin{pmatrix} \hat{\delta} & \hat{\beta} & \hat{\gamma} \end{pmatrix}' = \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n}$	Full-sample estimates of δ , β , and γ
\mathbf{S}_{n,p_n}^{-1}	Covariance of $\begin{pmatrix} \hat{\delta} & \hat{\beta} & \hat{\gamma} \end{pmatrix}'$

Note that if $y_{t,i}$ is not missing, then $\tilde{y}_{t,i} = E(y_{t,i} | \mathbf{Y}) = y_{t,i}$ and $\tilde{F}_{t,i} = \text{Var}(y_{t,i} | \mathbf{Y}) = 0$ because $y_{t,i}$ is completely known, given \mathbf{Y} . Therefore, $\tilde{y}_{t,i}$ provides nontrivial information only when $y_{t,i}$ is missing—in which case $\tilde{y}_{t,i}$ represents the best estimate of $y_{t,i}$ based on the available data. The full-sample estimates of components that are specified in the model equations are based on the corresponding linear combinations of $\tilde{\alpha}_t$. Similarly, their standard errors are computed by using appropriate functions of $\tilde{\mathbf{P}}_t$.

If the filtering process remains uninitialized until the end of the sample (that is, if \mathbf{S}_{n,p_n} is not invertible), some linear combinations of δ , β , and γ are not estimable. This, in turn, implies that some linear combinations of α_t are also inestimable. These inestimable quantities are reported as missing. For more information about the estimability of the state effects, see Selukar (2010).

Delete-One Cross Validation and Structural Breaks

In addition to the interpolation of missing response values and the full-sample estimation of components in the model, the smoothing phase can also produce several useful diagnostic measures that can indicate outlying observations and breaks in the state evolution process. The treatment of additive outliers and structural breaks that is described in this section is based on de Jong and Penzer (1998).

Delete-One Cross Validation and the Additive Outlier Detection

Let $\text{AO}_{t,i} = y_{t,i} - E(y_{t,i} | \mathbf{Y}^{t,i})$ denote the difference between the observed response value $y_{t,i}$ and its estimate or prediction by using all the data except $y_{t,i}$, which is denoted by $\mathbf{Y}^{t,i}$. The smoothing phase of DKFS can generate $\text{AO}_{t,i}$ (and its variance) at all (t, i) . A large value of $\text{AO}_{t,i}$ signifies that the observed response value ($y_{t,i}$) is unusual relative to the rest of the sample (according to the postulated model). Such values are called additive outliers. In the literature, $\text{AO}_{t,i}$ are referred by a few different names. Sometimes they are called *delete-one cross validation errors* or simply *prediction errors*. In this chapter, these names are

used interchangeably. Like the one-step-ahead residuals, $v_{t,i}$, the prediction errors can be used in checking the adequacy of the model. The prediction errors are normally distributed; however, unlike $v_{t,i}$, they are not serially uncorrelated. $AO_{t,i}$ is set to missing when $y_{t,i}$ is missing. The SSM procedure prints a summary table of extreme additive outliers by default. In addition, you can request the plotting of the standardized prediction errors, and they can be output to a data set.

The prediction error sum of squares (PRESS)

$$\sum_{t,i} AO_{t,i}^2$$

can be a useful measure of fit to compare different models. It is also called the *cross validation error sum of squares*. An additional measure of fit based on the prediction errors is called the *generalized cross validation error sum of squares* (GCV). Denoting the variance of $AO_{t,i}$ by $VAR_AO_{t,i}$, it is defined as

$$\frac{\sum_{t,i} (AO_{t,i}^2 / VAR_AO_{t,i})}{[\sum_{t,i} (1 / VAR_AO_{t,i})]^2}$$

You can request the printing of PRESS and GCV by specifying the PRESS option in the OUTPUT statement.

After inspecting the reported additive outliers, you can adjust the model to account for the effects of some of the extreme outlying observations. This can be done by including appropriate dummy variables in the observation equation.

Structural Breaks in the State Evolution

The additive outliers that are discussed in the preceding section are diagnostic measures associated with the measurement equation. The smoothing phase of DKFS can generate diagnostic measures that are also associated with the state equation.

For simplicity of notation and exposition, initially assume that the state equation has the following form:

$$\alpha_{t+1} = \mathbf{T}_t \alpha_t + \mathbf{c}_{t+1} + \eta_{t+1}$$

That is, the state regression term $\mathbf{W}_{t+1} \gamma$ is absent in the postulated model. Suppose that an unanticipated change of unknown size takes place in the i_0 th element of the state at time $(t_0 + 1)$. The model can then be adjusted to account for this change by including a suitable dummy regressor in the state equation as follows:

$$\alpha_{t+1} = \mathbf{T}_t \alpha_t + \mathbf{W}_{t+1} \gamma + \mathbf{c}_{t+1} + \eta_{t+1}$$

Here \mathbf{W}_t is a sequence of m -dimensional column vectors such that $\mathbf{W}_{t_0+1}[i_0] = 1$ and $\mathbf{W}_t[i] = 0$ for all other t and i . The estimate of the regression coefficient γ provides information about the size of the unanticipated change in the i_0 th element of α_t at time $t = t_0 + 1$. Similarly, an unanticipated change in a subsection of α_t at a time $t = t_0 + 1$ can be estimated by using a set of appropriate dummies (the number of dummies equals the number of elements in the state subsection) in the state equation. The algorithm of de Jong and Penzer (1998) efficiently generates the estimates of such one-time changes in the state at all distinct time points in the sample in one smoothing pass. A statistically significant value of γ at a time point t_0 indicates an unanticipated change in the relevant element (or the subsection) of α_{t_0} . Note that the change associated with an additive outlier is temporary: the previous or the subsequent measurements are not affected. On the other hand, because of the evolutionary nature of the state equation, a one-time change in the state affects all the subsequent states, which in turn affect the subsequent observations. In this sense, a significant unanticipated change in the state is a *structural break*.

In the preceding discussion, the absence of the state regression variables in the postulated model was assumed only for notational simplicity. If the postulated model does contain some state regression variables, the dummy variable that is associated with the one-time state change is simply added to the existing set of state regression variables, and the interpretation of its regression coefficient as the measure of unanticipated change in the state remains unaffected.

In the SSM procedure, you can request the computation of significance statistics that are associated with one-time changes in the state subsections specified by using the STATE statement in addition to the state subsections that are associated with the components specified by using the TREND statements. This is done by using the CHECKBREAK option in these statements. In addition, you can request the computation of such statistics for the entire state α_t by using the MAXSHOCK option in the OUTPUT statement. The significance statistics can be computed for both elementwise change and subsectionwise change. The computation of subsectionwise change statistics can be computationally expensive for large subsections (an inversion of a $p \times p$ -dimensional matrix at each distinct time point in the sample is needed for the computation of significance statistics for a state subsection of size p). For an example of structural break analysis, see [Example 27.8](#).

Estimation of User-Specified Linear Combination of State Elements

By default, the SSM procedure computes the estimates of all the components that are specified in the MODEL statements (you can print these estimates by using the PRINT= option in the respective TREND and COMPONENT statements, or you can output these estimates to a data set by specifying it in the OUT= option in the OUTPUT statement). However, in many cases it is desirable to obtain the estimates of additional linear combinations of the state elements and the regression effects. The SSM procedure provides two statements, the COMPONENT statement and the EVAL statement, that are useful for specifying virtually any desired linear combination of the elements of the state vector and the regression effects in the observation equation. After a desired linear combination is specified, you can print or output its estimate as you would for a component that is used in the MODEL statement. This feature of the SSM procedure is illustrated in many examples in the section “[Examples: SSM Procedure](#)” on page 1949. For example, in the second part of [Example 27.4](#), the COMPONENT and EVAL statements are used to define the contrasts between the growth profiles of cows that are receiving different treatments. Similarly, in [Example 27.7](#), the EVAL statement is used to define the yield curve as a sum of the components that are used in the MODEL statement.

Contrasting PROC SSM with Other SAS Procedures

The SSM procedure complements several SAS/ETS procedures and the MIXED procedure in SAS/STAT software (see Chapter 63, “The MIXED Procedure” (*SAS/STAT User’s Guide*)). The statistical models underlying all these procedures can be formulated as state space models; however, in many cases this formulation effort can be considerable. Generally speaking, when a problem can be formulated and satisfactorily solved either by using the SSM procedure or by using one of these other procedures, the other procedures are likely to be more efficient. However, in many instances, the SSM procedure can solve more general problems or offer more detailed analysis, or both. Throughout this discussion, it is assumed that the problem being solved can be modeled as a linear statistical model with Gaussian response variables. In particular, situations that require models such as autoregressive conditional heteroscedasticity (ARCH) models, and models with categorical response variables are not considered. The following list provides a more specific comparison of the SSM procedure with different procedures:

- All the SAS/ETS time series analysis procedures (the ARIMA, ESM, UCM, VARMAX, STATESPACE, and PANEL procedures) require time series data and are not applicable to the longitudinal data.
- For univariate time series analysis, the modeling facilities provided by the ARIMA, ESM, and UCM procedures are adequate in most cases. The SSM procedure can handle cases that do not fit neatly into one of these categories.
- For multivariate time series data analysis, you can use the VARMAX procedure for vector ARIMA modeling and the STATESPACE procedure for state space modeling. The capabilities of the SSM procedure are complementary to these procedures. In particular, the predefined multivariate structural models available in the SSM procedure cannot be specified by either of these procedures. In addition, you can formulate a much wider range of multivariate models—for example, models for series with different frequencies, by using the SSM procedure.
- When the \mathbf{R} side effects are not too complicated (for example, if \mathbf{R} is diagonal), the model considered by the MIXED procedure is a special case of the model considered by the SSM procedure. In the case of diagonal \mathbf{R} , it is easy to see that the state vector $\boldsymbol{\alpha}_t$ is equal to $\boldsymbol{\gamma}$, the MIXED random-effects vector, for all $t \geq 1$ (that is, $\boldsymbol{\alpha}_t$ is *time invariant*). Therefore, the random-effects MIXED model is obtained by setting $\mathbf{T} = \text{Identity}$, $\mathbf{Q}_t = \mathbf{0}, t \geq 2$, $\mathbf{Q}_1 = \mathbf{G}$ (the MIXED \mathbf{G} matrix), and $\mathbf{A}_1 = \mathbf{0}$.
- For the analysis of cross-sectional data, you can use the PANEL procedure. In this case, the SSM procedure capabilities are complementary. PROC SSM can provide alternate models, REML estimates, richer missing value support, and the estimates of the unobserved components (see the section “[Getting Started: SSM Procedure](#)” on page 1889 and the examples [Example 27.2](#) and [Example 27.11](#) for more information). In some situations the cross-sectional studies contain many panels but very few distinct time points. The PANEL procedure based analysis is better suited in such settings. In order for the analysis based on PROC SSM to be valid, the cross-sectional study must contain an adequate number of distinct time points.

Predefined Trend Models

The statistical models that govern the predefined trend components available in the SSM procedure are divided into two groups: models that are applicable to equally spaced data (possibly with replication), and models that are applicable more generally (the irregular data type). Each trend component can be described as a dot product $\mathbf{Z}\boldsymbol{\alpha}_t$ for some (time-invariant) vector \mathbf{Z} and a state vector $\boldsymbol{\alpha}_t$. The component specification is complete after the vector \mathbf{Z} is specified and the system matrices that govern the equations of $\boldsymbol{\alpha}_t$ are specified. For trend models for regular data, all the system matrices are time-invariant. For irregular data, \mathbf{T}_t and \mathbf{Q}_t depend on the spacing between the distinct time points: $(\tau_{t+1} - \tau_t)$.

Trend Models for Regular Data

These models are applicable when the data type is either regular or regular with replication. A good reference for these models is Harvey (1989).

Random Walk Trend

This model provides a trend pattern in which the level of the curve changes with time. The rapidity of this change is inversely proportional to the disturbance variance σ^2 that governs the underlying state. It can be

described as $Z\alpha_t$, where $Z = (1)$ and the (one-dimensional) state α_t follows a random walk:

$$\alpha_{t+1} = \alpha_t + \eta_{t+1}, \quad \eta_t \sim N(0, \sigma^2)$$

Here $\mathbf{T} = 1$ and $\mathbf{Q} = \sigma^2$. The initial condition is fully diffuse. Note that if $\sigma^2 = 0$, the resulting trend is a fixed constant.

Local Linear Trend

This model provides a trend pattern in which both the level and the slope of the curve change with time. This variation in the level and the slope is controlled by two parameters: σ_1^2 controls the level variation, and σ_2^2 controls the slope variation. If $\sigma_1^2 = 0$, the resulting trend is called an *integrated random walk*. If both $\sigma_1^2 = 0$ and $\sigma_2^2 = 0$, then the resulting model is the deterministic linear time trend. Here $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ 1, \ 0 \ 1)$, and $\mathbf{Q} = \text{Diag}(\sigma_1^2, \sigma_2^2)$. The initial condition is fully diffuse.

Damped Local Linear Trend

This trend pattern is similar to the local linear trend pattern. However, in the DLL trend the slope follows a first-order autoregressive model, whereas in the LL trend the slope follows a random walk. The autoregressive parameter or the damping factor, ϕ , must lie between 0.0 and 1.0, which implies that the long-run forecast according to this pattern has a slope that tends to 0. Here $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ 1, \ 0 \ \phi)$, and $\mathbf{Q} = \text{Diag}(\sigma_1^2, \sigma_2^2)$. The initial condition is partially diffuse with $\mathbf{Q}_1 = \text{Diag}(0, \sigma_2^2/(1 - \phi * \phi))$.

ARIMA Trend

This section describes the state space form for a component that follows an $\text{ARIMA}(p, d, q) \times (P, D, Q)_s$ model. The notation for ARIMA models is explained in the **TREND** statement.

First the state space form for the stationary case—that is, when $d = 0$ and $D = 0$, is explained. A number of alternate state space forms are possible in this case; the one described here is based on Jones (1980). With slight abuse of notation, let $p = p + s * P$ denote the effective autoregressive order, and let $q = q + sQ$ denote the effective moving average order of the model. Similarly, let ϕ be the effective autoregressive polynomial, and let θ be the effective moving average polynomial in the backshift operator with coefficients ϕ_1, \dots, ϕ_p and $\theta_1, \dots, \theta_q$, obtained by multiplying the respective nonseasonal and seasonal factors. Then, a random sequence ξ_t that follows an $\text{ARMA}(p, q) \times (P, Q)_s$ model with a white noise sequence a_t has a state space form with state vector of size $m = \max(p, q + 1)$. The system matrices are as follows: $\mathbf{Z} = [1 \ 0 \ \dots \ 0]$, and the transition matrix \mathbf{T} , in a blocked form, is given by

$$\mathbf{T} = \begin{bmatrix} 0 & I_{m-1} \\ \phi_m & \dots & \phi_1 \end{bmatrix}$$

where $\phi_i = 0$ if $i > p$ and I_{m-1} is an $(m - 1)$ dimensional identity matrix. The covariance of the state disturbance matrix $\mathbf{Q} = \sigma^2 \psi \psi'$, where σ^2 is the variance of the white noise sequence a_t and the vector $\psi = [\psi_0 \ \dots \ \psi_{m-1}]'$ contains the first m values of the impulse response function—that is, the first m coefficients in the expansion of the ratio θ/ϕ . The covariance matrix of the initial state, \mathbf{Q}_1 , is computed as

$$\text{vec}(\mathbf{Q}_1) = (\mathbf{I} - \mathbf{T} \otimes \mathbf{T})^{-1} \text{vec}(\mathbf{Q})$$

where \otimes denotes the Kronecker product and the *vec* operation on a matrix creates a vector formed by vertically stacking the rows of that matrix.

A number of alternate state space forms are possible in the nonstationary case also. The form used by the SSM procedure utilizes the state space form for the stationary case as a building block. Suppose that a random

sequence ξ_t follows an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model with a white noise sequence a_t . As in the notation for the stationary case, with slight abuse of notation, let $d = d + s * D$ denote the effective differencing order, and let Δ be the effective differencing polynomial in the backshift operator with coefficients $\Delta_1, \dots, \Delta_d$. It can be shown that ξ_t has a state space form with state vector size $m^\dagger = m + d$. In what follows, the system matrices and related quantities in the nonstationary case are described in terms of similar entities in the stationary case. A superscript dagger (\dagger) has been added to distinguish the entities from the nonstationary case. $\mathbf{Z}^\dagger = [0 \ 0 \ \dots \ 1 \ \dots \ 0]$ where the only nonzero value, 1, is at the index $m + 1$, and the transition matrix, \mathbf{T}^\dagger , in a blocked form, is given by

$$\mathbf{T}^\dagger = \begin{bmatrix} \mathbf{T} & 0 & 0 \\ \mathbf{Z}\mathbf{T} & \Delta_1 \dots & \Delta_d \\ 0 & I_{d-1} & 0 \end{bmatrix}$$

The state disturbance matrix \mathbf{Q}^\dagger is given by

$$\mathbf{Q}^\dagger = \begin{bmatrix} \mathbf{Q} & \mathbf{Q}\mathbf{Z}' & 0 \\ \mathbf{Z}\mathbf{Q} & \mathbf{Z}\mathbf{Q}\mathbf{Z}' & 0 \\ 0 & 0 & 0 \end{bmatrix}$$

Finally, the initial state is partially diffuse: the first m elements are nondiffuse and the last d elements are diffuse. The covariance matrix of the first m elements is \mathbf{Q}_1 .

Trend Models for Irregular Data

A good reference for these models is de Jong and Mazzi (2001). Throughout this section $h_t = (\tau_{t+1} - \tau_t)$ denotes the difference between the successive time points. The system matrices \mathbf{T}_t and \mathbf{Q}_t that govern these models depend on h_t . However, whenever the notation is unambiguous, the subscript t is omitted.

Polynomial Spline Trend

This model is a general-purpose tool for extracting a smooth trend from the noisy data. The order of the spline governs the order of the local polynomial that defines the spline. The order-1 spline corresponds to Brownian motion (continuous-time random walk), the order-2 spline corresponds to integrated Brownian motion (continuous-time integrated random walk), and the order-3 spline provides a locally quadratic trend; the default order is 1. The dimension of the state underlying this component is the same as the order of the spline. The system matrices for the orders up to 3 are described as follows (in all the cases the initial condition is fully diffuse):

- order-1 spline: $\mathbf{Z} = (1)$, $\mathbf{T} = (1)$, and $\mathbf{Q} = \sigma^2(h)$
- order-2 spline: $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ h, \ 0 \ 1)$, and $\mathbf{Q} = \sigma^2 \left(\frac{h^3}{3} \ \frac{h^2}{2}, \ \frac{h^2}{2} \ h \right)$
- order-3 spline: $\mathbf{Z} = (1 \ 0 \ 0)$, $\mathbf{T} = \left(1 \ h \ \frac{h^2}{2}, 0 \ 1 \ h, 0 \ 0 \ 1 \right)$, and

$$\mathbf{Q}[i, j] = \sigma^2 * \frac{h^{6-i-j+1}}{(6-i-j+1)(3-i)!(3-j)!} \quad 1 \leq i, j \leq 3$$

The system matrices for higher orders are similarly defined (for more information, see de Jong and Mazzi (2001)).

Note that, in addition to providing an estimate of the trend, this methodology can provide estimates of the higher-order derivatives of the trend. If α denotes the k -dimensional subsection that is associated with a polynomial spline of order k , then its j th element ($1 \leq j \leq k$), $\alpha[j]$, corresponds to the derivative of order $(j - 1)$ of this polynomial spline. For an example of the estimation of the first derivative of a trend component, see [Example 27.12](#). For additional information about using these types of trend patterns in data analysis, see Eubank, Huang, and Wang (2003) and Kohn, Ansley, and Tharm (1991).

Decay and Growth Trends

There are two choices for the decay trend: DECAY and DECAY(OU). Similarly, there are two choices for the growth trend: GROWTH and GROWTH(OU). The “OU” stands for the Ornstein-Uhlenbeck form of these models. The decay trend is a sum of two correlated components: one component is a random walk, and the other component is a stationary autoregression. In its Ornstein-Uhlenbeck form, the random walk component is replaced by a constant. The growth trend (and its Ornstein-Uhlenbeck variant) has the same form as the decay trend except that the autoregression is nonstationary (in fact, it is explosive). For growth trend models, floating-point errors can result for even moderately long forecast horizons because of the explosive growth in the trend values.

The system matrices for the decay and the growth types in their respective cases are identical, except for the sign of the rate parameter ϕ : $\phi < 0.0$ for the decay type, and $\phi > 0.0$ for the growth type. In addition, the initial conditions for the growth models are fully diffuse; they are only partially diffuse for the decay models. The underlying state vector for all these models is two-dimensional.

The system matrices for the DECAY type are:

$$\begin{aligned} \mathbf{Z} &= (1 \ 1) \\ \mathbf{T} &= \text{Diag}(1, \exp(h\phi)) \\ \mathbf{Q} &= \frac{\sigma^2}{\phi^3} (h\phi \ 1 - \exp(h\phi), \ 1 - \exp(h\phi) \ (\exp(2h\phi) - 1)/2) \end{aligned}$$

The initial condition is partially diffuse with $\mathbf{Q}_1 = \text{Diag}(0, \frac{-\sigma^2}{2\phi^3})$. The system matrices for the GROWTH type are the same (with $\phi > 0.0$), except that the initial condition is fully diffuse; so $\mathbf{Q}_1 = 0$.

For the DECAY(OU) type, \mathbf{Z} and \mathbf{T} are the same as DECAY, whereas

$$\mathbf{Q} = \text{Diag} \left(0, \sigma^2 \frac{(\exp(2h\phi) - 1)}{2\phi} \right) \text{ and } \mathbf{Q}_1 = \text{Diag}(0, \frac{-\sigma^2}{2\phi})$$

The system matrices for the GROWTH(OU) type are the same (with $\phi > 0.0$), except that the initial condition is fully diffuse; so $\mathbf{Q}_1 = 0$.

Predefined Structural Models

A set of predefined models is available in the SSM procedure for models called structural models in the time series literature. These predefined models can be used to model trend, seasonal, and cyclical patterns in the univariate and multivariate time series. For the most part, the multivariate models are straightforward generalizations of the corresponding univariate models—for example, the multivariate random walk trend described later in this section generalizes the univariate random walk trend that is described in the section “[Random Walk Trend](#)” on page 1933. All of these models, with the exception of the continuous-time cycle

model, are applicable only to the regular data type. The continuous-time cycle model is applicable to all the data types; however, it is available for the univariate case only.

To specify these models, you must first use the STATE statement with the correct **TYPE=** option. When you specify the **TYPE=**option, you do not need to specify other options of the STATE statement (for example, the **T** option, the **COV1** option, and the **A1** option). However, you must specify the **COV** option, which describes the covariance of the disturbance term that drives the state equation. Throughout this section, the symmetric matrix specified by using the **COV** option is denoted by Σ . For **TYPE=LL**, an additional matrix, specified by using the **SLOPECOV** suboption, also plays a role; it is denoted by Σ_{slope} . Subsequently you must specify one or more COMPONENT statements to define the (univariate) components that are based on this state subsection for their inclusion in the MODEL statement. These univariate components exhibit interesting behavior based on the structure of Σ (and Σ_{slope} , whenever applicable)—for example, imposing rank restrictions on Σ in the multivariate random walk results in these univariate trends moving together. For additional information about these models, see Harvey (1989).

The following example summarizes the steps needed to define a multivariate structural model by using a sequence of STATE and COMPONENT statements. For a full example, see [Example 27.1](#). Suppose that a three-dimensional time series is being studied with response variables y_1 , y_2 , and y_3 . Suppose you want to specify the trivariate structural model

$$y_t = \mu_t + \psi_t + \epsilon_t$$

where $y_t = (y_{1,t}, y_{2,t}, y_{3,t})$ denotes the response series, and μ_t , ψ_t , and ϵ_t denote the trivariate components, trend, cycle, and white noise, respectively. The three components of ϵ_t , the observation noise in the model, are not assumed to be independent. Therefore, you cannot specify them by using three **IRREGULAR** statements; you must include them in the state specification. The following (incomplete) statements show how to specify this model:

```
state whiteNoise(3) type=wn ...;
component wn1 = whiteNoise[1];
component wn2 = whiteNoise[2];
component wn3 = whiteNoise[3];

state randomWalk(3) type=rw ...;
component rw1 = randomWalk[1];
component rw2 = randomWalk[2];
component rw3 = randomWalk[3];

state cycleState(3) type=cycle ...;
component c1 = cycleState[1];
component c2 = cycleState[2];
component c3 = cycleState[3];

model y1 = rw1 c1 wn1;
model y2 = rw2 c2 wn2;
model y3 = rw3 c3 wn3;
```

The first STATE statement defines **whiteNoise**, a state subsection that is needed for defining a three-dimensional white noise component. In turn, **whiteNoise** is used to define the three univariate white noise components: **wn1**, **wn2**, and **wn3**. The components **wn1**, **wn2**, and **wn3** are correlated—their correlation structure is controlled by the covariance specification of **whiteNoise**. The second set of STATE and COMPONENT statements result in three correlated random walk trend components: **rw1**, **rw2**, and **rw3**. Finally, the last set of STATE and COMPONENT statements result in three correlated cycle components: **c1**,

c2, and c3. In the end, the desired multivariate model is defined by including these (univariate) components in the appropriate MODEL statements.

In the preceding example, it is important to note the relationship between the nominal dimension (denoted by *dim* throughout this section) that is specified in the STATE statement and the actual dimension of the resulting state subsection. Note that the three state subsections, whiteNoise, randomWalk, and cycleState, are defined by using the same *dim* specification: 3. However, the actual dimensions of these state subsections depend on their type; they do not need to equal this specified dimension. Here, whiteNoise and randomWalk do have the same size, 3, as the specified *dim*. However, the size of cycleState, which is of TYPE=CYCLE, is $2 * dim = 6$. Another important point to note: no matter what the underlying size of the state subsection, the desired univariate components were obtained by using an identical specification scheme in the COMPONENT statement. This happens because the component specification style that is based on the element operator—[]—in the COMPONENT statement behaves differently when the TYPE= option is used to define the state subsection (see the section “Multivariate Season” on page 1940 for an illustration).

The system matrices for all these models are time-invariant, with the exception of the continuous-time cycle model. In this section, α_t denotes the subsection of the overall model state α_t , and **T**, **Q**, and **A**₁ denote the corresponding blocks of the larger system matrices.

For the multivariate cycle system matrices described in the section “Multivariate Cycle” on page 1939, the Kronecker product notation is useful: if **A** is an $m \times n$ matrix and **B** is a $p \times q$ matrix, then the Kronecker product $\mathbf{A} \otimes \mathbf{B}$ is an $mp \times nq$ block matrix:

$$\mathbf{A} \otimes \mathbf{B} = \begin{bmatrix} a_{11}\mathbf{B} & \cdots & a_{1n}\mathbf{B} \\ \vdots & \ddots & \vdots \\ a_{m1}\mathbf{B} & \cdots & a_{mn}\mathbf{B} \end{bmatrix}$$

Multivariate White Noise

The STATE statement option TYPE=WN specifies white noise of dimension *dim*—that is, a sequence of zero mean, independent, Gaussian vectors with covariance Σ . The specification of the associated system matrices is trivial: **T** is zero, **Q** = Σ , and the initial condition is nondiffuse (**Q**₁ = Σ and **A**₁ = 0).

Multivariate white noise is needed to specify the observation equation noise term for the multivariate models for the time series data. Since the state space formulation for the SSM procedure requires the observation equation noise vector to have the diagonal form, you need to include the noise vector in the state. The noise term for the *i*th response variable is defined by a component that simply picks the *i*th element of this multivariate white noise. For example, the component wn_i defined as follows can be used as a noise term in the MODEL statement of the *i*th response variable:

```
state white(dim) type=wn ...;
component wn_3 = white[3];
```

Multivariate Random Walk Trend

The STATE statement option TYPE=RW specifies a *dim*-dimensional random walk

$$\alpha_{t+1} = \alpha_t + \eta_{t+1}$$

where η_t is a sequence of zero mean, independent, Gaussian vectors with covariance Σ . The specification of the associated system matrices is trivial: T is a dim -dimensional identity matrix, I_{dim} , $Q = \Sigma$, and the initial condition is fully diffuse ($Q_1 = 0$ and $A_1 = I_{dim}$).

The multivariate random walk is a useful trend model for multivariate time series data. The trend term for the i th response variable is defined by a component that simply picks the i th ($1 \leq i \leq dim$) element of α_t . For example, the component `rw_i` defined as follows can be used as a trend term in the MODEL statement of the i th response variable:

```
state randomWalk(3) type=rw ...;
component rw_2 = randomWalk[2];
```

Multivariate Local Linear Trend

The STATE statement option `TYPE=LL` specifies a $(2*dim)$ -dimensional α_t , needed for defining a dim -dimensional local linear trend. The first dim elements of α_t correspond to the needed multivariate trend, and the subsequent dim elements are needed to capture the slope vector of this trend. α_t can be defined as

$$\alpha_{t+1} = T\alpha_t + \eta_{t+1}$$

where η_t is a sequence of zero mean, independent, Gaussian vectors with covariance $\text{Diag}(\Sigma, \Sigma_{slope})$ and T is a $2*dim$ -dimensional block matrix $T = (I_{dim} \ I_{dim}, \ 0 \ I_{dim})$. The initial condition is fully diffuse ($Q_1 = 0$ and $A_1 = I_{2*dim}$). This is a multivariate generalization of the univariate local linear trend.

The multivariate local linear trend is a useful trend model for multivariate time series data. The trend term for the i th response variable is defined by a component that simply picks the i th element ($1 \leq i \leq dim$) of α_t . For example, the component `ll_i` defined as follows can be used as a trend term in the MODEL statement of the i th response variable:

```
state localLin(dim) type=ll(slopecov..) ...;
component ll_3 = localLin[3];
```

Multivariate Cycle

The STATE statement option `TYPE=CYCLE` specifies a $(2*dim)$ -dimensional α_t , needed for defining a dim -dimensional cycle. As in the LL case, the first dim elements of α_t correspond to the needed dim -dimensional cycle, and the remaining dim elements contain some auxiliary quantities. The cycle model defined in this subsection requires a regular data type—that is, the CT option is not included. Let ρ denote the damping factor, and let $\lambda = 2\pi/period$ be the frequency associated with the cycle. The admissible parameter ranges are $0 < \rho \leq 1$ and $period > 2$, which implies that $0 < \lambda < \pi$. Let $C = \rho(\cos(\lambda) \ \sin(\lambda), \ -\sin(\lambda) \ \cos(\lambda))$, a 2×2 matrix, and let $T = C \otimes I_{dim}$, a $2 * dim \times 2 * dim$ matrix. With this notation, the transition equation associated with α_t is

$$\alpha_{t+1} = T\alpha_t + \eta_{t+1}$$

where η_t is a sequence of zero mean, independent, $(2 * dim)$ -dimensional Gaussian vectors with covariance $\text{Diag}(\Sigma, \Sigma)$. If $\rho = 1$, the initial condition is fully diffuse ($Q_1 = 0$ and $A_1 = I_{2*dim}$). Otherwise, it is nondiffuse: $Q_1 = \frac{1}{(1-\rho^2)}\text{Diag}(\Sigma, \Sigma)$ and $A_1 = 0$.

The multivariate cycle is useful for capturing periodic behavior for multivariate time series data. The cycle term for the i th response variable is defined by a component that simply picks the i th element of α_t . For

example, the component `cycle_i` defined as follows can be used as a cycle term in the MODEL statement of the i th response variable:

```
state cycleState(dim) type=cycle ...;
component cycle_2 = cycleState[2];
```

Multivariate Season

The STATE statement option `TYPE=SEASON(LENGTH=s)` specifies a $((s-1)*dim)$ -dimensional α_t , needed for defining a dim -dimensional trigonometric season component with season length s . A (multivariate) trigonometric season component, ζ , is a sum of (multivariate) cycles of different frequencies,

$$\zeta = \sum_{j=1}^{[s/2]} \zeta_j$$

where the constituent cycles ζ_j , called harmonics, have frequencies $\lambda_j = 2\pi j/s$. All the harmonics are assumed to be statistically independent, have the same damping factor $\rho = 1$, and are governed by the disturbances with the same covariance matrix Σ . The number of harmonics, $[s/2]$, equals $s/2$ if s is even and $(s-1)/2$ if it is odd. This means that specifying `TYPE=SEASON(LENGTH=s)` is equivalent to specifying $[s/2]$ cycle specifications with correct frequencies, damping factor $\rho = 1$, and the `COV` option restricted to the same covariance Σ . The resulting α_t is necessarily $((s-1)*dim)$ -dimensional. When the season length s is even, the last harmonic cycle, $\zeta_{s/2}$, has frequency π and requires special attention. It is of dimension dim rather than $2*dim$ because its underlying state equation simplifies to a dim -variate autoregression with autoregression coefficient $-\mathbf{I}_{dim}$. As a result of this discussion, it is clear that the system matrices \mathbf{T} and \mathbf{Q} associated with the $((s-1)*dim)$ -dimensional α_t are block-diagonal with the blocks corresponding to the harmonics. The initial condition is fully diffuse.

For all the models discussed so far, the first dim elements of α_t provided the needed (multivariate) component. This is not the case for the (multivariate) season component. Extracting the i th seasonal component from α_t requires accumulating the contributions from the $[s/2]$ harmonics that are associated with this i th seasonal, which are not organized contiguously in α_t . For example, suppose that dim is 2 and the season length s is 4. In this case $[s/2]$ is 2, and the bivariate seasonal component is a sum of two independent bivariate cycles, ζ_1 and ζ_2 . The cycle ζ_1 has frequency $\pi/2$ and its underlying state, say α_t^a , has dimension $2 * dim = 4$. The last harmonic, ζ_2 , has frequency π , and therefore its underlying state, say α_t^b , has dimension 2. The combined state $\alpha_t = (\alpha_t^a, \alpha_t^b)$ has dimension $6 = 4 + 2$. In order to extract the first bivariate seasonal component, you must extract the first components of bivariate cycles ζ_1 and ζ_2 , which in turn implies the first elements of α_t^a and α_t^b , respectively. Thus, obtaining the first bivariate seasonal component requires extracting the first and the fifth elements of the combined state α_t . Similarly, obtaining the second bivariate seasonal component requires extracting the second and the sixth elements of the combined state α_t . All this can be summarized by the dot product expressions

$$\begin{aligned} s_{1t} &= (1 \ 0 \ 0 \ 0 \ 1 \ 0) \alpha_t \\ s_{2t} &= (0 \ 1 \ 0 \ 0 \ 0 \ 1) \alpha_t \end{aligned}$$

where s_{1t} and s_{2t} denote the first and second components, respectively, of the bivariate seasonal component. Note that s_{1t} and s_{2t} are univariate seasonal components, each of season length 4, in their own right. They are correlated components; their correlation structure depends on Σ .

Obtaining the desired components of the multivariate seasonal component is made easy by a special syntax convention of the **COMPONENT** statement. Continuing with the previous example, the following examples illustrate two equivalent ways of obtaining s_{1t} and s_{2t} . The first set of statements explicitly specify the linear combinations needed for defining s_{1t} and s_{2t} :

```
state seasonState(2) type=season(length=4) ...;
component s_1 = ( 1 0 0 0 1 0 ) * seasonState;
component s_2 = ( 0 1 0 0 0 1 ) * seasonState;
```

The following simpler specification achieves the same result:

```
state seasonState(2) type=season(length=4) ...;
component s_1 = seasonState[1];
component s_2 = seasonState[2];
```

In the latter specification, the meaning of the element operator **[]** changes if the state in question is defined by using the **TYPE=** option.

Multivariate ARMA

You can specify a state vector that follows a multivariate autoregressive, moving average (VARMA) model by using the **STATE** statement option **TYPE=VARMA**. The autoregressive and moving average orders can be either 0 or 1 ($0 \leq p \leq 1$ and $0 \leq q \leq 1$)—that is, only VAR(1), MA(1), and VARMA(1,1) models can be specified. The notation and the state space form of the VARMA model described here is taken from Reinsel (1997), which is a good reference for VARMA modeling.

A dim -dimensional vector process ζ_t follows a zero-mean, autoregressive order p , moving average order q (VARMA(p, q)) model if it satisfies the following matrix difference equation:

$$\zeta_t = \sum_{i=1}^p \Phi_i \zeta_{t-i} + \epsilon_t - \sum_{j=1}^q \Theta_j \epsilon_{t-j}$$

Here Φ_i and Θ_j are dim -dimensional square matrices and ϵ_t is a dim -dimensional, Gaussian, white noise sequence with covariance matrix Σ . If autoregressive order p is 0, the term that involves Φ_i is absent; similarly, if the moving average order q is 0, the term that involves Θ_j is absent. Since AR and MA orders can be at most 1, the subscripts of Φ_i and Θ_j can be ignored in this discussion—when applicable, an AR coefficient matrix is denoted by Φ and an MA coefficient matrix is denoted by Θ . The unknown elements of Φ , Θ , and Σ constitute the parameter vector that is associated with a VARMA state. The process ζ_t defined by the VARMA difference equation is stationary and invertible (Reinsel 1997) if and only if the eigenvalues of Φ and Θ are strictly less than 1 in magnitude. By default, the SSM procedure imposes these stationarity and invertibility restrictions on Φ and Θ . However, you can specify Φ to be an identity matrix, in which case the resulting process is nonstationary.

A VARMA model can be cast into a state space form. The state space form used by the SSM procedure is described in Reinsel (1997, pp 52–53). The system matrices for the supported VARMA models are as follows:

- The VAR(1) form is the simplest. In this case, the underlying state α_t is the same as the VAR(1) process ζ_t . Therefore, $T = \Phi$ and $Q_t = \Sigma$.

- Taking Φ equal to the zero matrix if $p = 0$, the VARMA(1,1) and MA(1) cases can be treated together. In this case, the underlying state α_t is $2 \times \text{dim}$ dimensional and the desired VARMA process ζ_t corresponds to its first dim elements. Let $\Psi = \Phi - \Theta$. Then, in the blocked form,

$$\mathbf{T} = \begin{bmatrix} 0 & \mathbf{I}_{\text{dim}} \\ 0 & \Phi \end{bmatrix} \quad \text{and} \quad \mathbf{Q}_t = \mathbf{Q} = \begin{bmatrix} \Sigma & \Sigma\Psi' \\ \Psi\Sigma & \Psi\Sigma\Psi' \end{bmatrix}$$

Unless Φ is restricted to be identity, the underlying state α_t is stationary and the covariance of the initial condition is computed by

$$\text{vec}(\mathbf{Q}_1) = (\mathbf{I} - \mathbf{T} \otimes \mathbf{T})^{-1} \text{vec}(\mathbf{Q})$$

where \otimes denotes the Kronecker product and the vec operation on a matrix creates a vector formed by vertically stacking the rows of that matrix. If Φ is restricted to be identity, the initial condition is fully diffuse.

Continuous-Time Cycle

The STATE statement option **TYPE=CYCLE(CT)** specifies a two-dimensional α_t , needed for defining a univariate continuous time cycle. In this case the nominal dimension, dim , must be 1. In particular, Σ becomes one-dimensional, which is denoted by σ^2 . This cycle can be used for any data type. As before, the parameters of the cycle are a damping factor ρ , $0 < \rho \leq 1$, and $\text{period} > 0$. Unlike in the discrete-time cycle described in the section “**Multivariate Cycle**” on page 1939, the period is not required to be larger than 2. Let $\lambda = 2\pi/\text{period}$, and let $h_t = (\tau_{t+1} - \tau_t)$ denote the difference between successive time points. In this case, the system matrices \mathbf{T} and \mathbf{Q} that govern α_t depend on h_t . They are:

$$\begin{aligned} \mathbf{T} &= \rho^{h_t} (\cos(\lambda h_t) \sin(\lambda h_t), -\sin(\lambda h_t) \cos(\lambda h_t)) \\ \mathbf{Q} &= \frac{\sigma^2(1 - \rho^{2h_t})}{-2 \ln(\rho)} * \mathbf{I}_2 \quad \text{if } \rho < 1 \\ \mathbf{Q} &= \sigma^2 h_t \mathbf{I}_2 \quad \text{if } \rho = 1 \end{aligned}$$

If $\rho < 1$, the initial condition is nondiffuse: $\mathbf{Q}_1 = \frac{\sigma^2}{-2 \ln(\rho)} \mathbf{I}_2$. For $\rho = 1$, the initial condition is fully diffuse.

The first element of α_t corresponds to the needed cycle, and the second element is an auxiliary quantity. You can define a cycle term based on this state as follows:

```
state cycleState(1) type=cycle(CT) ...;
component cycle = cycleState[1];
```

The CT option must be included in the use of **TYPE=CYCLE**.

Covariance Parameterization

The covariance matrices specified by the **COV** and **COV1** options in the STATE statement must be positive semidefinite. When these matrices are of general form and are not user-specified, they are internally parameterized by their Cholesky root. Suppose that Σ , an $m \times m$ positive semidefinite matrix of rank r , is such a covariance matrix. Then, Σ can always be written as

$$\Sigma = \mathbf{R}\mathbf{R}'$$

where the (generalized) Cholesky root, R , is an $m \times r$ lower triangular matrix with nonnegative diagonal elements (that is, $R[i, j] = 0$ if $j > i$ and $R[i, i] \geq 0$, $1 \leq i \leq r$). The SSM procedure parameterizes Σ by the elements of its Cholesky root, which adds $r * (r + 1)/2 + r * (m - r)$ elements to the parameter vector θ .

Missing Values

For a variety of reasons the data might contain missing response and predictor values. Before starting the analysis of a particular BY group, SSM procedure makes an internal copy of the data. The actual analysis is done by using this copy. The data in the copy are first examined for missing values in the response, predictor, and the ID variables. No missing values are permitted in the ID variable (if it is specified). If all the missing values are associated with only the response variables, then the internal copy of the data is not altered. However, if any of the predictors in the observation equation—the elements of \mathbf{X} matrix—are found to contain missing values, the internal copy of the data is altered as follows: any missing predictor value is replaced by 0, and the response values that are dependent on that predictor in the corresponding row are set to missing. These missing response values are called the *induced missing values*. The reported analysis is based on the (possibly altered) internal copy of the BY group.

Missing values are not permitted in any of the other system matrices that define the state space model. In particular, missing values are not permitted in \mathbf{Z} , \mathbf{T} , \mathbf{W} , and \mathbf{Q} matrices. In some cases the elements of these matrices depend on the data values. In such cases, care must be taken to ensure that these data values are not missing.

Computational Issues

A Well-Behaved Model

The model defined by the state space model equations (see the section “[State Space Model and Notation](#)” on page 1919) is very general. This generality is quite useful because it encompasses a wide variety of data generation processes. On the other hand, it also makes it easy to specify overly complex and numerically unstable models. If a suitable model is not already known and you are in the early phases of modeling, it is important to start with models that are relatively simple and well-behaved from the numerical standpoint. From the numerical and statistical considerations, two aspects of model formulation are particularly important: identifiability and numerical stability. A model is identifiable if the observed data has a distinct probability distribution for each admissible parameter vector. Unless proper care is taken, it is easy to specify an unidentifiable state space model. Similarly, predictions according to some types of state space models can display explosive growth or wild oscillations. This behavior is primarily governed by the transition matrix \mathbf{T} (or \mathbf{T}_t in the time-varying case). Unidentifiable models can run into difficulties during parameter estimation, and explosive growth (and wild oscillation) causes numerical problems associated with finite-precision arithmetic. Unfortunately, no simple identifiability check is available for a general state space model, and it is difficult to decide at the outset whether a specified model might suffer from numerical instability. See Harvey (1989, chap. 4, sec. 4) for a discussion of identifiability issues, and see Harvey (1989, chap. 3, sec. 3) for a discussion of the stability properties of time-invariant state space models. The following guidelines are likely to result in models that are identifiable and numerically stable:

- Build models by composing submodels that are known to be well-behaved. The predefined models provided by the SSM procedure are good submodel candidates (see the sections “[Predefined Trend Models](#)” on page 1933 and “[Predefined Structural Models](#)” on page 1936).

- Pay careful attention to the way the variety of system matrices are defined. The behavior of their elements, as functions of model parameters and other variables, must be well-understood. If these elements are defined by using DATA steps, you can validate their behavior by running these DATA steps outside of the SSM procedure. In particular, note the following:
 - The transition matrix \mathbf{T} (or \mathbf{T}_t in the time-varying case) determines the explosiveness characteristics of the model; it must be well-behaved for all parameters.
 - The disturbance covariances \mathbf{Q}_t must be positive semidefinite for all parameters.
 - If the system matrices in the state equation, such as the transition matrix \mathbf{T}_t or the disturbance covariance \mathbf{Q}_t , are time-varying and the data contain replicate observations (observations with the same ID value), check that the elements of these matrices do not vary during replicate observations. This follows from the fact that the underlying state does not vary during replications (see the state equation in the section “[State Space Model and Notation](#)” on page 1919 and the section “[Types of Sequence Data](#)” on page 1921).

Convergence Problems

As explained in the section “[Likelihood Computation and Model Fitting Phase](#)” on page 1928, the model parameters are estimated by nonlinear optimization of the likelihood. This process is not guaranteed to succeed. For some data sets, the optimization algorithm can fail to converge. Nonconvergence can result from a number of causes, including flat or ridged likelihood surfaces and ill-conditioned data. It is also possible for the algorithm to converge to a point that is not the global optimum of the likelihood.

If you experience convergence problems, consider the following:

- Data that are extremely large or extremely small can adversely affect results because of the internal tolerances used during the filtering steps of the likelihood calculation. Rescaling the data can improve stability.
- Examine your model for redundancies in the included components and regressors. The components or regressors that are nearly collinear to each other can cause the optimization process to become unstable.
- Lack of convergence can indicate model misspecification such as unidentifiable model or a violation of the normality assumption.

Computer Resource Requirements

The computing resources required for the SSM procedure depend on several factors. The memory requirement for the procedure is largely dependent on the number of observations to be processed and the size of the state vector underlying the specified model. If n denotes the sample size and m denotes the size of the state vector, the memory requirement for the smoothing phase of the Kalman filter is of the order of $6 \times 8 \times n \times m^2$ bytes, ignoring the lower-order terms. If the smoothed component estimates are not needed, then the memory requirement is of the order of $6 \times 8 \times (m^2 + n)$ bytes. Besides m and n , the computing time for the parameter estimation depends on the size of the parameter vector $\boldsymbol{\theta}$ and how many likelihood evaluations are needed to reach the optimum.

Displayed Output

The default printed output produced by the SSM procedure contains the following information:

- brief information about the input data set, including the data set name and label
- summary statistics for the response variables in the model, including the names of the variables, the total number of observations and the number of missing observations, the smallest and largest measurements, and the mean and standard deviation
- information about the index variable, including the index value of the first and the last observation, the maximum difference between the successive index values, and the categorization of the data into regular, regular with replication, or irregular types
- estimates of the regression parameters if the model contains any predictors, including their standard errors, t statistics, and p -values
- convergence status of the likelihood optimization process if any parameters are estimated
- estimates of the free parameters at the end of the model-fitting phase, including the parameter estimates and their approximate standard errors
- the likelihood-based goodness-of-fit statistics, including the full likelihood, the sum of squares of residuals normalized by their standard errors, and the information criteria: AIC, AICC, HQIC, BIC, and CAIC
- summary of most significant additive outliers

ODS Table Names

The SSM procedure assigns a name to each table it creates. You can use these names to refer to the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in [Table 27.9](#).

Table 27.9 ODS Tables Produced by PROC SSM

ODS Table Name	Description	Statement	Option
Tables That Summarize the Model Information			
ModelSummary	Summary information about the underlying state space model		Default
IdInformation	Summary information about the ID variable		Default
ResponseInfo	Summary information about the response variables		Default
StateSummary	Summary information about the model state vector	PROC SSM	STATEINFO

Table 27.9 *continued*

ODS Table Name	Description	Statement	Option
DiffuseStateSummary	Summary information about the diffuse initial state	PROC SSM	STATEINFO
Tables Related to Model Parameters and the Likelihood			
ConvergenceStatus	Convergence status of the estimation process		Default
RegressionEstimates	Estimates of the regression parameters	MODEL	Default
StateRegressionEstimates	Estimates of the state regression parameters	STATE	W
FixedStateEstimates	Estimates of time-invariant, non-stochastic state subsections		Default
NamedParameterEstimates	Estimates of the parameters specified in the PARMS statement	PARMS	Default
ParameterEstimates	Estimates of the unknown elements in the model system matrices		Default
DisturbanceCovariance	Estimate of the disturbance covariance	STATE	PRINT=COV
InitialCovariance	Estimate of the initial state covariance	STATE	PRINT=COV1
ARCoefficient	Estimate of the autoregressive coefficient matrix	STATE	PRINT=AR
MACoefficient	Estimate of the moving-average coefficient matrix	STATE	PRINT=MA
TransitionMatrix	Estimate of the state transition matrix	STATE	PRINT=T
FitSummary	Summary of the likelihood-based-fit-statistics		Default
InformationCriteria	Likelihood-based information criteria		Default
Tables Related to Series and Component Forecasts			
Forecasts	Series forecasts	MODEL	PRINT=FILTER
SmoothedResponse	Smoothed series values	MODEL	PRINT=SMOOTH
FilteredComponent	Component forecasts	COMPONENT	PRINT=FILTER
SmoothedComponent	Smoothed component	COMPONENT	PRINT=SMOOTH
Tables Related to Outlier Detection and Model Quality			
AOSummary	Summary of additive outliers	Default	Default

Table 27.9 *continued*

ODS Graph Names

You can refer to every graph produced through ODS Graphics with a name. The names of the graphs that PROC SSM generates are listed in [Table 27.10](#), along with the required statements and options.

Table 27.10 ODS Graphs Produced by PROC SSM

ODS Graph Name	Description	Statement	Option
Graphs for One-Step-Ahead Residual Analysis			
ResidualNormalityPlot	Normality check	PROC SSM	PLOTS=RESIDUAL(NORMAL)
ResidualHistogram	Residual histogram	PROC SSM	PLOTS(UNPACK)=RESIDUAL
ResidualQQPlot	Residual QQ Plot	PROC SSM	PLOTS(UNPACK)=RESIDUAL
StdResidualPlot	Time series plot of standardized residuals	PROC SSM	Default
Graphs Related to Outlier Detection and Structural Break			
PredErrorNormalityPlot	Normality check	PROC SSM	PLOTS=AO(NORMAL)
PredErrorHistogram	Prediction error histogram	PROC SSM	PLOTS(UNPACK)=AO
PredErrorQQPlot	Prediction error QQ plot	PROC SSM	PLOTS(UNPACK)=AO
StdPredErrorPlot	Time series plot of standardized additive-outlier statistics	PROC SSM	PLOTS=AO(STD)
MaximalShockPlot	Time series plot of maximal state shock chi-square statistics	PROC SSM	PLOTS=MAXSHOCK

OUT= Data Set

You can use the OUT= option in the OUTPUT statement to store the series and component forecasts that are produced by PROC SSM. Which columns are included in the data set depends on the model specification. The model can have one or more response variables, a variety of components that appear in the MODEL statement, and components specified by the EVAL statement. The OUT= data set contains the one-step-ahead and full-sample estimates of the response variables, and all these components.

The following list describes the columns of the data set:

- the BY variables
- the ID variable, if specified by the ID statement
- Obs, a variable that contains the observation number
- the response series (more than one in the multivariate case)
- the following columns associated with the response series (the wildcard * is substituted by the name of one of the response variables):
 - FORECAST_* contains the one-step-ahead predicted values, and the multistep forecasts of the response series.
 - RESIDUAL_* contains the difference between the actual and forecast values.
 - StdErr_* contains the standard error of prediction.
 - Lower_* and Upper_* contain the lower and upper forecast confidence limits.
 - Smoothed_* contains the smoothed values of the response variable.
 - StdErr_Smoothed_* contains standard errors of the smoothed values of the response variable.
 - AO_* contains the additive outlier estimate.
 - StdErr_AO_* contains the standard error of the additive outlier estimate.
- the following columns associated with the components (the wildcard * is substituted by the name of one of the components):
 - FORECAST_* contains the one-step-ahead predicted values and the multistep forecasts of the component.
 - StdErr_* contains the standard error of prediction.
 - Smoothed_* contains the smoothed values of the component.
 - StdErr_Smoothed_* contains standard errors of the smoothed values of the component.
 - Smoothed_Lower_* and Smoothed_Upper_* contain the lower and upper confidence limits of the smoothed component.
- the maximal state shock chi-square statistics at distinct time points (this column is present only if the MAXSHOCK option is used in the OUTPUT statement)

Confidence limits are not produced for the smoothed series values or for the component forecasts; they are produced for the smoothed components.

Examples: SSM Procedure

Example 27.1: Bivariate Basic Structural Model

This example illustrates how you can use the SSM procedure to analyze a bivariate time series. The following data set contains two variables, `f_KSI` and `r_KSI`, which are measured quarterly, starting the first quarter of 1969. The variable `f_KSI` represents the quarterly average of the log of the monthly totals of the front-seat passengers killed or seriously injured during the car accidents, and `r_KSI` represents a similar number for the rear-seat passengers. The data set has been extended at the end with eight missing values, which represent four quarters, to cause the SSM procedure to produce model forecasts for this span.

```

```

These data have been analyzed in Durbin and Koopman (2001, chap. 9, sec. 3). The analysis presented here is similar. To simplify the illustration, the monthly data have been converted to quarterly data and two predictors (the number of kilometers traveled and the real price of petrol) are excluded from the analysis. You can also use PROC SSM to carry out the more elaborate analysis in Durbin and Koopman (2001).

One of the original reasons for studying these data was to assess the effect on `f_KSI` of the enactment of a seat-belt law in February 1983 that compelled the front seat passengers to wear seat belts. A simple graphical inspection of the data (not shown here) reveals that `f_KSI` and `r_KSI` do not show a pronounced upward or downward trend but do show seasonal variation, and that these two series seem to move together. Additional inspection also shows that the seasonal effect is relatively stable throughout the data span. These considerations suggest the following model for $y = (f_KSI, r_KSI)$:

$$y_t = \begin{pmatrix} X_t \\ 0 \end{pmatrix} \beta + \mu_t + \zeta_t + \xi_t$$

All the terms on the right-hand side of this equation are assumed to be statistically independent. These terms are as follows:

- The predictor X_t (defined as `Q1_83_Shift` later in the program) denotes a variable that is 0 before the first quarter of 1983, and 1 thereafter. X_t is supposed to affect only `f_KSI` (the first element of y); it represents the enactment of the seat-belt law of 1983.
- μ_t denotes a bivariate random walk. It is supposed to capture the slowly changing level of the vector y_t . To capture the fact that `f_KSI` and `r_KSI` move together (that is, they are co-integrated), the covariance of the disturbance term of this random walk is assumed to be of lower than full rank.
- ζ_t denotes a bivariate trigonometric seasonal term. In this model, it is taken to be fixed (that is, the seasonal effects do not change over time).
- ξ_t denotes a bivariate white noise term, which captures the residual variation that is unexplained by the other terms in the model.

The preceding model is an example of a (bivariate) basic structural model (BSM). The following statements specify and fit this model to `f_KSI` and `r_KSI`:

```
proc ssm data=seatBelt stateinfo;
  id date interval=quarter;
  Q1_83_Shift = (date >= '1jan1983'd);
  state error(2) type=WN cov(g) print=cov;
  component wn1 = error[1];
  component wn2 = error[2];
  state level(2) type=RW cov(rank=1) print=cov;
  component rw1 = level[1];
  component rw2 = level[2];
  state season(2) type=season(length=4);
  component s1 = season[1];
  component s2 = season[2];
  model f_KSI = Q1_83_Shift rw1 s1 wn1 / print=(smooth);
  model r_KSI = rw2 s2 wn2;
  eval f_KSI_sa = rw1 + Q1_83_Shift;
  output out=For1;
run;
```

The PROC SSM statement specifies the input data set, `seatBelt`. The use of the STATEINFO option in the PROC SSM statement produces additional information about the model state vector and its diffuse initial state. The optional ID statement specifies an index variable, `date`. The INTERVAL=QUARTER option in the ID statement indicates that the measurements were collected on a quarterly basis. Next, a programming

statement defines `Q1_83_Shift`, the predictor that represents the enactment of the seat-belt law of 1983. It is used later in the `MODEL` statement for `f_KSI`. Separate `STATE` statements specify the terms μ_t , ξ_t , and ζ_t because they are statistically independent. Each model that governs them (white noise for ξ_t , random walk for μ_t , and trigonometric seasonal for ζ_t) can be specified by using the `TYPE=` option of the `STATE` statement. When you use the `TYPE=` option, you can use the `COV` option to specify the information about the disturbance covariance in the state transition equation. The other details, such as the transition matrix specification and the specification of A_1 in the initial condition, are inferred from the `TYPE=` option. The use of `PRINT=COV` in the `STATE` statement causes the estimated disturbance covariance to be printed. For ξ_t (a white noise), A_1 is zero and $Q_t = Q$ for all $t \geq 1$, where Q is specified by the `COV` option. For μ_t and ζ_t the initial condition is fully diffuse—that is, A_1 is an identity matrix of appropriate order and $Q_1 = 0$. The total diffuse dimension of this model, $(d + k)$, is $9 = 8 + 1$ as a result of one predictor, `Q1_83_Shift`, and two fully diffuse state subsections, μ_t and ζ_t . The components in the model are defined by suitable linear combinations of these different state subsections. The program statements define the model as follows:

- **state error(2) type=WN cov(g) ;** defines ξ_t as a two-dimensional white noise, named `error`, with the covariance of general form. Then two `COMPONENT` statements define `wn1` and `wn2` as the first and second elements of `error`, respectively.
- **state level(2) type=RW cov(rank=1) ;** defines μ_t as a two-dimensional random walk, named `level`, with covariance of general form whose rank is restricted to 1. Then two `COMPONENT` statements define `rw1` and `rw2` as the first and second elements of `level`, respectively.
- **state season(2) type=season(length=4) ;** defines ζ_t as a two-dimensional trigonometric seasonal of season length 4, named `season`, with zero covariance—signified by the absence of the `COV` option. Then two `COMPONENT` statements define `s1` and `s2` as appropriate linear combinations of `season` so that `s1` represents the seasonal for `f_KSI` and `s2` represents the seasonal for `r_KSI`. Because `TYPE=SEASON` in the `STATE` statement, the `COMPONENT` statement appropriately interprets `component s1 = season[1]`; as `s1` being a dot product: $(1\ 0\ 0\ 0\ 1\ 0) * \text{season}$. See the section “Multivariate Season” on page 1940 for more information.
- **model f_KSI = Q1_83_Shift rw1 s1 wn1 ;** defines the model for `f_KSI`, and **model r_KSI = rw2 s2 wn2 ;** defines the model for `r_KSI`.

The SSM procedure fits the model and reports the parameter estimates, their approximate standard errors, and the likelihood-based goodness-of-fit measures by default. In order to output the one-step-ahead and full-sample estimates of the components in the model, you can either use the `PRINT=` options in the `MODEL` statement and the respective `COMPONENT` statements or you can specify an output data set in the `OUTPUT` statement. In addition, you can use the `EVAL` statement to define specific linear combinations of the underlying state that should also be estimated. The statement `eval f_KSI_sa = rw1 + Q1_83_Shift ;` is an example of one such linear combination. It defines `f_KSI_sa`, a linear combination that represents the seasonal adjustment of `f_KSI`. The output data set, `For1` (named in the `OUTPUT` statement) contains estimates of all the model components in addition to the estimate of `f_KSI_sa`.

The model summary table, shown in [Output 27.1.1](#), provides basic model information, such as the dimension of the underlying state equation ($m = 10$), the diffuse dimension of the model $((d + k) = 9)$, and the number of parameters (5) in the model parameter vector θ .

Output 27.1.1 Bivariate Basic Structural Model

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	2
State Dimension	10
Dimension of the Diffuse Initial Condition	9
Number of Parameters	5

Additional details about the role of different components in forming the model state and its diffuse initial condition are shown in [Output 27.1.2](#) and [Output 27.1.3](#). They show that the 10-dimensional model state vector is made up of subsections that are associated with error and level (each of dimension 2) and season (of dimension 6). Similarly, the nine-dimensional diffuse vector in the initial condition is made up of subsections that correspond to level, season, and the regression variable, Q1_83_Shift. Note that error does not contribute to the diffuse initial vector because it has a fully nondiffuse initial state.

Output 27.1.2 Bivariate Basic Structural Model State Vector Summary

State Vector Composition	
Subsection	Dimension
error	2
level	2
season	6

Output 27.1.3 Bivariate Basic Structural Model Initial Diffuse State Vector Summary

Diffuse Initial State Composition (Including Regressors)	
Subsection	Dimension
level	2
season	6
Q1_83_Shift	1

The index variable information is shown in [Output 27.1.4](#).

Output 27.1.4 Index Variable Information

ID Variable Information				
Name	Start	End	Max Delta	Type
date	1969:1	1985:4	1	Regular

Output 27.1.5 provides simple summary information about the response variables. It shows that `f_KSI` and `r_KSI` have four missing values each and no induced missing values because the predictor in the model, `Q1_83_Shift`, has no missing values.

Output 27.1.5 Response Variable Summary

Response Variable Information							
Name	---Number of Observations---			Minimum	Maximum	Mean	Std Deviation
	Total	Missing	Induced Missing				
f_KSI	68	4	0	6.16	7.09	6.71	0.206
r_KSI	68	4	0	5.56	6.41	5.97	0.186

The regression coefficient of `Q1_83_Shift`, shown in Output 27.1.6, is negative and is statistically significant. This is consistent with the expected drop in `f_KSI` after the enactment of the seat-belt law.

Output 27.1.6 Regression Coefficient of `Q1_83_Shift`

Regression Parameter Estimates					
Response Variable	Regression Variable	Estimate	Standard Error	t Value	Pr > t
f_KSI	Q1_83_Shift	-0.408	0.0259	-15.74	<.0001

Output 27.1.7 shows the estimates of the elements of θ . The five parameters in θ correspond to unknown elements that are associated with the covariance matrices in the specifications of error and level. Whenever a covariance specification is of a general form and is not defined by a user-specified variable list, it is internally parameterized as a product of its Cholesky root: $\text{Cov} = \text{Root} \text{Root}'$. This ensures that the resulting covariance is positive semidefinite. The Cholesky root is constrained to be lower triangular, with positive diagonal elements. If rank constraints (such as the rank-one constraint on the covariance in the specification of level) are imposed, the number of free parameters in the Cholesky factor is reduced appropriately. See the section “Covariance Parameterization” on page 1942 for more information. In view of these considerations, the five parameters in θ are a result of three parameters from the Cholesky root of error and two parameters that are associated with the Cholesky root of level.

Output 27.1.7 Parameter Estimates

Model Parameter Estimates					
Component	Type		Parameter	Estimate	Standard Error
error	Disturbance Covariance		RootCov[1, 1]	0.0361	0.00736
error	Disturbance Covariance		RootCov[2, 1]	0.0338	0.01131
error	Disturbance Covariance		RootCov[2, 2]	0.0462	0.00470
level	Disturbance Covariance		RootCov[1, 1]	0.0375	0.00843
level	Disturbance Covariance		RootCov[2, 1]	0.0223	0.00569

Output 27.1.8 shows the resulting covariance estimate of error after multiplying the Cholesky factors.

Output 27.1.8 White Noise Covariance Estimate

Disturbance Covariance for error			
	Col1	Col2	
Row1	0.001307	0.001222	
Row2	0.001222	0.003277	

Similarly, Output 27.1.9 shows the covariance estimate of level disturbance. Note that because of the rank-one constraint, the determinant of this matrix is 0.

Output 27.1.9 Covariance Estimate of the Random Walk Disturbance

Disturbance Covariance for level			
	Col1	Col2	
Row1	0.001408	0.000837	
Row2	0.000837	0.000497	

Output 27.1.10 shows the likelihood computation summary. This table is produced by using the fitted model to carry out the filtering operation on the data. See the section “[Likelihood Computation and Model Fitting Phase](#)” on page 1928 for more information.

Output 27.1.10 Likelihood Computation Summary of the Fitted Model

Likelihood Computation Summary	
Statistic	Value
Nonmissing Response Values Used	128
Estimated Parameters	5
Initialized Diffuse State Elements	9
Normalized Residual Sum of Squares	119.00001
Diffuse Log Likelihood	166.15755
Profile Log Likelihood	199.91165

The output data set, For1, specified in the OUTPUT statement contains one-step-ahead and full-sample estimates of all the model components and the user-specified components (defined by the EVAL statement). Their standard errors and the upper and lower confidence limits (by default, 95%) are also produced.

The following statements use the For1 data set to produce a time series plot of the seasonally adjusted f_KSI:

```
proc sgplot data=For1;
  title "Seasonally Adjusted f_KSI with 95% Confidence Band";
  band x=date lower=smoothed_lower_f_KSI_sa
    upper=smoothed_upper_f_KSI_sa ;
  series x=date y=smoothed_f_KSI_sa;
  refline '1jan1985'd / axis=x lineattrs=(pattern=shortdash)
    LEGENDLABEL= "Start of Multistep Forecasts"
    name="Forecast Reference Line";
  scatter x=date y=f_KSI ;
run;
```

The generated plot is shown in [Output 27.1.11](#).

Output 27.1.11 Plot of Seasonally Adjusted f_KSI

Example 27.2: Panel Data: Two-Way Random-Effects and Autoregressive Models

This example shows how you can use the SSM procedure to specify and fit the two-way random-effects model and the autoregressive model to analyze a panel of time series. The fitting of dynamic panel model for such data is illustrated in [Example 27.11](#). These (and a few other) model types can also be fitted by the PANEL procedure, a SAS/ETS procedure that is specially designed to efficiently handle the cross-sectional time series data. However, because of the differences in their model fitting algorithms, generally the parameter estimates and other fit statistics produced by the SSM and PANEL procedures do not match. The SSM procedure always uses the (restricted) maximum likelihood for parameter estimation. The estimation method used by the PANEL procedure depends on the model type and the particular estimation options.

The cross-sectional data, Cigar, that are used in the section “[Getting Started: SSM Procedure](#)” on page 1889 are reused in this example. The output shown here is less extensive than the output shown in that section. The main emphasis of this example is how you can specify the two-way random effects model and the autoregressive model in the SSM procedure.

According to the two-way random effects model, the cigarette sales, $lsales$, can be described by the following equation:

$$lsales_{i,t} = \mu + lprice \beta_1 + lndi \beta_2 + lpimin \beta_3 + \zeta_i + \eta_t + \epsilon_{i,t}$$

This model represents $lsales$ in region i and in year t as a sum of an overall intercept μ , the regression effects due to $lprice$, $lndi$, and $lpimin$, a zero-mean, random effect ζ_i associated with region i , a zero-mean, random effect η_t associated with year t , and the observation noise $\epsilon_{i,t}$. The region-specific random effects ζ_i and the year-specific random effects η_t are assumed to be independent, Gaussian sequences with variances σ_ζ^2 and σ_η^2 , respectively. In addition, they are assumed to be independent of the observation noise, which is also assumed to be a sequence of independent, zero-mean, Gaussian variables with variance σ_ϵ^2 .

You can specify and fit this model by using the following statements:

```
proc ssm data=Cigar;
  id year interval=year;
  parms s2g/ lower=(1.e-6);
  array RegionArray{46} region1-region46;
  do i=1 to 46;
    RegionArray[i] = (region=i);
  end;
  /* region-specific random effects */
  state zeta(46) T(I) cov1(I)=(s2g);
  component regionEffect = zeta * (RegionArray);
  /* year-specific random effect */
  state eta(1) type=wn cov(D);
  component timeEffect = eta[1];
  irregular wn;
  intercept = 1.0;
  model lsales = intercept lprice lndi lpimin
    timeEffect regionEffect wn;
run;
```

The PARMS statement defines $s2g$, a parameter that is restricted to be positive and is used later as the variance parameter for the region effect. Similarly the 46-dimensional array, `RegionArray`, of region-specific dummy variables is defined to be used later. The state subsection `zeta` corresponds to ζ , which is the 46-dimensional vector of region-specific, zero-mean, random effects. The component `regionEffect` extracts the proper element of ζ by using the array `RegionArray`. A constant column, `intercept`, is defined to be used later as an intercept term. The component `timeEffect` corresponds to η_t , and `wn` specifies the observation noise $\epsilon_{i,t}$. Finally the MODEL statement defines the model. Some of the tables that are produced by running these statements are shown in [Output 27.2.1](#) through [Output 27.2.5](#).

The model summary, shown in [Output 27.2.1](#), shows that the model is defined by one MODEL statement, the dimension of the underlying state vector is 47 (because ζ is 46-dimensional and η_t is one-dimensional), the diffuse dimension is 4 (because of the four predictors in the model), and there are three parameters to be estimated.

Output 27.2.1 Two-Way Random-Effects Model: Model Summary

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	1
State Dimension	47
Dimension of the Diffuse Initial Condition	4
Number of Parameters	3

Output 27.2.2 provides the likelihood information about the fitted model.

Output 27.2.2 Two-Way Random-Effects Model: Likelihood Summary

Likelihood Computation Summary	
Statistic	Value
Nonmissing Response Values Used	1380
Estimated Parameters	3
Initialized Diffuse State Elements	4
Normalized Residual Sum of Squares	1376.0001
Diffuse Log Likelihood	1459.0277
Profile Log Likelihood	1470.8628

Output 27.2.3 shows the regression estimates.

Output 27.2.3 Two-Way Random-Effects Model: Regression Estimates

Regression Parameter Estimates					
Response Variable	Regression Variable	Estimate	Standard Error	t Value	Pr > t
lsales	intercept	2.798	0.1136	24.62	<.0001
lsales	lprice	-0.903	0.0365	-24.73	<.0001
lsales	lndi	0.592	0.0246	24.08	<.0001
lsales	lpimin	0.127	0.0398	3.18	0.0015

The ML estimate of s2g, a parameter specified in the PARMS statement, is shown in [Output 27.2.4](#). It corresponds to σ_{ξ}^2 , the variance of the region effect.

Output 27.2.4 Two-Way Random-Effects Model: Estimate of σ_{ξ}^2

Estimates of Named Parameters		
Parameter	Estimate	Standard Error
s2g	0.0241	0.00512

Output 27.2.5 Variance Estimates of η_t and ϵ_{it}

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
eta	Disturbance Covariance	Cov[1, 1]	0.000681	0.000264
wn	Irregular	Variance	0.005698	0.000224

The estimates of the other unknown parameters in the model are shown in [Output 27.2.5](#). It shows the estimate of the variance of the irregular component wn and the estimate of the variance of the time effect η_t .

The remainder of this example describes how you can specify and fit the following first-order vector autoregressive model to the cigarette data:

$$\begin{aligned} \text{lsales}_{i,t} &= \mu + \text{lprice} \beta_1 + \text{lndi} \beta_2 + \text{lpimin} \beta_3 + \zeta_t[i] \\ \zeta_t &= \Phi \zeta_{t-1} + \eta_t \end{aligned}$$

This model represents lsales in region i and in year t as a sum of an overall intercept μ , the regression effects due to lprice, lndi, and lpimin, and the i th element of a vector error term $\zeta_t[i]$. The multidimensional error sequence ζ_t is assumed to follow a first-order autoregression with a diagonal autoregressive coefficient matrix Φ and with a multivariate, white noise sequence η_t as its disturbance sequence. The covariance matrix of η_t , Σ , is assumed to be dense. Note that the dimension of the vectors ζ_t is the same as the number of cross-sections in the study (the number of regions in this example). Therefore, even for a relatively modest panel study, the total number of parameters to be estimated can get quite large. Therefore, in this example only the first three regions are considered in the analysis. The following statements specify and fit this model to the Cigar data set:

```
proc ssm data=Cigar;
  where region <= 3;
  id year interval=year;
  array RegionArray{3} region1-region3;
  do i=1 to 3;
    RegionArray[i] = (region=i);
  end;
  state zeta(3) type=varma(p(d)=1) cov(g) print=(ar cov);
  component eta = zeta*(RegionArray);
  intercept = 1.0;
  model lsales = intercept lprice lndi lpimin eta;
run;
```

The vectors ζ_t are specified in the STATE statement. The TYPE= specification signifies that the three-dimensional state subsection, zeta, follows a vector AR(1) model with a diagonal transition matrix and a disturbance covariance of a general form. The PRINT=(AR COV) option causes the SSM procedure to print the estimated AR coefficient matrix, Φ , and the disturbance error covariance Σ , respectively. The COMPONENT statement defines the appropriate error contribution (named eta), $\zeta_t[i]$. [Output 27.2.6](#) shows the estimated regression coefficients, [Output 27.2.7](#) shows the estimate of Φ , and [Output 27.2.8](#) shows the estimate of Σ :

Output 27.2.6 Autoregressive Model: Regression Estimates

Example 27.3: Backcasting, Forecasting, and Interpolation

This example illustrates how you can do model-based extrapolation—backcasting, forecasting, or interpolation—of a response variable. All you need is to appropriately augment the input data set with the relevant ID and predictor information and assign missing values to the response variable in these places. The following DATA step creates one such augmented data set by using a well-known data set that contains recordings of the Nile River water level measured between the years 1871 and 1970. Suppose you want to backcast the Nile water level for two years before 1871, forecast it for two years after 1970, and interpolate its value for the year 1921—for illustration purposes, this value is assumed to be missing in the available data set.

```
data Nile;
  input level @@;
  year = intnx( 'year', '1jan1869'd, _n_-1 );
  format year year4.;
  if year = '1jan1921'd then level=.;
datalines;
. .
1120 1160 963 1210 1160 1160 813 1230 1370 1140
995 935 1110 994 1020 960 1180 799 958 1140
1100 1210 1150 1250 1260 1220 1030 1100 774 840
874 694 940 833 701 916 692 1020 1050 969
831 726 456 824 702 1120 1100 832 764 821
768 845 864 862 698 845 744 796 1040 759
781 865 845 944 984 897 822 1010 771 676
649 846 812 742 801 1040 860 874 848 890
744 749 838 1050 918 986 797 923 975 815
1020 906 901 1170 912 746 919 718 714 740
. .
;
```

It is also known that for this time span the Nile water level can be reasonably modeled as a sum of a random walk trend, a level shift in the year 1899, and the observation error. The following statements fit this model to the data:

```
proc ssm data=Nile;
  id year interval=year;
  shift1899 = ( year >= '1jan1899'd );
  trend rw(rw);
  irregular wn;
  model level = shift1899 RW wn / print=smooth;
  output out=nileOut;
quit;
```

The model-based interpolated and extrapolated values of the Nile water level are shown in [Output 27.3.1](#), which is produced by using the PRINT=SMOOTH option in the MODEL statement.

Output 27.3.1 Interpolated and Extrapolated Nile Water Level

The SSM Procedure					
Full-Sample Prediction of Missing Values for level					
Obs	ID	Estimate	Standard Error	95% Confidence Limits	
1	1869	1098	130	843	1353
2	1870	1098	130	843	1353

103	1971	851	129	599	1104
104	1972	851	129	599	1104

Example 27.4: Longitudinal Data: Smoothing of Repeated Measures

This example of a repeated measures study is taken from Diggle, Liang, and Zeger (1994, p. 100). The data consist of body weights of 27 cows, measured at 23 unequally spaced time points over a period of approximately 22 months. Following Diggle, Liang, and Zeger (1994), one animal is removed from the analysis, one observation is removed according to their Figure 5.7, and the time is shifted to start at 0 and is measured in 10-day increments. The design is a 2×2 factorial, and the factors are the infection of an animal with *M. paratuberculosis* and whether the animal is receiving iron dosing. The data set contains five variables: cow assigns a unique identification number—from 1 to 26—to each cow in the study, tpoint denotes the time of the growth measurement, weight denotes the growth measurement, iron is a dummy variable that indicates whether the animal is receiving iron or not, and infection is a dummy variable that indicates whether the animal is infected or not. The goal of the study is to assess the effect of iron and infection—and their possible interaction—on weight. The following DATA steps create this data set:

```
data times;
  input time1-time23;
  datalines;
122 150 166 179 219 247 276 296 324 354 380 445
478 508 536 569 599 627 655 668 723 751 781
;

data Cows;
  if _n_ = 1 then merge times;
  array t{23} time1 - time23;
  array w{23} weight1 - weight23;
  input cow iron infection weight1-weight23 @@;
  do i=1 to 23;
    weight = w{i};
    tpoint = (t{i}-t{1})/10;
    output;
  end;
  keep cow iron infection tpoint weight;
```

```

datalines;
1 0 0 4.7      4.905  5.011  5.075  5.136  5.165  5.298  5.323
      5.416  5.438  5.541  5.652  5.687  5.737  5.814  5.799

... more lines ...

```

The following DATA step adds ironInf, a grouping variable that is used later during the plotting of the results. In the next step, the data are sorted by the index variable, tpoint.

```

data Cows;
  set Cows;
  ironInf = "No Iron and No Infection";
  if iron=1 and infection=1 then ironInf = "Iron and Infection";
  else if iron=1 and infection=0 then ironInf = "Iron and No Infection";
  else if iron=0 and infection=1 then ironInf = "No Iron and Infection";
  else ironInf = "No Iron and No Infection";
  run;

proc sort data=Cows;
  by tpoint ;
run;

```

To assess the effect of iron and infection on weight, the natural growth profile of the animals must also be accounted for. Here two alternate models for this problem are considered. The first model assumes that the observed weight of an animal is the sum of a common growth profile, which is modeled by a polynomial spline trend of order 2, the regression effects of iron and infection, and the observation error—modeled as white noise. An interaction term, for interaction between iron and infection, was found to be insignificant and is not included. In the second model, the common growth profile and the regression variables of the first model are replaced by four environment specific growth profiles.

The following statements fit the first model:

```

proc ssm data=Cows;
  id tpoint;
  trend growth(ps(2));
  irregular wn;
  model weight = iron infection growth wn;
  eval pattern = iron + infection + growth;
  output out=For;
quit;

```

Output 27.4.1 shows that the state dimension of this model is 2 (corresponding to the polynomial trend specification of order 2), the number of diffuse elements in the initial condition is 4 (corresponding to the trend and the two regressors iron and infection), and the number of unknown parameters is 2 (corresponding to the variance parameters of trend and irregular).

Output 27.4.1 Model1: Model Summary Information

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	1
State Dimension	2
Dimension of the Diffuse Initial Condition	4
Number of Parameters	2

Output 27.4.2 shows that the ID variable is irregularly spaced with replication.

Output 27.4.2 ID Variable Information

ID Variable Information				
Name	Start	End	Max Delta	Type
tpoint	0	65.9	6.5	Irregular with Replication

The estimated regression coefficients of iron and infection, shown in [Output 27.4.3](#), are significant and negative. This implies that both iron and infection adversely affect the response variable, weight.

Output 27.4.3 Model 1: Regression Estimates

Regression Parameter Estimates					
Response Variable	Regression Variable	Estimate	Standard Error	t Value	Pr > t
weight	iron	-0.0748	0.00761	-9.82	<.0001
weight	infection	-0.1292	0.00859	-15.04	<.0001

The variance estimates of the trend component and the irregular component are shown in [Output 27.4.4](#).

Output 27.4.4 Model 1: Estimates of Unnamed Parameters

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
growth	PS(2) Trend	Level Variance	0.0000162	9.01E-06
wn	Irregular	Variance	0.0085849	5.03E-04

After examining the model fit, it is useful to study how well the patterns implied by the model follow the data. `pattern`, defined by the `EVAL` statement, is a sum of the trend component and the regression effects. A graphical examination of the smoothed estimate of `pattern` is done next. The following `DATA` step merges the output data set specified in the `OUTPUT` statement, `For`, with the input data set, `Cows`. In particular, this adds `ironInf` (a grouping variable from `Cows`) to `For`.

```
data For;
  merge for Cows;
  by tpoint;
run;
```

The following statements produce the graphs of `smoothed_pattern`, grouped according to the environment condition (see [Output 27.4.5](#)). The plot clearly shows that the control group “No Iron and No Infection” has the best growth profile, while the worst growth profile is for the group “Iron and Infection.”

```
proc sgplot data=For noautolegend;
  title 'Common Growth Profile Adjusted by Iron and Infection Status';
  band x=tpoint lower=smoothed_lower_pattern
    upper=smoothed_upper_pattern / group=ironInf name="band";
  series x=tpoint y=smoothed_pattern / group=ironInf name="series";
  keylegend "series";
run;
```

Output 27.4.5 Model 1: Growth Profile Comparison with 95% Confidence Bands

The following statements produce a panel of plots that show how well `smoothed_pattern` follows the observed data:

```
proc sgpanel data=For noautolegend;
  title 'Growth Plots Grouped by Iron and Infection';
  label tpoint='Time' ;
  panelby iron infection / columns=2;
  band x=tpoint lower=smoothed_lower_pattern
        upper=smoothed_upper_pattern ;
  scatter x=tpoint y=weight;
  series x=tpoint y=smoothed_pattern ;
run;
```

Output 27.4.6 shows that the model fits the data reasonably well.

Output 27.4.6 Model 1: Smoothed Model Fit Lines

The following statements fit the second model. In this model separate polynomial trends are fit according to different settings of iron and infection by specifying an appropriate list of (dummy) variables in the **CROSS=** option of the trend specification.

```
proc ssm data=Cows;
  id tpoint;
  a1 = (iron=1 and infection=1);
  a2 = (iron=1 and infection=0);
```

```

a3 = (iron=0 and infection=1);
a4 = (iron=0 and infection=0);
trend growth(ps(2)) cross=(a1-a4);
irregular wn;
model weight = growth wn;
/* Define contrasts between a1 and other treatments */
comp a1Curve = growth_state_[1];
comp a2Curve = growth_state_[2];
comp a3Curve = growth_state_[3];
comp a4Curve = growth_state_[4];
eval contrast21 = a2Curve - a1Curve;
eval contrast31 = a3Curve - a1Curve;
eval contrast41 = a4Curve - a1Curve;
output out=for1;
quit;

```

As a result of the **CROSS=** option, the trend component growth is actually a sum of four separate trends that correspond to the different iron-infection settings. Denoting growth by μ_t and the four independent trends by $\mu_{1,t}$, $\mu_{2,t}$, $\mu_{3,t}$, and $\mu_{4,t}$,

$$\mu_t = a1 * \mu_{1,t} + a2 * \mu_{2,t} + a3 * \mu_{3,t} + a4 * \mu_{4,t}$$

where a1, a2, a3, and a4 are the dummy variables specified in the **CROSS=** option. This shows that, for any given setting (say, the one for a4) μ_t is simply the corresponding trend $\mu_{4,t}$. In addition, note the form of the **COMPONENT** statements that define the components a1Curve, a2Curve, a3Curve, and a4Curve. This form of the **COMPONENT** statement treats the state that is associated with growth, named growth_state_ by convention, as a state of nominal dimension 4—the number of variables in the **CROSS=** list. This, in turn, implies that a1Curve, which is defined as growth_state_[1], refers to $\mu_{1,t}$. These components are subsequently used in the **EVAL** statements to define contrasts between the trends—for example, contrast21 corresponds to the difference between the trends $\mu_{2,t}$ and $\mu_{1,t}$. The estimates of these components (a1Curve, a2Curve, . . . , contrast41) are output to the data set For1 named in the **OUT=** option of the **OUTPUT** data set.

The model summary, shown in [Output 27.4.7](#), reflects the increased state dimension and the increased number of parameters.

Output 27.4.7 Model2: Model Summary Information

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	1
State Dimension	8
Dimension of the Diffuse Initial Condition	8
Number of Parameters	5

Output 27.4.8 shows the parameter estimates for this model.

Output 27.4.8 Model2: Estimates of Unnamed Parameters (Partial Output)

Component	Parameter	Estimate	StdErr
growth(Cross = a1)	Level Variance	1.28E-05	6.83E-06
growth(Cross = a2)	Level Variance	8.72E-06	3.81E-06
growth(Cross = a3)	Level Variance	9.07E-06	4.23E-06
growth(Cross = a4)	Level Variance	8.45E-06	3.40E-06
wn	Variance	8.39E-03	4.98E-04

Next, the smoothed estimate of trend (growth) is graphically studied. The following DATA step prepares the data for the grouped plots of smoothed_growth by merging For1 with the input data set Cows. As before, the reason is merely to include ironInf (the grouping variable).

```
data For1;
  merge For1 Cows;
  by tpoint;
run;
```

The following statements produce the graphs of smoothed μ_t for the desired settings (since the grouping variable ironInf exactly corresponds to these settings). Once again, the plot in [Output 27.4.9](#) clearly shows that the control group “No Iron and No Infection” has the best growth profile, while the worst growth profile is for the group “Iron and Infection.” However, unlike the first model, the profile curves are not merely shifted versions of a common profile.

```
proc sgplot data=For1 noautolegend;
  title 'Iron and Infection Status-Specific Growth Profiles';
  band x=tpoint lower=smoothed_lower_growth
    upper=smoothed_upper_growth / group=ironInf name="band";
  series x=tpoint y=smoothed_growth / group=ironInf name="series";
  keylegend "series";
run;
```

Output 27.4.9 Model 2: Growth Profile Comparison with 95% Confidence Bands

The following statements produce the plot of smoothed $(\mu_{4,t} - \mu_{1,t})$ —contrast between the best and the worst growth profiles.

```
proc sgplot data=For1;
  title "Estimated Contrast Between the Treatments 4 and 1 ";
  band x=tpoint lower=smoothed_lower_contrast41
    upper=smoothed_upper_contrast41;
  series x=tpoint y=smoothed_contrast41;
run;
```

Output 27.4.10 shows that the growth pattern of the control group “No Iron and No Infection” consistently remains above the growth pattern of the treatment group “Iron and Infection.”

Output 27.4.10 Estimated Contrast Between the Treatments 4 and 1 with 95% Confidence Bands

Example 27.5: A User-Defined Trend Model

This example shows how to specify a continuous-time trend model discussed in Harvey (1989, chap. 9, sec. 9.2.1). This model is not one of the predefined trend models in the SSM procedure. The system matrices that govern the two-dimensional state of this model are

$$\mathbf{T} = \begin{bmatrix} 1 & h \\ 0 & 1 \end{bmatrix}$$

$$\mathbf{Q} = \begin{bmatrix} h\sigma_1^2 + \frac{h^3\sigma_2^2}{3} & \frac{h^2\sigma_2^2}{2} \\ \frac{h^2\sigma_2^2}{2} & h\sigma_2^2 \end{bmatrix}$$

where $h = h_t = (\tau_{t+1} - \tau_t)$ denotes the difference between the successive time points, and the parameters σ_1^2 and σ_2^2 are called the level variance and the slope variance, respectively. The initial condition is fully diffuse. The trend component corresponds to the first element of this state vector. The second element of the state vector corresponds to the slope of this trend component. This model reduces to the polynomial spline model of order 2 if the level variance $\sigma_1^2 = 0$. See the section “[Polynomial Spline Trend](#)” on page 1935.

The following statements specify a trend-plus-noise model to model the growth of cows in the previous example (Example 27.4). The only cows that are considered are the ones that received iron and are infected.

```
proc ssm data=Cows;
  where iron=1 and infection=1;
  id tpoint;
  parms var1 var2 / lower=(1.e-8 1.e-8);
  array tMat{2,2};
  tMat[1,1] = 1;
  tMat[2,2] = 1;
  tMat[1,2] = _ID_DELTA_;
  array covMat{2,2};
  covMat[1,1] = var1*_ID_DELTA_ + var2*_ID_DELTA_**3/3;
  covMat[1,2] = var2*_ID_DELTA_**2/2;
  covMat[2,1] = covMat[1,2] ;
  covMat[2,2] = var2*_ID_DELTA_;
  state harveyLL(2) T(g)=(tMat) cov(g)=(covMat) a1(2);
  component trend = harveyLL[1];
  component slope = harveyLL[2];
  irregular wn;
  model weight = trend wn;
  output out=for;
run;
```

The program is easy to follow. The PARMS statement declares var1 and var2 as positive parameters, which correspond to σ_1^2 and σ_2^2 , respectively. The programming statements define arrays tMat and covMat, which later become the matrices T and Q , respectively. Note that the element tMat[2,1] is left unassigned, since it is a structural zero of T (see the section “[Sparse Transition Matrix Specification](#)” on page 1924 for more information). Recall that the predefined variable _ID_DELTA_ contains the value of h_t , which is needed for defining the elements of T and Q (see the section “[ID Statement](#)” on page 1906). The STATE statement defines the trend state vector, harveyLL, and the COMPONENT statement defines the trend component, trend, by selecting the first element of harveyLL. An additional COMPONENT statement defines the slope component, slope, as the second element of harveyLL. The slope component (which represents the cow’s growth rate) is not part of the observation equation; it is specified so that its estimate is output to For (the OUT= data set specified in the OUTPUT statement). The IRREGULAR statement defines the observation noise, and the MODEL statement defines the trend-plus-noise model.

The estimates of var1 and var2 are shown in [Output 27.5.1](#). It shows that the estimate of the level variance is nearly 0, implying that the fitted trend model is identical to the polynomial spline trend of order 2.

Output 27.5.1 Estimates of the Named Parameters

The SSM Procedure		
Estimates of Named Parameters		
Parameter	Estimate	Standard Error
var1	1.00E-08	0.000849
var2	1.24E-05	.

The estimate of the noise variance is shown in [Output 27.5.2](#).

Output 27.5.2 Estimates of the Unnamed Parameters

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
wn	Irregular	Variance	0.00954	0.000909

The following statements produce the plot of the fit of this trend model (shown in [Output 27.5.3](#)).

```
proc sgplot data=For;
  title "Model Fit: Two-Parameter Polynomial Spline of Order 2";
  series x=tpoint y=smoothed_trend;
  scatter x=tpoint y=weight;
run;
```

Output 27.5.3 A User-Defined Trend Model

The following statements produce the plot of the estimate of the slope component (shown in [Output 27.5.4](#)). This plot complements the preceding plot of trend; it shows the pattern of decline in the growth rate as the animals age.

```
proc sgplot data=For;
  title "Smoothed Estimate of Growth-Rate";
  series x=tpoint y=smoothed_slope;
run;
```

Output 27.5.4 Estimate of the slope Component

Example 27.6: Model with Multiple ARIMA Components

This example shows how you can fit the REGCOMPONENT models in Bell (2011) by using the SSM procedure. The following DATA step generates the data used in the last example of this article (Example 6: “Modeling a time series with a sampling error component”). The variable *y* in this data set contains monthly values of the VIP series (value of construction put in place), a U.S. Census Bureau publication that measures the value of construction installed or erected at construction sites during a given month. The values of *y* are known to be contaminated with heterogeneous sampling errors; the variable *hwt* in the data set is a proxy for this sampling error in the log scale. The variable *hwt* is treated as a weight variable for the noise component in the model.

```

data Test;
  input y hwt;
  date = intnx('month', '01jan1997'd, _n_-1 );
  format date date.;
  logy = log(y);
  label logy = 'Log value of construction put in place';
  datalines;
115.2    0.042
110.4    0.042
111.5    0.067
127.9    0.122
150.0    0.129
149.5    0.135
139.5    0.152
144.6    0.168
176.0    0.173

... more lines ...

```

The article proposes the following model for the log VIP series:

$$\log(y) = \mu_t + hwt * \eta_t$$

where μ_t follows an $\text{ARIMA}(0,1,1) \times (0,1,1)_{12}$ model and η_t is a zero-mean, AR(2) error process. The following statements specify this model for logy:

```

proc ssm data=Test;
  id date interval=month;
  trend airlineTrend(arma(d=1 sd=1 q=1 sq=1 s=12));
  trend ar2Noise(arma(p=2)) cross=(hwt);
  model logy = airlineTrend ar2Noise;
  output outfor=For;
run;

```

Output 27.6.1 Estimates of the ARIMA Components Model

The SSM Procedure					
Model Parameter Estimates					
Component	Type	Parameter	Estimate	Standard Error	
airlineTrend	ARMA Trend	Error Variance	0.000642	0.00906	
airlineTrend	ARMA Trend	MA_1	0.251125	0.57239	
airlineTrend	ARMA Trend	SMA_1	-0.710211	11.78177	
ar2Noise	ARMA Trend	Error Variance	0.444514	0.14325	
ar2Noise	ARMA Trend	AR_1	0.481082	0.08027	
ar2Noise	ARMA Trend	AR_2	0.399923	0.21560	

The $\text{ARIMA}(0,1,1) \times (0,1,1)_{12}$ trend μ_t is named `airlineTrend` and the zero-mean, AR(2) error process η_t is named `ar2Noise`. See the [TREND](#) statement for more information about the ARIMA notation. The estimates

of model parameters are shown in [Output 27.6.1](#). These estimates are different from the estimates given in the article; however, the estimated trend and noise series are qualitatively similar. The article uses an estimation procedure that consists of a sequence of alternating steps in which one subset of parameters is held fixed and the remaining parameters are estimated by MLE in each step. This process continues until all the estimates stabilize. The SSM procedure estimates all the parameters simultaneously by MLE.

The following statements produce the plot of the estimate of the `airlineTrend` component (shown in [Output 27.6.2](#)). This plot is very similar to the trend plot shown in the article (the article plots are in the antilog scale).

```
proc sgplot data=For;
  title "Smoothed Estimate of the ARIMA(0,1,1)(0,1,1)12 Trend";
  series x= date y=smoothed_airlineTrend;
  scatter x= date y=logy;
run;
```

Output 27.6.2 Estimate of the `airlineTrend` Component

The following statements produce the plot of the estimate of the `ar2Noise` component (shown in [Output 27.6.3](#)). This plot is also very similar to the noise plot shown in the article (once again, the article plots are in the antilog scale).

```
proc sgplot data=For;
  title "Smoothed Estimate of the AR(2) Noise";
  series x= date y=smoothed_ar2Noise;
  refline 0;
run;
```

Output 27.6.3 Estimate of the ar2Noise Component

Example 27.7: Dynamic Factor Modeling

This example shows how you can fit the dynamic Nelson-Siegel (DNS) factor model discussed in Koopman, Mallee, and van der Wel (2010). The following DATA step creates the yield-curve data set, `Dns`, that is used in this article. The data are monthly bond yields that were recorded between the start of 1970 to the end of 2000 for 17 bonds of different maturities; the maturities range from three months to 10 years (120 months). The variable `date` contains the observation date, `yield` contains the bond yield, `maturity` contains the associated bond maturity, and `mtype` contains an index (ranging from 1 to 17) that sequentially labels bonds of increasing maturity. The data have been extended for two more years by adding missing yields for the years 2001 and 2002, which causes the SSM procedure to produce model forecasts for this span.

```

data Dns;
input date : date. yield maturity mtype;
format date date.;
datalines;
1-Jan-70      8.019      3      1
1-Jan-70      8.091      6      2
1-Jan-70      8.108      9      3
1-Jan-70      8.01      12     4
1-Jan-70      7.836     15     5
1-Jan-70      7.888     18     6
1-Jan-70      7.896     21     7
1-Jan-70      7.989     24     8
1-Jan-70      8.058     30     9
1-Jan-70      8.065     36    10
1-Jan-70      8.088     48    11
1-Jan-70      8.067     60    12

... more lines ...

```

Suppose that $\theta_t(\tau)$ denotes the (idealized) yield at time t that is associated with a bond of maturity τ (in months). Even if time is not measured continuously and the bonds of only certain maturities are traded, $\theta_t(\tau)$ is treated as a smooth function of two continuous variables, time t and maturity τ . Koopman, Mallee, and van der Wel (2010) discuss a variety of models for $\theta_t(\tau)$, which is called the yield surface. One of these models depends on a positive, time-varying, scalar parameter λ_t and a time-varying three-dimensional vector parameter β_t . This model can be described as follows:

$$\begin{aligned}
 \theta_t(\tau) &= \theta(\tau; \lambda_t, \beta_t) \\
 &= \beta_{1t} + \beta_{2t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} \right) + \beta_{3t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} - \exp(-\lambda_t \tau) \right)
 \end{aligned}$$

This model is a dynamic version of a static model discussed in Nelson and Siegel (1987), where λ_t and β_t are time invariant. For fixed time period t , the three terms in this model have relatively simple interpretation. The first term β_{1t} can be thought of as the overall yield level because it does not depend on τ , the bond maturity. It can also be thought of as the long term yield because as $\tau \uparrow \infty$ the other two terms vanish; the coefficients of both β_{2t} and β_{3t} converge to 0 as $\tau \uparrow \infty$ (recall that λ_t is positive). Next, note that as $\tau \downarrow 0$ the coefficient of β_{2t} in the second term converges to 1 while that of β_{3t} in the third term converges to 0; therefore the second term can be thought of as a correction to the overall yield that is associated with the short term bonds. Finally, note that the coefficient of β_{3t} in the third term is a unimodal function of τ that decays monotonically to 0 as $\tau \downarrow 0$ and as $\tau \uparrow \infty$; therefore the third term is associated with the medium term bond yields. It is postulated that the observed yield, denoted by $y_t(\tau)$, is a noisy version of this unobserved (true) yield $\theta_t(\tau)$. The observed yield can be modeled as

$$\begin{aligned}
 y_t(\tau) &= \theta(\tau; \lambda_t, \beta_t) + \epsilon_{t,\tau} \\
 &= \beta_{1t} + \beta_{2t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} \right) + \beta_{3t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} - \exp(-\lambda_t \tau) \right) + \epsilon_{t,\tau} \\
 (\beta_t - \mu) &= \Phi(\beta_{t-1} - \mu) + \eta_t
 \end{aligned}$$

where $\epsilon_{t,\tau}$ are zero-mean, independent, Gaussian variables with variance σ_τ^2 , and η_t is a three-dimensional, Gaussian white noise. That is, β_t is a VAR(1) process with mean vector μ . The remainder of this example explains how to use the SSM procedure to fit this model to the yield data in the Dns data set.

Suppose that variables Z1, Z2, and Z3 are defined as the coefficients of β_{1t} , β_{2t} , and β_{3t} , respectively. That is,

$$\begin{aligned} Z1 &= 1 \\ Z2 &= \frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} \\ Z3 &= \frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} - \exp(-\lambda_t \tau) \end{aligned}$$

In this case,

$$\theta_t(\tau) = Z1 * \beta_{1t} + Z2 * \beta_{2t} + Z3 * \beta_{3t}$$

Let $\zeta_t = \beta_t - \mu$. Then ζ_t is a zero-mean VAR(1) process and $\beta_t = \zeta_t + \mu$. In particular,

$$\begin{aligned} \theta_t(\tau) &= Z1 * \beta_{1t} + Z2 * \beta_{2t} + Z3 * \beta_{3t} \\ &= Z1 * \zeta_{1t} + Z2 * \zeta_{2t} + Z3 * \zeta_{3t} + Z1 * \mu_1 + Z2 * \mu_2 + Z3 * \mu_3 \end{aligned}$$

This shows that the model for $y_t(\tau)$ can be cast into a state space form with the following observation equation:

$$y_t(\tau) = Z\zeta_t + Z\mu + \epsilon_{t,\tau}$$

The underlying six-dimensional state vector α_t is formed by joining the two independent subvectors, ζ_t (which is a zero-mean, VAR(1) process) and the constant mean vector μ . That is, $\alpha_t = (\zeta_{1t} \zeta_{2t} \zeta_{3t} \mu_1 \mu_2 \mu_3)'$.

Note that the variables Z2 and Z3 depend on the time varying parameter λ_t , which is unknown. λ_t is assumed to be a smooth and positive function of time t . In what follows λ_t is represented as an exponential of a cubic spline—a B-spline—in time with four evenly spaced interior knots between January 1970 and December 2002. A cubic spline with four interior knots can be represented as a sum of seven (number of knots + spline degree + 1) B-spline basis functions, $c_{1t}, c_{2t}, \dots, c_{7t}$, for example. More specifically, λ_t can be expressed as

$$\lambda_t = \exp(v1 * c_{1t} + \dots + v7 * c_{7t})$$

for some parameters $v1, v2, \dots, v7$ and the B-spline basis functions (of time) $c_{1t}, c_{2t}, \dots, c_{7t}$. Thus, the variables Z2 and Z3 become known functions of time, except for the parameters $v1, v2, \dots, v7$, which are estimated from the data. The following statements augment the Dns data set with the B-spline basis columns in two steps. First a data set that contains the basis columns, c1–c7, is created by using the BSPLINE function in the IML procedure. This data set is then merged with the Dns data set.

```
proc iml;
  use dns;
  read all var {date} into x;
  bsp = bspline(x, 2, ., 4);
  create spline var{c1 c2 c3 c4 c5 c6 c7};
  append from bsp;
quit;
```

```
data dns;
  merge dns spline;
run;
```

The following statements use the SSM procedure to carry out the model fitting and forecasting calculations:

```
proc ssm data=Dns optimizer(technique=dbldog maxiter=400);
  id date interval=month;

  /* Time varying parameter lambda */
  parms v1-v7;
  lambda = exp(v1*c1 + v2*c2 + v3*c3 + v4*c4
    + v5*c5 + v6*c6 + v7*c7);

  /*Observation equation white noise -- separate variance for each maturity */
  parms sigma1-sigma17 / lower=1.e-4;
  array s_array(17) sigma1-sigma17;
  do i=1 to 17;
    if (mtype=i) then sigma = s_array[i];
  end;
  irregular wn variance=sigma;

  /* Variables Z1, Z2, Z3 needed in the observation equation */
  Z1= 1.0;
  tmp = lambda*maturity;
  Z2 = (1-exp(-tmp))/tmp;
  Z3 = ( 1-exp(-tmp)-tmp*exp(-tmp) )/tmp;

  /* Zero-mean VAR(1) factor zeta and the associated component */
  state zeta(3) type=VARMA(p(d)=1) cov(g) print=(cov ar);
  comp zetaComp = (Z1-Z3)*zeta;

  /* Constant mean vector mu and the associated component */
  state mu(3) type=rw;
  comp muComp = (Z1-Z3)*mu;

  /* Observation equation */
  model yield = muComp zetaComp wn;

  /* Various components defined only for the output purposes */
  eval yieldSurface = muComp + zetaComp;

  comp zeta1 = zeta[1];
  comp zeta2 = zeta[2];
  comp zeta3 = zeta[3];
  comp mu1 = mu[1];
  comp mu2 = mu[2];
  comp mu3 = mu[3];

  comp z2zeta = (Z2)*zeta[2];
  comp z3zeta = (Z3)*zeta[3];
  comp z2Mu = (Z2)*mu[2];
  comp z3Mu = (Z3)*mu[3];
```

```

eval beta1 = mu1 + zeta1;
eval beta2 = mu2 + zeta2;
eval beta3 = mu3 + zeta3;

eval shortTem = z2zeta + z2Mu;
eval medTerm = z3zeta + z3Mu;

/* output the component estimates and the forecasts */
output out=dnsFor pdv;
run;

```

The DBLDOG optimization technique is used for parameter estimation since it is computationally more efficient in this example. The transition matrix, Φ , in the VAR(1) specification of **zeta** is taken to be diagonal (TYPE=VARMA(P(D)=1)) because the use of more general square matrix did not improve the model fit significantly. The mean vector **mu** (recall that $\mathbf{beta}_t = \mathbf{zeta}_t + \mathbf{mu}$) is specified as a three-dimensional random walk with zero disturbance covariance (signified by the absence of COV= option). The model specification part of the program ends with the MODEL statement; the subsequent COMP and EVAL statements define some useful linear combinations of the underlying state. Their estimates are computed after the model fit is completed and are output to the output data set dnsFor. The dnsFor data set also contains all the program variables and the parameters defined in the PARMS statement because the OUTPUT statement contains the PDV option.

Output 27.7.1 shows the estimated mean vector (μ). It shows that the mean long-term yield is 7.64. Output 27.7.2 shows the estimates of v1–v7 (used for defining time-varying λ_t) and the maturity specific observation variances. Output 27.7.3 shows the estimate of the VAR(1) transition matrix Φ , and Output 27.7.4 shows the associated disturbance covariance matrix Σ . The model fit summary is shown in Output 27.7.5.

Output 27.7.1 Estimate of the Mean Vector (μ)

Normalized Residual Sum of Squares	6320.907
Diffuse Log Likelihood	3548.9546
Profile Log Likelihood	3547.4952

The following statements produce the time series plots of the smoothed estimate of the idealized bond yield ($\theta_t(\tau)$) for bonds with maturities 30, 60, and 120 months (shown in [Output 27.7.6](#)). To simplify the display, the plots exclude the time span prior to 1991.

```
proc sgplot data= dnsFor;
  title "The Estimated Yield Surface and the Observed Yields ";
  where maturity in (3 60 120) and date >= '31dec1990'd;
  series x=date y=smoothed_yieldSurface / group=maturity;
  scatter x=date y=yield / group=maturity;
  refline '31dec2000'd / axis=x lineattrs=GraphReference(pattern = Dash)
    name="RefLine" label="Start of multistep forecasts";
run;
```

Output 27.7.6 Smoothed Estimate of $\theta_t(\tau)$ for $\tau = 3, 60, 120$ 

The plots indicate that the DNS model is a reasonable description of the yield data. Similar plots (not shown here) for other maturities also indicate the adequacy of the DNS model. The following statements produce the time series plot of the smoothed estimate of β_{1t} , the long-term bond yield (shown in [Output 27.7.7](#)) :

```
proc sgplot data=dnsFor;
  title "Long-Term Bond Yields Over Time ";
  series x=date y=smoothed_betal ;
  refline '31dec2000'd / axis=x lineattrs=GraphReference(pattern = Dash)
    name="RefLine" label="Start of multistep forecasts";
run;
```

Output 27.7.7 Smoothed Estimate of β_{1t} , the Long-Term Yield

Similarly, [Output 27.7.8](#), which is produced by the following statements, shows the smoothed estimate of the correction to the overall yield that is provided by the second term ($Z_2 * \beta_{2t}$) for maturities of 3 months and 120 months. As expected, the correction for the (long-term) maturity of 120 months is negligible compared to the (short-term) maturity of 3 months.

```
proc sgplot data=dnsFor;
  title "The Correction Term for the Short-Term Yields ";
  where maturity in (3 120);
  series x=date y=smoothed_shortTem / group=maturity;
  refline '31dec2000'd / axis=x lineattrs=GraphReference(pattern = Dash)
    name="RefLine" label="Start of multistep forecasts";
run;
```

Output 27.7.8 Smoothed Estimate of $Z2 * \beta_{2t}$, the Correction Term for the Short-Term Yields

Example 27.8: Diagnostic Plots and Structural Break Analysis

This example provides information about the diagnostic plots that the SSM procedure produces. In addition, a simple illustration of structural break analysis is also provided. The following plots are available in the SSM procedure:

- a panel of two plots—a histogram and a Q-Q plot—for the normality check of the one-step-ahead residuals $v_{t,i}$. A separate panel is produced for each response variable.
- a time series plot of standardized residuals, one per response variable
- a panel of two plots—a histogram and a Q-Q plot—for the normality check of the prediction errors $AO_{t,i}$. A separate panel is produced for each response variable.
- a time series plot of standardized prediction errors, one per response variable
- a time series plot of maximal state shock chi-square statistics

All these plots are used primarily for model diagnostics. In this example, the automobile seat-belt data that are discussed in [Example 27.1](#) are revisited. In [Example 27.1](#), the question under consideration is whether the data show evidence of the effectiveness of the seat-belt law that was introduced in the first quarter of 1983. An intervention variable, `Q1_83_Shift`, was used in the model to measure the effect of this law on the drivers and front-seat passengers who were killed or seriously injured in car accidents (`f_KSI`). In the current example, the analysis of these data begins without the knowledge of this seat-belt law. In effect, the same model is fitted without the use of the intervention variable `Q1_83_Shift`.

The following statements specify the model (without the intervention variable):

```
proc ssm data=seatBelt optimizer(tech=interiorpoint) plots=all;
  id date interval=quarter;
  state error(2) type=WN cov(g);
  component wn1 = error[1];
  component wn2 = error[2];
  state level(2) type=RW cov(rank=1) checkbreak;
  component rw1 = level[1];
  component rw2 = level[2];
  state season(2) type=season(length=4);
  component s1 = season[1];
  component s2 = season[2];
  model f_KSI = rw1 s1 wn1;
  model r_KSI = rw2 s2 wn2;
run;
```

The PLOTS=ALL option in the PROC SSM statement turns on all the plotting options. Because there are two response variables, nine plots in total are produced: a separate set of four plots—two residual and two prediction error—is produced for f_KSI and r_KSI , and one maximal shock plot is produced. Only three of these plots are shown here. [Output 27.8.1](#) shows the normality check for the one-step-ahead residuals for f_KSI . It shows some evidence of lack of normality.

Output 27.8.1 Normality Check of One-Step-Ahead Residuals for f_KSI

Output 27.8.2 shows the time series plot of standardized prediction errors for f_KSI . It identifies some extreme observations (additive outliers): two near 1983 and one near 1970.

Output 27.8.2 Time Series Plot of Standardized Prediction Errors for f_KSI

Output 27.8.3 shows the time series plot of maximal shock statistics. This plot can be very informative in showing the temporal locations of the structural changes in the overall observation-generation process (treating the fitted model as the reference). It can indicate locations of shifts in the process level or shifts in other characteristics, such as its slope. The precise nature of the shift (whether the shift occurs in the level or in some other aspects) can be determined by using the CHECKBREAK option in the appropriate STATE and TREND statements (as is done in the STATE statement in this example that defines the bivariate state level). In this example, the maximal shock statistics plot indicates two locations—the last quarter of 1973 and the first quarter of 1983—as likely locations for the structural breaks that are associated with the traffic accident process. These are indeed reasonable findings, because the last quarter of 1973 (beginning in October 1973) is associated with the start of the oil crisis that severely curtailed worldwide automobile traffic, and the first quarter of 1983 is associated with the introduction of the seat-belt law that might have improved the safety of drivers and front-seat passengers. In addition, Output 27.8.4 shows the summary of most likely break locations for the bivariate state level. It identifies a break in the first element of level (which corresponds to the drivers and front-seat passengers) in the first quarter of 1983.

Output 27.8.3 Time Series Plot of Maximal Shock Statistics

Output 27.8.4 Elementwise Break Summary for the Bivariate State: level

Elementwise Break Summary for level			
ID	Element Index	Z Value	Pr > z
1983:1	1	-5.85	<.0001

The following statements fit a revised model that accounts for the break in the first element of level by introducing a dummy variable, Q1_83_Pulse, in the state equation:

```
ods output ElementStateBreakDetails=stateBreak;
proc ssm data=seatBelt optimizer(tech=interiorpoint) plots=all;
  id date interval=quarter;
  Q1_83_Pulse = (date = '1jan1983'd);
  zero = 0;
  state error(2) type=WN cov(g);
  component wn1 = error[1];
  component wn2 = error[2];
  state level(2) type=RW cov(rank=1) W(g)=(Q1_83_Pulse zero)
    checkbreak print=breakdetail;
  component rw1 = level[1];
  component rw2 = level[2];
  state season(2) type=season(length=4);
  component s1 = season[1];
  component s2 = season[2];
  model f_KSI = rw1 s1 wn1;
  model r_KSI = rw2 s2 wn2;
run;
```

Note that using Q1_83_Pulse in the definition of level is equivalent to using Q1_83_Shift in the MODEL statement for f_KSI in [Example 27.1](#). [Output 27.8.5](#) shows the estimated change in the first element of the state level, which is the same as the estimated level shift shown in [Output 27.1.6](#) (this is not surprising, because these two models are statistically equivalent).

Output 27.8.5 Estimate of the Regression Coefficient of Q1_83_Pulse

The SSM Procedure					
Estimate of the State Equation Regression Vector					
State	Element Index	Estimate	Standard Error	t Value	Pr > t
level	1	-0.408	0.0259	-15.74	<.0001

In the preceding SSM procedure statements, the CHECKBREAK option is used along with the PRINT=BREAKDETAIL option, which produces a table that contains the break statistics at every distinct time point (this table, in turn, is captured in the output data set stateBreak for later use). [Output 27.8.6](#) shows the time series plot of maximal shock statistics for this revised model. As expected, the plot no longer shows the first quarter of 1983 as a structural break location. It continues to show the last quarter of 1973 as a structural break location, because the fitted model does not try to explicitly account for this shift.

Output 27.8.6 Time Series Plot of Maximal Shock Statistics for the Model with Q1_83_Pulse

Note that the reference line in [Output 27.8.3](#) is drawn at the 99.9th percentile, whereas the reference line in [Output 27.8.6](#) is drawn at the 99th percentile. The reference line location in the maximal state shock chi-square statistics plot is based on the points in the plot. A reference line is drawn at percentile 80, 90, 99, or 99.9 based on the largest maximal shock statistic that is shown.

The detailed information in the data set `stateBreak` can be used to further investigate the possibility of significant breaks in the trend in and around 1973. The following statements produce scatter plots for the break statistics for both the drivers and front passengers and the rear passengers (reference lines are also drawn at -3 and 3 to check for extreme Z values):

```
proc sgpanel data=stateBreak;
  panelby elementIndex;
  scatter x=time y=zValue;
  refline 3 / axis=y lineattrs=(pattern=shortdash) noclip;
  refline -3 / axis=y lineattrs=(pattern=shortdash) noclip;
run;
```

Output 27.8.7 Elementwise Structural Break Statistics for level

The resulting graph, shown in [Output 27.8.7](#), shows possible breaks in the second element—rear side passengers—around 1969. In general, however, the evidence of breaks in the elements of level is not very strong. This means that you must look elsewhere to explain the extreme point in [Output 27.8.6](#).

Example 27.9: Longitudinal Data: Variable Bandwidth Smoothing

The data for this example, taken from Givens and Hoeting (2005, chap. 11, Example 11.8), contain two variables, x and y . The variable y represents noisy evaluation of an unknown smooth function at x . The data are sorted by x .

```
data Difficult;
input x y;
datalines;
0.002 0.040
0.011 0.009
0.013 0.719
0.016 0.199
0.017 -0.409

... more lines ...
```

Output 27.9.1 shows the scatter plot of y against x that is generated by the following statements:

```
proc sgplot data=Difficult;
  title "Scatter Plot of Y versus X";
  scatter x=x y=y ;
run;
```

Output 27.9.1 Scatter Plot of Y versus X

The plot clearly shows that the variance of y values varies considerably over the range of x values—the variance is larger for x values around 0.2 and gets increasingly smaller as the x values get closer to 1. Givens and Hoeting (2005) discuss the difficulties of extracting a smooth pattern from such data. Consider the following model for y :

$$y(x) = \mu_x + \epsilon_x$$

where μ_x is a smooth trend component and ϵ_x is the observation noise with variance, $h(x)$, which changes with x : $\epsilon_x \sim N(0, h(x))$. It is known (Durbin and Koopman 2001, chap. 3, sect. 10 and sect. 11) that modeling the trend μ_x as a polynomial smoothing spline (for example, the way the growth curves are modeled in Example 27.4) and taking the variance function of the observation noise ϵ_x a constant results in a trend estimate that can be termed a fixed-bandwidth-smoother. The optimal bandwidth turns out to be a

function of the signal-to-noise ratio: the ratio of the observation noise variance and the disturbance variance of the trend component. On the other hand, allowing the variance function of the observation noise to change with the x values results in a trend estimate that can be termed a variable-bandwidth-smoother. The rest of this example shows how to use the SSM procedure to create a data-dependent variance function $h(x)$ and to extract the associated (variable-bandwidth) smooth trend from such data. Suppose that the (unknown) variance function $h(x)$ can be approximated as

$$h(x) = \exp\left(\sum_{i=1}^7 v_i \text{SplineBasis}_i(x)\right)$$

where $v_i, i = 1, 2, \dots, 7$ are unknown parameters and $\text{SplineBasis}_i(x), i = 1, 2, \dots, 7$, are the full set of cubic spline basis functions (B-splines) with four evenly spaced internal knots between the range of x values—essentially, four equispaced points between 0.0 and 1.0. Note that the number of basis functions in the full set, 7, is the sum of the number of internal knots, 4, and the degree of the polynomial, 3. The following statements create a data set, Combined, that contains the variables x and y , along with the desired spline basis functions (col1–col7) that are created by using the BSPLINE function in PROC IML:

```
proc iml;
  use difficult;
  /* read x and y from difficult into temp */
  read all var _num_ into temp;
  x = temp[,1];
  /* generate B-spline basis for a cubic spline
     with 4 evenly spaced internal knots in the x-range */
  bsp = bspline(x, 2, ., 4);
  Combined = temp || bsp;
  /* create a merged data set with x, y, and
     spline basis columns */
  create Combined var {x y col1 col2 col3 col4 col5 col6 col7};
  append from Combined;
quit;
```

The following statements specify and fit the desired model to the data:

```
proc ssm data=Combined opt (tech=dbldog);
  id x;
  /* parameters needed to define h(x) */
  parms v1-v7;
  /* defining h(x) */
  var = exp(v1*col1 + v2*col2 + v3*col3 + v4*col4
            + v5*col5 + v6*col6 + v7*col7);
  /* defining the polynomial spline trend */
  trend trend(ps(2));
  /* defining the observation noise with variance h(x) */
  irregular wn variance=var;
  model y = trend wn;
  output out=For pdv;
run;
```

Output 27.9.2 shows the estimates of $v_i, i = 1, 2, \dots, 7$, and Output 27.9.3 shows the estimate of the disturbance variance associated with the polynomial spline trend that is specified in the TREND statement.

Output 27.9.2 Estimates of v1–v7

The SSM Procedure		
Estimates of Named Parameters		
Parameter	Estimate	Standard Error
v1	-3.302	1.501
v2	-0.826	0.619
v3	-2.234	0.453
v4	-3.130	0.412
v5	-4.306	0.415
v6	-6.901	0.588
v7	-19.514	2.306

Output 27.9.3 Estimate of the Disturbance Variance Associated with the Trend

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
trend	PS(2) Trend	Level Variance	339	110

The following statements produce a plot, shown in [Output 27.9.4](#), of the fitted trend with 95% confidence band:

```
proc sgplot data=For;
  title "Variable Bandwidth Smoothing Spline";
  band x=x lower=smoothed_lower_trend
    upper=smoothed_upper_trend ;
  series x=x y=smoothed_trend;
  scatter x=x y=y;
run;
```

Output 27.9.4 Fitted Trend with 95% Confidence Band

Clearly the fitted curve tracks the data quite well. Lastly, [Output 27.9.5](#) (produced by using the following statements) shows the estimated variance function $h(x)$.

```
proc sgplot data=For;
  title "Estimated Variance Function";
  series x=x y=var;
run;
```

As expected, the curve attains its peak at an x value around 0.18 and decays to nearly 0 as x values reach 1.0.

Output 27.9.5 Estimated Variance Function $h(x) = \exp(\sum_{i=1}^7 \hat{v}_i \text{SplineBasis}_i(x))$ 

Example 27.10: A Transfer Function Model for the Gas Furnace Data

This example describes how you can include components in your model that follow a transfer function model. Transfer function models, a generalization of distributed lag models, are useful for capturing the contributions from lagged values of the predictor series. Box and Jenkins popularized ARIMA models with transfer function inputs in their famous book (Box and Jenkins 1976). This example shows how you can specify an ARIMA model that is suggested in that book to analyze the data collected in an experiment at a chemical factory. The data set, called Series J by Box and Jenkins, contains sequentially recorded measurements of two variables: x , the input gas rate, and y , the output CO_2 . For the output CO_2 , Box and Jenkins suggest the model

$$y_t = \mu + f_t + \zeta_t$$

where μ is the intercept, ζ_t is a zero-mean noise term that follows a second-order autoregressive model (that is, $\zeta_t \sim \text{AR}(2)$), and f_t follows a transfer function model

$$f_t = \frac{(\gamma_1 B^3 + \gamma_2 B^4 + \gamma_3 B^5)}{(1 - \delta B)} x_t$$

The model for f_t is specified by using the ratio of two polynomials in the backshift operator B . Alternatively, this model can also be described as follows:

$$f_t = \delta f_{t-1} + \gamma_1 x_{t-3} + \gamma_2 x_{t-4} + \gamma_3 x_{t-5}$$

In this alternate form, it is easy to see that the equation for f_t can also be seen as a state evolution equation for a one-dimensional state with a (1×1) transition matrix δ and state regression variables x_{t-3} , x_{t-4} , and x_{t-5} (lagged values of x). This state equation has no disturbance term.

The following statements define the data set `Seriesj`. The variables `x3`, `x4`, and `x5`, which denote the appropriately lagged values of x , are also created. These variables are used later in the `STATE` statement that is used to specify f_t .

```
data Seriesj;
  input x y @@;
  label x = 'Input Gas Rate'
        y = 'Output CO2';
  x3 = lag3(x);
  x4 = lag4(x);
  x5 = lag5(x);
  obsIndex = _n_;
  label obsIndex = 'Observation Index';
datalines;
-0.109 53.8 0.000 53.6 0.178 53.5 0.339 53.5
 0.373 53.4 0.441 53.1 0.461 52.7 0.348 52.4
 0.127 52.2 -0.180 52.0 -0.588 52.0 -1.055 52.4
... more lines ...
```

The following SSM procedure statements carry out the modeling of y , the output CO_2 , according to the preceding model:

```
proc ssm data=Seriesj(firstobs=6);
  id obsIndex;
  parms delta /lower=-0.9999 upper=0.9999;
  state tfstate(1) T(g)=(delta) W(g)=(x3 x4 x5) a1(1) checkbreak;
  comp tfinput = tfstate[1];
  trend ar2(arma(p=2)) ;
  intercept = 1;
  model y = intercept tfinput ar2 ;
  eval modelCurve = intercept + tfinput;
  forecast out=For;
run;
```

The coefficient of the denominator polynomial, δ , is specified in a `PARMS` statement. It is constrained to be less than 1 in magnitude, which ensures that the transfer function term does not have explosive growth. The transfer function model for f_t is specified in a `STATE` statement that defines a one-dimensional state named `tfstate`. In this statement, the transition matrix (which contains only one element, δ) is specified by using the `T(g)=` option; the state regression variables `x3`, `x4`, and `x5` are specified by using the `W(g)=` option; and the `CHECKBREAK` option is used to turn on the search for unexpected changes in the behavior of f_t . The `COV` option is absent from this `STATE` statement because the disturbance term is absent from the state equation for f_t . Moreover, because nothing can be assumed about the initial condition of this state equation, it is taken to be diffuse (as signified by the `A1` option). Note that the first five observations of the input data

set, `Seriesj`, are excluded from the analysis to ensure that the state regression variables `x3`, `x4`, and `x5` do not contain any missing values. The component that is associated with `tfstate`, named `tfinput`, is specified in a `COMPONENT` statement that follows the `STATE` statement. A zero-mean, second-order autoregressive noise term, named `ar2`, is specified by using a `TREND` statement. Next, a constant regression variable, `intercept`, is defined to be used in the `MODEL` statement to capture the intercept term μ . Finally, the model specification is completed by specifying the response variable, `y`, and the three right-hand terms in the `MODEL` statement. Next, an `EVAL` statement is used to specify a component, `modelCurve`, which is the sum of the intercept and the transfer function input ($\mu + f_t$). The `modelCurve` component represents the structural part of the model and is defined only for output purposes: its estimate is output (along with the estimates of other components) to the data set that is specified in the `OUT=` option of the `OUTPUT` statement.

Note that the modeling of output `CO2` according to this model is also illustrated in [Example 7.3](#) of the PROC ARIMA documentation (see Chapter 7, “[The ARIMA Procedure](#)”). The ARIMA procedure handles the computation of the transfer function f_t slightly differently than the way it is estimated by the SSM procedure. However, despite this algorithmic difference in the modeling procedures, for this example the estimated parameters agree quite closely (barring the sign conventions that are used to specify the model parameters).

[Output 27.10.1](#) shows the estimate of μ , the intercept in the model. [Output 27.10.2](#) shows the estimate of δ , the coefficient in the denominator polynomial of the transfer function. [Output 27.10.3](#) shows the regression estimates of the state regression variables `x3`, `x4`, and `x5` (which correspond to the coefficients of the numerator polynomial). [Output 27.10.4](#) shows the estimates of the parameters of the AR(2) noise term.

Output 27.10.1 Estimate of μ

The SSM Procedure					
Regression Parameter Estimates					
Response Variable	Regression Variable	Estimate	Standard Error	t Value	Pr > t
y	intercept	53.4	0.145	368.15	<.0001

Output 27.10.2 Estimate of δ , the Coefficient of the Denominator Polynomial in the Transfer Function

Estimates of Named Parameters		
Parameter	Estimate	Standard Error
delta	0.548	0.0396

Output 27.10.3 Regression Estimates of the State Regression Variables x3, x4, and x5

Estimate of the State Equation Regression Vector					
State	Element Index	Estimate	Standard Error	t Value	Pr > t
tfstate	1	-0.530	0.0743	-7.13	<.0001
tfstate	2	-0.380	0.1022	-3.72	0.0002
tfstate	3	-0.519	0.0743	-6.99	<.0001

Output 27.10.4 Estimates of the Parameters of the Autoregressive Term

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
ar2	ARMA Trend	Error Variance	0.0581	0.00486
ar2	ARMA Trend	AR_1	1.5320	0.02291
ar2	ARMA Trend	AR_2	-0.6292	0.01322

The following statements produce a time series plot of the estimate of modelCurve—that is, the estimate of the structural part of the model ($\mu + f_t$)—along with the scatter plot of the observed values of the output CO₂. The plot, shown in [Output 27.10.5](#), seems to indicate that the model captures the relationship between the input gas rate and the output CO₂ quite well, at least up to the observation index 250.

```
proc sgplot data=For;
  title "Smoothed estimate of the model curve: Intercept + Transfer Function Input";
  series x=obsIndex y=smoothed_modelCurve;
  scatter x=obsIndex y=y;
run;
```

Output 27.10.5 Smoothed Estimate of $\mu + f_t$ 

The plot shown in [Output 27.10.6](#) shows the estimate of the noise term, $ar2$, which is produced by the following statements:

```
proc sgplot data=For;
  title "Smoothed estimate of the AR(2) Noise Term";
  series x=obsIndex y=smoothed_ar2;
  refline 0 / axis=y lineattrs=GraphReference(pattern = Dash);
run;
```

If you compare the scales of these two plots, it appears that the noise term is relatively small and that most of the variation in output CO₂ can be explained by the structural part of the model. It does, however, appear that the model fit deteriorates toward the latter part of the sample. The structural break analysis summary, shown in [Output 27.10.7](#), indicates strong evidence of structural break in the behavior of f_t at or near the observation index 264. Obviously, this type of structural break analysis can be quite useful in industrial quality-control applications.

Output 27.10.6 Smoothed Estimate of the AR(2) Noise Term

Output 27.10.7 Summary of Breaks in f_t

Elementwise Break Summary for tfstate			
ID	Element Index	Z Value	Pr > z
264	1	-5.03	<.0001
199	1	4.62	<.0001

Example 27.11: Panel Data: Dynamic Panel Model for the Cigar Data

This example shows how you can use the SSM procedure to specify and fit the so-called dynamic panel model, which is commonly used to analyze a panel of time series. Suppose that a panel of time series $y_{t,i}$

follows the model

$$y_{t,i} = \rho y_{(t-1),i} + \mu_i + \beta X_{t,i} + \zeta_t + \epsilon_{t,i}$$

where t denotes the time index (for example, $t = 1, \dots, T$); i denotes the panel index (for example, $i = 1, \dots, P$); ρ is the autoregression coefficient; μ_i denote the panel-specific intercepts; $X_{t,i}$ are observations on a regression variable with regression coefficient β (the same for all panels); ζ_t are unobserved, random time effects; and $\epsilon_{t,i}$ are the observation errors. The sequences ζ_t and $\epsilon_{t,i}$ are assumed to be independent, zero-mean Gaussian variables with variances σ_1^2 and σ_0^2 , respectively. This is an example of a dynamic panel model that contains one regressor variable. It is easy to formulate this model equation as a state equation with state α_t of size P —the number of panels. Taking $y_{t,i} = \alpha_t[i]$, it is easy to see that the states α_t evolve according to the equation

$$\alpha_{t+1} = T\alpha_t + W_{t+1}\beta + \eta_{t+1}$$

where $T = \rho I_P$ (a P -dimensional, diagonal matrix with all its diagonal elements equal to ρ); $W_t = (X_t \ I_P)$ is a $P \times (1 + P)$ -dimensional matrix (in a block form) of state regression variables, where the first block is a column that includes all the values $X_{t,i}$ that are associated with a given time index (t) and the second block is a P -dimensional identity matrix; $\beta = (\beta \ \mu_1, \dots, \mu_P)'$ is the $(1 + P)$ -dimensional column vector of regression coefficients; and $\eta_t = (\zeta_t + \epsilon_{t,1}, \dots, \zeta_t + \epsilon_{t,P})'$ is a P -dimensional column vector of all the disturbances that are associated with time index t . Because ζ_t and $\epsilon_{t,i}$ are independent, the covariance matrix of η_t —for example, Q_t —is easy to calculate: $Q_t[i, i] = \sigma_0^2 + \sigma_1^2$ and, for $i \neq j$, $Q_t[i, j] = \sigma_1^2$. This formulation can be easily extended to multiple regression variables, such as r variables, by appropriately modifying the term that is associated with the state regression variables— $W_t\beta$: the new W_t matrix becomes $P \times (r + P)$ -dimensional and the new regression vector β becomes $(r + P)$ -dimensional.

The cross-sectional data, Cigar, that are used in the section “[Getting Started: SSM Procedure](#)” on page 1889 are reused in this example. In order to use the SSM procedure to perform the dynamic panel model-based analysis, the input data set must be reorganized so that it contains the variables that form the $P \times (r + P)$ -dimensional matrix W_t . For the Cigar data, the number of panels $P = 46$ (the number of regions considered in the study), and the number of regression variables $r = 3$. Therefore, the input data set needs to be augmented by $46 * (3 + 46) = 2,254$ variables that constitute the matrix $W_t = (X_t \ I_{46})$ —the first 46×3 -dimensional block X_t contains the values of the three regression variables, lprice, lndi, and lpimin, at a given time index (a particular year in this case). The following DATA steps accomplish this task in two steps. In the first step, the raw data that form the rows of the Cigar data set are read into a temporary data set, Tmp, such that all $6*46 = 276$ values that are associated with a given year (values of six variables—year, region, lsales, lprice, lndi, and lpimin for 46 panels in a given year) are read in a single row that consists of 276 columns. In the second step, the final input data set is formed by rearranging Tmp so that it contains the necessary variables in the proper order—year (the time index), region (the panel index), lsales (the response variable), and the variables that form the 46×49 -dimensional W matrix (w1, . . . , w2254).

```
data Tmp;
    input u1-u276;
datalines;
63 1 4.54223 3.35341 7.3514 3.26194
63 2 4.82831 3.17388 7.5729 3.21487
63 3 4.63860 3.29584 7.3000 3.25037

... more lines ...
```

```

data cigar(keep=year region lsales w1-w2254);
  array wmat{46, 49} w1-w2254;
  array ivar{46, 6} u1-u276;
  set tmp;
  year = intnx( 'year', '1jan63'd, u1-63 );
  format year year.;
  do i=1 to 46;
    region = ivar[i, 2];
    lsales = ivar[i, 3];
    do j=1 to 46;
      do k=1 to 49;
        wmat[j,k] = 0;
        if k = j+3 then wmat[j,k] = 1;
        if k=1 then wmat[j,k] = ivar[j, 4];
        if k=2 then wmat[j,k] = ivar[j, 5];
        if k=3 then wmat[j,k] = ivar[j, 6];
      end;
    end;
    output;
  end;
run;

```

The following statements specify and fit the dynamic panel model:

```

proc ssm data=Cigar opt(tech=dbldog maxiter=75);
  id year interval=year;
  parms rho / lower=-0.9999 upper=0.9999;
  parms sigma0 sigma1 / lower=1.e-8;
  array RegionArray{46} region1-region46;
  do i=1 to 46;
    RegionArray[i] = (region=i);
  end;
  array cov{46,46};
  do i=1 to 46;
    do j=1 to 46;
      if(i=j) then cov[i,j] = sigma0 + sigma1;
      else cov[i,j] = sigma1;
    end;
  end;
  state panelState(46) T(I)=(rho) W(g)=(w1-w2254)
    cov(g)=(cov) a1(46) checkbreak;
  comp dynPanel = (RegionArray)*panelState;
  model lsales = dynPanel;
  output out=for1 press;
run;

```

The estimates of the regression coefficients and the regional intercepts, which are all statistically significant, are shown in [Output 27.11.1](#). In particular, the estimated coefficients of *lprice*, *lndi*, and *lpimin*, are -0.26, 0.13, and 0.07, respectively.

Output 27.11.1 Estimates of $\beta_1, \beta_2, \beta_3$ and the Regional Intercepts

HQIC (lower is better)	-4484.220	-3955.472
CAIC (lower is better)	-4475.776	-3540.952

Similarly, Output 27.11.5 shows fit criteria based on the delete-one cross validation error for the dynamic panel model, and Output 27.11.6 shows the same information for the other model.

Output 27.11.5 Delete-One Cross Validation Criteria: Dynamic Panel Model

Delete-One Cross Validation Error Criteria			
Variable	N	PRESS	Generalized Cross-Validation
lsales	1380	1.115309	5.62798E-7

Output 27.11.6 Delete-One Cross Validation Criteria: Getting Started Example

Delete-One Cross Validation Error Criteria			
Variable	N	PRESS	Generalized Cross-Validation
lsales	1380	1.290420	6.18144E-7

On the basis of both these considerations, the dynamic panel model appears to provide a better fit for the Cigar data than the model that is fit in the section “[Getting Started: SSM Procedure](#)” on page 1889.

Example 27.12: Multivariate Modeling: Analysis of Long-Term Temperature Trends

In a presentation by Ansley and de Jong (2012), three monthly time series are jointly modeled to obtain long-term—several decades long—temperature predictions for certain regions of the northern hemisphere. This example shows how you can specify and fit the final model that this presentation proposed. The following data set, Temp, contains four variables: date dates the monthly observations; UAH contains monthly satellite global temperature readings, starting in December 1978; CRU contains monthly temperature data, starting in January 1850 (from a different source); and GISS contains monthly temperature data, starting in January 1880 (from yet another source). All these temperature data are scaled suitably so that the numbers represent temperature readings in centigrade.

```

data Temp;
input UAH CRU GISS @@;
date = intnx('month', '01jan1850'd, _n_-1);
format date date.;
datalines;
.      8.243      .
.      9.733      .

... more lines ...

```

The following statements produce scatter plots of these three series in a single graph:

```

proc sgplot data=Temp;
    title "Scatter Plots of the Temperature Series";
    scatter x=date y=cru;
    scatter x=date y=uah ;
    scatter x=date y=giss;
run;

```

Output 27.12.1 shows the resulting graph. As already noted, these three series start at different points in the past. However, they all end at the same time: they all have measurements until January 2012, which is the last month in the data set. The mean levels of these series are different: the GISS measurements are generally larger than CRU and UAH by about 4 degrees. In addition, the variability in the CRU values seems to decrease with time (this is more apparent when the series is plotted by itself). The goal of the analysis is to use these data to make long-term predictions about future temperature levels. The following statements append 1,200 missing measurements to Temp, so that the model fitted by using the SSM procedure can be extrapolated to obtain temperature forecasts 100 years in the future:

```

data append(keep=date cru giss uah);
do i=1 to 1200;
    cru = .; giss=.; uah=.;
    date = intnx('month', '01jan2012'D, i);
    format date monyy7.;
    output;
end;
run;

proc append base=Temp data=Append; run;

```

Output 27.12.1 Scatter Plots of CRU, UAH, and GISS

Ansley and de Jong propose a parsimonious model that links these three time series. It can be described as

$$\begin{aligned} GISS_t &= \mu_t + a \zeta_t + a r_1 \epsilon_{1t} \\ CRU_t &= \beta_{cru} + \mu_t + a \zeta_t + a \epsilon_{2t} \\ UAH_t &= \beta_{uah} + \mu_t + a \zeta_t + a r_3 \epsilon_{3t} \end{aligned}$$

where β_{cru} and β_{uah} are intercepts that are associated with CRU and UAH, respectively; μ_t is an integrated random walk trend; ζ_t is a zero-mean, autoregressive noise term (which is scaled by an unknown scaling factor a); and ϵ_{it} ($i = 1, 2, 3$) are independent observation errors with different variances that are also scaled suitably. Note that the trend μ_t and the autoregressive noise term ζ_t are shared by the models of the three series, and, for identification purposes, the intercept for GISS is taken to be zero. In addition, the model parameters are assumed to be interrelated and are parameterized in a particular way (which leads to fewer parameters to estimate, and their relative scaling helps in parameter estimation). This special parameterization can be expressed as a function of seven basic parameters: *loga1*, *logr1*, *logr3*, *logsigma*, *b*, *c*, and *rhoParm* (this naming convention is different from that used by Ansley and de Jong 2012).

Let $\sigma^2 = \exp(2\logsigma)$, and let the scaling factors $a = \exp(\loga1)$, $r_1 = \exp(\logr1)$, and $r_3 = \exp(\logr3)$. Then the model parameters can be described as follows:

- The parameters that are associated with the autoregression ζ_t : the damping factor $\rho = \frac{\exp(\text{rhoParm})-1}{\exp(\text{rhoParm})+1}$, the variance of the disturbance term $= a^2\sigma^2$, and the variance of the initial state $= a^2\sigma^2/(1 - \rho^2)$
- The parameters that are associated with the integrated random walk trend: the variance of the disturbance term in the slope equation $= \sigma^2$
- The variance of the observation errors for GISS $= a^2r_1^2\sigma^2$
- The variance of the observation errors for UAH $= a^2r_3^2\sigma^2$
- The variance of the observation errors for CRU is taken to be time-varying with the following form: for $t \leq \text{nobs}$,

$$\sigma_{2,t}^2 = a^2\sigma^2 \exp(2b + 2c \ t/\text{nobs})$$

where $\text{nobs} = 1,945$ (the number of observations in the unappended data set). For $t > 1,945$, it is fixed at its last value: $\sigma_{2,t}^2 = a^2\sigma^2 \exp(2b + 2c)$.

The following DATA step adds an observation index, `tindex`, to `Temp`, which is used in the SSM procedure to define the time-varying observation error variance for CRU:

```
data temp;
  set temp;
  tindex = _n_;
run;
```

The following statements fit the preceding model to the `Temp` data:

```
ods output RegressionEstimates=regEst;
proc ssm data=Temp;
  id date interval=month;
  parms logal logr1 logr3  logsigma;
  parms b=0 c=0;
  parms rhoParm;
  rho = (exp(rhoParm)-1) / (exp(rhoParm)+1);
  sigmaSq = exp(2*logsigma);
  initSigmaSq = sigmaSq / (1-rho*rho);
  a1 = exp(logal);
  a1Sq = a1*a1;
  r1sq = exp(2*logr1);
  r3sq = exp(2*logr3);
  giss_var = a1Sq*r1sq*sigmaSq;
  nobs=1945;
  if tindex <= nobs then
    cru_var = a1Sq*exp(2*b + 2*c*tindex/nobs)*sigmaSq;
  else cru_var = a1Sq*exp(2*b + 2*c)*sigmaSq;
  uah_var = a1Sq*r3sq*sigmaSq;
  UAH_Intercept=1.0;
  CRU_Intercept=1.0;
  trend level(11) variance=0 slopevar=sigmaSq;
  state auto(1) T(g)=(rho) cov(g)=(sigmaSq) covl(g)=(initSigmaSq);
  comp auto_common = auto*(a1);
  state wn(3) type=wn cov(d)=(giss_var cru_var uah_var);
  comp wn_giss = wn[1];
```

```

comp wn_cru = wn[2];
comp wn_uah = wn[3];
model GISS = level auto_common wn_giss;
model CRU = CRU_Intercept level auto_common wn_cru;
model UAH = UAH_Intercept level auto_common wn_uah;
comp slope = level_state*(0 1);
output out=For pdv press;
run;

```

Output 27.12.2 shows the estimated intercepts $\hat{\beta}_{cru}$ and $\hat{\beta}_{uah}$. As expected, they are quite close (see the scatter plots of CRU and UAH in Output 27.12.1).

Output 27.12.2 Estimated Intercepts for CRU and UAH

The SSM Procedure					
Regression Parameter Estimates					
Response Variable	Regression Variable	Estimate	Standard Error	t Value	Pr > t
CRU	CRU_Intercept	-4.10	0.00360	-1139.2	<.0001
UAH	UAH_Intercept	-4.48	0.00671	-666.48	<.0001

The estimates of the basic parameters that underlie the model parameters are shown in Output 27.12.3.

Output 27.12.3 Estimates of Basic Model Parameters

Estimates of Named Parameters		
Parameter	Estimate	Standard Error
loga1	7.820	0.3819
logr1	-1.005	0.0884
logr3	-0.231	0.0453
logsigma	-9.682	0.3806
b	0.737	0.0502
c	-1.403	0.0689
rhoParm	1.432	0.0767

The following DATA steps add two variables ($CRU_ADJ = CRU - \hat{\beta}_{cru}$ and $UAH_ADJ = UAH - \hat{\beta}_{uah}$) to the output data set For. These adjusted versions of CRU and UAH have the same mean level as GISS—estimated μ_t .

```
data _NULL_;
  set regEst;
  if _n_ = 1 then call symput('intercept1',trim(left(estimate)));
  else call symput('intercept2',trim(left(estimate)));
run;
data for;
  set For;
  cru_adj = cru - &intercept1;
  uah_adj = uah - &intercept2;
run;
```

The following statements produce a graph that contains four plots: scatter plots of GISS, CRU_ADJ, and UAH_ADJ and a series plot of the estimated μ_t .

```
proc sgplot data=For;
  where date < '01feb2021'd;
  title "Fitted Trend for the Temp Series (Up to Year 2020) ";
  title2 "(CRU and UAH Adjusted by Their Estimated Intercepts) ";
  scatter x=date y=cru_adj / LEGENDLABEL="Adjusted CRU"
    MARKERATTRS=GraphData1(symbol=star size=3);
  scatter x=date y=uah_adj / LEGENDLABEL="Adjusted UAH"
    MARKERATTRS=GraphData2(symbol=plus size=3);
  scatter x=date y=giss /
    MARKERATTRS=GraphData3(symbol=triangle size=3);
  series x=date y=smoothed_level / MARKERATTRS=GraphData4;
run;
```

Output 27.12.4 shows the resulting graph. It shows that the estimated mean level μ_t tracks the observed data quite well.

Output 27.12.4 Fitted Trend μ_t 

The following statements produce the time series plot of the estimated μ_t along with the 95% confidence band:

```
proc sgplot data=For;
  title "Temperature Projections for the Next 100 Years";
  band x=date lower=smoothed_lower_level upper=smoothed_upper_level;
  series x=date y=smoothed_level;
  refline '01feb2012'd / axis=x lineattrs=(pattern=shortdash)
    LEGENDLABEL= "Start of Multistep Forecasts"
    name="Forecast Reference Line";
run;
```

Output 27.12.5 shows the resulting graph.

Output 27.12.5 Long-Term Forecasts of μ_t

The following statements produce a similar graph for the estimated slope of μ_t :

```
proc sgplot data=For;
  where date <= '01feb2031'd;
  title "The Monthly Rate of Temperature Change (Up to Year 2030)";
  band x=date lower=smoothed_lower_slope upper=smoothed_upper_slope;
  series x=date y=smoothed_slope;
  refline '01feb2012'd / axis=x lineattrs=(pattern=shortdash)
    LEGENDLABEL= "Start of Multistep Forecasts"
    name="Forecast Reference Line";
  refline 0 / axis=y lineattrs=(pattern=dash);
run;
```

Output 27.12.6 shows the resulting plot of the estimated slope of μ_t .

Output 27.12.6 Forecasts of the Slope of μ_t 

Based on the preceding analysis (see the plots of μ_t and its slope in [Output 27.12.5](#) and [Output 27.12.6](#)), it appears that there has been statistically significant warming over the last 10 years but the warming does not appear to be accelerating.

Overview: STATESPACE Procedure

The STATESPACE procedure has largely been superseded by the newer [SSM procedure](#). PROC SSM fits and forecasts very general linear state space models. It supports irregularly spaced time series and replicated longitudinal data, in addition to supporting regular fixed-period time series. The SSM procedure also provides a powerful expressive language for specifying state space models, and allows programming statements to define model elements through user-written functions of unlimited complexity. The SSM procedure also provides more modern estimation, filtering, and forecasting algorithms than the older STATESPACE procedure. See Chapter 27, “[The SSM Procedure](#),” for information about PROC SSM.

Although the [SSM procedure](#) should be preferred to the STATESPACE procedure for most state space modeling applications, the STATESPACE procedure should be considered if you wish to perform automated multivariate forecasting using a state space model selected through the modeling strategy proposed by Akaike (1976). This strategy employs an initial sequence of unrestricted vector autoregressive (VAR) models, selection of an initial VAR model using Akaike’s information criterion (AIC), followed by a canonical correlation analysis for the automatic identification of the state space model to use to forecast the vector of time series.

The operation of the STATESPACE procedure and the form of state space model it supports are described in the following.

The STATESPACE procedure uses the state space model to analyze and forecast multivariate time series. The STATESPACE procedure is appropriate for jointly forecasting several related time series that have dynamic interactions. By taking into account the autocorrelations among all the variables in a set, it is possible that the STATESPACE procedure may give better forecasts than methods that model each series separately.

By default, the STATESPACE procedure automatically selects a state space model appropriate for the time series, making the procedure a good tool for automatic forecasting of multivariate time series. Alternatively, you can specify the state space model by giving the form of the state vector and the state transition and innovation matrices.

The methods used by the STATESPACE procedure assume that the time series are jointly stationary. Nonstationary series must be made stationary by some preliminary transformation, usually by differencing. The STATESPACE procedure enables you to specify differencing of the input data. When differencing is specified, the STATESPACE procedure automatically integrates forecasts of the differenced series to produce forecasts of the original series.

The State Space Model

The *state space model* represents a multivariate time series through auxiliary variables, some of which might not be directly observable. These auxiliary variables are called the *state vector*. The state vector summarizes all the information from the present and past values of the time series that is relevant to the prediction of future values of the series. The observed time series are expressed as linear combinations of the state variables. The state space model is also called a Markovian representation, or a canonical representation, of a multivariate time series process. The state space approach to modeling a multivariate stationary time series is summarized in Akaike (1976).

The state space form encompasses a very rich class of models. Any Gaussian multivariate stationary time series can be written in a state space form, provided that the dimension of the predictor space is finite. In particular, any autoregressive moving average (ARMA) process has a state space representation and, conversely, any state space process can be expressed in an ARMA form (Akaike 1974). More details on the relation of the state space and ARMA forms are given in the section “[Relation of ARMA and State Space Forms](#)” on page 2050.

Let \mathbf{x}_t be the $r \times 1$ vector of observed variables, after differencing (if differencing is specified) and subtracting the sample mean. Let \mathbf{z}_t be the state vector of dimension s , $s \geq r$, where the first r components of \mathbf{z}_t consist of \mathbf{x}_t . Let the notation $\mathbf{x}_{t+k|t}$ represent the conditional expectation (or prediction) of \mathbf{x}_{t+k} based on the information available at time t . Then the last $s - r$ elements of \mathbf{z}_t consist of elements of $\mathbf{x}_{t+k|t}$, where $k > 0$ is specified or determined automatically by the procedure.

There are various forms of the state space model in use. The form of the state space model used by the STATESPACE procedure is based on Akaike (1976). The model is defined by the following *state transition equation* :

$$\mathbf{z}_{t+1} = \mathbf{F}\mathbf{z}_t + \mathbf{G}\mathbf{e}_{t+1}$$

In the state transition equation, the $s \times s$ coefficient matrix \mathbf{F} is called the *transition matrix*; it determines the dynamic properties of the model.

The $s \times r$ coefficient matrix \mathbf{G} is called the *input matrix*; it determines the variance structure of the transition equation. For model identification, the first r rows and columns of \mathbf{G} are set to an $r \times r$ identity matrix.

The input vector \mathbf{e}_t is a sequence of independent normally distributed random vectors of dimension r with mean $\mathbf{0}$ and covariance matrix Σ_{ee} . The random error \mathbf{e}_t is sometimes called the innovation vector or shock vector.

In addition to the state transition equation, state space models usually include a *measurement equation* or *observation equation* that gives the observed values \mathbf{x}_t as a function of the state vector \mathbf{z}_t . However, since PROC STATESPACE always includes the observed values \mathbf{x}_t in the state vector \mathbf{z}_t , the measurement equation in this case merely represents the extraction of the first r components of the state vector.

The measurement equation used by the STATESPACE procedure is

$$\mathbf{x}_t = [\mathbf{I}_r \mathbf{0}] \mathbf{z}_t$$

where \mathbf{I}_r is an $r \times r$ identity matrix. In practice, PROC STATESPACE performs the extraction of \mathbf{x}_t from \mathbf{z}_t without reference to an explicit measurement equation.

In summary:

\mathbf{x}_t	is an observation vector of dimension r .
\mathbf{z}_t	is a state vector of dimension s , whose first r elements are \mathbf{x}_t and whose last $s - r$ elements are conditional prediction of future \mathbf{x}_t .
\mathbf{F}	is an $s \times s$ transition matrix.
\mathbf{G}	is an $s \times r$ input matrix, with the identity matrix \mathbf{I}_r forming the first r rows and columns.
\mathbf{e}_t	is a sequence of independent normally distributed random vectors of dimension r with mean $\mathbf{0}$ and covariance matrix Σ_{ee} .

How PROC STATESPACE Works

The design of the STATESPACE procedure closely follows the modeling strategy proposed by Akaike (1976). This strategy employs canonical correlation analysis for the automatic identification of the state space model.

Following Akaike (1976), the procedure first fits a sequence of unrestricted vector autoregressive (VAR) models and computes Akaike's information criterion (AIC) for each model. The vector autoregressive models are estimated using the sample autocovariance matrices and the Yule-Walker equations. The order of the VAR model that produces the smallest Akaike information criterion is chosen as the order (number of lags into the past) to use in the canonical correlation analysis.

The elements of the state vector are then determined via a sequence of canonical correlation analyses of the sample autocovariance matrices through the selected order. This analysis computes the sample canonical correlations of the past with an increasing number of steps into the future. Variables that yield significant correlations are added to the state vector; those that yield insignificant correlations are excluded from further consideration. The importance of the correlation is judged on the basis of another information criterion proposed by Akaike. See the section "[Canonical Correlation Analysis Options](#)" on page 2035 for details. If you specify the state vector explicitly, these model identification steps are omitted.

After the state vector is determined, the state space model is fit to the data. The free parameters in the F , G , and Σ_{ee} matrices are estimated by approximate maximum likelihood. By default, the F and G matrices are unrestricted, except for identifiability requirements. Optionally, conditional least squares estimates can be computed. You can impose restrictions on elements of the F and G matrices.

After the parameters are estimated, the Kalman filtering technique is used to produce forecasts from the fitted state space model. If differencing was specified, the forecasts are integrated to produce forecasts of the original input variables.

Getting Started: STATESPACE Procedure

The following introductory example uses simulated data for two variables X and Y. The following statements generate the X and Y series.

```
data in;
  x=10;  y=40;
  x1=0;  y1=0;
  a1=0;  b1=0;
  iseed=123;
  do t=-100 to 200;
    a=rannor(iseed);
    b=rannor(iseed);
    dx = 0.5*x1 + 0.3*y1 + a - 0.2*a1 - 0.1*b1;
    dy = 0.3*x1 + 0.5*y1 + b;
    x = x + dx + .25;
    y = y + dy + .25;
    if t >= 0 then output;
    x1 = dx; y1 = dy;
    a1 = a; b1 = b;
  end;
```

```
keep t x y;
run;
```

The simulated series X and Y are shown in Figure 28.1.

Figure 28.1 Example Series

Automatic State Space Model Selection

The STATESPACE procedure is designed to automatically select the best state space model for forecasting the series. You can specify your own model if you want, and you can use the output from PROC STATESPACE to help you identify a state space model. However, the easiest way to use PROC STATESPACE is to let it choose the model.

Stationarity and Differencing

Although PROC STATESPACE selects the state space model automatically, it does assume that the input series are stationary. If the series are nonstationary, then the process might fail. Therefore the first step is to examine your data and test to see if differencing is required. (See the section “Stationarity and Differencing” on page 2039 for further discussion of this issue.)

The series shown in [Figure 28.1](#) are nonstationary. In order to forecast X and Y with a state space model, you must difference them (or use some other detrending method). If you fail to difference when needed and try to use PROC STATESPACE with nonstationary data, an inappropriate state space model might be selected, and the model estimation might fail to converge.

The following statements identify and fit a state space model for the first differences of X and Y, and forecast X and Y 10 periods ahead:

```
proc statespace data=in out=out lead=10;
  var x(1) y(1);
  id t;
run;
```

The DATA= option specifies the input data set and the OUT= option specifies the output data set for the forecasts. The LEAD= option specifies forecasting 10 observations past the end of the input data. The VAR statement specifies the variables to forecast and specifies differencing. The notation X(1) Y(1) specifies that the state space model analyzes the first differences of X and Y.

Descriptive Statistics and Preliminary Autoregressions

The first page of the printed output produced by the preceding statements is shown in [Figure 28.2](#).

Figure 28.2 Descriptive Statistics and VAR Order Selection

The STATESPACE Procedure			
Number of Observations		200	
Variable	Mean	Standard Error	
x	0.144316	1.233457	Has been differenced. With period(s) = 1.
y	0.164871	1.304358	Has been differenced. With period(s) = 1.

The STATESPACE Procedure								
Information Criterion for Autoregressive Models								
Lag=0	Lag=1	Lag=2	Lag=3	Lag=4	Lag=5	Lag=6	Lag=7	Lag=8
149.697	8.387786	5.517099	12.05986	15.36952	21.79538	24.00638	29.88874	33.55708

Information Criterion for Autoregressive Models		
Lag=9	Lag=10	
41.17606	47.70222	

Figure 28.2 continued

Schematic Representation of Correlations											
Name/Lag	0	1	2	3	4	5	6	7	8	9	10
x	++	++	++	++	++	++	+	..	+	+	..
y	++	++	++	++	++	+	+	+	+
+ is > 2*std error, - is < -2*std error, . is between											

Descriptive statistics are printed first, giving the number of nonmissing observations after differencing and the sample means and standard deviations of the differenced series. The sample means are subtracted before the series are modeled (unless the NOCENTER option is specified), and the sample means are added back when the forecasts are produced.

Let X_t and Y_t be the observed values of X and Y, and let x_t and y_t be the values of X and Y after differencing and subtracting the mean difference. The series x_t modeled by the STATESPACE procedure is

$$\mathbf{x}_t = \begin{bmatrix} x_t \\ y_t \end{bmatrix} = \begin{bmatrix} (1 - B)X_t - 0.144316 \\ (1 - B)Y_t - 0.164871 \end{bmatrix}$$

where B represents the backshift operator.

After the descriptive statistics, PROC STATESPACE prints the Akaike information criterion (AIC) values for the autoregressive models fit to the series. The smallest AIC value, in this case 5.517 at lag 2, determines the number of autocovariance matrices analyzed in the canonical correlation phase.

A schematic representation of the autocorrelations is printed next. This indicates which elements of the autocorrelation matrices at different lags are significantly greater than or less than 0.

The second page of the STATESPACE printed output is shown in Figure 28.3.

Figure 28.3 Partial Autocorrelations and VAR Model

Schematic Representation of Partial Autocorrelations											
Name/Lag	1	2	3	4	5	6	7	8	9	10	
x	++	+	
y	++	
+ is > 2*std error, - is < -2*std error, . is between											
Yule-Walker Estimates for Minimum AIC											
-----Lag=1-----				-----Lag=2-----							
	x		y		x		y				
x	0.257438		0.202237		0.170812		0.133554				
y	0.292177		0.469297		-0.00537		-0.00048				

Figure 28.3 shows a schematic representation of the partial autocorrelations, similar to the autocorrelations shown in Figure 28.2. The selection of a second order autoregressive model by the AIC statistic looks reasonable in this case because the partial autocorrelations for lags greater than 2 are not significant.

Next, the Yule-Walker estimates for the selected autoregressive model are printed. This output shows the coefficient matrices of the vector autoregressive model at each lag.

Selected State Space Model Form and Preliminary Estimates

After the autoregressive order selection process has determined the number of lags to consider, the canonical correlation analysis phase selects the state vector. By default, output for this process is not printed. You can use the CANCELL option to print details of the canonical correlation analysis. See the section “[Canonical Correlation Analysis Options](#)” on page 2035 for an explanation of this process.

After the state vector is selected, the state space model is estimated by approximate maximum likelihood. Information from the canonical correlation analysis and from the preliminary autoregression is used to form preliminary estimates of the state space model parameters. These preliminary estimates are used as starting values for the iterative estimation process.

The form of the state vector and the preliminary estimates are printed next, as shown in Figure 28.4.

Figure 28.4 Preliminary Estimates of State Space Model

The STATESPACE Procedure		
Selected Statespace Form and Preliminary Estimates		
State Vector		
$\mathbf{x}(T;T)$	$\mathbf{y}(T;T)$	$\mathbf{x}(T+1;T)$
Estimate of Transition Matrix		
0	0	1
0.291536	0.468762	-0.00411
0.24869	0.24484	0.204257
Input Matrix for Innovation		
1	0	
0	1	
0.257438	0.202237	
Variance Matrix for Innovation		
0.945196	0.100786	
0.100786	1.014703	

Figure 28.4 first prints the state vector as $X[T;T] \ Y[T;T] \ X[T+1;T]$. This notation indicates that the state vector is

$$\mathbf{z}_t = \begin{bmatrix} x_{t|t} \\ y_{t|t} \\ x_{t+1|t} \end{bmatrix}$$

The notation $x_{t+1|t}$ indicates the conditional expectation or prediction of x_{t+1} based on the information available at time t , and $x_{t|t}$ and $y_{t|t}$ are x_t and y_t , respectively.

The remainder of Figure 28.4 shows the preliminary estimates of the transition matrix \mathbf{F} , the input matrix \mathbf{G} , and the covariance matrix Σ_{ee} .

Estimated State Space Model

The next page of the STATESPACE output prints the final estimates of the fitted model, as shown in Figure 28.5. This output has the same form as in Figure 28.4, but it shows the maximum likelihood estimates instead of the preliminary estimates.

Figure 28.5 Fitted State Space Model

The STATESPACE Procedure		
Selected Statespace Form and Fitted Model		
State Vector		
$\mathbf{x}(T;T)$	$\mathbf{y}(T;T)$	$\mathbf{x}(T+1;T)$
Estimate of Transition Matrix		
0	0	1
0.297273	0.47376	-0.01998
0.2301	0.228425	0.256031
Input Matrix for Innovation		
1	0	
0	1	
0.257284	0.202273	
Variance Matrix for Innovation		
0.945188	0.100752	
0.100752	1.014712	

The estimated state space model shown in Figure 28.5 is

$$\begin{bmatrix} x_{t+1|t+1} \\ y_{t+1|t+1} \\ x_{t+2|t+1} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 \\ 0.297 & 0.474 & -0.020 \\ 0.230 & 0.228 & 0.256 \end{bmatrix} \begin{bmatrix} x_t \\ y_t \\ x_{t+1|t} \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0.257 & 0.202 \end{bmatrix} \begin{bmatrix} e_{t+1} \\ n_{t+1} \end{bmatrix}$$

$$\text{var} \begin{bmatrix} e_{t+1} \\ n_{t+1} \end{bmatrix} = \begin{bmatrix} 0.945 & 0.101 \\ 0.101 & 1.015 \end{bmatrix}$$

The next page of the STATESPACE output lists the estimates of the free parameters in the **F** and **G** matrices with standard errors and *t* statistics, as shown in Figure 28.6.

Figure 28.6 Final Parameter Estimates

Parameter Estimates				
Parameter	Estimate	Standard Error	t Value	
F(2,1)	0.297273	0.129995	2.29	
F(2,2)	0.473760	0.115688	4.10	
F(2,3)	-0.01998	0.313025	-0.06	
F(3,1)	0.230100	0.126226	1.82	
F(3,2)	0.228425	0.112978	2.02	
F(3,3)	0.256031	0.305256	0.84	
G(3,1)	0.257284	0.071060	3.62	
G(3,2)	0.202273	0.068593	2.95	

Convergence Failures

The maximum likelihood estimates are computed by an iterative nonlinear maximization algorithm, which might not converge. If the estimates fail to converge, warning messages are printed in the output.

If you encounter convergence problems, you should recheck the stationarity of the data and ensure that the specified differencing orders are correct. Attempting to fit state space models to nonstationary data is a common cause of convergence failure. You can also use the MAXIT= option to increase the number of iterations allowed, or experiment with the convergence tolerance options DETTOL= and PARMTOL=.

Forecast Data Set

The following statements print the output data set. The WHERE statement excludes the first 190 observations from the output, so that only the forecasts and the last 10 actual observations are printed.

```
proc print data=out;
  id t;
  where t > 190;
run;
```

The PROC PRINT output is shown in Figure 28.7.

Figure 28.7 OUT= Data Set Produced by PROC STATESPACE

The OUT= data set produced by PROC STATESPACE contains the VAR and ID statement variables. In addition, for each VAR statement variable, the OUT= data set contains the variables FOR_i , RES_i , and STD_i . These variables contain the predicted values, residuals, and forecast standard errors for the i th variable in the VAR statement list. In this case, X is listed first in the VAR statement, so FOR1 contains the forecasts of X, while FOR2 contains the forecasts of Y.

The following statements plot the forecasts and actuals for the series.

```
proc sgplot data=out noautolegend;
  where t > 150;
  series x=t y=for1 / markers
    markerattrs=(symbol=circle color=blue)
    lineattrs=(pattern=solid color=blue);
  series x=t y=for2 / markers
    markerattrs=(symbol=circle color=blue)
    lineattrs=(pattern=solid color=blue);
  series x=t y=x / markers
    markerattrs=(symbol=circle color=red)
    lineattrs=(pattern=solid color=red);
  series x=t y=y / markers
    markerattrs=(symbol=circle color=red)
    lineattrs=(pattern=solid color=red);
  refline 200.5 / axis=x;
run;
```

The forecast plot is shown in Figure 28.8. The last 50 observations are also plotted to provide context, and a reference line is drawn between the historical and forecast periods.

Figure 28.8 Plot of Forecasts

Controlling Printed Output

By default, the STATESPACE procedure produces a large amount of printed output. The NOPRINT option suppresses all printed output. You can suppress the printed output for the autoregressive model selection process with the PRINTOUT=NONE option. The descriptive statistics and state space model estimation output are still printed when PRINTOUT=NONE is specified. You can produce more detailed output with the PRINTOUT=LONG option and by specifying the printing control options CANCELL, COVB, and PRINT.

Specifying the State Space Model

Instead of allowing the STATESPACE procedure to select the model automatically, you can use FORM and RESTRICT statements to specify a state space model.

Specifying the State Vector

Use the FORM statement to control the form of the state vector. You can use this feature to force PROC STATESPACE to estimate and forecast a model different from the model it would select automatically. You can also use this feature to reestimate the automatically selected model (possibly with restrictions) without repeating the canonical correlation analysis.

The FORM statement specifies the number of lags of each variable to include in the state vector. For example, the statement FORM X 3; forces the state vector to include $x_{t|t}$, $x_{t+1|t}$, and $x_{t+2|t}$. The following statement specifies the state vector $(x_{t|t}, y_{t|t}, x_{t+1|t})$, which is the same state vector selected in the preceding example:

```
form x 2 y 1;
```

You can specify the form for only some of the variables and allow PROC STATESPACE to select the form for the other variables. If only some of the variables are specified in the FORM statement, canonical correlation analysis is used to determine the number of lags included in the state vector for the remaining variables not specified by the FORM statement. If the FORM statement includes specifications for all the variables listed in the VAR statement, the state vector is completely defined and the canonical correlation analysis is not performed.

Restricting the F and G matrices

After you know the form of the state vector, you can use the RESTRICT statement to fix some parameters in the F and G matrices to specified values. One use of this feature is to remove insignificant parameters by restricting them to 0.

In the introductory example shown in the preceding section, the F[2,3] parameter is not significant. (The parameters estimation output shown in [Figure 28.6](#) gives the t statistic for F[2,3] as -0.06 . F[3,3] and F[3,1] also have low significance with $t < 2$.)

The following statements reestimate this model with F[2,3] restricted to 0. The FORM statement is used to specify the state vector and thus bypass the canonical correlation analysis.

```
proc statespace data=in out=out lead=10;
  var x(1) y(1);
  id t;
  form x 2 y 1;
  restrict f(2,3)=0;
run;
```

The final estimates produced by these statements are shown in [Figure 28.10](#).

Syntax: STATESPACE Procedure

The STATESPACE procedure uses the following statements:

```

PROC STATESPACE options ;
  BY variable ... ;
  FORM variable value ... ;
  ID variable ;
  INITIAL F (row,column)=value ... G (row,column)=value ... ;
  RESTRICT F (row,column)=value ... G (row,column)=value ... ;
  VAR variable (difference, difference, ...) ... ;

```

Functional Summary

Table 28.1 summarizes the statements and options used by PROC STATESPACE.

Table 28.1 STATESPACE Functional Summary

Description	Statement	Option
Input Data Set Options		
specify the input data set	PROC STATESPACE	DATA=
prevent subtraction of sample mean	PROC STATESPACE	NOCENTER
specify the ID variable	ID	
specify the observed series and differencing	VAR	
Options for Autoregressive Estimates		
specify the maximum order	PROC STATESPACE	ARMAX=
specify maximum lag for autocovariances	PROC STATESPACE	LAGMAX=
output only minimum AIC model	PROC STATESPACE	MINIC
specify the amount of detail printed	PROC STATESPACE	PRINTOUT=
write preliminary AR models to a data set	PROC STATESPACE	OUTAR=
Options for Canonical Correlation Analysis		
print the sequence of canonical correlations	PROC STATESPACE	CANCORR
specify upper limit of dimension of state vector	PROC STATESPACE	DIMMAX=
specify the minimum number of lags	PROC STATESPACE	PASTMIN=
specify the multiplier of the degrees of freedom	PROC STATESPACE	SIGCORR=
Options for State Space Model Estimation		
specify starting values	INITIAL	
print covariance matrix of parameter estimates	PROC STATESPACE	COVB
specify the convergence criterion	PROC STATESPACE	DETTOL=
specify the convergence criterion	PROC STATESPACE	PARMTOL=
print the details of the iterations	PROC STATESPACE	ITPRINT
specify an upper limit of the number of lags	PROC STATESPACE	KLAG=
specify maximum number of iterations allowed	PROC STATESPACE	MAXIT=
suppress the final estimation	PROC STATESPACE	NOEST
write the state space model parameter estimates to an output data set	PROC STATESPACE	OUTMODEL=
use conditional least squares for final estimates	PROC STATESPACE	RESIDEST
specify criterion for testing for singularity	PROC STATESPACE	SINGULAR=
Options for Forecasting		
start forecasting before end of the input data	PROC STATESPACE	BACK=
specify the time interval between observations	PROC STATESPACE	INTERVAL=
specify multiple periods in the time series	PROC STATESPACE	INTPER=
specify how many periods to forecast	PROC STATESPACE	LEAD=
specify the output data set for forecasts	PROC STATESPACE	OUT=

specify the state vector	FORM	
specify the parameter values	RESTRICT	
BY Groups		
specify BY-group processing	BY	
Printing		
suppresses all printed output	NOPRINT	

PROC STATESPACE Statement

PROC STATESPACE *options* ;

The following options can be specified in the PROC STATESPACE statement.

Printing Options

NOPRINT

suppresses all printed output.

Input Data Options

DATA=SAS-data-set

specifies the name of the SAS data set to be used by the procedure. If the DATA= option is omitted, the most recently created SAS data set is used.

LAGMAX=k

specifies the number of lags for which the sample autocovariance matrix is computed. The LAGMAX= option controls the number of lags printed in the schematic representation of the autocorrelations.

The sample autocovariance matrix of lag i , denoted as C_i , is computed as

$$C_i = \frac{1}{N-1} \sum_{t=1+i}^N \mathbf{x}_t \mathbf{x}'_{t-i}$$

where \mathbf{x}_t is the differenced and centered data and N is the number of observations. (If the NOCENTER option is specified, 1 is not subtracted from N .) LAGMAX= k specifies that C_0 through C_k are computed. The default is LAGMAX=10.

NOCENTER

prevents subtraction of the sample mean from the input series (after any specified differencing) before the analysis.

Options for Preliminary Autoregressive Models

ARMAX=*n*

specifies the maximum order of the preliminary autoregressive models. The ARMAX= option controls the autoregressive orders for which information criteria are printed, and controls the number of lags printed in the schematic representation of partial autocorrelations. The default is ARMAX=10. See the section “[Preliminary Autoregressive Models](#)” on page 2041 for details.

MINIC

writes to the OUTAR= data set only the preliminary Yule-Walker estimates for the VAR model that produces the minimum AIC. See the section “[OUTAR= Data Set](#)” on page 2051 for details.

OUTAR=*SAS-data-set*

writes the Yule-Walker estimates of the preliminary autoregressive models to a SAS data set. See the section “[OUTAR= Data Set](#)” on page 2051 for details.

PRINTOUT=SHORT | LONG | NONE

determines the amount of detail printed. PRINTOUT=LONG prints the lagged covariance matrices, the partial autoregressive matrices, and estimates of the residual covariance matrices from the sequence of autoregressive models. PRINTOUT=NONE suppresses the output for the preliminary autoregressive models. The descriptive statistics and state space model estimation output are still printed when PRINTOUT=NONE is specified. PRINTOUT=SHORT is the default.

Canonical Correlation Analysis Options

CANCORR

prints the canonical correlations and information criterion for each candidate state vector considered. See the section “[Canonical Correlation Analysis Options](#)” on page 2035 for details.

DIMMAX=*n*

specifies the upper limit to the dimension of the state vector. The DIMMAX= option can be used to limit the size of the model selected. The default is DIMMAX=10.

PASTMIN=*n*

specifies the minimum number of lags to include in the canonical correlation analysis. The default is PASTMIN=0. See the section “[Canonical Correlation Analysis Options](#)” on page 2035 for details.

SIGCORR=*value*

specifies the multiplier of the degrees of freedom for the penalty term in the information criterion used to select the state space form. The default is SIGCORR=2. The larger the value of the SIGCORR= option, the smaller the state vector tends to be. Hence, a large value causes a simpler model to be fit. See the section “[Canonical Correlation Analysis Options](#)” on page 2035 for details.

State Space Model Estimation Options

COVB

prints the inverse of the observed information matrix for the parameter estimates. This matrix is an estimate of the covariance matrix for the parameter estimates.

DETTOL=*value*

specifies the convergence criterion. The DETTOL= and PARMTOL= option values are used together to test for convergence of the estimation process. If, during an iteration, the relative change of the parameter estimates is less than the PARMTOL= value and the relative change of the determinant of the innovation variance matrix is less than the DETTOL= value, then iteration ceases and the current estimates are accepted. The default is DETTOL=1E-5.

ITPRINT

prints the iterations during the estimation process.

KLAG=*n*

sets an upper limit for the number of lags of the sample autocovariance matrix used in computing the approximate likelihood function. If the data have a strong moving average character, a larger KLAG= value might be necessary to obtain good estimates. The default is KLAG=15. See the section “[Parameter Estimation](#)” on page 2046 for details.

MAXIT=*n*

sets an upper limit to the number of iterations in the maximum likelihood or conditional least squares estimation. The default is MAXIT=50.

NOEST

suppresses the final maximum likelihood estimation of the selected model.

OUTMODEL=*SAS-data-set*

writes the parameter estimates and their standard errors to a SAS data set. See the section “[OUTMODEL= Data Set](#)” on page 2053 for details.

PARMTOL=*value*

specifies the convergence criterion. The DETTOL= and PARMTOL= option values are used together to test for convergence of the estimation process. If, during an iteration, the relative change of the parameter estimates is less than the PARMTOL= value and the relative change of the determinant of the innovation variance matrix is less than the DETTOL= value, then iteration ceases and the current estimates are accepted. The default is PARMTOL=0.001.

RESIDEST

computes the final estimates by using conditional least squares on the raw data. This type of estimation might be more stable than the default maximum likelihood method but is usually more computationally expensive. See the section “[Parameter Estimation](#)” on page 2046 for details about the conditional least squares method.

SINGULAR=*value*

specifies the criterion for testing for singularity of a matrix. A matrix is declared singular if a scaled pivot is less than the SINGULAR= value when sweeping the matrix. The default is SINGULAR=1E-7.

Forecasting Options

BACK=*n*

starts forecasting *n* periods before the end of the input data. The BACK= option value must not be greater than the number of observations. The default is BACK=0.

INTERVAL=*interval*

specifies the time interval between observations. The INTERVAL= value is used in conjunction with the ID variable to check that the input data are in order and have no missing periods. The INTERVAL= option is also used to extrapolate the ID values past the end of the input data. See Chapter 4, “[Date Intervals, Formats, and Functions](#),” for details about the INTERVAL= values allowed.

INTPER=*n*

specifies that each input observation corresponds to *n* time periods. For example, the options INTERVAL=MONTH and INTPER=2 specify bimonthly data and are equivalent to specifying INTERVAL=MONTH2. If the INTERVAL= option is not specified, the INTPER= option controls the increment used to generate ID values for the forecast observations. The default is INTPER=1.

LEAD=*n*

specifies how many forecast observations are produced. The forecasts start at the point set by the BACK= option. The default is LEAD=0, which produces no forecasts.

OUT=*SAS-data-set*

writes the residuals, actual values, forecasts, and forecast standard errors to a SAS data set. See the section “[OUT= Data Set](#)” on page 2051 for details.

PRINT

prints the forecasts.

BY Statement

BY *variable ... ;*

A BY statement can be used with the STATESPACE procedure to obtain separate analyses on observations in groups defined by the BY variables.

FORM Statement

FORM *variable value ... ;*

The FORM statement specifies the number of times a variable is included in the state vector. Values can be specified for any variable listed in the VAR statement. If a value is specified for each variable in the VAR statement, the state vector for the state space model is entirely specified, and automatic selection of the state space model is not performed.

The FORM statement forces the state vector, \mathbf{z}_t , to contain a specific variable a given number of times. For example, if Y is one of the variables in \mathbf{x}_t , then the statement

```
form y 3;
```

forces the state vector to contain Y_t , $Y_{t+1|t}$, and $Y_{t+2|t}$, possibly along with other variables.

The following statements illustrate the use of the FORM statement:

```
proc statespace data=in;
  var x y;
  form x 3 y 2;
run;
```

These statements fit a state space model with the following state vector:

$$\mathbf{z}_t = \begin{bmatrix} x_{t|t} \\ y_{t|t} \\ x_{t+1|t} \\ y_{t+1|t} \\ x_{t+2|t} \end{bmatrix}$$

ID Statement

ID *variable* ;

The ID statement specifies a variable that identifies observations in the input data set. The variable specified in the ID statement is included in the OUT= data set. The values of the ID variable are extrapolated for the forecast observations based on the values of the INTERVAL= and INTPER= options.

INITIAL Statement

INITIAL *F* (row,column)= *value* ... *G*(row, column)= *value* ... ;

The INITIAL statement gives initial values to the specified elements of the **F** and **G** matrices. These initial values are used as starting values for the iterative estimation.

Parts of the **F** and **G** matrices represent fixed structural identities. If an element specified is a fixed structural element instead of a free parameter, the corresponding initialization is ignored.

The following is an example of an INITIAL statement:

```
initial f(3,2)=0 g(4,1)=0 g(5,1)=0;
```

RESTRICT Statement

RESTRICT *F*(row,column)= *value* ... *G*(row,column)= *value* ... ;

The RESTRICT statement restricts the specified elements of the **F** and **G** matrices to the specified values.

To use the restrict statement, you need to know the form of the model. Either specify the form of the model with the FORM statement, or do a preliminary run (perhaps with the NOEST option) to find the form of the model that PROC STATESPACE selects for the data.

The following is an example of a RESTRICT statement:

```
restrict f(3,2)=0 g(4,1)=0 g(5,1)=0 ;
```

Parts of the **F** and **G** matrices represent fixed structural identities. If a restriction is specified for an element that is a fixed structural element instead of a free parameter, the restriction is ignored.

VAR Statement

VAR *variable (difference, difference, ...) ... ;*

The VAR statement specifies the variables in the input data set to model and forecast. The VAR statement also specifies differencing of the input variables. The VAR statement is required.

Differencing is specified by following the variable name with a list of difference periods separated by commas. See the section “[Stationarity and Differencing](#)” on page 2039 for more information about differencing of input variables.

The order in which variables are listed in the VAR statement controls the order in which variables are included in the state vector. Usually, potential inputs should be listed before potential outputs.

For example, assuming the input data are monthly, the following VAR statement specifies modeling and forecasting of the one period and seasonal second difference of X and Y:

```
var x(1,12) y(1,12);
```

In this example, the vector time series analyzed is

$$\mathbf{x}_t = \begin{bmatrix} (1-B)(1-B^{12})X_t - \bar{x} \\ (1-B)(1-B^{12})Y_t - \bar{y} \end{bmatrix}$$

where B represents the back shift operator and \bar{x} and \bar{y} represent the means of the differenced series. If the NOCENTER option is specified, the mean differences are not subtracted.

Details: STATESPACE Procedure

Missing Values

The STATESPACE procedure does not support missing values. The procedure uses the first contiguous group of observations with no missing values for any of the VAR statement variables. Observations at the beginning of the data set with missing values for any VAR statement variable are not used or included in the output data set.

Stationarity and Differencing

The state space model used by the STATESPACE procedure assumes that the time series are stationary. Hence, the data should be checked for stationarity. One way to check for stationarity is to plot the series. A graph of series over time can show a time trend or variability changes.

You can also check stationarity by using the sample autocorrelation functions displayed by the ARIMA procedure. The autocorrelation functions of nonstationary series tend to decay slowly. See Chapter 7, “[The ARIMA Procedure](#),” for more information.

Another alternative is to use the STATIONARITY= option in the IDENTIFY statement in PROC ARIMA to apply Dickey-Fuller tests for unit roots in the time series. See Chapter 7, “[The ARIMA Procedure](#),” for more information about Dickey-Fuller unit root tests.

The most popular way to transform a nonstationary series to stationarity is by differencing. Differencing of the time series is specified in the VAR statement. For example, to take a simple first difference of the series X, use this statement:

```
var x(1);
```

In this example, the change in X from one period to the next is analyzed. When the series has a seasonal pattern, differencing at a period equal to the length of the seasonal cycle can be desirable. For example, suppose the variable X is measured quarterly and shows a seasonal cycle over the year. You can use the following statement to analyze the series of changes from the same quarter in the previous year:

```
var x(4);
```

To difference twice, add another differencing period to the list. For example, the following statement analyzes the series of second differences $(X_t - X_{t-1}) - (X_{t-1} - X_{t-2}) = X_t - 2X_{t-1} + X_{t-2}$:

```
var x(1,1);
```

The following statement analyzes the seasonal second difference series:

```
var x(1,4);
```

The series that is being modeled is the 1-period difference of the 4-period difference:

$$(X_t - X_{t-4}) - (X_{t-1} - X_{t-5}) = X_t - X_{t-1} - X_{t-4} + X_{t-5}.$$

Another way to obtain stationary series is to use a regression on time to detrend the data. If the time series has a deterministic linear trend, regressing the series on time produces residuals that should be stationary. The following statements write residuals of X and Y to the variable RX and RY in the output data set DETREND.

```
data a;
  set a;
  t=_n_;
run;

proc reg data=a;
  model x y = t;
  output out=detrend r=rx ry;
run;
```

You then use PROC STATESPACE to forecast the detrended series RX and RY. A disadvantage of this method is that you need to add the trend back to the forecast series in an additional step. A more serious disadvantage of the detrending method is that it assumes a deterministic trend. In practice, most time series appear to have a stochastic rather than a deterministic trend. Differencing is a more flexible and often more appropriate method.

There are several other methods to handle nonstationary time series. For more information and examples, see Brockwell and Davis (1991).

Preliminary Autoregressive Models

After computing the sample autocovariance matrices, PROC STATESPACE fits a sequence of vector autoregressive models. These preliminary autoregressive models are used to estimate the autoregressive order of the process and limit the order of the autocovariances considered in the state vector selection process.

Yule-Walker Equations for Forward and Backward Models

Unlike a univariate autoregressive model, a multivariate autoregressive model has different forms, depending on whether the present observation is being predicted from the past observations or from the future observations.

Let \mathbf{x}_t be the r -component stationary time series given by the VAR statement after differencing and subtracting the vector of sample means. (If the NOCENTER option is specified, the mean is not subtracted.) Let n be the number of observations of \mathbf{x}_t from the input data set.

Let \mathbf{e}_t be a vector white noise sequence with mean vector $\mathbf{0}$ and variance matrix Σ_p , and let \mathbf{n}_t be a vector white noise sequence with mean vector $\mathbf{0}$ and variance matrix Ω_p . Let p be the order of the vector autoregressive model for \mathbf{x}_t .

The forward autoregressive form based on the past observations is written as follows:

$$\mathbf{x}_t = \sum_{i=1}^p \Phi_i^p \mathbf{x}_{t-i} + \mathbf{e}_t$$

The backward autoregressive form based on the future observations is written as follows:

$$\mathbf{x}_t = \sum_{i=1}^p \Psi_i^p \mathbf{x}_{t+i} + \mathbf{n}_t$$

Letting E denote the expected value operator, the autocovariance sequence for the \mathbf{x}_t series, Γ_i , is

$$\Gamma_i = E\mathbf{x}_t \mathbf{x}_{t-i}'$$

The Yule-Walker equations for the autoregressive model that matches the first p elements of the autocovariance sequence are

$$\begin{bmatrix} \Gamma_0 & \Gamma_1 & \cdots & \Gamma_{p-1} \\ \Gamma_1' & \Gamma_0 & \cdots & \Gamma_{p-2} \\ \vdots & \vdots & & \vdots \\ \Gamma_{p-1}' & \Gamma_{p-2}' & \cdots & \Gamma_0 \end{bmatrix} \begin{bmatrix} \Phi_1^p \\ \Phi_2^p \\ \vdots \\ \Phi_p^p \end{bmatrix} = \begin{bmatrix} \Gamma_1 \\ \Gamma_2 \\ \vdots \\ \Gamma_p \end{bmatrix}$$

and

$$\begin{bmatrix} \Gamma_0 & \Gamma_1' & \cdots & \Gamma_{p-1}' \\ \Gamma_1 & \Gamma_0 & \cdots & \Gamma_{p-2}' \\ \vdots & \vdots & & \vdots \\ \Gamma_{p-1} & \Gamma_{p-2} & \cdots & \Gamma_0 \end{bmatrix} \begin{bmatrix} \Psi_1^p \\ \Psi_2^p \\ \vdots \\ \Psi_p^p \end{bmatrix} = \begin{bmatrix} \Gamma_1' \\ \Gamma_2' \\ \vdots \\ \Gamma_p' \end{bmatrix}$$

Here Φ_i^p are the coefficient matrices for the past observation form of the vector autoregressive model, and Ψ_i^p are the coefficient matrices for the future observation form. More information about the Yule-Walker equations in the multivariate setting can be found in Whittle (1963); Ansley and Newbold (1979).

The innovation variance matrices for the two forms can be written as follows:

$$\Sigma_p = \Gamma_0 - \sum_{i=1}^p \Phi_i^p \Gamma_i'$$

$$\Omega_p = \Gamma_0 - \sum_{i=1}^p \Psi_i^p \Gamma_i$$

The autoregressive models are fit to the data by using the preceding Yule-Walker equations with Γ_i replaced by the sample covariance sequence C_i . The covariance matrices are calculated as

$$C_i = \frac{1}{N-1} \sum_{t=i+1}^N \mathbf{x}_t \mathbf{x}_{t-i}'$$

Let $\hat{\Phi}_p$, $\hat{\Psi}_p$, $\hat{\Sigma}_p$, and $\hat{\Omega}_p$ represent the Yule-Walker estimates of Φ_p , Ψ_p , Σ_p , and Ω_p , respectively. These matrices are written to an output data set when the OUTAR= option is specified.

When the PRINTOUT=LONG option is specified, the sequence of matrices $\hat{\Sigma}_p$ and the corresponding correlation matrices are printed. The sequence of matrices $\hat{\Sigma}_p$ is used to compute Akaike information criteria for selection of the autoregressive order of the process.

Akaike Information Criterion

The Akaike information criterion (AIC) is defined as $-2(\text{maximum of log likelihood}) + 2(\text{number of parameters})$. Since the vector autoregressive models are estimates from the Yule-Walker equations, not by maximum likelihood, the exact likelihood values are not available for computing the AIC. However, for the vector autoregressive model the maximum of the log likelihood can be approximated as

$$\ln(L) \approx -\frac{n}{2} \ln(|\hat{\Sigma}_p|)$$

Thus, the AIC for the order p model is computed as

$$AIC_p = n \ln(|\hat{\Sigma}_p|) + 2pr^2$$

You can use the printed AIC array to compute a likelihood ratio test of the autoregressive order. The log-likelihood ratio test statistic for testing the order p model against the order $p-1$ model is

$$-n \ln(|\hat{\Sigma}_p|) + n \ln(|\hat{\Sigma}_{p-1}|)$$

This quantity is asymptotically distributed as a χ^2 with r^2 degrees of freedom if the series is autoregressive of order $p - 1$. It can be computed from the AIC array as

$$AIC_{p-1} - AIC_p + 2r^2$$

You can evaluate the significance of these test statistics with the PROBCHI function in a SAS DATA step or with a χ^2 table.

Determining the Autoregressive Order

Although the autoregressive models can be used for prediction, their primary value is to aid in the selection of a suitable portion of the sample covariance matrix for use in computing canonical correlations. If the multivariate time series \mathbf{x}_t is of autoregressive order p , then the vector of past values to lag p is considered to contain essentially all the information relevant for prediction of future values of the time series.

By default, PROC STATESPACE selects the order p that produces the autoregressive model with the smallest AIC_p . If the value p for the minimum AIC_p is less than the value of the PASTMIN= option, then p is set to the PASTMIN= value. Alternatively, you can use the ARMAX= and PASTMIN= options to force PROC STATESPACE to use an order you select.

Significance Limits for Partial Autocorrelations

The STATESPACE procedure prints a schematic representation of the partial autocorrelation matrices that indicates which partial autocorrelations are significantly greater than or significantly less than 0. Figure 28.11 shows an example of this table.

Figure 28.11 Significant Partial Autocorrelations

The partial autocorrelations are from the sample partial autoregressive matrices $\hat{\Phi}_p^p$. The standard errors used for the significance limits of the partial autocorrelations are computed from the sequence of matrices Σ_p and Ω_p .

Under the assumption that the observed series arises from an autoregressive process of order $p - 1$, the p th sample partial autoregressive matrix $\hat{\Phi}_p^p$ has an asymptotic variance matrix $\frac{1}{n}\Omega_p^{-1} \otimes \Sigma_p$.

The significance limits for $\hat{\Phi}_p^p$ used in the schematic plot of the sample partial autoregressive sequence are derived by replacing Ω_p and Σ_p with their sample estimators to produce the variance estimate, as follows:

$$\widehat{Var}(\hat{\Phi}_p^p) = \left(\frac{1}{n - rp} \right) \hat{\Omega}_p^{-1} \otimes \hat{\Sigma}_p$$

Canonical Correlation Analysis

Given the order p , let \mathbf{p}_t be the vector of current and past values relevant to prediction of \mathbf{x}_{t+1} :

$$\mathbf{p}_t = (\mathbf{x}'_t, \mathbf{x}'_{t-1}, \dots, \mathbf{x}'_{t-p})'$$

Let \mathbf{f}_t be the vector of current and future values:

$$\mathbf{f}_t = (\mathbf{x}'_t, \mathbf{x}'_{t+1}, \dots, \mathbf{x}'_{t+p})'$$

In the canonical correlation analysis, consider submatrices of the sample covariance matrix of \mathbf{p}_t and \mathbf{f}_t . This covariance matrix, \mathbf{V} , has a block Hankel form:

$$\mathbf{V} = \begin{bmatrix} \mathbf{C}_0 & \mathbf{C}'_1 & \mathbf{C}'_2 & \cdots & \mathbf{C}'_p \\ \mathbf{C}'_1 & \mathbf{C}'_2 & \mathbf{C}'_3 & \cdots & \mathbf{C}'_{p+1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{C}'_p & \mathbf{C}'_{p+1} & \mathbf{C}'_{p+2} & \cdots & \mathbf{C}'_{2p} \end{bmatrix}$$

State Vector Selection Process

The canonical correlation analysis forms a sequence of potential state vectors \mathbf{z}_t^j . Examine a sequence \mathbf{f}_t^j of subvectors of \mathbf{f}_t , form the submatrix \mathbf{V}^j that consists of the rows and columns of \mathbf{V} that correspond to the components of \mathbf{f}_t^j , and compute its canonical correlations.

The smallest canonical correlation of \mathbf{V}^j is then used in the selection of the components of the state vector. The selection process is described in the following discussion. For more details about this process, see Akaike (1976).

In the following discussion, the notation $\mathbf{x}_{t+k|t}$ denotes the wide sense conditional expectation (best linear predictor) of \mathbf{x}_{t+k} , given all \mathbf{x}_s with s less than or equal to t . In the notation $x_{i,t+1}$, the first subscript denotes the i th component of \mathbf{x}_{t+1} .

The initial state vector \mathbf{z}_t^1 is set to \mathbf{x}_t . The sequence \mathbf{f}_t^j is initialized by setting

$$\mathbf{f}_t^1 = (\mathbf{z}_t^{1'}, x_{1,t+1|t})' = (\mathbf{x}_t', x_{1,t+1|t})'$$

That is, start by considering whether to add $x_{1,t+1|t}$ to the initial state vector \mathbf{z}_t^1 .

The procedure forms the submatrix \mathbf{V}^1 that corresponds to \mathbf{f}_t^1 and computes its canonical correlations. Denote the smallest canonical correlation of \mathbf{V}^1 as ρ_{min} . If ρ_{min} is significantly greater than 0, $x_{1,t+1|t}$ is added to the state vector.

If the smallest canonical correlation of \mathbf{V}^1 is not significantly greater than 0, then a linear combination of \mathbf{f}_t^1 is uncorrelated with the past, \mathbf{p}_t . Assuming that the determinant of \mathbf{C}_0 is not 0, (that is, no input series is a constant), you can take the coefficient of $x_{1,t+1|t}$ in this linear combination to be 1. Denote the coefficients of \mathbf{z}_t^1 in this linear combination as ℓ . This gives the relationship:

$$x_{1,t+1|t} = \ell' \mathbf{x}_t$$

Therefore, the current state vector already contains all the past information useful for predicting $x_{1,t+1}$ and any greater leads of $x_{1,t}$. The variable $x_{1,t+1|t}$ is not added to the state vector, nor are any terms $x_{1,t+k|t}$ considered as possible components of the state vector. The variable x_1 is no longer active for state vector selection.

The process described for $x_{1,t+1|t}$ is repeated for the remaining elements of \mathbf{f}_t . The next candidate for inclusion in the state vector is the next component of \mathbf{f}_t that corresponds to an active variable. Components of \mathbf{f}_t that correspond to inactive variables that produced a zero ρ_{min} in a previous step are skipped.

Denote the next candidate as $x_{l,t+k|t}$. The vector \mathbf{f}_t^j is formed from the current state vector and $x_{l,t+k|t}$ as follows:

$$\mathbf{f}_t^j = (\mathbf{z}_t^{j'}, x_{l,t+k|t})'$$

The matrix \mathbf{V}^j is formed from \mathbf{f}_t^j and its canonical correlations are computed. The smallest canonical correlation of \mathbf{V}^j is judged to be either greater than or equal to 0. If it is judged to be greater than 0, $x_{l,t+k|t}$ is added to the state vector. If it is judged to be 0, then a linear combination of \mathbf{f}_t^j is uncorrelated with the \mathbf{p}_t , and the variable x_l is now inactive.

The state vector selection process continues until no active variables remain.

Testing Significance of Canonical Correlations

For each step in the canonical correlation sequence, the significance of the smallest canonical correlation ρ_{min} is judged by an information criterion from Akaike (1976). This information criterion is

$$-n \ln(1 - \rho_{min}^2) - \lambda(r(p + 1) - q + 1)$$

where q is the dimension of \mathbf{f}_t^j at the current step, r is the order of the state vector, p is the order of the vector autoregressive process, and λ is the value of the SIGCORR= option. The default is SIGCORR=2. If this information criterion is less than or equal to 0, ρ_{min} is taken to be 0; otherwise, it is taken to be significantly greater than 0. (Do not confuse this information criterion with the AIC.)

Variables in $\mathbf{x}_{t+p|t}$ are not added in the model, even with positive information criterion, because of the singularity of \mathbf{V} . You can force the consideration of more candidate state variables by increasing the size of the \mathbf{V} matrix by specifying a PASTMIN= option value larger than p .

Printing the Canonical Correlations

To print the details of the canonical correlation analysis process, specify the CANCORR option in the PROC STATESPACE statement. The CANCORR option prints the candidate state vectors, the canonical correlations, and the information criteria for testing the significance of the smallest canonical correlation.

Bartlett's χ^2 and its degrees of freedom are also printed when the CANCORR option is specified. The formula used for Bartlett's χ^2 is

$$\chi^2 = -(n - .5(r(p + 1) - q + 1)) \ln(1 - \rho_{min}^2)$$

with $r(p + 1) - q + 1$ degrees of freedom.

Figure 28.12 shows the output of the CANCORR option for the introductory example shown in the “Getting Started: STATESPACE Procedure” on page 2022.

```

Figure 28.12 Canonical Correlations Analysis

The STATESPACE Procedure Canonical Correlations Analysis					
$\mathbf{x}(T;T)$	$\mathbf{y}(T;T)$	$\mathbf{x}(T+1;T)$	Information Criterion	Chi Square	DF
1	1	0.237045	3.566167	11.4505	4

New variables are added to the state vector if the information criteria are positive. In this example, $\mathbf{y}_{t+1|t}$ and $\mathbf{x}_{t+2|t}$ are not added to the state space vector because the information criteria for these models are negative.

If the information criterion is nearly 0, then you might want to investigate models that arise if the opposite decision is made regarding ρ_{min} . This investigation can be accomplished by using a FORM statement to specify part or all of the state vector.

Preliminary Estimates of F

When a candidate variable $x_{l,t+k|t}$ yields a zero ρ_{min} and is not added to the state vector, a linear combination of \mathbf{f}_t^j is uncorrelated with the \mathbf{p}_t . Because of the method used to construct the \mathbf{f}_t^j sequence, the coefficient of $x_{l,t+k|t}$ in \mathbf{l} can be taken as 1. Denote the coefficients of \mathbf{z}_t^j in this linear combination as \mathbf{l} .

This gives the relationship:

$$x_{l,t+k|t} = \mathbf{l}'\mathbf{z}_t^j$$

The vector \mathbf{l} is used as a preliminary estimate of the first r columns of the row of the transition matrix \mathbf{F} corresponding to $x_{l,t+k-1|t}$.

Parameter Estimation

The model is $\mathbf{z}_{t+1} = \mathbf{F}\mathbf{z}_t + \mathbf{G}\mathbf{e}_{t+1}$, where \mathbf{e}_t is a sequence of independent multivariate normal innovations with mean vector $\mathbf{0}$ and variance Σ_{ee} . The observed sequence \mathbf{x}_t composes the first r components of \mathbf{z}_t , and thus $\mathbf{x}_t = \mathbf{H}\mathbf{z}_t$, where \mathbf{H} is the $r \times s$ matrix $[\mathbf{I}_r \ \mathbf{0}]$.

Let \mathbf{E} be the $r \times n$ matrix of innovations:

$$\mathbf{E} = [\mathbf{e}_1 \ \cdots \ \mathbf{e}_n]$$

If the number of observations n is reasonably large, the log likelihood L can be approximated up to an additive constant as follows:

$$L = -\frac{n}{2} \ln(|\Sigma_{ee}|) - \frac{1}{2} \text{trace}(\Sigma_{ee}^{-1} \mathbf{E}\mathbf{E}')$$

The elements of Σ_{ee} are taken as free parameters and are estimated as follows:

$$S_0 = \frac{1}{n} \mathbf{E} \mathbf{E}'$$

Replacing Σ_{ee} by S_0 in the likelihood equation, the log likelihood, up to an additive constant, is

$$L = -\frac{n}{2} \ln(|S_0|)$$

Letting B be the backshift operator, the formal relation between \mathbf{x}_t and \mathbf{e}_t is

$$\begin{aligned} \mathbf{x}_t &= \mathbf{H}(\mathbf{I} - B\mathbf{F})^{-1} \mathbf{G} \mathbf{e}_t \\ \mathbf{e}_t &= (\mathbf{H}(\mathbf{I} - B\mathbf{F})^{-1} \mathbf{G})^{-1} \mathbf{x}_t = \sum_{i=0}^{\infty} \Xi_i \mathbf{x}_{t-i} \end{aligned}$$

Letting C_i be the i th lagged sample covariance of \mathbf{x}_t and neglecting end effects, the matrix S_0 is

$$S_0 = \sum_{i,j=0}^{\infty} \Xi_i C_{-i+j} \Xi_j'$$

For the computation of S_0 , the infinite sum is truncated at the value of the KLAG= option. The value of the KLAG= option should be large enough that the sequence Ξ_i is approximately 0 beyond that point.

Let θ be the vector of free parameters in the \mathbf{F} and \mathbf{G} matrices. The derivative of the log likelihood with respect to the parameter θ is

$$\frac{\partial L}{\partial \theta} = -\frac{n}{2} \text{trace} \left(S_0^{-1} \frac{\partial S_0}{\partial \theta} \right)$$

The second derivative is

$$\frac{\partial^2 L}{\partial \theta \partial \theta'} = \frac{n}{2} \left(\text{trace} \left(S_0^{-1} \frac{\partial S_0}{\partial \theta'} S_0^{-1} \frac{\partial S_0}{\partial \theta} \right) - \text{trace} \left(S_0^{-1} \frac{\partial^2 S_0}{\partial \theta \partial \theta'} \right) \right)$$

Near the maximum, the first term is unimportant and the second term can be approximated to give the following second derivative approximation:

$$\frac{\partial^2 L}{\partial \theta \partial \theta'} \cong -n \text{trace} \left(S_0^{-1} \frac{\partial \mathbf{E}}{\partial \theta} \frac{\partial \mathbf{E}'}{\partial \theta'} \right)$$

The first derivative matrix and this second derivative matrix approximation are computed from the sample covariance matrix C_0 and the truncated sequence Ξ_i . The approximate likelihood function is maximized by a modified Newton-Raphson algorithm that employs these derivative matrices.

The matrix S_0 is used as the estimate of the innovation covariance matrix, Σ_{ee} . The negative of the inverse of the second derivative matrix at the maximum is used as an approximate covariance matrix for the parameter estimates. The standard errors of the parameter estimates printed in the parameter estimates tables are taken

from the diagonal of this covariance matrix. The parameter covariance matrix is printed when the COVB option is specified.

If the data are nearly nonstationary, a better estimate of Σ_{ee} and the other parameters can sometimes be obtained by specifying the RESIDEST option. The RESIDEST option estimates the parameters by using conditional least squares instead of maximum likelihood.

The residuals are computed using the state space equation and the sample mean values of the variables in the model as start-up values. The estimate of S_0 is then computed using the residuals from the i th observation on, where i is the maximum number of times any variable occurs in the state vector. A multivariate Gauss-Marquardt algorithm is used to minimize $|S_0|$. See Harvey (1981a) for a further description of this method.

Forecasting

Given estimates of F , G , and Σ_{ee} , forecasts of x_t are computed from the conditional expectation of z_t .

In forecasting, the parameters F , G , and Σ_{ee} are replaced with the estimates or by values specified in the RESTRICT statement. One-step-ahead forecasting is performed for the observation x_t , where $t \leq n - b$. Here n is the number of observations and b is the value of the BACK= option. For the observation x_t , where $t > n - b$, m -step-ahead forecasting is performed for $m = t - n + b$. The forecasts are generated recursively with the initial condition $z_0 = 0$.

The m -step-ahead forecast of z_{t+m} is $z_{t+m|t}$, where $z_{t+m|t}$ denotes the conditional expectation of z_{t+m} given the information available at time t . The m -step-ahead forecast of x_{t+m} is $x_{t+m|t} = H z_{t+m|t}$, where the matrix $H = [I_r \ 0]$.

Let $\Psi_i = F^i G$. Note that the last $s - r$ elements of z_t consist of the elements of $x_u|t$ for $u > t$.

The state vector z_{t+m} can be represented as

$$z_{t+m} = F^m z_t + \sum_{i=0}^{m-1} \Psi_i e_{t+m-i}$$

Since $e_{t+i|t} = 0$ for $i > 0$, the m -step-ahead forecast $z_{t+m|t}$ is

$$z_{t+m|t} = F^m z_t = F z_{t+m-1|t}$$

Therefore, the m -step-ahead forecast of x_{t+m} is

$$x_{t+m|t} = H z_{t+m|t}$$

The m -step-ahead forecast error is

$$z_{t+m} - z_{t+m|t} = \sum_{i=0}^{m-1} \Psi_i e_{t+m-i}$$

The variance of the m -step-ahead forecast error is

$$V_{z,m} = \sum_{i=0}^{m-1} \Psi_i \Sigma_{ee} \Psi_i'$$

Letting $\mathbf{V}_{z,0} = \mathbf{0}$, the variance of the m -step-ahead forecast error of \mathbf{z}_{t+m} , $\mathbf{V}_{z,m}$, can be computed recursively as follows:

$$\mathbf{V}_{z,m} = \mathbf{V}_{z,m-1} + \mathbf{\Psi}_{m-1} \mathbf{\Sigma}_{ee} \mathbf{\Psi}_{m-1}'$$

The variance of the m -step-ahead forecast error of \mathbf{x}_{t+m} is the $r \times r$ left upper submatrix of $\mathbf{V}_{z,m}$; that is,

$$\mathbf{V}_{x,m} = \mathbf{H} \mathbf{V}_{z,m} \mathbf{H}'$$

Unless the NOCENTER option is specified, the sample mean vector is added to the forecast. When differencing is specified, the forecasts $\mathbf{x}_{t+m|t}$ plus the sample mean vector are integrated back to produce forecasts for the original series.

Let \mathbf{y}_t be the original series specified by the VAR statement, with some 0 values appended that correspond to the unobserved past observations. Let B be the backshift operator, and let $\mathbf{\Delta}(B)$ be the $s \times s$ matrix polynomial in the backshift operator that corresponds to the differencing specified by the VAR statement. The off-diagonal elements of $\mathbf{\Delta}_i$ are 0. Note that $\mathbf{\Delta}_0 = \mathbf{I}_s$, where \mathbf{I}_s is the $s \times s$ identity matrix. Then $\mathbf{z}_t = \mathbf{\Delta}(B)\mathbf{y}_t$.

This gives the relationship

$$\mathbf{y}_t = \mathbf{\Delta}^{-1}(B)\mathbf{z}_t = \sum_{i=0}^{\infty} \mathbf{\Lambda}_i \mathbf{z}_{t-i}$$

where $\mathbf{\Delta}^{-1}(B) = \sum_{i=0}^{\infty} \mathbf{\Lambda}_i B^i$ and $\mathbf{\Lambda}_0 = \mathbf{I}_s$.

The m -step-ahead forecast of \mathbf{y}_{t+m} is

$$\mathbf{y}_{t+m|t} = \sum_{i=0}^{m-1} \mathbf{\Lambda}_i \mathbf{z}_{t+m-i|t} + \sum_{i=m}^{\infty} \mathbf{\Lambda}_i \mathbf{z}_{t+m-i}$$

The m -step-ahead forecast error of \mathbf{y}_{t+m} is

$$\sum_{i=0}^{m-1} \mathbf{\Lambda}_i (\mathbf{z}_{t+m-i} - \mathbf{z}_{t+m-i|t}) = \sum_{i=0}^{m-1} \left(\sum_{u=0}^i \mathbf{\Lambda}_u \mathbf{\Psi}_{i-u} \right) \mathbf{e}_{t+m-i}$$

Letting $\mathbf{V}_{y,0} = \mathbf{0}$, the variance of the m -step-ahead forecast error of \mathbf{y}_{t+m} , $\mathbf{V}_{y,m}$, is

$$\begin{aligned} \mathbf{V}_{y,m} &= \sum_{i=0}^{m-1} \left(\sum_{u=0}^i \mathbf{\Lambda}_u \mathbf{\Psi}_{i-u} \right) \mathbf{\Sigma}_{ee} \left(\sum_{u=0}^i \mathbf{\Lambda}_u \mathbf{\Psi}_{i-u} \right)' \\ &= \mathbf{V}_{y,m-1} + \left(\sum_{u=0}^{m-1} \mathbf{\Lambda}_u \mathbf{\Psi}_{m-1-u} \right) \mathbf{\Sigma}_{ee} \left(\sum_{u=0}^{m-1} \mathbf{\Lambda}_u \mathbf{\Psi}_{m-1-u} \right)' \end{aligned}$$

Relation of ARMA and State Space Forms

Every state space model has an ARMA representation, and conversely every ARMA model has a state space representation. This section discusses this equivalence. The following material is adapted from Akaike (1974), where there is a more complete discussion. Pham (1978) also contains a discussion of this material.

Suppose you are given the following ARMA model:

$$\Phi(B)\mathbf{x}_t = \Theta(B)\mathbf{e}_t$$

or, in more detail,

$$\mathbf{x}_t - \Phi_1\mathbf{x}_{t-1} - \cdots - \Phi_p\mathbf{x}_{t-p} = \mathbf{e}_t + \Theta_1\mathbf{e}_{t-1} + \cdots + \Theta_q\mathbf{e}_{t-q} \quad (1)$$

where \mathbf{e}_t is a sequence of independent multivariate normal random vectors with mean $\mathbf{0}$ and variance matrix Σ_{ee} , B is the backshift operator ($B\mathbf{x}_t = \mathbf{x}_{t-1}$), $\Phi(B)$ and $\Theta(B)$ are matrix polynomials in B , and \mathbf{x}_t is the observed process.

If the roots of the determinantal equation $|\Phi(B)| = 0$ are outside the unit circle in the complex plane, the model can also be written as

$$\mathbf{x}_t = \Phi^{-1}(B)\Theta(B)\mathbf{e}_t = \sum_{i=0}^{\infty} \Psi_i \mathbf{e}_{t-i}$$

The Ψ_i matrices are known as the impulse response matrices and can be computed as $\Phi^{-1}(B)\Theta(B)$.

You can assume $p > q$ since, if this is not initially true, you can add more terms Φ_i that are identically 0 without changing the model.

To write this set of equations in a state space form, proceed as follows. Let $\mathbf{x}_{t+i|t}$ be the conditional expectation of \mathbf{x}_{t+i} given \mathbf{x}_w for $w \leq t$. The following relations hold:

$$\mathbf{x}_{t+i|t} = \sum_{j=i}^{\infty} \Psi_j \mathbf{e}_{t+i-j}$$

$$\mathbf{x}_{t+i|t+1} = \mathbf{x}_{t+i|t} + \Psi_{i-1}\mathbf{e}_{t+1}$$

However, from equation (1) you can derive the following relationship:

$$\mathbf{x}_{t+p|t} = \Phi_1\mathbf{x}_{t+p-1|t} + \cdots + \Phi_p\mathbf{x}_t \quad (2)$$

Hence, when $i = p$, you can substitute for $\mathbf{x}_{t+p|t}$ in the right-hand side of equation (2) and close the system of equations.

This substitution results in the following model in the state space form $\mathbf{z}_{t+1} = \mathbf{F}\mathbf{z}_t + \mathbf{G}\mathbf{e}_{t+1}$:

$$\begin{bmatrix} \mathbf{x}_{t+1} \\ \mathbf{x}_{t+2|t+1} \\ \vdots \\ \mathbf{x}_{t+p|t+1} \end{bmatrix} = \begin{bmatrix} 0 & \mathbf{I} & 0 & \cdots & 0 \\ 0 & 0 & \mathbf{I} & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \Phi_p & \Phi_{p-1} & \cdots & \Phi_1 & 0 \end{bmatrix} \begin{bmatrix} \mathbf{x}_t \\ \mathbf{x}_{t+1|t} \\ \vdots \\ \mathbf{x}_{t+p-1|t} \end{bmatrix} + \begin{bmatrix} \mathbf{I} \\ \Psi_1 \\ \vdots \\ \Psi_{p-1} \end{bmatrix} \mathbf{e}_{t+1}$$

Note that the state vector \mathbf{z}_t is composed of conditional expectations of \mathbf{x}_t and the first r components of \mathbf{z}_t are equal to \mathbf{x}_t .

The state space form can be cast into an ARMA form by solving the system of difference equations for the first r components.

When converting from an ARMA form to a state space form, you can generate a state vector larger than needed; that is, the state space model might not be a minimal representation. When going from a state space form to an ARMA form, you can have nontrivial common factors in the autoregressive and moving average operators that yield an ARMA model larger than necessary.

If the state space form used is not a minimal representation, some but not all components of $\mathbf{x}_{t+i|t}$ might be linearly dependent. This situation corresponds to $[\Phi_p \Theta_{p-1}]$ being of less than full rank when $\Phi(B)$ and $\Theta(B)$ have no common nontrivial left factors. In this case, \mathbf{z}_t consists of a subset of the possible components of $[\mathbf{x}_{t+i|t}]$ $i = 1, 2, \dots, p - 1$. However, once a component of $\mathbf{x}_{t+i|t}$ (for example, the j th one) is linearly dependent on the previous conditional expectations, then all subsequent j th components of $\mathbf{x}_{t+k|t}$ for $k > i$ must also be linearly dependent. Note that in this case, equivalent but seemingly different structures can arise if the order of the components within \mathbf{x}_t is changed.

OUT= Data Set

The forecasts are contained in the output data set specified by the OUT= option in the PROC STATESPACE statement. The OUT= data set contains the following variables:

- the BY variables
- the ID variable
- the VAR statement variables. These variables contain the actual values from the input data set.
- FOR i , numeric variables that contain the forecasts. The variable FOR i contains the forecasts for the i th variable in the VAR statement list. Forecasts are one-step-ahead predictions until the end of the data or until the observation specified by the BACK= option.
- RES i , numeric variables that contain the residual for the forecast of the i th variable in the VAR statement list. For forecast observations, the actual values are missing and the RES i variables contain missing values.
- STD i , numeric variables that contain the standard deviation for the forecast of the i th variable in the VAR statement list. The values of the STD i variables can be used to construct univariate confidence limits for the corresponding forecasts. However, such confidence limits do not take into account the covariance of the forecasts.

OUTAR= Data Set

The OUTAR= data set contains the estimates of the preliminary autoregressive models. The OUTAR= data set contains the following variables:

- ORDER, a numeric variable that contains the order p of the autoregressive model that the observation represents

- AIC, a numeric variable that contains the value of the information criterion AIC_p
- SIGF*l*, numeric variables that contain the estimate of the innovation covariance matrices for the forward autoregressive models. The variable SIGF*l* contains the *l*th column of $\widehat{\Sigma}_p$ in the observations with ORDER=*p*.
- SIGB*l*, numeric variables that contain the estimate of the innovation covariance matrices for the backward autoregressive models. The variable SIGB*l* contains the *l*th column of $\widehat{\Omega}_p$ in the observations with ORDER=*p*.
- FOR*k*_*l*, numeric variables that contain the estimates of the autoregressive parameter matrices for the forward models. The variable FOR*k*_*l* contains the *l*th column of the lag *k* autoregressive parameter matrix $\widehat{\Phi}_k^p$ in the observations with ORDER=*p*.
- BACK*k*_*l*, numeric variables that contain the estimates of the autoregressive parameter matrices for the backward models. The variable BACK*k*_*l* contains the *l*th column of the lag *k* autoregressive parameter matrix $\widehat{\Psi}_k^p$ in the observations with ORDER=*p*.

The estimates for the order *p* autoregressive model can be selected as those observations with ORDER=*p*. Within these observations, the *k*,*l*th element of Φ_i^p is given by the value of the FOR*i*_*l* variable in the *k*th observation. The *k*,*l*th element of Ψ_i^p is given by the value of BAC*i*_*l* variable in the *k*th observation. The *k*,*l*th element of Σ_p is given by SIGF*l* in the *k*th observation. The *k*,*l*th element of Ω_p is given by SIGB*l* in the *k*th observation.

Table 28.2 shows an example of the OUTAR= data set, with ARMAX=3 and \mathbf{x}_t of dimension 2. In Table 28.2, (*i*, *j*) indicate the *i*,*j*th element of the matrix.

The estimated autoregressive parameters can be used in the IML procedure to obtain autoregressive estimates of the spectral density function or forecasts based on the autoregressive models.

OUTMODEL= Data Set

The OUTMODEL= data set contains the estimates of the \mathbf{F} and \mathbf{G} matrices and their standard errors, the names of the components of the state vector, and the estimates of the innovation covariance matrix. The variables contained in the OUTMODEL= data set are as follows:

- the BY variables
- STATEVEC, a character variable that contains the name of the component of the state vector corresponding to the observation. The STATEVEC variable has the value STD for standard deviations observations, which contain the standard errors for the estimates given in the preceding observation.
- F_j, numeric variables that contain the columns of the \mathbf{F} matrix. The variable F_j contains the jth column of \mathbf{F} . The number of F_j variables is equal to the value of the DIMMAX= option. If the model is of smaller dimension, the extraneous variables are set to missing.
- G_j, numeric variables that contain the columns of the \mathbf{G} matrix. The variable G_j contains the jth column of \mathbf{G} . The number of G_j variables is equal to r , the dimension of \mathbf{x}_t given by the number of variables in the VAR statement.
- SIG_j, numeric variables that contain the columns of the innovation covariance matrix. The variable SIG_j contains the jth column of Σ_{ee} . There are r variables SIG_j.

Table 28.3 shows an example of the OUTMODEL= data set, with $\mathbf{x}_t = (x_t, y_t)'$, $\mathbf{z}_t = (x_t, y_t, x_{t+1}|t)'$, and DIMMAX=4. In Table 28.3, $F_{i,j}$ and $G_{i,j}$ are the i,j th elements of \mathbf{F} and \mathbf{G} respectively. Note that all elements for F_4 are missing because \mathbf{F} is a 3×3 matrix.

Printed Output

The printed output produced by the STATESPACE procedure includes the following:

1. descriptive statistics, which include the number of observations used, the names of the variables, their means and standard deviations (Std), and the differencing operations used
2. the Akaike information criteria for the sequence of preliminary autoregressive models

3. if the PRINTOUT=LONG option is specified, the sample autocovariance matrices of the input series at various lags
4. if the PRINTOUT=LONG option is specified, the sample autocorrelation matrices of the input series
5. a schematic representation of the autocorrelation matrices, showing the significant autocorrelations
6. if the PRINTOUT=LONG option is specified, the partial autoregressive matrices. (These are Φ_p^p as described in the section “[Preliminary Autoregressive Models](#)” on page 2041.)
7. a schematic representation of the partial autocorrelation matrices, showing the significant partial autocorrelations
8. the Yule-Walker estimates of the autoregressive parameters for the autoregressive model with the minimum AIC
9. if the PRINTOUT=LONG option is specified, the autocovariance matrices of the residuals of the minimum AIC model. This is the sequence of estimated innovation variance matrices for the solutions of the Yule-Walker equations.
10. if the PRINTOUT=LONG option is specified, the autocorrelation matrices of the residuals of the minimum AIC model
11. If the CANCELL option is specified, the canonical correlations analysis for each potential state vector considered in the state vector selection process. This includes the potential state vector, the canonical correlations, the information criterion for the smallest canonical correlation, Bartlett’s χ^2 statistic (“Chi Square”) for the smallest canonical correlation, and the degrees of freedom of Bartlett’s χ^2 .
12. the components of the chosen state vector
13. the preliminary estimate of the transition matrix, \mathbf{F} , the input matrix, \mathbf{G} , and the variance matrix for the innovations, Σ_{ee}
14. if the ITPRINT option is specified, the iteration history of the likelihood maximization. For each iteration, this shows the iteration number, the number of step halvings, the determinant of the innovation variance matrix, the damping factor Lambda, and the values of the parameters.
15. the state vector, printed again to aid interpretation of the following listing of \mathbf{F} and \mathbf{G}
16. the final estimate of the transition matrix \mathbf{F}
17. the final estimate of the input matrix \mathbf{G}
18. the final estimate of the variance matrix for the innovations Σ_{ee}
19. a table that lists the estimates of the free parameters in \mathbf{F} and \mathbf{G} and their standard errors and t statistics
20. if the COVB option is specified, the covariance matrix of the parameter estimates
21. if the COVB option is specified, the correlation matrix of the parameter estimates
22. if the PRINT option is specified, the forecasts and their standard errors

ODS Table Names

PROC STATESPACE assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 28.4 ODS Tables Produced in PROC STATESPACE

ODS Table Name	Description	Option
NObs	number of observations	default
Summary	simple summary statistics table	default
InfoCriterion	information criterion table	default
CovLags	covariance matrices of input series	PRINTOUT=LONG
CorrLags	correlation matrices of input series	PRINTOUT=LONG
PartialAR	partial autoregressive matrices	PRINTOUT=LONG
YWEstimates	Yule-Walker estimates for minimum AIC	default
CovResiduals	covariance of residuals	PRINTOUT=LONG
CorrResiduals	residual correlations from AR models	PRINTOUT=LONG
StateVector	state vector table	default
CorrGraph	schematic representation of correlations	default
TransitionMatrix	transition matrix	default
InputMatrix	input matrix	default
VarInnov	variance matrix for the innovation	default
CovB	covariance of parameter estimates	COVB
CorrB	correlation of parameter estimates	COVB
CanCorr	canonical correlation analysis	CANCORR
IterHistory	iterative fitting table	ITPRINT
ParameterEstimates	parameter estimates table	default
Forecasts	forecasts table	PRINT
ConvergenceStatus	convergence status table	default

Examples: STATESPACE Procedure

Example 28.1: Series J from Box and Jenkins

This example analyzes the gas furnace data (series J) from Box and Jenkins. (The data are not shown; see Box and Jenkins (1976) for the data.)

First, a model is selected and fit automatically using the following statements.

```

title1 'Gas Furnace Data';
title2 'Box & Jenkins Series J';
title3 'Automatically Selected Model';

proc statespace data=seriesj cancorr;
  var x y;
run;

```

The results for the automatically selected model are shown in [Output 28.1.1](#).

Output 28.1.1 Results for Automatically Selected Model

G(5,2)	1.353204	0.091388	14.81

The two series are believed to have a transfer function relation with the gas rate (variable X) as the input and the CO₂ concentration (variable Y) as the output. Since the parameter estimates shown in [Output 28.1.1](#) support this kind of model, the model is reestimated with the feedback parameters restricted to 0. The following statements fit the transfer function (no feedback) model.

```

title3 'Transfer Function Model';
proc statespace data=seriesj printout=none;
  var x y;
  restrict f(3,2)=0 f(3,4)=0
           g(3,2)=0 g(4,1)=0 g(5,1)=0;
run;

```

The last two pages of the output are shown in [Output 28.1.8](#).

Overview: SYSLIN Procedure

The SYSLIN procedure estimates parameters in an interdependent system of linear regression equations.

Ordinary least squares (OLS) estimates are biased and inconsistent when current period endogenous variables appear as regressors in other equations in the system. The errors of a set of related regression equations are often correlated, and the efficiency of the estimates can be improved by taking these correlations into account. The SYSLIN procedure provides several techniques that produce consistent and asymptotically efficient estimates for systems of regression equations.

The SYSLIN procedure provides the following estimation methods:

- ordinary least squares (OLS)
- two-stage least squares (2SLS)
- limited information maximum likelihood (LIML)
- K-class
- seemingly unrelated regressions (SUR)
- iterated seemingly unrelated regressions (ITSUR)
- three-stage least squares (3SLS)
- iterated three-stage least squares (IT3SLS)
- full information maximum likelihood (FIML)
- minimum expected loss (MELO)

Other features of the SYSLIN procedure enable you to:

- impose linear restrictions on the parameter estimates

- test linear hypotheses about the parameters
- write predicted and residual values to an output SAS data set
- write parameter estimates to an output SAS data set
- write the crossproducts matrix (SSCP) to an output SAS data set
- use raw data, correlations, covariances, or cross products as input

Getting Started: SYSLIN Procedure

This section introduces the use of the SYSLIN procedure. The problem of dependent regressors is introduced using a supply and demand example. This section explains the terminology used for variables in a system of regression equations and introduces the SYSLIN procedure statements for declaring the roles the variables play. The syntax used for the different estimation methods and the output produced is shown.

An Example Model

In simultaneous systems of equations, endogenous variables are determined jointly rather than sequentially. Consider the following supply and demand functions for some product:

$$Q_D = a_1 + b_1 P + c_1 Y + d_1 S + \epsilon_1 \text{ (demand)}$$

$$Q_S = a_2 + b_2 P + c_2 U + \epsilon_2 \text{ (supply)}$$

$$Q = Q_D = Q_S \text{ (market equilibrium)}$$

The variables in this system are as follows:

Q_D	quantity demanded
Q_S	quantity supplied
Q	the observed quantity sold, which equates quantity supplied and quantity demanded in equilibrium
P	price per unit
Y	income
S	price of substitutes
U	unit cost
ϵ_1	the random error term for the demand equation
ϵ_2	the random error term for the supply equation

In this system, quantity demanded depends on price, income, and the price of substitutes. Consumers normally purchase more of a product when prices are lower and when income and the price of substitute goods are higher. Quantity supplied depends on price and the unit cost of production. Producers supply more when price is high and when unit cost is low. The actual price and quantity sold are determined jointly by the values that equate demand and supply.

Since price and quantity are jointly endogenous variables, both structural equations are necessary to adequately describe the observed values. A critical assumption of OLS is that the regressors are uncorrelated with the residual. When current endogenous variables appear as regressors in other equations (endogenous variables depend on each other), this assumption is violated and the OLS parameter estimates are biased and inconsistent. The bias caused by the violated assumptions is called *simultaneous equation bias*. Neither the demand nor supply equation can be estimated consistently by OLS.

Variables in a System of Equations

Before explaining how to use the SYSLIN procedure, it is useful to define some terms. The variables in a system of equations can be classified as follows:

- *Endogenous variables*, which are also called *jointly dependent* or *response variables*, are the variables determined by the system. Endogenous variables can also appear on the right-hand side of equations.
- *Exogenous variables* are independent variables that do not depend on any of the endogenous variables in the system.
- *Predetermined variables* include both the exogenous variables and *lagged endogenous variables*, which are past values of endogenous variables determined at previous time periods. PROC SYSLIN does not compute lagged values; any lagged endogenous variables must be computed in a preceding DATA step.
- *Instrumental variables* are predetermined variables used in obtaining predicted values for the current period endogenous variables by a first-stage regression. The use of instrumental variables characterizes estimation methods such as two-stage least squares and three-stage least squares. Instrumental variables estimation methods substitute these first-stage predicted values for endogenous variables when they appear as regressors in model equations.

Using PROC SYSLIN

First specify the input data set and estimation method in the PROC SYSLIN statement. If any model uses dependent regressors, and you are using an instrumental variables regression method, declare the dependent regressors with an ENDOGENOUS statement and declare the instruments with an INSTRUMENTS statement. Next, use MODEL statements to specify the structural equations of the system.

The use of different estimation methods is shown by the following examples. These examples use the simulated dataset WORK.IN given below.

```
data in;
  label q = "Quantity"
        p = "Price"
        s = "Price of Substitutes"
        y = "Income"
        u = "Unit Cost";
  drop i e1 e2;
  p = 0; q = 0;
  do i = 1 to 60;
    y = 1 + .05*i + .15*rannor(123);
    u = 2          + .05*rannor(123) + .05*rannor(123);
    s = 4 - .001*(i-10)*(i-110) + .5*rannor(123);
    e1 = .15 * rannor(123);
    e2 = .15 * rannor(123);
    demandx = 1 + .3 * y + .35 * s + e1;
    supplyx = -1 - 1 * u + e2 - .4*e1;
    q = 1.4/2.15 * demandx + .75/2.15 * supplyx;
    p = ( - q + supplyx ) / -1.4;
    output;
  end;
run;
```

OLS Estimation

PROC SYSLIN performs OLS regression if you do not specify a method of estimation in the PROC SYSLIN statement. OLS does not use instruments, so the ENDOGENOUS and INSTRUMENTS statements can be omitted.

The following statements estimate the supply and demand model shown previously:

```
proc syslin data=in;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

The PROC SYSLIN output for the demand equation is shown in [Figure 29.1](#), and the output for the supply equation is shown in [Figure 29.2](#).

u	1	-1.07757	0.234150	-4.60	<.0001	Unit Cost

For each MODEL statement, the output first shows the model label and dependent variable name and label. This is followed by an analysis-of-variance table for the model, which shows the model, error, and total mean squares, and an F test for the no-regression hypothesis. Next, the procedure prints the root mean squared error, dependent variable mean and coefficient of variation, and the R^2 and adjusted R^2 statistics.

Finally, the table of parameter estimates shows the estimated regression coefficients, standard errors, and t tests. You would expect the price coefficient in a demand equation to be negative. However, note that the OLS estimate of the price coefficient P in the demand equation (0.1233) has a positive sign. This could be caused by simultaneous equation bias.

Two-Stage Least Squares Estimation

In the supply and demand model, P is an endogenous variable, and consequently the OLS estimates are biased. The following example estimates this model using two-stage least squares.

```
proc syslin data=in 2sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

The 2SLS option in the PROC SYSLIN statement specifies the two-stage least squares method. The ENDOGENOUS statement specifies that P is an endogenous regressor for which first-stage predicted values are substituted. You need to declare an endogenous variable in the ENDOGENOUS statement only if it is used as a regressor; thus although Q is endogenous in this model, it is not necessary to list it in the ENDOGENOUS statement.

Usually, all predetermined variables that appear in the system are used as instruments. The INSTRUMENTS statement specifies that the exogenous variables Y, U, and S are used as instruments for the first-stage regression to predict P.

The 2SLS results are shown in Figure 29.3 and Figure 29.4. The first-stage regressions are not shown. To see the first-stage regression results, use the FIRST option in the PROC SYSLIN statement.

u	1	-1.14623	0.243491	-4.71	<.0001	Unit Cost

The 2SLS output is similar in form to the OLS output. However, the 2SLS results are based on predicted values for the endogenous regressors from the first stage instrumental regressions. This makes the analysis-of-variance table and the R^2 statistics difficult to interpret. See the sections “ANOVA Table for Instrumental Variables Methods” on page 2098 and “The R-Square Statistics” on page 2099 for details.

Note that, unlike the OLS results, the 2SLS estimate for the P coefficient in the demand equation (−1.115) is negative.

LIML, K-Class, and MELO Estimation

To obtain limited information maximum likelihood, general K-class, or minimum expected loss estimates, use the ENDOGENOUS, INSTRUMENTS, and MODEL statements as in the 2SLS case but specify the LIML, K=, or MELO option instead of 2SLS in the PROC SYSLIN statement. The following statements show this for K-class estimation.

```
proc syslin data=in k=.5;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

For more information about these estimation methods, see the section “Estimation Methods” on page 2096 and consult econometrics textbooks.

SUR, 3SLS, and FIML Estimation

In a multivariate regression model, the errors in different equations might be correlated. In this case, the efficiency of the estimation might be improved by taking these cross-equation correlations into account.

Seemingly Unrelated Regression

Seemingly unrelated regression (SUR), also called joint generalized least squares (JGLS) or Zellner estimation, is a generalization of OLS for multi-equation systems. Like OLS, the SUR method assumes that all the regressors are independent variables, but SUR uses the correlations among the errors in different equations to improve the regression estimates. The SUR method requires an initial OLS regression to compute residuals. The OLS residuals are used to estimate the cross-equation covariance matrix.

The SUR option in the PROC SYSLIN statement specifies seemingly unrelated regression, as shown in the following statements:

```
proc syslin data=in sur;
    demand: model q = p y s;
    supply: model q = p u;
run;
```

INSTRUMENTS and ENDOGENOUS statements are not needed for SUR, because the SUR method assumes there are no endogenous regressors. For SUR to be effective, the models must use different regressors. SUR produces the same results as OLS unless the model contains at least one regressor not used in the other equations.

Three-Stage Least Squares

The three-stage least squares method generalizes the two-stage least squares method to take into account the correlations between equations in the same way that SUR generalizes OLS. Three-stage least squares requires three steps: first-stage regressions to get predicted values for the endogenous regressors; a two-stage least squares step to get residuals to estimate the cross-equation correlation matrix; and the final 3SLS estimation step.

The 3SLS option in the PROC SYSLIN statement specifies the three-stage least squares method, as shown in the following statements.

```
proc syslin data=in 3sls;
    endogenous p;
    instruments y u s;
    demand: model q = p y s;
    supply: model q = p u;
run;
```

The 3SLS output begins with a two-stage least squares regression to estimate the cross-model correlation matrix. This output is the same as the 2SLS results shown in [Figure 29.3](#) and [Figure 29.4](#), and is not repeated here. The next part of the 3SLS output prints the cross-model correlation matrix computed from the 2SLS residuals. This output is shown in [Figure 29.5](#) and includes the cross-model covariances, correlations, the inverse of the correlation matrix, and the inverse covariance matrix.

Parameter Estimates						
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t	Variable Label
Intercept	1	-0.51878	0.490999	-1.06	0.2952	Intercept
p	1	1.333080	0.059271	22.49	<.0001	Price
u	1	-1.14623	0.243491	-4.71	<.0001	Unit Cost

This output first prints the system weighted mean squared error and system weighted R^2 statistics. The system weighted MSE and system weighted R^2 measure the fit of the joint model obtained by stacking all the models together and performing a single regression with the stacked observations weighted by the inverse of the model error variances. See the section “[The R-Square Statistics](#)” on page 2099 for details.

Next, the table of 3SLS parameter estimates for each model is printed. This output has the same form as for the other estimation methods.

Note that, in some cases, the 3SLS and 2SLS results can be the same. Such a case could arise because of the same principle that causes OLS and SUR results to be identical, unless an equation includes a regressor not used in the other equations of the system. However, the application of this principle is more complex when instrumental variables are used. When all the exogenous variables are used as instruments, linear combinations of all the exogenous variables appear in the third-stage regressions through substitution of first-stage predicted values.

In this example, 3SLS produces different (and, it is hoped, more efficient) estimates for the demand equation. However, the 3SLS and 2SLS results for the supply equation are the same. This is because the supply equation has one endogenous regressor and one exogenous regressor not used in other equations. In contrast, the demand equation has fewer endogenous regressors than exogenous regressors not used in other equations in the system.

Full Information Maximum Likelihood

The FIML option in the PROC SYSLIN statement specifies the full information maximum likelihood method, as shown in the following statements.

```

proc syslin data=in fiml;
  endogenous p q;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
run;

```

The FIML results are shown in Figure 29.7.

Computing Reduced Form Estimates

A system of structural equations with endogenous regressors can be represented as functions of only the predetermined variables. For this to be possible, there must be as many equations as endogenous variables. If

there are more endogenous variables than regression models, you can use IDENTITY statements to complete the system. See the section “[Reduced Form Estimates](#)” on page 2101 for details.

The REDUCED option in the PROC SYSLIN statement prints reduced form estimates. The following statements show this by using the 3SLS estimates of the structural parameters.

```
proc syslin data=in 3sls reduced;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

The first four pages of this output were as shown previously and are not repeated here. (See [Figure 29.3](#), [Figure 29.4](#), [Figure 29.5](#), and [Figure 29.6](#).) The final page of the output from this example contains the reduced form coefficients from the 3SLS structural estimates, as shown in [Figure 29.8](#).

Restricting Parameter Estimates

You can impose restrictions on the parameter estimates with RESTRICT and SRESTRICT statements. The RESTRICT statement imposes linear restrictions on parameters in the equation specified by the preceding MODEL statement. The SRESTRICT statement imposes linear restrictions that relate parameters in different models.

To impose restrictions involving parameters in different equations, use the SRESTRICT statement. Specify the parameters in the linear hypothesis as *model-label.regressor-name*. (If the MODEL statement does not have a label, you can use the dependent variable name as the label for the model, provided the dependent variable uniquely labels the model.)

Tests for the significance of the restrictions are printed when RESTRICT or SRESTRICT statements are used. You can label RESTRICT and SRESTRICT statements to identify the restrictions in the output.

The RESTRICT statement in the following example restricts the price coefficient in the demand equation to equal 0.015. The SRESTRICT statement restricts the estimate of the income coefficient in the demand equation to be 0.01 times the estimate of the unit cost coefficient in the supply equation.

```
proc syslin data=in 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  peq015: restrict p = .015;
  supply: model q = p u;
  yeq01u: srestrict demand.y = .01 * supply.u;
run;
```

The restricted estimation results are shown in Figure 29.9.

Parameter Estimates						
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t	Variable Label
RESTRICT	-1	342.3605	38.12094	8.98	<.0001	YEQ01U

The standard error for P in the demand equation is 0, since the value of the P coefficient was specified by the RESTRICT statement and not estimated from the data. The “Parameter Estimates” table for the demand equation contains an additional row for the restriction specified by the RESTRICT statement. The parameter estimate for the restriction is the value of the Lagrange multiplier used to impose the restriction. The restriction is highly significant ($t = 6.777$), which means that the data are not consistent with the restriction, and the model does not fit as well with the restriction imposed. See the section “[RESTRICT Statement](#)” on page 2090 for details.

Following the “Parameter Estimates” table for the supply equation, the results for the cross model restrictions are printed. This shows that the restriction specified by the SRESTRICT statement is not consistent with the data ($t = 8.98$). See the section “[SRESTRICT Statement](#)” on page 2091 for details.

Testing Parameters

You can test linear hypotheses about the model parameters with TEST and STEST statements. The TEST statement tests hypotheses about parameters in the equation specified by the preceding MODEL statement. The STEST statement tests hypotheses that relate parameters in different models.

For example, the following statements test the hypothesis that the price coefficient in the demand equation is equal to 0.015.

```
proc syslin data=in 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  test_1: test p = .015;
  supply: model q = p u;
run;
```

The TEST statement results are shown in [Figure 29.10](#). This reports an F test for the hypothesis specified by the TEST statement. In this case, the F statistic is 6.79 (3.879/.571) with 1 and 113 degrees of freedom. The

p value for this F statistic is 0.0104, which indicates that the hypothesis tested is almost but not quite rejected at the 0.01 level. See the section “[TEST Statement](#)” on page 2094 for details.

Figure 29.10 TEST Statement Results

The SYSLIN Procedure

Test Results						
Num DF	Den DF	F Value	Pr > F	Label		
1	113	6.79	0.0104	TEST_1		

To test hypotheses that involve parameters in different equations, use the **STEST** statement. Specify the parameters in the linear hypothesis as *model-label.regressor-name*. (If the **MODEL** statement does not have a label, you can use the dependent variable name as the label for the model, provided the dependent variable uniquely labels the model.)

For example, the following statements test the hypothesis that the income coefficient in the demand equation is 0.01 times the unit cost coefficient in the supply equation:

```
proc syslin data=in 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
  stest1: stest demand.y = .01 * supply.u;
run;
```

The **STEST** statement results are shown in [Figure 29.11](#). The form and interpretation of the **STEST** statement results are like the **TEST** statement results. In this case, the F test produces a p value less than 0.0001, and strongly rejects the hypothesis tested. See the section “[STEST Statement](#)” on page 2093 for details.

You can combine TEST and STEST statements with RESTRICT and SRESTRICT statements to perform hypothesis tests for restricted models. Of course, the validity of the TEST and STEST statement results depends on the correctness of any restrictions you impose on the estimates.

Saving Residuals and Predicted Values

You can store predicted values and residuals from the estimated models in a SAS data set. Specify the `OUT=` option in the `PROC SYSLIN` statement and use the `OUTPUT` statement to specify names for new variables to contain the predicted and residual values.

For example, the following statements store the predicted quantity from the supply and demand equations in a data set `PRED`:

```
proc syslin data=in out=pred 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  output predicted=q_demand;
  supply: model q = p u;
  output predicted=q_supply;
run;
```

Plotting Residuals

You can plot the residuals against the regressors by using the `PROC SGPLOT`. For example, the following statements plot the 2SLS residuals for the demand model against price, income, and price of substitutes.

```
proc syslin data=in 2sls out=out;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  output residual=residual_q;
run;

proc sgplot data=out;
  scatter x=p y=residual_q;
  refline 0 / axis=y;
run;

proc sgplot data=out;
  scatter x=y y=residual_q;
  refline 0 / axis=y;
run;

proc sgplot data=out;
  scatter x=s y=residual_q;
  refline 0 / axis=y;
run;
```

The plot for income is shown in [Figure 29.12](#). The other plots are not shown.

Figure 29.12 Plot of Residuals against Income

Syntax: SYSLIN Procedure

The SYSLIN procedure uses the following statements:

```

PROC SYSLIN options ;
  BY variables ;
  ENDOGENOUS variables ;
  IDENTITY identities ;
  INSTRUMENTS variables ;
  MODEL response = regressors / options ;
  OUTPUT PREDICTED= variable RESIDUAL= variable ;
  RESTRICT restrictions ;
  SRESTRICT restrictions ;
  STEST equations ;
  TEST equations ;
  VAR variables ;
  WEIGHT variable ;

```

Functional Summary

The SYSLIN procedure statements and options are summarized in the following table.

Description	Statement	Option
Data Set Options		
specify the input data set	PROC SYSLIN	DATA=
specify the output data set	PROC SYSLIN	OUT=
write parameter estimates to an output data set	PROC SYSLIN	OUTEST=
write covariances to the OUTEST= data set	PROC SYSLIN	OUTCOV OUTCOV3
write the SSCP matrix to an output data set	PROC SYSLIN	OUTSSCP=
Estimation Method Options		
specify full information maximum likelihood estimation	PROC SYSLIN	FIML
specify iterative SUR estimation	PROC SYSLIN	ITSUR
specify iterative 3SLS estimation	PROC SYSLIN	IT3SLS
specify K-class estimation	PROC SYSLIN	K=
specify limited information maximum likelihood estimation	PROC SYSLIN	LIML
specify minimum expected loss estimation	PROC SYSLIN	MELO
specify ordinary least squares estimation	PROC SYSLIN	OLS
specify seemingly unrelated estimation	PROC SYSLIN	SUR
specify two-stage least squares estimation	PROC SYSLIN	2SLS
specify three-stage least squares estimation	PROC SYSLIN	3SLS
specify Fuller's modification to LIML	PROC SYSLIN	ALPHA=
specify convergence criterion	PROC SYSLIN	CONVERGE=
specify maximum number of iterations	PROC SYSLIN	MAXIT=
use diagonal of S instead of S	PROC SYSLIN	SDIAG
exclude RESTRICT statements in final stage	PROC SYSLIN	NOINCLUDE
specify criterion for testing for singularity	PROC SYSLIN	SINGULAR=
specify denominator for variance estimates	PROC SYSLIN	VARDEF=
Printing Control Options		
print all results	PROC SYSLIN	ALL
print first-stage regression statistics	PROC SYSLIN	FIRST
print estimates and SSE at each iteration	PROC SYSLIN	ITPRINT
print the reduced form estimates	PROC SYSLIN	REDUCED
print descriptive statistics	PROC SYSLIN	SIMPLE
print uncorrected SSCP matrix	PROC SYSLIN	USSCP
print correlations of the parameter estimates	MODEL	CORRB

Description	Statement	Option
print covariances of the parameter estimates	MODEL	COVB
print Durbin-Watson statistics	MODEL	DW
print Basmann's test	MODEL	OVERID
plot residual values against regressors	MODEL	PLOT
print standardized parameter estimates	MODEL	STB
print unrestricted parameter estimates	MODEL	UNREST
print the model crossproducts matrix	MODEL	XPX
print the inverse of the crossproducts matrix	MODEL	I
suppress printed output	MODEL	NOPRINT
suppress all printed output	PROC SYSLIN	NOPRINT
Model Specification		
specify structural equations	MODEL	
suppress the intercept parameter	MODEL	NOINT
specify linear relationship among variables	IDENTITY	
perform weighted regression	WEIGHT	
Tests and Restrictions on Parameters		
place restrictions on parameter estimates	RESTRICT	
place restrictions on parameter estimates	SRESTRICT	
test linear hypothesis	STEST	
test linear hypothesis	TEST	
Other Statements		
specify BY-group processing	BY	
specify the endogenous variables	ENDOGENOUS	
specify instrumental variables	INSTRUMENTS	
write predicted and residual values to a data set	OUTPUT	
name variable for predicted values	OUTPUT	PREDICTED=
name variable for residual values	OUTPUT	RESIDUAL=
include additional variables in $X'X$ matrix	VAR	

PROC SYSLIN Statement

PROC SYSLIN *options* ;

The following options can be used with the PROC SYSLIN statement.

Data Set Options

DATA=SAS-data-set

specifies the input data set. If the DATA= option is omitted, the most recently created SAS data set is used. In addition to ordinary SAS data sets, PROC SYSLIN can analyze data sets of TYPE=CORR, TYPE=COV, TYPE=UCORR, TYPE=UCOV, and TYPE=SSCP. See the section “[Special TYPE= Input Data Sets](#)” on page 2096 for details.

OUT=SAS-data-set

specifies an output SAS data set for residuals and predicted values. The OUT= option is used in conjunction with the OUTPUT statement. See the section “[OUT= Data Set](#)” on page 2102 for details.

OUTEST=SAS-data-set

writes the parameter estimates to an output data set. See the section “[OUTEST= Data Set](#)” on page 2103 for details.

OUTCOV

COVOUT

writes the covariance matrix of the parameter estimates to the OUTEST= data set in addition to the parameter estimates.

OUTCOV3

COV3OUT

writes covariance matrices for each model in a system to the OUTEST= data set when the 3SLS, SUR, or FIML option is used.

OUTSSCP=SAS-data-set

writes the sum-of-squares-and-crossproducts matrix to an output data set. See the section “[OUTSSCP= Data Set](#)” on page 2104 for details.

Estimation Method Options

2SLS

specifies the two-stage least squares estimation method.

3SLS

specifies the three-stage least squares estimation method.

ALPHA=value

specifies Fuller’s modification to the LIML estimation method. See the section “[Fuller’s Modification to LIML](#)” on page 2102 for details.

CONVERGE=value

specifies the convergence criterion for the iterative estimation methods IT3SLS, ITSUR, and FIML. The default is CONVERGE=0.0001.

FIML

specifies the full information maximum likelihood estimation method.

ITSUR

specifies the iterative seemingly unrelated estimation method.

IT3SLS

specifies the iterative three-stage least squares estimation method.

K=value

specifies the K-class estimation method.

LIML

specifies the limited information maximum likelihood estimation method.

MAXITER=*n*

specifies the maximum number of iterations allowed for the IT3SLS, ITSUR, and FIML estimation methods. The MAXITER= option can be abbreviated as MAXIT=. The default is MAXITER=30.

MELO

specifies the minimum expected loss estimation method.

NOINCLUDE

excludes the RESTRICT statements from the final stage for the 3SLS, IT3SLS, SUR, and ITSUR estimation methods.

OLS

specifies the ordinary least squares estimation method. This is the default.

SDIAG

uses the diagonal of **S** instead of **S** to do the estimation, where **S** is the covariance matrix of equation errors. See the section “[Uncorrelated Errors across Equations](#)” on page 2102 for details.

SINGULAR=value

specifies a criterion for testing singularity of the crossproducts matrix. This is a tuning parameter used to make PROC SYSLIN more or less sensitive to singularities. The value must be between 0 and 1. The default is SINGULAR=1E-8.

SUR

specifies the seemingly unrelated estimation method.

Printing Control Options**ALL**

specifies the CORRB, COVB, DW, I, OVERID, PLOT, STB, and XPX options for every MODEL statement.

FIRST

prints first-stage regression statistics for the endogenous variables regressed on the instruments. This output includes sums of squares, estimates, variances, and standard deviations.

ITPRINT

prints parameter estimates, system-weighted residual sum of squares, and R^2 at each iteration for the IT3SLS and ITSUR estimation methods. For the FIML method, the ITPRINT option prints parameter estimates, negative of log-likelihood function, and norm of gradient vector at each iteration.

NOPRINT

suppresses all printed output. Specifying NOPRINT in the PROC SYSLIN statement is equivalent to specifying NOPRINT in every MODEL statement.

REDUCED

prints the reduced form estimates. If the REDUCED option is specified, you should specify any IDENTITY statements needed to make the system square. See the section “[Reduced Form Estimates](#)” on page 2101 for details.

SIMPLE

prints descriptive statistics for the dependent variables. The statistics printed include the sum, mean, uncorrected sum of squares, variance, and standard deviation.

USSCP

prints the uncorrected sum-of-squares-and-crossproducts matrix.

USSCP2

prints the uncorrected sum-of-squares-and-crossproducts matrix for all variables used in the analysis, including predicted values of variables generated by the procedure.

VARDEF=DF | N | WEIGHT | WGT

specifies the denominator to use in calculating cross-equation error covariances and parameter standard errors and covariances. The default is VARDEF=DF, which corrects for model degrees of freedom. VARDEF=N specifies no degrees-of-freedom correction. VARDEF=WEIGHT specifies the sum of the observation weights. VARDEF=WGT specifies the sum of the observation weights minus the model degrees of freedom. See the section “[Computation of Standard Errors](#)” on page 2101 for details.

BY Statement

BY *variables* ;

A BY statement can be used with PROC SYSLIN to obtain separate analyses on observations in groups defined by the BY variables.

ENDOGENOUS Statement

ENDOGENOUS *variables* ;

The ENDOGENOUS statement declares the jointly dependent variables that are projected in the first-stage regression through the instrument variables. The ENDOGENOUS statement is not needed for the SUR, ITSUR, or OLS estimation methods. The default ENDOGENOUS list consists of all the dependent variables in the MODEL and IDENTITY statements that do not appear in the INSTRUMENTS statement.

IDENTITY Statement

IDENTITY *equation* ;

The **IDENTITY** statement specifies linear relationships among variables to write to the OUTEST= data set. It provides extra information in the OUTEST= data set but does not create or compute variables. The OUTEST= data set can be processed by the SIMLIN procedure in a later step.

The **IDENTITY** statement is also used to compute reduced form coefficients when the **REDUCED** option in the **PROC SYSLIN** statement is specified. See the section “[Reduced Form Estimates](#)” on page 2101 for details.

The *equation* given by the **IDENTITY** statement has the same form as equations in the **MODEL** statement. A label can be specified for an **IDENTITY** statement as follows:

label : **IDENTITY** ...;

INSTRUMENTS Statement

INSTRUMENTS *variables* ;

The **INSTRUMENTS** statement declares the variables used in obtaining first-stage predicted values. All the instruments specified are used in each first-stage regression. The **INSTRUMENTS** statement is required for the 2SLS, 3SLS, IT3SLS, LIML, MELO, and K-class estimation methods. The **INSTRUMENTS** statement is not needed for the SUR, ITSUR, OLS, or FIML estimation methods.

MODEL Statement

MODEL *response = regressors / options* ;

The **MODEL** statement regresses the response variable on the left side of the equal sign against the regressors listed on the right side.

Models can be given labels. Model labels are used in the printed output to identify the results for different models. Model labels are also used in **SRESTRICT** and **STEST** statements to refer to parameters in different models. If no label is specified, the response variable name is used as the label for the model. The model label is specified as follows:

label : **MODEL** ...;

The following options can be used in the **MODEL** statement after a slash (/).

ALL

specifies the **CORRB**, **COVB**, **DW**, **I**, **OVERID**, **PLOT**, **STB**, and **XPX** options.

ALPHA=*value*
