with the PROC PRINCOMP statement. The remaining statements are described in alphabetical order.

PROC PRINCOMP Statement

PROC PRINCOMP < *options* > **;**

The PROC PRINCOMP statement starts the PRINCOMP procedure and optionally identifies input and output data sets, specifies the analyses performed, and controls displayed output. Table 69.1 summarizes the options.

Table 69.1 Summary of PROC PRINCOMP Statement Options

Option	Description
Specify data sets	
DATA=	specifies input data set name
OUT=	specifies output data set name
OUTSTAT=	specifies output data set name containing various statistics
Specify details of analysis	
COV	computes the principal components from the covariance matrix
N=	specifies the number of principal components to be computed
NOINT	omits the intercept from the model
PREFIX=	specifies a prefix for naming the principal components
RPREFIX=	specifies a prefix for naming the residual variables
SINGULAR=	specifies the singularity criterion
STD	standardizes the principal component scores
VARDEF=	specifies the divisor used in calculating variances and standard deviations
Suppress the display of output	
NOPRINT	suppresses the display of all output
Specify ODS Graphics details	
PLOTS=	specifies options that control the details of the plots

The following list provides details about these options.

COVARIANCE

COV

computes the principal components from the covariance matrix. If you omit the COV option, the correlation matrix is analyzed. Use of the COV option causes variables with large variances to be more strongly associated with components with large eigenvalues and causes variables with small variances to be more strongly associated with components with small eigenvalues. You should not specify the COV option unless the units in which the variables are measured are comparable or the variables are standardized in some way.

DATA=*SAS-data-set*

specifies the SAS data set to be analyzed. The data set can be an ordinary SAS data set or a TYPE=ACE, TYPE=CORR, TYPE=COV, TYPE=FACTOR, TYPE=SSCP, TYPE=UCORR, or TYPE=UCOV data set (see Appendix A, "Special SAS Data Sets"). Also, the PRINCOMP procedure can read the _TYPE_='COVB' matrix from a TYPE=EST data set. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

N=*number*

specifies the number of principal components to be computed. The default is the number of variables. The value of the N= option must be an integer greater than or equal to zero.

NOINT

omits the intercept from the model. In other words, the NOINT option requests that the covariance or correlation matrix not be corrected for the mean. When you use the PRINCOMP procedure with the NOINT option, the covariance matrix and, hence, the standard deviations are not corrected for the mean. If you are interested in the standard deviations corrected for the mean, you can get them by using a procedure such as the MEANS procedure.

If you use a TYPE=SSCP data set as input to the PRINCOMP procedure and list the variable Intercept in the VAR statement, the procedure acts as if you had also specified the NOINT option. If you use NOINT and also create an OUTSTAT= data set, the data set is TYPE=UCORR or TYPE=UCOV rather than TYPE=CORR or TYPE=COV.

NOPRINT

suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 20, "Using the Output Delivery System."

OUT=*SAS-data-set*

creates an output SAS data set that contains all the original data as well as the principal component scores.

If you want to create a permanent SAS data set, you must specify a two-level name. For details about OUT= data sets, see the section "Output Data Sets" on page 5158. See *SAS Language Reference: Concepts* for more information about permanent SAS data sets.

OUTSTAT=*SAS-data-set*

creates an output SAS data set that contains means, standard deviations, number of observations, correlations or covariances, eigenvalues, and eigenvectors. If you specify the COV option, the data set is TYPE=COV or TYPE=UCOV, depending on the NOINT option, and it contains covariances; otherwise, the data set is TYPE=CORR or TYPE=UCORR, depending on the NOINT option, and it contains correlations. If you specify the PARTIAL statement, the OUTSTAT= data set contains R squares as well.

If you want to create a permanent SAS data set, you must specify a two-level name. For details about OUTSTAT= data sets, see the section "Output Data Sets" on page 5158. See *SAS Language Reference: Concepts* for more information about permanent SAS data sets.

PLOTS < **(***global-plot-options***)** > < **=** *plot-request* < *(options)* > >

PLOTS < **(***global-plot-options***)** > < **= (***plot-request* < *(options)* > < **...** *plot-request* < *(options)* > **>) >**

controls the plots produced through ODS Graphics. When you specify only one plot request, you can omit the parentheses around the plot request. Here are some examples:

```
plots=none
plots=(scatter pattern)
plots(unpack)=scree
plots(ncomp=3 flip)=(pattern(circles=0.5 1.0) score)
```

You must enable ODS Graphics before requesting plots—for example, like this:

```
ods graphics on;
proc princomp plots=all;
   var x1--x10;
run;
ods graphics off;
```

For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." If you have enabled ODS Graphics but do not specify the PLOTS= option, PROC PRINCOMP produces the scree plot by default.

The global plot options include the following:

FLIP

flips or interchanges the X-axis and Y-axis dimension for the component score plots and the component pattern plots. For example, if there are three components, the default plots (y * x) are Component 2 * Component 1, Component 3 * Component 1, and Component 3 * Component 2. When you specify PLOTS(FLIP), the plots are Component 1 * Component 2, Component 1 * Component 3, and Component 2 * Component 3.

NCOMP=*n*

specifies the number of components $n(\geq 2)$ to be plotted for the component pattern plots and the component score plots. If the NCOMP= option is again specified in an individual plot, such as PLOTS=SCORE(NCOMP= m), the value m will determine the number of components to be plotted in the component score plots. Be aware that the number of plots ($\frac{n\times(n-1)}{2}$) produced grows quadratically when n increases. The default is 5 or the total number of components $m(\geq 2)$, whichever is smaller. If $n > m$, NCOMP= m will be used.

ONLY

suppresses the default plots. Only plots specifically requested are displayed.

UNPACKPANEL

UNPACK

suppresses paneling in the scree plot. By default, multiple plots can appear in an output panel. Specify UNPACKPANEL to get each plot in a separate panel. You can specify PLOTS(UNPACKPANEL) to unpack the default plots. You can also specify UNPACKPANEL as a suboption with SCREE (such as PLOTS=SCREE(UNPACKPANEL)).

The plot requests include the following:

ALL
produces all appropriate plots. You can specify other options with ALL; for example, to request all plots and unpack only the scree plot, specify PLOTS=(ALL SCREE(UNPACKPANEL)).

EIGEN | EIGENVALUE | SCREE < (UNPACKPANEL) >
produces the scree plot of eigenvalues and proportion variance explained. By default, both plots are output in a panel. Specify PLOTS= SCREE(UNPACKPANEL) to get each plot in a separate panel.

MATRIX
produces the matrix plot of principal component scores.

NONE
suppresses the display of all graphics output.

PATTERN < (*pattern-options*) >
produces the pairwise component pattern plots. Each variable is plotted as an observation whose coordinates are correlations between the variable and the two corresponding components on the plot. Use the NCOMP= option (for instance, PLOTS=PATTERN(NCOMP=3)) described in the following to control the number of plots to be displayed.

The available *pattern-options* are as follows:

CIRCLES < = *number list* >
plots the variance percentage circles. Each number in the list must be greater than 0. If the number is greater than or equal to 1, it is interpreted as a percentage and divided by 100; CIRCLES=0.05 and CIRCLES=5 are equivalent. For each number (c) specified, a ($c \times 100\%$) variance circle is created.

By default, there is no circle for the scatter pattern plot (PLOTS=PATTERN) and a unit circle with a 100% variance circle is plotted for the vector pattern plot (PLOTS=PATTERN (VECTOR)). You can display multiple circles by specifying PLOTS=PATTERN(CIRCLES=). For example, specifying PLOTS=PATTERN(CIRCLES= .3 .6 1.0) will display the 30%, 60%, and 100% variance circles in the pattern plots.

FLIP
flips or interchanges the X-axis and Y-axis dimensions for the component pattern plots. Specify PLOTS=PATTERN(FLIP) to flip the X-axis and Y-axis dimensions.

NCOMP=*n*
specifies the number of components $n(\geq 2)$ to be plotted. The default is 5 or the total number of components $m(\geq 2)$, whichever is smaller. If $n > m$, NCOMP= m will be used. Be aware that the number of plots ($\frac{n \times (n-1)}{2}$) produced grows quadratically when n increases.

VECTOR

plots pattern in a vector form.

PATTERNPROFILE | PROFILE

produces the pattern profile plot. There is a profile for each component. The Y-axis value represents the correlation between the variable (corresponding to the X-axis value) and the profiled principal component.

SCORE < (*score-options*) >

produces the pairwise component score plots. Use the NCOMP= option (for instance, PLOTS=SCORE(NCOMP=3)) described in the following to control the number of plots to be displayed.

The available *score-options* are as follows:

ALPHA=*number list*

specifies a list of numbers for the prediction ellipses to be displayed in the score plots. Each value (α) in the list must be greater than 0. If α is greater than or equal to 1, it is interpreted as a percentage and divided by 100; ALPHA=0.05 and ALPHA=5 are equivalent.

ELLIPSE

requests prediction ellipses for the principal component scores of a new observation to be created in the principal component score plots. See the section "Confidence and Prediction Ellipses" in "The CORR Procedure" (*Base SAS Procedures Guide: Statistical Procedures*), for details about the computation of a prediction ellipse.

FLIP

flips or interchanges the X-axis and Y-axis dimensions for the component score plots. Specify PLOTS=SCORE(FLIP) to flip the X-axis and Y-axis dimensions.

NCOMP=*n*

specifies the number of components $n(\geq 2)$ to be plotted. The default is 5 or the total number of components $m(\geq 2)$, whichever is smaller. If $n > m$, NCOMP= m will be used. Be aware that the number of plots ($\frac{n\times(n-1)}{2}$) produced grows quadratically when n increases.

PREFIX=*name*

specifies a prefix for naming the principal components. By default, the names are Prin1, Prin2, ..., Prin$n$. If you specify PREFIX=ABC, the components are named ABC1, ABC2, ABC3, and so on. The number of characters in the prefix plus the number of digits required to designate the variables should not exceed the current name length defined by the VALIDVARNAME= system option.

PARPREFIX=*name*

PPREFIX=*name*

specifies a prefix for naming the residual variables in the OUT= data set and the OUTSTAT= data set. By default, the prefix is R_. The number of characters in the prefix plus the maximum length of the variable names should not exceed the current name length defined by the VALIDVARNAME= system option.

SINGULAR=*p*

SING=*p*

specifies the singularity criterion, where $0 < p < 1$. If a variable in a PARTIAL statement has an R square as large as $1-p$ when predicted from the variables listed before it in the statement, the variable is assigned a standardized coefficient of 0. By default, SINGULAR=1E−8.

STANDARD

STD

standardizes the principal component scores in the OUT= data set to unit variance. If you omit the STANDARD option, the scores have variance equal to the corresponding eigenvalue. Note that STANDARD has no effect on the eigenvalues themselves.

VARDEF=DF | N | WDF | WEIGHT | WGT

specifies the divisor used in calculating variances and standard deviations. By default, VARDEF=DF. The following table displays the values and associated divisors.

Value	Divisor		Formula
DF	error degrees of freedom	$n - i$	(before partialing)
		$n - p - i$	(after partialing)
N	number of observations	n	
WEIGHT | WGT	sum of weights	$\sum_{j=1}^{n} w_j$	
WDF	sum of weights minus one	$\left(\sum_{j=1}^{n} w_j\right) - i$	(before partialing)
		$\left(\sum_{j=1}^{n} w_j\right) - p - i$	(after partialing)

In the formulas for VARDEF=DF and VARDEF=WDF, p is the number of degrees of freedom of the variables in the PARTIAL statement, and i is 0 if the NOINT option is specified and 1 otherwise.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC PRINCOMP to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for PROC PRINCOMP. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.

- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide.*

FREQ Statement

FREQ *variable* **;**

The FREQ statement specifies a variable that provides frequencies for each observation in the DATA= data set. Specifically, if n is the value of the FREQ variable for a given observation, then that observation is used n times.

The analysis produced using a FREQ statement reflects the expanded number of observations. The total number of observations is considered equal to the sum of the FREQ variable. You could produce the same analysis (without the FREQ statement) by first creating a new data set that contains the expanded number of observations. For example, if the value of the FREQ variable is 5 for the first observation, the first 5 observations in the new data set would be identical. Each observation in the old data set would be replicated n_j times in the new data set, where n_j is the value of the FREQ variable for that observation.

If the value of the FREQ variable is missing or is less than one, the observation is not used in the analysis. If the value is not an integer, only the integer portion is used.

ID Statement

ID *variables* **;**

The ID statement labels observations with values from the first ID variable in the principal component score plot. If one or more ID variables are specified, their values are displayed in tooltips of the component score plot and the matrix plot of component scores.

PARTIAL Statement

PARTIAL *variables* **;**

If you want to analyze a partial correlation or covariance matrix, specify the names of the numeric variables to be partialed out in the PARTIAL statement. The PRINCOMP procedure computes the principal components of the residuals from the prediction of the VAR variables by the PARTIAL variables. If you request an OUT= or OUTSTAT= data set, the residual variables are named by prefixing the characters R_ by default or the string specified in the RPREFIX= option to the VAR variables.

VAR Statement

VAR *variables* **;**

The VAR statement lists the numeric variables to be analyzed. If you omit the VAR statement, all numeric variables not specified in other statements are analyzed. If, however, the DATA= data set is TYPE=SSCP, the default set of variables used as VAR variables does not include Intercept so that the correlation or covariance matrix is constructed correctly. If you want to analyze Intercept as a separate variable, you should specify it in the VAR statement.

WEIGHT Statement

WEIGHT *variable* **;**

If you want to use relative weights for each observation in the input data set, place the weights in a variable in the data set and specify the name in a WEIGHT statement. This is often done when the variance associated with each observation is different and the values of the weight variable are proportional to the reciprocals of the variances.

The observation is used in the analysis only if the value of the WEIGHT statement variable is nonmissing and is greater than zero.

Details: PRINCOMP Procedure

Missing Values

Observations with missing values for any variable in the VAR, PARTIAL, FREQ, or WEIGHT statement are omitted from the analysis and are given missing values for principal component scores in the OUT= data set. If a correlation, covariance, or SSCP matrix is read, it can contain missing values as long as every pair of variables has at least one nonmissing entry.

Output Data Sets

OUT= Data Set

The OUT= data set contains all the variables in the original data set plus new variables containing the principal component scores. The N= option determines the number of new variables. The

names of the new variables are formed by concatenating the value given by the PREFIX= option (or Prin if PREFIX= is omitted) and the numbers 1, 2, 3, and so on. The new variables have mean 0 and variance equal to the corresponding eigenvalue, unless you specify the STANDARD option to standardize the scores to unit variance. Also, if you specify the COV option, the procedure computes the principal component scores from the corrected or the uncorrected (if the NOINT option is specified) variables rather than the standardized variables.

If you use a PARTIAL statement, the OUT= data set also contains the residuals from predicting the VAR variables from the PARTIAL variables.

An OUT= data set cannot be created if the DATA= data set is TYPE=ACE, TYPE=CORR, TYPE=COV, TYPE=EST, TYPE=FACTOR, TYPE=SSCP, TYPE=UCORR, or TYPE=UCOV.

OUTSTAT= Data Set

The OUTSTAT= data set is similar to the TYPE=CORR data set produced by the CORR procedure. The following table relates the TYPE= value for the OUTSTAT= data set to the options specified in the PROC PRINCOMP statement.

Options	**TYPE=**
(default)	CORR
COV	COV
NOINT	UCORR
COV NOINT	UCOV

Note that the default (neither the COV nor NOINT option) produces a TYPE=CORR data set.

The new data set contains the following variables:

- the BY variables, if any
- two new variables, _TYPE_ and _NAME_, both character variables
- the variables analyzed (that is, those in the VAR statement); or, if there is no VAR statement, all numeric variables not listed in any other statement; or, if there is a PARTIAL statement, the residual variables as described under the OUT= data set

Each observation in the new data set contains some type of statistic as indicated by the _TYPE_ variable. The values of the _TYPE_ variable are as follows:

MEAN — mean of each variable. If you specify the PARTIAL statement, this observation is omitted.

STD — standard deviations. If you specify the COV option, this observation is omitted, so the SCORE procedure does not standardize the variables before computing scores. If you use the PARTIAL statement, the standard deviation of a variable is computed as its root mean squared error as predicted from the PARTIAL variables.

USTD — uncorrected standard deviations. When you specify the NOINT option in the PROC PRINCOMP statement, the OUTSTAT= data set contains standard deviations not corrected for the mean. However, if you also specify the COV option in the PROC PRINCOMP statement, this observation is omitted.

N — number of observations on which the analysis is based. This value is the same for each variable. If you specify the PARTIAL statement and the value of the VARDEF= option is DF or unspecified, then the number of observations is decremented by the degrees of freedom for the PARTIAL variables.

SUMWGT — the sum of the weights of the observations. This value is the same for each variable. If you specify the PARTIAL statement and VARDEF=WDF, then the sum of the weights is decremented by the degrees of freedom for the PARTIAL variables. This observation is output only if the value is different from that in the observation with _TYPE_='N'.

CORR — correlations between each variable and the variable specified by the _NAME_ variable. The number of observations with _TYPE_='CORR' is equal to the number of variables being analyzed. If you specify the COV option, no _TYPE_='CORR' observations are produced. If you use the PARTIAL statement, the partial correlations, not the raw correlations, are output.

UCORR — uncorrected correlation matrix. When you specify the NOINT option without the COV option in the PROC PRINCOMP statement, the OUTSTAT= data set contains a matrix of correlations not corrected for the means. However, if you also specify the COV option in the PROC PRINCOMP statement, this observation is omitted.

COV — covariances between each variable and the variable specified by the _NAME_ variable. _TYPE_='COV' observations are produced only if you specify the COV option. If you use the PARTIAL statement, the partial covariances, not the raw covariances, are output.

UCOV — uncorrected covariance matrix. When you specify the NOINT and COV options in the PROC PRINCOMP statement, the OUTSTAT= data set contains a matrix of covariances not corrected for the means.

EIGENVAL — eigenvalues. If the N= option requested fewer than the maximum number of principal components, only the specified number of eigenvalues are produced, with missing values filling out the observation.

SCORE — eigenvectors. The _NAME_ variable contains the name of the corresponding principal component as constructed from the PREFIX= option. The number of observations with _TYPE_='SCORE' equals the number of principal components computed. The eigenvectors have unit length unless you specify the STD option, in which case the unit-length eigenvectors are divided by the square roots of the eigenvalues to produce scores with unit standard deviations.

To obtain the principal component scores, if the COV option is not specified, these coefficients should be multiplied by the standardized data. With the COV option, these coefficients should be multiplied by the centered data. Means obtained from the observation with _TYPE_='MEAN' and standard deviations obtained from the observation with _TYPE_='STD' should be used for centering and standardizing the data.

USCORE	scoring coefficients to be applied without subtracting the mean from the raw variables. _TYPE_='USCORE' observations are produced when you specify the NOINT option in the PROC PRINCOMP statement. To obtain the principal component scores, these coefficients should be multiplied by the data that are standardized by the uncorrected standard deviations obtained from the observation with _TYPE_='USTD'.
RSQUARED	R squares for each VAR variable as predicted by the PARTIAL variables
B	regression coefficients for each VAR variable as predicted by the PARTIAL variables. This observation is produced only if you specify the COV option.
STB	standardized regression coefficients for each VAR variable as predicted by the PARTIAL variables. If you specify the COV option, this observation is omitted.

The data set can be used with the SCORE procedure to compute principal component scores, or it can be used as input to the FACTOR procedure specifying METHOD=SCORE to rotate the components. If you use the PARTIAL statement, the scoring coefficients should be applied to the residuals, not the original variables.

Computational Resources

Let

$$
\begin{aligned}
n &= \text{number of observations} \\
v &= \text{number of VAR variables} \\
p &= \text{number of PARTIAL variables} \\
c &= \text{number of components}
\end{aligned}
$$

- The minimum allocated memory required (in bytes) is

$$232v + 120p + 48c + \max(8cv, 8vp + 4(v + p)(v + p + 1))$$

- The time required to compute the correlation matrix is roughly proportional to

$$n(v + p)^2 + \frac{p}{2}(v + p)(v + p + 1)$$

- The time required to compute eigenvalues is roughly proportional to v^3.
- The time required to compute eigenvectors is roughly proportional to cv^2.

Displayed Output

The PRINCOMP procedure displays the following items if the DATA= data set is not TYPE=CORR, TYPE=COV, TYPE=SSCP, TYPE=UCORR, or TYPE=UCOV:

- simple statistics, including the mean and std (standard deviation) for each variable. If you specify the NOINT option, the uncorrected standard deviation (ustd) is displayed.
- the correlation or, if you specify the COV option, the covariance matrix

The PRINCOMP procedure displays the following items if you use the PARTIAL statement:

- regression statistics, giving the R square and RMSE (root mean squared error) for each VAR variable as predicted by the PARTIAL variables (not shown)
- standardized regression coefficients or, if you specify the COV option, regression coefficients for predicting the VAR variables from the PARTIAL variables (not shown)
- the partial correlation matrix or, if you specify the COV option, the partial covariance matrix (not shown)

The PRINCOMP procedure displays the following item if you specify the COV option:

- the total variance

The PRINCOMP procedure displays the following items unless you specify the NOPRINT option:

- eigenvalues of the correlation or covariance matrix, as well as the difference between successive eigenvalues, the proportion of variance explained by each eigenvalue, and the cumulative proportion of variance explained
- the eigenvectors

ODS Table Names

PROC PRINCOMP assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 69.2. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

All of the tables are created with the specification of the PROC PRINCOMP statement; a few tables need an additional PARTIAL statement.

Table 69.2 ODS Tables Produced by PROC PRINCOMP

ODS Table Name	Description	Statement / Option
Corr	Correlation matrix	default
Cov	Covariance matrix	COV
Eigenvalues	Eigenvalues	default
Eigenvectors	Eigenvectors	default
NObsNVar	Number of observations, variables, and partial variables	default
ParCorr	Partial correlation matrix	PARTIAL statement
ParCov	Uncorrected partial covariance matrix	PARTIAL statement and COV
RegCoef	Regression coefficients	PARTIAL statement and COV
RSquareRMSE	Regression statistics: R squares and RMSEs	PARTIAL statement
SimpleStatistics	Simple statistics	default
StdRegCoef	Standardized regression coefficients	PARTIAL statement
TotalVariance	Total variance	COV

ODS Graphics

To request graphics with PROC PRINCOMP, you must first enable ODS Graphics by specifying the **ods graphics on** statement. See Chapter 21, "Statistical Graphics Using ODS," for more information. Some graphs are produced by default; other graphs are produced by using statements and options. You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC PRINCOMP generates are listed in Table 69.3, along with the required statements and options.

Table 69.3 ODS Graphics Produced by PROC PRINCOMP

ODS Graph Name	Plot Description	Statement and Option
PaintedScorePlot	Score plot of component 3 versus component 2, painted by component 1	PLOTS=SCORE when number of variables ≥ 3
PatternPlot	Component pattern plot	PLOTS=PATTERN
PatternProfilePlot	Component pattern profile plot	PLOTS=PATTERNPROFILE
ScoreMatrixPlot	Matrix plot of component scores	PLOTS=MATRIX
ScorePlot	Component score plot	PLOTS=SCORE
ScreePlot	Scree and variance plots	default and PLOTS=SCREE
VariancePlot	Variance proportion explained plot	PLOTS=SCREE(UNPACKPANEL)

Examples: PRINCOMP Procedure

Example 69.1: Temperatures

This example analyzes mean daily temperatures in selected cities in January and July. Both the raw data and the principal components are plotted to illustrate how principal components are orthogonal rotations of the original variables.

The following statements create the Temperature data set.

```
data Temperature;
   length Cityid $ 2;
   title 'Mean Temperature in January and July for Selected Cities ';
   input City $1-15 January July;
   Cityid = substr(City,1,2);
   datalines;
Mobile          51.2 81.6
Phoenix         51.2 91.2

Cheyenne        26.6 69.1
;
```

The following statements plot the temperature data set. The Cityid variable instead of City is used as a data label in the scatter plot for possible label clashing.

```
title 'Mean Temperature in January and July for Selected Cities';
title2 'Plot of Raw Data';
proc sgplot data=Temperature;
   scatter x=July y=January / datalabel=Cityid;
run;
```

The results are displayed in Output 69.1.1, which shows a scatter diagram of the 64 pairs of data points with July temperatures plotted against January temperatures.

Output 69.1.1 Plot of Raw Data

The following statement requests a principal component analysis on the Temperature data set:

```
ods graphics on;
title 'Mean Temperature in January and July for Selected Cities';
proc princomp data=Temperature cov plots=score(ellipse);
   var July January;
   id Cityid;
run;
ods graphics off;
```

Output 69.1.2 displays the PROC PRINCOMP output. The standard deviation of January (11.712) is higher than the standard deviation of July (5.128). The COV option in the PROC PRINCOMP statement requests the principal components to be computed from the covariance matrix. The total variance is 163.474. The first principal component explains about 94% of the total variance, and the second principal component explains only about 6%. The eigenvalues sum to the total variance.

Note that January receives a higher loading on Prin1 because it has a higher standard deviation than July, and the PRINCOMP procedure calculates the scores by using the centered variables rather than the standardized variables.

Output 69.1.2 Results of Principal Component Analysis

Mean Temperature in January and July for Selected Cities

The PRINCOMP Procedure

Observations	64
Variables	2

Simple Statistics

	July	January
Mean	75.60781250	32.09531250
StD	5.12761910	11.71243309

Covariance Matrix

	July	January
July	26.2924777	46.8282912
January	46.8282912	137.1810888

Total Variance 163.47356647

Eigenvalues of the Covariance Matrix

	Eigenvalue	Difference	Proportion	Cumulative
1	154.310607	145.147647	0.9439	0.9439
2	9.162960		0.0561	1.0000

Eigenvectors

	Prin1	Prin2
July	0.343532	0.939141
January	0.939141	-.343532

PLOTS=SCORE in the PROC PRINCOMP statement requests a plot of the second principal component against the first principal component as shown in Output 69.1.3. It is clear from this plot that the principal components are orthogonal rotations of the original variables and that the first principal component has a larger variance than the second principal component. In fact, the first component has a larger variance than either of the original variables July and January. The ellipse indicates that Miami, Phoenix, and Portland are possible outliers.

Output 69.1.3 Plot of Component 2 by Component 1

Example 69.2: Basketball Data

The data in this example are rankings of 35 college basketball teams. The rankings were made before the start of the 1985–86 season by 10 news services.

The purpose of the principal component analysis is to compute a single variable that best summarizes all 10 of the preseason rankings.

Note that the various news services rank different numbers of teams, varying from 20 through 30 (there is a missing rank in one of the variables, WashPost). And, of course, not all services rank the same teams, so there are missing values in these data. Each of the 35 teams is ranked by at least one news service.

The PRINCOMP procedure omits observations with missing values. To obtain principal component scores for all of the teams, it is necessary to replace the missing values. Since it is the best teams that are ranked, it is not appropriate to replace missing values with the mean of the nonmissing values. Instead, an ad hoc method is used that replaces missing values with the mean of the unassigned ranks. For example, if 20 teams are ranked by a news service, then ranks 21 through 35 are unassigned. The mean of ranks 21 through 35 is 28, so missing values for that variable are replaced

by the value 28. To prevent the method of missing-value replacement from having an undue effect on the analysis, each observation is weighted according to the number of nonmissing values it has. See Example 70.2 in Chapter 70, "The PRINQUAL Procedure," for an alternative analysis of these data.

Since the first principal component accounts for 78% of the variance, there is substantial agreement among the rankings. The eigenvector shows that all the news services are about equally weighted; this is also suggested by the nearly horizontal line of the pattern profile plot in Output 69.2.3. So a simple average would work almost as well as the first principal component. The following statements produce Output 69.2.1.

```
/*-------------------------------------------------------------*/
/*                                                             */
/* Pre-season 1985 College Basketball Rankings                 */
/* (rankings of 35 teams by 10 news services)                  */
/*                                                             */
/* Note: (a) news services rank varying numbers of teams;      */
/*       (b) not all teams are ranked by all news services;    */
/*       (c) each team is ranked by at least one service;      */
/*       (d) rank 20 is missing for UPI.                       */

The data set Jobratings contains 14 variables. Each variable contains the job ratings, using a scale measurement from 1 to 10 (1=fail to comply, 10=exceptional). The last variable Overall Rating contains a score as an overall index on how each officer performs.

The following statements request a principal component analysis on the Jobratings data set, output the scores to the Scores data set (OUT= Scores), and produce default plots. Note that variable Overall Rating is excluded from the analysis.

```
ods graphics on;
proc princomp data=Jobratings(drop='Overall Rating'n);
run;
```

Figure 69.3.1 and Figure 69.3.2 display the PROC PRINCOMP output, beginning with simple statistics followed by the correlation matrix. By default, the PROC PRINCOMP statement requests

principal components computed from the correlation matrix, so the total variance is equal to the number of variables, 13. In this example, it would also be reasonable to use the COV option, which would cause variables with a high variance (such as Dependability) to have more influence on the results than variables with a low variance (such as Learning Ability). If you used the COV option, scores would be computed from centered rather than standardized variables.

Figure 69.3.2 displays the eigenvalues. The first principal component explains about 50% of the total variance, the second principal component explains about 13.6%, and the third principal component explains about 7.7%. Note that the eigenvalues sum to the total variance. The eigenvalues indicate that three to five components provide a good summary of the data, with three components accounting for about 71.7% of the total variance and five components explaining about 82.7%. Subsequent components contribute less than 5% each.

Output 69.3.2 Eigenvalues and Eigenvectors from the PRINCOMP Procedure

When the **ods graphics on** statement is specified, PROC PRINCOMP produces the scree plot as shown in Figure 69.3.3 by default, which helps to visualize and choose the number of components. You can obtain more plots by specifying the PLOTS= option in the PROC PRINCOMP statement.

The "Scree Plot" on the left shows that the eigenvalue of the first component is approximately 6.5 and the eigenvalue of the second component is largely decreased to under 2.0. The "Variance Explained" plot on the right shows that you can explain a near 80% of total variance with the first four principal components.

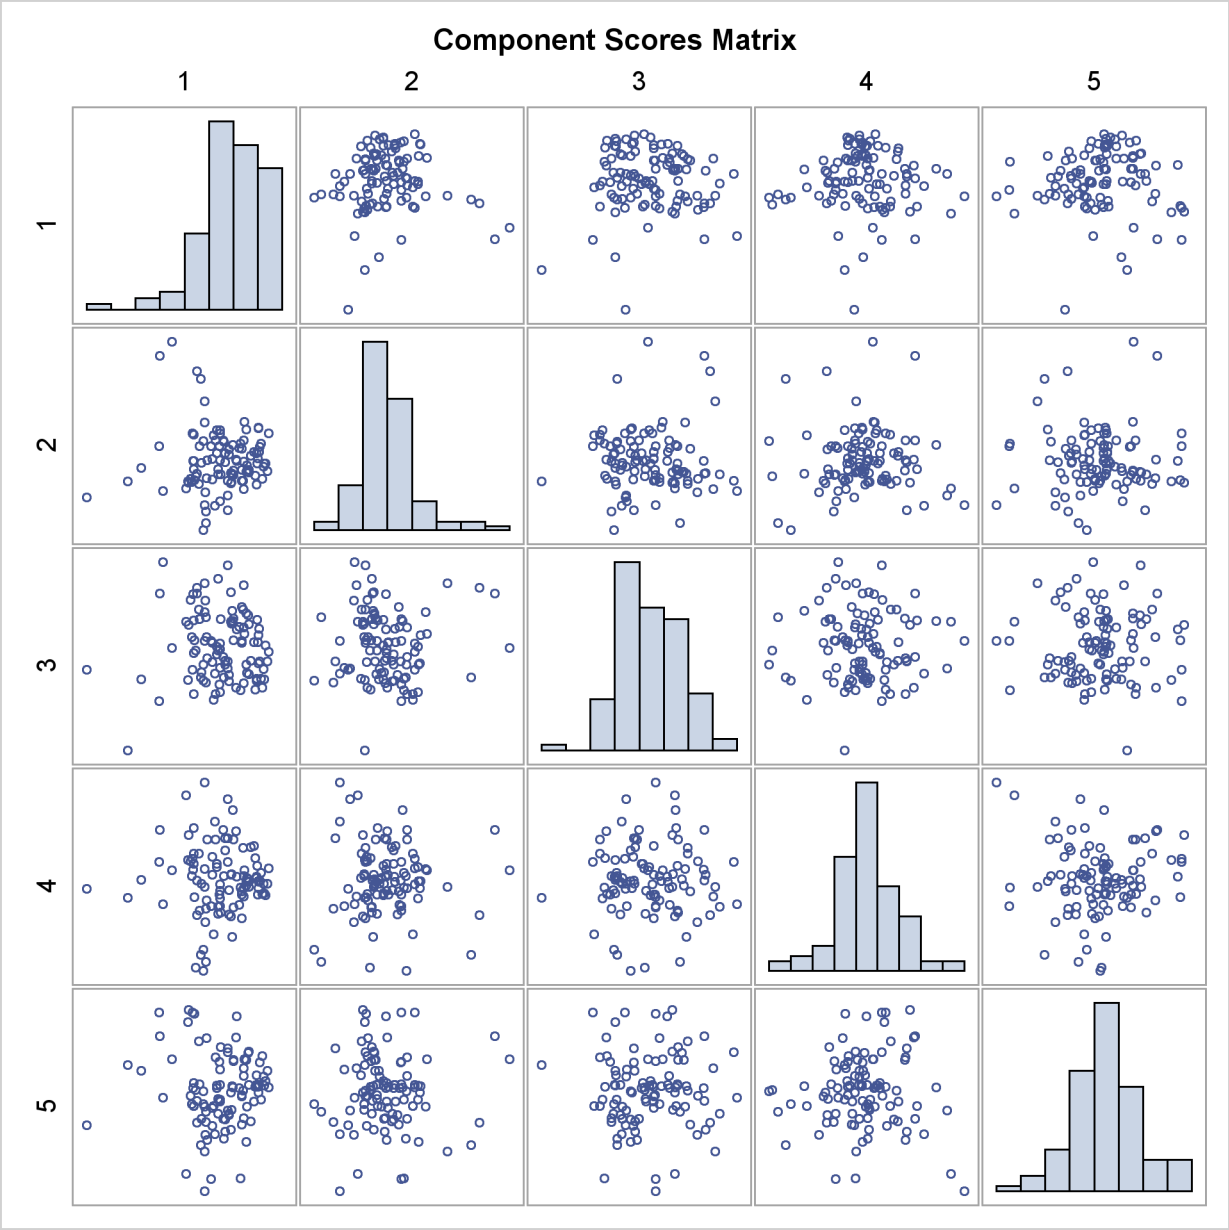
Output 69.3.3 Scree Plot from the PRINCOMP Procedure

The first component reflects overall performance since the first eigenvector shows approximately equal loadings on all variables. The second eigenvector has high positive loadings on the variables Observational Skills and Willingness to Confront Problems but even higher negative loadings on the variables Interest in People and Interpersonal Sensitivity. This component seems to reflect the ability to take action, but it also reflects a lack of interpersonal skills. The third eigenvector has a very high positive loading on the variable Physical Ability and high negative loadings on the variables Problem Solving and Learning Ability. This component seems to reflect physical strength, but also shows poor learning and problem-solving skills.

In short, the three components represent the following:

First Component:	overall performance
Second Component:	smart, tough, and introverted
Third Component:	superior strength and average intellect

PROC PRINCOMP also produces other plots besides the scree plot, which are helpful while interpreting the results. The following statements request plots from the PRINCOMP procedure:

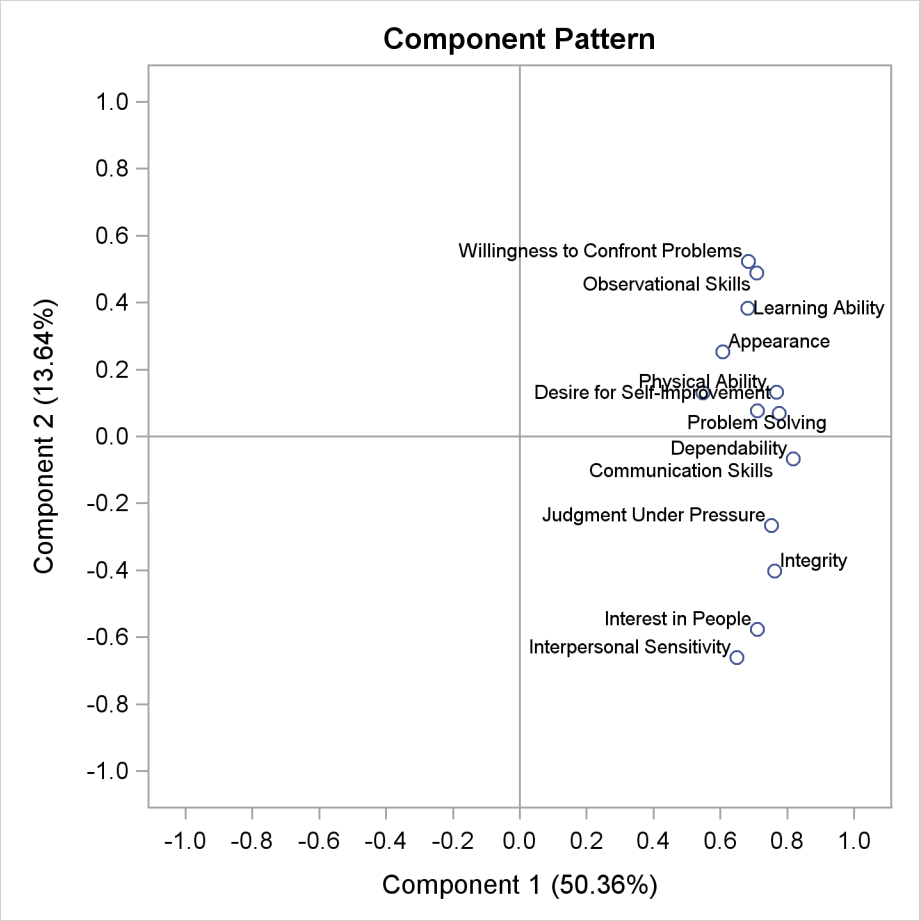


```
proc princomp data=Jobratings(drop='Overall Rating'n)
              plots(ncomp=3)=all n=5;
run;
ods graphics off;
```

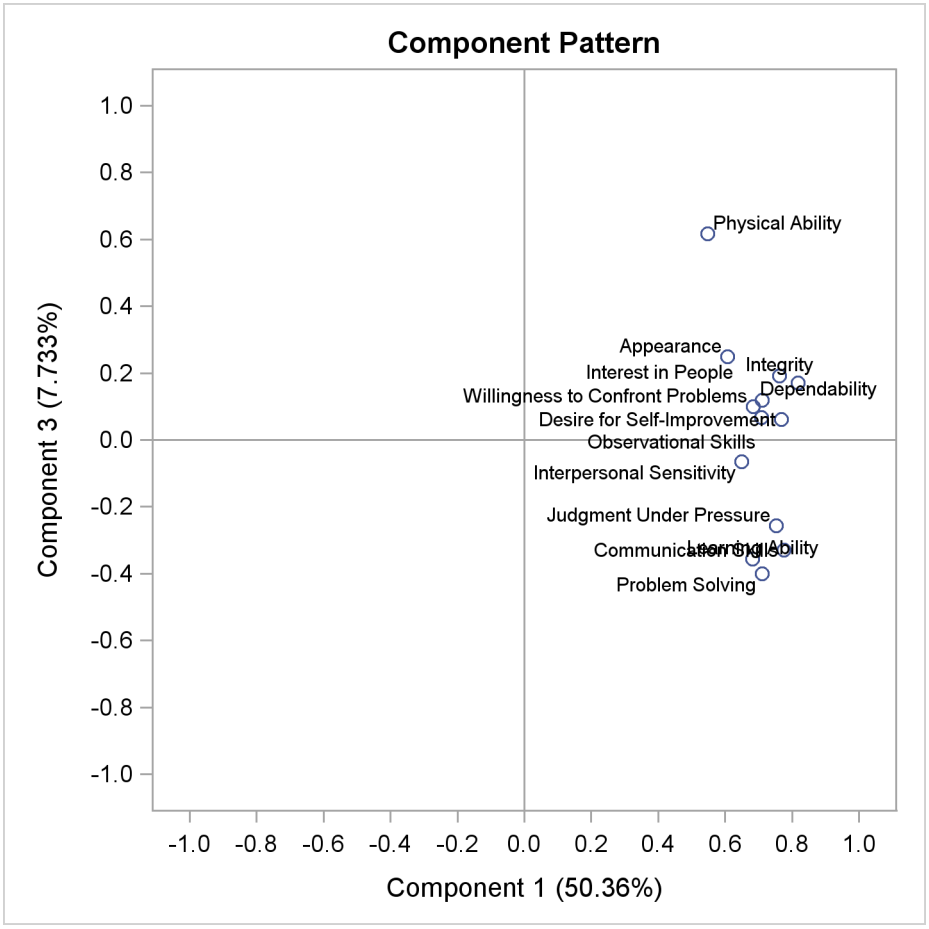
PLOTS=ALL(NCOMP=3) in the PROC PRINCOMP statement requests all plots to be produced but limits the number of components to be plotted in the component pattern plots and the component score plots to three. The N=5 option sets the number of principal components to be computed to

five. Besides a scree plot similar to the one shown before, the rest of plots are displayed in the following context.

Output 69.3.4 shows a matrix plot of component scores between the first five principal components. The histogram of each component is displayed in the diagonal element of the matrix. The histograms indicate that the first principal component is skewed to the left and the second principal component is slightly skewed to the right.

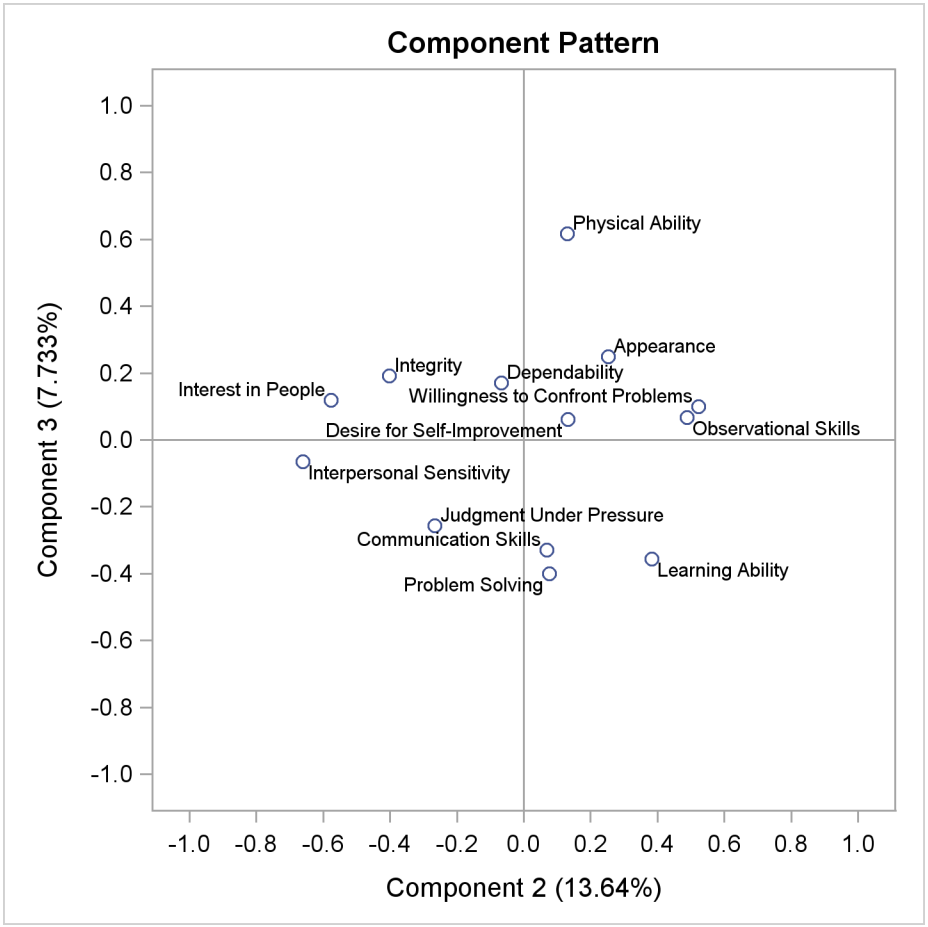


Output 69.3.4 Matrix Plot of Component Scores



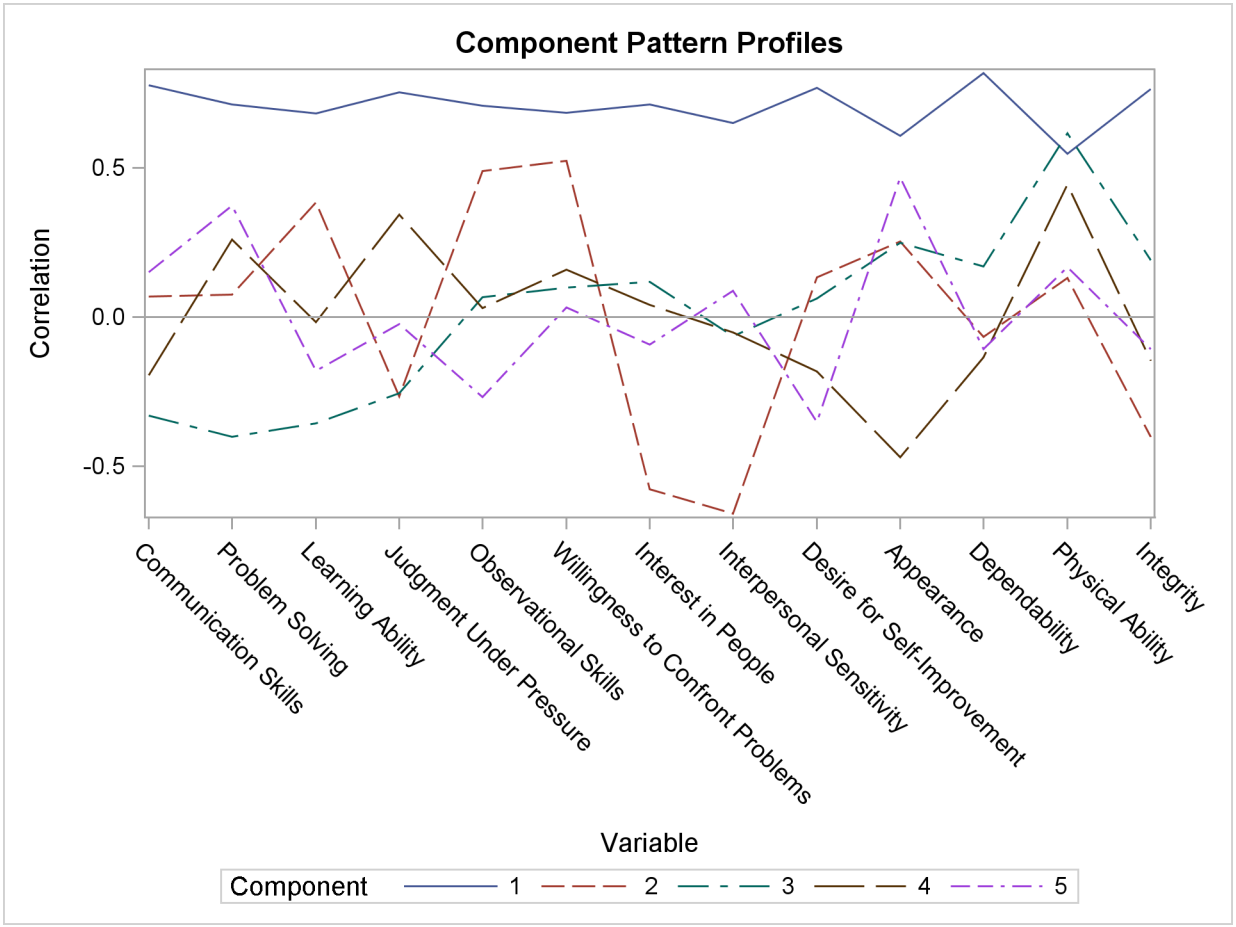
The pairwise component pattern plots are shown in Output 69.3.5 to Output 69.3.7. The pattern plots show the following:

- All variables positively and evenly correlate with the first principal component (Output 69.3.5 and Output 69.3.6).
- The variables Observational Skills and Willingness to Confront Problems correlate highly with the second component, and the variables Interest in People and Interpersonal Sensitivity correlate highly but negatively with the second component (Output 69.3.5).
- The variable Physical Ability correlates highly with the third component, and the variables Problem Solving and Learning Ability correlate highly but negatively with the third component (Output 69.3.6).
- The variable Observational Skills, Willingness to Confront Problems, Interest in People, and Interpersonal Sensitivity correlate highly (either positively or negatively) with the second component, but all have very low correlations with the third component; the variables Physical Ability and Problem Solving correlate highly (either positively or negatively) with the third component, but both have very low correlations with the second component (Output 69.3.7).



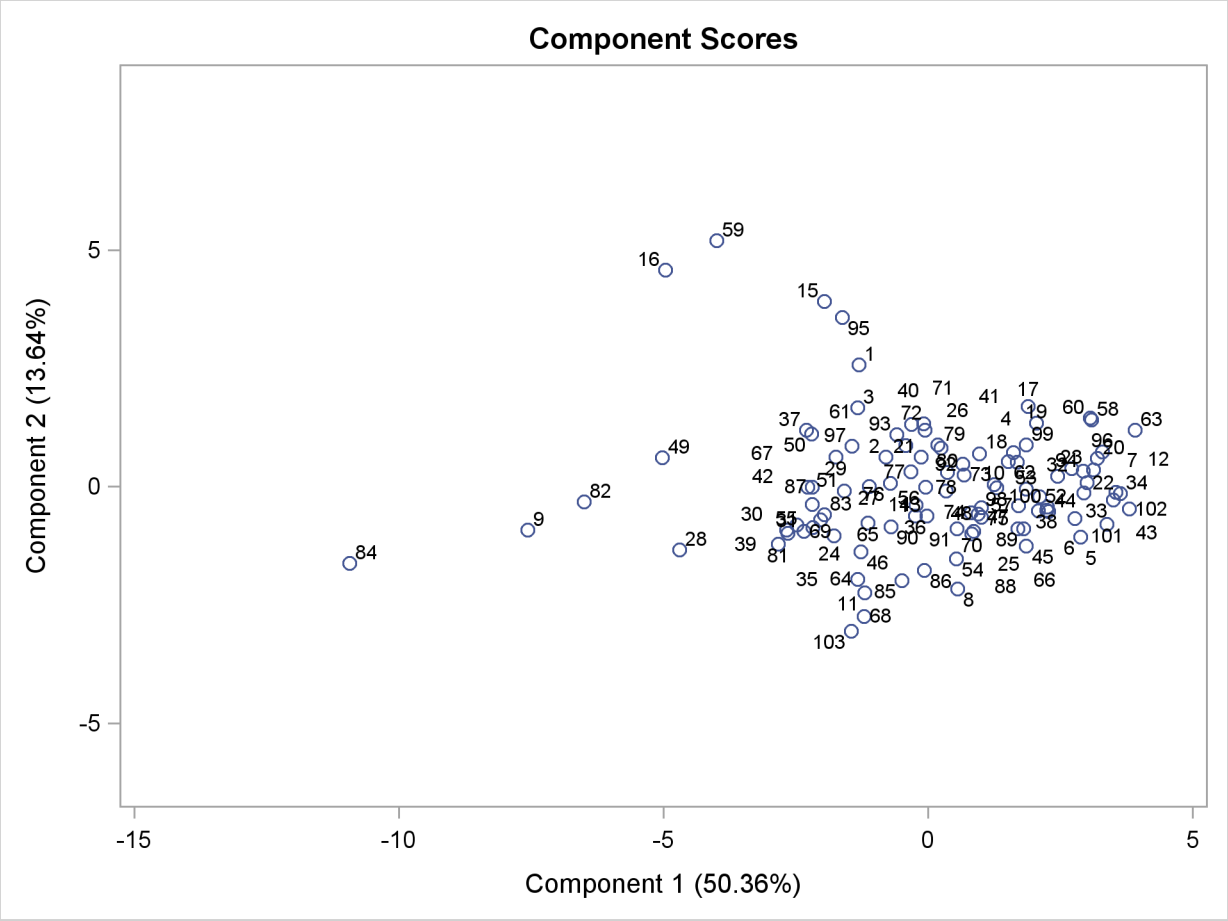
Output 69.3.5 Pattern Plot of Component 2 by Component 1

Output 69.3.6 Pattern Plot of Component 3 by Component 1



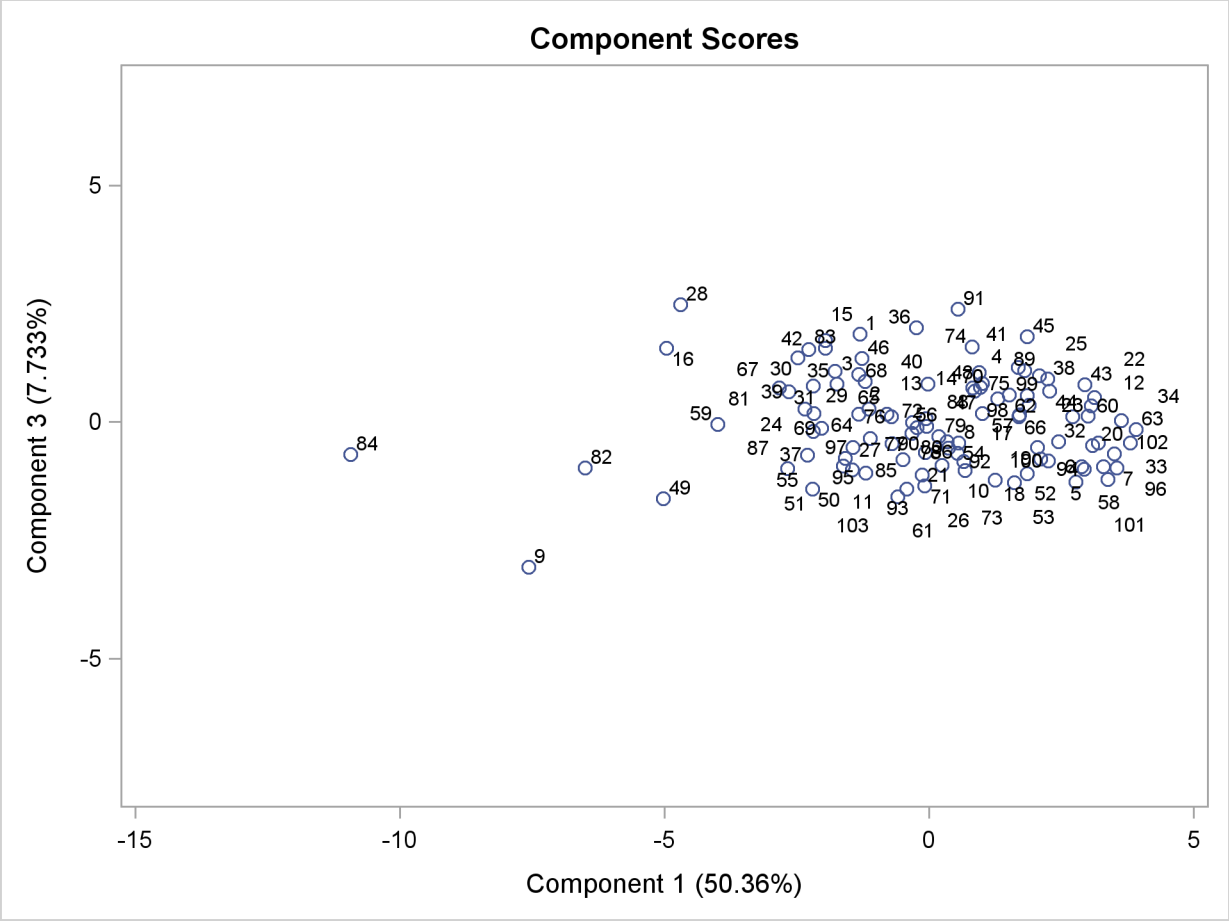
Output 69.3.7 Pattern Plot of Component 3 by Component 2

Output 69.3.8 shows a component pattern profile. As it was shown in the pattern plots, the nearly horizontal profile from the first component indicates that the first component is mostly correlated evenly across all variables.



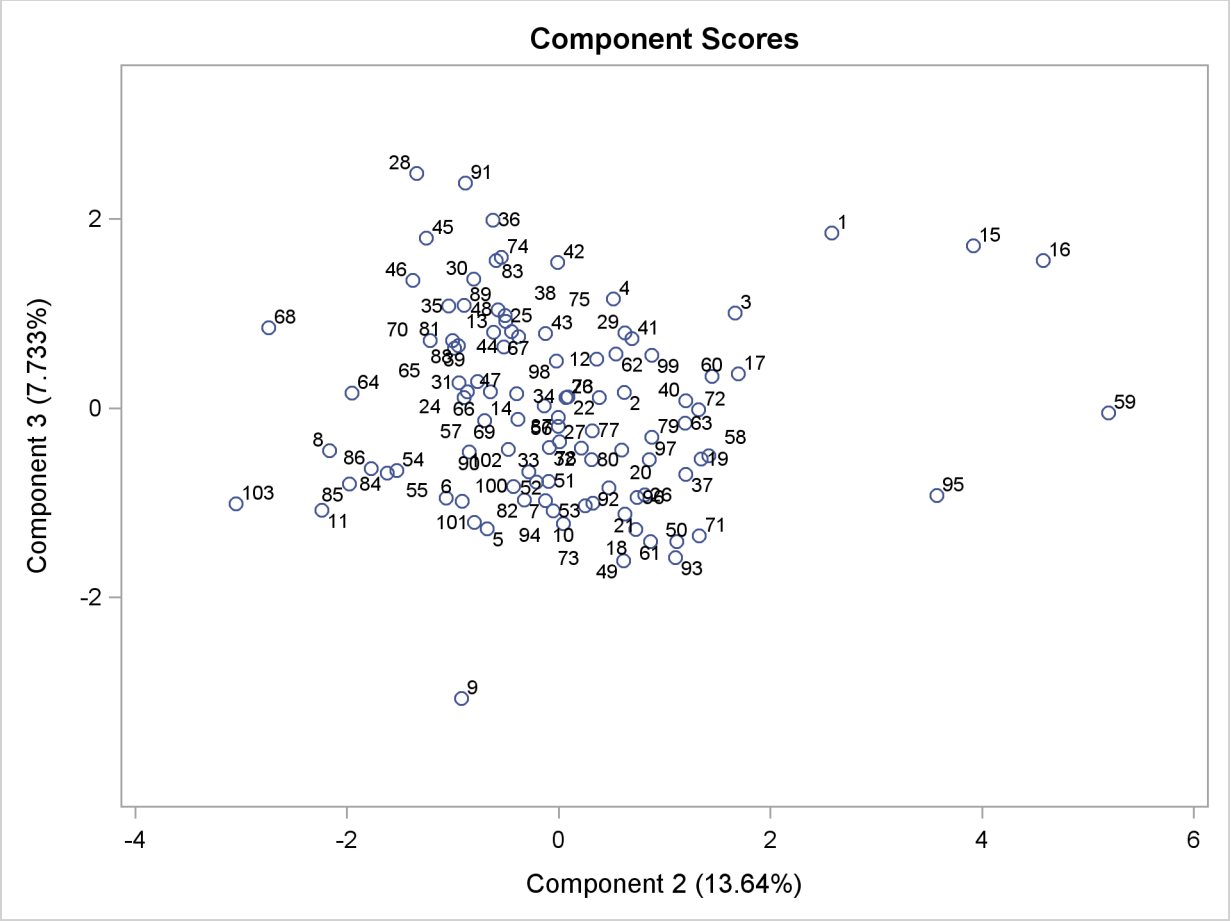
Output 69.3.8 Component Pattern Profile Plot from the PRINCOMP Procedure

Output 69.3.9 through Output 69.3.11 display the pairwise component score plots. Observation numbers are used as the plotting symbol.



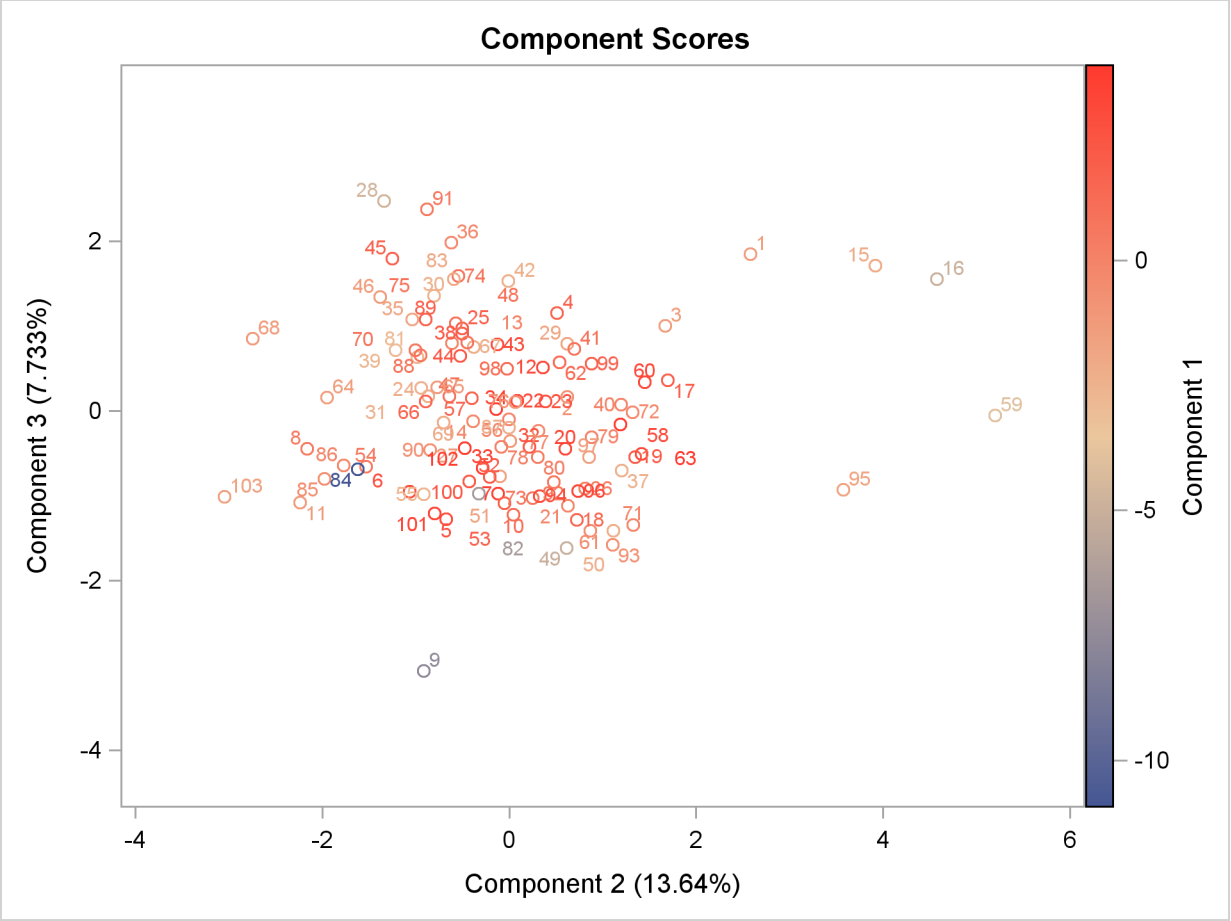
Output 69.3.9 shows a scatter plot of the first and third components. Observations 82, 9, and 84 seem like outliers on the first component; Observations 16 and 59 can be potential outliers on the second component.

Output 69.3.9 Component 2 versus Component 1



Output 69.3.10 shows a scatter plot of the first and third components. Observations 82, 9, and 84 seem like outliers on the first component.

Output 69.3.10 Component 3 versus Component 1



Output 69.3.11 shows a scatter plot of the second and third components. Observations 95, 15, 16, and 59 can be potential outliers on the second component.

Output 69.3.11 Component 3 versus Component 2

Output 69.3.12 shows a scatter plot of the second and third components, displaying density with color. Color interpolation is based on the first component, such as in the statistical style, going from blue (minimum density) to tan (median density) and to red (maximum density).

Output 69.3.12 Component 3 versus Component 2, Painted by Component 1

Overview: PRINQUAL Procedure

The PRINQUAL procedure performs principal component analysis (PCA) of qualitative, quantitative, or mixed data. PROC PRINQUAL is based on the work of Kruskal and Shepard (1974); Young, Takane, and de Leeuw (1978); Young (1981); and Winsberg and Ramsay (1983). PROC PRINQUAL finds linear and nonlinear transformations of variables, using the method of alternating least squares, that optimize properties of the transformed variables' correlation or covariance matrix. Nonoptimal transformations such as logarithm and rank are also available. You can use ODS Graphics to display the results. You can use PROC PRINQUAL to do the following:

- fit metric and nonmetric principal component analyses
- perform metric and nonmetric multidimensional preference (MDPREF) analyses (Carroll 1972)
- transform data prior to their use in other analyses
- reduce the number of variables for subsequent use in regression analyses, cluster analyses, and other analyses
- detect nonlinear relationships

PROC PRINQUAL provides three methods, each of which seeks to optimize a different property of the transformed variables' covariance or correlation matrix. These methods are as follows:

- maximum total variance, or MTV
- minimum generalized variance, or MGV
- maximum average correlation, or MAC

The MTV method is based on a PCA model, and it is the most commonly used method. All three methods attempt to find transformations that decrease the rank of the covariance matrix computed from the transformed variables. Transforming the variables to maximize the total variance accounted for by a few linear combinations locates the observations in a space with a dimensionality that approximates the stated number of linear combinations as much as possible, given the transformation constraints. Transforming the variables to minimize their generalized variance or maximize the average correlations also reduces the dimensionality, but without a stated target for the final dimensionality. See the section "The Three Methods of Variable Transformation" on page 5220 for more information about all three methods.

The data can contain variables measured on nominal, ordinal, interval, and ratio scales of measurement (Siegel 1956). Any mix is allowed with all methods. PROC PRINQUAL can do the following:

- transform nominal variables by optimally scoring the categories (Fisher 1938)
- transform ordinal variables monotonically by scoring the ordered categories so that order is weakly preserved (adjacent categories can be merged) and the covariance matrix is optimized. You can undo ties optimally or leave them tied (Kruskal 1964). You can also transform ordinal variables to ranks.
- transform interval and ratio scale of measurement variables linearly, or transform them nonlinearly with spline transformations (de Boor 1978; van Rijckevorsel 1982) or monotone spline transformations (Winsberg and Ramsay 1983). In addition, nonoptimal transformations for logarithm, rank, exponential, power, logit, and inverse trigonometric sine are available.
- estimate missing data without constraint, with category constraints (missing values within the same group get the same value), and with order constraints (missing value estimates in adjacent groups can be tied to preserve a specified ordering). See Gifi (1990) and Young (1981).

The transformed qualitative (nominal and ordinal) variables can be thought of as being quantified by the analysis, with the quantification done in the context set by the algorithm. The data are quantified so that the proportion of variance accounted for by a stated number of principal components is locally maximized, the generalized variance of the variables is locally minimized, or the average of the correlations is locally maximized.

The PROC PRINQUAL iterations produce a set of transformed variables. Each variable's new scoring satisfies a set of constraints based on the original scoring of the variable and the specified transformation type. First, all variables are required to satisfy standardization constraints; that is, all variables have a fixed mean and variance. The other constraints include linear constraints, weak order constraints, category constraints, and smoothness constraints. The new set of scores is selected from the sets of possible scorings that do not violate the constraints so that the method criterion is locally optimized.

Getting Started: PRINQUAL Procedure

PROC PRINQUAL can be used to fit a principal component model with nonlinear transformations of the variables and graphically display the results. This example finds monotonic transformations of ratings of automobiles.

;

ods graphics on;

proc prinqual data=cars plots=all maxiter=100;
   transform monotone(mpg -- cargo);
   id model;
run;

ods graphics off;
```

The PROC PRINQUAL statement names the input data set Cars. The ODS GRAPHICS statement, along with the PLOTS=ALL option, requests all graphical displays. The MDPREF option requests the PCA plot with the scores (automobiles) represented as points and the structure (variables) represented as vectors. By default, the vector lengths are increased by a factor of 2.5 to produce a better graphical display. If instead you were to specify MDPREF=1, you would get the actual vectors, and they would all be short and would end near the origin where there are a lot of points. It is often the case that increasing the vector lengths by a factor of 2 or 3 makes a better graphical display, so by default the vector lengths are increased by a factor of 2.5. Up to 100 iterations are requested with the MAXITER= option. All of the numeric variable are specified with a MONOTONE transformation, so their original values, 1 to 5, are optimally rescored to maximize fit to a two-component model while preserving the original order. The Model variable provides the labels for the row points in the plot.

The iteration history table is shown in Figure 70.1. The monotonic transformations allow the PCA to account for 5% more variance in two principal components than the ordinary PCA model applied to the untransformed data.

Figure 70.1 Automobile Ratings Iteration History

Ratings for Automobiles Manufactured in 1980

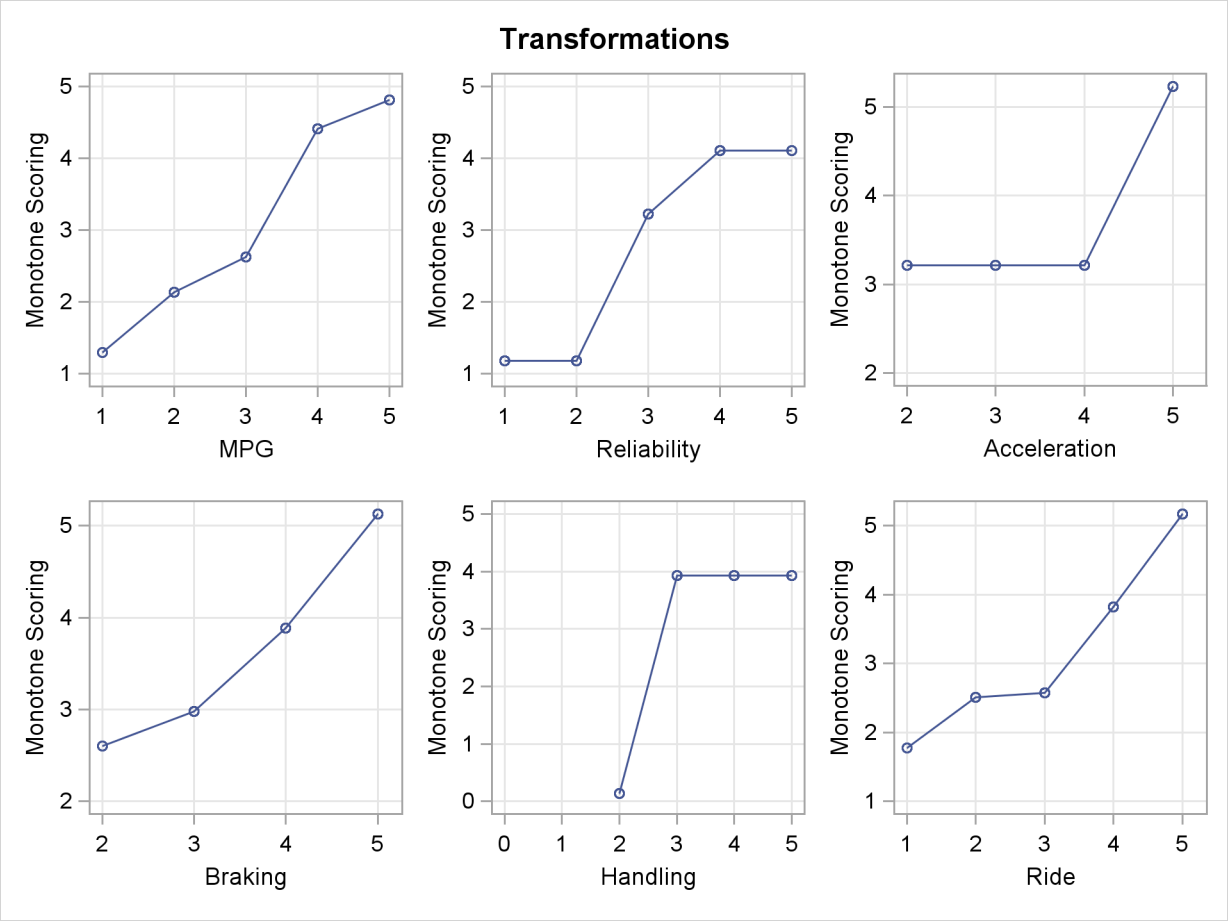
Algorithm converged.

The PCA biplot in Figure 70.2 shows the transformed automobile ratings projected into the two-dimensional plane of the analysis. The automobiles on the left tend to be smaller than the autos on the right, and the autos at the top tend to be cheaper than the autos at the bottom. The vectors can help you interpret the plot of the scores. Longer vectors show the variables that better fit the two-dimensional model. A larger component of them is in the plane of the plot. In contrast, shorter vectors show the variables that do not fit the two-dimensional model as well. They tend to be located less in the plot and more away from the plot; hence their projection into the plot is shorter. To envision this, lay a pencil on your desk directly under a light, and slowly rotate it up to form a 90-degree angle with your desk. As you do so, the shadow or projection of the pencil onto your desk will get progressively shorter. The results show, for example, that the Chevette would be expected to do well on gas mileage but not well on quiet and acceleration. In contrast, the Corvette and the Firebird have the opposite pattern.

Figure 70.2 Automobile Ratings PCA Biplot

There are many patterns shown in the transformations in Figure 70.3. The transformation of Braking, for example, is not very different from the original scoring. The optimal scoring for other variables, such as Acceleration and Handling, is binary. Automobiles are differentiated by high versus everything else or low versus everything else.

Figure 70.3 Automobile Ratings Transformations



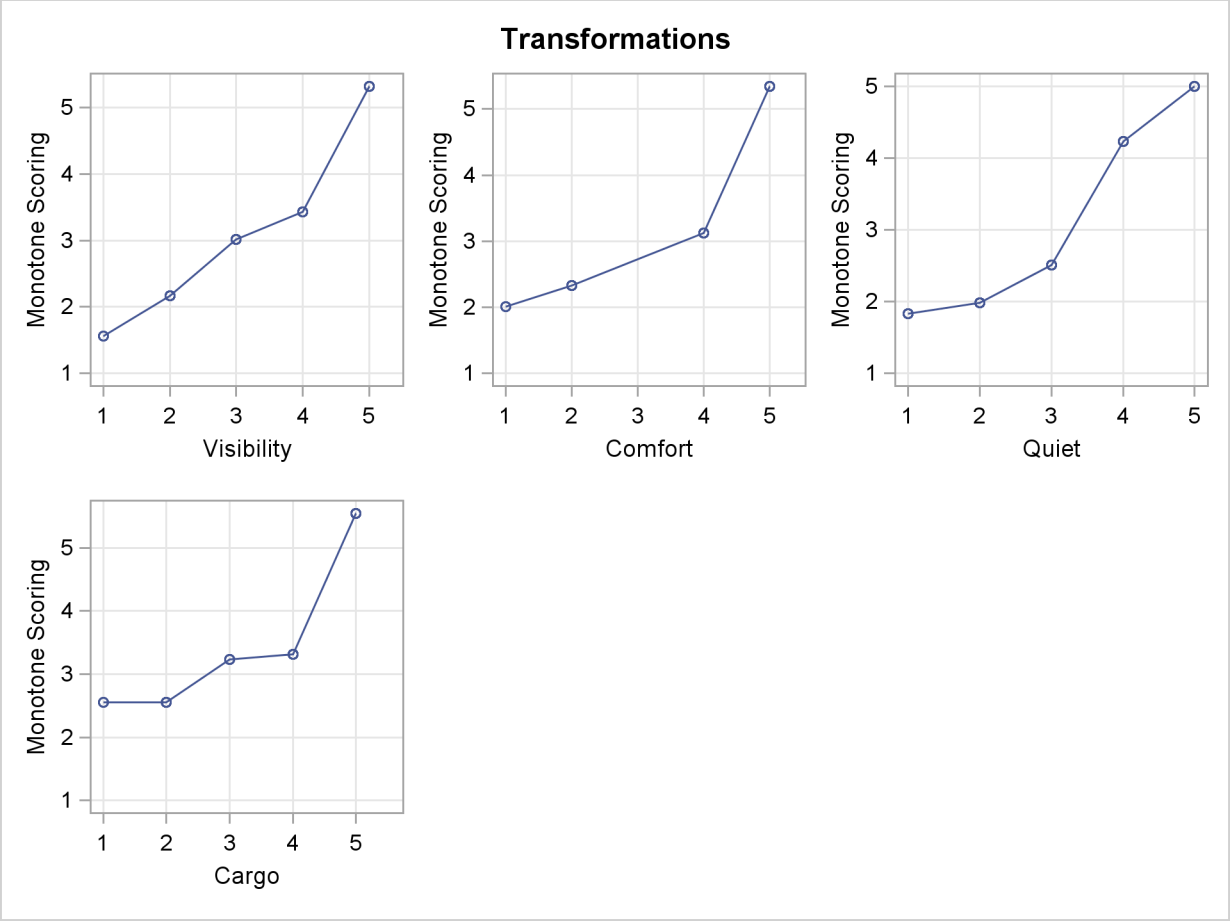


Figure 70.3 *continued*

Syntax: PRINQUAL Procedure

The following statements are available in PROC PRINQUAL.

PROC PRINQUAL < *options* > ;
  TRANSFORM *transform(variables* < / *t-options* >*)*
    < *transform(variables* < / *t-options* >*) . . .* > ;
  ID *variables* ;
  FREQ *variable* ;
  WEIGHT *variable* ;
  BY *variables* ;

To use PROC PRINQUAL, you need the PROC PRINQUAL and TRANSFORM statements. You can abbreviate all *options* and *t-options* to their first three letters. This is a special feature of PROC PRINQUAL and is not generally true of other SAS/STAT procedures.

The rest of this section provides detailed syntax information about each of the preceding statements, beginning with the PROC PRINQUAL statement. The remaining statements are described in alphabetical order.

PROC PRINQUAL Statement

PROC PRINQUAL < *options* > **;**

The PROC PRINQUAL statement invokes the PRINQUAL procedure. Optionally, this statement identifies an input data set, creates an output data set, specifies the algorithm and other computational details, and controls displayed output. The options listed in Table 70.1 are available in the PROC PRINQUAL statement.

Table 70.1 Summary of PROC PRINQUAL Statement Options

Option	Description
Input Data Set Options	
DATA=	specifies input SAS data set
Output Data Set Details	
APPROXIMATIONS	outputs approximations to transformed variables
APREFIX=	specifies prefix for approximation variables
CORRELATIONS	outputs correlations and component structure matrix
MDPREF=	specifies a multidimensional preference analysis
OUT=	specifies output data set
PREFIX=	specifies prefix for principal component scores
REPLACE	replaces raw data with transformed data
SCORES	outputs principal component scores
STANDARD	standardizes principal component scores
TPREFIX=	specifies prefix for transformed variables
TSTANDARD=	specifies transformation standardization
Method and Iterations	
CCONVERGE=	specifies minimum criterion change
CHANGE=	specifies number of first iteration to be displayed
CONVERGE=	specifies minimum data change
COVARIANCE	analyzes covariances
DUMMY	initializes using dummy variables
INITITER=	specifies number of MAC initialization iterations
MAXITER=	specifies maximum number of iterations
METHOD=	specifies iterative algorithm
NOCHECK	suppresses numerical error checking
N	specifies number of principal components
REFRESH=	specifies number of MGV models before refreshing
REITERATE	restarts iterations
SINGULAR=	specifies singularity criterion
TYPE=	specifies input observation type
Missing Data Handling	
MONOTONE=	includes monotone special missing values
NOMISS	excludes observations with missing values
UNTIE=	unties special missing values

Table 70.1 *continued*

Option	Description
Control Displayed Output	
NOPRINT	suppresses displayed output
PLOTS=	specifies ODS Graphics details

The following list describes these options in alphabetical order.

APREFIX=*name*

APR=*name*

specifies a prefix for naming the approximation variables. By default, APREFIX=A. Specifying the APREFIX= option also implies the APPROXIMATIONS option.

APPROXIMATIONS

APPROX

APP

includes principal component approximations to the transformed variables (Eckart and Young 1936) in the output data set. Variable names are constructed from the value of the APREFIX= option and the input variable names. If you specify the APREFIX= option, then approximations are automatically included. If you specify the APPROXIMATIONS option and not the APREFIX= option, then the APPROXIMATIONS option uses the default, APREFIX=A, to construct the variable names.

CCONVERGE=*n*

CCO=*n*

specifies the minimum change in the criterion being optimized that is required to continue iterating. By default, CCONVERGE=0.0. The CCONVERGE= option is ignored for METHOD=MAC. For the MGV method, specify CCONVERGE=–2 to ensure data convergence.

CHANGE=*n*

CHA=*n*

specifies the number of the first iteration to be displayed in the iteration history table. The default is CHANGE=1. When you specify a larger value for n, the first $n - 1$ iterations are not displayed, thus speeding up the analysis. The CHANGE= option is most useful with the MGV method, which is much slower than the other methods.

CONVERGE=*n*

CON=*n*

specifies the minimum average absolute change in standardized variable scores that is required to continue iterating. By default, CONVERGE=0.00001. Average change is computed over only those variables that can be transformed by the iterations—that is, all LINEAR, OPSCORE, MONOTONE, UNTIE, SPLINE, MSPLINE, and SSPLINE variables and nonoptimal transformation variables with missing values. For more information, see the section "Optimal Transformations" on page 5215.

COVARIANCE
COV

computes the principal components from the covariance matrix. The variables are always centered to mean zero. If you do not specify the COVARIANCE option, the variables are also standardized to variance one, which means the analysis is based on the correlation matrix.

CORRELATIONS
COR

includes correlations and the component structure matrix in the output data set. By default, this information is not included.

DATA=*SAS-data-set*

specifies the SAS data set to be analyzed. The data set must be an ordinary SAS data set; it cannot be a TYPE=CORR or TYPE=COV data set. If you omit the DATA= option, PROC PRINQUAL uses the most recently created SAS data set.

DUMMY
DUM

expands variables specified for OPSCORE optimal transformations to dummy variables for the initialization (Tenenhaus and Vachette 1977). By default, the initial values of OPSCORE variables are the actual data values. The dummy variable nominal initialization requires considerable time and memory, so it might not be possible to use the DUMMY option with large data sets. No separate report of the initialization is produced. Initialization results are incorporated into the first iteration displayed in the iteration history table. For details, see the section "Optimal Transformations" on page 5215.

INITITER=*n*
INI=*n*

specifies the number of MAC iterations required to initialize the data before starting MTV or MGV iterations. By default, INITITER=0. The INITITER= option is ignored if METHOD=MAC.

MAXITER=*n*
MAX=*n*

specifies the maximum number of iterations. By default, MAXITER=30.

MDPREF<=*n***>**
MDP<=*n***>**

specifies a multidimensional preference analysis by implying the STANDARD, SCORES, and CORRELATIONS options. This option also suppresses warnings when there are more variables than observations.

When ODS Graphics is enabled, an MDPREF plot is produced with points for each row and vectors for each column. Often, the vectors are short, and a better graphical display is produced when the vectors are stretched. The absolute lengths of each vector can optionally be changed by specifying MDPREF=n. Then the vector coordinates are all multiplied by n. Usually, n will be a value such as 2, 2.5, or 3. The default is 2.5. Specify MDPREF=1 to see the vectors without any stretching. The relative lengths of the different vectors is important and interpretable, and these are preserved by the stretching.

METHOD=MAC | MGV | MTV

MET=MAC | MGV | MTV

specifies the optimization method. By default, METHOD=MTV. Values of the METHOD= option are MTV, for maximum total variance; MGV, for minimum generalized variance; and MAC, for maximum average correlation. You can use the MAC method when all variables are positively correlated or when no monotonicity constraints are placed on any transformations. See the section "The Three Methods of Variable Transformation" on page 5220 for more information.

MONOTONE=*two-letters*

MON=*two-letters*

specifies the first and last special missing value in the list of those special missing values to be estimated using within-variable order and category constraints. By default, there are no order constraints on missing value estimates. The *two-letters* value must consist of two letters in alphabetical order. For example, MONOTONE=DF means that the estimate of .D must be less than or equal to the estimate of .E, which must be less than or equal to the estimate of .F; no order constraints are placed on estimates of ._, .A through .C, and .G through .Z. For details, see the sections "Missing Values" on page 5227 and "Optimal Scaling" on page 7259 in Chapter 90, "The TRANSREG Procedure."

N=*n*

specifies the number of principal components to be computed. By default, N=2.

NOCHECK

NOC

turns off computationally intensive numerical error checking for the MGV method. If you do not specify the NOCHECK option, the procedure computes R square from the squared length of the predicted values vector and compares this value to the R square computed from the error sum of squares that is a byproduct of the sweep algorithm (Goodnight 1978). If the two values of R square differ by more than the square root of the value of the SINGULAR= option, a warning is displayed, the value of the REFRESH= option is halved, and the model is refit after refreshing. Specifying the NOCHECK option slightly speeds up the algorithm. Note that other less computationally intensive error checking is always performed.

NOMISS

NOM

excludes all observations with missing values from the analysis, but does not exclude them from the OUT= data set. If you omit the NOMISS option, PROC PRINQUAL simultaneously computes the optimal transformations of the nonmissing values and estimates the missing values that minimize squared error.

Casewise deletion of observations with missing values occurs when you specify the NOMISS option, when there are missing values in IDENTITY variables, when there are weights less than or equal to 0, or when there are frequencies less than 1. Excluded observations are output with a blank value for the _TYPE_ variable, and they have a weight of 0. They do not contribute to the analysis but are scored and transformed as *supplementary* or passive observations. See the sections "Passive Observations" on page 5234 and "Missing Values" on page 5227 for more information about excluded observations and missing data.

NOPRINT

NOP

suppresses the display of all output. This option disables the Output Delivery System (ODS), including ODS Graphics, for the duration of the procedure. For more information, see Chapter 20, "Using the Output Delivery System."

OUT=*SAS-data-set*

specifies an output SAS data set that contains results of the analysis. If you omit the OUT= option, PROC PRINQUAL still creates an output data set and names it by using the DATA*n* convention. If you want to create a permanent SAS data set, you must specify a two-level name. (See the discussion in *SAS Language Reference: Concepts*.) You can use the REPLACE, APPROXIMATIONS, SCORES, and CORRELATIONS options to control what information is included in the output data set. For details, see the section "Output Data Set" on page 5229.

PLOTS <(*global-plot-options***)> <=** *plot-request* **<(***options***)>>**

PLOTS <(*global-plot-options***)> <= (***plot-request* **<(***options***)> <...** *plot-request* **<(***options***)>>)>**

controls the plots produced through ODS Graphics. When you specify only one plot request, you can omit the parentheses from around the plot request. Here are some examples:

```
plots=none
plots=transformation
plots(unpack)=transformation
```

You must enable ODS Graphics before requesting plots, for example, like this:

```
ods graphics on;

proc prinqual plots=all;
   transformation spline(x1-x10);
run;

ods graphics off;
```

For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." If you have enabled ODS Graphics but do not specify the PLOTS= option, then PROC PRINQUAL produces an MDPREF plot when the MDPREF option is specified.

The global plot options include the following:

FLIP

FLI

flips or interchanges the X-axis and Y-axis dimensions for MDPREF plots. The FLIP option can be specified either as a global plot option (for example, PLOTS(FLIP)) or with the MDPREF option (for example, PLOTS=MDPREF(FLIP)).

INTERPOLATE

INT

uses observations that are excluded from the analysis for interpolation in the fit and transformation plots. By default, observations with zero weight are excluded from all plots. These include observations with a zero, negative, or missing weight or frequency and observations excluded due to missing and invalid values. You can specify PLOTS(INTERPOLATE)=(*plot-requests*) to include some of these observations in the plots. You can use this option, for example, with sparse data sets to show smoother functions over the range of the data (see the section "The PLOTS(INTERPOLATE) Option" on page 7302 in Chapter 90, "The TRANSREG Procedure").

ONLY

ONL

suppresses the default plots. Only plots specifically requested are displayed.

UNPACKPANEL

UNPACK

UNP

suppresses paneling. By default, multiple plots can appear in some output panels. Specify UNPACKPANEL to get each plot in a separate panel.

The plot requests include the following:

ALL

produces all appropriate plots.

TRANSFORMATION

TRA

TRANSFORMATION(UNPACK)

TRA(UNP)

plots the variable transformations. By default, multiple plots can appear in some output panels. Specify UNPACKPANEL to display each plot in a separate panel.

MDPREF

MDP

plots multidimensional preference analysis results. The MDPREF plot can also be requested by specifying the MDPREF option in the PROC statement outside the PLOTS= option.

NONE

suppresses all plots.

PREFIX=*name*

PRE=*name*

specifies a prefix for naming the principal components. By default, PREFIX=Prin. As a result, the principal component default names are Prin1, Prin2,..., Prin$n$.

REFRESH=*n*

REF=*n*

specifies the number of variables to scale in the MGV method before computing a new inverse. By default, REFRESH=5. PROC PRINQUAL uses the REFRESH= option in the sweep algorithm of the MGV method. Large values for the REFRESH= option make the method run faster but with more numerical error. Small values make the method run more slowly but with more numerical accuracy.

REITERATE

REI

enables PROC PRINQUAL to use previous transformations as starting points. The REITERATE option affects only variables that are iteratively transformed (specified as LINEAR, SPLINE, MSPLINE, SSPLINE, UNTIE, OPSCORE, and MONOTONE). For iterative transformations, the REITERATE option requests a search in the input data set for a variable that consists of the value of the TPREFIX= option followed by the original variable name. If such a variable is found, it is used to provide the initial values for the first iteration. The final transformation is a member of the transformation family defined by the original variable, not the transformation family defined by the initialization variable. See the section "REITERATE Option Usage" on page 5233.

REPLACE

REP

replaces the original data with the transformed data in the output data set. The names of the transformed variables in the output data set correspond to the names of the original variables in the input data set. If you do not specify the REPLACE option, both original variables and transformed variables (with names constructed from the TPREFIX= option and the original variable names) are included in the output data set.

SCORES

SCO

includes principal component scores in the output data set. By default, scores are not included.

SINGULAR=*n*

SIN=*n*

specifies the largest value within rounding error of zero. By default, SINGULAR=1E–8. PROC PRINQUAL uses the value of the SINGULAR= option for checking $(1 - R^2)$ when constructing full-rank matrices of predictor variables, checking denominators before dividing, and so on.

STANDARD

STD

standardizes the principal component scores in the output data set to mean zero and variance one instead of the default mean zero and variance equal to the corresponding eigenvalue. See the SCORES option.

TPREFIX=*name*

TPR=*name*

specifies a prefix for naming the transformed variables. By default, TPREFIX=T. The TPREFIX= option is ignored if you specify the REPLACE option.

TSTANDARD=CENTER | NOMISS | ORIGINAL | Z

TST=CEN | NOM | ORI | Z

specifies the standardization of the transformed variables in the OUT= data set. By default, TSTANDARD=ORIGINAL. When you specify the TSTANDARD= option in the PROC statement, it the default standardization for all variables. When you specify TSTANDARD= as a *t-option*, it overrides the default standardization just for selected variables.

CENTER centers the output variables to mean zero, but the variances are the same as the variances of the input variables.

NOMISS sets the means and variances of the transformed variables in the OUT= data set, computed over all output values that correspond to nonmissing values in the input data set, to the means and variances computed from the nonmissing observations of the original variables. The TSTANDARD=NOMISS specification is useful with missing data. When a variable is linearly transformed, the final variable contains the original nonmissing values and the missing value estimates. In other words, the nonmissing values are unchanged. If your data have no missing values, TSTANDARD=NOMISS and TSTANDARD=ORIGINAL produce the same results.

ORIGINAL sets the means and variances of the transformed variables to the means and variances of the original variables. This is the default.

Z standardizes the variables to mean zero, variance one.

For nonoptimal variable transformations, the means and variances of the original variables are actually the means and variances of the nonlinearly transformed variables, unless you specify the ORIGINAL nonoptimal *t-option* in the TRANSFORM statement. For example, if a variable X with no missing values is specified as LOG, then, by default, the final transformation of X is simply LOG(X), not LOG(X) standardized to the mean of X and variance of X.

TYPE='*text* '|*name*

TYP='*text* '|*name*

specifies the valid value for the _TYPE_ variable in the input data set. If PROC PRINQUAL finds an input _TYPE_ variable, it uses only observations with a _TYPE_ value that matches the TYPE= value. This enables a PROC PRINQUAL OUT= data set containing correlations to be used as input to PROC PRINQUAL without requiring a WHERE statement to exclude the correlations. If a _TYPE_ variable is not in the data set, all observations are used. The default is TYPE='SCORE', so if you do not specify the TYPE= option, only observations with _TYPE_ = 'SCORE' are used.

PROC PRINQUAL displays a note when it reads observations with blank values of _TYPE_, but it does not automatically exclude those observations. Data sets created by the TRANSREG and PRINQUAL procedures have blank _TYPE_ values for those observations that

were excluded from the analysis due to nonpositive weights, nonpositive frequencies, or missing data. When these observations are read again, they are excluded for the same reason that they were excluded from their original analysis, not because their _TYPE_ value is blank.

UNTIE=*two-letters*
UNT=*two-letters*
specifies the first and last special missing values in the list of those special missing values that are to be estimated with within-variable order constraints but no category constraints. The *two-letters* value must consist of two letters in alphabetical order. By default, there are category constraints but no order constraints on special missing value estimates. For details, see the section "Missing Values" on page 5227. Also, see the section "Optimal Scaling" on page 7259 in Chapter 90, "The TRANSREG Procedure."

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC PRINQUAL to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for PROC PRINQUAL. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

FREQ Statement

FREQ *variable* **;**

If one variable in the input data set represents the frequency of occurrence for other values in the observation, list the variable's name in a FREQ statement. PROC PRINQUAL then treats the data set as if each observation appeared n times, where n is the value of the FREQ variable for the observation. Noninteger values of the FREQ variable are truncated to the largest integer less than the FREQ value. The observation is used in the analysis only if the value of the FREQ statement variable is greater than or equal to 1.

ID Statement

ID *variables* **;**

The ID statement includes additional character or numeric variables in the output data set. The variables must be contained in the input data set.

TRANSFORM Statement

TRANSFORM *transform(variables < / t-options >) < transform(variables < / t-options >) . . . >* **;**

The TRANSFORM statement lists the variables to be analyzed (*variables*) and specifies the transformation (*transform*) to apply to each variable listed. You must specify a transformation for each variable list in the TRANSFORM statement. The variables are variables in the data set. The *t-options* are transformation options that provide details for the transformation; these depend on the *transform* chosen. The *t-options* are listed after a slash in the parentheses that enclose the variables.

For example, the following statements find a quadratic polynomial transformation of all variables in the data set:

```
proc princqual;
   transform spline(_all_ / degree=2);
run;
```

Or, if N1 through N10 are nominal variables and M1 through M10 are ordinal variables, you can use the following statements:

```
proc princqual;
   transform opscore(N1-N10) monotone(M1-M10);
run;
```

The following sections describe the transformations available (specified with *transform*) and the options available for some of the transformations (specified with *t-options*).

Families of Transformations

There are three types of transformation families: nonoptimal, optimal, and other. The families are described as follows:

Nonoptimal transformations	preprocess the specified variables, replacing each one with a single new nonoptimal, nonlinear transformation.
Optimal transformations	replace the specified variables with new, iteratively derived optimal transformation variables that fit the specified model better than the original variable (except in contrived cases where the transformation fits the model exactly as well as the original variable).

Other transformations are the IDENTITY and SSPLINE transformations. These do not fit into either of the preceding categories.

Table 70.2 summarizes the transformations in each family.

Table 70.2 Transformation Families

Transformation	Description
Nonoptimal Transformations	
ARSIN	inverse trigonometric sine
EXP	exponential
LOG	logarithm
LOGIT	logit
POWER	raises variables to specified power
RANK	transforms to ranks
Optimal Transformations	
LINEAR	linear
MONOTONE	monotonic, ties preserved
MSPLINE	monotonic B-spline
OPSCORE	optimal scoring
SPLINE	B-spline
UNTIE	monotonic, ties not preserved
Other Transformations	
IDENTITY	identity, no transformation
SSPLINE	iterative smoothing spline

The *transform* is followed by a variable (or list of variables) enclosed in parentheses. Optionally, depending on the *transform*, the parentheses can also contain *t-options*, which follow the variables and a slash. For example, the following statement computes the LOG transformation of X and Y:

```
transform log(X Y);
```

A more complex example follows:

```
transform spline(Y / nknots=2) log(X1 X2 X3);
```

The preceding statement uses the SPLINE transformation of the variable Y and the LOG transformation of the variables X1, X2, and X3. In addition, it uses the NKNOTS= option with the SPLINE transformation and specifies two knots.

The rest of this section provides syntax details for members of the three families of transformations. The *t-options* are discussed in the section "Transformation Options (t-options)" on page 5216.

Nonoptimal Transformations

Nonoptimal transformations are computed before the iterative algorithm begins. Nonoptimal transformations create a single new transformed variable that replaces the original variable. The new variable is not transformed by the subsequent iterative algorithms (except for a possible linear transformation and missing value estimation).

The following list provides syntax and details for nonoptimal variable transformations.

ARSIN

ARS

finds an inverse trigonometric sine transformation. Variables specified in the ARSIN *transform* must be numeric and in the interval ($-1.0 \leq x \leq 1.0$), and they are typically continuous.

EXP

exponentiates variables (x is transformed to a^x). To specify the value of a, use the PARAMETER= *t-option*. By default, a is the mathematical constant $e = 2.718\ldots$. Variables specified with the EXP *transform* must be numeric, and they are typically continuous.

LOG

transforms variables to logarithms (x is transformed to $\log_a(x)$). To specify the base of the logarithm, use the PARAMETER= *t-option*. The default is a natural logarithm with base $e = 2.718\ldots$. Variables specified with the LOG *transform* must be numeric and positive, and they are typically continuous.

LOGIT

finds a logit transformation on the variables. The logit of x is $\log(x/(1-x))$. Unlike other transformations, LOGIT does not have a three-letter abbreviation. Variables specified with the LOGIT *transform* must be numeric and in the interval ($0.0 < x < 1.0$), and they are typically continuous.

POWER

POW

raises variables to a specified power (x is transformed to x^a). You must specify the power parameter a by specifying the PARAMETER= *t-option* following the variables.

```
power(variable / parameter=number)
```

You can use POWER for squaring variables (PARAMETER=2), reciprocal transformations (PARAMETER=–1), square roots (PARAMETER=0.5), and so on. Variables specified with the POWER *transform* must be numeric, and they are typically continuous.

RANK

RAN

transforms variables to ranks. Ranks are averaged within ties. The smallest input value is assigned the smallest rank. Variables specified with the RANK *transform* must be numeric.

Optimal Transformations

Optimal transformations are iteratively derived. Missing values for these types of variables can be optimally estimated (see the section "Missing Values" on page 5227). See the sections "OPSCORE, MONOTONE, UNTIE, and LINEAR Transformations" on page 7260 and "SPLINE and MSPLINE Transformations" on page 7261 in Chapter 90, "The TRANSREG Procedure," for more information about the optimal transformations.

The following list provides syntax and details for optimal transformations.

LINEAR

LIN

finds an optimal linear transformation of each variable. For variables with no missing values, the transformed variable is the same as the original variable. For variables with missing values, the transformed nonmissing values have a different scale and origin than the original values. Variables specified with the LINEAR *transform* must be numeric.

MONOTONE

MON

finds a monotonic transformation of each variable, with the restriction that ties are preserved. The Kruskal (1964) secondary least-squares monotonic transformation is used. This transformation weakly preserves order and category membership (ties). Variables specified with the MONOTONE *transform* must be numeric, and they are typically discrete.

MSPLINE

MSP

finds a monotonically increasing B-spline transformation with monotonic coefficients (de Boor 1978; de Leeuw 1986) of each variable. You can specify the DEGREE=, KNOTS=, NKNOTS=, and EVENLY= *t-options* with MSPLINE. By default, PROC PRINQUAL uses a quadratic spline. Variables specified with the MSPLINE *transform* must be numeric, and they are typically continuous.

OPSCORE

OPS

finds an optimal scoring of each variable. The OPSCORE transformation assigns scores to each class (level) of the variable. The Fisher (1938) optimal scoring method is used. Variables specified with the OPSCORE *transform* can be either character or numeric; numeric variables should be discrete.

SPLINE

SPL

finds a B-spline transformation (de Boor 1978) of each variable. By default, PROC PRINQUAL uses a cubic polynomial transformation. You can specify the DEGREE=, KNOTS=, NKNOTS=, and EVENLY *t-options* with SPLINE. Variables specified with the SPLINE *transform* must be numeric, and they are typically continuous.

UNTIE
UNT

finds a monotonic transformation of each variable without the restriction that ties are preserved. PROC PRINQUAL uses the Kruskal (1964) primary least-squares monotonic transformation method. This transformation weakly preserves order but not category membership (it might untie some previously tied values). Variables specified with the UNTIE *transform* must be numeric, and they are typically discrete.

Other Transformations

IDENTITY
IDE

specifies variables that are not changed by the iterations. The IDENTITY transformation is used for variables when no transformation and no missing data estimation are desired. However, the REFLECT, ADDITIVE, TSTANDARD=Z, and TSTANDARD=CENTER options can linearly transform all variables, including IDENTITY variables, after the iterations. Observations with missing values in IDENTITY variables are excluded from the analysis, and no optimal scores are computed for missing values in IDENTITY variables. Variables specified with the IDENTITY *transform* must be numeric.

SSPLINE
SSP

finds an iterative smoothing spline transformation of each variable. The SSPLINE transformation does not generally minimize squared error. You can specify the smoothing parameter with either the SM= *t-option* or the PARAMETER= *t-option*. The default smoothing parameter is SM=0. Variables specified with the SSPLINE *transform* must be numeric, and they are typically continuous.

Transformation Options (t-options)

If you use a nonoptimal, optimal, or other transformation, you can use *t-options*, which specify additional details of the transformation. The *t-options* are specified within the parentheses that enclose variables and are listed after a slash. For example:

```
proc prinqual;
   transform spline(X Y / nknots=3);
run;
```

The preceding statements find an optimal variable transformation (SPLINE) of the variables X and Y and use a *t-option* to specify the number of knots (NKNOTS=). The following is a more complex example:

```
proc prinqual;
   transform spline(Y / nknots=3) spline(X1 X2 / nknots=6);
run;
```

These statements use the SPLINE transformation for all three variables and use *t-options* as well; the NKNOTS= option specifies the number of knots for the spline.

The following sections discuss the *t-options* available for nonoptimal, optimal, and other transformations.

Table 70.3 summarizes the *t-options*.

Table 70.3 Transformation Options

Option	Description
Nonoptimal Transformation	
ORIGINAL	uses original mean and variance
Parameter Specification	
PARAMETER=	specifies miscellaneous parameters
SM	specifies smoothing parameter
Spline	
DEGREE=	specifies the degree of the spline
EVENLY	spaces the knots evenly
KNOTS=	specifies the interior knots or break points
NKNOTS=	creates *n* knots
Other t-options	
NAME=	renames variables
REFLECT	reflects the variable around the mean
TSTANDARD=	specifies transformation standardization

Nonoptimal Transformation t-options

ORIGINAL

ORI

matches the variable's final mean and variance to the mean and variance of the original variable. By default, the mean and variance are based on the transformed values. The ORIGINAL *t-option* is available for all of the nonoptimal transformations.

Parameter t-options

PARAMETER=*number*

PAR=*number*

specifies the transformation parameter. The PARAMETER= *t-option* is available for the EXP, LOG, POWER, SMOOTH, and SSPLINE transformations. For EXP, the parameter is the value to be exponentiated; for LOG, the parameter is the base value; and for POWER, the parameter is the power. For SMOOTH and SSPLINE, the parameter is the raw smoothing parameter. (See the SM= option for an alternative way to specify the smoothing parameter.) The default for the PARAMETER= *t-option* for the LOG and EXP transformations is $e = 2.718\ldots$. The default parameter for SSPLINE is computed from SM=0. For the POWER transformation, you must specify the PARAMETER= *t-option*; there is no default.

SM=*n*

specifies a smoothing parameter in the range 0 to 100, just like PROC GPLOT uses. For example, SM=50 in PROC PRINQUAL is equivalent to I=SM50 on the SYMBOL statement with PROC GPLOT. You can specify the SM= *t-option* only with the SSPLINE transformation. The smoothness of the function increases as the value of the smoothing parameter increases. By default, SM=0.

Spline t-options

The following *t-options* are available with the SPLINE and MSPLINE optimal transformations.

DEGREE=*n*

DEG=*n*

specifies the degree of the B-spline transformation. The degree must be a nonnegative integer. The defaults are DEGREE=3 for SPLINE variables and DEGREE=2 for MSPLINE variables.

The polynomial degree should be a small integer, usually 0, 1, 2, or 3. Larger values are rarely useful. If you have any doubt as to what degree to specify, use the default.

EVENLY<=*n***>**

EVE<=*n***>**

is used with the NKNOTS= *t-option* to space the knots evenly. The differences between adjacent knots are constant. If you specify NKNOTS=k, k knots are created at

$$\text{minimum} + i\,((\text{maximum} - \text{minimum})/(k+1))$$

for $i = 1, \ldots, k$. For example, if you specify

```
spline(X / knots=2 evenly)
```

and the variable X has a minimum of 4 and a maximum of 10, then the two interior knots are 6 and 8. Without the EVENLY *t-option*, the NKNOTS= *t-option* places knots at percentiles, so the knots are not evenly spaced.

By default for the SPLINE and MSPLINE transformations, the smaller exterior knots are all the same and just a little smaller than the minimum. Similarly, by default, the larger exterior knots are all the same and just a little larger than the maximum. However, if you specify EVENLY=*n*, then the n exterior knots are evenly spaced as well. The number of exterior knots must be greater than or equal to the degree. You can specify values larger than the degree when you want to interpolate slightly beyond the range or your data. The exterior knots must be less than the minimum or greater than the maximum, and hence the knots across all sets are not precisely equally spaced. For example, with data ranging from 0 to 10, and with EVENLY=3 and NKNOTS=4, the first exterior knots are –4.000000000001, –2.000000000001, and –0.000000000001, the interior knots are 2, 4, 6, and 8, and the second exterior knots are 10.000000000001, 12.000000000001, and 14.000000000001.

KNOTS=*number-list* | *n* **TO** *m* **BY** *p*

KNO=*number-list* | *n* **TO** *m* **BY** *p*

specifies the interior knots or break points. By default, there are no knots. The first time you specify a value in the knot list, it indicates a discontinuity in the nth (from DEGREE=n) derivative of the transformation function at the value of the knot. The second mention of a value indicates a discontinuity in the $(n-1)$th derivative of the transformation function at the value of the knot. Knots can be repeated any number of times to decrease the smoothness at the break points, but the values in the knot list can never decrease.

You cannot use the KNOTS= *t-option* with the NKNOTS= *t-option*. You should keep the number of knots small. (See the section "Specifying the Number of Knots" on page 7262 in Chapter 90, "The TRANSREG Procedure.")

NKNOTS=*n*

NKN=*n*

creates n knots, the first at the $100/(n+1)$ percentile, the second at the $200/(n+1)$ percentile, and so on. Knots are always placed at data values; there is no interpolation. For example, if NKNOTS=3, knots are placed at the 25th percentile, the median, and the 75th percentile. By default, NKNOTS=0. The NKNOTS= *t-option* must be ≥ 0.

You cannot use the NKNOTS= *t-option* with the KNOTS= *t-option*. You should keep the number of knots small. (See the section "Specifying the Number of Knots" on page 7262 in Chapter 90, "The TRANSREG Procedure.")

Other t-options

The following *t-options* are available for all transformations.

NAME=*(variable-list)*

NAM=*(variable-list)*

renames variables as they are used in the TRANSFORM statement. This option allows a variable to be used more than once. For example, if the variable X is a character variable, then the following step stores both the original character variable X and a numeric variable XC that contains category numbers in the output data set.

```
proc princual data=A n=1 out=B;
   transform linear(Y) opscore(X / name=(XC));
   id X;
run;
```

REFLECT

REF

reflects the transformation

$$y = -(y - \bar{y}) + \bar{y}$$

after the iterations are completed and before the final standardization and results calculations.

TSTANDARD=CENTER | NOMISS | ORIGINAL | Z

TST=CEN | NOM | ORI | Z

specifies the standardization of the transformed variables in the OUT= data set. By default, TSTANDARD=ORIGINAL. When the TSTANDARD= option is specified in the PROC PRINQUAL statement, it specifies the default standardization for all variables. When you specify TSTANDARD= as a *t-option*, it overrides the default standardization only for selected variables.

WEIGHT Statement

WEIGHT *variable* **;**

When you use a WEIGHT statement, a weighted residual sum of squares is minimized. The WEIGHT statement has no effect on degrees of freedom or number of observations, but the weights affect most other calculations. The observation is used in the analysis only if the value of the WEIGHT statement variable is greater than 0.

Details: PRINQUAL Procedure

The Three Methods of Variable Transformation

The three methods of variable transformation provided by PROC PRINQUAL are discussed in the following sections.

The Maximum Total Variance (MTV) Method

The MTV method (Young, Takane, and de Leeuw 1978) is based on the principal component model, and it attempts to maximize the sum of the first r eigenvalues of the covariance matrix. This method transforms variables to be (in a least-squares sense) as similar to linear combinations of r principal component score variables as possible, where r can be much smaller than the number of variables. This maximizes the total variance of the first r components (the trace of the covariance matrix of the first r principal components). See *SAS Technical Report R-108*.

On each iteration, the MTV algorithm alternates classical principal component analysis (Hotelling 1933) with optimal scaling (Young 1981). When all variables are ordinal preference ratings, this corresponds to MDPREF analysis (Carroll 1972). You can request the dummy variable initialization method suggested by Tenenhaus and Vachette (1977), who independently propose the same iterative algorithm for nominal and interval scale-of-measurement variables.

The Minimum Generalized Variance (MGV) Method

The MGV method (Sarle 1984) uses an iterated multiple regression algorithm in an attempt to minimize the determinant of the covariance matrix of the transformed variables. This method transforms each variable to be (in a least-squares sense) as similar to linear combinations of the remaining variables as possible. This locally minimizes the generalized variance of the transformed variables, the determinant of the covariance matrix, the volume of the parallelepiped defined by the transformed variables, and the sphericity (the extent to which a quadratic form in the optimized covariance matrix defines a sphere). See *SAS Technical Report R-108*.

On each iteration for each variable, the MGV algorithm alternates multiple regression with optimal scaling. The multiple regression involves predicting the selected variable from all other variables. You can request a dummy variable initialization by using a modification of the Tenenhaus and Vachette (1977) method that is appropriate with a regression algorithm. This method can be viewed as a way of investigating the nature of the linear and nonlinear dependencies in, and the rank of, a data matrix containing variables that can be nonlinearly transformed. This method tries to create a less-than-full-rank data matrix. The matrix contains the transformation of each variable that is most similar to what the other transformed variables predict.

The Maximum Average Correlation (MAC) Method

The MAC method (de Leeuw 1985) uses an iterated constrained multiple regression algorithm in an attempt to maximize the average of the elements of the correlation matrix. This method transforms each variable to be (in a least-squares sense) as similar to the average of the remaining variables as possible.

On each iteration for each variable, the MAC algorithm alternates computing an equally weighted average of the other variables with optimal scaling. The MAC method is similar to the MGV method in that each variable is scaled to be as similar to a linear combination of the other variables as possible, given the constraints on the transformation. However, optimal weights are not computed. You can use the MAC method when all variables are positively correlated or when no monotonicity constraints are placed on any transformations. Do not use this method with negatively correlated variables when some optimal transformations are constrained to be increasing because the signs of the correlations are not taken into account. The MAC method is useful as an initialization method for the MTV and MGV methods.

Understanding How PROC PRINQUAL Works

In the following example, PROC PRINQUAL uses the MTV method to linearize a curved scatter plot. Let

$$\begin{aligned} X_1 &= -1 \text{ to } 1 \text{ by } 0.02 \\ X_2 &= X_1^3 + \epsilon \\ X_3 &= X_2^5 + \epsilon \end{aligned}$$

where ϵ is normal error.

These three variables define a curved swarm of points in three-dimensional space. First, the SGSCATTER procedure is used to display two-dimensional views of these data. Next, PROC PRINQUAL is used to straighten the scatter plot, making it more one-dimensional by finding a smooth transformation of each variable. The N=1 option in the PROC PRINQUAL statement requests one principal component. The TRANSFORM statement requests a cubic spline transformation with nine knots. *Splines* are curves, which are usually required to be continuous and smooth. See the section "Splines" on page 5226 for more information about splines. See Smith (1979) for an excellent introduction to splines.

PROC PRINQUAL transforms each variable to be as much as possible like the first principal component (or more generally, to be close to the space defined by the first N= principal components). One component accounts for 92 percent of the variance of the untransformed data and over 99 percent of the variance of the transformed data (see Figure 70.5). Note that the results did not converge in the default 50 iterations, so more iterations were requested using the MAXITER= option. The transformations are requested by specifying PLOTS=TRANSFORMATION and are displayed in Figure 70.6.

PROC PRINQUAL creates an output data set that contains both the original and transformed variables. The original variables are named X1, X2, and X3, and the transformed variables are named TX1, TX2, and TX3. The transformed variables are displayed using the SGSCATTER procedure in Figure 70.7.

The following statements produce Figure 70.4 through Figure 70.7:

```
ods graphics on;

* Generate Three-Dimensional Data;
data X;
   do X1 = -1 to 1 by 0.02;
      X2 = X1 ** 3 + 0.05 * normal(7);
      X3 = X1 ** 5 + 0.05 * normal(7);
      output;
   end;
run;
```

```
proc sgscatter data=x;
   plot x1*x2 x1*x3 x3*x2;
   run;

* Try to Straighten the Scatter Plot;
proc prinqual data=X n=1 maxiter=2000 plots=transformation out=results;
   title 'Linearize the Scatter Plot';
   transform spline(X1-X3 / nknots=9);
run;

* Plot the Linearized Scatter Plot;
proc sgscatter data=results;
   plot tx1*tx2 tx1*tx3 tx3*tx2;
   run;
```

The three-dimensional data in Figure 70.4 and Figure 70.7 are displayed in three two-dimensional plots, arrayed as if they were three faces of a cube that was flattened as you might flatten a box.

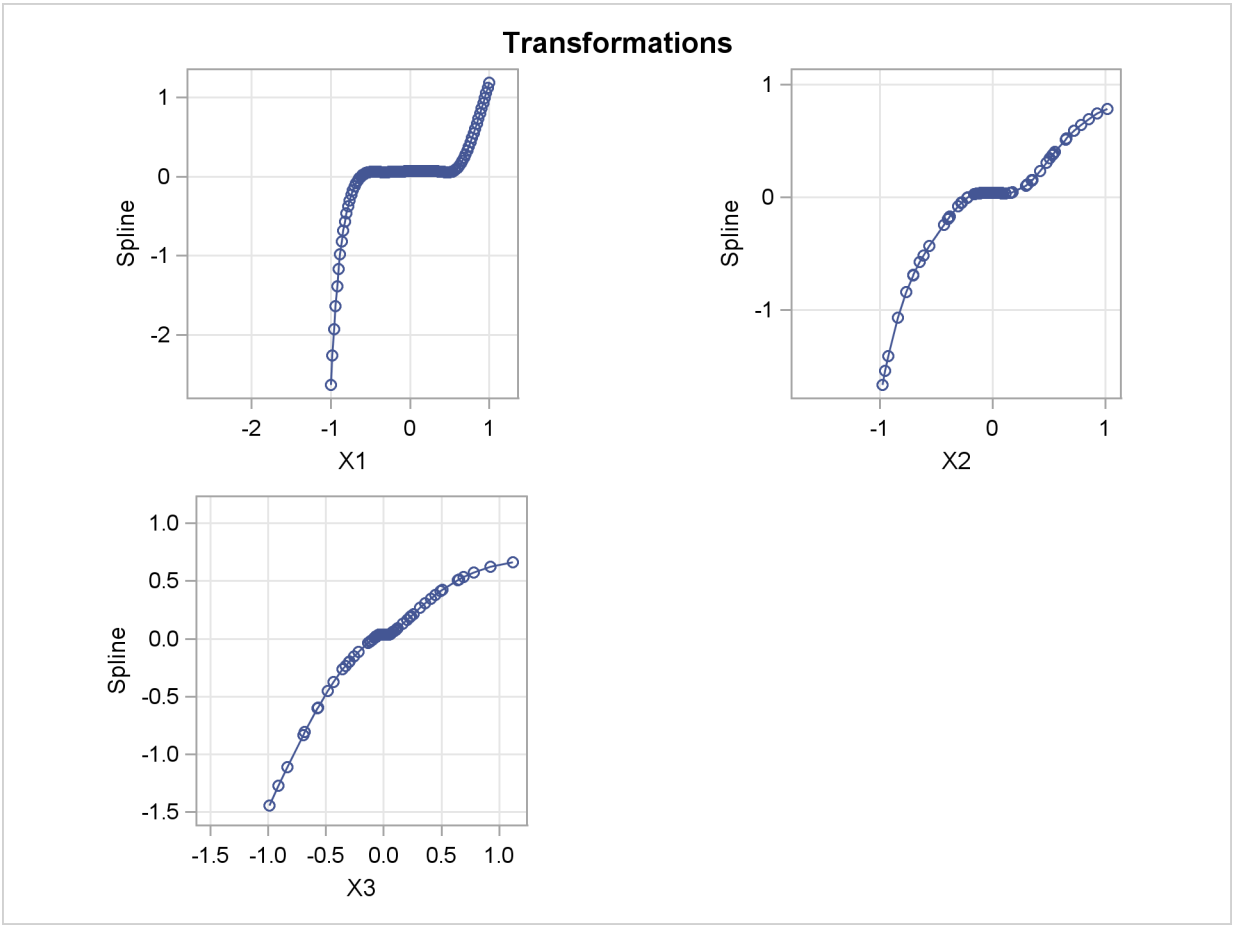

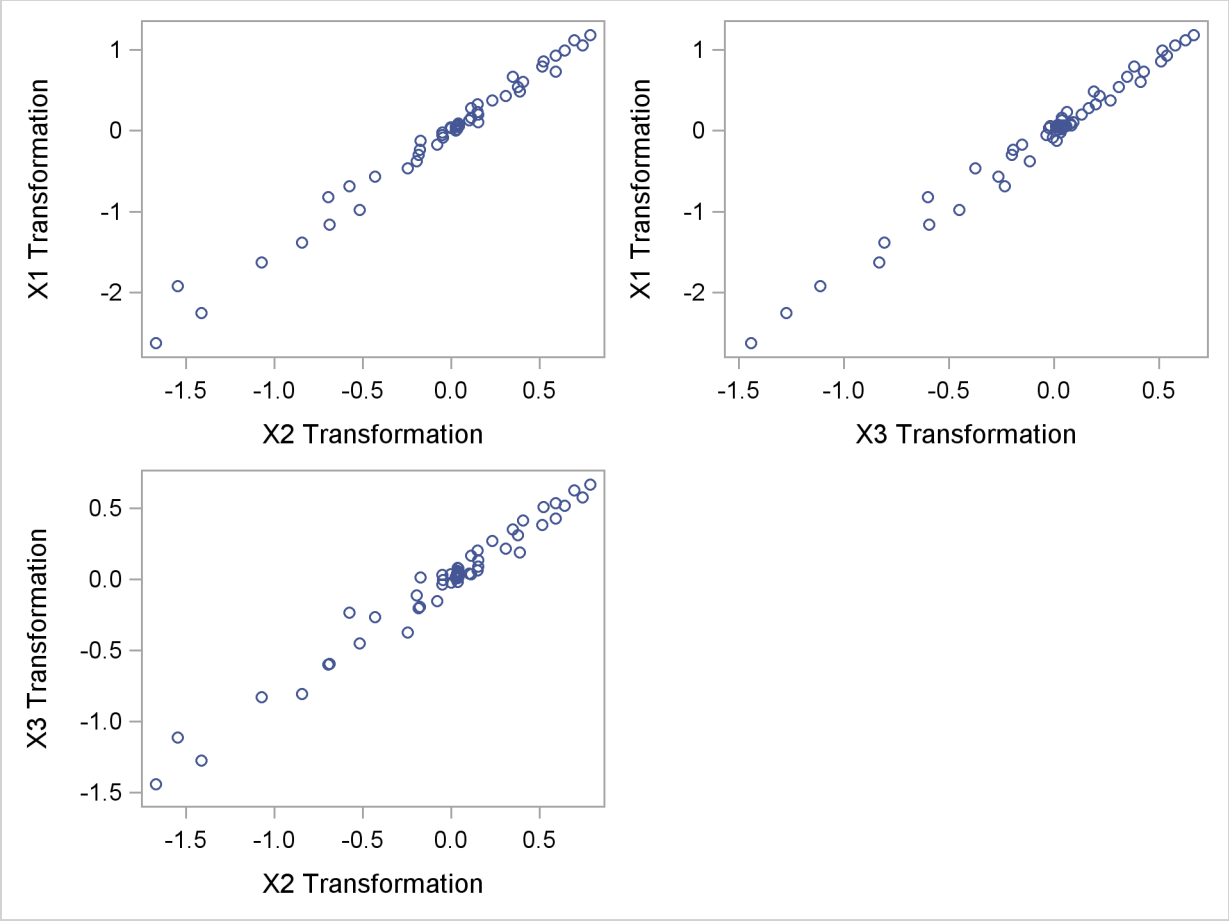

Figure 70.7 Linearized Scatter Plot

Splines

Splines are curves, and they are usually required to be continuous and smooth. Splines are usually defined as piecewise polynomials of degree n with function values and first $n - 1$ derivatives that agree at the points where they join. The abscissa values of the join points are called *knots*. The term "spline" is also used for polynomials (splines with no knots) and piecewise polynomials with more than one discontinuous derivative. Splines with no knots are generally smoother than splines with knots, which are generally smoother than splines with multiple discontinuous derivatives. Splines with few knots are generally smoother than splines with many knots; however, increasing the number of knots usually increases the fit of the spline function to the data. Knots give the curve freedom to bend to follow the data more closely. See Smith (1979) for an excellent introduction to splines. There are many examples and detailed discussions of splines in Chapter 90, "The TRANSREG Procedure." See the sections "Linear and Nonlinear Regression Functions" on page 7209, "Smoothing Splines" on page 7222, "SPLINE and MSPLINE Transformations" on page 7261, "Specifying the Number of Knots" on page 7262, "SPLINE, BSPLINE, and PSPLINE Comparisons" on page 7264, "Linear and Nonlinear Regression Functions" on page 7209, "Simultaneously Fitting Two Regression Functions" on page 7213, and examples Example 90.18 and Example 90.1.

Missing Values

PROC PRINQUAL can estimate missing values, subject to optional constraints, so that the covariance matrix is optimized. The procedure provides several approaches for handling missing data. When you specify the NOMISS option in the PROC PRINQUAL statement, observations with missing values are excluded from the analysis. Otherwise, missing data are estimated, using variable means as initial estimates. Missing values for OPSCORE character variables are treated the same as any other category during the initialization. See the section "Missing Values" on page 7249 in Chapter 90, "The TRANSREG Procedure," for more information about missing data estimation.

Controlling the Number of Iterations

Several options in the PROC PRINQUAL statement control the number of iterations performed. Iteration terminates when any one of the following conditions is satisfied:

- The number of iterations equals the value of the MAXITER= option.
- The average absolute change in variable scores from one iteration to the next is less than the value of the CONVERGE= option.
- The criterion change is less than the value of the CCONVERGE= option.

With the MTV method, the change in the proportion of variance criterion can become negative when the data have converged so that it is numerically impossible, within machine precision, to increase the criterion. Because the MTV algorithm is convergent, a negative criterion change is the result of very small amounts of rounding error. The MGV method displays the average squared multiple correlation (which is not the criterion being optimized), so the criterion change can become negative well before convergence. The MAC method criterion (average correlation) is never computed, so the CCONVERGE= option is ignored for METHOD=MAC. You can specify a negative value for either convergence option if you want to define convergence only in terms of the other convergence option.

With the MGV method, iterations minimize the generalized variance (determinant), but the generalized variance is not reported for two reasons. First, in most data sets, the generalized variance is almost always near zero (or will be after one or two iterations), which is its minimum. This does not mean that iteration is complete; it simply means that at least one multiple correlation is at or near one. The algorithm continues minimizing the determinant in $(m-1), (m-2)$ dimensions, and so on. Because the generalized variance is almost always near zero, it does not provide a good indication of how the iterations are progressing. The mean R square provides a better indication of convergence. The second reason for not reporting the generalized variance is that almost no additional time is required to compute R square values for each step. This is because the error sum of squares is a byproduct of the algorithm at each step. Computing the determinant at the end of each iteration adds more computations to an already computationally intensive algorithm.

You can increase the number of iterations to ensure convergence by increasing the value of the MAXITER= option and decreasing the value of the CONVERGE= option. Because the average absolute change in standardized variable scores seldom decreases below 1E–11, you typically do not specify a value for the CONVERGE= option less than 1E–8 or 1E–10. Most of the data changes occur during the first few iterations, but the data can still change after 50 or even 100 iterations. You can try different combinations of values for the CONVERGE= and MAXITER= options to ensure convergence without extreme overiteration. If the data do not converge with the default specifications, specify the REITERATE option, or try CONVERGE=1E–8 and MAXITER=50, or CONVERGE=1E–10 and MAXITER=200.

Performing a Principal Component Analysis of Transformed Data

PROC PRINQUAL produces an iteration history table that displays (for each iteration) the iteration number, the maximum and average absolute change in standardized variable scores computed over the iteratively transformed variables, the criterion being optimized, and the criterion change. In order to examine the results of the analysis in more detail, you can analyze the information in the output data set by using other SAS procedures.

Specifically, use the PRINCOMP procedure to perform a principal components analysis on the transformed data. PROC PRINCOMP accepts the raw data from PROC PRINQUAL but issues a warning, because the PROC PRINQUAL output data set has _NAME_ and _TYPE_ variables but is not a TYPE=CORR data set. You can ignore this warning.

If the output data set contains both scores and correlations, you must subset it for analysis with PROC PRINCOMP. Otherwise, the correlation observations are treated as ordinary observations and the PROC PRINCOMP results are incorrect. For example, consider the following statements:

```
proc prinqual data=a out=b correlations replace;
   transform spline(var1-var50 / nknots=3);
run;

proc princomp data=b;
   where _TYPE_='SCORE';
run;
```

Also note that the proportion of variance accounted for, as reported by PROC PRINCOMP, can exceed the proportion of variance accounted for in the last PROC PRINQUAL iteration. This is because PROC PRINQUAL reports the variance accounted for by the components analysis that generated the current scaling of the data, not a components analysis of the current scaling of the data.

Using the MAC Method

You can use the MAC algorithm alone by specifying METHOD=MAC, or you can use it as an initialization algorithm for METHOD=MTV and METHOD=MGV analyses by specifying the iteration option INITITER=. If any variables are negatively correlated, do not use the MAC algorithm with monotonic transformations (MONOTONE, UNTIE, and MSPLINE) because the signs of the correlations among the variables are not used when computing variable approximations. If an approximation is negatively correlated with the original variable, monotone constraints would make the optimally scaled variable a constant, which is not allowed (see the section "Avoiding Constant Transformations" on page 5232). When used with other transformations, the MAC algorithm can reverse the scoring of the variables. So, for example, if variable X is designated LOG(X) with METHOD=MAC and TSTANDARD=ORIGINAL, the final transformation (for example, TX) might not be LOG(X). If TX is not LOG(X), it has the same mean as LOG(X) and the same variance as LOG(X), and it is perfectly negatively correlated with LOG(X). PROC PRINQUAL displays a note for every variable that is reversed in this manner.

You can use the METHOD=MAC algorithm to reverse the scorings of some rating variables before a factor analysis. The correlations among bipolar ratings such as 'like - dislike', 'hot - cold', and 'fragile - monumental' are typically both positive and negative. If some items are reversed to say 'dislike - like', 'cold - hot', and 'monumental - fragile', some of the negative signs can be eliminated, and the factor pattern matrix would be cleaner. You can use PROC PRINQUAL with METHOD=MAC and LINEAR transformations to reverse some items, maximizing the average of the intercorrelations.

Output Data Set

PROC PRINQUAL produces an output data set by default. By specifying the OUT=, APPROXIMATIONS, SCORES, REPLACE, and CORRELATIONS options in the PROC PRINQUAL statement, you can name this data set and control its contents.

By default, the procedure creates an output data set that contains variables with _TYPE_='SCORE'. These observations contain original variables, transformed variables, components, or data approximations. If you specify the CORRELATIONS option in the PROC PRINQUAL statement, the data set also contains observations with _TYPE_='CORR'; these observations contain correlations or component structure information.

Structure and Content

The output data set can have 16 different forms, depending on the specified combinations of the REPLACE, SCORES, APPROXIMATIONS, and CORRELATIONS options. You can specify any combination of these options. To illustrate, assume that the data matrix consists of N observations and m variables, and n components are computed. Then define the following:

D the $N \times m$ matrix of original data with variable names that correspond to the names of the variables in the input data set. However, when you use the OPSCORE transformation on character variables, those variables are replaced by numeric variables that contain category numbers.

T the $N \times m$ matrix of transformed data with variable names constructed from the value of the TPREFIX= option (if you do not specify the REPLACE option) and the names of the variables in the input data set

S the $N \times n$ matrix of component scores with variable names constructed from the value of the PREFIX= option and integers

A the $N \times m$ matrix of data approximations with variable names constructed from the value of the APREFIX= option and the names of the variables in the input data set

$\mathbf{R_{TD}}$ the $m \times m$ matrix of correlations between the transformed variables and the original variables with variable names that correspond to the names of the variables in the input data set. When missing values exist, casewise deletion is used to compute the correlations.

$\mathbf{R_{TT}}$ the $m \times m$ matrix of correlations among the transformed variables with the variable names constructed from the value of the TPREFIX= option (if you do not specify the REPLACE option) and the names of the variables in the input data set

$\mathbf{R_{TS}}$ the $m \times n$ matrix of correlations between the transformed variables and the principal component scores (component structure matrix) with variable names constructed from the value of the PREFIX= option and integers

$\mathbf{R_{TA}}$ the $m \times m$ matrix of correlations between the transformed variables and the variable approximations with variable names constructed from the value of the APREFIX= option and the names of the variables in the input data set

To create a data set WORK.A that contains all information, specify the following options in the PROC PRINQUAL statement:

```
proc prinqual scores approximations correlations out=a;
```

Also use a TRANSFORM statement appropriate for your data. Then the WORK.A data set contains the following:

D	T	S	A
$\mathbf{R_{TD}}$	$\mathbf{R_{TT}}$	$\mathbf{R_{TS}}$	$\mathbf{R_{TA}}$

To eliminate the bottom partitions that contain the correlations and component structure, do not specify the CORRELATIONS option. For example, use the following PROC PRINQUAL statement with an appropriate TRANSFORM statement:

```
proc prinqual scores approximations out=a;
```

Then the WORK.A data set contains the following:

D	T	S	A

Suppose you use the following PROC PRINQUAL statement (with an appropriate TRANSFORM statement):

```
proc prinqual out=a;
```

This creates a data set WORK.A of the following form:

```
D T
```

To output transformed data and component scores only, specify the following options in the PROC PRINQUAL statement:

```
proc prinqual replace scores out=a;
```

Then the WORK.A data set contains the following:

```
T S
```

TYPE and _NAME_ Variables

In addition to the preceding information, the output data set contains two character variables, the variable _TYPE_ (length 8) and the variable _NAME_ (length 32).

The _TYPE_ variable has the value 'SCORE' if the observation contains variables, transformed variables, components, or data approximations; the _TYPE_ variable has the value 'CORR' if the observation contains correlations or component structure.

By default, the _NAME_ variable has values 'ROW1', 'ROW2', and so on, for the observations with _TYPE_='SCORE'. If you use an ID statement, the variable _NAME_ contains the formatted ID variable for SCORES observations. The values of the variable _NAME_ for observations with _TYPE_='CORR' are the names of the transformed variables.

Certain procedures, such as PROC PRINCOMP, which can use the PROC PRINQUAL output data set, issue a warning that the PROC PRINQUAL data set contains _NAME_ and _TYPE_ variables but is not a TYPE=CORR data set. You can ignore this warning.

Variable Names

The TPREFIX=, APREFIX=, and PREFIX= options specify prefixes for the transformed and approximation variable names and for principal component score variables, respectively. PROC PRINQUAL constructs transformed and approximation variable names from a prefix and the first characters of the original variable name. The number of characters in the prefix plus the number of characters in the original variable name (including the final digits, if any) required to uniquely designate the new variables should not exceed 32. For example, if the APREFIX= parameter that you specify is one character, PROC PRINQUAL adds the first 31 characters of the original variable name; if your prefix is four characters, only the first 28 characters of the original variable name are added.

Effect of the TSTANDARD= and COVARIANCE Options

The values in the output data set are affected by the TSTANDARD= and COVARIANCE options. If you specify TSTANDARD=NOMISS, the NOMISS standardization is performed on the transformed data after the iterations have been completed, but before the output data set is created. The new means and variances are used in creating the output data set. Then, if you do not specify the COVARIANCE option, the data are transformed to mean zero and variance one. The principal component scores and data approximations are computed from the resulting matrix. The data are then linearly transformed to have the mean and variance specified by the TSTANDARD= option. The data approximations are transformed so that the means within each pair of a transformed variable and its approximation are the same. The ratio of the variance of a variable approximation to the variance of the corresponding transformed variable equals the proportion of the variance of the variable that is accounted for by the components model.

If you specify the COVARIANCE option and do not specify TSTANDARD=Z, you can input the transformed data to PROC PRINCOMP, again specifying the COVARIANCE option, to perform a components analysis of the results of PROC PRINQUAL. Similarly, if you do not specify the COVARIANCE option with PROC PRINQUAL and you input the transformed data to PROC PRINCOMP without the COVARIANCE option, you receive the same report. However, some combinations of PROC PRINQUAL options, such as COVARIANCE and TSTANDARD=Z, while valid, produce approximations and scores that cannot be reproduced by PROC PRINCOMP.

The component scores in the output data set are computed from the correlations among the transformed variables, or from the covariances if you specified the COVARIANCE option. The component scores are computed after the TSTANDARD=NOMISS transformation, if specified. The means of the component scores in the output data set are always zero. The variances equal the corresponding eigenvalues, unless you specify the STANDARD option; then the variances are set to one.

Avoiding Constant Transformations

There are times when the optimal scaling produces a constant transformed variable. This can happen with the MONOTONE, UNTIE, and MSPLINE transformations when the target is negatively correlated with the original input variable. It can happen with all transformations when the target is uncorrelated with the original input variable. When this happens, the procedure modifies the target to avoid a constant transformation. This strategy avoids certain nonoptimal solutions.

If the transformation is monotonic and a constant transformed variable results, the procedure multiplies the target by –1 and tries the optimal scaling again. If the transformation is not monotonic or if the multiplication by –1 did not help, the procedure tries using a random target. If the transformation is still constant, the previous nonconstant transformation is retained. When a constant transformation is avoided by any strategy, this message is displayed: “A constant transformation was avoided for *name*.”

Constant Variables

Constant and almost constant variables are zeroed and ignored.

Character OPSCORE Variables

Character OPSCORE variables are replaced by a numeric variable containing category numbers before the iterations, and the character values are discarded. Only the first eight characters are considered in determining category membership. If you want the original character variable in the output data set, give it a different name in the OPSCORE specification (OPSCORE(x / name=(x2)) and name the original variable in the ID statement (ID x;).

REITERATE Option Usage

You can use the REITERATE option to perform additional iterations when PROC PRINQUAL stops before the data have adequately converged. For example, suppose you execute the following code:

```
proc prinqual data=A cor out=B;
   transform mspline(X1-X5);
run;
```

If the transformations do not converge in the default 30 iterations, you can perform more iterations without repeating the first 30 iterations, as follows:

```
proc prinqual data=B reiterate cor out=B;
   transform mspline(X1-X5);
run;
```

Note that a WHERE statement is not necessary to exclude the correlation observations. They are automatically excluded because their _TYPE_ variable value is not 'SCORE'.

You can also use the REITERATE option to specify starting values other than the original values for the transformations. Providing alternate starting points might avoid local optima. Here are two examples.

```
proc prinqual data=A out=B;
   transform rank(X1-X5);
run;

proc prinqual data=B reiterate out=C;
   /* Use ranks as the starting point. */
   transform monotone(X1-X5);
run;
```

```
data B;
   set A;
   array TXS[5] TX1-TX5;
   do j = 1 to 5;
      TXS[j] = normal(0);
   end;
run;

proc prinqual data=B reiterate out=C;
   /* Use a random starting point. */
   transform monotone(X1-X5);
run;
```

Note that divergence with the REITERATE option, particularly in the second iteration, is not an error since the initial transformation is not required to be a valid member of the transformation family. When you specify the REITERATE option, the iteration does not terminate when the criterion change is negative during the first 10 iterations.

Passive Observations

Observations can be excluded from the analysis for several reasons, including zero weight, zero frequency, missing values in variables designated as IDENTITY, or missing values with the NOMISS option specified. These observations are passive in that they do not contribute to determining transformations, R square, total variance, and so on. However, some information can be computed for them, such as approximations, principal component scores, and transformed values. Passive observations in the output data set have a blank value for the variable _TYPE_.

Missing value estimates for passive observations might converge slowly with METHOD=MTV. In the following example, the missing value estimates should be 2, 5, and 8. Since the nonpassive observations do not change, the procedure converges in one iteration but the missing value estimates do not converge. The extra iterations produced by specifying CONVERGE=–1 and CCONVERGE=–1, as shown in the second PROC PRINQUAL step that follows, generate the expected results.

```
data A;
   input X Y;
   datalines;
1 1
2 .
3 3
4 4
5 .
6 6

   transform lin(X Y);
run;
```

```
proc print;
run;

proc prinqual nomiss data=A nomiss n=1 out=B method=mtv
   converge=-1 cconverge=-1;
   transform lin(X Y);
run;

proc print;
run;
```

Computational Resources

This section provides information about the computational resources required to run PROC PRINQUAL.

Let

N = number of observations
m = number of variables
n = number of principal components
k = maximum spline degree
p = maximum number of knots

- For the MTV algorithm, more than

$$56m + 8Nm + 8\,(6N + (p + k + 2)(p + k + 11))$$

  bytes of array space are required.

- For the MGV and MAC algorithms, more than $56m$ plus the maximum of the data matrix size and the optimal scaling work space bytes of array space are required. The data matrix size is $8Nm$ bytes. The optimal scaling work space requires less than $8\,(6N + (p + k + 2)(p + k + 11))$ bytes.

- For the MTV and MGV algorithms, more than $56m + 4m(m + 1)$ bytes of array space are required.

- PROC PRINQUAL tries to store the original and transformed data in memory. If there is not enough memory, a utility data set is used, potentially resulting in a large increase in execution time. The amount of memory for the preceding data formulas is an underestimate of the amount of memory needed to handle most problems. These formulas give an absolute minimum amount of memory required. If a utility data set is used, and if memory could be used with perfect efficiency, then roughly the amount of memory stated previously would be needed. In reality, most problems require at least two or three times the minimum.

- PROC PRINQUAL sorts the data once. The sort time is roughly proportional to $mN^{3/2}$.
- For the MTV algorithm, the time required to compute the variable approximations is roughly proportional to $2Nm^2 + 5m^3 + nm^2$.
- For the MGV algorithm, one regression analysis per iteration is required to compute model parameter estimates. The time required to accumulate the crossproduct matrix is roughly proportional to Nm^2. The time required to compute the regression coefficients is roughly proportional to m^3. For each variable for each iteration, the swept crossproduct matrix is updated with time roughly proportional to m(N+m). The swept crossproduct matrix is updated for each variable with time roughly proportional to m^2, until computations are refreshed, requiring all sweeps to be performed again.
- The only computationally intensive part of the MAC algorithm is the optimal scaling, since variable approximations are simple averages.
- Each optimal scaling is a multiple regression problem, although some transformations are handled with faster special-case algorithms. The number of regressors for the optimal scaling problems depends on the original values of the variable and the type of transformation. For each monotone spline transformation, an unknown number of multiple regressions is required to find a set of coefficients that satisfies the constraints. The B-spline basis is generated twice for each SPLINE and MSPLINE transformation for each iteration. The time required to generate the B-spline basis is roughly proportional to Nk^2.

Displayed Output

The main output from PROC PRINQUAL is the output data set. However, the procedure does produce displayed output in the form of an iteration history table that includes the following:

- iteration number
- the criterion being optimized
- criterion change
- maximum and average absolute change in standardized variable scores computed over variables that can be iteratively transformed
- notes
- final convergence status

ODS Table Names

PROC PRINQUAL assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 70.4 along with the PROC statement options needed to produce the table. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 70.4 ODS Tables Produced by PROC PRINQUAL

ODS Table Name	Description	Option
ConvergenceStatus	Convergence Status	default
Footnotes	Iteration History Footnotes	default
MAC	MAC Iteration History	METHOD=MAC
MGV	MGV Iteration History	METHOD=MGV
MTV	MTV Iteration History	METHOD=MTV

ODS Graphics

To request graphics with PROC PRINQUAL, you must first enable ODS Graphics by specifying the ODS GRAPHICS ON statement. See Chapter 21, "Statistical Graphics Using ODS," for more information. The plots are produced only when you specify the options shown in the table. You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC PRINQUAL generates are listed in Table 70.5, along with the required statements and options.

Table 70.5 ODS Graphics Produced by PROC PRINQUAL

ODS Graph Name	Plot Description	Option
MDPrefPlot	Multidimensional preference analysis	MDPREF
TransformationPlot	Variable transformation	PLOTS=TRANSFORMATION

Examples: PRINQUAL Procedure

Example 70.1: Multidimensional Preference Analysis of Automobile Data

This example uses PROC PRINQUAL to perform a nonmetric multidimensional preference (MDPREF) analysis (Carroll 1972). MDPREF analysis is a principal component analysis of a data matrix with columns that correspond to people and rows that correspond to objects. The data are ratings or rankings of each person's preference for each object. The data are the transpose of the usual multivariate data matrix. (In other words, the columns are people; in the more typical matrix the rows represent people.) The final result of an MDPREF analysis is a biplot (Gabriel 1981) of the resulting preference space. A biplot displays the judges and objects in a single plot by projecting them onto the plane in the transformed variable space that accounts for the most variance.

In 1980, 25 judges gave their preferences for each of 17 new automobiles. The ratings were made on a 0 to 9 scale, with 0 meaning very weak preference and 9 meaning very strong preference for the automobile. The following statements create a SAS data set with the manufacturer and model of each automobile along with the ratings:

```

;
```

The following statements run PROC PRINCOMP and create a scree plot. The results of this step are shown in Output 70.1.1.

```
ods graphics on;

* Principal Component Analysis of the Original Data;
proc princomp data=CarPref;
   ods select EigenvaluePlot;
   var '1'n-'25'n;
run;
```

Output 70.1.1 Eigenvalue Plot

The scree or eigenvalue plot in Output 70.1.1 shows that two principal components should be retained. There is a clear separation between the first two components and the remaining components. There are eight eigenvalues that are precisely zero because there are eight fewer observations than variables in the data matrix. One additional eigenvalue is zero, for a total of nine zero eigenvalues, since the correlation matrix is based on centered data. The following statements create the data set and perform a principal component analysis of the original data.

PROC PRINQUAL fits the nonmetric MDPREF model. PROC PRINQUAL monotonically transforms the raw judgments to maximize the proportion of variance accounted for by the first two principal components. The MONOTONE option is specified in the TRANSFORM statement to request a nonmetric MDPREF analysis; alternatively, you can instead specify the IDENTITY option for a metric analysis. Several options are used in the PROC PRINQUAL statement. The option DATA=CarPref specifies the input data set, OUT=Results creates an output data set, and N=2 and the default METHOD=MTV transform the data to better fit a two-component model. The REPLACE option replaces the original data with the monotonically transformed data in the OUT= data set. The MDPREF option standardizes the component scores to variance one so that the geometry of the biplot is correct, and it creates two variables in the OUT= data set named Prin1 and Prin2. These

variables contain the standardized principal component scores and structure matrix, which are used to make the biplot. If the variables in data matrix $\mathbf{X}$ are standardized to mean zero and variance one, and n is the number of rows in $\mathbf{X}$, then $\mathbf{X} = \mathbf{V}\mathbf{\Lambda}^{1/2}\mathbf{W}'$ is the principal component model, where $\mathbf{X}'\mathbf{X}/(n-1) = \mathbf{W}\mathbf{\Lambda}\mathbf{W}'$. The $\mathbf{W}$ and $\mathbf{\Lambda}$ contain the eigenvectors and eigenvalues of the correlation matrix of $\mathbf{X}$. The first two columns of $\mathbf{V}$, the standardized component scores, and $\mathbf{W}\mathbf{\Lambda}^{1/2}$, which is the structure matrix, are output. The advantage of creating a biplot based on principal components is that coordinates do not depend on the sample size. The following statements transform the data and produce Output 70.1.2.

```
* Transform the Data to Better Fit a Two Component Model;
proc prinqual data=CarPref out=Results n=2 replace mdpref;
   title2 'Multidimensional Preference (MDPREF) Analysis';
   title3 'Optimal Monotonic Transformation of Preference Data';
   id model;
   transform monotone('1'n-'25'n);
run;
```

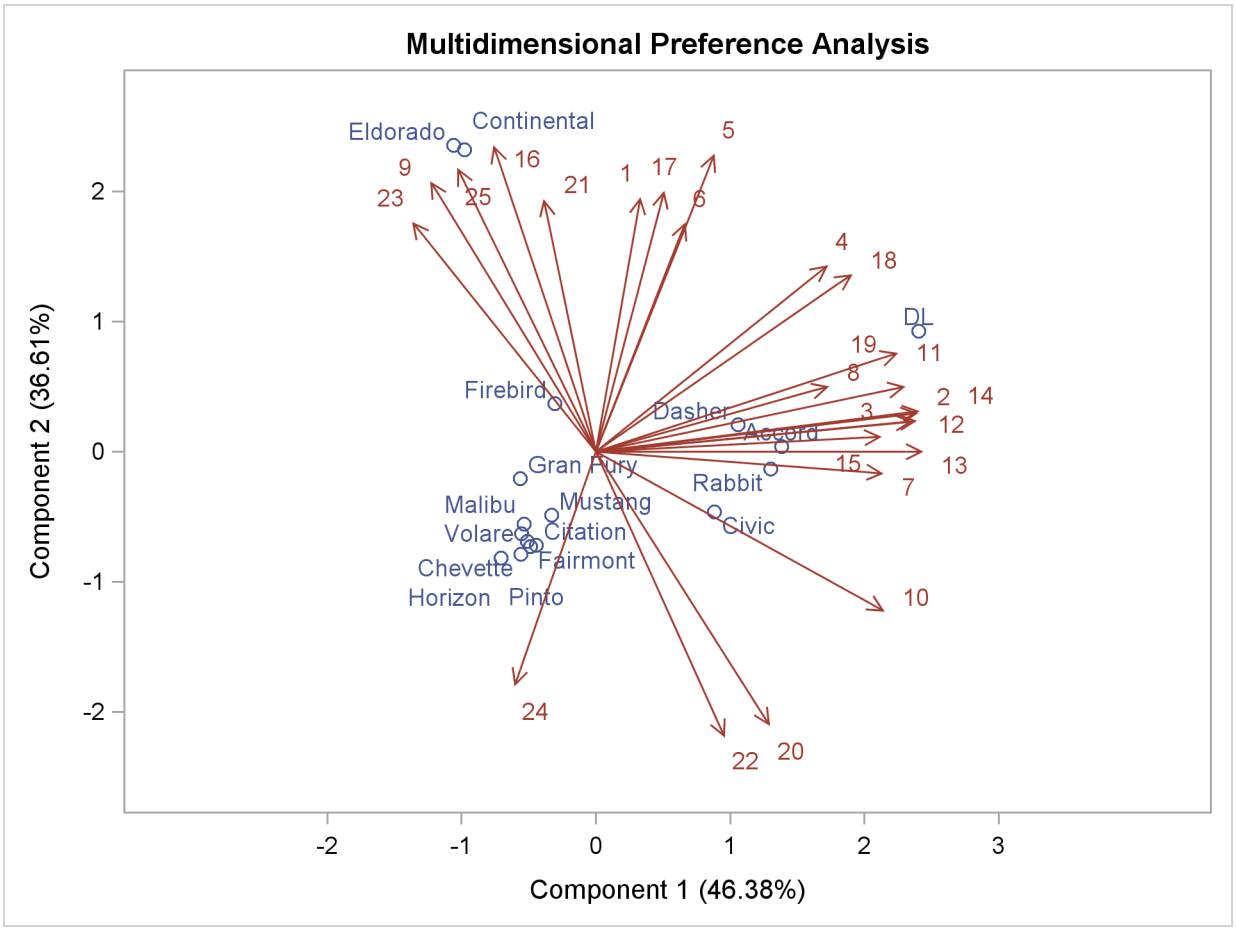
29	0.00031	0.00510	0.82995	0.00000	
30	0.00027	0.00454	0.82995	0.00000	Not Converged



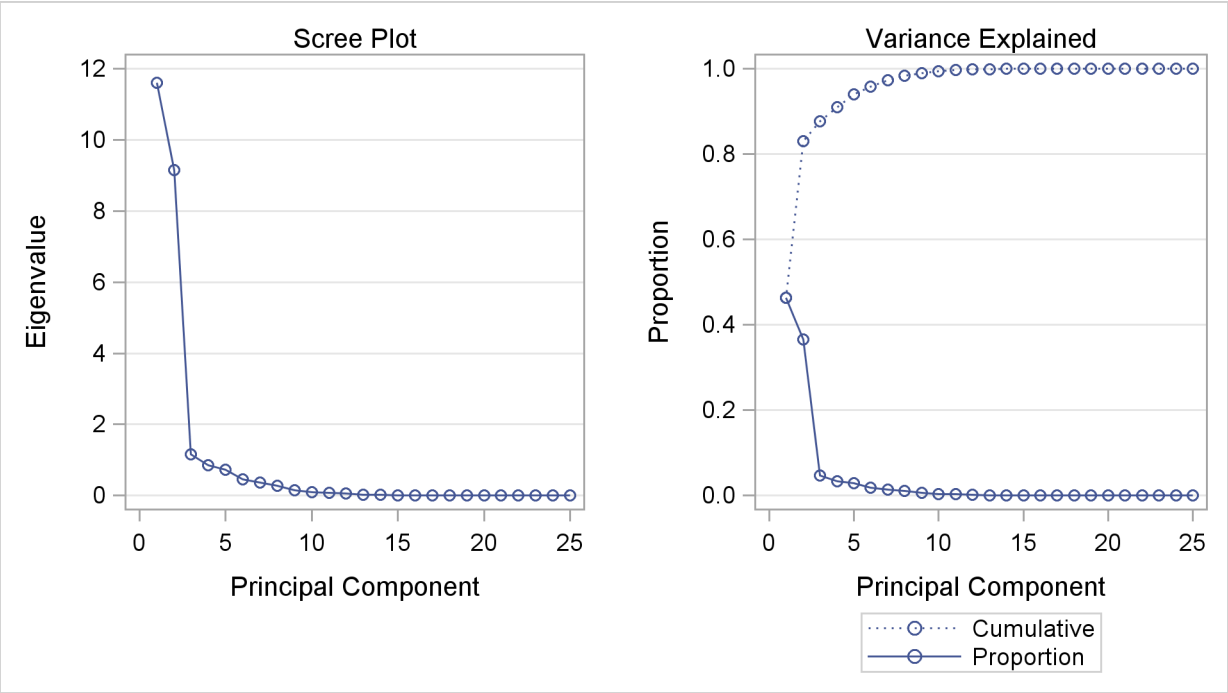
WARNING: Failed to converge, however criterion change is less than 0.0001.

The iteration history displayed by PROC PRINQUAL indicates that the proportion of variance is increased from an initial 0.66946 to 0.82995. The proportion of variance accounted for by PROC PRINQUAL on the first iteration equals the cumulative proportion of variance shown by PROC PRINCOMP for the first two principal components. PROC PRINQUAL's initial iteration performs a standard principal component analysis of the raw data. The columns labeled Average Change, Maximum Change, and Criterion Change contain values that always decrease, indicating that PROC PRINQUAL is improving the transformations at a monotonically decreasing rate over the iterations. This does not always happen, and when it does not, it suggests that the analysis might be converging

to a degenerate solution. See Example 70.2 for a discussion of a degenerate solution. The algorithm does not converge in 30 iterations. However, the criterion change is small, indicating that more iterations are unlikely to have much effect on the results.

The biplot, shown in Output 70.1.3, is automatically displayed by PROC PRINQUAL when ODS Graphics is enabled and the MDPREF option is specified.

Output 70.1.3 Biplot Made with PRINQUAL



The second PROC PRINCOMP analysis is performed on the transformed data. The WHERE statement is used to retain only the monotonically transformed judgments. The scree plot shows that the first two eigenvalues are now much larger than the remaining smaller eigenvalues. The second eigenvalue has increased markedly at the expense of the next several eigenvalues. Two principal components seem to be necessary and sufficient to adequately describe these judges' preferences for these automobiles. The cumulative proportion of variance displayed by PROC PRINCOMP for the first two principal components is 0.83. The following statements perform the analysis and produce Output 70.1.4:

```
* Final Principal Component Analysis;
proc princomp data=Results;
   ods select EigenvaluePlot;
   var '1'n-'25'n;
   where _TYPE_='SCORE';
run;

ods graphics off;
```

Output 70.1.4 Transformed Data Eigenvalue Plot

The remainder of the example discusses the MDPREF biplot. A biplot is a plot that displays the relation between the row points and the columns of a data matrix. The rows of $\mathbf{V}$, the standardized component scores, and $\mathbf{W}\mathbf{\Lambda}^{1/2}$, the structure matrix, contain enough information to reproduce $\mathbf{X}$. The (i, j) element of $\mathbf{X}$ is the product of row i of $\mathbf{V}$ and row j of $\mathbf{W}\mathbf{\Lambda}^{1/2}$. If all but the first two columns of $\mathbf{V}$ and $\mathbf{W}\mathbf{\Lambda}^{1/2}$ are discarded, the (i, j) element of $\mathbf{X}$ is approximated by the product of row i of $\mathbf{V}$ and row j of $\mathbf{W}\mathbf{\Lambda}^{1/2}$.

Since the MDPREF analysis is based on a principal component model, the dimensions of the MDPREF biplot are the first two principal components. The first principal component is the longest dimension through the MDPREF biplot. The first principal component is overall preference, which is the most salient dimension in the preference judgments. One end points in the direction that is on the average preferred most by the judges, and the other end points in the least preferred direction. The second principal component is orthogonal to the first principal component, and it is the orthogonal direction that is the second most salient. The interpretation of the second dimension varies from example to example.

With an MDPREF biplot, it is geometrically appropriate to represent each automobile (object) by a point and each judge by a vector. The automobile points have coordinates that are the scores of the automobile on the first two principal components. The judge vectors emanate from the origin of the space and go through a point whose coordinates are the coefficients of the judge (variable) on the first two principal components.

The absolute length of a vector is arbitrary. However, the relative lengths of the vectors indicate fit, with the squared lengths being proportional to the communalities that you can get in PROC FACTOR output. The direction of the vector indicates the direction that is most preferred by the individual judge, with preference increasing as the vector moves from the origin. Let $\mathbf{v}'$ be row i of $\mathbf{V}$, $\mathbf{u}'$ be row j of $\mathbf{U} = \mathbf{W}\mathbf{\Lambda}^{1/2}$, $\|\mathbf{v}\|$ be the length of $\mathbf{v}$, $\|\mathbf{u}\|$ be the length of $\mathbf{u}$, and θ be the angle between $\mathbf{v}$ and $\mathbf{u}$. The predicted degree of preference that an individual judge has for an automobile is $\mathbf{u}'\mathbf{v} = \|\mathbf{u}\|\ \|\mathbf{v}\| \cos\theta$. Each automobile point can be orthogonally projected onto the vector. The projection of automobile i on vector j is $\mathbf{u}((\mathbf{u}'\mathbf{v})/(\mathbf{u}'\mathbf{u}))$, and the length of this projection is $\|\mathbf{v}\| \cos\theta$. The automobile that projects farthest along a vector in the direction it points is that judge's most preferred automobile, since the length of this projection, $\|\mathbf{v}\| \cos\theta$, differs from the predicted preference, $\|\mathbf{u}\|\ \|\mathbf{v}\| \cos\theta$, only by $\|\mathbf{u}\|$, which is constant for each judge.

To interpret the biplot, look for directions through the plot that show a continuous change in some attribute of the automobiles, or look for regions in the plot that contain clusters of automobile points and determine what attributes the automobiles have in common. Points that are tightly clustered in a region of the plot represent automobiles that have the same preference patterns across the judges. Vectors that point in roughly the same direction represent judges who have similar preference patterns.

In the biplot, American automobiles are located at the left of the space, while European and Japanese automobiles are located at the right. At the top of the space are expensive American automobiles (Cadillac Eldorado, Lincoln Continental), while at the bottom are inexpensive ones (Ford Pinto, Chevrolet Chevette). The first principal component differentiates American from imported automobiles, and the second arranges automobiles by price and other associated characteristics.

The two expensive American automobiles form a cluster, the sporty automobile (Pontiac Firebird) is by itself, the Volvo DL is by itself, and the remaining imported autos form a cluster, as do the remaining American autos. It seems there are 5 prototypical automobiles in this set of 17, in terms of preference patterns among the 25 judges.

Most of the judges prefer the imported automobiles, especially the Volvo. There is also a fairly large minority that prefer the expensive autos, whether or not they are American (those with vectors that point toward one o'clock), or simply prefer expensive American automobiles (vectors that point toward eleven o'clock). There are two judges who prefer anything except expensive American autos (five o'clock vectors), and one who prefers inexpensive American autos (seven o'clock vector).

Several vectors point toward the upper-right corner of the plot, toward a region with no automobiles. This is the region between the European and Japanese autos at the right and the luxury autos at the top. This suggests that there is a market for luxury Japanese and European automobiles.

Example 70.2: Principal Components of Basketball Rankings

The data in this example are 1985–1986 preseason rankings of 35 U.S. college basketball teams by 10 different news services. The services do not all rank the same teams or the same number of teams, so there are missing values in these data. Each of the 35 teams in the data set is ranked by at least one news service. One way of summarizing these data is with a principal component analysis, since the rankings should all be related to a single underlying variable, the first principal component.

You can use PROC PRINQUAL to estimate the missing ranks and compute scores for all observations. You can formulate a PROC PRINQUAL analysis that assumes that the observed ranks are ordinal variables and replaces the ranks with new numbers that are monotonic with the ranks and better fit the one principal component model. The missing rank estimates need to be constrained since a news service would have positioned the unranked teams below the teams it ranked. PROC PRINQUAL should impose order constraints within the nonmissing values and between the missing and nonmissing values, but not within the missing values. PROC PRINQUAL has sophisticated missing data handling facilities; however, these facilities cannot directly handle this problem. The solution requires reformulating the problem.

By performing some preliminary data manipulations, specifying the N=1 option in the PROC PRINQUAL statement, and specifying the UNTIE transformation in the TRANSFORM statement, you can make the missing value estimates conform to the requirements. The PROC MEANS step finds the largest rank for each variable. The next DATA step replaces missing values with a value that is one larger than the largest observed rank. The PROC PRINQUAL N=1 option specifies that the variables should be transformed to make them as one-dimensional as possible. The UNTIE transformation in the TRANSFORM statement monotonically transforms the ranks, untying any ties in an optimal way. Because the only ties are for the values that replace the missing values, and because these values are larger than the observed values, the rescoring of the data satisfies the preceding requirements.

The following statements create the data set and perform the transformations discussed previously. These statements produce Output 70.2.1 and Output 70.2.2.

```
*  Preseason 1985 College Basketball Rankings
*  (rankings of 35 teams by 10 news services)
*
*  Note:(a) Various news services rank varying numbers of teams.
*       (b) Not all 35 teams are ranked by all news services.
*       (c) Each team is ranked by at least one service.

An alternative approach is to use the pairwise deletion option of the CORR procedure to compute the correlation matrix and then use PROC PRINCOMP or PROC FACTOR to perform the principal component analysis. This approach has several disadvantages. The correlation matrix might not be positive semidefinite (psd), an assumption required for principal component analysis. PROC PRINQUAL always produces a psd correlation matrix. Even with pairwise deletion, PROC CORR removes the six observations that have only a single nonmissing value from this data set. Finally, it is still not possible to calculate scores on the principal components for those teams that have missing values.

You can compute the composite ranking by using PROC PRINCOMP and some preliminary data manipulations, similar to those discussed previously.

Chapter 69, "The PRINCOMP Procedure," contains an example where the average of the unused ranks in each poll is substituted for the missing values, and each observation is weighted by the number of nonmissing values. This method has much to recommend it. It is much faster and simpler than using PROC PRINQUAL. It is also much less prone to degeneracies and capitalization on chance. However, PROC PRINCOMP does not allow the nonmissing ranks to be monotonically transformed and the missing values untied to optimize fit.

PROC PRINQUAL monotonically transforms the observed ranks and estimates the missing ranks (within the constraints given previously) to account for almost 95 percent of the variance of the transformed data by just one dimension. PROC FACTOR is then used to report details of the principal component analysis of the transformed data. As shown by the Factor Pattern values in Output 70.2.3, nine of the ten news services have a correlation of 0.95 or larger with the scores on the first principal component after the data are optimally transformed. The scores are sorted and the composite ranking is displayed following the PROC FACTOR output. More confidence can be placed in the stability of the scores for teams that are ranked by the majority of the news services than in scores for teams that are seldom ranked.

The monotonic transformations are plotted for each of the ten news services. See Output 70.2.2. These plots show the values of the raw ranks (with the missing ranks replaced by the maximum rank plus one) versus the rescored (transformed) ranks. The transformations are the step functions that maximize the fit of the data to the principal component model. Smoother transformations could be found by using MSPLINE transformations, but MSPLINE transformations would not correctly handle the missing data problem.

The following statements perform the final analysis and produce Output 70.2.3:

35	Houston	4.69614

The ordinary PROC PRINQUAL missing data handling facilities do not work for these data because they do not constrain the missing data estimates properly. If you code the missing ranks as missing and specify linear transformations, then you can compute least-squares estimates of the missing values without transforming the observed values. The first principal component then accounts for 92 percent of the variance after 20 iterations. However, Virginia Tech is ranked number 11 by its score even though it appeared in only one poll (Inside Sports ranked it number 13, anchoring it firmly in the middle). Specifying monotone transformations is also inappropriate since they too allow unranked teams to move in between ranked teams.

With these data, the combination of monotone transformations and the freedom to score the missing ranks without constraint leads to degenerate transformations. PROC PRINQUAL tries to merge the 35 points into two points, producing a perfect fit in one dimension. There is evidence for this after 20 iterations when the Average Change, Maximum Change, and Criterion Change values are all increasing, instead of the more stable decreasing change rate seen in the analysis shown. The change rates all stop increasing after 41 iterations, and it is clear by 70 or 80 iterations that one component will account for 100 percent of the transformed variables variance after sufficient iteration. While this might seem desirable (after all, it is a perfect fit), you should, in fact, be on guard when this happens. Whenever convergence is slow, the rates of change increase, or the final data perfectly fit the model, the solution is probably degenerating because of too few constraints on the scorings.

PROC PRINQUAL can account for 100 percent of the variance by scoring Montana and UCLA with one positive value on all variables and scoring all the other teams with one negative value on all variables. This inappropriate analysis suggests that all ranked teams are equally good except for two teams that are less good. Both of these two teams are ranked by only one news service, and their only nonmissing rank is last in the poll. This accounts for the degeneracy.

Overview: PROBIT Procedure

The PROBIT procedure calculates maximum likelihood estimates of regression parameters and the natural (or threshold) response rate for quantal response data from biological assays or other discrete event data. This includes probit, logit, ordinal logistic, and extreme value (or gompit) regression models.

Probit analysis developed from the need to analyze qualitative (dichotomous or polytomous) dependent variables within the regression framework. Many response variables are binary by nature (yes/no), while others are measured ordinally rather than continuously (degree of severity). Collett (1991) and Agresti (1990), for example, have shown ordinary least squares (OLS) regression to be inadequate when the dependent variable is discrete. Probit or logit analyses are more appropriate in this case.

The PROBIT procedure computes maximum likelihood estimates of the parameters β and C of the probit equation by using a modified Newton-Raphson algorithm. When the response Y is binary, with values 0 and 1, the probit equation is

$$p = \Pr(Y = 0) = C + (1 - C)F(\mathbf{x}'\beta)$$

where

β is a vector of parameter estimates

F is a cumulative distribution function (normal, logistic, or extreme value)

$\mathbf{x}$ is a vector of explanatory variables

p is the probability of a response

C is the natural (threshold) response rate

Notice that PROC PROBIT, by default, models the probability of the *lower* response levels. The choice of the distribution function F (normal for the probit model, logistic for the logit model, and extreme value or Gompertz for the gompit model) determines the type of analysis. For most problems, there is relatively little difference between the normal and logistic specifications of the model. Both distributions are symmetric about the value zero. The extreme value (or Gompertz) distribution, however, is not symmetric, approaching 0 on the left more slowly than it approaches 1 on the right. You can use the extreme value distribution where such asymmetry is appropriate.

For ordinal response models, the response, Y, of an individual or an experimental unit can be restricted to one of a (usually small) number, $k+1 (k \geq 1)$, of ordinal values, denoted for convenience by $1, \ldots, k, k+1$. For example, the severity of coronary disease can be classified into three response

categories as 1=no disease, 2=angina pectoris, and 3=myocardial infraction. The PROBIT procedure fits a common slopes cumulative model, which is a parallel-lines regression model based on the cumulative probabilities of the response categories rather than on their individual probabilities. The cumulative model has the form

$$\Pr(Y \leq 1 \mid \mathbf{x}) = F(\mathbf{x}'\beta)$$

$$\Pr(Y \leq i \mid \mathbf{x}) = F(\alpha_i + \mathbf{x}'\beta), \quad 2 \leq i \leq k$$

where $\alpha_2, \ldots, \alpha_k$ are $k - 1$ intercept parameters. By default, the covariate vector $\mathbf{x}$ contains an overall intercept term.

You can set or estimate the natural (threshold) response rate C. Estimation of C can begin either from an initial value that you specify or from the rate observed in a control group. By default, the natural response rate is fixed at zero.

An observation in the data set analyzed by the PROBIT procedure might contain the response and explanatory values for one subject. Alternatively, it might provide the number of observed events from a number of subjects at a particular setting of the explanatory variables. In this case, PROC PROBIT models the probability of an event.

The PROBIT procedure now uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS."

Getting Started: PROBIT Procedure

The following example illustrates how you can use the PROBIT procedure to compute the threshold response rate and regression parameter estimates for quantal response data.

Estimating the Natural Response Threshold Parameter

Suppose you want to test the effect of a drug at 12 dosage levels. You randomly divide 180 subjects into 12 groups of 15—one group for each dosage level. You then conduct the experiment and, for each subject, record the presence or absence of a positive response to the drug. You summarize the data by counting the number of subjects responding positively in each dose group. Your data set is as follows:

```
data study;
   input Dose Respond @@;
   Number = 15;
   datalines;
0     3   1.1   4   1.3   4   2.0   3   2.2   5   2.8   4
3.7   5   3.9   9   4.4   8   4.8  11   5.9  12   6.8  13
;
run;
```

The variable dose represents the amount of drug administered. The first group, receiving a dose level of 0, is the control group. The variable number represents the number of subjects in each group. All groups are equal in size; hence, number has the value 15 for all observations. The variable respond represents the number of subjects responding to the associated drug dosage.

You can model the probability of positive response as a function of dosage by using the following statements:

```
ods graphics on;

proc probit data=study log10 optc plots=(predpplot ippplot);
   model respond/number=dose;
   output out=new p=p_hat;
run;

ods graphics off;
```

The DATA= option specifies that PROC PROBIT analyze the SAS data set study. The LOG10 option replaces the first continuous independent variable (dose) with its common logarithm. The OPTC option estimates the natural response rate. When you use the LOG10 option with the OPTC option, any observations with a dose value less than or equal to zero are used in the estimation as a control group.

The PLOTS= option in the PROC PROBIT statement, together with the ODS GRAPHICS statement, requests two plots for the estimated probability values and dosage levels. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." For specific information about the graphics available in the PROBIT procedure, see the section "ODS Graphics" on page 5325.

The MODEL statement specifies a proportional response by using the variables respond and number in *events/trials* syntax. The variable dose is the stimulus or explanatory variable.

The OUTPUT statement creates a new data set, new, that contains all the variables in the original data set, and a new variable, p_hat, that represents the predicted probabilities.

The results from this analysis are displayed in the following figures.

Figure 71.1 displays background information about the model fit. Included are the name of the input data set, the response variables used, and the number of observations, events, and trials. The last line in Figure 71.1 shows the final value of the log-likelihood function.

Figure 71.2 displays the table of parameter estimates for the model. The parameter C, which is the natural response threshold or the proportion of individuals responding at zero dose, is estimated to be 0.2409. Since both the intercept and the slope coefficient have significant p-values (0.0020, 0.0010), you can write the model for

$$\Pr(\text{response}) = C + (1 - C)F(\mathbf{x}'\beta)$$

as

$$\Pr(\text{response}) = 0.2409 + 0.7591(\Phi(-4.1439 + 6.2308 \times \log_{10}(\text{dose})))$$

where Φ is the normal cumulative distribution function.

Finally, PROC PROBIT specifies the resulting tolerance distribution by providing the mean MU and scale parameter SIGMA as well as the covariance matrix of the distribution parameters in Figure 71.3.

Figure 71.1 Model Fitting Information for the PROBIT Procedure

The Probit Procedure

Model Information

Data Set	WORK.STUDY
Events Variable	Respond
Trials Variable	Number

Figure 71.3 Tolerance Distribution Estimates for the PROBIT Procedure

Estimated Covariance Matrix for Tolerance Parameters

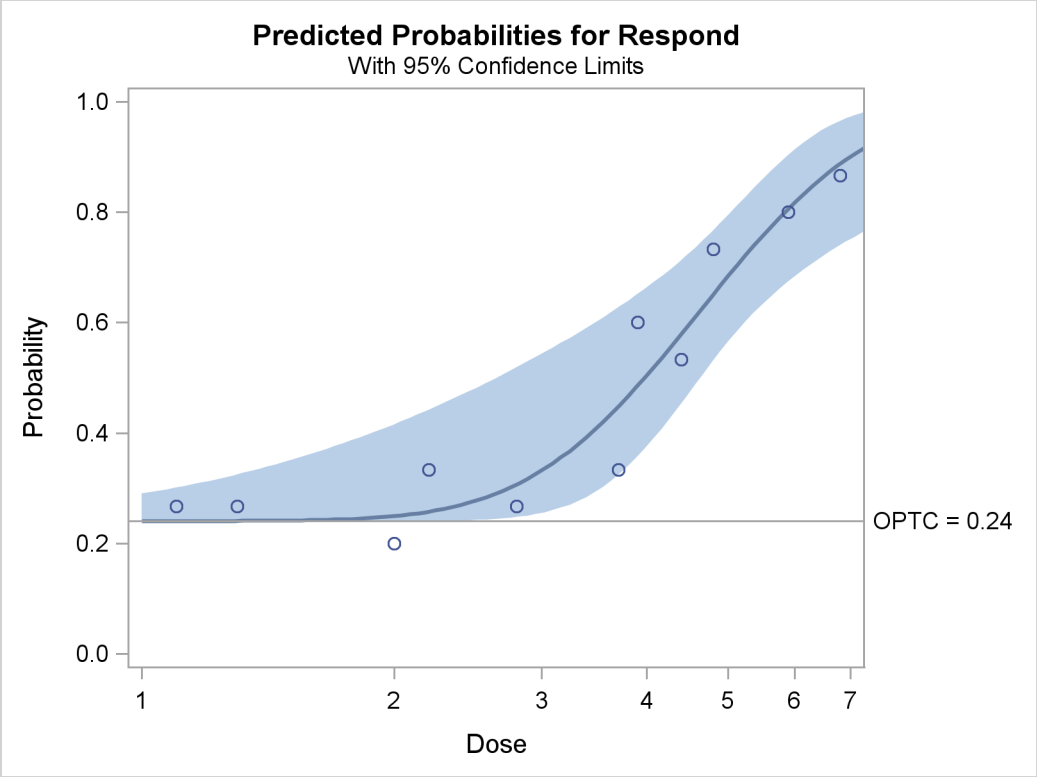
	MU	SIGMA	_C_
MU	0.001158	-0.000493	0.000954
SIGMA	-0.000493	0.002394	-0.000999
_C_	0.000954	-0.000999	0.002731

The PLOT=PREDPPLOT option creates the plot in Figure 71.4, showing the relationship between dosage level, observed response proportions, and estimated probability values. The dashed lines represent pointwise confidence bands for the fitted probabilities, and a reference line is plotted at the estimated threshold value of 0.24.

The PLOT=IPPPLOT option creates the plot in Figure 71.5, showing the inverse relationship between dosage level and observed response proportions/estimated probability values. The dashed lines represent pointwise fiducial limits for the predicted values of the dose variable, and a reference line is also plotted at the estimated threshold value of 0.24.

The two plot options can be put together with the PLOTS= option, as shown in the PROC PROBIT statement.

Figure 71.4 Plot of Observed and Fitted Probabilities versus Dose Level



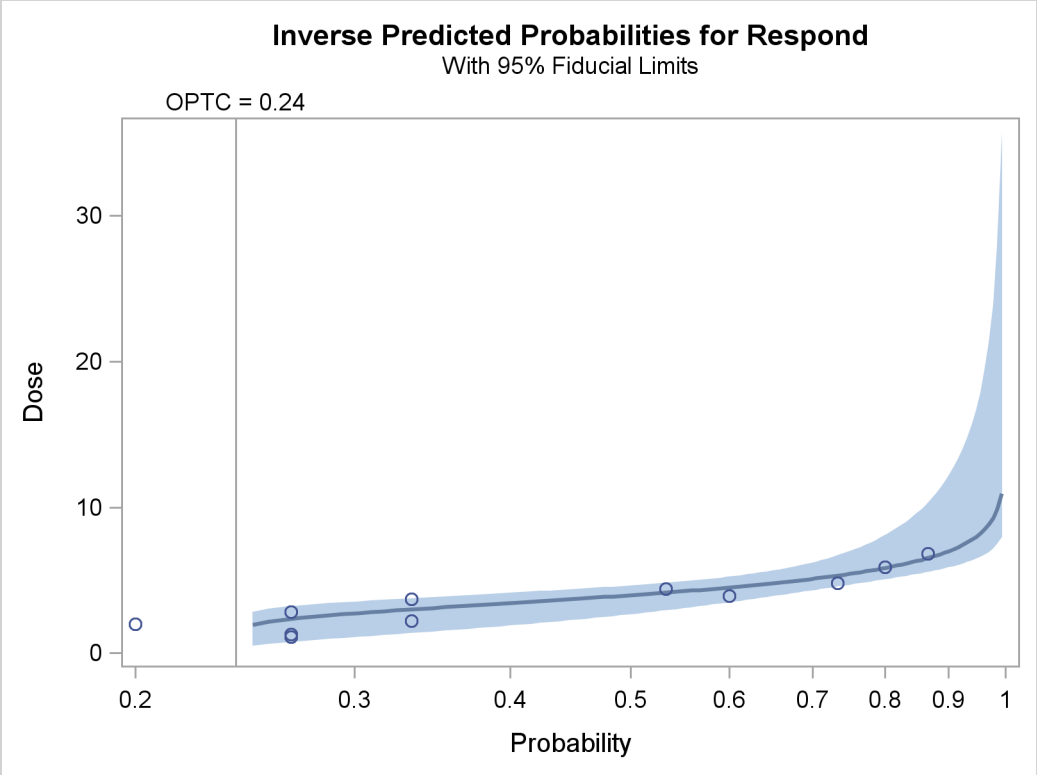


Figure 71.5 Inverse Predicted Probability Plot with Fiducial Limits

Syntax: PROBIT Procedure

The following statements are available in PROC PROBIT:

PROC PROBIT < *options* > ;
MODEL *response=independents* < / *options* > ;

BY *variables* ;
CLASS *variables* ;
OUTPUT < *OUT=SAS-data-set* > < *options* > ;
WEIGHT *variable* ;

CDFPLOT < *VAR = variable* > < *options* > ;
INSET < *keyword-list* > < / *options* > ;
IPPPLOT < *VAR = variable* > < *options* > ;
LPREDPLOT < *VAR = variable* > < *options* > ;
PREDPPLOT < *VAR = variable* > < *options* > ;

A MODEL statement is required. Only a single MODEL statement can be used with one invocation of the PROBIT procedure. If multiple MODEL statements are present, only the last one is used. Main effects and higher-order terms can be specified in the MODEL statement, as in the GLM procedure. If a CLASS statement is used, it must precede the MODEL statement.

The CDFPLOT, INSET, IPPPLOT, LPREDPLOT, and PREDPPLOT statements are used to produce graphical output. You can use any appropriate combination of the graphical statements after the MODEL statement.

PROC PROBIT Statement

PROC PROBIT < *options* > **;**

The PROC PROBIT statement starts the procedure. You can specify the following options in the PROC PROBIT statement.

COVOUT
writes the parameter estimate covariance matrix to the OUTEST= data set.

C=*rate*
OPTC
controls how the natural response is handled. Specify the OPTC option to request that the natural response rate C be estimated. Specify the C=*rate* option to set the natural response rate or to provide the initial estimate of the natural response rate. The natural response rate value must be a number between 0 and 1.

- If you specify neither the OPTC nor the C= option, a natural response rate of zero is assumed.
- If you specify both the OPTC and the C= option, the C= option should be a reasonable initial estimate of the natural response rate. For example, you could use the ratio of the number of responses to the number of subjects in a control group.
- If you specify the C= option but not the OPTC option, the natural response rate is set to the specified value and not estimated.
- If you specify the OPTC option but not the C= option, PROC PROBIT's action depends on the response variable, as follows:
  - If you specify either the LN or LOG10 option and some subjects have the first independent variable (dose) values less than or equal to zero, these subjects are treated as a control group. The initial estimate of C is then the ratio of the number of responses to the number of subjects in this group.
  - If you do not specify the LN or LOG10 option or if there is no control group, then one of the following occurs:
    - If all responses are greater than zero, the initial estimate of the natural response rate is the minimal response rate (the ratio of the number of responses to the number of subjects in a dose group) across all dose levels.
    - If one or more of the responses is zero (making the response rate zero in that dose group), the initial estimate of the natural rate is the reciprocal of twice the largest number of subjects in any dose group in the experiment.

DATA=*SAS-data-set*
specifies the SAS data set to be used by PROC PROBIT. By default, the procedure uses the most recently created SAS data set.

GOUT=*graphics-catalog*

specifies a graphics catalog in which to save graphics output.

HPROB=*p*

specifies a minimum probability level for the Pearson chi-square to indicate a good fit. The default value is 0.10. The LACKFIT option must also be specified for this option to have any effect. For Pearson goodness-of-fit chi-square values with probability greater than the HPROB= value, the fiducial limits, if requested with the INVERSECL option, are computed by using a critical value of 1.96. For chi-square values with probability less than the value of the HPROB= option, the critical value is a 0.95 two-sided quantile value taken from the t distribution with degrees of freedom equal to $(k-1)\times m-q$, where k is the number of levels for the response variable, m is the number of different sets of independent variable values, and q is the number of parameters fit in the model. Note that the HPROB= option can also appear in the MODEL statement.

INEST=*SAS-data-set*

specifies an input SAS data set that contains initial estimates for all the parameters in the model. See the section "INEST= *SAS-data-set*" on page 5312 for a detailed description of the contents of the INEST= data set.

INVERSECL

computes confidence limits for the values of the first continuous independent variable (such as dose) that yield selected response rates. If the algorithm fails to converge (this can happen when C is nonzero), missing values are reported for the confidence limits. See the section "Inverse Confidence Limits" on page 5315 for details. Note that the INVERSECL option can also appear in the MODEL statement.

LACKFIT

performs two goodness-of-fit tests (a Pearson chi-square test and a log-likelihood ratio chi-square test) for the fitted model.

To compute the test statistics, proper grouping of the observations into subpopulations is needed. You can use the AGGREGATE or AGGREGATE= option for this end. See the entry for the AGGREGATE and AGGREGATE= options under the MODEL statement. If neither AGGREGATE nor AGGREGATE= is specified, PROC PROBIT assumes each observation is from a separate subpopulation and computes the goodness-of-fit test statistics only for the *events/trials* syntax.

NOTE: This test is not appropriate if the data are very sparse, with only a few values at each set of the independent variable values.

If the Pearson chi-square test statistic is significant, then the covariance estimates and standard error estimates are adjusted. See the section "Lack-of-Fit Tests" on page 5313 for a description of the tests. Note that the LACKFIT option can also appear in the MODEL statement.

LOG

LN

analyzes the data by replacing the first continuous independent variable with its natural logarithm. This variable is usually the level of some treatment such as dosage. In addition to the

usual output given by the INVERSECL option, the estimated dose values and 95% fiducial limits for dose are also displayed. If you specify the OPTC option, any observations with a dose value less than or equal to zero are used in the estimation as a control group. If you do not specify the OPTC option with the LOG or LN option, then any observations with the first continuous independent variable values less than or equal to zero are ignored.

LOG10

specifies an analysis like that of the LN or LOG option, except that the common logarithm (log to the base 10) of the dose value is used rather than the natural logarithm.

NAMELEN=*n*

specifies the length of effect names in tables and output data sets to be *n* characters, where *n* is a value between 20 and 200. The default length is 20 characters.

NOPRINT

suppresses the display of all output including graphics. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 20, "Using the Output Delivery System."

OPTC

controls how the natural response is handled. See the description of the C= option on page 5264 for details.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sorting order for the levels of the classification variables specified in the CLASS statement, including the levels of the response variable. Response level ordering is important since PROC PROBIT always models the probability of response levels at the beginning of the ordering. See the section "Response Level Ordering" on page 5309 for further details. This ordering also determines which parameters in the model correspond to each level in the data. The following table shows how PROC PROBIT interprets values of the ORDER= option.

Value of ORDER=	Levels Sorted By
DATA	order of appearance in the input data set
FORMATTED	formatted value
FREQ	descending frequency count; levels with the most observations come first in the order
INTERNAL	unformatted value

By default, ORDER=FORMATTED. For the values FORMATTED and INTERNAL, the sort order is machine dependent. For more information about sorting order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide*.

OUTEST=*SAS-data-set*

specifies a SAS data set to contain the parameter estimates and, if the COVOUT option is specified, their estimated covariances. If you omit this option, the output data set is not created. The contents of the data set are described in the section "OUTEST= *SAS-data-set*" on page 5316.

PLOT | PLOTS <=*plot-request*>

PLOT | PLOTS <=(*plot-request* <...*plot-request*>)>

specifies options that control details of the plots created by ODS Graphics. These plots are related to a dose variable, which is identified as the first single continuous independent variable in the MODEL statement. If there are interaction terms with this variable in the model, the PROBIT procedure will not produce any plot.

You can specify more than one plot request within the parentheses after PLOTS=. For a single plot request, you can omit the parentheses. The following plot requests are available.

ALL

creates all appropriate plots.

CDFPLOT<(LEVEL=(*character-list*))>

requests the plot of predicted cumulative distribution function (CDF) of the multinomial response variable as a function of a single continuous independent variable (dose variable). This single continuous independent variable must be the first single continuous independent variable listed in the MODEL statement. You can request this plot only with a multinomial model.

The LEVEL= suboption specify the levels of the multinomial response variable for which the CDF curves are requested. There are $k-1$ curves for a k-level multinomial response variable (for the highest level, it is the constant line 1). You can specify any of them to be plotted by the LEVEL= suboption.

IPPPLOT

requests the inverse plot of the predicted probability against the first single continuous variable (dose variable) in the MODEL statement for the binomial model. You can request this plot only with a binomial model. The confidence limits for the predicted values of the dose variable are the computed fiducial limits, not the inverse of the confidence limits of the predicted probabilities. Refer to the section "Inverse Confidence Limits" on page 5315 for more details.

LPREDPLOT<(LEVEL=(*character-list*))>

requests the plot of the linear predictor $\mathbf{x}'\mathbf{b}$ against the first single continuous variable (dose variable) in the MODEL statement for either the binomial model or the multinomial model. The confidence limits for the predicted values are available only for the binomial model.

For the multinomial model, you can use the LEVEL= suboption to specify the levels for which the linear predictor lines are plotted.

NONE

suppresses all plots.

PREDPPLOT<(LEVEL=(*character-list*))>

requests the plot of the predicted probability against the first single continuous variable (dose variable) in the MODEL statement for both the binomial model and the multinomial model. Confidence limits are available only for the binomial model.

For the multinomial model, you can use the LEVEL= suboption to specify the levels for which the linear predictor lines are plotted.

XDATA=*SAS-data-set*
specifies an input SAS data set that contains values for all the independent variables in the MODEL statement and variables in the CLASS statement. If there are covariates specified in a MODEL statement, you specify fixed values for the effects in the MODEL statement by the XDATA= data set when predicted values and/or fiducial limits for a single continuous variable (dose variable) are required. These specified values for the effects in the MODEL statement are also used for generating plots. See the section "XDATA= *SAS-data-set*" on page 5317 for a detailed description of the contents of the XDATA= data set.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC PROBIT to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order on each of the BY variables, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the PROBIT procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

CDFPLOT Statement

CDFPLOT < *var = variable* > < *options* > **;**

The CDFPLOT statement plots the predicted cumulative distribution function (CDF) of the multinomial response variable as a function of a single continuous independent variable (dose variable). You can use this statement only after a multinomial model statement.

VAR=*variable*

specifies a single continuous variable (dose variable) in the independent variable list of the MODEL statement. If a VAR= variable is not specified, the first single continuous variable in the independent variable list of the MODEL statement is used. If such a variable does not exist in the independent variable list of the MODEL statement, an error is reported.

The predicted cumulative distribution function is defined as

$$\hat{F}_j(\mathbf{x}) = C + (1 - C)F(\hat{a}_j + \mathbf{x}'\hat{\mathbf{b}})$$

where $j = 1, \ldots, k$ are the indexes of the k levels of the multinomial response variable, F is the CDF of the distribution used to model the cumulative probabilities, $\hat{\mathbf{b}}$ is the vector of estimated parameters, $\mathbf{x}$ is the covariate vector, $\hat{a}_j$ are estimated ordinal intercepts with $\hat{a}_1 = 0$, and C is the threshold parameter, either known or estimated from the model. Let x_1 be the covariate corresponding to the dose variable and $\mathbf{x}_{-1}$ be the vector of the rest of the covariates. Let the corresponding estimated parameters be $\hat{b}_1$ and $\hat{\mathbf{b}}_{-1}$. Then

$$\hat{F}_j(\mathbf{x}) = C + (1 - C)F(\hat{a}_j + x_1\hat{b}_1 + \mathbf{x}'_{-1}\hat{\mathbf{b}}_{-1})$$

To plot $\hat{F}_j$ as a function of x_1, $\mathbf{x}_{-1}$ must be specified. You can use the XDATA= option to provide the values of $\mathbf{x}_{-1}$ (see the XDATA= option in the PROC PROBIT statement for details), or use the default values that follow the rules:

- If the effect contains a continuous variable (or variables), the overall mean of this effect is used.
- If the effect is a single classification variable, the highest level of the variable is used.

options

specify the levels of the multinomial response variable for which the CDF curves are requested, and add features to the plot. There are $k - 1$ curves for a k-level multinomial response variable (for the highest level, it is the constant line 1). You can specify any of them to be plotted by the LEVEL= option in the CDFPLOT statement. See the LEVEL= option for how to specify the levels.

An attached box on the right side of the plot is used to label these curves with the names of their levels. You can specify the color of this box by using the CLABBOX= option.

You can use options in the CDFPLOT statement to do the following:

- superimpose specification limits
- specify the levels for which the CDF curves are requested
- specify graphical enhancements (such as color or text height)

Summary of Options

Table 71.1 through Table 71.7 list all *options* by function. The "Dictionary of Options" on page 5272 describes each option in detail.

CDF Options

Table 71.1 Options for CDFPLOT

LEVEL=(*character-list*)	specifies the names of the levels for which the CDF curves are requested
NOTHRESH	suppresses the threshold line
THRESHLABPOS=*value*	specifies the position for the label of the threshold line

General Options

Table 71.2 Color Options

CAXIS=*color*	specifies color for axis
CFIT=*color*	specifies color for fitted curves
CFRAME=*color*	specifies color for frame
CGRID=*color*	specifies color for grid lines
CHREF=*color*	specifies color for HREF= lines
CLABBOX=*color*	specifies color for label box
CTEXT=*color*	specifies color for text
CVREF=*color*	specifies color for VREF= lines

Table 71.3 Options to Enhance Plots Produced on Graphics Devices

ANNOTATE=*SAS-data-set*	specifies an Annotate data set
INBORDER	requests a border around plot
LFIT=*linetype*	specifies line style for fitted curves
LGRID=*linetype*	specifies line style for grid lines
NOFRAME	suppresses the frame around plotting areas
NOGRID	suppresses grid lines
NOFIT	suppresses CDF curves
NOHLABEL	suppresses horizontal labels
NOHTICK	suppresses horizontal ticks
NOVTICK	suppresses vertical ticks
TURNVLABELS	vertically strings out characters in vertical labels
WFIT=*n*	specifies thickness for fitted curves
WGRID=*n*	specifies thickness for grids
WREFL=*n*	specifies thickness for reference lines

Table 71.4 Axis Options

HAXIS=*value1 to value2 <by value3>*	specifies tick mark values for horizontal axis
HOFFSET=*value*	specifies offset for horizontal axis
HLOWER=*value*	specifies lower limit on horizontal axis scale
HUPPER=*value*	specifies upper limit on horizontal axis scale
NHTICK=*n*	specifies number of ticks for horizontal axis
NVTICK=*n*	specifies number of ticks for vertical axis
VAXIS=*value1 to value2 <by value3>*	specifies tick mark values for vertical axis
VAXISLABEL=*'label'*	specifies label for vertical axis
VOFFSET=*value*	specifies offset for vertical axis
VLOWER=*value*	specifies lower limit on vertical axis scale
VUPPER=*value*	specifies upper limit on vertical axis scale
WAXIS=*n*	specifies thickness for axis

Table 71.5 Graphics Catalog Options

DESCRIPTION=*'string'*	specifies description for graphics catalog member
NAME=*'string'*	specifies name for plot in graphics catalog

Table 71.6 Options for Text Enhancement

FONT=*font*	specifies software font for text
HEIGHT=*value*	specifies height of text outside framed areas
INFONT=*font*	specifies software font for text inside framed areas
INHEIGHT=*value*	specifies height of text inside framed areas

Table 71.7 Options for Reference Lines

HREF< (INTERSECT)> =value-list	requests horizontal reference line
HREFLABELS= ('label1',...,'labeln')	specifies labels for HREF= lines
HREFLABPOS=*n*	specifies vertical position of labels for HREF= lines
LHREF=*linetype*	specifies line style for HREF= lines
LVREF=*linetype*	specifies line style for VREF= lines
VREF<(INTERSECT)> =value-list	requests vertical reference line
VREFLABELS= ('label1',...,'labeln')	specifies labels for VREF= lines
VREFLABPOS=*n*	specifies horizontal position of labels for VREF= lines

Dictionary of Options

The following entries provide detailed descriptions of the *options* in the CDFPLOT statement.

ANNOTATE=*SAS-data-set*

ANNO=*SAS-data-set*

specifies an Annotate data set, as described in *SAS/GRAPH Software: Reference*, that enables you to add features to the CDF plot. The ANNOTATE= data set you specify in the CDFPLOT statement is used for all plots created by the statement.

CAXIS=*color*

CAXES=*color*

specifies the color used for the axes and tick marks. This option overrides any COLOR= specifications in an AXIS statement. The default is the first color in the device color list.

CFIT=*color*

specifies the color for the fitted CDF curves. The default is the first color in the device color list.

CFRAME=*color*

CFR=*color*

specifies the color for the area enclosed by the axes and frame. This area is not shaded by default.

CGRID=*color*

specifies the color for grid lines. The default is the first color in the device color list.

CLABBOX=*color*

specifies the color for the area enclosed by the label box for CDF curves. This area is not shaded by default.

CHREF=*color*

CH=*color*

specifies the color for lines requested by the HREF= option. The default is the first color in the device color list.

CTEXT=*color*

specifies the color for tick mark values and axis labels. The default is the color specified for the CTEXT= option in the most recent GOPTIONS statement.

CVREF=*color*

CV=*color*

specifies the color for lines requested by the VREF= option. The default is the first color in the device color list.

DESCRIPTION="*string*"

DES="*string*"

specifies a description, up to 40 characters, that appears in the PROC GREPLAY master menu. The default is the variable name.

FONT=*font*

specifies a software font for reference line and axis labels. You can also specify fonts for axis labels in an AXIS statement. The FONT= font takes precedence over the FTEXT= font specified in the most recent GOPTIONS statement. Hardware characters are used by default.

HAXIS=*value1 to value2< by value3>*

specifies tick mark values for the horizontal axis; *value1*, *value2*, and *value3* must be numeric, and *value1* must be less than *value2*. The lower tick mark is *value1*. Tick marks are drawn at increments of *value3*. The last tick mark is the greatest value that does not exceed *value2*. If *value3* is omitted, a value of 1 is used.

Examples of HAXIS= lists follow:

```
haxis = 0 to 10
haxis = 2 to 10 by 2
haxis = 0 to 200 by 10
```

HEIGHT=*value*

specifies the height of text used outside framed areas. The default value is 3.846 (in percentage).

HLOWER=*value*

specifies the lower limit on the horizontal axis scale. The HLOWER= option specifies *value* as the lower horizontal axis tick mark. The tick mark interval and the upper axis limit are determined automatically. This option has no effect if the HAXIS= option is used.

HOFFSET=*value*

specifies offset for horizontal axis. The default value is 1.

HUPPER=*value*

specifies *value* as the upper horizontal axis tick mark. The tick mark interval and the lower axis limit are determined automatically. This option has no effect if the HAXIS= option is used.

HREF < (INTERSECT) > =*value-list*

requests reference lines perpendicular to the horizontal axis. If (INTERSECT) is specified, a second reference line perpendicular to the vertical axis is drawn that intersects the fit line at the same point as the horizontal axis reference line. If a horizontal axis reference line label is specified, the intersecting vertical axis reference line is labeled with the vertical axis value. See also the CHREF=, HREFLABELS=, and LHREF= options.

HREFLABELS=*'label1',...,'labeln'*

HREFLABEL=*'label1',...,'labeln'*

HREFLAB=*'label1',...,'labeln'*

specifies labels for the lines requested by the HREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

HREFLABPOS=*n*

specifies the vertical position of labels for HREF= lines. The following table shows valid values for *n* and the corresponding label placements.

n	**label placement**
1	top
2	staggered from top
3	bottom
4	staggered from bottom
5	alternating from top
6	alternating from bottom

INBORDER

requests a border around CDF plots.

LEVEL=(*character-list***)**

ORDINAL=(*character-list***)**

specifies the names of the levels for which CDF curves are requested. Names should be quoted and separated by space. If there is no correct name provided, no CDF curve is plotted.

LFIT=*linetype*

specifies a line style for fitted curves. By default, fitted curves are drawn by connecting solid lines (*linetype = 1*).

LGRID=*linetype*

specifies a line style for all grid lines. *linetype* is between 1 and 46. The default is 35.

LHREF=*linetype*

LH=*linetype*

specifies the line type for lines requested by the HREF= option. The default is 2, which produces a dashed line.

LVREF=*linetype*

LV=*linetype*

specifies the line type for lines requested by the VREF= option. The default is 2, which produces a dashed line.

NAME=*'string'*

specifies a name for the plot, up to eight characters, that appears in the PROC GREPLAY master menu. The default is 'PROBIT'.

NOFIT

suppresses the fitted CDF curves.

NOFRAME

suppresses the frame around plotting areas.

NOGRID

suppresses grid lines.

NOHLABEL

suppresses horizontal labels.

NOHTICK

suppresses horizontal tick marks.

NOTHRESH

suppresses the threshold line.

NOVLABEL

suppresses vertical labels.

NOVTICK

suppresses vertical tick marks.

THRESHLABPOS=*n*

specifies the horizontal position of labels for the threshold line. The following table shows valid values for *n* and the corresponding label placements.

n	**label placement**
1	left
2	right

VAXIS=*value1 to value2< by value3 >*

specifies tick mark values for the vertical axis; *value1*, *value2*, and *value3* must be numeric, and *value1* must be less than *value2*. The lower tick mark is *value1*. Tick marks are drawn at increments of *value3*. The last tick mark is the greatest value that does not exceed *value2*. This method of specification of tick marks is not valid for logarithmic axes. If *value3* is omitted, a value of 1 is used.

Examples of VAXIS= lists follow:

```
vaxis = 0 to 10
vaxis = 0 to 2 by .1
```

VAXISLABEL=*'string'*
specifies a label for the vertical axis.

VLOWER=*value*
specifies the lower limit on the vertical axis scale. The VLOWER= option specifies *value* as the lower vertical axis tick mark. The tick mark interval and the upper axis limit are determined automatically. This option has no effect if the VAXIS= option is used.

VREF=*value-list*
requests reference lines perpendicular to the vertical axis. If (INTERSECT) is specified, a second reference line perpendicular to the horizontal axis is drawn that intersects the fit line at the same point as the vertical axis reference line. If a vertical axis reference line label is specified, the intersecting horizontal axis reference line is labeled with the horizontal axis value. See also the CVREF=, LVREF=, and VREFLABELS= options.

VREFLABELS=*'label1',...,'labeln'*

VREFLABEL=*'label1',...,'labeln'*

VREFLAB=*'label1',...,'labeln'*
specifies labels for the lines requested by the VREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

VREFLABPOS=*n*
specifies the horizontal position of labels for VREF= lines. The following table shows valid values for *n* and the corresponding label placements.

n	**label placement**
1	left
2	right

VUPPER=*value*
specifies the upper limit on the vertical axis scale. The VUPPER= option specifies *value* as the upper vertical axis tick mark. The tick mark interval and the lower axis limit are determined automatically. This option has no effect if the VAXIS= option is used.

WAXIS=*n*
specifies line thickness for axes and frame. The default value is 1.

WFIT=*n*
specifies line thickness for fitted curves. The default value is 1.

WGRID=*n*
specifies line thickness for grids. The default value is 1.

WREFL=*n*
specifies line thickness for reference lines. The default value is 1.

CLASS Statement

CLASS *variables* **;**

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric. If a single response variable is specified in the MODEL statement, it must also be specified in a CLASS statement.

Class levels are determined from the formatted values of the CLASS variables. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in *SAS Language Reference: Dictionary*.

If the CLASS statement is used, it must appear before any of the MODEL statements.

INSET Statement

INSET < *keyword-list* > < / *options* > **;**

The box or table of summary information produced on plots made with the CDFPLOT, IPPPLOT, LPREDPLOT, or PREDPPLOT statement is called an *inset*. You can use the INSET statement to customize both the information that is printed in the inset box and the appearance of the inset box. To supply the information that is displayed in the inset box, you specify *keywords* corresponding to the information you want shown. For example, the following statements produce a predicted probability plot with the number of trials, the number of events, the name of the distribution, and the estimated optimum natural threshold in the inset.

```
proc probit data=epidemic;
   model r/n = dose;
   predpplot ;
   inset nobs ntrials nevents dist optc;
run;
```

By default, inset entries are identified with appropriate labels. However, you can provide a customized label by specifying the *keyword* for that entry followed by the equal sign (=) and the label in quotes. For example, the following INSET statement produces an inset containing the number of observations and the name of the distribution, labeled “Sample Size” and “Distribution” in the inset.

```
inset nobs='Sample Size' dist='Distribution';
```

If you specify a keyword that does not apply to the plot you are creating, then the keyword is ignored.

The *options* control the appearance of the box.

If you specify more than one INSET statement, only the first one is used.

Keywords Used in the INSET Statement

Table 71.8 and Table 71.9 list keywords available in the INSET statement to display summary statistics, distribution parameters, and distribution fitting information.

Table 71.8 Summary Statistics

NOBS	number of observations
NTRIALS	number of trials
NEVENTS	number of events
C	user-input threshold
OPTC	estimated natural threshold
NRESPLEV	number of levels of the response variable

Table 71.9 General Information

CONFIDENCE	confidence coefficient for all confidence intervals or for the Weibayes fit
DIST	name of the distribution

Options Used in the INSET Statement

Table 71.10 and Table 71.11 list the options available in the INSET statement.

Table 71.10 Color and Pattern Options

CFILL=*color*	specifies color for filling box
CFILLH=*color*	specifies color for filling box header
CFRAME=*color*	specifies color for frame
CHEADER=*color*	specifies color for text in header
CTEXT=*color*	specifies color for text

Table 71.11 General Appearance Options

FONT=*font*	specifies software font for text
HEIGHT=*value*	specifies height of text
HEADER=*'quoted string'*	specifies text for header or box title
NOFRAME	omits frame around box
POS= *value* <DATA | PERCENT>	determines the position of the inset. The *value* can be a compass point (N, NE, E, SE, S, SW, W, NW) or a pair of coordinates (x, y) enclosed in parentheses. The coordinates can be specified in axis percentage units or axis data units.
REFPOINT= *name*	specifies the reference point for an inset that is positioned by a pair of coordinates with the POS= option. You use the REFPOINT= option in conjunction with the POS= coordinates. The REFPOINT= option specifies which corner of the inset frame you have specified with coordinates (x, y), and it can take the value of BR (bottom right), BL (bottom left), TR (top right), or TL (top left). The default is REFPOINT=BL. If the inset position is specified as a compass point, then the REFPOINT= option is ignored.

IPPPLOT Statement

IPPPLOT < *var = variable* > < *options* > **;**

The IPPPLOT statement plots the inverse of the predicted probability against a single continuous variable (dose variable) in the MODEL statement for the binomial model. You can only use this statement after a binomial model statement. The confidence limits for the predicted values of the dose variable are the computed fiducial limits, not the inverse of the confidence limits of the predicted probabilities. Refer to the section "Inverse Confidence Limits" on page 5315 for more details.

VAR= *variable*

specifies a single continuous variable (dose variable) in the independent variable list of the MODEL statement. If a VAR= variable is not specified, the first single continuous variable in the independent variable list of the MODEL statement is used. If such a variable does not exist in the independent variable list of the MODEL statement, an error is reported.

For the binomial model, the response variable is a probability. An estimate of the dose level $\hat{x}_1$ needed for a response of p is given by

$$\hat{x}_1 = (F^{-1}(p) - \mathbf{x}'_{-1}\hat{\mathbf{b}}_{-1})/\hat{b}_1$$

where F is the cumulative distribution function used to model the probability, $\mathbf{x}_{-1}$ is the vector of the rest of the covariates, $\hat{\mathbf{b}}_{-1}$ is the vector of the estimated parameters corresponding to $\mathbf{x}_{-1}$, and $\hat{b}_1$ is the estimated parameter for the dose variable of interest.

To plot $\hat{x}_1$ as a function of p, $\mathbf{x}_{-1}$ must be specified. You can use the XDATA= option to provide the values of $\mathbf{x}_{-1}$ (see the XDATA= option in the PROC PROBIT statement for details), or use the default values that follow the rules:

- If the effect contains a continuous variable (or variables), the overall mean of this effect is used.
- If the effect is a single classification variable, the highest level of the variable is used.

options

add features to the plot.

You can use options in the IPPPLOT statement to do the following:

- superimpose specification limits
- suppress or add the observed data points on the plot
- suppress or add the fiducial limits on the plot
- specify graphical enhancements (such as color or text height)

Summary of Options

Table 71.12 through Table 71.18 list all *options* by function. The "Dictionary of Options" on page 5282 describes each option in detail.

IPP Options

Table 71.12 Plot Layout Options for IPPPLOT

NOCONF	suppresses fiducial limits
NODATA	suppresses observed data points on the plot
NOTHRESH	suppresses the threshold line
THRESHLABPOS=*value*	specifies the position for the label of the threshold line

General Options

Table 71.13 Color Options

CAXIS=*color*	specifies color for axis
CFIT=*color*	specifies color for fitted curves
CFRAME=*color*	specifies color for frame
CGRID=*color*	specifies color for grid lines
CHREF=*color*	specifies color for HREF= lines
CTEXT=*color*	specifies color for text
CVREF=*color*	specifies color for VREF= lines

Table 71.14 Options to Enhance Plots Produced on Graphics Devices

ANNOTATE=*SAS-data-set*	specifies an Annotate data set
INBORDER	requests a border around plot
LFIT=*linetype*	specifies line style for fitted curves and confidence limits
LGRID=*linetype*	specifies line style for grid lines
NOFRAME	suppresses the frame around plotting areas
NOGRID	suppresses grid lines
NOFIT	suppresses fitted curves
NOHLABEL	suppresses horizontal labels
NOHTICK	suppresses horizontal ticks
NOVTICK	suppresses vertical ticks
TURNVLABELS	vertically strings out characters in vertical labels
WFIT=*n*	specifies thickness for fitted curves
WGRID=*n*	specifies thickness for grids
WREFL=*n*	specifies thickness for reference lines

Table 71.15 Axis Options

HAXIS=*value1 to value2 <by value3>*	specifies tick mark values for horizontal axis
HOFFSET=*value*	specifies offset for horizontal axis
HLOWER=*value*	specifies lower limit on horizontal axis scale
HUPPER=*value*	specifies upper limit on horizontal axis scale
NHTICK=*n*	specifies number of ticks for horizontal axis
NVTICK=*n*	specifies number of ticks for vertical axis
VAXIS=*value1 to value2 <by value3>*	specifies tick mark values for vertical axis
VAXISLABEL=*'label'*	specifies label for vertical axis
VOFFSET=*value*	specifies offset for vertical axis
VLOWER=*value*	specifies lower limit on vertical axis scale
VUPPER=*value*	specifies upper limit on vertical axis scale
WAXIS=*n*	specifies thickness for axis

Table 71.16 Options for Reference Lines

HREF<(INTERSECT)> =*value-list*	requests horizontal reference line
HREFLABELS= ('label1',...,'labeln')	specifies labels for HREF= lines
HREFLABPOS=*n*	specifies vertical position of labels for HREF= lines
LHREF=*linetype*	specifies line style for HREF= lines
LVREF=*linetype*	specifies line style for VREF= lines
VREF<(INTERSECT)> =*value-list*	requests vertical reference line
VREFLABELS= ('label1',...,'labeln')	specifies labels for VREF= lines
VREFLABPOS=*n*	specifies horizontal position of labels for VREF= lines

Table 71.17 Graphics Catalog Options

DESCRIPTION='*string*'	specifies description for graphics catalog member
NAME='*string*'	specifies name for plot in graphics catalog

Table 71.18 Options for Text Enhancement

FONT=*font*	specifies software font for text
HEIGHT=*value*	specifies height of text used outside framed areas
INFONT=*font*	specifies software font for text inside framed areas
INHEIGHT=*value*	specifies height of text inside framed areas

Dictionary of Options

The following entries provide detailed descriptions of the *options* in the IPPPLOT statement.

ANNOTATE=*SAS-data-set*

ANNO=*SAS-data-set*

specifies an Annotate data set, as described in *SAS/GRAPH Software: Reference*, that enables you to add features to the ipp plot. The ANNOTATE= data set you specify in the IPPPLOT statement is used for all plots created by the statement.

CAXIS=*color*

CAXES=*color*

specifies the color used for the axes and tick marks. This option overrides any COLOR= specifications in an AXIS statement. The default is the first color in the device color list.

CFIT=*color*

specifies the color for the fitted ipp curves. The default is the first color in the device color list.

CFRAME=*color*

CFR=*color*

specifies the color for the area enclosed by the axes and frame. This area is not shaded by default.

CGRID=*color*

specifies the color for grid lines. The default is the first color in the device color list.

CHREF=*color*

CH=*color*

specifies the color for lines requested by the HREF= option. The default is the first color in the device color list.

CTEXT=*color*

specifies the color for tick mark values and axis labels. The default is the color specified for the CTEXT= option in the most recent GOPTIONS statement.

CVREF=*color*

CV=*color*

specifies the color for lines requested by the VREF= option. The default is the first color in the device color list.

DESCRIPTION=*'string'*

DES=*'string'*

specifies a description, up to 40 characters, that appears in the PROC GREPLAY master menu. The default is the variable name.

FONT=*font*

specifies a software font for reference line and axis labels. You can also specify fonts for axis labels in an AXIS statement. The FONT= font takes precedence over the FTEXT= font specified in the most recent GOPTIONS statement. Hardware characters are used by default.

HAXIS=*value1 to value2< by value3>*

specifies tick mark values for the horizontal axis; *value1*, *value2*, and *value3* must be numeric, and *value1* must be less than *value2*. The lower tick mark is *value1*. Tick marks are drawn at increments of *value3*. The last tick mark is the greatest value that does not exceed *value2*. If *value3* is omitted, a value of 1 is used.

Examples of HAXIS= lists follow:

```
haxis = 0 to 10
haxis = 2 to 10 by 2
haxis = 0 to 200 by 10
```

HEIGHT=*value*

specifies the height of text used outside framed areas. The default value is 3.846 (in percentage).

HLOWER=*value*

specifies the lower limit on the horizontal axis scale. The HLOWER= option specifies *value* as the lower horizontal axis tick mark. The tick mark interval and the upper axis limit are determined automatically. This option has no effect if the HAXIS= option is used.

HOFFSET=*value*

specifies offset for horizontal axis. The default value is 1.

HUPPER=*value*

specifies *value* as the upper horizontal axis tick mark. The tick mark interval and the lower axis limit are determined automatically. This option has no effect if the HAXIS= option is used.

HREF < (INTERSECT) > =*value-list*

requests reference lines perpendicular to the horizontal axis. If (INTERSECT) is specified, a second reference line perpendicular to the vertical axis is drawn that intersects the fit line at the same point as the horizontal axis reference line. If a horizontal axis reference line label is specified, the intersecting vertical axis reference line is labeled with the vertical axis value. See also the CHREF=, HREFLABELS=, and LHREF= options.

HREFLABELS=*'label1'***,...,***'labeln'*

HREFLABEL=*'label1'***,...,***'labeln'*

HREFLAB=*'label1'***,...,***'labeln'*

specifies labels for the lines requested by the HREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

HREFLABPOS=*n*

specifies the vertical position of labels for HREF= lines. The following table shows valid values for *n* and the corresponding label placements.

n	label placement
1	top
2	staggered from top
3	bottom
4	staggered from bottom
5	alternating from top
6	alternating from bottom

INBORDER

requests a border around ipp plots.

LFIT=*linetype*

specifies a line style for fitted curves and confidence limits. By default, fitted curves are drawn by connecting solid lines (*linetype = 1*) and confidence limits are drawn by connecting dashed lines (*linetype = 3*).

LGRID=*linetype*

specifies a line style for all grid lines. The value for *linetype* must be between 1 and 46. The default is 35.

LHREF=*linetype*

LH=*linetype*

specifies the line type for lines requested by the HREF= option. The default is 2, which produces a dashed line.

LVREF=*linetype*

LV=*linetype*

specifies the line type for lines requested by the VREF= option. The default is 2, which produces a dashed line.

NAME=*'string'*

specifies a name for the plot, up to eight characters, that appears in the PROC GREPLAY master menu. The default is 'PROBIT'.

NOCONF

suppresses fiducial limits from the plot.

NODATA

suppresses observed data points from the plot.

NOFIT

suppresses the fitted ipp curves.

NOFRAME

suppresses the frame around plotting areas.

NOGRID

suppresses grid lines.

NOHLABEL

suppresses horizontal labels.

NOHTICK

suppresses horizontal tick marks.

NOTHRESH

suppresses the threshold line.

NOVLABEL

suppresses vertical labels.

NOVTICK

suppresses vertical tick marks.

THRESHLABPOS=*n*

specifies the vertical position of labels for the threshold line. The following table shows valid values for *n* and the corresponding label placements.

n	label placement
1	top
2	bottom

VAXIS=*value1 to value2< by value3 >*

specifies tick mark values for the vertical axis; *value1*, *value2*, and *value3* must be numeric, and *value1* must be less than *value2*. The lower tick mark is *value1*. Tick marks are drawn at increments of *value3*. The last tick mark is the greatest value that does not exceed *value2*. This method of specification of tick marks is not valid for logarithmic axes. If *value3* is omitted, a value of 1 is used.

Examples of VAXIS= lists follow:

```
vaxis = 0 to 10
vaxis = 0 to 2 by .1
```

VAXISLABEL=*'string'*

specifies a label for the vertical axis.

VLOWER=*value*

specifies the lower limit on the vertical axis scale. The VLOWER= option specifies *value* as the lower vertical axis tick mark. The tick mark interval and the upper axis limit are determined automatically. This option has no effect if the VAXIS= option is used.

VREF=*value-list*

requests reference lines perpendicular to the vertical axis. If (INTERSECT) is specified, a second reference line perpendicular to the horizontal axis is drawn that intersects the fit line at the same point as the vertical axis reference line. If a vertical axis reference line label is specified, the intersecting horizontal axis reference line is labeled with the horizontal axis value. See also the CVREF=, LVREF=, and VREFLABELS= options.

VREFLABELS=*'label1',...,'labeln'*

VREFLABEL=*'label1',...,'labeln'*

VREFLAB=*'label1',...,'labeln'*

specifies labels for the lines requested by the VREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

VREFLABPOS=*n*

specifies the horizontal position of labels for VREF= lines. The following table shows valid values for *n* and the corresponding label placements.

n	label placement
1	left
2	right

VUPPER=*value*

specifies the upper limit on the vertical axis scale. The VUPPER= option specifies *value* as the upper vertical axis tick mark. The tick mark interval and the lower axis limit are determined automatically. This option has no effect if the VAXIS= option is used.

WAXIS=*n*

specifies line thickness for axes and frame. The default value is 1.

WFIT=*n*
specifies line thickness for fitted curves. The default value is 1.

WGRID=*n*
specifies line thickness for grids. The default value is 1.

WREFL=*n*
specifies line thickness for reference lines. The default value is 1.

LPREDPLOT Statement

LPREDPLOT < *var = variable* > < *options* > **;**

The LPREDPLOT statement plots the linear predictor $\mathbf{x}'\mathbf{b}$ against a single continuous variable (dose variable) in the MODEL statement for either the binomial model or the multinomial model. The confidence limits for the predicted values are available only for the binomial model.

VAR= *variable*
specifies a single continuous variable (dose variable) in the independent variable list of the MODEL statement for which the linear predictor plot is plotted. If a VAR= variable is not specified, the first single continuous variable in the independent variable list of the MODEL statement is used. If such a variable does not exist in the independent variable list of the MODEL statement, an error is reported.

Let x_1 be the covariate of the dose variable, $\mathbf{x}_{-1}$ be the vector of the rest of the covariates, $\hat{\mathbf{b}}_{-1}$ be the vector of estimated parameters corresponding to $\mathbf{x}_{-1}$, and $\hat{b}_1$ be the estimated parameter for the dose variable of interest.

To plot $\hat{\mathbf{x}}'\mathbf{b}$ as a function of x_1, $\mathbf{x}_{-1}$ must be specified. You can use the XDATA= option to provide the values of $\mathbf{x}_{-1}$ (see the XDATA= option in the PROC PROBIT statement for details), or use the default values that follow these rules:

- If the effect contains a continuous variable (or variables), the overall mean of this effect is used.
- If the effect is a single classification variable, the highest level of the variable is used.

options
add features to the plot.

For the multinomial model, you can use the LEVEL= option to specify the levels for which the linear predictor lines are plotted. The lines are labeled by the names of their levels in the middle.

You can use options in the LPREDPLOT statement to do the following:

- superimpose specification limits
- suppress or add the observed data points on the plot for the binomial model
- suppress or add the confidence limits for the binomial model

- specify the levels for which the linear predictor lines are requested for the multinomial model
- specify graphical enhancements (such as color or text height)

Summary of Options

Table 71.19 through Table 71.25 list all *options* by function. The "Dictionary of Options" on page 5290 describes each option in detail.

LPRED Options

Table 71.19 Plot Layout Options for LPREDPLOT

LEVEL=(*character-list*)	specifies the names of the levels for which the linear predictor lines are requested (only for the multinomial model)
NOCONF	suppresses fiducial limits (only for the binomial model)
NODATA	suppresses observed data points on the plot (only for the binomial model)
NOTHRESH	suppresses the threshold line
THRESHLABPOS=*value*	specifies the position for the label of the threshold line

Dictionary of Options

The following entries provide detailed descriptions of the *options* in the LPREDPLOT statement.

ANNOTATE=*SAS-data-set*

ANNO=*SAS-data-set*

specifies an Annotate data set, as described in *SAS/GRAPH Software: Reference*, that enables you to add features to the lpred plot. The ANNOTATE= data set you specify in the LPREDPLOT statement is used for all plots created by the statement.

CAXIS=*color*

CAXES=*color*

specifies the color used for the axes and tick marks. This option overrides any COLOR= specifications in an AXIS statement. The default is the first color in the device color list.

CFIT=*color*

specifies the color for the fitted lpred lines. The default is the first color in the device color list.

CFRAME=*color*

CFR=*color*

specifies the color for the area enclosed by the axes and frame. This area is not shaded by default.

CGRID=*color*

specifies the color for grid lines. The default is the first color in the device color list.

CHREF=*color*

CH=*color*

specifies the color for lines requested by the HREF= option. The default is the first color in the device color list.

CTEXT=*color*

specifies the color for tick mark values and axis labels. The default is the color specified for the CTEXT= option in the most recent GOPTIONS statement.

CVREF=*color*

CV=*color*

specifies the color for lines requested by the VREF= option. The default is the first color in the device color list.

DESCRIPTION=*'string'*

DES=*'string'*

specifies a description, up to 40 characters, that appears in the PROC GREPLAY master menu. The default is the variable name.

FONT=*font*

specifies a software font for reference line and axis labels. You can also specify fonts for axis labels in an AXIS statement. The FONT= font takes precedence over the FTEXT= font specified in the most recent GOPTIONS statement. Hardware characters are used by default.

HAXIS=*value1 to value2< by value3 >*

specifies tick mark values for the horizontal axis; *value1*, *value2*, and *value3* must be numeric, and *value1* must be less than *value2*. The lower tick mark is *value1*. Tick marks are drawn at increments of *value3*. The last tick mark is the greatest value that does not exceed *value2*. If *value3* is omitted, a value of 1 is used.

Examples of HAXIS= lists follow:

```
haxis = 0 to 10
haxis = 2 to 10 by 2
haxis = 0 to 200 by 10
```

HEIGHT=*value*

specifies the height of text used outside framed areas. The default value is 3.846 (in percentage).

HLOWER=*value*

specifies the lower limit on the horizontal axis scale. The HLOWER= option specifies *value* as the lower horizontal axis tick mark. The tick mark interval and the upper axis limit are determined automatically. This option has no effect if the HAXIS= option is used.

HOFFSET=*value*

specifies offset for horizontal axis. The default value is 1.

HUPPER=*value*

specifies *value* as the upper horizontal axis tick mark. The tick mark interval and the lower axis limit are determined automatically. This option has no effect if the HAXIS= option is used.

HREF <(INTERSECT)> =*value-list*

requests reference lines perpendicular to the horizontal axis. If (INTERSECT) is specified, a second reference line perpendicular to the vertical axis is drawn that intersects the fit line at the same point as the horizontal axis reference line. If a horizontal axis reference line label is specified, the intersecting vertical axis reference line is labeled with the vertical axis value. See also the CHREF=, HREFLABELS=, and LHREF= options.

HREFLABELS=*'label1'***,...,***'labeln'*

HREFLABEL=*'label1'***,...,***'labeln'*

HREFLAB=*'label1'***,...,***'labeln'*

specifies labels for the lines requested by the HREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

HREFLABPOS=*n*

specifies the vertical position of labels for HREF= lines. The following table shows valid values for *n* and the corresponding label placements.

n	label placement
1	top
2	staggered from top
3	bottom
4	staggered from bottom
5	alternating from top
6	alternating from bottom

INBORDER

requests a border around lpred plots.

LEVEL=(*character-list***)**

ORDINAL=(*character-list***)**

specifies the names of the levels for which linear predictor lines are requested. Names should be quoted and separated by space. If there is no correct name provided, no lpred line is plotted.

LFIT=*linetype*

specifies a line style for fitted curves and confidence limits. By default, fitted curves are drawn by connecting solid lines (*linetype = 1*) and confidence limits are drawn by connecting dashed lines (*linetype = 3*).

LGRID=*linetype*

specifies a line style for all grid lines. The value for *linetype* is between 1 and 46. The default is 35.

LHREF=*linetype*

LH=*linetype*

specifies the line type for lines requested by the HREF= option. The default is 2, which produces a dashed line.

LVREF=*linetype*

LV=*linetype*

specifies the line type for lines requested by the VREF= option. The default is 2, which produces a dashed line.

NAME=*'string'*

specifies a name for the plot, up to eight characters, that appears in the PROC GREPLAY master menu. The default is 'PROBIT'.

NOCONF

suppresses confidence limits from the plot. This works only for the binomial model. Confidence limits are not plotted for the multinomial model.

NODATA

suppresses observed data points from the plot. This works only for the binomial model. Data points are not plotted for the multinomial model.

NOFIT

suppresses the fitted lpred lines.

NOFRAME

suppresses the frame around plotting areas.

NOGRID

suppresses grid lines.

NOHLABEL

suppresses horizontal labels.

NOHTICK

suppresses horizontal tick marks.

NOTHRESH

suppresses the threshold line.

NOVLABEL

suppresses vertical labels.

NOVTICK

suppresses vertical tick marks.

THRESHLABPOS=*n*

specifies the horizontal position of labels for the threshold line. The following table shows valid values for *n* and the corresponding label placements.

n	label placement
1	left
2	right

VAXIS=*value1 to value2< by value3 >*

specifies tick mark values for the vertical axis; *value1*, *value2*, and *value3* must be numeric, and *value1* must be less than *value2*. The lower tick mark is *value1*. Tick marks are drawn at increments of *value3*. The last tick mark is the greatest value that does not exceed *value2*. This method of specification of tick marks is not valid for logarithmic axes. If *value3* is omitted, a value of 1 is used.

Examples of VAXIS= lists follow:

```
vaxis = 0 to 10
vaxis = 0 to 2 by .1
```

VAXISLABEL=*'string'*

specifies a label for the vertical axis.

VLOWER=*value*

specifies the lower limit on the vertical axis scale. The VLOWER= option specifies *value* as the lower vertical axis tick mark. The tick mark interval and the upper axis limit are determined automatically. This option has no effect if the VAXIS= option is used.

VREF=*value-list*

requests reference lines perpendicular to the vertical axis. If (INTERSECT) is specified, a second reference line perpendicular to the horizontal axis is drawn that intersects the fit line at the same point as the vertical axis reference line. If a vertical axis reference line label is specified, the intersecting horizontal axis reference line is labeled with the horizontal axis value. See also the CVREF=, LVREF=, and VREFLABELS= options.

VREFLABELS=*'label1',...,'labeln'*

VREFLABEL=*'label1',...,'labeln'*

VREFLAB=*'label1',...,'labeln'*

specifies labels for the lines requested by the VREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

VREFLABPOS=*n*

specifies the horizontal position of labels for VREF= lines. The following table shows valid values for *n* and the corresponding label placements.

n	label placement
1	left
2	right

VUPPER=*number*
specifies the upper limit on the vertical axis scale. The VUPPER= option specifies *number* as the upper vertical axis tick mark. The tick mark interval and the lower axis limit are determined automatically. This option has no effect if the VAXIS= option is used.

WAXIS=*n*
specifies line thickness for axes and frame. The default value is 1.

WFIT=*n*
specifies line thickness for fitted lines. The default value is 1.

WGRID=*n*
specifies line thickness for grids. The default value is 1.

WREFL=*n*
specifies line thickness for reference lines. The default value is 1.

MODEL Statement

< label: > MODEL *response=effects* < / *options* > **;**

< label: > MODEL *events/trials=effects* < / *options* > **;**

The MODEL statement names the variables used as the response and the independent variables. Additionally, you can specify the distribution used to model the response, as well as other options. Only a single MODEL statement can be used with one invocation of the PROBIT procedure. If multiple MODEL statements are present, only the last is used. Main effects and interaction terms can be specified in the MODEL statement, as in the GLM procedure.

The optional *label*, which must be a valid SAS name, is used to label output from the matching MODEL statement.

The *response* can be a single variable with a value that is used to indicate the level of the observed response. For example, the response might be a variable called Symptoms that takes on the values 'None,' 'Mild,' or 'Severe.' Note that, for dichotomous response variables, the probability of the lower sorted value is modeled by default (see the section "Details: PROBIT Procedure" on page 5309). Because the model fit by the PROBIT procedure requires ordered response levels, you might need to use either the ORDER=DATA option in the PROC PROBIT statement or a numeric coding of the response to get the desired ordering of levels.

Alternatively, the response can be specified as a pair of variable names separated by a slash (/). The value of the first variable, *events*, is the number of positive responses (or events). The value of the second variable, *trials*, is the number of trials. Both variables must be numeric and nonnegative, and the ratio of the first variable value to the second variable value must be between 0 and 1, inclusive. For example, the variables might be hits, a variable containing the number of hits for a baseball player, and AtBats, a variable containing the number of times at bat. A model for hitting proportion (batting average) as a function of age could be specified as

```
model hits/AtBats=age;
```

The *effects* following the equal sign are the covariates in the model. Higher-order effects, such as interactions and nested terms, are allowed in the list, as in the GLM procedure. Variable names and combinations of variable names representing higher-order terms are allowed to appear in this list. Classification variables can be used as effects, and indicator variables are generated for the class levels. If you do not specify any covariates following the equal sign, an intercept-only model is fit.

The following options are available in the MODEL statement.

AGGREGATE

AGGREGATE=*variable-list*

specifies the subpopulations on which the Pearson chi-square test statistic and the log-likelihood ratio chi-square test statistic (deviance) are calculated if the LACKFIT option is specified. See the section "Rescaling the Covariance Matrix" on page 5314 for details of Pearson's chi-square and deviance calculations.

Observations with common values in the given list of variables are regarded as coming from the same subpopulation. Variables in the list can be any variables in the input data set. Specifying the AGGREGATE option is equivalent to specifying the AGGREGATE= option with a variable list that includes all independent variables in the MODEL statement. The PROBIT procedure sorts the input data set according to the variables specified in this list. Information for the sorted data set is reported in the "Response-Covariate Profile" table.

The deviance and Pearson goodness-of-fit statistics are calculated if the LACKFIT option is specified in the MODEL statement. The calculated results are reported in the "Goodness-of-Fit" table. If the Pearson chi-square test is significant with the test level specified by the HPROB= option, the fiducial limits, if required with the INVERSECL option in the MODEL statement, are modified (see the section "Inverse Confidence Limits" on page 5315 for details). Also, the covariance matrix is rescaled by the dispersion parameter when the SCALE= option is specified.

ALPHA=*value*

sets the significance level for the confidence intervals for regression parameters, fiducial limits for the predicted values, and confidence intervals for the predicted probabilities. The value must be between 0 and 1. The default value is ALPHA=0.05.

CONVERGE=*value*

specifies the convergence criterion. Convergence is declared when the maximum change in the parameter estimates between Newton-Raphson steps is less than the value specified. The change is a relative change if the parameter is greater than 0.01 in absolute value; otherwise, it is an absolute change.

By default, CONVERGE=1.0E−8.

CORRB

displays the estimated correlation matrix of the parameter estimates.

COVB

displays the estimated covariance matrix of the parameter estimates.

DISTRIBUTION=*distribution-type*

DIST=*distribution-type*

D=*distribution-type*

specifies the cumulative distribution function used to model the response probabilities. The distributions are described in the section "Details: PROBIT Procedure" on page 5309. Valid values for *distribution-type* are as follows:

NORMAL the normal distribution for the probit model

LOGISTIC the logistic distribution for the logit model

EXTREMEVALUE | EXTREME | GOMPERTZ the extreme value, or Gompertz distribution for the gompit model

By default, DISTRIBUTION=NORMAL.

HPROB=*p*

specifies a minimum probability level for the Pearson chi-square to indicate a good fit. The default value is 0.10. The LACKFIT option must also be specified for this option to have any effect. For Pearson goodness-of-fit chi-square values with probability greater than the HPROB= value, the fiducial limits, if requested with the INVERSECL option, are computed by using a critical value of 1.96. For chi-square values with probability less than the value of the HPROB= option, the critical value is a 0.95 two-sided quantile value taken from the t distribution with degrees of freedom equal to $(k-1)\times m-q$, where k is the number of levels for the response variable, m is the number of different sets of independent variable values, and q is the number of parameters fit in the model. If you specify the HPROB= option in both the PROC PROBIT and MODEL statements, the MODEL statement option takes precedence.

INITIAL=*values*

sets initial values for the parameters in the model other than the intercept. The values must be given in the order in which the variables are listed in the MODEL statement. If some of the independent variables listed in the MODEL statement are classification variables, then there must be as many values given for that variable as there are classification levels minus 1. The INITIAL option can be specified as follows.

Type of List	Specification
list separated by blanks	`initial=3 4 5`
list separated by commas	`initial=3,4,5`

By default, all parameters have initial estimates of zero.

NOTE: The INITIAL= option is overwritten by the INEST= option in the PROC PROBIT statement.

INTERCEPT=*value*

initializes the intercept parameter to *value*. By default, INTERCEPT=0.

INVERSECL

computes confidence limits for the values of the first continuous independent variable (such as dose) that yield selected response rates. If the algorithm fails to converge (this can happen

when C is nonzero), missing values are reported for the confidence limits. See the section "Inverse Confidence Limits" on page 5315 for details.

ITPRINT

displays the iteration history, the final evaluation of the gradient, and the second derivative matrix (Hessian).

LACKFIT

performs two goodness-of-fit tests (a Pearson chi-square test and a log-likelihood ratio chi-square test) for the fitted model.

To compute the test statistics, proper grouping of the observations into subpopulations is needed. You can use the AGGREGATE or AGGREGATE= option for this purpose. See the entry for the AGGREGATE and AGGREGATE= options under the MODEL statement. If neither AGGREGATE nor AGGREGATE= is specified, PROC PROBIT assumes each observation is from a separate subpopulation and computes the goodness-of-fit test statistics only for the *events/trials* syntax.

NOTE: This test is not appropriate if the data are very sparse, with only a few values at each set of the independent variable values.

If the Pearson chi-square test statistic is significant, then the covariance estimates and standard error estimates are adjusted. See the section "Lack-of-Fit Tests" on page 5313 for a description of the tests. Note that the LACKFIT option can also appear in the PROC PROBIT statement. See the section "PROC PROBIT Statement" on page 5264 for details.

MAXITER=*value*

MAXIT=*value*

specifies the maximum number of iterations to be performed in estimating the parameters. By default, MAXITER=50.

NOINT

fits a model with no intercept parameter. If the INTERCEPT= option is also specified, the intercept is fixed at the specified value; otherwise, it is set to zero. This is most useful when the response is binary. When the response has k levels, then $k-1$ intercept parameters are fit. The NOINT option sets the intercept parameter corresponding to the lowest response level equal to zero. A Lagrange multiplier, or score, test for the restricted model is computed when the NOINT option is specified.

SCALE=*scale*

enables you to specify the method for estimating the dispersion parameter. To correct for overdispersion or underdispersion, the covariance matrix is multiplied by the estimate of the dispersion parameter. Valid values for *scale* are as follows:

D | DEVIANCE	specifies that the dispersion parameter be estimated by the deviance divided by its degrees of freedom.
P | PEARSON	specifies that the dispersion parameter be estimated by the Pearson chi-square statistic divided by its degrees of freedom. This is set as the default method for estimating the dispersion parameter.

You can use the AGGREGATE= option to define the subpopulations for calculating the Pearson chi-square statistic and the deviance.

The "Goodness-of-Fit " table includes the Pearson chi-square statistic, the deviance, their degrees of freedom, the ratio of each statistic divided by its degrees of freedom, and the corresponding p-value.

SINGULAR=*value*
specifies the singularity criterion for determining linear dependencies in the set of independent variables. The sum of squares and crossproducts matrix of the independent variables is formed and swept. If the relative size of a pivot becomes less than the value specified, then the variable corresponding to the pivot is considered to be linearly dependent on the previous set of variables considered. By default, SINGULAR=1E−12.

OUTPUT Statement

OUTPUT < *OUT=SAS-data-set* > *keyword=name* < . . . *keyword=name* > **;**

The OUTPUT statement creates a new SAS data set containing all variables in the input data set and, optionally, the fitted probabilities, the estimate of $\mathbf{x}'\beta$, and the estimate of its standard error. Estimates of the probabilities, $\mathbf{x}'\beta$, and the standard errors are computed for observations with missing response values as long as the values of all the explanatory variables are nonmissing. This enables you to compute these statistics for additional settings of the explanatory variables that are of interest but for which responses are not observed.

You can specify multiple OUTPUT statements. Each OUTPUT statement creates a new data set and applies only to the preceding MODEL statement. If you want to create a permanent SAS data set, you must specify a two-level name (refer to *SAS Language Reference: Concepts* for more information about permanent SAS data sets).

Details on the specifications in the OUTPUT statement are as follows:

keyword=name specifies the statistics to include in the output data set and assigns names to the new variables that contain the statistics. Specify a keyword for each desired statistic (see the following list of keywords), an equal sign, and the variable to contain the statistic.

The keywords allowed and the statistics they represent are as follows:

PROB | P cumulative probability estimates

$$p = C + (1 - C)F(a_j + \mathbf{x}'\beta)$$

STD standard error estimates of $a_j + \mathbf{x}'\mathbf{b}$

XBETA estimates of $a_j + \mathbf{x}'\beta$

OUT=*SAS-data-set* names the output data set. By default, the new data set is named by using the DATA*n* convention.

When the *single variable response* syntax is used, the _LEVEL_ variable is added to the output data set, and there are $k-1$ output observations for each input observation, where k is the number of response levels. There is no observation output corresponding to the highest response level. For each of the $k-1$ observations, the PROB variable contains the fitted probability of obtaining a response level up to the level indicated by the _LEVEL_ variable, the XBETA variable contains $a_j + \mathbf{x}'\mathbf{b}$, where j references the levels ($a_1 = 0$), and the STD variable contains the standard error estimate of the XBETA variable. See the section "Details: PROBIT Procedure" on page 5309 for the formulas for the parameterizations.

PREDPPLOT Statement

PREDPPLOT < *var = variable* > < *options* > **;**

The PREDPPLOT statement plots the predicted probability against a single continuous variable (dose variable) in the MODEL statement for both the binomial model and the multinomial model. Confidence limits are available only for the binomial model. An attached box on the right side of the plot is used to label predicted probability curves with the names of their levels for the multinomial model. You can specify the color of this box by using the CLABBOX= option.

VAR=*variable*

specifies a single continuous variable (dose variable) in the independent variable list of the MODEL statement. If a VAR= variable is not specified, the first single continuous variable in the independent variable list of the MODEL statement is used. If such a variable does not exist in the independent variable list of the MODEL statement, an error is reported.

The predicted probability is

$$\hat{p} = C + (1-C)F(\mathbf{x}'\hat{\mathbf{b}})$$

for the binomial model and

$$\begin{aligned}
\hat{p}_1 &= C + (1-C)F(\mathbf{x}'\hat{\mathbf{b}}) \\
\hat{p}_j &= (1-C)(F(\hat{a}_j + \mathbf{x}'\hat{\mathbf{b}}) - F(\hat{a}_{j-1} + \mathbf{x}'\hat{\mathbf{b}})) \quad j = 2, \ldots, k-1 \\
\hat{p}_k &= (1-C)(1 - F(\hat{a}_{k-1} + \mathbf{x}'\hat{\mathbf{b}}))
\end{aligned}$$

for the multinomial model with k response levels, where F is the cumulative distribution function used to model the probability, $\mathbf{x}'$ is the vector of the covariates, $\hat{a}_j$ are the estimated ordinal intercepts with $\hat{a}_1 = 0$, C is the threshold parameter, either known or estimated from the model, and $\hat{\mathbf{b}}'$ is the vector of estimated parameters.

To plot $\hat{p}$ (or $\hat{p}_j$) as a function of a continuous variable x_1, the remaining covariates $\mathbf{x}_{-1}$ must be specified. You can use the XDATA= option to provide the values of $\mathbf{x}_{-1}$ (see the XDATA= option in the PROC PROBIT statement for details), or use the default values that follow these rules:

- If the effect contains a continuous variable (or variables), the overall mean of this effect is used.
- If the effect is a single classification variable, the highest level of the variable is used.

options

enable you to plot the observed data and add features to the plot.

You can use options in the PREDPPLOT statement to do the following:

- superimpose specification limits
- suppress or add observed data points for the binomial model
- suppress or add confidence limits for the binomial model
- specify the levels for which predicted probability curves are requested for the multinomial model
- specify graphical enhancements (such as color or text height)

Summary of Options

Table 71.26 through Table 71.32 list all *options* by function. The "Dictionary of Options" on page 5304 describes each option in detail.

PREDPPLOT Options

Table 71.26 Plot Layout Options for PREDPPLOT

LEVEL=(*character-list*)	specifies the names of the levels for which the predicted probability curves are requested (only for the multinomial model)
NOCONF	suppresses confidence limits
NODATA	suppresses observed data points on the plot
NOTHRESH	suppresses the threshold line
THRESHLABPOS=*value*	specifies the position for the label of the threshold line

General Options

Table 71.27 Color Options

CAXIS=*color*	specifies color for the axes
CFIT=*color*	specifies color for fitted curves
CFRAME=*color*	specifies color for frame
CGRID=*color*	specifies color for grid lines
CHREF=*color*	specifies color for HREF= lines
CLABBOX=*color*	specifies color for label box
CTEXT=*color*	specifies color for text
CVREF=*color*	specifies color for VREF= lines

Table 71.28 Options to Enhance Plots Produced on Graphics Devices

ANNOTATE=*SAS-data-set*	specifies an Annotate data set
INBORDER	requests a border around plot
LFIT=*linetype*	specifies line style for fitted curves and confidence limits
LGRID=*linetype*	specifies line style for grid lines
NOFRAME	suppresses the frame around plotting areas
NOGRID	suppresses grid lines
NOFIT	suppresses fitted curves
NOHLABEL	suppresses horizontal labels
NOHTICK	suppresses horizontal ticks
NOVTICK	suppresses vertical ticks
TURNVLABELS	vertically strings out characters in vertical labels
WFIT=*n*	specifies thickness for fitted curves
WGRID=*n*	specifies thickness for grids
WREFL=*n*	specifies thickness for reference lines

Table 71.29 Axis Options

HAXIS=*value1 to value2 <by value3>*	specifies tick mark values for horizontal axis
HOFFSET=*value*	specifies offset for horizontal axis
HLOWER=*value*	specifies lower limit on horizontal axis scale
HUPPER=*value*	specifies upper limit on horizontal axis scale
NHTICK=*n*	specifies number of ticks for horizontal axis
NVTICK=*n*	specifies number of ticks for vertical axis
VAXIS=*value1 to value2 <by value3>*	specifies tick mark values for vertical axis
VAXISLABEL=*'label'*	specifies label for vertical axis
VOFFSET=*value*	specifies offset for vertical axis
VLOWER=*value*	specifies lower limit on vertical axis scale
VUPPER=*value*	specifies upper limit on vertical axis scale
WAXIS=*n*	specifies thickness for axis

Table 71.30 Graphics Catalog Options

DESCRIPTION=*'string'*	specifies description for graphics catalog member
NAME=*'string'*	specifies name for plot in graphics catalog

Table 71.31 Options for Text Enhancement

FONT=*font*	specifies software font for text
HEIGHT=*value*	specifies height of text used outside framed areas
INFONT=*font*	specifies software font for text inside framed areas
INHEIGHT=*value*	specifies height of text inside framed areas

Table 71.32 Options for Reference Lines

HREF<(INTERSECT)> =*value-list*	requests horizontal reference line
HREFLABELS= ('label1',...,'labeln')	specifies labels for HREF= lines
HREFLABPOS=*n*	specifies vertical position of labels for HREF= lines
LHREF=*linetype*	specifies line style for HREF= lines
LVREF=*linetype*	specifies line style for VREF= lines
VREF<(INTERSECT)> =*value-list*	requests vertical reference line
VREFLABELS= ('label1',...,'labeln')	specifies labels for VREF= lines
VREFLABPOS=*n*	specifies horizontal position of labels for VREF= lines

Dictionary of Options

The following entries provide detailed descriptions of the *options* in the PREDPPLOT statement.

ANNOTATE=*SAS-data-set*

ANNO=*SAS-data-set*

specifies an Annotate data set, as described in *SAS/GRAPH Software: Reference*, that enables you to add features to the predicted probability plot. The ANNOTATE= data set you specify in the PREDPPLOT statement is used for all plots created by the statement.

CAXIS=*color*

CAXES=*color*

specifies the color used for the axes and tick marks. This option overrides any COLOR= specifications in an AXIS statement. The default is the first color in the device color list.

CFIT=*color*

specifies the color for the fitted predicted probability curves. The default is the first color in the device color list.

CFRAME=*color*

CFR=*color*

specifies the color for the area enclosed by the axes and frame. This area is not shaded by default.

CGRID=*color*

specifies the color for grid lines. The default is the first color in the device color list.

CHREF=*color*

CH=*color*

specifies the color for lines requested by the HREF= option. The default is the first color in the device color list.

CTEXT=*color*

specifies the color for tick mark values and axis labels. The default is the color specified for the CTEXT= option in the most recent GOPTIONS statement.

CVREF=*color*

CV=*color*

specifies the color for lines requested by the VREF= option. The default is the first color in the device color list.

DESCRIPTION=*'string'*

DES=*'string'*

specifies a description, up to 40 characters, that appears in the PROC GREPLAY master menu. The default is the variable name.

FONT=*font*

specifies a software font for reference line and axis labels. You can also specify fonts for axis labels in an AXIS statement. The FONT= font takes precedence over the FTEXT= font specified in the most recent GOPTIONS statement. Hardware characters are used by default.

HAXIS=*value1 to value2< by value3 >*

specifies tick mark values for the horizontal axis; *value1*, *value2*, and *value3* must be numeric, and *value1* must be less than *value2*. The lower tick mark is *value1*. Tick marks are drawn at increments of *value3*. The last tick mark is the greatest value that does not exceed *value2*. If *value3* is omitted, a value of 1 is used.

Examples of HAXIS= lists follow:

```
haxis = 0 to 10
haxis = 2 to 10 by 2
haxis = 0 to 200 by 10
```

HEIGHT=*value*

specifies the height of text used outside framed areas.

HLOWER=*value*

specifies the lower limit on the horizontal axis scale. The HLOWER= option specifies *value* as the lower horizontal axis tick mark. The tick mark interval and the upper axis limit are determined automatically. This option has no effect if the HAXIS= option is used.

HOFFSET=*value*

specifies the offset for the horizontal axis. The default value is 1.

HUPPER=*value*

specifies *value* as the upper horizontal axis tick mark. The tick mark interval and the lower axis limit are determined automatically. This option has no effect if the HAXIS= option is used.

HREF < (INTERSECT) > =*value-list*

requests reference lines perpendicular to the horizontal axis. If (INTERSECT) is specified, a second reference line perpendicular to the vertical axis is drawn that intersects the fit line at

the same point as the horizontal axis reference line. If a horizontal axis reference line label is specified, the intersecting vertical axis reference line is labeled with the vertical axis value. See also the CHREF=, HREFLABELS=, and LHREF= options.

HREFLABELS=*'label1',...,'labeln'*

HREFLABEL=*'label1',...,'labeln'*

HREFLAB=*'label1',...,'labeln'*

specifies labels for the lines requested by the HREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

HREFLABPOS=*n*

specifies the vertical position of labels for HREF= lines. The following table shows valid values for *n* and the corresponding label placements.

n	label placement
1	top
2	staggered from top
3	bottom
4	staggered from bottom
5	alternating from top
6	alternating from bottom

INBORDER

requests a border around predicted probability plots.

LEVEL=(*character-list***)**

ORDINAL= (*character-list***)**

specifies the names of the levels for which predicted probability curves are requested. Names should be quoted and separated by space. If there is no correct name provided, no fitted probability curve is plotted.

LFIT=*linetype*

specifies a line style for fitted curves and confidence limits. By default, fitted curves are drawn by connecting solid lines (*linetype = 1*) and confidence limits are drawn by connecting dashed lines (*linetype = 3*).

LGRID=*linetype*

specifies a line style for all grid lines. The value for *linetype* is between 1 and 46. The default is 35.

LHREF=*linetype*

LH=*linetype*

specifies the line type for lines requested by the HREF= option. The default is 2, which produces a dashed line.

LVREF=*linetype*

LV=*linetype*

specifies the line type for lines requested by the VREF= option. The default is 2, which produces a dashed line.

NAME=*'string'*

specifies a name for the plot, up to eight characters, that appears in the PROC GREPLAY master menu. The default is 'PROBIT'.

NOCONF

suppresses confidence limits from the plot. This works only for the binomial model. Confidence limits are not plotted for the multinomial model.

NODATA

suppresses observed data points from the plot. This works only for the binomial model. The data points are not plotted for the multinomial model.

NOFIT

suppresses the fitted predicted probability curves.

NOFRAME

suppresses the frame around plotting areas.

NOGRID

suppresses grid lines.

NOHLABEL

suppresses horizontal labels.

NOHTICK

suppresses horizontal tick marks.

NOTHRESH

suppresses the threshold line.

NOVLABEL

suppresses vertical labels.

NOVTICK

suppresses vertical tick marks.

THRESHLABPOS=*n*

specifies the horizontal position of labels for the threshold line. The following table shows valid values for *n* and the corresponding label placements.

n	label placement
1	left
2	right

VAXIS=*value1 to value2< by value3 >*

specifies tick mark values for the vertical axis; *value1*, *value2*, and *value3* must be numeric, and *value1* must be less than *value2*. The lower tick mark is *value1*. Tick marks are drawn at increments of *value3*. The last tick mark is the greatest value that does not exceed *value2*. This method of specification of tick marks is not valid for logarithmic axes. If *value3* is omitted, a value of 1 is used.

Examples of VAXIS= lists follow:

```
vaxis = 0 to 10
vaxis = 0 to 2 by .1
```

VAXISLABEL=*'string'*
specifies a label for the vertical axis.

VLOWER=*value*
specifies the lower limit on the vertical axis scale. The VLOWER= option specifies *value* as the lower vertical axis tick mark. The tick mark interval and the upper axis limit are determined automatically. This option has no effect if the VAXIS= option is used.

VREF=*value-list*
requests reference lines perpendicular to the vertical axis. If (INTERSECT) is specified, a second reference line perpendicular to the horizontal axis is drawn that intersects the fit line at the same point as the vertical axis reference line. If a vertical axis reference line label is specified, the intersecting horizontal axis reference line is labeled with the horizontal axis value. See also the CVREF=, LVREF=, and VREFLABELS= options.

VREFLABELS=*'label1',...,'labeln'*

VREFLABEL=*'label1',...,'labeln'*

VREFLAB=*'label1',...,'labeln'*
specifies labels for the lines requested by the VREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

VREFLABPOS=*n*
specifies the horizontal position of labels for VREF= lines. The following table shows valid values for *n* and the corresponding label placements.

n	label placement
1	left
2	right

VUPPER=*value*
specifies the upper limit on the vertical axis scale. The VUPPER= option specifies *value* as the upper vertical axis tick mark. The tick mark interval and the lower axis limit are determined automatically. This option has no effect if the VAXIS= option is used.

WAXIS=*n*
specifies line thickness for axes and frame. The default value is 1.

WFIT=*n*
specifies line thickness for fitted curves. The default value is 1.

WGRID=*n*
specifies line thickness for grids. The default value is 1.

WREFL=*n*
specifies line thickness for reference lines. The default value is 1.

WEIGHT Statement

WEIGHT *variable* **;**

A WEIGHT statement can be used with PROC PROBIT to weight each observation by the value of the variable specified. The contribution of each observation to the likelihood function is multiplied by the value of the weight variable. Observations with zero, negative, or missing weights are not used in model estimation.

Details: PROBIT Procedure

Missing Values

PROC PROBIT does not use any observations having missing values for any of the independent variables, the response variables, or the weight variable. If only the response variables are missing, statistics requested in the OUTPUT statement are computed.

Response Level Ordering

For binary response data, PROC PROBIT fits the following model by default:

$$\Phi^{-1}\left(\frac{p-C}{1-C}\right) = \mathbf{x}'\beta$$

where p is the probability of the response level identified as the first level in the "Weighted Frequency Counts for the Ordered Response Categories" table in the output and Φ is the normal cumulative distribution function. By default, the covariate vector $\mathbf{x}$ contains an intercept term. This is sometimes called Abbot's formula.

Because of the symmetry of the normal (and logistic) distribution, the effect of reversing the order of the two response values is to change the signs of β in the preceding equation.

By default, response levels appear in ascending, sorted order (that is, the lowest level appears first, and then the next lowest, and so on). There are a number of ways that you can control the sort order of the response categories and, therefore, which level is assigned the first ordered level. One of the most common sets of response levels is {0,1}, with 1 representing the event with the probability that is to be modeled.

Consider the example where Y takes the values 1 and 0 for event and nonevent, respectively, and EXPOSURE is the explanatory variable. By default, PROC PROBIT assigns the first ordered level

to response level 0, causing the probability of the nonevent to be modeled. There are several ways to change this.

Besides recoding the variable Y, you can do the following:

- assign a format to Y such that the first formatted value (when the formatted values are put in sorted order) corresponds to the event. For the following example, Y=0 could be assigned formatted value 'nonevent' and Y=1 could be assigned formatted value 'event.' Since ORDER=FORMATTED by default, Y=1 becomes the first ordered level. See Example 71.3 for an illustration of this method.

```
proc format;
   value disease 1='event' 0='nonevent';
run;
proc probit;
   model y=exposure;
   format y disease.;
run;
```

- arrange the input data set so that Y=1 appears first and use the ORDER=DATA option in the PROC PROBIT statement. Since ORDER=DATA sorts levels in order of their appearance in the data set, Y=1 becomes the first ordered level. Note that this option causes classification variables to be sorted by their order of appearance in the data set, also.

Computational Method

The log-likelihood function is maximized by means of a ridge-stabilized Newton-Raphson algorithm. Initial regression parameter estimates are set to zero. The INITIAL= and INTERCEPT= options in the MODEL statement can be used to give nonzero initial estimates.

The log-likelihood function, L, is computed as

$$L = \sum_i w_i \ln(p_i)$$

where the sum is over the observations in the data set, w_i is the weight for the ith observation, and p_i is the modeled probability of the observed response. In the case of the events/trials syntax in the MODEL statement, each observation contributes two terms corresponding to the probability of the event and the probability of its complement:

$$L = \sum_i w_i [r_i \ln(p_i) + (n_i - r_i) \ln(1 - p_i)]$$

where r_i is the number of events and n_i is the number of trials for observation i. This log-likelihood function differs from the log-likelihood function for a binomial or multinomial distribution by additive terms consisting of the log of binomial or multinomial coefficients. These terms are parameter-independent and do not affect the model estimation or the standard errors and tests.

The estimated covariance matrix, $\mathbf{V}$, of the parameter estimates is computed as the negative inverse of the information matrix of second derivatives of L with respect to the parameters evaluated at

the final parameter estimates. Thus, the estimated covariance matrix is derived from the observed information matrix rather than the expected information matrix (these are generally not the same). The standard error estimates for the parameter estimates are taken as the square roots of the corresponding diagonal elements of **V**.

If convergence of the maximum likelihood estimates is attained, a Type III chi-square test statistic is computed for each effect, testing whether there is any contribution from any of the levels of the effect. This statistic is computed as a quadratic form in the appropriate parameter estimates by using the corresponding submatrix of the asymptotic covariance matrix estimate. Refer to Chapter 39, "The GLM Procedure," and Chapter 15, "The Four Types of Estimable Functions," for more information about Type III estimable functions.

The asymptotic covariance matrix is computed as the inverse of the observed information matrix. Note that if the NOINT option is specified and classification variables are used, the first classification variable contains a contribution from an intercept term. The results are displayed in an ODS table named Type3Analysis.

Chi-square tests for individual parameters are Wald tests based on the observed information matrix and the parameter estimates. If an effect has a single degree of freedom in the parameter estimates table, the chi-square test for this parameter is equivalent to the Type III test for this effect.

Prior to SAS 8.2, a multiple-degrees-of-freedom statistic was computed for each effect to test for contribution from any level of the effect. In general, the Type III test statistic in a main-effect-only model (no interaction terms) will be equal to the previously computed effect statistic, unless there are collinearities among the effects. If there are collinearities, the Type III statistic will adjust for them, and the value of the Type III statistic and the number of degrees of freedom might not be equal to those of the previous effect statistic.

The theory behind these tests assumes large samples. If the samples are not large, it might be better to base the tests on log-likelihood ratios. These changes in log likelihood can be obtained by fitting the model twice, once with all the parameters of interest and once leaving out the parameters to be tested. Refer to Cox and Oakes (1984) for a discussion of the merits of some possible test methods.

If some of the independent variables are perfectly correlated with the response pattern, then the theoretical parameter estimates can be infinite. Although fitted probabilities of 0 and 1 are not especially pathological, infinite parameter estimates are required to yield these probabilities. Due to the finite precision of computer arithmetic, the actual parameter estimates are not infinite. Indeed, since the tails of the distributions allowed in the PROBIT procedure become small rapidly, an argument to the cumulative distribution function of around 20 becomes effectively infinite. In the case of such parameter estimates, the standard error estimates and the corresponding chi-square tests are not trustworthy.

Distributions

The distributions, $F(x)$, allowed in the PROBIT procedure are specified with the DISTRIBUTION= option in the MODEL statement. The cumulative distribution functions for the available distributions are

$$\int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{z^2}{2}\right) dz \text{ (normal)}$$

$$\frac{1}{1+e^{-x}} \text{(logistic)}$$

$$1 - e^{-e^{x}} \text{(extreme value or Gompertz)}$$

The variances of these three distributions are not all equal to 1, and their means are not all equal to zero. Their means and variances are shown in the following table, where γ is the Euler constant.

Distribution	Mean	Variance
Normal	0	1
Logistic	0	$\pi^2/3$
Extreme value or Gompertz	$-\gamma$	$\pi^2/6$

When comparing parameter estimates by using different distributions, you need to take into account the different scalings and, for the extreme value (or Gompertz) distribution, a possible shift in location. For example, if the fitted probabilities are in the neighborhood of 0.1 to 0.9, then the parameter estimates from the logistic model should be about $\pi/\sqrt{3}$ larger than the estimates from the probit model.

INEST= *SAS-data-set*

The INEST= data set names a SAS data set that specifies initial estimates for all the parameters in the model.

The INEST= data set must contain the intercept variables (named Intercept for binary response model and Intercept, Intercept2, Intercept3, and so forth, for multinomial response models) and all independent variables in the MODEL statement.

If BY processing is used, the INEST= data set should also include the BY variables, and there must be at least one observation for each BY group. If there is more than one observation in a BY group, the first one read is used for that BY group.

If the INEST= data set also contains the _TYPE_ variable, only observations with the _TYPE_ value "PARMS" are used as starting values. Combining the INEST= data set and the option MAXIT= in the MODEL statement, partial scoring can be done, such as predicting on a validation data set by using the model built from a training data set.

You can specify starting values for the iterative algorithm in the INEST= data set. This data set overwrites the INITIAL= option in the MODEL statement, which is a little difficult to use for models with multilevel interaction effects. The INEST= data set has the same structure as the "OUTEST= *SAS-data-set*" on page 5316, but it is not required to have all the variables or observations that appear in the OUTEST= data set. One simple use of the INEST= option is passing the previous OUTEST= data set directly to the next model as an INEST= data set, assuming that the two models have the same parameterization.

Model Specification

For a two-level response, the probability that the lesser response occurs is modeled by the probit equation as

$$p = C + (1 - C)F(\mathbf{x}'\mathbf{b})$$

The probability of the other (complementary) event is $1 - p$.

For a multilevel response with outcomes labeled l_i for $i = 1, 2, \ldots, k$, the probability, p_j, of observing level l_j is as follows:

$$\begin{aligned}
p_1 &= C + (1 - C)F(\mathbf{x}'\mathbf{b}) \\
p_2 &= (1 - C)\left(F(a_2 + \mathbf{x}'\mathbf{b}) - F(\mathbf{x}'\mathbf{b})\right) \\
&\vdots \\
p_j &= (1 - C)\left(F(a_j + \mathbf{x}'\mathbf{b}) - F(a_{j-1} + \mathbf{x}'\mathbf{b})\right) \\
&\vdots \\
p_k &= (1 - C)(1 - F(a_{k-1} + \mathbf{x}'\mathbf{b}))
\end{aligned}$$

Thus, for a k-level response, there are $k - 2$ additional parameters, $a_2, a_3, \ldots, a_{k-1}$, estimated. These parameters are denoted by Intercept$j$, $j = 2, 3, \ldots, k - 1$, in the output.

An intercept parameter is always added to the set of independent variables as the first term in the model unless the NOINT option is specified in the MODEL statement. If a classification variable taking on k levels is used as one of the independent variables, a set of k indicator variables is generated to model the effect of this variable. Because of the presence of the intercept term, there are at most $k - 1$ degrees of freedom for this effect in the model.

Lack-of-Fit Tests

Two goodness-of-fit tests can be requested from the PROBIT procedure: a Pearson chi-square test and a log-likelihood ratio chi-square test.

To compute the test statistics, you can use the AGGREGATE or AGGREGATE= option grouping the observations into subpopulations. If neither AGGREGATE nor AGGREGATE= is specified, PROC PROBIT assumes that each observation is from a separate subpopulation and computes the goodness-of-fit test statistics only for the *events/trials* syntax.

If the Pearson goodness-of-fit chi-square test is requested and the p-value for the test is too small, variances and covariances are adjusted by a heterogeneity factor (the goodness-of-fit chi-square

divided by its degrees of freedom) and a critical value from the t distribution is used to compute the fiducial limits. The Pearson chi-square test statistic is computed as

$$\chi^2_P = \sum_{i=1}^{m}\sum_{j=1}^{k}\frac{(r_{ij} - n_i\hat{p}_{ij})^2}{n_i\hat{p}_{ij}}$$

where the sum on i is over grouping, the sum on j is over levels of response, r_{ij} is the frequency of response level j for the ith grouping, n_i is the total frequency for the ith grouping, and $\hat{p}_{ij}$ is the fitted probability for the jth level at the ith grouping.

The likelihood ratio chi-square test statistic is computed as

$$\chi^2_D = 2\sum_{i=1}^{m}\sum_{j=1}^{k} r_{ij}\ln\left(\frac{r_{ij}}{n_i\hat{p}_{ij}}\right)$$

This quantity is sometimes called the deviance. If the modeled probabilities fit the data, these statistics should be approximately distributed as chi-square with degrees of freedom equal to $(k-1)\times m - q$, where k is the number of levels of the multinomial or binomial response, m is the number of sets of independent variable values (covariate patterns), and q is the number of parameters fit in the model.

In order for the Pearson statistic and the deviance to be distributed as chi-square, there must be sufficient replication within the groupings. When this is not true, the data are sparse, and the p-values for these statistics are not valid and should be ignored. Similarly, these statistics, divided by their degrees of freedom, cannot serve as indicators of overdispersion. A large difference between the Pearson statistic and the deviance provides some evidence that the data are too sparse to use either statistic.

Rescaling the Covariance Matrix

One way of correcting overdispersion is to multiply the covariance matrix by a dispersion parameter. You can supply the value of the dispersion parameter directly, or you can estimate the dispersion parameter based on either the Pearson chi-square statistic or the deviance for the fitted model.

The Pearson chi-square statistic χ^2_P and the deviance χ^2_D are defined in the section "Lack-of-Fit Tests" on page 5313. If the SCALE= option is specified in the MODEL statement, the dispersion parameter is estimated by

$$\widehat{\sigma}^2 = \begin{cases} \chi^2_P/(m(k-1)-q) & \text{SCALE=PEARSON} \\ \chi^2_D/(m(k-1)-q) & \text{SCALE=DEVIANCE} \\ (constant)^2 & \text{SCALE=}constant \end{cases}$$

In order for the Pearson statistic and the deviance to be distributed as chi-square, there must be sufficient replication within the subpopulations. When this is not true, the data are sparse, and the p-values for these statistics are not valid and should be ignored. Similarly, these statistics, divided by their degrees of freedom, cannot serve as indicators of overdispersion. A large difference between

the Pearson statistic and the deviance provides some evidence that the data are too sparse to use either statistic.

You can use the AGGREGATE (or AGGREGATE=) option to define the subpopulation profiles. If you do not specify this option, each observation is regarded as coming from a separate subpopulation. For *events/trials* syntax, each observation represents n Bernoulli trials, where n is the value of the *trials* variable; for *single-trial* syntax, each observation represents a single trial. Without the AGGREGATE (or AGGREGATE=) option, the Pearson chi-square statistic and the deviance are calculated only for *events/trials* syntax.

Note that the parameter estimates are not changed by this method. However, their standard errors are adjusted for overdispersion, affecting their significance tests.

Tolerance Distribution

For a single independent variable, such as a dosage level, the models for the probabilities can be justified on the basis of a population with mean μ and scale parameter σ of tolerances for the subjects. Then, given a dose x, the probability, P, of observing a response in a particular subject is the probability that the subject's tolerance is less than the dose or

$$P = F\left(\frac{x-\mu}{\sigma}\right)$$

Thus, in this case, the intercept parameter, b_0, and the regression parameter, b_1, are related to μ and σ by

$$b_0 = -\frac{\mu}{\sigma},\ b_1 = \frac{1}{\sigma}$$

NOTE: The parameter σ is not equal to the standard deviation of the population of tolerances for the logistic and extreme value distributions.

Inverse Confidence Limits

In bioassay problems, estimates of the values of the independent variables that yield a desired response are often needed. For instance, the value yielding a 50% response rate (called the ED50 or LD50) is often used. The INVERSECL option requests that confidence limits be computed for the value of the independent variable that yields a specified response. These limits are computed only for the first continuous variable effect in the model. The other variables are set either at their mean values if they are continuous or at the reference (last) level if they are discrete variables. For a discussion of inverse confidence limits, see Hubert, Bohidar, and Peace (1988).

For the PROBIT procedure, the response variable is a probability. An estimate of the first continuous variable value needed to achieve a response of p is given by

$$\hat{x}_1 = \frac{1}{b_1}\left(F^{-1}(p) - \mathbf{x}^{*\prime}\mathbf{b}^*\right)$$

where F is the cumulative distribution function used to model the probability, $\mathbf{x}^*$ is the vector of independent variables excluding the first one, which can be specified by the XDATA= option described in the section "XDATA= *SAS-data-set*" on page 5317, $\mathbf{b}^*$ is the vector of parameter estimates excluding the first one, and b_1 is the estimated regression coefficient for the independent variable of interest. This estimate assumes that there is no natural response rate ($C = 0$). When C is nonzero, the quantiles and confidence limits for the independent variable correspond to the adjusted probability $C+(1-C)p$, rather than to p. As a result, an estimate of the value yielding response rate p is associated with the $(p-C)/(1-C)$ quantile. For example, if $C = 0.1$ then an estimate of the LD50 is found corresponding to the 0.44 quantile. This value can be thought of as yielding 50% of the variable's effect, but a 44% response rate. For both binary and ordinal models, the INVERSECL option provides estimates of the value of x_1, which yields Pr(first response level) $= p$, for various values of p.

This estimator is given as a ratio of random variables, such as $r = a/b$. Confidence limits for this ratio can be computed by using Fieller's theorem. A brief description of this theorem follows. See Finney (1971) for a more complete description of Fieller's theorem.

If the random variables a and b are thought to be distributed as jointly normal, then for any fixed value r the following probability statement holds if z is an $\alpha/2$ quantile from the standard normal distribution and $\mathbf{V}$ is the variance-covariance matrix of a and b:

$$\Pr\left((a-rb)^2 > z^2(V_{aa} - 2rV_{ab} + r^2V_{bb})\right) = \alpha$$

Usually the inequality can be solved for r to yield a confidence interval. The PROBIT procedure uses a value of 1.96 for z, corresponding to an α value of 0.05, unless the goodness-of-fit p-value is less than the specified value of the HPROB= option. When this happens, the covariance matrix is scaled by the heterogeneity factor, and a t distribution quantile is used for z.

It is possible for the roots of the equation for r to be imaginary or for the confidence interval to be all points outside of an interval. In these cases, the limits are set to missing by the PROBIT procedure.

Although the normal and logistic distribution give comparable fitted values of p if the empirically observed proportions are not too extreme, they can give appreciably different values when extrapolated into the tails. Correspondingly, the estimates of the confidence limits and dose values can be different for the two distributions even when they agree quite well in the body of the data. Extrapolation outside of the range of the actual data is often sensitive to model assumptions, and caution is advised if extrapolation is necessary.

It should be pointed out that, when there is a natural threshold C, the quantiles and confidence limits for the independent variable correspond to the adjusted probability $C + (1-C)p$.

OUTEST= *SAS-data-set*

The OUTEST= data set contains parameter estimates and the log likelihood for the model. You can specify a label in the MODEL statement to distinguish between the estimates for different models used by the PROBIT procedure. If you specify the COVOUT option, the OUTEST= data set also contains the estimated covariance matrix of the parameter estimates.

The OUTEST= data set contains each variable used as a dependent or independent variable in any MODEL statement. One observation consists of parameter values for the model with the dependent variable having the value −1. If you specify the COVOUT option, there are additional observations containing the rows of the estimated covariance matrix. For these observations, the dependent variable contains the parameter estimate for the corresponding row variable. The following variables are also added to the data set:

MODEL	a character variable containing the label of the MODEL statement, if present, or blank otherwise
NAME	a character variable containing the name of the dependent variable for the parameter estimates observations or the name of the row for the covariance matrix estimates
TYPE	a character variable containing the type of the observation, either PARMS for parameter estimates or COV for covariance estimates
DIST	a character variable containing the name of the distribution modeled
LNLIKE	a numeric variable containing the last computed value of the log likelihood
_C_	a numeric variable containing the estimated threshold parameter
INTERCEPT	a numeric variable containing the intercept parameter estimates and covariances

Any BY variables specified are also added to the OUTEST= data set.

XDATA= *SAS-data-set*

The XDATA= data set is used for specifying values for the effects in the MODEL statement when predicted values and/or fiducial limits for a single continuous variable (dose variable) are required. It is also used for plots specified by the CDFPLOT, IPPPLOT, LPREDPLOT, and PREDPPLOT statement.

The XDATA= data names a SAS data set that contains user input values for all the independent variables in the MODEL statement and the variables in the CLASS statement. The XDATA= data set has the same structure as the DATA= data set but is not required to have all the variables or observations that appear in the DATA= data set.

The XDATA= data set must contain all the independent variables in the MODEL statement and variables in the CLASS statement. Even though variables in the CLASS statement are not used in the MODEL statement, valid values are required for these variables in the XDATA= data set. Missing values are not allowed. For independent variables in the MODEL statement, although the dose variable's value is not used in the computing of predicted values and/or fiducial limits for the dose variable, missing values are not allowed in the XDATA= data set for any of the independent variables. Missing values are allowed for the dependent variables and other variables if they are included in the XDATA= data set and not listed in the CLASS statement.

If BY processing is used, the XDATA= data set should also include the BY variables, and there must be at least one valid observation for each BY group. If there is more than one valid observation in one BY group, the last one read is used for that BY group.

If there is no XDATA= data set in the PROC PROBIT statement, by default, the PROBIT procedure will use overall mean for effects containing continuous variable (or variables) and the highest level of a single classification variable as reference level. The rules are summarized as follows:

- If the effect contains a continuous variable (or variables), the overall mean of this effect is used.
- If the effect is a single classification variable, the highest level of the variable is used.

Traditional High-Resolution Graphics

This section provides examples of using syntax available with the traditional high-resolution plots. There are four plot statements that you can use to request traditional high-resolution plots: CDFPLOT, IPPPLOT, LPREDPLOT, and PREDPPLOT. Some of these statements apply only to either the binomial model or the multinomial model. Table 71.33 shows the availability of these statements for different models.

Table 71.33 Plot Statement Availability

Statement	Binomial	Multinomial
CDFPLOT	NO	YES
IPPPLOT	YES	NO
LPREDPLOT	YES	YES
PREDPPLOT	YES	YES

An alternative is to use ODS Graphics to obtain these plots. See the section "ODS Graphics" on page 5325 for details.

The following example uses the data set study in the section "Estimating the Natural Response Threshold Parameter" on page 5259 to illustrate how to create high-resolution plots for the binomial model:

```
proc probit data=study log10 optc;
   model respond/number=dose;
   predpplot var=dose cfit=blue; inset;
   lpredplot var=dose cfit=blue; inset;
   ippplot   var=dose cfit=blue; inset/pos=se;
run;
```

All plot statements must follow the MODEL statement. The VAR= option specifies a continuous independent variable (dose variable) against which the predicted probability or the linear predictor is plotted. The INSET statement requests the inset box with summary information. See the section "INSET Statement" on page 5277 for more details.

The PREDPPLOT statement creates the plot in Figure 71.6. This plot, similar to that in Figure 71.4, shows the relationship between dosage level, observed response proportions, and estimated probability values. The dashed lines represent pointwise confidence bands for the fitted probabilities,

which can be suppressed with the NOCONF option. See the section "PREDPPLOT Statement" on page 5300 for more details.

The IPPPLOT statement creates the plot in Figure 71.8, similar to that in Figure 71.5. See the section "IPPPLOT Statement" on page 5279 for details about this plot. The LPREDPLOT statement creates the linear predictor plot in Figure 71.7, which is described in the section "LPREDPLOT Statement" on page 5287.

Figure 71.6 Predicted Probability Plot

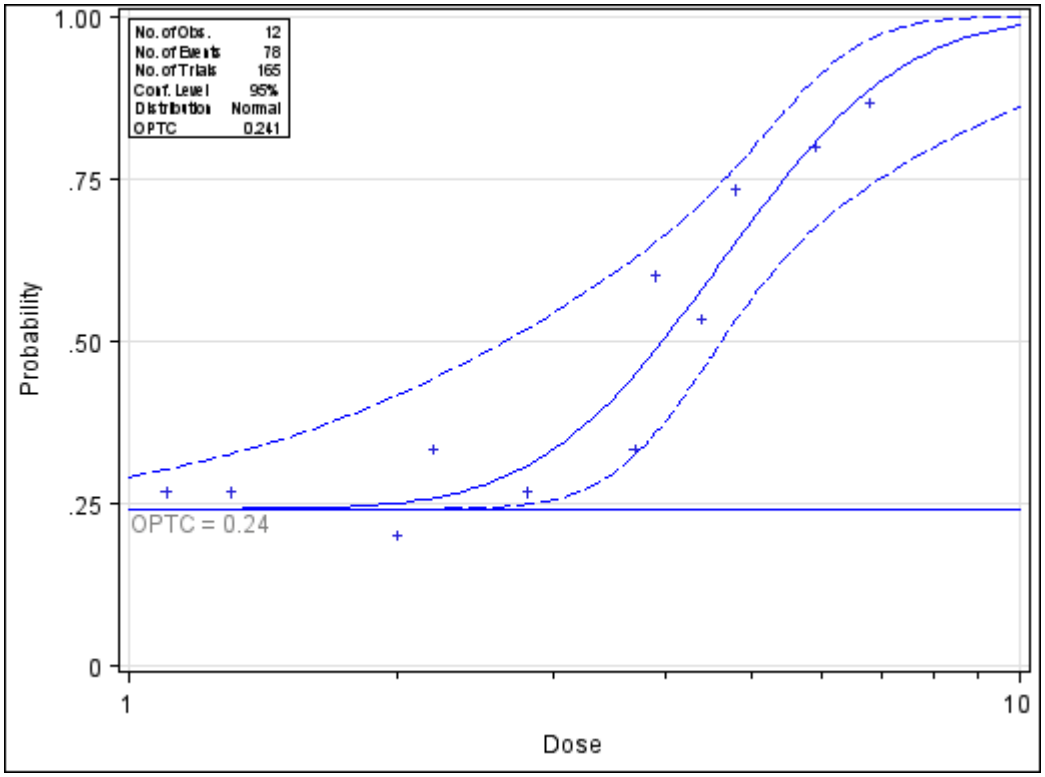

Figure 71.7 Linear Predictor Plot

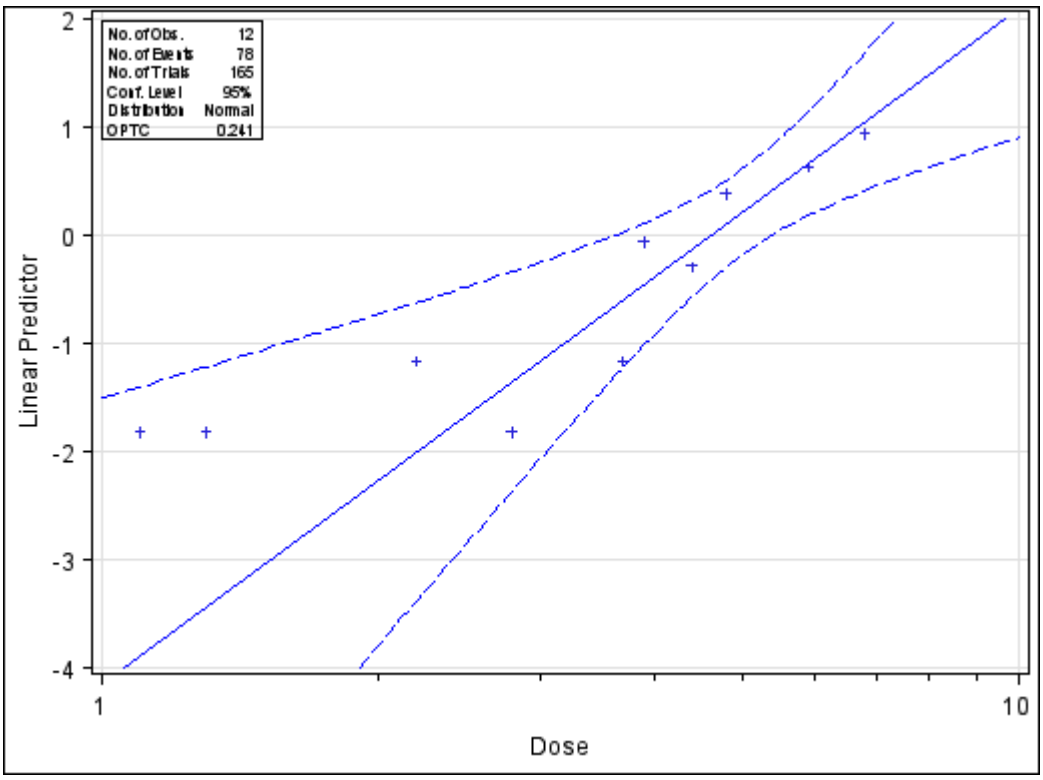

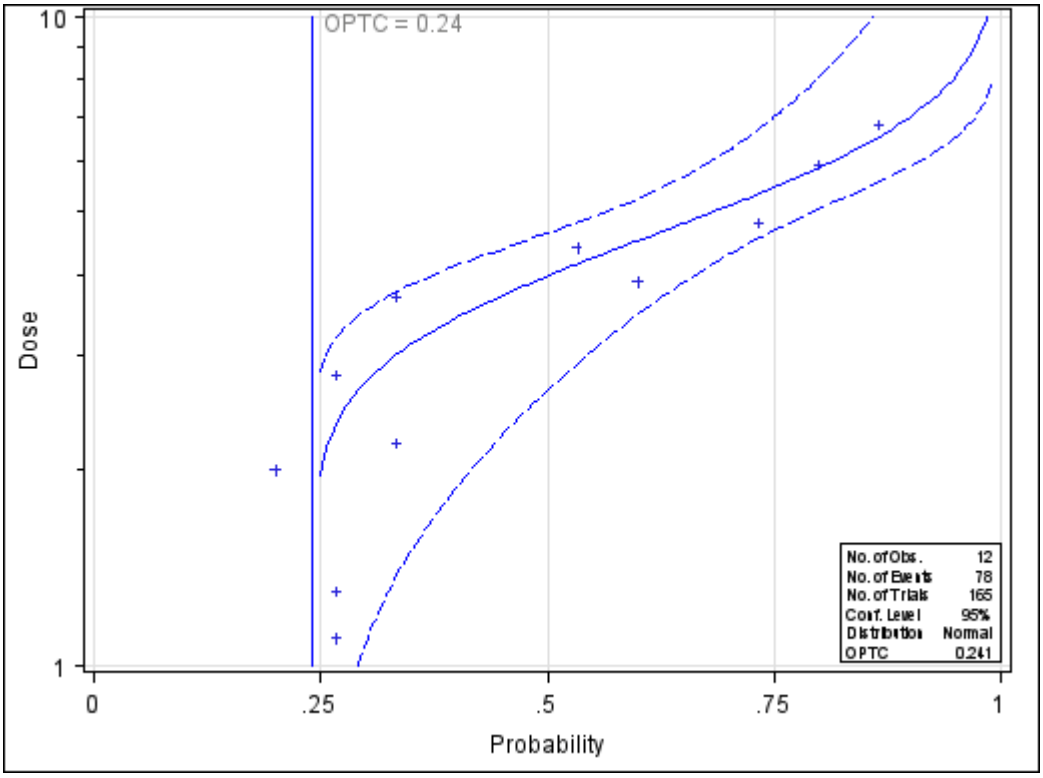

Figure 71.8 Inverse Predicted Probability Plot

The following example uses the data set multi from Example 71.2 to illustrate how to create high-resolution plots for the multinomial model:

```
proc probit data=multi order=data;
   class prep symptoms;
   model symptoms=prep ldose;
   cdfplot var=ldose  level=("None" "Mild" "Severe")
             cfit=blue cframe=ligr noconf;
   lpredplot var=ldose  level=("None" "Mild" "Severe")
             cfit=blue cframe=ligr;
   predpplot var=ldose  level=("None" "Mild" "Severe")
             cfit=blue cframe=ligr;
   weight n;
run;
```

The CDFPLOT statement creates the plot in Figure 71.9. This plot, similar to that in Output 71.2.4, shows the relationship between the cumulative response probabilities and the dose levels. The plots in Figure 71.10 and Figure 71.11 are similar to those with the binomial model.

Figure 71.9 Cumulative Probability Plot

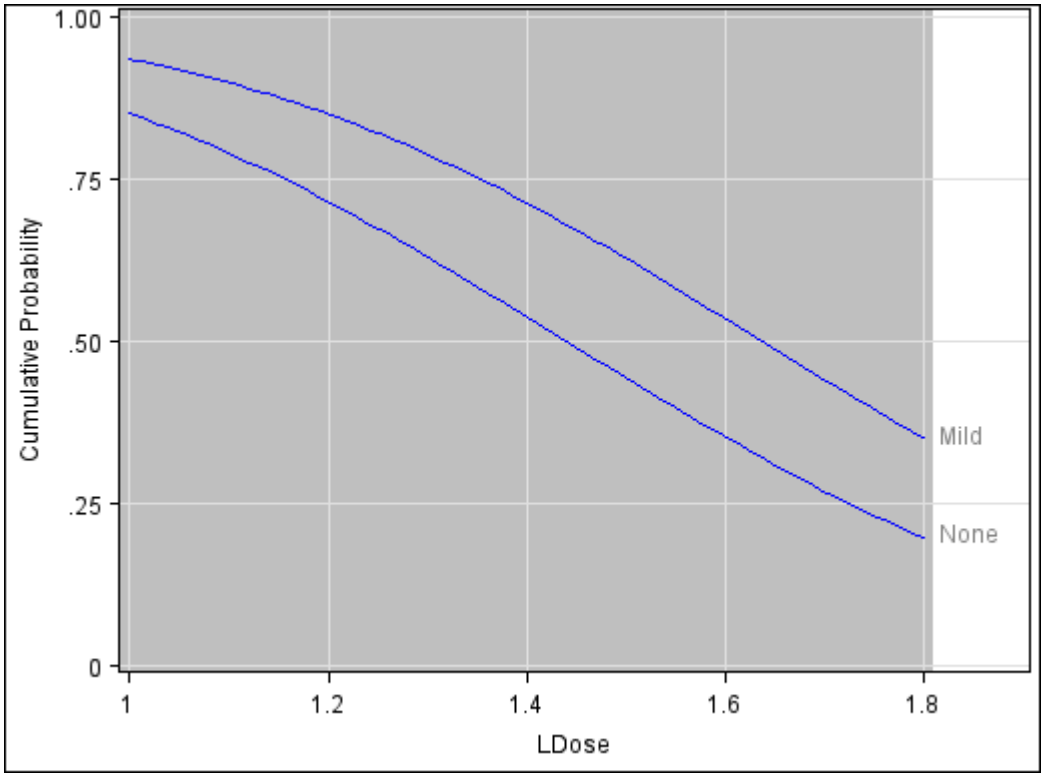

Figure 71.10 Linear Predictor Plot

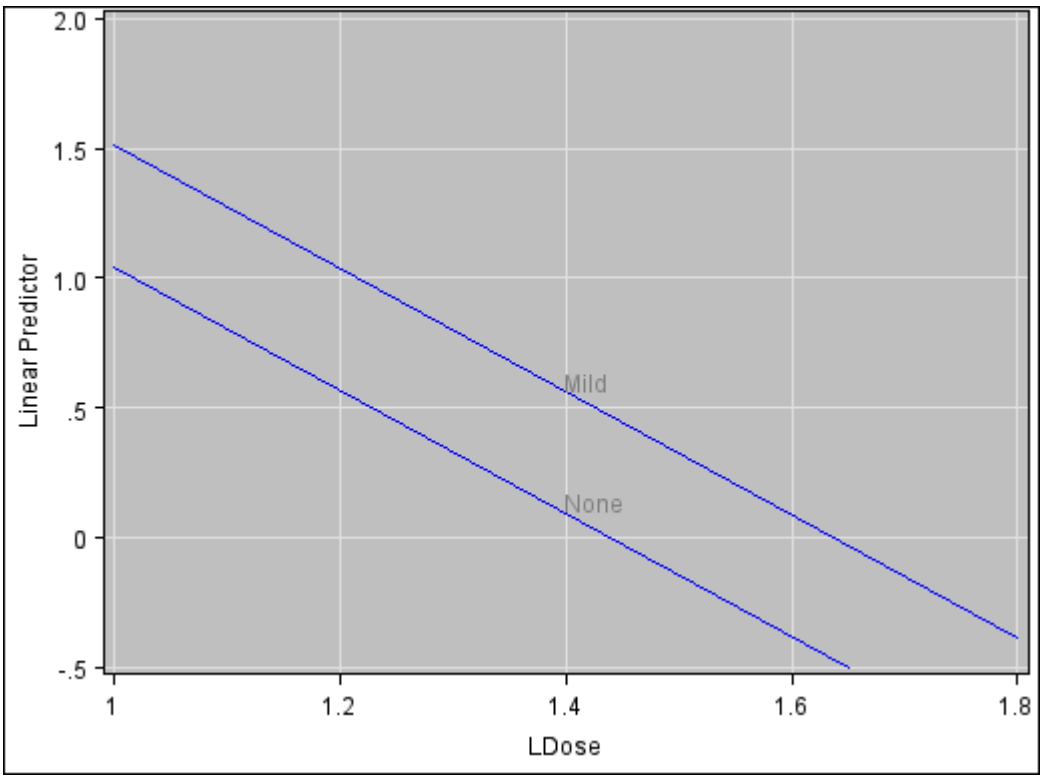

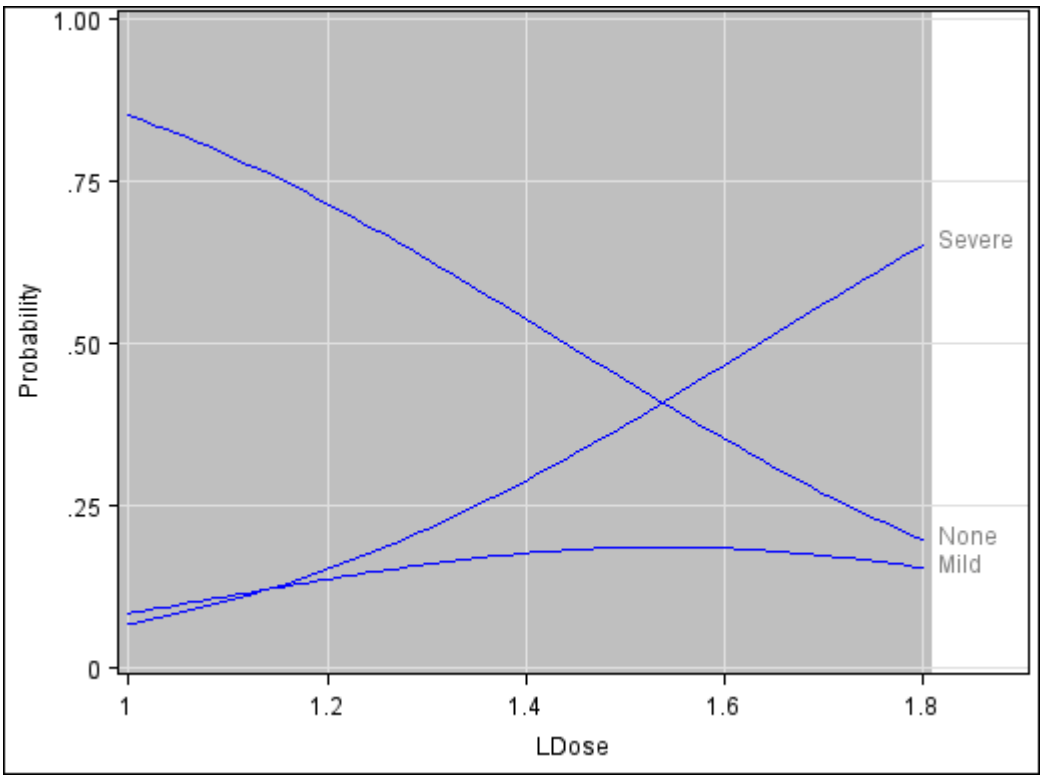

Figure 71.11 Predicted Probability Plot

Displayed Output

If you request the iteration history (ITPRINT), PROC PROBIT displays the following:

- the current value of the log likelihood
- the ridging parameter for the modified Newton-Raphson optimization process
- the current estimate of the parameters
- the current estimate of the parameter C for a natural (threshold) model
- the values of the gradient and the Hessian on the last iteration

If you include classification variables, PROC PROBIT displays the following:

- the numbers of levels for each classification variable
- the (ordered) values of the levels
- the number of observations used

After the model is fit, PROC PROBIT displays the following:

- the name of the input data set
- the name of the dependent variables
- the number of observations used
- the number of events and the number of trials
- the final value of the log-likelihood function
- the parameter estimates
- the standard error estimates of the parameter estimates
- approximate chi-square test statistics for the test

If you specify the COVB or CORRB options, PROC PROBIT displays the following:

- the estimated covariance matrix for the parameter estimates
- the estimated correlation matrix for the parameter estimates

If you specify the LACKFIT option, PROC PROBIT displays the following:

- a count of the number of levels of the response and the number of distinct sets of independent variables
- a goodness-of-fit test based on the Pearson chi-square
- a goodness-of-fit test based on the likelihood-ratio chi-square

If you specify only one independent variable, the normal distribution is used to model the probabilities, and the response is binary, then PROC PROBIT displays the following:

- the mean MU of the stimulus tolerance
- the scale parameter SIGMA of the stimulus tolerance
- the covariance matrix for MU, SIGMA, and the natural response parameter *C*

If you specify the INVERSECL options, PROC PROBIT also displays the following:

- the estimated dose along with the 95% fiducial limits for probability levels 0.01 to 0.10, 0.15 to 0.85 by 0.05, and 0.90 to 0.99

ODS Table Names

PROC PROBIT assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 71.34 ODS Tables Produced by PROC PROBIT

ODS Table Name	Description	Statement	Option
ClassLevels	Classification variable levels	CLASS	default
ConvergenceStatus	Convergence status	MODEL	default
CorrB	Parameter estimate correlation matrix	MODEL	CORRB
CovB	Parameter estimate covariance matrix	MODEL	COVB
CovTolerance	Covariance matrix for location and scale	MODEL	default
GoodnessOfFit	Goodness-of-fit tests	MODEL	LACKFIT
Heterogeneity	Heterogeneity correction	MODEL	LACKFIT
IterHistory	Iteration history	MODEL	ITPRINT
LagrangeStatistics	Lagrange statistics	MODEL	NOINT
LastGrad	Last evaluation of the gradient	MODEL	ITPRINT
LastHess	Last evaluation of the Hessian	MODEL	ITPRINT
LogProbitAnalysis	Probit analysis for log dose	MODEL	INVERSECL
ModelInfo	Model information	MODEL	default

Table 71.34 (continued)

ODS Table Name	Description	Statement	Option
MuSigma	Location and scale	MODEL	default
NObs	Observations summary	PROC	default
ParameterEstimates	Parameter estimates	MODEL	default
ParmInfo	Parameter indices	MODEL	default
ProbitAnalysis	Probit analysis for linear dose	MODEL	INVERSECL
ResponseLevels	Response-covariate profile	MODEL	LACKFIT
ResponseProfiles	Counts for ordinal data	MODEL	default
Type3Analysis	Type 3 tests	MODEL	default

ODS Graphics

The PROBIT procedure has two different systems to produce graphics. You can use the CDFPLOT, IPPPLOT, LPREDPLOT, and PREDPPLOT statements with a specified graph output destination to produce GRSEG type graphs. In SAS 9.2, you can also use ODS Graphics to produce these graphs.

These ODS graphs are controlled by the PLOTS= option in the PROC statement. You can specify more than one graph request with the PLOTS= option. Table 71.35 summarizes these requests.

In addition to the PLOTS= option, you must specify the ODS GRAPHICS statement. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

The names of the graphs that PROC PROBIT generates are listed in Table 71.36, along with the required statements and options. The following subsections provide information about these graphs.

Table 71.35 Options for Plots

Option	Plot
ALL	All appropriate plots
CDFPLOT	Estimated cumulative probability
IPPPLOT	Inverse predicted probability
LPREDPLOT	Linear predictor
NONE	No plot
PREDPPLOT	Predicted probability

CDF Plot

For a multinomial model, the predicted cumulative distribution function is defined as

$$\hat{F}_j(\mathbf{x}) = C + (1 - C)F(\hat{a}_j + \mathbf{x}'\hat{\mathbf{b}})$$

where $j = 1, \ldots, k$ are the indexes of the k levels of the multinomial response variable, F is the CDF of the distribution used to model the cumulative probabilities, $\hat{\mathbf{b}}$ is the vector of estimated

parameters, $\mathbf{x}$ is the covariate vector, $\hat{a}_j$ are estimated ordinal intercepts with $\hat{a}_1 = 0$, and C is the threshold parameter, either known or estimated from the model. Let x_1 be the covariate corresponding to the dose variable and $\mathbf{x}_{-1}$ be the vector of the rest of the covariates. Let the corresponding estimated parameters be $\hat{b}_1$ and $\hat{\mathbf{b}}_{-1}$. Then

$$\hat{F}_j(\mathbf{x}) = C + (1 - C)F(\hat{a}_j + x_1\hat{b}_1 + \mathbf{x}'_{-1}\hat{\mathbf{b}}_{-1})$$

To plot $\hat{F}_j$ as a function of x_1, $\mathbf{x}_{-1}$ must be specified. You can use the XDATA= option to provide the values of $\mathbf{x}_{-1}$ (see the XDATA= option in the PROC PROBIT statement for details), or use the default values that follow these rules:

- If the effect contains a continuous variable (or variables), the overall mean of this effect is used.
- If the effect is a single classification variable, the highest level of the variable is used.

The LEVEL= suboption specify the levels of the multinomial response variable for which the CDF curves are requested. There are $k - 1$ curves for a k-level multinomial response variable (for the highest level, it is the constant line 1). You can specify any of them to be plotted by the LEVEL= suboption. See the plot in Output 71.2.6 for an example.

Inverse Predicted Probability Plot

For the binomial model, the response variable is a probability. An estimate of the dose level $\hat{x}_1$ needed for a response of p is given by

$$\hat{x}_1 = (F^{-1}(p) - \mathbf{x}'_{-1}\hat{\mathbf{b}}_{-1})/\hat{b}_1$$

where F is the cumulative distribution function used to model the probability, $\mathbf{x}_{-1}$ is the vector of the rest of the covariates, $\hat{\mathbf{b}}_{-1}$ is the vector of the estimated parameters corresponding to $\mathbf{x}_{-1}$, and $\hat{b}_1$ is the estimated parameter for the dose variable of interest.

To plot $\hat{x}_1$ as a function of p, $\mathbf{x}_{-1}$ must be specified. You can use the XDATA= option to provide the values of $\mathbf{x}_{-1}$ (see the XDATA= option in the PROC PROBIT statement for details), or use the default values that follow these rules:

- If the effect contains a continuous variable (or variables), the overall mean of this effect is used.
- If the effect is a single classification variable, the highest level of the variable is used.

Output 71.4.12 in Example 71.4 shows an inverse predicted probability plot.

Linear Predictor Plot

For both binomial models and multinomial models, the linear predictor $\mathbf{x}'\mathbf{b}$ can be plotted against the first single continuous variable (dose variable) in the MODEL statement.

Let x_1 be the covariate of the dose variable, $\mathbf{x}_{-1}$ be the vector of the rest of the covariates, $\hat{\mathbf{b}}_{-1}$ be the vector of estimated parameters corresponding to $\mathbf{x}_{-1}$, and $\hat{b}_1$ be the estimated parameter for the dose variable of interest.

To plot $\hat{\mathbf{x}}'\mathbf{b}$ as a function of x_1, $\mathbf{x}_{-1}$ must be specified. You can use the XDATA= option to provide the values of $\mathbf{x}_{-1}$ (see the XDATA= option in the PROC PROBIT statement for details), or use the default values that follow these rules:

- If the effect contains a continuous variable (or variables), the overall mean of this effect is used.
- If the effect is a single classification variable, the highest level of the variable is used.

For the multinomial model, you can use the LEVEL= suboption to specify the levels for which the linear predictor lines are plotted.

The confidence limits for the predicted values are only available for the binomial model. Output 71.4.13 in Example 71.4 shows a linear predictor plot for a binomial model.

Predicted Probability Plot

The predicted probability is

$$\hat{p} = C + (1 - C)F(\mathbf{x}'\hat{\mathbf{b}})$$

for the binomial model and

$$\begin{aligned}
\hat{p}_1 &= C + (1 - C)F(\mathbf{x}'\hat{\mathbf{b}}) \\
\hat{p}_j &= (1 - C)(F(\hat{a}_j + \mathbf{x}'\hat{\mathbf{b}}) - F(\hat{a}_{j-1} + \mathbf{x}'\hat{\mathbf{b}})), \quad j = 2, \ldots, k-1 \\
\hat{p}_k &= (1 - C)(1 - F(\hat{a}_{k-1} + \mathbf{x}'\hat{\mathbf{b}}))
\end{aligned}$$

for the multinomial model with k response levels, where F is the cumulative distribution function used to model the probability, $\mathbf{x}'$ is the vector of the covariates, $\hat{a}_j$ are the estimated ordinal intercepts with $\hat{a}_1 = 0$, C is the threshold parameter, either known or estimated from the model, and $\hat{\mathbf{b}}'$ is the vector of estimated parameters.

To plot $\hat{p}$ (or $\hat{p}_j$) as a function of a continuous variable x_1, the remaining covariates $\mathbf{x}_{-1}$ must be specified. You can use the XDATA= option to provide the values of $\mathbf{x}_{-1}$ (see the XDATA= option in the PROC PROBIT statement for details), or use the default values that follow these rules:

- If the effect contains a continuous variable (or variables), the overall mean of this effect is used.
- If the effect is a single classification variable, the highest level of the variable is used.

For the multinomial model, you can use the LEVEL= suboption to specify the levels for which the linear predictor lines are plotted.

Confidence limits are plotted only for the binomial model. Output 71.1.7 in Example 71.1 shows a predicted probability plot for a binomial model; and Output 71.2.3 in Example 71.2 shows a predicted probability plot for a multinomial model.

ODS Graph Names

PROC PROBIT assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 71.36.

To request these graphs you must specify the ODS GRAPHICS statement in addition to the PLOTS= option described in Table 71.35. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

Table 71.36 ODS Graphics Produced by PROC PROBIT

ODS Graph Name	Plot Description	Statement	PLOTS= Option
CDFPlot	Estimated cumulative probability	PROC	CDFPLOT
IPPPlot	Inverse predicted probability	PROC	IPPPLOT
LPredPlot	Linear predictor	PROC	LPREDPLOT
PredPPlot	Predicted probability	PROC	PREDPPLOT

Examples: PROBIT Procedure

Example 71.1: Dosage Levels

In this example, Dose is a variable representing the level of a stimulus, N represents the number of subjects tested at each level of the stimulus, and Response is the number of subjects responding to that level of the stimulus. Both probit and logit response models are fit to the data. The LOG10 option in the PROC PROBIT statement requests that the log base 10 of Dose is used as the independent variable. Specifically, for a given level of Dose, the probability p of a positive response is modeled as

$$p = \Pr(\text{Response}) = F\left(b_0 + b_1 \times \log_{10}(\text{Dose})\right)$$

The probabilities are estimated first by using the normal distribution function (the default) and then by using the logistic distribution function. Note that, in this model specification, the natural rate is assumed to be zero.

The LACKFIT option specifies lack-of-fit tests and the INVERSECL option specifies inverse confidence limits.

In the DATA step that reads the data, a number of observations are generated that have a missing value for the response. Although the PROBIT procedure does not use the observations with the missing values to fit the model, it does give predicted values for all nonmissing sets of independent variables. These data points fill in the plot of fitted and observed values in the logistic model displayed in Output 71.1.7. The plot, requested with the PLOT=PREDPPLOT option, displays the estimated logistic cumulative distribution function and the observed response rates.

The following statements produce Output 71.1.1:

```
data a;
   infile cards eof=eof;
   input Dose N Response @@;
   Observed= Response/N;
   output;
   return;
eof: do Dose=0.5 to 7.5 by 0.25;
        output;
     end;
   datalines;
1 10 1  2 12 2  3 10 4  4 10 5
5 12 8  6 10 8  7 10 10
;
proc probit log10;
   model Response/N=Dose / lackfit inversecl itprint;
   output out=B p=Prob std=std xbeta=xbeta;
run;
```

Output 71.1.1 Probit Analysis with Normal Distribution

0.53032254	0.29255866

Estimated Covariance Matrix for Tolerance Parameters

	MU	SIGMA
MU	0.002418	−0.000409
SIGMA	−0.000409	0.004072

The p-values in the goodness-of-fit table of 0.6009 for the Pearson chi-square and 0.4616 for the likelihood ratio chi-square indicate an adequate fit for the model fit with the normal distribution.

Tolerance distribution parameter estimates for the normal distribution indicate a mean tolerance for the population of 0.5303.

Output 71.1.2 displays probit analysis with the logarithm of dose levels. The LD50 (ED50 for log dose) is 0.5303, the dose corresponding to a probability of 0.5. This is the same as the mean tolerance for the normal distribution.

Output 71.1.2 Probit Analysis with Normal Distribution

The PLOT=PREDPPLOT option together with the ODS GRAPHICS statement creates the plot of observed and fitted probabilities in Output 71.1.7. The dashed line represent pointwise confidence bands for the probabilities.

Output 71.1.7 Plot of Observed and Fitted Probabilities

Example 71.2: Multilevel Response

In this example, two preparations, a standard preparation and a test preparation, are each given at several dose levels to groups of insects. The symptoms are recorded for each insect within each group, and two multilevel probit models are fit. Because the natural sort order of the three levels is not the same as the response order, the ORDER=DATA option is specified in the PROC PROBIT statement to get the desired order.

The following statements fit two models:

```
data multi;
   input Prep $ Dose Symptoms $ N;
   LDose=log10(Dose);
   if Prep='test' then PrepDose=LDose;
   else PrepDose=0;
   datalines;
stand     10      None       33
stand     10      Mild        7
stand     10      Severe     10
stand     20      None       17
stand     20      Mild       13
stand     20      Severe     17
stand     30      None       14
stand     30      Mild        3
stand     30      Severe     28
```

```
   stand      40       None         9
   stand      40       Mild         8
   stand      40       Severe      32
   test       10       None        44
   test       10       Mild         6
   test       10       Severe       0
   test       20       None        32
   test       20       Mild        10
   test       20       Severe      12

   weight N;
run;
```

Results of these two models are shown in Output 71.2.1 and Output 71.2.2. The first model allows for nonparallelism between the dose response curves for the two preparations by inclusion of an interaction between Prep and LDose. The interaction term is labeled PrepDose in the "Analysis of Parameter Estimates" table. The results of this first model indicate that the parameter for the interaction term is not significant, having a Wald chi-square of 0.73. Also, since the first model is a generalization of the second, a likelihood ratio test statistic for this same parameter can be obtained by multiplying the difference in log likelihoods between the two models by 2. The value obtained, $2 \times (-345.94 - (-346.31))$, is 0.73. This is in close agreement with the Wald chi-square from the first model. The lack-of-fit test statistics for the two models do not indicate a problem with either fit.

Output 71.2.1 Multilevel Response: Nonparallel Analysis

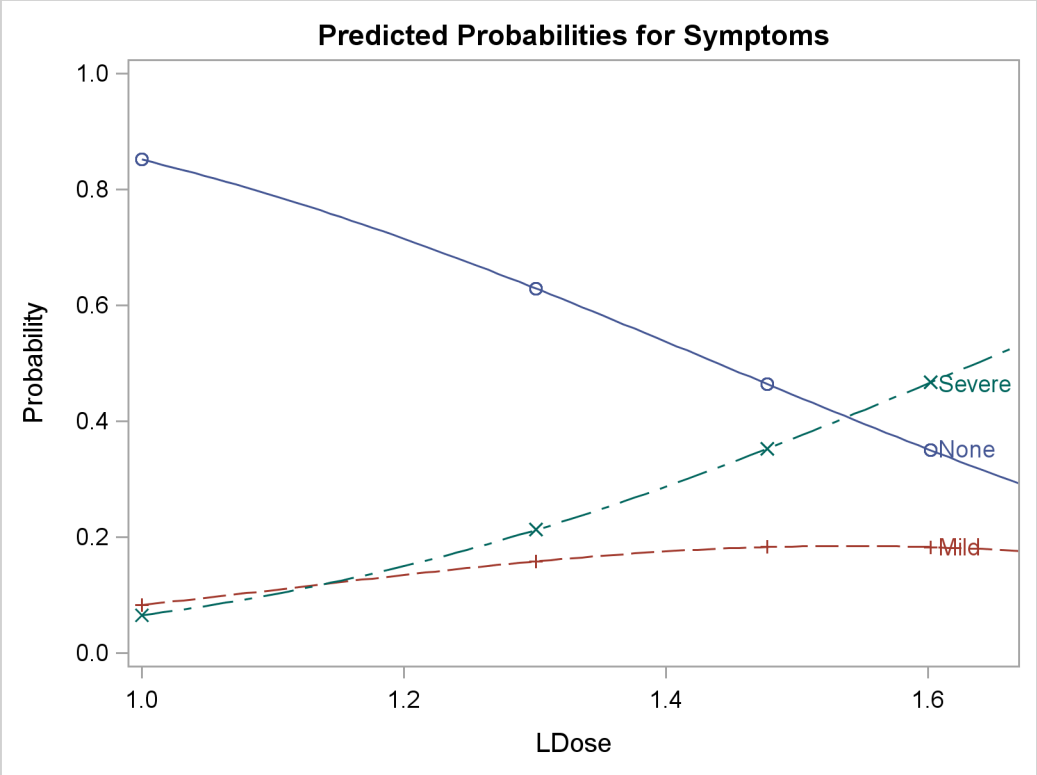
LDose		1	-2.3721	0.2949	-2.9502	-1.7940	64.68	<.0001

The negative coefficient associated with LDose indicates that the probability of having no symptoms (Symptoms='None') or no or mild symptoms (Symptoms='None' or Symptoms='Mild') decreases as LDose increases; that is, the probability of a severe symptom increases with LDose. This association is apparent for both treatment groups.

The negative coefficient associated with the standard treatment group (Prep = stand) indicates that the standard treatment is associated with more severe symptoms across all Ldose values.



The following statements use the PLOTS= option to create the plot shown in Output 71.2.3 and Output 71.2.4. Output 71.2.3 is the plot of the probabilities of the response taking on individual levels as a function of LDose. Since there are two covariates, LDose and Prep, the value of the classification variable Prep is fixed at the highest level, test. Instead of individual response level probabilities, the CDFPLOT option creates the plot of the cumulative response probabilities with confidence limits shown in Output 71.2.4.

```

run;

ods graphics off;
```

Output 71.2.5 Plot of Predicted Probabilities for the Standard Preparation Group

Output 71.2.6 Plot of Predicted Cumulative Probabilities for the Standard Preparation Group

Example 71.3: Logistic Regression

In this example, a series of people are asked whether or not they would subscribe to a new newspaper. For each person, the variables sex (Female, Male), age, and subs (1=yes,0=no) are recorded. The PROBIT procedure is used to fit a logistic regression model to the probability of a positive response (subscribing) as a function of the variables sex and age. Specifically, the probability of subscribing is modeled as

$$p = \Pr(\text{subs} = 1) = F\left(b_0 + b_1 \times \text{sex} + b_2 \times \text{age}\right)$$

where F is the cumulative logistic distribution function.

By default, the PROBIT procedure models the probability of the lower response level for binary data. One way to model $\Pr(\text{subs} = 1)$ is to format the response variable so that the formatted value corresponding to subs=1 is the lower level. The following statements format the values of subs as 1 = 'accept' and 0 = 'reject', so that PROBIT models Pr(accept) = $\Pr(\text{subs} = 1)$. They produce Output 71.3.1.

```
   data news;
      input sex $ age subs @@;
      datalines;
   Female     35    0   Male       44    0

age	292.04051848	216.20829515	13487.329973

Analysis of Maximum Likelihood Parameter Estimates

Parameter		DF	Estimate	Standard Error	95% Confidence Limits		Chi-Square	Pr > ChiSq
Intercept		1	-5.7620	2.7635	-11.1783	-0.3458	4.35	0.0371
sex	Female	1	-2.4224	0.9559	-4.2959	-0.5489	6.42	0.0113
sex	Male	0	0.0000	.	.	.	.	.
age		1	0.1649	0.0652	0.0371	0.2927	6.40	0.0114

Output 71.3.1 shows that there appears to be an effect due to both the variables sex and age. The positive coefficient for age indicates that older people are more likely to subscribe than younger people. The negative coefficient for sex indicates that females are less likely to subscribe than males.

Example 71.4: An Epidemiology Study

The data in this example, which are from an epidemiology study, consist of five variables: the number, r, of individuals surviving after an epidemic, out of n treated, for combinations of medicine dosage (dose), treatment (treat = A, B), and sex (sex = 0(Female), 1(Male)).

To see whether the two treatments have different effects on male and female individual survival rates, the interaction term between the two variables treat and sex is included in the model.

The following invocation of PROC PROBIT fits the binary probit model to the grouped data:

```
   data epidemic;
      input treat$ dose n r sex @@;
      label dose = Dose;
      datalines;
   A  2.17 142 142  0   A   .57 132  47  1
   A  1.68 128 105  1   A  1.08 126 100  0
   A  1.79 125 118  0   B  1.66 117 115  1
   B  1.49 127 114  0   B  1.17  51  44  1
   B  2.00 127 126  0   B   .80 129 100  1
   ;

   data xval;
      input treat $ dose sex ;
      datalines;
   B  2.  1
   ;

ods graphics on;

proc probit optc lackfit covout data=epidemic
            outest = out1 xdata = xval
            Plots=(predpplot ippplot lpredplot)           ;
   class treat sex;
   model r/n = dose treat sex sex*treat/corrb covb inversecl;
   output out = out2 p =p;
run;

ods graphics off;
```

The results of this analysis are shown in the outputs that follow.

Beginning with SAS 8.2, the PROBIT procedure does not support multiple MODEL statements. Only the last one is used if there is more than one MODEL statement in an invocation of the PROBIT procedure.

Output 71.4.1 displays the table of level information for *all* classification variables in the CLASS statement.

Output 71.4.1 Class Level Information

The Probit Procedure

Class Level Information

Name	Levels	Values
treat	2	A B
sex	2	0 1

Output 71.4.2 displays the table of parameter information for the effects in the MODEL statement. The name of a parameter is generated by combining the variable names and level names in the effect. The maximum length of a parameter name is 32. The names of the effects are specified in the MODEL statement. The length of names of effects can be specified by the NAMELEN= option in the PROC PROBIT statement, with the default length 20.

Output 71.4.2 Parameter Information

Parameter Information

Parameter	Effect	treat	sex
Intercept	Intercept		
dose	dose		
treatA	treat	A	
treatB	treat	B	
sex0	sex		0
sex1	sex		1
treatAsex0	treat*sex	A	0
treatAsex1	treat*sex	A	1
treatBsex0	treat*sex	B	0
treatBsex1	treat*sex	B	1

Output 71.4.3 displays background information about the model fit. Included are the name of the input data set, the response variables used, and the number of observations, events, and trials. The table also includes the status of the convergence of the model fitting algorithm and the final value of the log-likelihood function.

Output 71.4.3 Model Information

The Probit Procedure

Model Information

Data Set	WORK.EPIDEMIC
Events Variable	r
Trials Variable	n
Number of Observations	10
Number of Events	1011
Number of Trials	1204
Name of Distribution	Normal
Log Likelihood	-387.2467391

Output 71.4.4 displays the table of goodness-of-fit tests requested with the LACKFIT option in the PROC PROBIT statement. Two goodness-of-fit statistics, the Pearson chi-square statistic and the likelihood ratio chi-square statistic, are computed. The grouping method for computing these statistics can be specified by the AGGREGATE= option. The details can be found in the AGGREGATE= option, and an example can be found in the second part of this example. By default, the PROBIT procedure uses the covariates in the MODEL statement to do grouping. Observations with the same values of the covariates in the MODEL statement are grouped into cells and the two statistics are computed according to these cells. The total number of cells and the number of levels for the response variable are reported next in the "Response-Covariate Profile."

In this example, neither the Pearson chi-square nor the log-likelihood ratio chi-square tests are significant at the 0.1 level, which is the default test level used by the PROBIT procedure. That means that the model, which includes the interaction of treat and sex, is suitable for this epidemiology data set. (Further investigation shows that models without the interaction of treat and sex are not acceptable by either test.)

Output 71.4.4 Goodness-of-Fit Tests and Response-Covariate Profile

Goodness-of-Fit Tests

Statistic	Value	DF	Value/DF	Pr > ChiSq
Pearson Chi-Square	4.9317	4	1.2329	0.2944
L.R. Chi-Square	5.7079	4	1.4270	0.2220

Response-Covariate Profile

Response Levels	2
Number of Covariate Values	10

Output 71.4.5 displays the Type III test results for all effects specified in the MODEL statement, which include the degrees of freedom for the effect, the Wald Chi-Square test statistic, and the p-value.

Output 71.4.5 Type III Tests

Type III Analysis of Effects

Effect	DF	Wald Chi-Square	Pr > ChiSq
dose	1	42.1691	<.0001
treat	1	16.1421	<.0001
sex	1	1.7710	0.1833
treat*sex	1	13.9343	0.0002

Output 71.4.6 displays the table of parameter estimates for the model. The PROBIT procedure displays information for all the parameters of an effect. Degenerate parameters are indicated by 0 degree of freedom. Confidence intervals are computed for all parameters with nonzero degrees of freedom, including the natural threshold C if the OPTC option is specified in the PROC PROBIT statement. The confidence level can be specified by the ALPHA= option in the MODEL statement. The default confidence level is 95%.

Output 71.4.6 Analysis of Parameter Estimates

Analysis of Maximum Likelihood Parameter Estimates

Parameter		DF	Estimate	Standard Error	95% Confidence Limits		Chi-Square	Pr > ChiSq

From Table 71.4.6, you can see the following results:

- The variable dose has a significant positive effect on the survival rate.
- Individuals under treatment A have a lower survival rate.
- Male individuals have a higher survival rate.
- Female individuals under treatment A have a higher survival rate.

Output 71.4.7 and Output 71.4.8 display tables of estimated covariance matrix and estimated correlation matrix for estimated parameters with a nonzero degree of freedom, respectively. They are computed by the inverse of the Hessian matrix of the estimated parameters.

If the XDATA= option is used to input a data set for the independent variables in the MODEL statement, the PROBIT procedure uses these values for the independent variables other than the single continuous variable. Missing values are not permitted in the XDATA= data set for the independent variables, although the value for the single continuous variable is not used in the computing of the fiducial limits. A suitable valid value should be given. In the data set xval created by the SAS statements on page 5345, dose = 2.

See the section "XDATA= *SAS-data-set*" on page 5317 for the default values for those effects other than the single continuous variable, for which the fiducial limits are computed.

In this example, there are two classification variables, treat and sex. Fiducial limits for the dose

variable are computed for the highest level of the classification variables, treat = B and sex = 1, which is the default specification. Since these are the default values, you would get the same values and fiducial limits if you did not specify the XDATA= option in this example. The confidence level for the fiducial limits can be specified by the ALPHA= option in the MODEL statement. The default level is 95%.

If a LOG10 or LOG option is used in the PROC PROBIT statement, the values and the fiducial limits are computed for both the single continuous variable and its logarithm.

Output 71.4.10 displays the OUTEST= data set. All parameters for an effect are included.

Output 71.4.10 Outest Data Set for Epidemiology Study

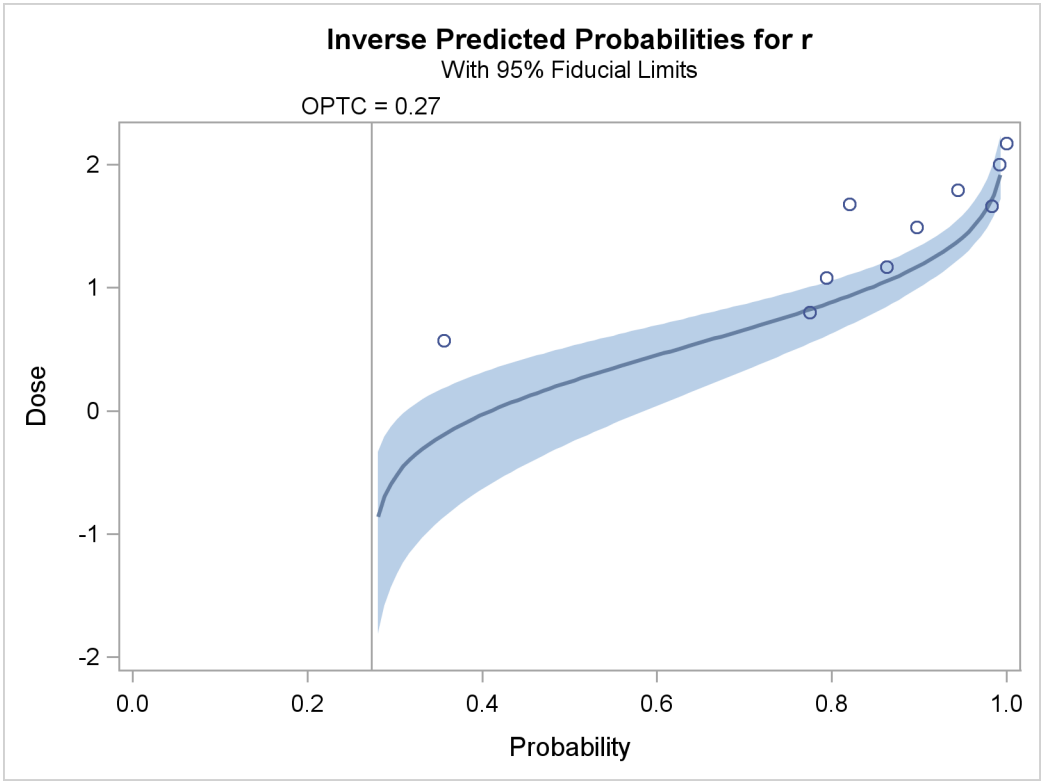
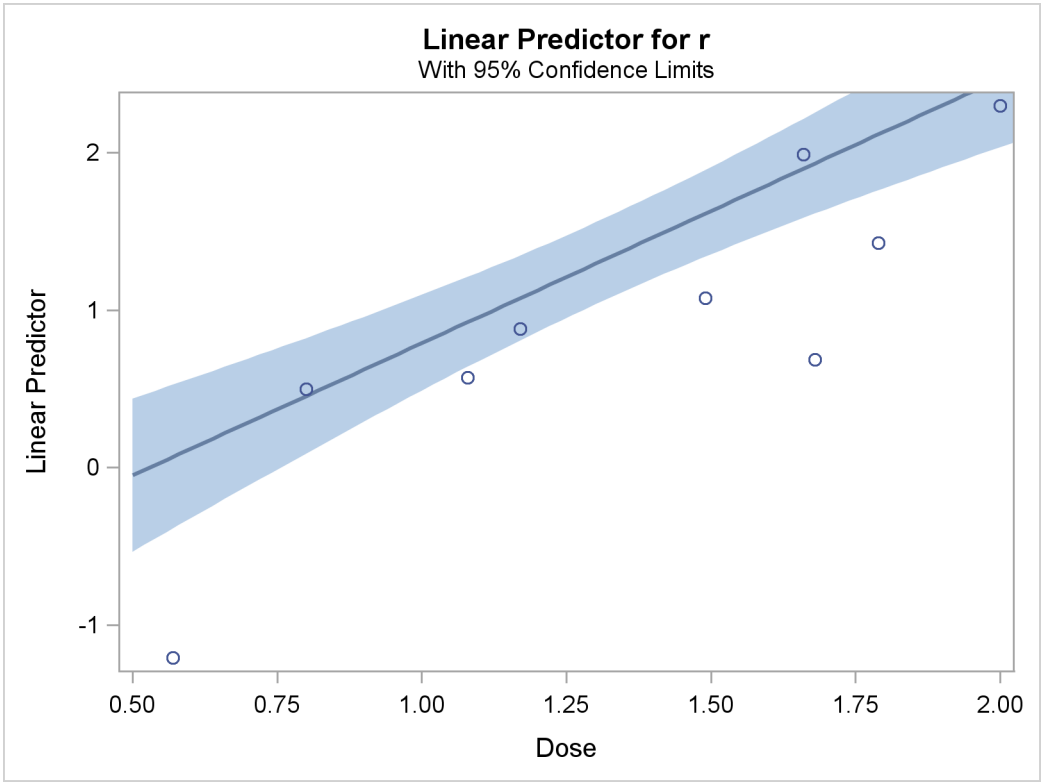
The plots in the following three outputs, Output 71.4.11, Output 71.4.12, and Output 71.4.13, are generated by the PLOTS= option. The first plot, specified with the PREDPPLOT option, is the plot of the predicted probability against the first single continuous variable dose in the MODEL statement. You can specify values of other independent variables in the MODEL statement by using an XDATA= data set or by using the default values.



The second plot, specified with the IPPPLOT option, is the inverse of the predicted probability plot with the fiducial limits. It should be pointed out that the fiducial limits are *not* just the inverse of the confidence limits in the predicted probability plot; see the section "Inverse Confidence Limits"

on page 5315 for the computation of these limits. The third plot, specified with the LPREDPLOT option, is the plot of the linear predictor $\mathbf{x}'_i$ against the first single continuous variable with the Wald confidence intervals.



Output 71.4.11 Predicted Probability Plot

Output 71.4.12 Inverse Predicted Probability Plot

Output 71.4.13 Linear Predictor Plot

When you combine the INEST= data set and the MAXIT= option in the MODEL statement, the PROBIT procedure can do prediction, if the parameterizations for the models used for the training data and the validation data are exactly the same. The following SAS statements show an example:

```
   data validate;
      input treat $ dose  sex  n r group;
      datalines;
   B  2.0  0  44 43  1   B  2.0  1  54 52  2
   B  1.5  1  36 32  3   B  1.5  0  45 40  4
   A  2.0  0  66 64  5   A  2.0  1  89 89  6
   A  1.5  1  45 39  7   A  1.5  0  66 60  8
   B  2.0  0  44 44  1   B  2.0  1  54 54  2
   B  1.5  1  36 30  3   B  1.5  0  45 41  4
   A  2.0  0  66 65  5   A  2.0  1  89 88  6
   A  1.5  1  45 38  7   A  1.5  0  66 59  8
   ;

proc probit optc data=validate inest=out1;
   class treat sex;
   model r/n = dose treat sex sex*treat  / maxit = 0 ;
   output out = out3 p =p;
run ;

proc probit optc lackfit data=validate inest=out1;
   class treat sex;
   model r/n = dose treat sex sex*treat / aggregate = group ;
   output out = out4 p =p;
run ;
```

After the first invocation of PROC PROBIT, you have the estimated parameters and their covariance matrix in the data set OUTEST = Out1, and the fitted probabilities for the training data set epidemic in the data set OUTPUT = Out2. See Output 71.4.10 for the data set Out1 and Output 71.4.14 for the data set Out2.

The validation data are collected in data set validate. The second invocation of PROC PROBIT simply passes the estimated parameters from the training data set epidemic to the validation data set validate for prediction. The predicted probabilities are stored in the data set OUTPUT = Out3 (see Output 71.4.15). The third invocation of PROC PROBIT passes the estimated parameters as initial values for a new fit of the validation data set with the same model. Predicted probabilities are stored in the data set OUTPUT = Out4 (see Output 71.4.16). Goodness-of-fit tests are computed based on the cells grouped by the AGGREGATE= group variable. Results are shown in Output 71.4.17.

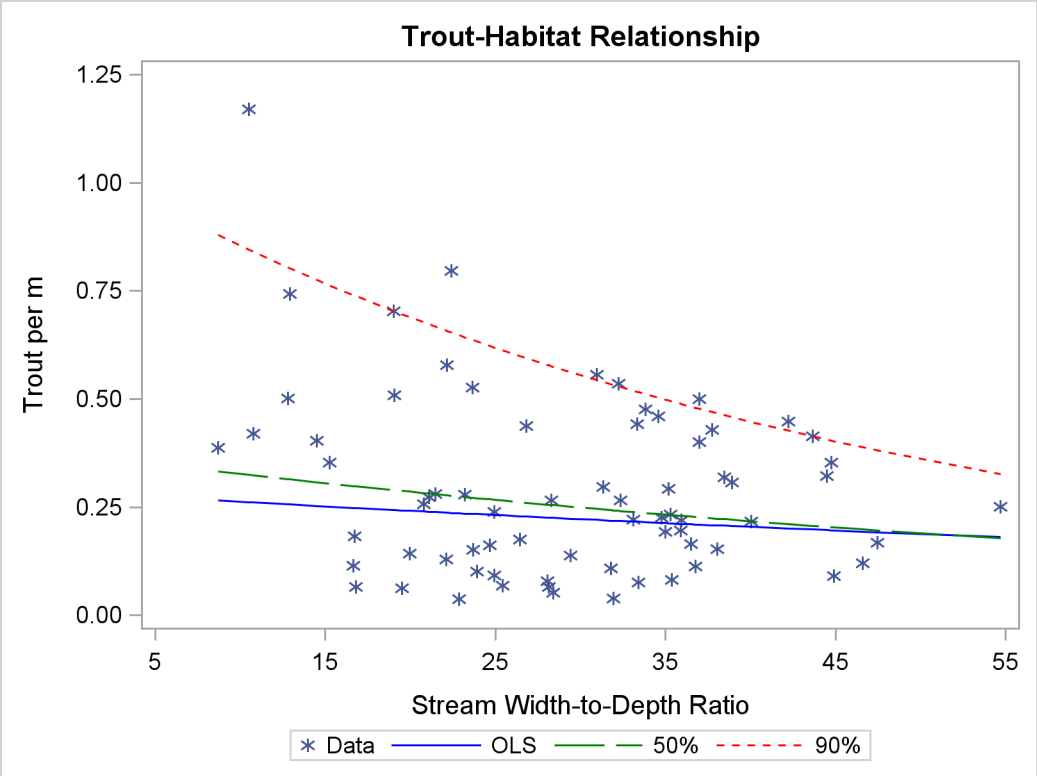
Overview: QUANTREG Procedure

The QUANTREG procedure models the effects of covariates on the conditional quantiles of a response variable by means of quantile regression.

Ordinary least squares (OLS) regression models the relationship between one or more covariates X and the *conditional mean* of the response variable Y given $X = x$. Quantile regression, which was introduced by Koenker and Bassett (1978), extends the regression model to *conditional quantiles* of the response variable, such as the median or the 90th percentile. Quantile regression is particularly useful when the rate of change in the conditional quantile, expressed by the regression coefficients, depends on the quantile.

Figure 72.1 Trout Density in Streams



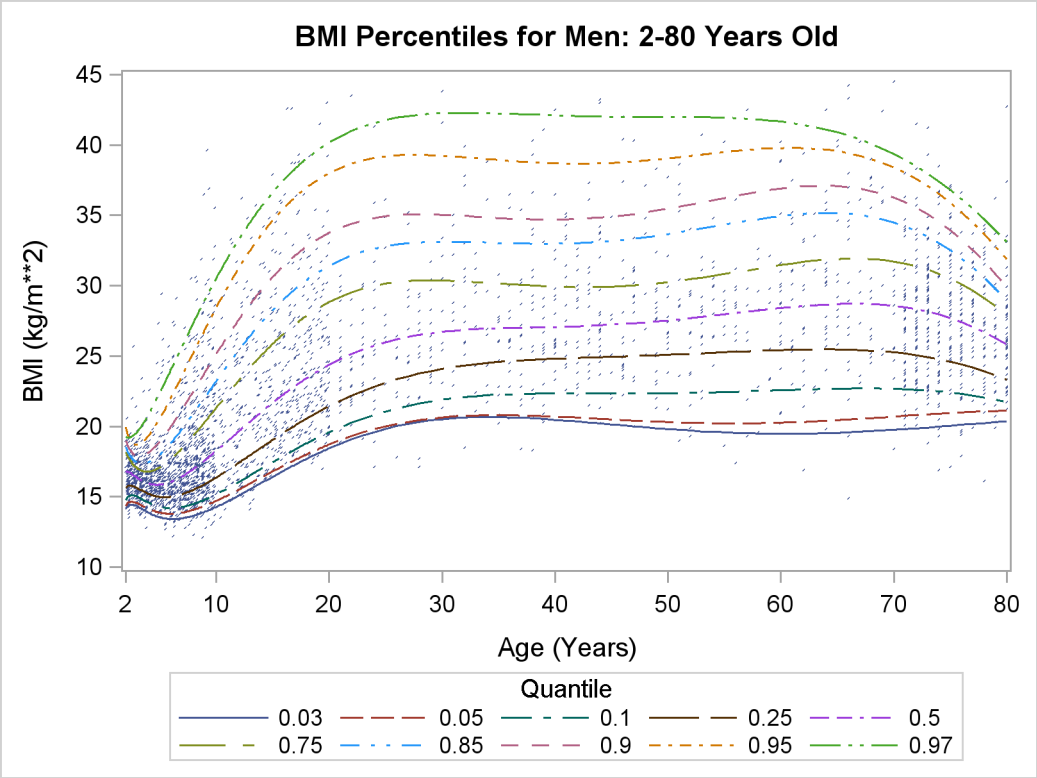


Figure 72.1 illustrates an ecological study in which it is revealing to model upper conditional quantiles. The points represent measurements of trout density and stream width-to-depth ratio taken at 13 streams over seven years.

As analyzed by Dunham, Cade, and Terrell (2002), in addition to the ratio, trout density depends on

a number of unmeasured limiting factors related to the integrity of stream habitat. The interaction of these factors results in unequal variances for the conditional distributions of density given the ratio. When the ratio is the "active" limiting effect, changes in the upper conditional percentiles of density provide a better estimate of this effect than changes in the conditional mean.

The two dashed curves represent the conditional 90th and 50th percentiles of density as determined with the QUANTREG procedure. The analysis was done by using a simple linear regression model for the logarithm of density. (The curves in Figure 72.1 were obtained by transforming the fitted lines back to the original scale. For more details, see the section "Analysis of Fish-Habitat Relationships" on page 5363.) The slope parameter for the 90th percentile has an estimated value of -0.0215 and is significant with a p-value less than 0.01. On the other hand, the slope parameter for the 50th percentile is not significantly different from zero. Similarly, the slope parameter for the mean, obtained with OLS regression, is not significantly different from zero.

Figure 72.2 Quantiles for Body Mass Index

Quantile regression is especially useful with data that are heterogeneous in the sense that the tails and the central location of the conditional distributions vary differently with the covariates. An even more pronounced example of heterogeneity is shown in Figure 72.2, which plots the body mass index of 8,250 men versus their age.

Here, both upper (overweight) and lower (underweight) conditional quantiles are important because they provide the basis for developing growth charts and establishing health standards. The curves in Figure 72.2 were determined with the QUANTREG procedure by using polynomial quantile regression; details are provided in the section "Growth Charts for Body Mass Index" on page 5368. Clearly, the rate of change with age (as expressed by the regression coefficients), particularly for ages less than 20, is different for each conditional quantile.

Heterogeneous data occur in many fields, including biomedicine, econometrics, survival analysis, and ecology. Quantile regression, which includes median regression as a special case, provides a complete picture of the covariate effect when a set of percentiles is modeled, and so it offers the capability to capture important features of the data that might be missed by models that average over the conditional distribution.

Because it makes no distributional assumption about the error term in the model, quantile regression offers considerable model robustness. The assumption of normality, which is often made with OLS regression in order to compute conditional quantiles as offsets from the mean, forces a common set of regression coefficients for all the quantiles. Obviously, quantiles with common slopes would be inappropriate in the preceding examples.

Quantile regression is also flexible in the sense that it does not involve a link function that relates the variance and the mean of the response variable. Generalized linear models, which you can fit with the GENMOD procedure, require both a link function and a distributional assumption such as the normal or Poisson distribution. The goal of generalized linear models is inference about the regression parameters in the linear predictor for the mean of the population. In contrast, the goal of quantile regression is inference on regression coefficients for the conditional quantiles of a response variable that is usually assumed to be continuous.

Quantile regression also offers a degree of data robustness. Unlike OLS regression, it is robust to extreme points in the response direction (outliers). However, it is not robust to extreme points in the covariate space (leverage points). When both types of robustness are of concern, you should consider using the ROBUSTREG procedure (Chapter 74, "The ROBUSTREG Procedure.")

Also, unlike OLS regression, quantile regression is equivariant to monotone transformations of the response variable. For instance, as illustrated in the trout example, the logarithm of the 90th conditional percentile of trout density is the 90th conditional percentile of the logarithm of density.

Note that quantile regression cannot be carried out simply by segmenting the unconditional distribution of the response variable and then obtaining least squares fits for the subsets. This approach leads to disastrous results when, for example, the data include outliers. In contrast, quantile regression uses *all* of the data for fitting quantiles, even the extreme quantiles.

Features

The main features of the QUANTREG procedure are as follows:

- offers simplex, interior point, and smoothing algorithms for estimation
- provides sparsity, rank, and resampling methods for confidence intervals
- provides asymptotic and bootstrap methods for covariance and correlation matrices of the estimated parameters
- provides the Wald and likelihood ratio tests for the regression parameter estimates
- provides outlier and leverage-point diagnostics

- enables parallel computing when multiple processors are available
- provides row-wise or column-wise output data sets with multiple quantiles
- provides regression quantile spline fits
- produces fit plots, diagnostic plots, and quantile process plots by using ODS Graphics

The next section provides notation and a formal definition for quantile regression.

Quantile Regression

Quantile regression generalizes the concept of a univariate quantile to a conditional quantile given one or more covariates. Recall that a student's score on a test is at the τth quantile if his or her score is better than that of $100\tau\%$ of the students who took the test. The score is also said to be at the 100τth percentile.

For a random variable Y with probability distribution function

$$F(y) = \text{Prob}\,(Y \leq y)$$

the τth quantile of Y is defined as the inverse function

$$Q(\tau) = \inf\{y : F(y) \geq \tau\}$$

where $0 < \tau < 1$. In particular, the median is $Q(1/2)$.

For a random sample $\{y_1, \ldots, y_n\}$ of Y, it is well known that the sample median minimizes the sum of absolute deviations

$$\text{median} = \arg\min_{\xi \in \mathbf{R}} \sum_{i=1}^{n} |y_i - \xi|$$

Likewise, the general τth sample quantile $\xi(\tau)$, which is the analog of $Q(\tau)$, is formulated as the minimizer

$$\xi(\tau) = \arg\min_{\xi \in \mathbf{R}} \sum_{i=1}^{n} \rho_\tau(y_i - \xi)$$

where $\rho_\tau(z) = z(\tau - I(z < 0))$, $0 < \tau < 1$, and where $I(\cdot)$ denotes the indicator function. The loss function ρ_τ assigns a weight of τ to positive residuals $y_i - \xi$ and a weight of $1 - \tau$ to negative residuals.

Using this loss function, the linear conditional quantile function extends the τth sample quantile $\xi(\tau)$ to the regression setting in the same way that the linear conditional mean function extends the sample mean. Recall that OLS regression estimates the linear conditional mean function $E(Y|X = x) = x'\beta$ by solving for

$$\hat{\beta} = \arg\min_{\beta \in \mathbf{R}^p} \sum_{i=1}^{n} (y_i - x_i'\beta)^2$$

The estimated parameter $\hat{\beta}$ minimizes the sum of squared residuals in the same way that the sample mean $\hat{\mu}$ minimizes the sum of squares:

$$\hat{\mu} = \arg\min_{\mu \in \mathbf{R}} \sum_{i=1}^{n} (y_i - \mu)^2$$

Likewise, quantile regression estimates the linear conditional quantile function, $Q(\tau|X = x) = x'\beta(\tau)$, by solving

$$\hat{\beta}(\tau) = \arg\min_{\beta \in \mathbf{R}^p} \sum_{i=1}^{n} \rho_\tau(y_i - x_i'\beta)$$

for any quantile $\tau \in (0, 1)$. The quantity $\hat{\beta}(\tau)$ is called the τth *regression quantile*. The case $\tau = 0.5$, which minimizes the sum of absolute residuals, corresponds to median regression, which is also known as L_1 regression.

The set of regression quantiles

$$\{\beta(\tau) : \tau \in (0, 1)\}$$

is referred to as the *quantile process*.

The QUANTREG procedure computes the quantile function $Q(\tau|X = x)$ and conducts statistical inference on the estimated parameters $\hat{\beta}(\tau)$.

Getting Started: QUANTREG Procedure

The following examples demonstrate how you can use the QUANTREG procedure to fit linear models for selected quantiles or for the entire quantile process. The first example explains the use of the procedure in the fish-habitat example, and the second example explains the use of the procedure to construct growth charts for body mass index.

Analysis of Fish-Habitat Relationships

Quantile regression is used extensively in ecological studies (Cade and Noon 2003). Recently, Dunham, Cade, and Terrell (2002) applied quantile regression to analyze fish-habitat relationships for Lahontan cutthroat trout in 13 streams of the eastern Lahontan basin, which covers most of northern Nevada and parts of southern Oregon. The density of trout (number of trout per meter) was measured by sampling stream sites from 1993 to 1999. The width-to-depth ratio of the stream site was determined as a measure of stream habitat.

The goal of this study was to explore the relationship between the conditional quantiles of trout density and the width-to-depth ratio. The scatter plot of the data in Figure 72.1 indicates a nonlinear relationship, and so it is reasonable to fit regression models for the conditional quantiles of the log of density. Since regression quantiles are equivariant under any monotonic (linear or nonlinear) transformation (Koenker and Hallock 2001), the exponential transformation converts the conditional quantiles to the original density scale.

The data set trout, which follows, includes the average numbers of Lahontan cutthroat trout per meter of stream (Density), the logarithm of Density (LnDensity), and the width-to-depth ratios (WDRatio) for 71 samples.

```

The following statements use the QUANTREG procedure to fit a simple linear model for the 90th percentile of LnDensity:

```
proc quantreg data=trout alpha=0.01 ci=resampling;
   model LnDensity = WDRatio / quantile=0.9
                               CovB CorrB
                               seed=12345;
   test WDRatio / wald lr;
run;
```

The MODEL statement specifies a simple linear regression model with LnDensity as the response variable Y and WDRatio as the covariate X. The option QUANTILE=0.9 requests that the regression quantile function $Q(0.9|X = x) = x'\beta(0.9)$ is to be estimated by solving

$$\hat{\beta}(0.9) = \arg\min_{\beta \in \mathbf{R}^2} \sum_{i=1}^{n} \rho_{0.9}(y_i - x_i'\beta)$$

By default, the regression coefficients $\hat{\beta}(0.9)$ are estimated with the simplex algorithm, which is explained in the section "Simplex Algorithm" on page 5385. The option ALPHA=0.01 requests 99% confidence limits for the regression parameters, and the option CI=RESAMPLING specifies that the intervals are to be computed with the MCMB resampling method of He and Hu (2002). By specifying the CI=RESAMPLING option, the QUANTREG procedure also computes standard errors, t values, and p-values of regression parameters with the MCMB resampling method. The SEED= option specifies a seed for the resampling method. The options COVB and CORRB request covariance and correlation matrices for the estimated regression coefficients, and the TEST statement requests tests for the hypothesis that the slope parameter (the coefficient of WDRatio) is zero.

Figure 72.3 displays model information and summary statistics for the variables in the model. The summary statistics include the median and the standardized median absolute deviation (MAD), which are robust measures of univariate location and scale, respectively. See Huber (1981, p. 108) for more details about the standardized MAD.

Figure 72.3 Model Fitting Information and Summary Statistics

The QUANTREG Procedure

Model Information

Data Set	WORK.TROUT
Dependent Variable	LnDensity
Number of Independent Variables	1
Number of Observations	71
Optimization Algorithm	Simplex
Method for Confidence Limits	Resampling

Summary Statistics

Variable	Q1	Median	Q3	Mean	Standard Deviation	MAD
WDRatio	22.0917	29.4083	35.9382	29.1752	9.9859	10.4970
LnDensity	-2.0511	-1.3813	-0.8669	-1.4973	0.7682	0.8214

Figure 72.4 displays the parameter estimates, standard errors, 99% confidence limits, t values, and p-values computed by the resampling method.

Figure 72.4 Parameter Estimates

Parameter Estimates

Parameter	DF	Estimate	Standard Error	99% Confidence Limits		t Value	Pr > |t|
Intercept	1	0.0576	0.2727	-0.6648	0.7801	0.21	0.8333
WDRatio	1	-0.0215	0.0073	-0.0408	-0.0022	-2.96	0.0042

The 90th percentile of trout density can be predicted from the width-to-depth ratio as follows:

$$y_{90} = \exp(0.0576 - 0.0215x)$$

This is the upper dashed curve plotted in Figure 72.1. The lower dashed curve for the median can be obtained by changing the option QUANTILE=0.9 to QUANTILE=0.5.

The covariance and correlation matrices for the estimated parameters are shown in Figure 72.5. The resampling method used for the confidence intervals is used to compute these matrices.

Figure 72.5 Covariance and Correlation

Estimated Covariance Matrix

	Intercept	WDRatio
Intercept	0.074384	-.001934
WDRatio	-.001934	0.000053

Figure 72.5 *continued*

Estimated Correlation Matrix

	Intercept	WDRatio
Intercept	1.00000	-0.97357
WDRatio	-0.97357	1.00000

The tests requested with the TEST statement are shown in Figure 72.6. Both the Wald test and the likelihood ratio test indicate that the coefficient of width-to-depth ratio is significantly different from zero.

Likelihood Ratio	9.0529	1	9.05	0.0026

In many quantile regression problems it is useful to examine how the estimated regression parameters for each covariate change as a function of the quantile τ in the interval $(0, 1)$. The following statements use the QUANTREG procedure to request the estimated quantile processes $\hat{\beta}(\tau)$ for the slope and intercept parameters:

```
ods graphics on;

proc quantreg data=trout alpha=0.1 ci=resampling;
   model LnDensity = WDRatio / quantile=process seed=12345
                               plot=quantplot;
run;

ods graphics off;
```

The QUANTILE=PROCESS option requests an estimate of the quantile process for each regression parameter. The options ALPHA=0.1 and CI=RESAMPLING specify that 90% confidence bands for the quantile processes are to be computed with the resampling method.

Figure 72.7 displays a portion of the objective function table for the entire quantile process. The objective function is evaluated at 77 values of τ in the interval $(0, 1)$. The table also provides predicted values of the conditional quantile function $Q(\tau)$ at the mean for WDRatio, which can be used to estimate the conditional density function.

Figure 72.7 Objective Function

Objective Function for Quantile Process

Label	Quantile	Objective Function	Predicted at Mean
t0	0.005634	0.7044	−3.2582
t1	0.020260	2.5331	−3.0331

The PLOT=QUANTPLOT option in the MODEL statement, together with the ODS GRAPHICS statement, requests a plot of the estimated quantile processes. The left side of Figure 72.9 displays the process for the intercept, and the right side displays the process for the coefficient of WDRatio.

The process plot for WDRatio shows that the slope parameter changes from positive to negative as the quantile increases, and it changes sign with a sharp drop at the 40th percentile. The 90% confidence bands show that the relationship between LnDensity and WDRatio (expressed by the slope) is not significant below the 78th percentile. This situation can also be seen in Figure 72.8, which shows that 0 falls between the lower and upper confidence limits of the slope parameter for quantiles below 0.78. Since the confidence intervals for the extreme quantiles are not stable due to insufficient data, the confidence band is not displayed outside the interval (0.05, 0.95).

Figure 72.9 Quantile Processes for Intercept and Slope

Growth Charts for Body Mass Index

Body mass index (BMI) is defined as the ratio of weight (kg) to squared height (m^2) and is a widely used measure for categorizing individuals as overweight or underweight. The percentiles of BMI for specified ages are of particular interest. As age increases, these percentiles provide growth patterns of BMI not only for the majority of the population, but also for underweight or overweight extremes of the population. In addition, the percentiles of BMI for a specified age provide a reference for individuals at that age with respect to the population.

Smooth quantile curves have been widely used for reference charts in medical diagnosis to identify unusual subjects, whose measurements lie in the tails of the reference distribution. This example explains how to use the QUANTREG procedure to create growth charts for BMI.

A SAS data set named bmimen was created by merging and cleaning the 1999–2000 and 2001–2002 survey results for men published by the National Center for Health Statistics. This data set contains the variables WEIGHT (kg), HEIGHT (m), BMI (kg/m^2), AGE (year), and SEQN (respondent sequence number) for 8,250 men. More details can be found in Chen (2005).

The data set used in this example is a subset of the original data set of Chen (2005). It contains the two variables BMI and AGE with 3264 observations.

```

;
```

The logarithm of BMI is used as the response (although this does not improve the quantile regression fit, it helps with statistical inference.) A preliminary median regression is fitted with a parametric model, which involves six powers of AGE.

```
data bmimen;
   set bmimen0;
   sqrtage = sqrt(age);
   inveage = 1/age;
   logbmi  = log(bmi);
run;
```

The following statements invoke the QUANTREG procedure:

```
proc quantreg data=bmimen algorithm=interior ci=resampling;
   model logbmi = inveage sqrtage age sqrtage*age
                  age*age age*age*age
                  / diagnostics cutoff=4.5 quantile=.5;
   id age bmi;
   test_age_cubic: test age*age*age / wald lr;
run;
```

The MODEL statement provides the model, and the option QUANTILE=0.5 requests median regression, which computes $\hat{\beta}(\frac{1}{2})$ by using the interior point algorithm as requested with the ALGORITHM= option. See the section "Interior Point Algorithm" on page 5386 for details about this algorithm.

Figure 72.10 displays the estimated parameters, standard errors, 95% confidence intervals, t values, and p-values that are computed by the resampling method as requested by the CI= option. All of the parameters are considered significant since the p-values are smaller than 0.001.

Figure 72.10 Parameter Estimates with Median Regression: Men

The QUANTREG Procedure

Parameter Estimates

Parameter	DF	Estimate	Standard Error	95% Confidence Limits		t Value	Pr > |t|
Intercept	1	7.8909	0.7755	6.3704	9.4115	10.17	<.0001
inveage	1	−1.8354	0.4187	−2.6563	−1.0144	−4.38	<.0001
sqrtage	1	−5.1247	0.6765	−6.4511	−3.7983	−7.58	<.0001
age	1	1.9759	0.2410	1.5033	2.4484	8.20	<.0001
sqrtage*age	1	−0.3347	0.0405	−0.4141	−0.2554	−8.27	<.0001
age*age	1	0.0227	0.0028	0.0172	0.0282	8.12	<.0001
age*age*age	1	−0.0000	0.0000	−0.0001	−0.0000	−7.69	<.0001

The TEST statement requests Wald and likelihood ratio tests for the significance of the cubic term in AGE. The test results, shown in Figure 72.11, indicate that this term is significant. Higher-order terms are not significant.

Figure 72.11 Test of Significance for Cubic Term

Tests

test_age_cubic

Test	Test Statistic	DF	Chi-Square	Pr > ChiSq
Wald	59.0752	1	59.08	<.0001
Likelihood Ratio	56.9473	1	56.95	<.0001

Median regression and, more generally, quantile regression are robust to extremes of the response variable. The DIAGNOSTICS option in the MODEL statement requests a diagnostic table of outliers, shown in Figure 72.12, which uses a cutoff value specified with the CUTOFF= option. The variables specified in the ID statement are included in the table.

With CUTOFF=4.5, 14 men are identified as outliers. All of these men have large positive standardized residuals, which indicates that they are overweight for their age. The cutoff value 4.5 is ad hoc; it corresponds to a probability less than 0.5E−5 if normality is assumed, but the standardized residuals for median regression usually do not meet this assumption.

In order to construct the chart shown in Figure 72.2, the same model used for median regression is used for other quantiles. Note that the QUANTREG procedure can compute fitted values for multiple quantiles.

Figure 72.12 Diagnostics with Median Regression

Diagnostics

Obs	age	bmi	Standardized Residual	Outlier
1337	8.900000	36.500000	5.3575	*
1376	9.200000	39.600000	5.8723	*
1428	9.400000	36.900000	5.3036	*
1505	9.900000	35.500000	4.8862	*
1764	14.900000	46.800000	5.6403	*
1838	16.200000	50.400000	5.9138	*
1845	16.300000	42.600000	4.6683	*
1870	16.700000	42.600000	4.5930	*
1957	18.100000	49.900000	5.5053	*
2002	18.700000	52.700000	5.8106	*
2016	18.900000	48.400000	5.1603	*
2264	32.000000	55.600000	5.3085	*
2291	35.000000	60.900000	5.9406	*
2732	66.000000	14.900000	-4.7849	*

The following statements request fitted values for 10 quantiles ranging from 0.03 to 0.97:

```
proc quantreg data=bmimen ci=none algorithm=interior(tolerance=1e-6);
model logbmi = inveage sqrtage age sqrtage*age
                 age*age age*age*age
                 / quantile=0.03,0.05,0.1,0.25,0.5,0.75,
                            0.85,0.90,0.95,0.97;
output out=outp pred=p/columnwise;
run;

data outbmi;
   set outp;
   pbmi = exp(p);
run;

proc sgplot data=outbmi;
   title 'BMI Percentiles for Men: 2-80 Years Old';
   yaxis label='BMI (kg/m**2)' min=10 max=45
         values=(10 15 20 25 30 35 40 45);
   xaxis label='Age (Years)' min=2 max=80
         values=(2 10 20 30 40 50 60 70 80);
   scatter x=age y=bmi /markerattrs=(size=1);
   series  x=age y=pbmi/group=QUANTILE;
run;
```

The fitted values are stored in the OUTPUT data set outp. The COLUMNWISE option arranges these fitted values for all quantiles in the single variable p by groups of the quantiles. After the exponential transformation, the fitted BMI values together with the original BMI values are plotted against AGE to create the display shown in Figure 72.2.

The fitted quantile curves reveal important information. During the quick growth period (ages 2 to 20), the dispersion of BMI increases dramatically; it becomes stable during middle age, and then it

contracts after age 60. This pattern suggests that effective population weight control should start in childhood.

Compared to the 97th percentile in reference growth charts published by CDC in 2000 (Kuczmarski et al. 2002), the 97th percentile for 10-year-old boys in Figure 72.2 is 6.4 BMI units higher (an increase of 27%). This can be interpreted as a warning of overweight or obesity. See Chen (2005) for a detailed analysis.

Syntax: QUANTREG Procedure

PROC QUANTREG < *options* > ;
  BY *variables* ;
  CLASS *variables* ;
  EFFECT *name* = *effect-type* (*variables* < / *options* >) ;
  ID *variables* ;
  MODEL *response* = *independents* < / *options* > ;
  OUTPUT < *OUT= SAS-data-set* > < *options* > ;
  PERFORMANCE < *options* > ;
  TEST *effects* < / *options* > ;
  WEIGHT *variable* ;

The PROC QUANTREG statement invokes the procedure. The CLASS statement specifies which explanatory variables are treated as categorical. The ID statement names variables to identify observations in the outlier diagnostics tables. The MODEL statement is required and specifies the variables used in the regression. Main effects and interaction terms can be specified in the MODEL statement, as in the GLM procedure (Chapter 39, "The GLM Procedure.") The OUTPUT statement creates an output data set containing predicted values, residuals, and estimated standard errors. The PERFORMANCE statement tunes the performance of PROC QUANTREG by using single or multiple processors available in the hardware. The TEST statement requests linear tests for the model parameters. The WEIGHT statement identifies a variable in the input data set whose values are used to weight the observations. In one invocation of PROC QUANTREG, multiple OUTPUT and TEST statements are allowed.

PROC QUANTREG Statement

PROC QUANTREG < *options* > ;

The PROC QUANTREG statement invokes the procedure. You can specify the following options in the PROC QUANTREG statement.

ALGORITHM=*algorithm* **< (** *suboptions* **) >**
  specifies an algorthm to estimate the regression parameters. Three algorithms are available:

simplex (SIMPLEX), interior point (INTERIOR), and smoothing (SMOOTH). The default algorithm is simplex. The following table summarizes these methods.

Table 72.1 Options for Estimation Algorithms

ALGORITHM= Value	Algorithm	Suboptions
SIMPLEX	simplex	
INTERIOR	interior point	KAPPA= MAXIT= TOLERANCE=
SMOOTH	smoothing	RRATIO=

With ALGORITHM=INTERIOR you can specify the following *suboptions*:

- KAPPA=*value* specifies the step length parameter for the interior point algorithm. This parameter should be between 0 and 1. The larger the parameter, the faster the algorithm. However, numeric instability can occur as the parameter approaches 1. By default, KAPPA=0.99995. See the section "Interior Point Algorithm" on page 5386 for details.
- MAXIT=*n* sets the maximum number of iterations for the interior point algorithm. By default, *n*=1000.
- TOLERANCE=*value* specifies the tolerance for the convergence criterion of the interior point algorithm. The default *value* is 1E−8. The QUANTREG procedure uses the duality gap as the convergence criterion. See the section "Interior Point Algorithm" on page 5386 for details.

With the interior point algorithm, you can use the PERFORMANCE statement to enable parallel computing when multiple processors are available in the hardware.

With ALGORITHM=SMOOTH you can specify the following *suboption*:

- RRATIO=*value* specifies the reduction ratio for the smoothing algorithm. This ratio is used for reducing the threshold of the smoothing algorithm. The *value* should be between 0 and 1. In theory, the smaller the reduction ration, the faster the smoothing algorithm. However, the optimal ratio is quite data dependent in practice. See the section "Smoothing Algorithm" on page 5390 for details.

ALPHA=*value*

sets the confidence level for the confidence intervals for regression parameters. The *value* must be between 0 and 1. The default is ALPHA=0.05, corresponding to a 0.95 confidence interval.

CI=NONE | RANK | SPARSITY<(BF | HS)></IID> | RESAMPLING<(NREP=*n*)>

specifies a method to compute confidence intervals for regression parameters. When you specify CI=SPARSITY or CI=RESAMPLING, the QUANTREG procedure also computes standard errors, t values, and p-values for regression parameters.

The following table summarizes these methods.

Table 72.2 Options for Confidence Intervals

Value of CI=	Method	Additional Options
NONE	no confidence intervals computed	
RANK	by inverting rank-score tests	
SPARSITY	by estimating sparsity function	HS BF IID
RESAMPLING	by resampling	NREP

By default, the QUANTREG procedure computes confidence intervals by using the rank method for data sets with fewer than 5,000 observations and fewer than 20 variables; otherwise, the default is the resampling method.

By default, confidence intervals are not computed for the quantile process, which is estimated when you specify the QUANTILE=PROCESS option in the MODEL statement. Confidence intervals for the quantile process are computed with the sparsity or resampling methods when you specify CI=SPARSITY or CI=RESAMPLING, respectively. The rank method for confidence intervals is not available with quantile processes because it is computationally prohibitive.

With the SPARSITY option, there are two suboptions for estimating the sparsity function. If you specify the IID suboption, the sparsity function is estimated by assuming that the errors in the linear model are i.i.d. By default, the sparsity function is estimated by assuming that the conditional quantile function is locally linear. See the section "Sparsity" on page 5393 for details. With both methods two bandwidth selection methods are available. You can specify the Bofinger method with the BF suboption or the Hall-Sheather method with the HS suboption. By default, the Hall-Sheather method is used.

With the RESAMPLING option, you can specify the number of repeats with the NREP=*n* suboption. By default, NREP=200. The value of *n* must be greater than 50.

DATA=*SAS-data-set*

specifies the input SAS data set used by the QUANTREG procedure. By default, the most recently created SAS data set is used.

INEST=*SAS-data-set*

specifies an input SAS data set that contains initial estimates for all the parameters in the model. The interior point algorithm and the smoothing algorithm use these estimates as a start. See the section "INEST= Data Set" on page 5398 for a detailed description of the contents of the INEST= data set.

NAMELEN=*n*

specifies the length of effect names in tables and output data sets to be *n* characters, where *n* is a value between 20 and 200. The default length is 20 characters.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sorting order for the levels of the classification variables (specified in the CLASS statement). This order determines which parameters in the model correspond to each level in

the data. The following table illustrates how the QUANTREG procedure interprets values of the ORDER= option.

Table 72.3 Options for Order

Value of ORDER=	Levels Sorted By
DATA	order of appearance in the input data set
FORMATTED	formatted value
FREQ	descending frequency count; levels with the most observations come first in the order
INTERNAL	unformatted value

By default, ORDER=FORMATTED. For FORMATTED and INTERNAL, the sort order is machine dependent. For more information about sorting order, refer to the chapter titled "The SORT Procedure" in the *Base SAS Procedures Guide*.

OUTEST=*SAS-data-set*

specifies an output SAS data set containing the parameter estimates for all quantiles. See the section "OUTEST= Data Set" on page 5399 for a detailed description of the contents of the OUTEST= data set.

PLOT | PLOTS<(*global-plot-options***)> <=***plot-request***>**

PLOT | PLOTS<(*global-plot-options***)> <=(***plot-request* **< . . .** *plot-request* **>)>**

specifies options that control details of the plots. These plots fall into two categories, diagnostic plots and fit plots. If you do not specify the PLOTS= option, PROC QUANTREG produces the quantile fit plot by default when a single continuous variable is specified in the model. You can use the PLOTS= option in the PROC statement to request various diagnostic plots. In addition to these two categories of plots, you can use the PLOT= option in the MODEL statement to request the quantile process plot for any effects specified in the model.

To request any plots you must specify the ODS GRAPHICS statement. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

The *global-plot-options* apply to all plots generated by the QUANTREG procedure. The following global plot option is available:

ONLY

suppresses the default quantile fit plot. Only plots specifically requested are displayed.

You can specify more than one plot request within the parentheses after PLOTS=. For a single plot request, you can omit the parentheses. The following plot requests are available.

ALL

creates all appropriate plots.

DDPLOT<(LABEL=ALL | LEVERAGE | NONE | OUTLIER)>

creates a plot of robust distance against Mahalanobis distance. See the section "Leverage Point and Outlier Detection" on page 5397 for details about robust distance.

The LABEL= option specifies how the points on this plot are to be labeled, as summarized by the following table.

Table 72.4 Options for Label

Value of LABEL=	Label Method
ALL	label all points
LEVERAGE	label leverage points
NONE	no labels
OUTLIERS	label outliers

By default, the QUANTREG procedure labels both outliers and leverage points.

If you specify ID variables in the ID statement, the values of the first ID variable are used as labels; otherwise, observation numbers are used as labels.

FITPLOT<(NOLIMITS | NODATA)>
creates a plot of fitted conditional quantiles against the single continuous variable specified in the model. You can request this plot when only a single continuous variable is specified in the model in the form of one or more polynomials or spline effects. Multiple lines or curves are drawn on this plot if you specify several quantiles with the QUANTILE= option in the MODEL statement. For a single quantile, confidence limits are added to the plot by default. The NOLIMITS option suppresses these limits. The NODATA option suppresses the observed data, which are superimposed on the plot by default.

HISTOGRAM
creates a histogram for the standardized residuals based on the quantile regression estimates. The histogram is superimposed with a normal density curve and a kernel density curve.

NONE
suppresses all plots.

QQPLOT
creates the normal quantile-quantile plot for the standardized residuals based on the quantile regression estimates.

RDPLOT<(LABEL=ALL | LEVERAGE | NONE | OUTLIER)>
creates the plot of standardized residual against robust distance. See the section "Leverage Point and Outlier Detection" on page 5397 for details about robust distance. The LABEL= option specifies a label method for points on this plot. These label methods are described in Table 72.4.

By default, the QUANTREG procedure labels both outliers and leverage points.

If you specify ID variables in the ID statement, the values of the first ID variable are used as labels; otherwise, observation numbers are used as labels.

PP

requests preprocessing to speed up the interior point algorithm or the smoothing algorithm. The preprocessing uses a subsampling algorithm to reduce the original problem to a smaller one iteratively. It assumes that the data set is evenly distributed. Preprocessing should be used only for very large data sets, such as data sets with more than 100,000 observations. See Portnoy and Koenker (1997) for details.

BY Statement

BY *variables* **;**

You can specify a BY statement with the QUANTREG procedure to obtain separate analysis on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the QUANTREG procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variables* **;**

Variables that are classification variables rather than quantitative numeric variables must be listed in the CLASS statement. For each explanatory variable listed in the CLASS statement, indicator variables are generated for the levels assumed by the CLASS variable. The parameterization of the CLASS variable is the same as in the GLM procedure (Chapter 39, "The GLM Procedure.") If the CLASS statement is used, it must appear before the MODEL statement.

EFFECT Statement (Experimental)

EFFECT *name = spline(variables < / options >)* **;**

The experimental EFFECT statement names a constructed effect that you can use to specify terms in the MODEL statement. Each constructed effect corresponds to a collection of columns that are referred to using the name you supply. You can specify multiple EFFECT statements, and all EFFECT statements must precede the MODEL statement.

After the keyword EFFECT, the name of the effect is specified. This name must appear in only one EFFECT statement and must not be the name of a variable in the input data set. After an equal sign, the *effect-type* is specified followed by the list of variables used in defining the effect within parentheses. In SAS 9.2, the QUANTREG procedure supports only spline effects. You can also specify options pertaining to the effect definition after a slash following the variable list. The SPLIT option is always turned on for the QUANTREG procedure. For more details about the syntax with spline effects, see the section "Constructed Effects and the EFFECT Statement (Experimental)" on page 377 of Chapter 18, "Shared Concepts and Topics."

The QUANTREG procedure supports the regression spline effect. A spline effect expands variables into spline bases whose form depends on the options that you specify. Design matrix columns are generated separately for each of the numeric variables specified, and these columns are collectively referred to by the name that you specify. By default the spline basis generated for each variable is a cubic B-spline basis with three equally spaced knots positioned between the minimum and maximum values of that variable. You can find more details about regression splines and spline bases in the section "Constructed Effects and the EFFECT Statement (Experimental)" on page 377 of Chapter 18, "Shared Concepts and Topics."

ID Statement

ID *variables* **;**

When the diagnostics table is requested with the DIAGNOSTICS option in the MODEL statement, the variables listed in the ID statement are displayed in addition to the observation number. These values are useful for identifying observations. If the ID statement is omitted, only the observation number is displayed.

MODEL Statement

< label: > MODEL *response = < effects > < / options >* **;**

Main effects and interaction terms can be specified in the MODEL statement, as in the GLM procedure (Chapter 39, "The GLM Procedure.") Classification variables in the MODEL statement must be specified in the CLASS statement.

The optional *label*, which must be a valid SAS name, is used to label output from the matching MODEL statement.

Options

You can specify the following options for the model fit.

CORRB
produces the estimated correlation matrix of the parameter estimates. When the resampling method is used to compute the confidence intervals, the QUANTREG procedure computes the bootstrap correlation. When the sparsity method is used to compute the confidence intervals, the procedure computes the asymptotic correlation based on an estimator of the sparsity function. The rank method for confidence intervals does not provide a correlation estimate.

COVB
produces the estimated covariance matrix of the parameter estimates. When the resampling method is used to compute the confidence intervals, the QUANTREG procedure computes the bootstrap covariance. When the sparsity method is used to compute the confidence intervals, the procedure computes the asymptotic covariance based on an estimator of the sparsity function. The rank method for confidence intervals does not provide a covariance estimate.

CUTOFF=*value*
specifies the multiplier of the cutoff value for outlier detection. The default *value* is 3.

DIAGNOSTICS<(ALL)>
requests the outlier diagnostics. By default, only observations identified as outliers or leverage points are displayed. To request that all observations be displayed, specify the ALL option.

ITPRINT
displays the iteration history of the interior point algorithm or the smoothing algorithm.

LEVERAGE<(CUTOFF=*value* | **CUTOFFALPHA=***value* | **H=***n***)>**
requests an analysis of leverage points for the continuous covariates. The results are added to the diagnostics table, which you can request with the DIAGNOSTICS option in the MODEL statement. You can specify the cutoff value for leverage-point detection with the CUTOFF= option. The default cutoff value is $\sqrt{\chi^2_{p;1-\alpha}}$, where α can be specified with the CUTOFFALPHA= option. By default, $\alpha = 0.025$. You can use the H= option to specify the number of points to be minimized for the MCD algorithm used for the leverage-point analysis. By default, H=$[(3n + p + 1)/4]$, where n is the number of observations and p is the number of independent variables. The LEVERAGE option is ignored if the model includes classification variables as covariates.

NODIAG
suppresses the computation for outlier diagnostics. If you specify the NODIAG option, the diagnostics summary table will not be provided.

NOINT
specifies no intercept regression.

NOSUMMARY

suppresses the computation for summary statistics. If you specify the NOSUMMARY option, the summary statistics table will not be provided.

PLOT=*plot-option*

PLOTS=(*plot-options***)**

You can use the PLOTS= option in the MODEL statement together with the ODS GRAPHICS statement to request the quantile process plot in addition to all plots available with the PLOT= option in the PROC statement. The plot options in the PROC statement overwrite the plot options in the MODEL statement if you specify the same options in both statements.

You can specify the following plot option only in the MODEL statement:

QUANTPLOT<(EFFECTS) </ <NOLIMITS> <UNPACK> <OLS> > >

plots the regression quantile process. The estimated coefficient of each specified covariate effect is plotted as a function of the quantile. If you do not specify a covariate effect, quantile processes are plotted for all covariate effects in the MODEL statement. You can use the NOLIMITS option to suppress confidence bands for the quantile processes. By default, confidence bands are plotted, and process plots are displayed in panels, each of which can hold up to four plots. You can use the UNPACK option to create individual process plots. For an individual process plot, you can superimpose the ordinary least squares estimate and its confidence limits by specifying the OLS option. The confidence level of the ordinary least squares estimate is specified with the ALPHA= option in the PROC statement.

Again, to request these plots you must specify the ODS GRAPHICS statement. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

QUANTILE=*number-list* | **PROCESS**

specifies the quantiles for the quantile regression. You can specify any number of quantiles in $(0, 1)$. You can also compute the entire quantile process by specifying the PROCESS option. Only the simplex algorithm is available for computing the quantile process. Statistical inference is available only when a single quantile is specified.

If you do not specify the QUANTILE= option, the QUANTREG procedure fits a median regression, which corresponds to QUANTILE=0.5.

SCALE=*number*

specifies the scale value used to compute the standardized residuals. By default, the scale is computed as the corrected median of absolute residuals. See the section "Leverage Point and Outlier Detection" on page 5397 for details.

SEED=*number*

specifies the seed for the random number generator used to compute the MCMB confidence intervals. This seed is also used to randomly select the subgroups for preprocessing when you specify the PP option in the PROC statement. If you do not specify a seed, or if you specify a value less than or equal to zero, the seed is generated from reading the time of day from the computer clock.

By default or if you specify zero, the QUANTREG procedure generates a seed between one and one billion.

SINGULAR=*value*
sets the tolerance for testing singularity of the information matrix and the crossproducts matrix for the initial least squares estimates. Roughly, the test requires that a pivot be at least this value times the original diagonal value. By default, SINGULAR=1E−12.

OUTPUT Statement

OUTPUT < *OUT=SAS-data-set* > *keyword=name* < *. . . keyword=name* > < / *COLUMNWISE* > **;**

The OUTPUT statement creates a SAS data set containing statistics calculated after fitting models for all specified quantiles with the QUANTILE= option in the MODEL statement. At least one specification of the form *keyword=name* is required.

All variables in the original data set are included in the new data set, along with the variables created as options to the OUTPUT statement. These new variables contain fitted values and estimated quantiles. If you want to create a permanent SAS data set, you must specify a two-level name (refer to *SAS Language Reference: Concepts* for more information about permanent SAS data sets).

If you specify multiple quantiles in the MODEL statement, the COLUMNWISE option arranges the created OUTPUT data set in column-wise form. This arrangement repeats the input data for each quantile. By default, the OUTPUT data set is created in row-wise form. For each appropriate keyword specified in the OUTPUT statement, one variable for each specified quantile is generated. These variables appear in the sorted order of the specified quantiles.

The following specifications can appear in the OUTPUT statement:

OUT=*SAS-data-set* specifies the new data set. By default, the procedure uses the DATA*n* convention to name the new data set.

keyword=name specifies the statistics to include in the output data set and gives names to the new variables. Specify a keyword for each desired statistic (see the following list of keywords), an equal sign, and the variable to contain the statistic. The diagnostic statistics LEVERAGE, MAHADIST, OUTLIER, and ROBDIST can be requested when only a single quantile is specified in the MODEL statement.

The keywords allowed and the statistics they represent are as follows:

LEVERAGE specifies a variable to indicate leverage points. To include this variable in the OUTPUT data set, you must specify the LEVERAGE option in the MODEL statement. See the section "Leverage Point and Outlier Detection" on page 5397 for how to define LEVERAGE.

MAHADIST | MD specifies a variable to contain the Mahalanobis distance. To include this variable in the OUTPUT data set, you must specify the LEVERAGE option in the MODEL statement.

OUTLIER specifies a variable to indicate outliers. See the section "Leverage Point and Outlier Detection" on page 5397 for how to define OUTLIER.

PREDICTED | P specifies a variable to contain the estimated response.

QUANTILE | Q specifies a variable to contain the quantile for which the quantile regression is fitted. If you specify the COLUMNWISE option, this variable is created by default. If multiple quantiles are specified in the MODEL statement and the COLUMNWISE option is not specified, this variable is not created.

RESIDUAL | RES specifies a variable to contain the residuals (unstandardized)

$$y_i - \mathbf{x}_i^T \hat{\beta}$$

ROBDIST | RD specifies a variable to contain the robust MCD distance. To include this variable in the OUTPUT data set, you must specify the LEVERAGE option in the MODEL statement.

SPLINE | SP specifies a variable to contain the estimated spline effect, which includes all spline effects in the model and their interactions.

SRESIDUAL | SR specifies a variable to contain the standardized residuals

$$\frac{y_i - \mathbf{x}_i^T \hat{\beta}}{\hat{\sigma}}$$

See the section "Leverage Point and Outlier Detection" on page 5397 for how to compute σ.

STDP specifies a variable to contain the estimates of the standard errors of the estimated response.

PERFORMANCE Statement

The PERFORMANCE statement is used to change default options that affect the performance of PROC QUANTREG and to request tables that show the performance options in effect and timing details.

PERFORMANCE < *options* > **;**

The following options are available:

CPUCOUNT= *1-1024*

CPUCOUNT= *ACTUAL*

specifies the number of processors to use in the computation of the interior point algorithm. CPUCOUNT=ACTUAL sets CPUCOUNT to be the number of physical processors available. Note that this can be less than the physical number of CPUs if the SAS process has been restricted by system administration tools. Setting CPUCOUNT= to a number greater than the

actual number of available CPUs might result in reduced performance. This option overrides the SAS system option CPUCOUNT=. If CPUCOUNT=1, then NOTHREADS is in effect, and PROC QUANTREG uses singly threaded code.

DETAILS
requests the "PerfSettings" table that shows the performance settings in effect and the "Timing" table that provides a broad timing breakdown of the PROC QUANTREG step.

THREADS
enables multithreaded computation for the interior point algorithm. This option overrides the SAS system option THREADS | NOTHREADS. If you do not specify the ALGORITHM=INTERIOR option, then PROC QUANTREG ignores this option and uses singly threaded code.

NOTHREADS
disables multithreaded computation for the interior point algorithm. This option overrides the SAS system option THREADS | NOTHREADS.

TEST Statement

< label: > TEST *effects* < */WALD | LR* > **;**

The TEST statement provides a means of obtaining a test for the canonical linear hypothesis concerning the parameters of the tested effects:

$$\beta_j = 0, \quad j = i_1, \ldots, i_q$$

where q is the total number of parameters of the tested effects.

You can request Wald tests with the WALD option and likelihood ratio tests with the LR option. By default, only Wald tests are provided. See the section "Details: QUANTREG Procedure" on page 5384 for more information about these tests.

The optional *label*, which must be a valid SAS name, is used to label output from the corresponding TEST statement.

WEIGHT Statement

WEIGHT *variable* **;**

The WEIGHT statement specifies a weight variable in the input data set.

To request weighted quantile regression, place the weights in a variable and specify the name in the WEIGHT statement. The values of the WEIGHT variable can be nonintegral and are not truncated. Observations with nonpositive or missing values for the weight variable do not contribute to the fit of the model. See the section "Details: QUANTREG Procedure" on page 5384 for more information about weighted quantile regression.

Details: QUANTREG Procedure

Quantile Regression as an Optimization Problem

The model for linear quantile regression is

$$y = A'\beta + \epsilon$$

where $y = (y_1, \ldots, y_n)'$ is the $(n \times 1)$ vector of responses, $A' = (x_1, \ldots, x_n)'$ is the $(n \times p)$ regressor matrix, $\beta = (\beta_1, \ldots, \beta_p)'$ is the $(p \times 1)$ vector of unknown parameters, and $\epsilon = (\epsilon_1, \ldots, \epsilon_n)'$ is the $(n \times 1)$ vector of unknown errors.

L_1 regression, also known as median regression, is a natural extension of the sample median when the response is conditioned on the covariates. In L_1 regression, the least absolute residuals estimate $\hat{\beta}_{LAR}$, referred to as the L_1-*norm estimate*, is obtained as the solution of the minimization problem

$$\min_{\beta \in \mathbf{R}^p} \sum_{i=1}^{n} |y_i - x_i'\beta|$$

More generally, for quantile regression Koenker and Bassett (1978) defined the τth *regression quantile*, $0 < \tau < 1$, as any solution to the minimization problem

$$\min_{\beta \in \mathbf{R}^p} [\sum_{i \in \{i: y_i \geq x_i'\beta\}} \tau |y_i - x_i'\beta| + \sum_{i \in \{i: y_i < x_i'\beta\}} (1-\tau)|y_i - x_i'\beta|]$$

The solution is denoted as $\hat{\beta}(\tau)$, and the L_1-norm estimate corresponds to $\hat{\beta}(1/2)$. The τth regression quantile is an extension of the τth sample quantile $\hat{\xi}(\tau)$, which can be formulated as the solution of

$$\min_{\xi \in \mathbf{R}} \left[\sum_{i \in \{i: y_i \geq \xi\}} \tau |y_i - \xi| + \sum_{i \in \{i: y_i < \xi\}} (1-\tau)|y_i - \xi| \right]$$

If you specify weights $w_i, i = 1, \ldots, n$, with the WEIGHT statement, weighted quantile regression is carried out by solving

$$\min_{\beta_w \in \mathbf{R}^p} [\sum_{i \in \{i: y_i \geq x_i'\beta_w\}} w_i \tau |y_i - x_i'\beta_w| + \sum_{i \in \{i: y_i < x_i'\beta_w\}} w_i (1-\tau)|y_i - x_i'\beta_w|]$$

Weighted regression quantiles β_w can be used for L-estimation; refer to Koenker and Zhao (1994).

Optimization Algorithms

The optimization problem for median regression has been formulated and solved as a linear programming (LP) problem since the 1950s. Variations of the simplex algorithm, especially the method of Barrodale and Roberts (1973), have been widely used to solve this problem. The simplex algorithm is computationally demanding in large statistical applications, and in theory the number of iterations can increase exponentially with the sample size. This algorithm is often useful with data containing no more than tens of thousands of observations.

Several alternatives have been developed to handle L_1 regression for larger data sets. The interior point approach of Karmarkar (1984) solves a sequence of quadratic problems in which the relevant interior of the constraint set is approximated by an ellipsoid. The worst-case performance of the interior point algorithm has been proved to be better than that of the simplex algorithm. More important, experience has shown that the interior point algorithm is advantageous for larger problems.

Like L_1 regression, general quantile regression fits nicely into the standard primal-dual formulations of linear programming.

In addition to the interior point method, various heuristic approaches are available for computing L_1-type solutions. Among these, the finite smoothing algorithm of Madsen and Nielsen (1993) is the most useful. It approximates the L_1-type objective function with a smoothing function, so that the Newton-Raphson algorithm can be used iteratively to obtain a solution after a finite number of iterations. The smoothing algorithm extends naturally to general quantile regression.

The QUANTREG procedure implements the simplex, interior point, and smoothing algorithms. The remainder of this section describes these algorithms in more detail.

Simplex Algorithm

Let $\mu = [y - A'\beta]_+$, $\nu = [A'\beta - y]_+$, $\phi = [\beta]_+$, and $\varphi = [-\beta]_+$, where $[z]_+$ is the nonnegative part of z.

Let $D_{LAR}(\beta) = \sum_{i=1}^{n} |y_i - x_i'\beta|$. For the L_1 problem, the simplex approach solves $\min_\beta D_{LAR}(\beta)$ by reformulating it as the constrained minimization problem

$$\min_{\beta}\{e'\mu + e'\nu | y = A'\beta + \mu - \nu, \{\mu, \nu\} \in \mathbf{R}^n_+\}$$

where e denotes an $(n \times 1)$ vector of ones.

Let $B = [A' \; -A' \; I \; -I]$, $\theta = (\phi' \; \varphi' \; \mu' \; \nu')'$, and $d = (\mathbf{0}' \; \mathbf{0}' \; e' \; e')'$, where $\mathbf{0}' = (0\,0 \; \ldots \; 0)_p$. The reformulation presents a standard LP problem:

$$\begin{array}{ll} (P) & \min_{\theta} d'\theta \\ \text{subject to} & B\theta = y \\ & \theta \geq 0 \end{array}$$

This problem has the dual formulation

$$\begin{aligned} (D) \qquad & \max_z y'z \\ \text{subject to} \quad & B'z \leq d \end{aligned}$$

which can be simplified as

$$\max_z y'z; \;\; \text{subject to } Az = 0, z \in [-1, 1]^n$$

By setting $\eta = \frac{1}{2}z + \frac{1}{2}e, b = \frac{1}{2}Ae$, the problem becomes

$$\max_\eta y'\eta; \;\; \text{subject to } A\eta = b, \eta \in [0, 1]^n$$

For quantile regression, the minimization problem is $\min_\beta \sum \rho_\tau(y_i - x_i'\beta)$, and a similar set of steps leads to the dual formulation

$$\max_z y'z; \;\; \text{subject to } Az = (1-\tau)Ae, z \in [0, 1]^n$$

The QUANTREG procedure solves this LP problem by using the simplex algorithm of Barrodale and Roberts (1973). This algorithm solves the primary LP problem (P) by two stages, which exploit the special structure of the coefficient matrix B. The first stage picks the columns in A' or $-A'$ as pivotal columns. The second stage interchanges the columns in I or $-I$ as basis or nonbasis columns, respectively. The algorithm obtains an optimal solution by executing these two stages interactively. Moreover, because of the special structure of B, only the main data matrix A is stored in the current memory.

Although this special version of the simplex algorithm was introduced for median regression, it extends naturally to quantile regression for any given quantile and even to the entire quantile process (Koenker and d'Orey 1994). It greatly reduces the computing time required by the general simplex algorithm, and it is suitable for data sets with fewer than 5,000 observations and 50 variables.

Interior Point Algorithm

There are many variations of interior point algorithms. The QUANTREG procedure uses the primal-dual predictor-corrector algorithm implemented by Lustig, Marsden, and Shanno (1992). The text by Roos, Terlaky, and Vial (1997) provides more information about this particular algorithm. The following brief introduction of this algorithm uses the notation in the first reference.

To be consistent with the conventional LP setting, let $c = -y$, $b = (1-\tau)Ae$, and let u be the general upper bound. The linear program to be solved is

$$\begin{aligned} & min\{c'z\} \\ \text{subject to} \quad & Az = b \\ & 0 \leq z \leq u \end{aligned}$$

To simplify the computation, this is treated as the *primal* problem. The problem has n variables. The index i denotes a variable number, and k denotes an iteration number. If k is used as a subscript or superscript, it denotes "of iteration k."

Let v be the primal slack so that $z + v = u$. Associate dual variables w with these constraints. The interior point algorithm solves the system of equations to satisfy the Karush-Kuhn-Tucker (KKT) conditions for optimality:

$$Az = b$$
$$z + v = u$$
$$A't + s - w = c$$
$$ZSe = 0$$
$$VWe = 0$$
$$z, s, v, w \geq 0$$

where $W = diag(w)$ (that is, $W_{i,j} = w_i$ if $i = j$, $W_{i,j} = 0$ otherwise)

$V = diag(v), Z = diag(z), S = diag(s)$

These are the conditions for feasibility, with the addition of *complementarity* conditions $ZSe = 0$ and $VWe = 0$. $c'z = b't - u'w$ must occur at the optimum. Complementarity forces the optimal objectives of the primal and dual to be equal, $c'z_{opt} = b't_{opt} - u'w_{opt}$, as

$$0 = v'_{opt}w_{opt} = (u - z_{opt})'w_{opt} = u'w_{opt} - z'_{opt}w_{opt}$$

$$0 = z'_{opt}s_{opt} = s'_{opt}z_{opt} = (c - A't_{opt} + w_{opt})'z_{opt} =$$
$$c'z_{opt} - t'_{opt}(Az_{opt}) + w'_{opt}z_{opt} = c'z_{opt} - b't_{opt} + u'w_{opt}$$

Therefore

$$0 = c'z_{opt} - b't_{opt} + u'w_{opt}$$

The *duality gap*, $c'z - b't + u'w$, is used to measure the convergence of the algorithm. You can specify a tolerance for this convergence criterion with the TOLERANCE= option in the PROC statement.

Before the optimum is reached, it is possible for a solution (z, t, s, v, w) to violate the KKT conditions in one of several ways:

- Primal bound constraints can be broken, $\delta_b = u - z - v \neq 0$.
- Primal constraints can be broken, $\delta_c = b - Az \neq 0$.
- Dual constraints can be broken, $\delta_d = c - A't - s + w \neq 0$.
- Complementarity conditions are unsatisfied, $z's \neq 0$ and $v'w \neq 0$.

The interior point algorithm works by using Newton's method to find a direction $(\Delta z^k, \Delta t^k, \Delta s^k, \Delta v^k, \Delta w^k)$ to move from the current solution $(z^k, t^k, s^k, v^k, w^k)$ toward a better solution:

$$(z^{k+1}, t^{k+1}, s^{k+1}, v^{k+1}, w^{k+1}) = (z^k, t^k, s^k, v^k, w^k) + \kappa(\Delta z^k, \Delta t^k, \Delta s^k, \Delta v^k, \Delta w^k)$$

κ is the *step length* and is assigned a value as large as possible, but not so large that a z_i^{k+1} or s_i^{k+1} is "too close" to zero. You can control the step length with the KAPPA= option in the PROC statement.

The QUANTREG procedure implements a predictor-corrector variant of the primal-dual interior point algorithm. First, Newton's method is used to find a direction $(\Delta z_{aff}^k, \Delta t_{aff}^k, \Delta s_{aff}^k, \Delta v_{aff}^k, \Delta w_{aff}^k)$ in which to move. This is known as the *affine* step.

In iteration k, the *affine* step system that must be solved is

$$
\begin{aligned}
&\Delta z_{aff} + \Delta v_{aff} = \delta_b \\
&A\Delta z_{aff} = \delta_c \\
&A'\Delta t_{aff} + \Delta s_{aff} - \Delta w_{aff} = \delta_d \\
&S\Delta z_{aff} + Z\Delta s_{aff} = -ZSe \\
&V\Delta w_{aff} + W\Delta z_{aff} = -VWe
\end{aligned}
$$

Therefore, the computations involved in solving the affine step are

$$
\begin{aligned}
&\Theta = SZ^{-1} + WV^{-1} \\
&\rho = \Theta^{-1}(\delta_d + (S - W)e - V^{-1}W\delta_b) \\
&\Delta t_{aff} = (A\Theta^{-1}A')^{-1}(\delta_c + A\rho) \\
&\Delta z_{aff} = \Theta^{-1}A'\Delta t_{aff} - \rho \\
&\Delta v_{aff} = \delta_b - \Delta z_{aff} \\
&\Delta w_{aff} = -We - V^{-1}W\Delta z_{aff} \\
&\Delta s_{aff} = -Se - Z^{-1}S\Delta z_{aff}
\end{aligned}
$$

$$
\begin{aligned}
&(z_{aff}, t_{aff}, s_{aff}, v_{aff}, w_{aff}) = (z, t, s, v, w) + \\
&\kappa(\Delta z_{aff}, \Delta t_{aff}, \Delta s_{aff}, \Delta v_{aff}, \Delta w_{aff})
\end{aligned}
$$

κ is the *step length* as before.

The success of the affine step is gauged by calculating the complementarity of $z's$ and $v'w$ at $(z_{aff}^k, t_{aff}^k, s_{aff}^k, v_{aff}^k, w_{aff}^k)$ and comparing it with the complementarity at the starting point $(z^k, t^k, s^k, v^k, w^k)$. If the affine step was successful in reducing the complementarity by a substantial amount, the need for centering is not great, and a value close to zero is assigned to σ in a second linear system (see following), which is used to determine a centering vector. If, however, the affine step was unsuccessful, then centering is deemed beneficial, and a value close to 1.0 is assigned to σ. In other words, the value of σ is adaptively altered depending on progress made toward the optimum.

The following linear system is solved to determine a centering vector $(\Delta z_c, \Delta t_c, \Delta s_c, \Delta v_c, \Delta w_c)$ from $(z_{aff}, t_{aff}, s_{aff}, v_{aff}, w_{aff})$:

$$
\begin{aligned}
&\Delta z_c + \Delta v_c = 0 \\
&A\Delta z_c = 0
\end{aligned}
$$

$$A'\Delta t_c + \Delta s_c - \Delta w_c = 0$$
$$S\Delta z_c + Z\Delta s_c = -Z_{aff}S_{aff}e + \sigma\mu e$$
$$V\Delta w_c + W\Delta v_c = -V_{aff}W_{aff}e + \sigma\mu e$$

where

$\zeta_{start} = z's + v'w$, complementarity at the start of the iteration
$\zeta_{aff} = z'_{aff}s_{aff} + v'_{aff}w_{aff}$, the affine complementarity
$\mu = \zeta_{aff}/2n$, the average complementarity
$\sigma = (\zeta_{aff}/\zeta_{start})^3$

Therefore, the computations involved in solving the centering step are

$$\rho = \Theta^{-1}(\sigma\mu(Z^{-1} - V^{-1})e - Z^{-1}Z_{aff}S_{aff}e + V^{-1}V_{aff}W_{aff}e)$$
$$\Delta t_c = (A\Theta^{-1}A')^{-1}A\rho$$
$$\Delta z_c = \Theta^{-1}A'\Delta t_c - \rho$$
$$\Delta v_c = -\Delta z_c$$
$$\Delta w_c = \sigma\mu V^{-1}e - V^{-1}V_{aff}W_{aff}e - V^{-1}W_{aff}\Delta v_c$$
$$\Delta s_c = \sigma\mu Z^{-1}e - Z^{-1}Z_{aff}S_{aff}e - Z^{-1}S_{aff}\Delta z_c$$

Then

$$(\Delta z, \Delta t, \Delta s, \Delta v, \Delta w) =$$
$$(\Delta z_{aff}, \Delta t_{aff}, \Delta s_{aff}, \Delta v_{aff}, \Delta w_{aff}) +$$
$$(\Delta z_c, \Delta t_c, \Delta s_c, \Delta v_c, \Delta w_c)$$

$$(z^{k+1}, t^{k+1}, s^{k+1}, v^{k+1}, w^{k+1}) =$$
$$(z^k, t^k, s^k, v^k, w^k) +$$
$$\kappa(\Delta z, \Delta t, \Delta s, \Delta v, \Delta w)$$

where, as before, κ is the *step length* assigned a value as large as possible, but not so large that a z_i^{k+1}, s_i^{k+1}, v_i^{k+1}, or w_i^{k+1} is "too close" to zero.

Although the predictor-corrector variant entails solving two linear systems instead of one, fewer iterations are usually required to reach the optimum. The additional overhead of the second linear system is small because the matrix $(A\Theta^{-1}A')$ has already been factorized in order to solve the first linear system.

You can specify the starting point with the INEST= option in the PROC statement. By default, the starting point is set to be the least squares estimate.

Smoothing Algorithm

To minimize the sum of the absolute residuals $D_{LAR}(\beta)$, the smoothing algorithm approximates the nondifferentiable function D_{LAR} by the following smooth function, which is referred to as the Huber function:

$$D_\gamma(\beta) = \sum_{i=1}^{n} H_\gamma(r_i(\beta))$$

where

$$H_\gamma(t) = \begin{cases} t^2/(2\gamma) & \text{if } |t| \le \gamma \\ |t| - \gamma/2 & \text{if } |t| > \gamma \end{cases}$$

Here $r_i(\beta) = y_i - x_i'\beta$, and the *threshold* γ is a positive real number. The function D_γ is continuously differentiable and a minimizer β_γ of D_γ is close to a minimizer $\hat{\beta}_{LAR}$ of $D_{LAR}(\beta)$ when γ is close to zero.

The advantage of the smoothing algorithm as described in Madsen and Nielsen (1993) is that the L_1 solution $\hat{\beta}_{LAR}$ can be detected when $\gamma > 0$ is small. In other words, it is not necessary to let γ converge to zero in order to find a minimizer of $D_{LAR}(\beta)$. The algorithm terminates before going through the entire sequence of values of γ that are generated by the algorithm. Convergence is indicated by no change of the status of residuals $r_i(\beta)$ as γ goes through this sequence.

The smoothing algorithm extends naturally from L_1 regression to general quantile regression; refer to Chen (2007). The function

$$D_{\rho_\tau}(\beta) = \sum_{i=1}^{n} \rho_\tau(y_i - x_i'\beta)$$

can be approximated by the smooth function

$$D_{\gamma,\tau}(\beta) = \sum_{i=1}^{n} H_{\gamma,\tau}(r_i(\beta))$$

where

$$H_{\gamma,\tau}(t) = \begin{cases} t(\tau-1) - \frac{1}{2}(\tau-1)^2\gamma & \text{if } t \le (\tau-1)\gamma \\ \frac{t^2}{2\gamma} & \text{if } (\tau-1)\gamma \le t \le \tau\gamma \\ t\tau - \frac{1}{2}\tau^2\gamma & \text{if } t \ge \tau\gamma \end{cases}$$

The function $H_{\gamma,\tau}$ is determined by whether $r_i(\beta) \le (\tau-1)\gamma$, $r_i(\beta) \ge \tau\gamma$, or $(\tau-1)\gamma \le r_i(\beta) \le \tau\gamma$. These inequalities divide $\mathbf{R}^p$ into subregions separated by the parallel hyperplanes $r_i(\beta) = (\tau-1)\gamma$ and $r_i(\beta) = \tau\gamma$. The set of all such hyperplanes is denoted by $B_{\gamma,\tau}$:

$$B_{\gamma,\tau} = \{\beta \in \mathbf{R}^p | \exists i : r_i(\beta) = (\tau-1)\gamma \text{ or } r_i(\beta) = \tau\gamma\}$$

Define the sign vector $s_\gamma(\beta) = (s_1(\beta), \ldots, s_n(\beta))'$ as

$$s_i = s_i(\beta) = \begin{cases} -1 & \text{if } r_i(\beta) \le (\tau-1)\gamma \\ 0 & \text{if } (\tau-1)\gamma \le r_i(\beta) \le \tau\gamma \\ 1 & \text{if } r_i(\beta) \ge \tau\gamma \end{cases}$$

and introduce

$$w_i = w_i(\beta) = 1 - s_i^2(\beta)$$

Therefore,

$$H_{\gamma,\tau}(r_i(\beta)) = \frac{1}{2\gamma} w_i r_i^2(\beta)$$
$$+ s_i[\frac{1}{2} r_i(\beta) + \frac{1}{4}(1-2\tau)\gamma + s_i(r_i(\beta)(\tau - \frac{1}{2}) - \frac{1}{4}(1 - 2\tau + 2\tau^2)\gamma)]$$

yielding

$$D_{\gamma,\tau}(\beta) = \frac{1}{2\gamma} r' W_{\gamma,\tau} r + v'(s) r + c(s)$$

where $W_{\gamma,\tau}$ is the diagonal $n \times n$ matrix with diagonal elements $w_i(\beta)$, $v'(s) = (s_1((2\tau-1)s_1+1)/2, \ldots, s_n((2\tau - 1)s_n + 1)/2)$, $c(s) = \sum[\frac{1}{4}(1 - 2\tau)\gamma s_i - \frac{1}{4} s_i^2(1 - 2\tau + 2\tau^2)\gamma]$, and $r(\beta) = (r_1(\beta), \ldots, r_n(\beta))'$.

The gradient of $D_{\gamma,\tau}$ is given by

$$D^{(1)}_{\gamma,\tau}(\beta) = -A[\frac{1}{\gamma} W_{\gamma,\tau}(\beta) r(\beta) + v(s)]$$

and for $\beta \in \mathbf{R}^p \backslash B_{\gamma,\tau}$ the Hessian exists and is given by

$$D^{(2)}_{\gamma,\tau}(\beta) = \frac{1}{\gamma} A W_{\gamma,\tau}(\beta) A'$$

The gradient is a continuous function in $\mathbf{R}^p$, whereas the Hessian is piecewise constant.

Following Madsen and Nielsen (1993), the vector s is referred to as a *γ-feasible sign vector* if there exists $\beta \in \mathbf{R}^p \backslash B_{\gamma,\tau}$ with $s_\gamma(\beta) = s$. If s is *γ-feasible*, then Q_s is defined as the quadratic function $Q_s(\alpha)$ that is derived from $D_{\gamma,\tau}(\beta)$ by substituting s for s_γ. Thus, for any β with $s_\gamma = s$,

$$Q_s(\alpha) = \frac{1}{2}(\alpha - \beta)' D^{(2)}_{\gamma,\tau}(\beta)(\alpha - \beta) + D^{(1)}_{\gamma,\tau}(\beta)(\alpha - \beta) + D_{\gamma,\tau}(\beta)$$

In the domain $C_s = \{\alpha | s_\gamma(\alpha) = s\}$

$$D_{\gamma,\tau}(\alpha) = Q_s(\alpha)$$

For each $\gamma > 0$ and $\theta \in \mathbf{R}^p$, there can be one or several corresponding quadratics Q_s. If $\theta \notin B_{\gamma,\tau}$ then Q_s is characterized by θ and γ, but for $\theta \in B_{\gamma,\tau}$ the quadratic is not unique. Therefore, a *reference*

$$(\gamma, \theta, s)$$

determines the quadratic.

Again following Madsen and Nielsen (1993), let

(γ, θ, s) be a *feasible reference* if s is a γ-*feasible sign vector* with $\theta \in C_s$, and

(γ, θ, s) be a *solution reference* if it is feasible and θ minimizes $D_{\gamma,\tau}$.

The smoothing algorithm for minimizing D_{ρ_τ} is based on minimizing $D_{\gamma,\tau}$ for a set of decreasing γ. For each new value of γ, information from the previous solution is used. Finally, when γ is small enough, a solution can be found by the modified Newton-Raphson algorithm as stated by Madsen and Nielsen (1993):

find an initial solution reference $(\gamma, \beta_\gamma, s)$

repeat

decrease γ

find a solution reference $(\gamma, \beta_\gamma, s)$

until $\gamma = 0$

β_0 is the solution.

By default, the initial solution reference is found by letting β_γ be the least squares solution. Alternatively, you can specify the initial solution reference with the INEST= option in the PROC statement. Then γ and s are chosen according to these initial values.

There are several approaches for determining a decreasing sequence of values of γ. The QUANTREG procedure uses a strategy by Madsen and Nielsen (1993). The computation involved is not significant comparing with the Newton-Raphson step. You can control the ratio of consecutive decreasing values of γ with the RRATIO= suboption of the ALGORITHM= option in the PROC statement. By default,

$$\text{RRATIO} = \begin{cases} 0.1 & \text{if } n \geq 10000 \text{ and } p \leq 20 \\ 0.9 & \text{if } \frac{p}{n} \geq 0.1 \text{ or } \{n \leq 5000 \text{ and } p \geq 300\} \\ 0.5 & \text{otherwise} \end{cases}$$

For the L_1 and quantile regression, it turns out that the smoothing algorithm is very efficient and competitive, especially for a *fat* data set—namely, when $\frac{p}{n} > 0.05$ and AA' is dense. Refer to Chen (2007) for a complete smoothing algorithm and details.

Confidence Interval

The QUANTREG procedure provides three methods to compute confidence intervals for the regression quantile parameter $\beta(\tau)$: sparsity, rank, and resampling. The sparsity method is the most direct and the fastest, but it involves estimation of the sparsity function, which is not robust for data that are not independently and identically distributed. To deal with this problem, the QUANTREG procedure computes a Huber sandwich estimate by using a local estimate of the sparsity function. The rank method, which computes confidence intervals by inverting the rank score test, does not suffer

from this problem, but it uses the simplex algorithm and is computationally expensive with large data sets. The resampling method, which uses the bootstrap, can overcome all of these problems, but it is unstable for small data sets.

Based on these properties, the QUANTREG uses a combination of the resampling and rank methods as the default. For data sets with more than either 5,000 observations or 20 variables, the QUANTREG procedure uses the MCMB resampling method; otherwise it uses the rank method. You can request a particular method by using the CI= option in the PROC statement.

Sparsity

Consider the linear model

$$y_i = x_i'\beta + \epsilon_i$$

and assume that $\{\epsilon_i\}$, $i = 1, \ldots, n$, are i.i.d. with a distribution F and a density $f = F'$, where $f(F^{-1}(\tau)) > 0$ in a neighborhood of τ. Under some mild conditions

$$\sqrt{n}(\hat{\beta}(\tau) - \beta(\tau)) \rightarrow N(0, \omega^2(\tau, F)\Omega^{-1})$$

where $\omega^2(\tau, F) = \tau(1-\tau)/f^2(F^{-1}(\tau))$ and $\Omega = \lim_{n\rightarrow\infty} n^{-1}\sum x_i x_i'$. Refer to Koenker and Bassett (1982).

This asymptotic distribution for the regression quantile $\hat{\beta}(\tau)$ can be used to construct confidence intervals. However, the reciprocal of the density function

$$s(\tau) = [f(F^{-1}(\tau))]^{-1}$$

which is called the *sparsity function*, must first be estimated.

Since

$$s(t) = \frac{d}{dt}F^{-1}(t)$$

$s(t)$ can be estimated by the difference quotient of the empirical quantile function—that is,

$$\hat{s}_n(t) = [\hat{F}_n^{-1}(t + h_n) - \hat{F}_n^{-1}(t - h_n)]/2h_n$$

where $\hat{F}_n$ is an estimate of F^{-1} and h_n is a bandwidth that tends to zero as $n \rightarrow \infty$.

The QUANTREG procedure provides two bandwidth methods. The Bofinger bandwidth

$$h_n = n^{-1/5}\left(\frac{4.5s^2(t)}{(s^{(2)}(t))^2}\right)^{1/5}$$

is an optimizer of mean squared error for standard density estimation, and the Hall-Sheather bandwidth

$$h_n = n^{-1/3}z_\alpha^{2/3}\left(\frac{1.5s(t)}{s^{(2)}(t)}\right)^{1/3}$$

is based on Edgeworth expansions for studentized quantiles, where $s^{(2)}(t)$ is the second derivative of $s(t)$ and z_α satisfies $\Phi(z_\alpha) = 1 - \alpha/2$ for the construction of $1 - \alpha$ confidence intervals. The quantity

$$\frac{s(t)}{s^{(2)}(t)} = \frac{f^2}{2(f^{(1)}/f)^2 + [(f^{(1)}/f)^2 - f^{(2)}/f]}$$

is not sensitive to f and can be estimated by assuming f is Gaussian.

$\hat{F}^{-1}$ can be estimated by the empirical quantile function of the residuals from the quantile regression fit,

$$\hat{F}^{-1}(t) = r_{(i)}, \quad \text{for } t \in [(i-1)/n, i/n),$$

or the empirical quantile function of regression proposed by Bassett and Koenker (1982),

$$\hat{F}^{-1}(t) = \overline{x}'\hat{\beta}(t)$$

The QUANTREG procedure interpolates the first empirical quantile function and gets the piecewise linear version

$$\hat{F}^{-1}(t) = \begin{cases} r_{(1)} & \text{if } t \in [0, 1/2n) \\ \lambda r_{(i+1)} + (1-\lambda) r_{(i)} & \text{if } t \in [(2j-1)/2n, (2i+1)/2n) \\ r_{(n)} & \text{if } t \in [(2n-1), 1] \end{cases}$$

$\hat{F}^{-1}$ is set to a constant if $t \pm h_n$ falls outside $[0, 1]$.

This estimator of the sparsity function is sensitive to the i.i.d. assumption. Alternately, Koenker and Machado (1999) considered the non-i.i.d. case. By assuming local linearity of the conditional quantile function $Q(\tau|x)$ in x, they proposed a local estimator of the density function by using the difference quotient. A Huber sandwich estimate of the covariance and standard error is computed and used to construct the confidence intervals. One difficulty with this method is the selection of the bandwidth when using the difference quotient. With a small sample size, either the Bofinger or the Hall-Sheather bandwidth tends to be too large to assure local linearity of the conditional quantile function. The QUANTREG procedure uses a heuristic bandwidth selection in these cases.

By default, the QUANTREG procedure computes non-i.i.d. confidence intervals. You can request i.i.d. confidence intervals with the IID option in the PROC statement.

Inversion of Rank Tests

The classical theory of rank tests can be extended to test the hypothesis H_0: $\beta_2 = \eta$ in the linear regression model $y = X_1\beta_1 + X_2\beta_2 + \epsilon$. Here $(X_1, X_2) = A'$. See Gutenbrunner and Jureckova (1992) for more details. By inverting this test, confidence intervals can be computed for the regression quantiles corresponding to β_2.

The rank score function $\hat{a}_n(t) = (\hat{a}_{n1}(t), \ldots, \hat{a}_{nn}(t))$ can be obtained by solving the dual problem

$$\max_a \{(y - X_2\eta)'a | X_1'a = (1-t)X_1'e,\ a \in [0,1]^n\}$$

For a fixed quantile τ, integrating $\hat{a}_{ni}(t)$ with respect to the τ-quantile score function

$$\varphi_\tau(t) = \tau - I(t < \tau)$$

yields the τ-quantile scores

$$\hat{b}_{ni} = -\int_0^1 \varphi_\tau(t) d\hat{a}_{ni}(t) = \hat{a}_{ni}(\tau) - (1-\tau)$$

Under the null hypothesis H_0: $\beta_2 = \eta$

$$S_n(\eta) = n^{-1/2} X_2' \hat{b}_n(\eta) \to N(0, \tau(1-\tau)\Omega_n)$$

for large n, where $\Omega_n = n^{-1} X_2'(I - X_1(X_1'X_1)^{-1}X_1')X_2$.

Let

$$T_n(\eta) = \frac{1}{\sqrt{\tau(1-\tau)}} S_n(\eta)\Omega_n^{-1/2}$$

then $T_n(\hat{\beta}_2(\tau)) = 0$ from the constraint $A\hat{a} = (1-\tau)Ae$ in the full model. In order to obtain confidence intervals for β_2, a critical value can be specified for T_n. The dual vector $\hat{a}_n(\eta)$ is a piecewise constant in η, and η can be altered without compromising the optimality of $\hat{a}_n(\eta)$ as long as the sign of the residuals in the primal quantile regression problem do not change. When η gets to such a boundary the solution does change, but can be restored by taking one simplex pivot. The process can continue in this way until $T_n(\eta)$ exceeds the specified critical value. Since $T_n(\eta)$ is piecewise constant, interpolation can be used to obtain the desired level of confidence interval; see Koenker and d'Orey (1994).

Resampling

The bootstrap can be implemented to compute confidence intervals for regression quantile estimates. As in other regression applications, both the residual bootstrap and the xy-pair bootstrap can be used. The former assumes i.i.d. random errors and resamples from the residuals, while the later resamples xy pairs and accommodates some forms of heteroscedasticity. Koenker (1994) considered a more interesting resampling mechanism, resampling directly from the full regression quantile process, which he called the Heqf bootstrap.

In contrast with these bootstrap methods, Parzen, Wei, and Ying (1994) observed that

$$S(\beta) = n^{-1/2} \sum_{i=1}^{n} x_i(\tau - I(y_i \le x_i'\beta))$$

which is the estimating equation for the τth regression quantile, is a pivotal quantity for the τth quantile regression parameter β_τ. In other words, the distribution of $S(\beta)$ can be generated exactly by a random vector U, which is a weighted sum of independent, re-centered Bernoulli variables. They further showed that for large n, the distribution of $\hat{\beta}(\tau) - \beta_\tau$ can be approximated by the conditional distribution of $\hat{\beta}_U - \hat{\beta}_n(\tau)$, where $\hat{\beta}_U$ solves an augmented quantile regression problem with $n+1$ observations with $x_{n+1} = -n^{-1/2}u/\tau$ and y_{n+1} sufficiently large for a given realization

of u. By exploiting the asymptotically pivot role of the quantile regression "gradient condition," this approach also achieves some robustness to certain heteroscedasticity.

Although the bootstrap method by Parzen, Wei, and Ying (1994) is much simpler, it is too time-consuming for relatively large data sets, especially for high-dimensional data sets. The QUANTREG procedure implements a new, general resampling method developed by He and Hu (2002), which is referred to as the Markov chain marginal bootstrap (MCMB). For quantile regression, the MCMB method has the advantage that it solves p one-dimensional equations instead of p-dimensional equations, as do the previous bootstrap methods. This greatly improves the feasibility of the resampling method in computing confidence intervals for regression quantiles. Since resampling methods achieve stability only for relatively large data sets, they are not recommended for small data sets ($n < 5000$ and $p < 20$).

Covariance-Correlation

You can specify the COVB and CORRB options in the MODEL statement to request covariance and correlation matrices for the estimated parameters. The QUANTREG procedure computes these matrices only for a single quantile at a time.

The QUANTREG procedure provides two methods for computing the covariance and correlation matrices of the estimated parameters: an asymptotic method and a bootstrap method. Bootstrap covariance and correlation matrices are computed when resampling confidence intervals are computed. Asymptotic covariance and correlation matrices are computed when asymptotic confidence intervals are computed. The rank method for confidence intervals does not provide a covariance-correlation estimate.

Asymptotic Covariance-Correlation

This method corresponds to the sparsity method for the confidence intervals. For the sparsity function in the computation of the asymptotic covariance and correlation, the QUANTREG procedure provides both i.i.d. and non-i.i.d. estimates. By default, the QUANTREG procedure computes non-i.i.d. estimates.

Bootstrap Covariance-Correlation

This method corresponds to the resampling method for the confidence intervals. The Markov chain marginal bootstrap (MCMB) method is used.

Linear Test

Two tests are available in the QUANTREG procedure for the linear null hypothesis $H_0 : \beta_2 = 0$. Here β_2 denotes a subset of the parameters, where the parameter vector $\beta(\tau)$ is partitioned as

$\beta'(\tau) = (\beta_1'(\tau), \beta_2'(\tau))$, and the covariance matrix Ω for the parameter estimates is partitioned correspondingly as Ω_{ij} with $i = 1, 2$; $j = 1, 2$; and $\Omega^{22} = (\Omega_{22} - \Omega_{21}\Omega_{11}^{-1}\Omega_{12})^{-1}$.

The Wald test statistic, which is based on the estimated coefficients for the unrestricted model, is given by

$$T_W(\tau) = \hat{\beta}_2'(\tau)\hat{\Sigma}(\tau)^{-1}\hat{\beta}_2(\tau)$$

where $\hat{\Sigma}(\tau)$ is an estimator of the covariance of $\hat{\beta}_2(\tau)$. The QUANTREG procedure provides two estimators for the covariance, as described in the previous section. The estimator based on the asymptotic covariance is

$$\hat{\Sigma}(\tau) = \frac{1}{n}\hat{\omega}(\tau)^2\Omega^{22}$$

where $\hat{\omega}(\tau) = \sqrt{\tau(1-\tau)}\hat{s}(\tau)$ and $\hat{s}(\tau)$ is the estimated sparsity function. The estimator based on the bootstrap covariance is the empirical covariance of the MCMB samples.

The likelihood ratio test is based on the difference between the objective function values in the restricted and unrestricted models. Let $D_0(\tau) = \sum \rho_\tau(y_i - x_i\hat{\beta}(\tau))$ and $D_1(\tau) = \sum \rho_\tau(y_i - x_{1i}\hat{\beta}_1(\tau))$, and set

$$T_{LR}(\tau) = 2(\tau(1-\tau)\hat{s}(\tau))^{-1}(D_1(\tau) - D_0(\tau))$$

where $\hat{s}(\tau)$ is the estimated sparsity function.

Koenker and Machado (1999) prove that these two tests are asymptotically equivalent and that the distributions of the test statistics converge to χ_q^2 under the null hypothesis, where q is the dimension of β_2.

Leverage Point and Outlier Detection

The QUANTREG procedure uses robust multivariate location and scale estimates for leverage-point detection.

Mahalanobis distance is defined as

$$MD(x_i) = [(x_i - \bar{x})'\bar{C}(A)^{-1}(x_i - \bar{x})]^{1/2}$$

where $\bar{x} = \frac{1}{n}\sum_{i=1}^n x_i$ and $\bar{C}(A) = \frac{1}{n-1}\sum_{i=1}^n (x_i - \bar{x})'(x_i - \bar{x})$ are the empirical multivariate location and scale. Here, $x_i = (x_{i1}, \ldots, x_{i(p-1)})'$ does not include the intercept variable. The relationship between the Mahalanobis distance $MD(x_i)$ and the matrix $H = (h_{ij}) = A'(AA')^{-1}A$ is

$$h_{ii} = \frac{1}{n-1}MD_i^2 + \frac{1}{n}$$

Robust distance is defined as

$$RD(x_i) = [(x_i - T(A))' C(A)^{-1} (x_i - T(A))]^{1/2}$$

where $T(A)$ and $C(A)$ are robust multivariate location and scale estimates computed with the minimum covariance determinant (MCD) method of Rousseeuw and Van Driessen (1999).

These distances are used to detect leverage points. You can use the DIAGNOSTICS and LEVERAGE options in the MODEL statement to request leverage-point and outlier diagnostics. Two new variables, LEVERAGE and OUTLIER, are created and saved in an output data set specified in the OUTPUT statement.

Let $C(p) = \sqrt{\chi^2_{p;1-\alpha}}$ be the cutoff value. The variable LEVERAGE is defined as

$$\text{LEVERAGE} = \begin{cases} 0 & \text{if } RD(x_i) \le C(p) \\ 1 & \text{otherwise} \end{cases}$$

You can specify a cutoff value with the LEVERAGE option in the MODEL statement.

Residuals $r_i, i = 1, \ldots, n$, based on quantile regression estimates are used to detect vertical outliers. The variable OUTLIER is defined as

$$\text{OUTLIER} = \begin{cases} 0 & \text{if } |r_i| \le k\sigma \\ 1 & \text{otherwise} \end{cases}$$

You can specify the multiplier k of the cutoff value with the CUTOFF= option in the MODEL statement. You can specify the scale σ with the SCALE= option in the MODEL statement. By default, $k = 3$ and the scale σ is computed as the corrected median of the absolute residuals $\sigma = \text{median}\{|r_i|/\beta_0, i = 1, \ldots, n\}$, where $\beta_0 = \Phi^{-1}(0.75)$ is an adjustment constant for consistency with the normal distribution.

An ODS table called DIAGNOSTICS contains these two variables.

INEST= Data Set

The INEST= data set specifies initial estimates for all the parameters in the model. The INEST= data set must contain the intercept variable (named Intercept) and all independent variables in the MODEL statement.

If BY processing is used, the INEST= data set should also include the BY variables, and there must be at least one observation for each BY group. If there is more than one observation in one BY group, the first one read is used for that BY group.

If the INEST= data set also contains the _TYPE_ variable, only observations with the _TYPE_ value 'PARMS' are used as starting values.

You can specify starting values for the interior point algorithm or the smoothing algorithm in the INEST= data set. The INEST= data set has the same structure as the OUTEST= data set but is not required to have all the variables or observations that appear in the OUTEST= data set. One simple

use of the INEST= option is passing the previous OUTEST= data set directly to the next model as an INEST= data set, assuming that the two models have the same parameterization. If you specify more than one quantile in the MODEL statement, the same initial values are used for all quantiles.

OUTEST= Data Set

The OUTEST= data set contains parameter estimates for the specified model with all quantiles. A set of observations is created for each quantile specified. You can also specify a label in the MODEL statement to distinguish between the estimates for different models used by the QUANTREG procedure.

Note that, if the QUANTREG procedure does not produce valid solutions, the parameter estimates are set to missing in the OUTEST data set.

If created, this data set contains all variables specified in the MODEL statement and the BY statement. Each observation consists of parameter values for a specified quantile with the dependent variable having the value -1.

The following variables are also added to the data set:

MODEL	a character variable of length 8 containing the label of the MODEL statement, if present. Otherwise, the variable's value is blank.
ALGORITHM	a character variable of length 8 containing the name of the algorithm used for computing the parameter estimates, either SIMPLEX, INTERIOR, or SMOOTH
TYPE	a character variable of length 8 containing the type of the observation. it is fixed as PARMS to indicate that the observation includes parameter estimates.
STATUS	a character variable of length 12 containing the status of model fitting, either NORMAL, NOUNIQUE, or NOVALID
INTERCEPT	a numeric variable containing the intercept parameter estimates
QUANTILE	a numeric variable containing the specified quantiles

Any BY variables specified are also added to the OUTEST= data set.

Computational Resources

The various algorithms need different amounts of memory for working space. Let p be the number of parameters estimated and n be the number of observations used in the model estimation.

For the simplex algorithm, the minimum working space (in bytes) needed is

$$2np + 6n + 10p$$

for the interior point algorithm,

$$np + p^2 + 13n + 4p$$

and for the smoothing algorithm,

$$np + p^2 + 6n + 4p$$

For the last two algorithms, if you want to use preprocessing, an extra amount

$$np + 6n + 2p$$

is needed.

If sufficient space is available, the input data set is kept in memory; otherwise, the input data set is reread as necessary, and the execution time of the procedure increases substantially.

ODS Table Names

The QUANTREG procedure assigns a name to each table it creates. You can specify these names when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 72.5 ODS Tables Produced in PROC QUANTREG

ODS Table Name	Description	Statement	Option
ClassLevels	Classification variable levels	CLASS	default
CorrB	Parameter estimate correlation matrix	MODEL	CORRB
CovB	Parameter estimate covariance matrix	MODEL	COVB
Diagnostics	Outlier diagnostics	MODEL	DIAGNOSTICS
DiagSummary	Summary of the outlier diagnostics	MODEL	DIAGNOSTICS
IPIterHistory	Iteration history (Interior Point)	MODEL	ITPRINT
ModelInfo	Model information	MODEL	default
NObs	Number of observations	PROC	default
ObjFunction	Objective function	MODEL	default
ParameterEstimates	Parameter estimates	MODEL	default
ParmInfo	Parameter indices	MODEL	default
PerfSettings	Performance settings	PERFORMANCE	DETAILS
ProcessEst	Quantile process estimates	MODEL	QUANTILE=
ProcessObj	Objective function for quantile process	MODEL	QUANTILE=
SMIterHistory	Iteration history (Smoothing)	MODEL	ITPRINT
SummaryStatistics	Summary statistics for model variables	MODEL	default
Tests	Results for tests	TEST	default
ScalableTiming	Timing details	PERFORMANCE	DETAILS

ODS Graphics

The QUANTREG procedure uses ODS Graphics to produce graphical displays for model fitting and model diagnostics. To request these plots you must specify the ODS GRAPHICS statement in addition to specific plot options in the PROC statement or the MODEL statement. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

For a single quantile, two plots are particularly useful in revealing outliers and leverage points. The first is a scatter plot of the standardized residuals for the specified quantile against the robust distances. The second is a scatter plot of the robust distances against the classical Mahalanobis distances. You can request these two plots by using the PLOT=RDPLOT and PLOT=DDPLOT options.

You can also request a normal quantile-quantile plot and a histogram of the standardized residuals for the specified quantile with the PLOT=QQPLOT and PLOT=HISTOGRAM options, respectively.

You can request a plot of fitted conditional quantiles by the single continuous variable specified in the model with the PLOT=FITPLOT option.

All these plots can be requested by specifying corresponding plot options in either the PROC statement or the MODEL statement. If you specify same plot options in both statements, options in the PROC statement override options in the MODEL statement.

You can specify the PLOT=QUANTPLOT option in only the MODEL statement to request a quantile process plot with confidence bands.

The plot options in the PROC statement and the MODEL statement are summarized in Table 72.6. See the PLOT= option in the PROC statement and the PLOT= option in the MODEL statement for details.

Table 72.6 Options for Plots

Keyword	Plot
ALL	All appropriate plots
DDPLOT	Robust distance vs. Mahalanobis distance
FITPLOT	Conditional quantile fit vs. independent variable
HISTOGRAM	Histogram of standardized robust residuals
NONE	No plot
QUANTPLOT	Scatter plot of regression quantile
QQPLOT	Q-Q plot of standardized robust residuals
RDPLOT	Standardized robust residual vs. robust distance

The names of the graphs that PROC QUANTREG generates are listed in Table 72.7, along with the required statements and options. The following subsections provide information about these graphs.

Fit Plot

When the model has a single independent continuous variable (with or without the intercept), the QUANTREG procedure automatically creates a plot of fitted conditional quantiles against this independent variable for one or more quantiles specified in the MODEL statement.

The following example reuses the trout data set in the section "Analysis of Fish-Habitat Relationships" on page 5363 to show the fit plot for one or several quantiles.

```
ods graphics on;

proc quantreg data=trout ci=resampling;
   model LnDensity = WDRatio / quantile=0.9 ;
run;

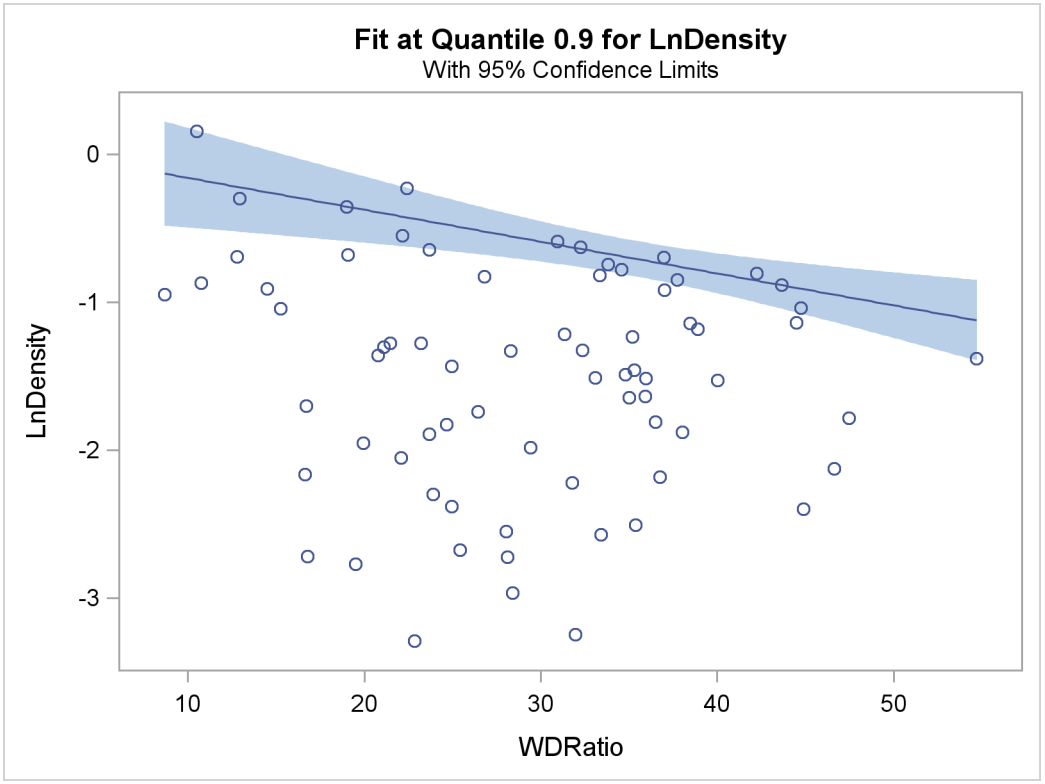
proc quantreg data=trout ci=resampling;
   model LnDensity = WDRatio / quantile=0.5 0.75 0.9 ;
run;

ods graphics off;
```

For a single quantile, the confidence limits for the fitted conditional quantiles are also plotted if you specify the CI=RESAMPLING or CI=SPARSITY option. (See Figure 72.13.) For multiple quantiles, confidence limits are not plotted. (See Figure 72.14.)

The QUANTREG procedure also provides fit plots for quantile regression splines and polynomials if they are based on a single continuous variable. Refer to Example 72.4 and Example 72.5 for some examples.

Figure 72.13 Fit Plot with Confidence Limits



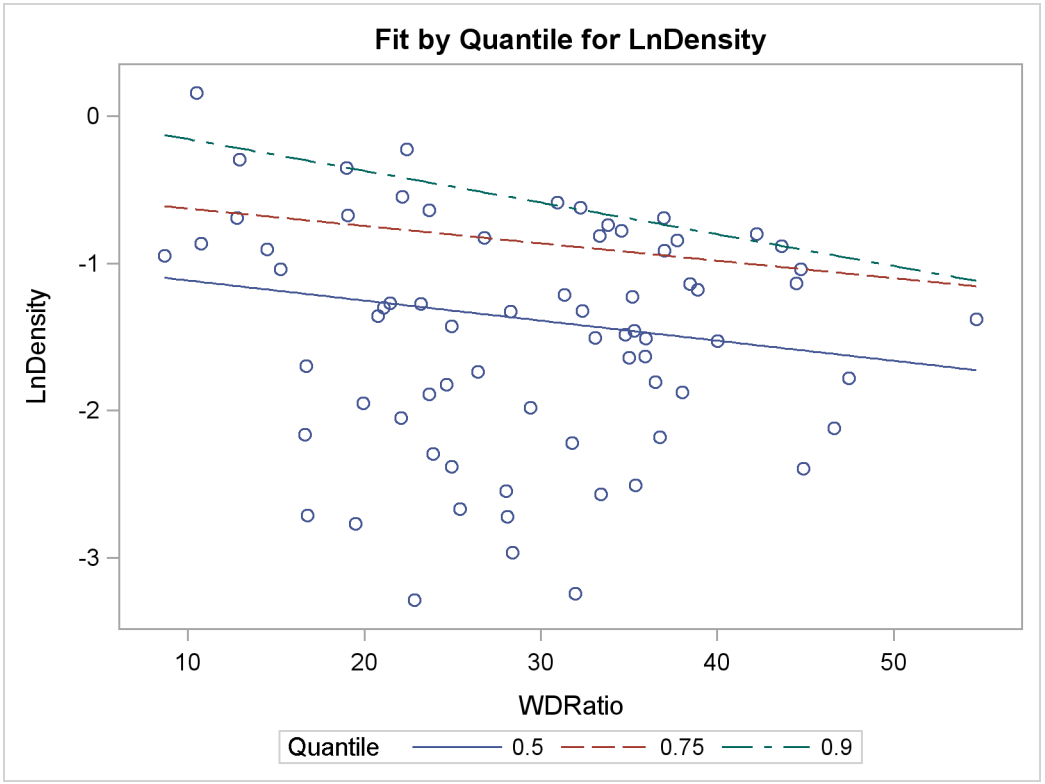


Figure 72.14 Fit Plot for Multiple Quantiles

Quantile Process Plot

A quantile process plot is a scatter plot of an estimated regression parameter against quantile. You can request this plot with the PLOT=QUANTPLOT option in the MODEL statement when multiple regression quantiles or the entire quantile process is computed. Quantile process plots are often used to check model variations at different quantiles, which is usually called model heterogeneity.

By default, panels are used to hold multiple process plots (up to four in each panel). You can use the UNPACK option to request individual process plots. Figure 72.9 in the section "Analysis of Fish-Habitat Relationships" on page 5363 shows a panel with two quantile process plots. Output 72.2.9 in Example 72.2 shows a single quantile process plot. Example 72.3 demonstrates more quantile process plots and their usage.

The diagnostics plots discussed in the following sections are available when you fit the regression model with a single quantile, especially the median.

Distance-Distance Plot

The distance-distance plot (DDPLOT) is mainly used for leverage-point diagnostics. It is a scatter plot of the robust distances against the classical Mahalanobis distances for the continuous independent variables. See the section "Leverage Point and Outlier Detection" on page 5397 for details about the robust distance. If there is a classification variable specified in the model, this plot is not created.

You can use the PLOT=DDPLOT option to request this plot. The following statements use the growth data set in Example 72.2 to create a single plot, shown in Output 72.2.4 in Example 72.2:

```
ods graphics on;

proc quantreg data=growth ci=resampling plot=ddplot;
    model GDP = lgdp2 mse2 fse2 fhe2 mhe2 lexp2
                lintr2 gedy2 Iy2 gcony2 lblakp2 pol2 ttrad2
                / quantile=.5 diagnostics leverage(cutoff=8);
    id Country;
run;

ods graphics off;
```

The reference lines represent the cutoff values. The diagonal line is also drawn to show the distribution of the distances. By default, all outliers and leverage points are labeled with observation numbers. To change the default, you can use the LABEL= option as described in Table 72.4.

Residual-Distance Plot

The residual-distance plot (RDPLOT) is used for both outlier and leverage-point diagnostics. It is a scatter plot of the standardized residuals against the robust distances. See the section "Leverage Point and Outlier Detection" on page 5397 for details about the robust distance. If a classification variable is specified in the model, this plot is not created.

You can use the PLOT=RDPLOT option to request this plot. The following statements use the growth data set in Example 72.2 to create a single plot, shown in Output 72.2.3 in Example 72.2:

```
ods graphics on;

proc quantreg data=growth ci=resampling plot=rdplot;
    model GDP = lgdp2 mse2 fse2 fhe2 mhe2 lexp2
                lintr2 gedy2 Iy2 gcony2 lblakp2 pol2 ttrad2
                / quantile=.5 diagnostics leverage(cutoff=8);
    id Country;
run;

ods graphics off;
```

The reference lines represent the cutoff values. By default, all outliers and leverage points are labeled with observation numbers. To change the default, you can use the LABEL= option as described in Table 72.4.

If you specify ID variables in the ID statement, instead of observation numbers, the values of the first ID variable are used as labels.

Histogram and Q-Q Plot

PROC QUANTREG produces a histogram and a Q-Q plot for the standardized residuals. The histogram is superimposed with a normal density curve and a kernel density curve. Using the growth data set in Example 72.2, the following statements create the plot shown in Output 72.2.5 in Example 72.2:

```
ods graphics on;

proc quantreg data=growth ci=resampling plot=histogram;
    model GDP = lgdp2 mse2 fse2 fhe2 mhe2 lexp2
                lintr2 gedy2 Iy2 gcony2 lblakp2 pol2 ttrad2
                / quantile=.5 diagnostics leverage(cutoff=8);
    id Country;
run;

ods graphics off;
```

ODS Graph Names

The QUANTREG procedure assigns a name to each graph it creates. You can use these names to reference the graphs when using ODS. The names are listed in Table 72.7.

To request these graphs you must specify the ODS GRAPHICS statement in addition to the plot options in the PROC statement or the MODEL statement. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

Table 72.7 ODS Graphics Produced by PROC QUANTREG

ODS Graph Name	Plot Description	Statement	Option
DDPlot	Robust distance vs. Mahalanobis distance	PROC MODEL	DDPLOT
FitPlot	Quantile fit vs. independent variable	PROC MODEL	FITPLOT
Histogram	Histogram of standardized robust residuals	PROC MODEL	HISTOGRAM
QQPlot	Q-Q plot of standardized robust residuals	PROC MODEL	QQPLOT
QuantPanel	Panel of quantile plots with confidence limits	MODEL	QUANTPLOT
QuantPlot	Scatter plot for regression quantiles with confidence limits	MODEL	QUANTPLOT UNPACK
RDPlot	Standardized robust residual vs. robust distance	PROC MODEL	RDPLOT

Examples: QUANTREG Procedure

Example 72.1: Comparison of Algorithms

This example illustrates and compares the three algorithms for regression estimation available in the QUANTREG procedure. The simplex algorithm is the default because of its stability. Although this algorithm is slower than the interior point and smoothing algorithms for large data sets, the difference is not as significant for data sets with fewer than 5,000 observations and 50 variables. The simplex algorithm can also compute the entire quantile process, which is shown in Example 72.2.

The following statements generate 1,000 random observations. The first 950 observations are from a linear model, and the last 50 observations are significantly biased in the y-direction. In other words, 5% of the observations are contaminated with outliers.

```
data a (drop=i);
   do i=1 to 1000;
      x1=rannor(1234);
      x2=rannor(1234);
      e=rannor(1234);
      if i > 950 then y=100 + 10*e;
      else y=10 + 5*x1 + 3*x2 + 0.5 * e;
      output;
   end;
run;
```

The following statements invoke the QUANTREG procedure to fit a median regression model with the default simplex algorithm. They produce the results in Output 72.1.1 through Output 72.1.3.

```
proc quantreg data=a;
   model y = x1 x2;
run;
```

Output 72.1.1 displays model information and summary statistics for variables in the model. It indicates that the simplex algorithm is used to compute the optimal solution and the rank method is used to compute confidence intervals of the parameters.

By default, the QUANTREG procedure fits a median regression model. This is indicated by the quantile value 0.5 in Output 72.1.2, which also displays the objective function value and the predicted value of the response at the means of the covariates.

Output 72.1.3 displays parameter estimates and confidence limits. These estimates are reasonable, which indicates that median regression is robust to the 50 outliers.

Output 72.1.1 Model Fit Information and Summary Statistics with Simplex Algorithm

The QUANTREG Procedure

Model Information

Data Set	WORK.A
Dependent Variable	y
Number of Independent Variables	2
Number of Observations	1000
Optimization Algorithm	Simplex
Method for Confidence Limits	Inv_Rank

Summary Statistics

Variable	Q1	Median	Q3	Mean	Standard Deviation	MAD
x1	-0.6546	0.0230	0.7099	0.0222	0.9933	1.0085
x2	-0.7891	-0.0747	0.6839	-0.0401	1.0394	1.0857
y	6.1045	10.6936	14.9569	14.4864	20.4087	6.5696

Output 72.1.2 Quantile and Objective Function with Simplex Algorithm

Quantile and Objective Function

Quantile	0.5
Objective Function	2441.1927
Predicted Value at Mean	10.0259

Output 72.1.3 Parameter Estimates with Simplex Algorithm

Parameter Estimates

Parameter	DF	Estimate	95% Confidence Limits	
Intercept	1	10.0364	9.9959	10.0756
x1	1	5.0106	4.9602	5.0388
x2	1	3.0294	2.9944	3.0630

The following statements refit the model by using the interior point algorithm:

```
proc quantreg algorithm=interior(tolerance=1e-6)
              ci=none data=a;
   model y = x1 x2 / itprint nosummary;
run;
```

The TOLERANCE= option specifies the stopping criterion for convergence of the interior point algorithm, which is controlled by the duality gap. Although the default criterion is 1E−8, the value 1E−6 is often sufficient. The ITPRINT option requests the iteration history for the algorithm. The option CI=NONE suppresses the computation of confidence limits, and the option NOSUMMARY suppresses the table of summary statistics.

Output 72.1.4 displays model fit information.

Output 72.1.4 Model Fit Information with Interior Point Algorithm

The QUANTREG Procedure

Model Information

Data Set	WORK.A
Dependent Variable	y
Number of Independent Variables	2
Number of Observations	1000
Optimization Algorithm	Interior

Output 72.1.5 displays the iteration history of the interior point algorithm. Note that the duality gap is less than 1E−6 in the final iteration. The table also provides the number of iterations, the number of corrections, the primal step length, the dual step length, and the objective function value at each iteration.

Output 72.1.5 Iteration History for the Interior Point Algorithm

Iteration History of Interior Point Algorithm

Duality Gap	Iter	Correction	Primal Step	Dual Step	Objective Function
2623	1	1	0.3113	0.4910	3303.4688

5.44651E-8	12	12	1.0000	1.0000	2441.1927

Output 72.1.6 displays the parameter estimates obtained with the interior point algorithm, which are identical to those obtained with the simplex algorithm.

Output 72.1.6 Parameter Estimates with Interior Point Algorithm

Parameter Estimates

Parameter	DF	Estimate
Intercept	1	10.0364
x1	1	5.0106
x2	1	3.0294

The following statements refit the model by using the smoothing algorithm. They produce the results in Output 72.1.7 through Output 72.1.9.

```
proc quantreg algorithm=smooth(rratio=.5) ci=none data=a;
   model y = x1 x2 / itprint nosummary;
run;
```

The RRATIO= option controls the reduction speed of the threshold. Output 72.1.7 displays the model fit information.

Output 72.1.7 Model Fit Information with Smoothing Algorithm

The QUANTREG Procedure

Model Information

Data Set	WORK.A
Dependent Variable	y
Number of Independent Variables	2
Number of Observations	1000
Optimization Algorithm	Smooth

Output 72.1.8 displays the iteration history of the smoothing algorithm. The threshold controls the convergence. Note that the thresholds decrease by a factor of at least 0.5, the value specified with the RRATIO= option. The table also provides the number of iterations, the number of factorizations, the number of full updates, the number of partial updates, and the objective function value in each iteration. For details concerning the smoothing algorithm, refer to Chen (2007).

Output 72.1.8 Iteration History for the Smoothing Algorithm

Iteration History of Smoothing Algorithm

Threshold	Iter	Refac	Full Update	Partial Update	Objective Function
227.24557	1	1	1000	0	4267.0988
116.94090	15	4	1480	2420	3631.9653

0.02251	30	10	2497	2618	2441.1956
0.01126	32	11	2505	2620	2441.1946
0.00563	34	12	2510	2621	2441.1933
0.00281	35	13	2514	2621	2441.1930
0.0000846	36	14	2517	2621	2441.1927
1E-12	37	14	2517	2621	2441.1927

Output 72.1.9 displays the parameter estimates obtained with the smoothing algorithm, which are identical to those obtained with the simplex and interior point algorithms. All three algorithms should have the same parameter estimates unless the problem does not have a unique solution.

Output 72.1.9 Parameter Estimates with Smoothing Algorithm

Parameter Estimates		
Parameter	**DF**	**Estimate**
Intercept	1	10.0364
x1	1	5.0106
x2	1	3.0294

The interior point algorithm and the smoothing algorithm offer better performance than the simplex algorithm for large data sets. Refer to Chen (2004) for more details on choosing an appropriate algorithm on the basis of data set size. All three algorithms should have the same parameter estimates, unless the optimization problem has multiple solutions.

Example 72.2: Quantile Regression for Econometric Growth Data

This example uses a SAS data set named growth, which contains economic growth rates for countries during two time periods, 1965–1975 and 1975–1985. The data come from a study by Barro and Lee (1994) and have also been analyzed by Koenker and Machado (1999).

There are 161 observations and 15 variables in the data set. The variables, which are listed in the following table, include the national growth rates (GDP) for the two periods, 13 covariates, and a name variable (Country) for identifying the countries in one of the two periods.

Variable	Description
Country	Country's Name and Period
GDP	Annual Change Per Capita GDP
lgdp2	Initial Per Capita GDP
mse2	Male Secondary Education
fse2	Female Secondary Education
fhe2	Female Higher Education
mhe2	Male Higher Education
lexp2	Life Expectancy
lintr2	Human Capital
gedy2	Education/GDP
Iy2	Investment/GDP
gcony2	Public Consumption/GDP
lblakp2	Black Market Premium
pol2	Political Instability
ttrad2	Growth Rate Terms Trade

The goal is to study the effect of the covariates on GDP. The following statements request median regression for a preliminary exploration. They produce the results in Output 72.2.1 through Output 72.2.6.

```

The QUANTREG procedure employs the default simplex algorithm to estimate the parameters. The MCMB resampling method is used to compute confidence limits.

Output 72.2.1 displays model information and summary statistics for the variables in the model. Six summary statistics are computed, including the median and the median absolute deviation (MAD), which are robust measures of univariate location and scale, respectively. For the variable lintr2 (Human Capital), both the mean and standard deviation are much larger than the corresponding robust measures, median and MAD. This indicates that this variable might have outliers.

Output 72.2.2 displays parameter estimates and 95% confidence limits computed with the rank method.

Output 72.2.1 Model Information and Summary Statistics

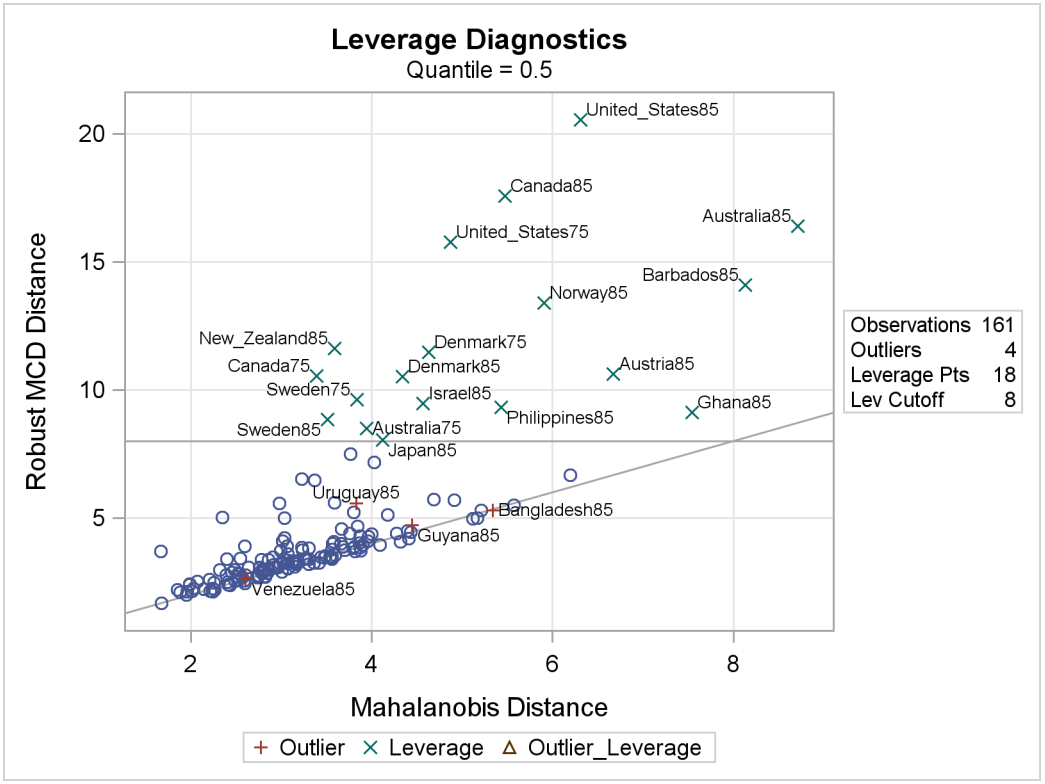
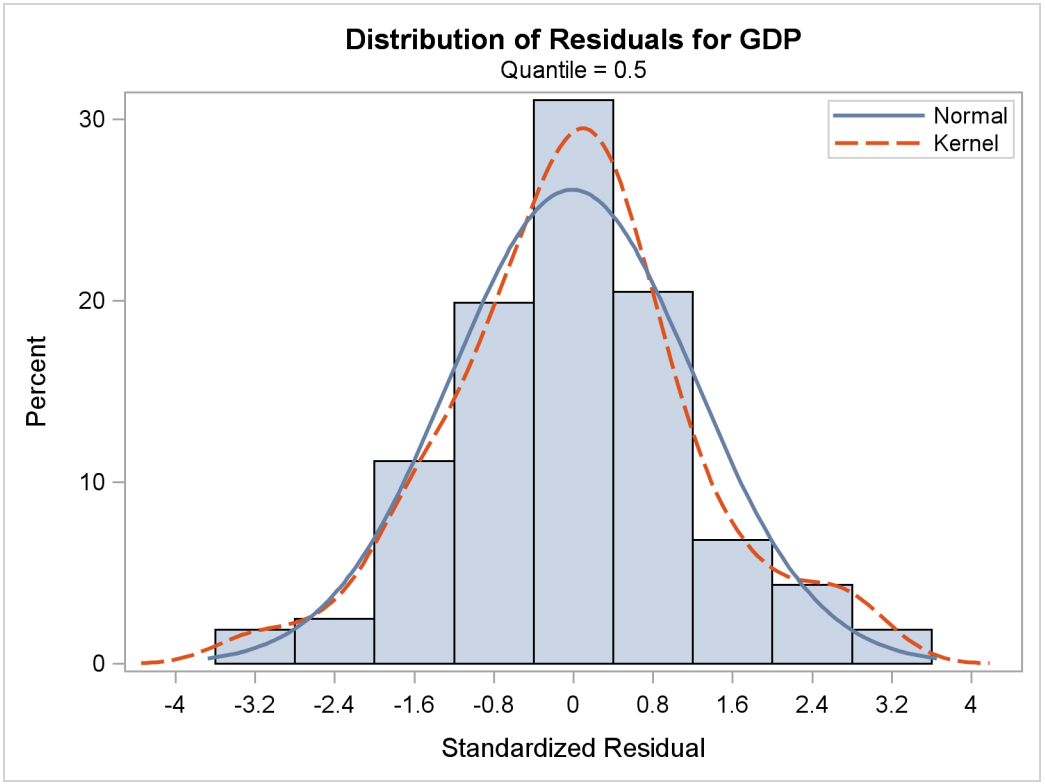
Diagnostics for the median regression fit are displayed in Output 72.2.3 and Output 72.2.4, which are requested with the PLOTS= option. Output 72.2.3 plots the standardized residuals from median regression against the robust MCD distance. This display is used to diagnose both vertical outliers and horizontal leverage points. Output 72.2.4 plots the robust MCD distance against the Mahalanobis distance. This display is used to diagnose leverage points.



The cutoff value 8 specified with the LEVERAGE option is close to the maximum of the Mahalanobis distance. Eighteen points are diagnosed as high leverage points, and almost all are countries with high human capital, which is the major contributor to the high leverage as observed from the summary statistics. Four points are diagnosed as outliers by using the default cutoff value of 3. However, these are not extreme outliers.

A histogram of the standardized residuals and two fitted density curves are displayed in Output 72.2.5. This shows that median regression fits the data well.



Output 72.2.3 Residual-Robust Distance Plot

Output 72.2.4 Robust Distance-Mahalanobis Distance Plot

Output 72.2.5 Histogram for Residuals

Tests of significance for the initial per-capita GDP (LGDP2) are shown in Output 72.2.6.

Output 72.2.6 Tests for Regression Coefficient

Tests

test_lgdp2

Test	Test Statistic	DF	Chi-Square	Pr > ChiSq

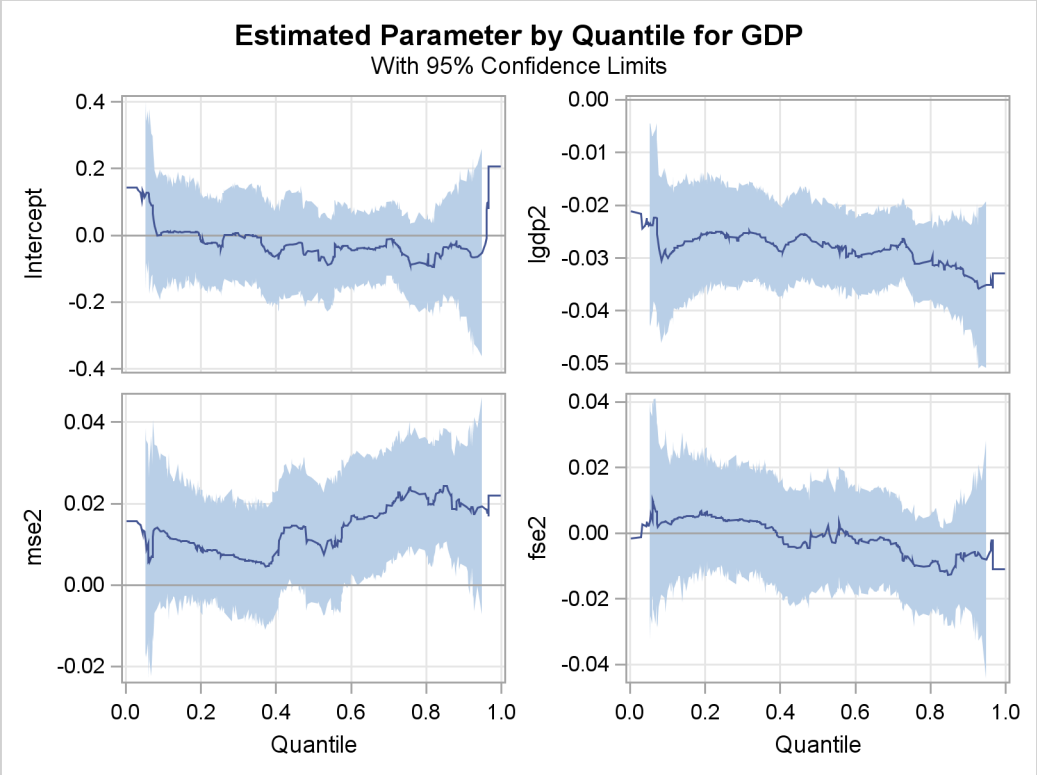
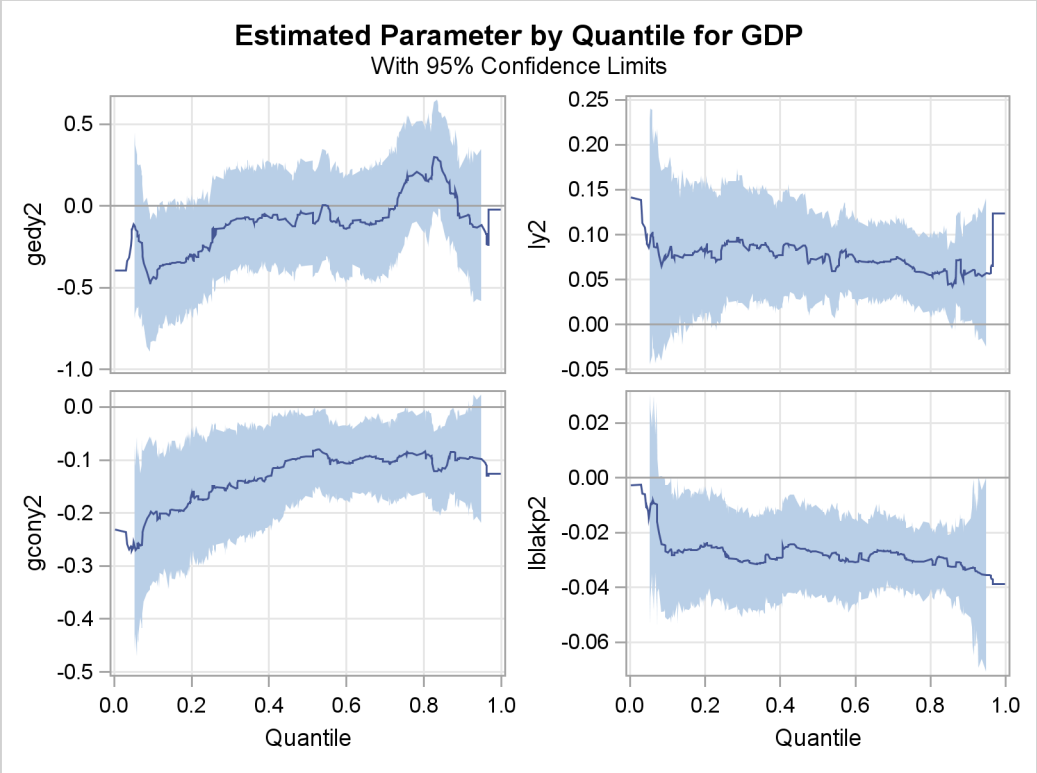
The QUANTREG procedure computes entire quantile processes for covariates when you specify QUANTILE=PROCESS in the MODEL statement, as follows:

```
ods graphics on;



proc quantreg data=growth ci=resampling;
    model GDP = lgdp2 mse2 fse2 fhe2 mhe2 lexp2 lintr2
                gedy2 Iy2 gcony2 lblakp2 pol2 ttrad2
                / quantile=process plot=quantplot;
run;

ods graphics off;
```



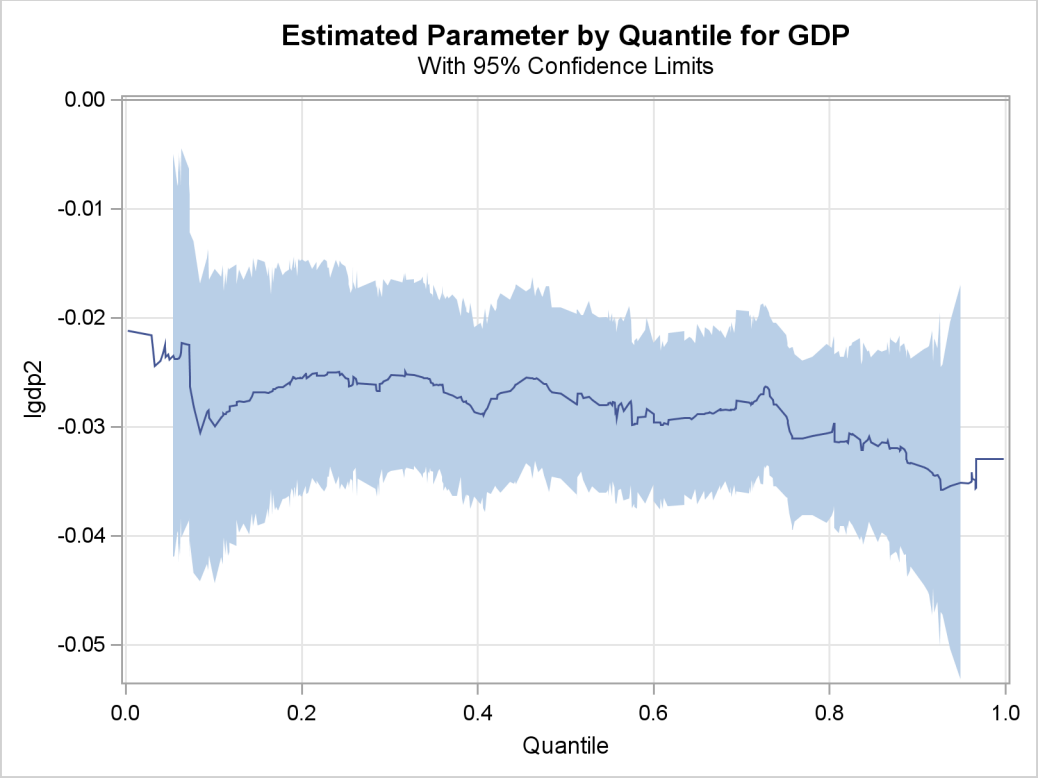
Confidence limits for quantile processes can be computed with the sparsity or resampling methods, but not the rank method, because the computation would be prohibitively expensive.

A total of 14 quantile process plots are produced. Output 72.2.7 and Output 72.2.8 display two panels of eight selected process plots. The 95% confidence bands are shaded.

Output 72.2.7 Quantile Processes with 95% Confidence Bands

Output 72.2.8 Quantile Processes with 95% Confidence Bands

As pointed out by Koenker and Machado (1999), previous studies of the Barro growth data have focused on the effect of the initial per-capita GDP on the growth of this variable (annual change per-capita GDP). A single process plot for this effect can be requested with the following statements:



```
ods graphics on;

proc quantreg data=growth ci=resampling;
    model GDP = lgdp2 mse2 fse2 fhe2 mhe2 lexp2 lintr2
                gedy2 Iy2 gcony2 lblakp2 pol2 ttrad2
                / quantile=process plot=quantplot(lgdp2);
run;

ods graphics off;
```

The plot is shown in Output 72.2.9.

Output 72.2.9 Quantile Process Plot for LGDP2

The confidence bands here are computed with the MCMB resampling method, unlike in Koenker and Machado (1999), where the rank method was used to compute confidence limits for a few selected points. Output 72.2.9 suggests that the effect of the initial level of GDP is relatively constant over the entire distribution, with a slightly stronger effect in the upper tail.

The effects of other covariates are quite varied. An interesting covariate is public consumption/GDP (gcony2) (first plot in second panel), which has a constant effect over the upper half of the distribution and a larger effect in the lower tail. For an analysis of the effects of the other covariates, refer to Koenker and Machado (1999).

Example 72.3: Quantile Regression Analysis of Birth-Weight Data

This example is patterned after a quantile regression analysis of covariates associated with birth weight that was carried out by Koenker and Hallock (2001). Their study used a subset of the June 1997 Detailed Natality Data published by the National Center for Health Statistics and demonstrated that conditional quantile functions provide more complete information about the covariate effects than ordinary least squares regression.

As in Koenker and Hallock (2001) and Abreveya (2001), this example uses data for live, singleton births to mothers in the United States who were recorded as black or white, and who were between the ages of 18 and 45. For convenience, this example uses 50,000 observations, which were randomly selected from the qualified observations. Observations with missing data for any of the variables were deleted.

The following table describes the variables in the data.

Variable	Description
weight	Infant's Birth Weight
black	Indicator of Black Mother
married	Indicator of Married Mother
boy	Indicator of Boy
visit	Prenatal Visit: 0 - no visit, 1 - visit in second trimester, 2 - visit in last trimester, 3 - visit in first trimester
ed	Mother's Education Level: 0 - high school, 1 - some college, 2 - college, 3 - less than high school
smoke	Indicator of Smoking Mother
cigsper	Number of Cigarettes Smoked per Day
mom_age	Mother's Age
m_wtgain	Mother's Weight Gain during Pregnancy

There are four levels of education of the mother. By default, the QUANTREG procedure treats the highest level (3 - less than high school) as a reference level. The regression coefficients of other levels measure the effect relative to this level. Likewise, there are four levels of prenatal medical care of the mother, and a first visit in the first trimester serves as the reference level. These two variables are treated as classification variables in the model.

The following statements fit a regression model for 19 quantiles of birth weight, which are evenly spaced in the interval $(0, 1)$. The model includes linear and quadratic effects for the age of the mother and for weight gain during pregnancy.

```
ods graphics on;

proc quantreg ci=sparsity/iid algorithm=interior(tolerance=1.e-4)
              data=sashelp.bweight;
   class visit ed;
   model weight = black married boy visit ed smoke
                  cigsper mom_age mom_age*mom_age
                  m_wtgain m_wtgain*m_wtgain /
                  quantile= 0.05 to 0.95 by 0.05
                  plot=quantplot;
run;

ods graphics off;
```

Output 72.3.1 Model Information and Summary Statistics

weight	3062.0	3402.0	3720.0	3370.8	566.4	504.1

Output 72.3.1 displays the model information and summary statistics for the variables in the model.

Among the 11 independent variables, black, married, boy, and smoke are binary variables. For these variables, the mean represents the proportion in the category. The two continuous variables, mom_age and m_wtgain, are centered at their medians, which are 27 and 30, respectively.

The quantile plots for the intercept and the other 15 factors with nonzero degree of freedom are shown in the following four panels. In each plot, the regression coefficient at a given quantile

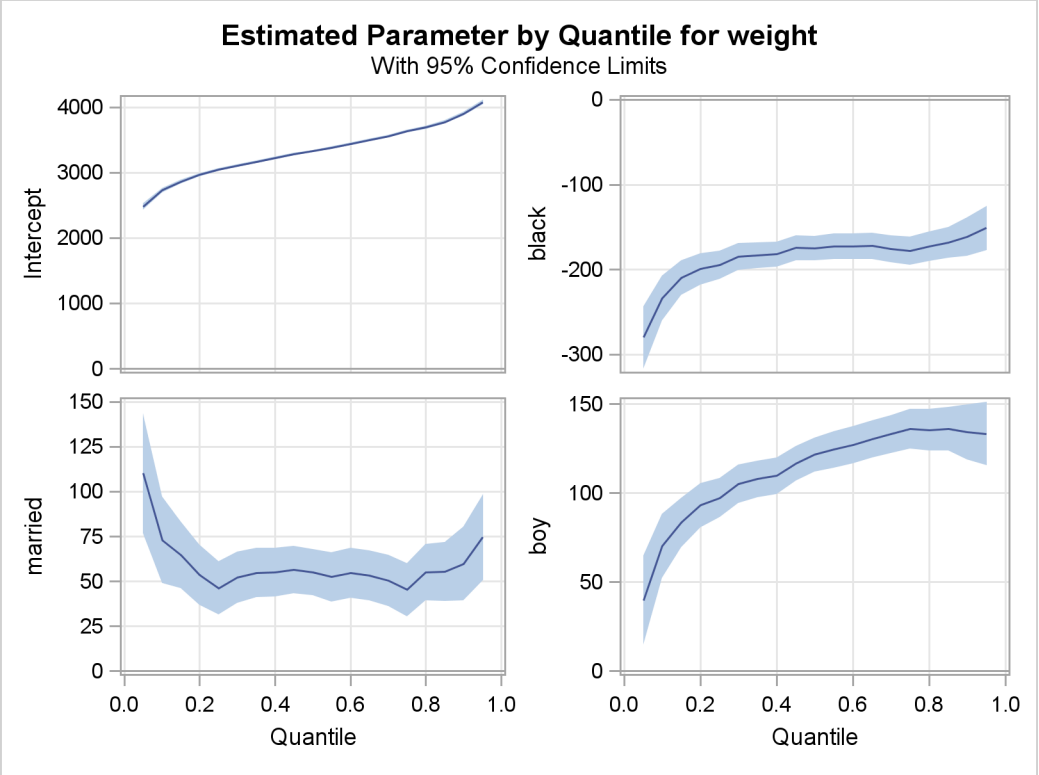
indicates the effect on birth weight of a unit change in that factor, assuming that the other factors are fixed. The bands represent 95% confidence intervals.

Although the data set used here is a subset of the Natality data set, the results are quite similar to those of Koenker and Hallock (2001) for the full data set.

In Output 72.3.2, the first plot is for the intercept. As explained by Koenker and Hallock (2001), the intercept "may be interpreted as the estimated conditional quantile function of the birth-weight distribution of a girl born to an unmarried, white mother with less than a high school education, who is 27 years old and had a weight gain of 30 pounds, didn't smoke, and had her first prenatal visit in the first trimester of the pregnancy."

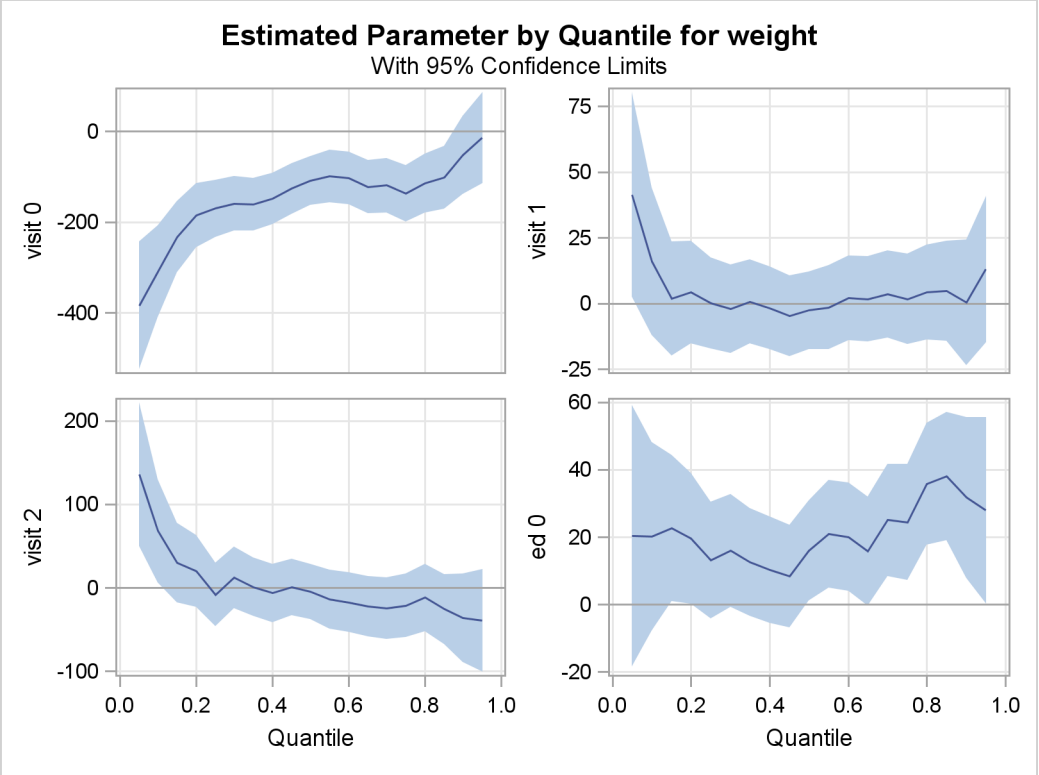
The second plot shows that infants born to black mothers weigh less than infants born to white mothers, especially in the lower tail of the birth-weight distribution. The third plot shows that marital status has a large positive effect on birth weight, especially in the lower tail. The fourth plot shows that boys weigh more than girls for any chosen quantile; this difference is smaller in the lower quantiles of the distribution.

In Output 72.3.3, the first three plots deal with prenatal care. Compared with babies born to mothers who had a prenatal visit in the first trimester, babies born to mothers who received no prenatal care weigh less, especially in the lower quantiles of the birth-weight distributions. As noted by Koenker and Hallock (2001), "babies born to mothers who delayed prenatal visits until the second or third trimester have substantially *higher* birthweights in the lower tail than mothers who had a prenatal visit in the first trimester. This might be interpreted as the self-selection effect of mothers confident about favorable outcomes."



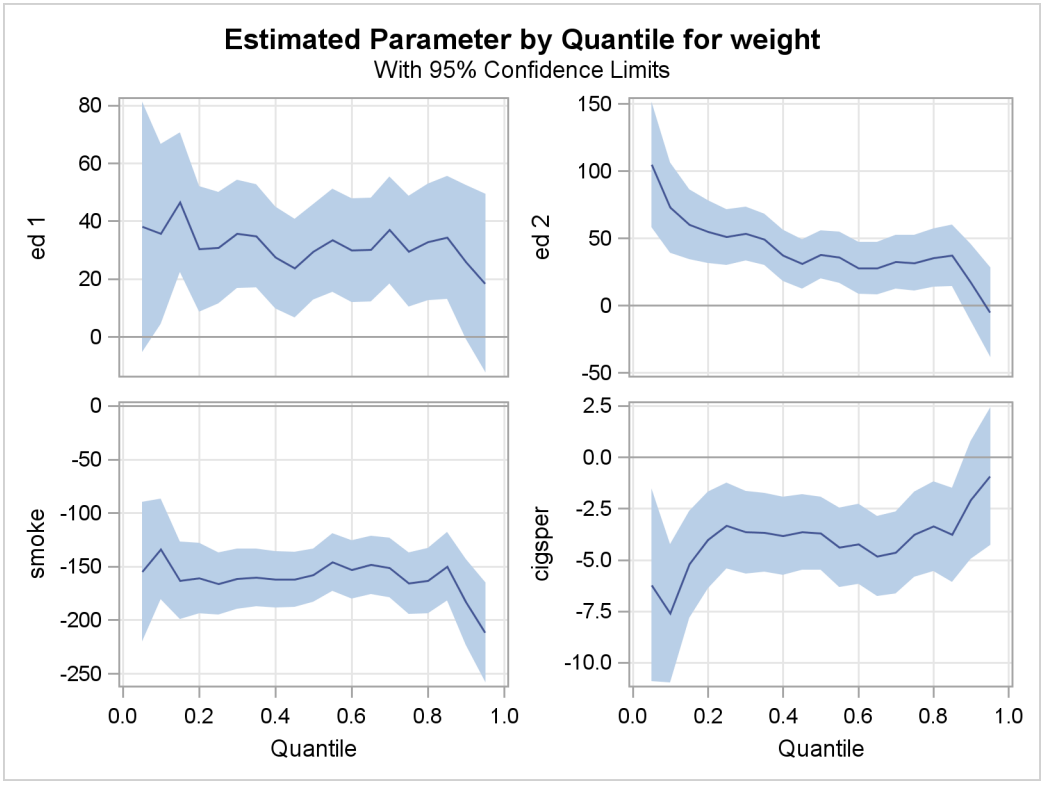
The fourth plot in Output 72.3.3 and the first two plots in Output 72.3.4 are for variables related to education. Education beyond high school is associated with a positive effect on birth weight. The effect of high school education is uniformly around 15 grams across the entire birth-weight distribution (this is a pure location shift effect), while the effect of some college and college education is more positive in the lower quantiles than the upper quantiles.

The remaining two plots in Output 72.3.4 show that smoking is associated with a large negative effect on birth weight.

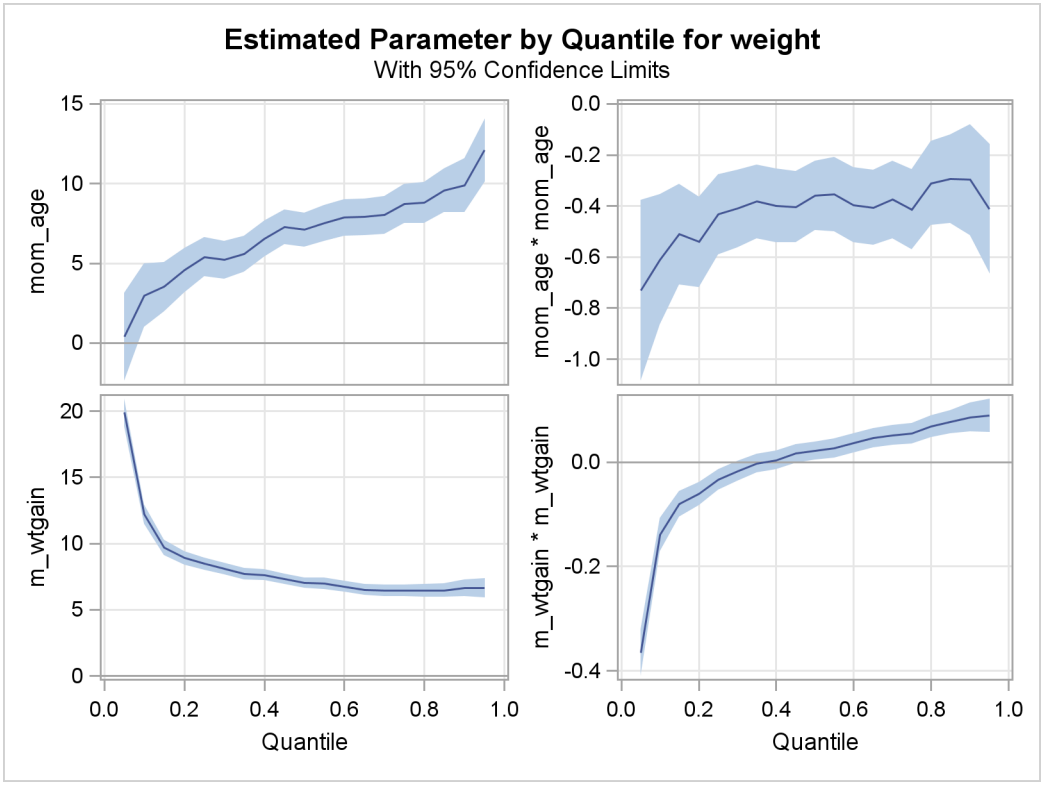


The linear and quadratic effects for the two continuous variables are shown in Output 72.3.5. Both of these variables are centered at their median. At the lower quantiles, the quadratic effect of the mother's age is more concave. The optimal age at the first quantile is about 33, and the optimal age at the third quantile is about 38. The effect of the mother's weight gain is clearly positive, as indicated by the narrow confidence bands for both linear and quadratic coefficients.

Refer to Koenker and Hallock (2001) for more details about the covariate effects discovered with quantile regression.



Output 72.3.2 Quantile Processes with 95% Confidence Bands



Output 72.3.3 Quantile Processes with 95% Confidence Bands

Output 72.3.4 Quantile Processes with 95% Confidence Bands

Output 72.3.5 Quantile Processes with 95% Confidence Bands

Example 72.4: Nonparametric Quantile Regression for Ozone Levels

Tracing seasonal trends in the level of tropospheric ozone is essential for predicting high-level periods, observing long-term trends, and discovering potential changes in pollution. Traditional methods for modeling seasonal effects are based on the conditional mean of ozone concentration; however, the upper conditional quantiles are more critical from a public health perspective. In this example, the QUANTREG procedure fits conditional quantile curves for seasonal effects by using nonparametric quantile regression with cubic B-splines.

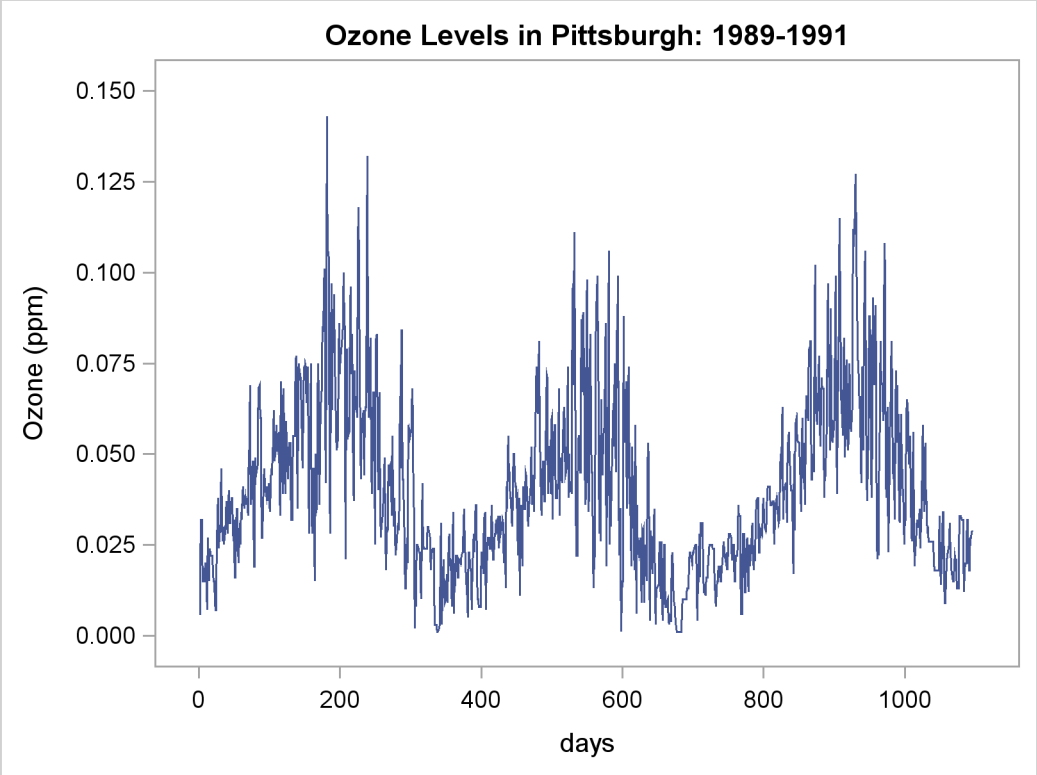
The data used here are from Chock, Winkler, and Chen (2000), who studied the association between daily mortality and ambient air pollutant concentrations in Pittsburgh, Pennsylvania. The data set ozone contains the following two variables: ozone (daily-maximum one-hour ozone concentration (ppm)) and days (index of 1,095 days (3 years)).

```
data ozone;
  days = _n_;
  input ozone @@;
datalines;
0.0060 0.0060 0.0320 0.0320 0.0320 0.0150 0.0150 0.0150 0.0200 0.0200
0.0160 0.0070 0.0270 0.0160 0.0150 0.0240 0.0220 0.0220 0.0220 0.0185
0.0150 0.0150 0.0110 0.0070 0.0070 0.0240 0.0380 0.0240 0.0265 0.0290

... more lines ...

0.0220 0.0210 0.0210 0.0130 0.0130 0.0130 0.0330 0.0330 0.0330 0.0325
0.0320 0.0320 0.0320 0.0120 0.0200 0.0200 0.0200 0.0320 0.0320 0.0250
0.0180 0.0180 0.0270 0.0270 0.0290
;
```

Output 72.4.1, which displays the time series plot of ozone concentration for the three years, shows a clear seasonal pattern.



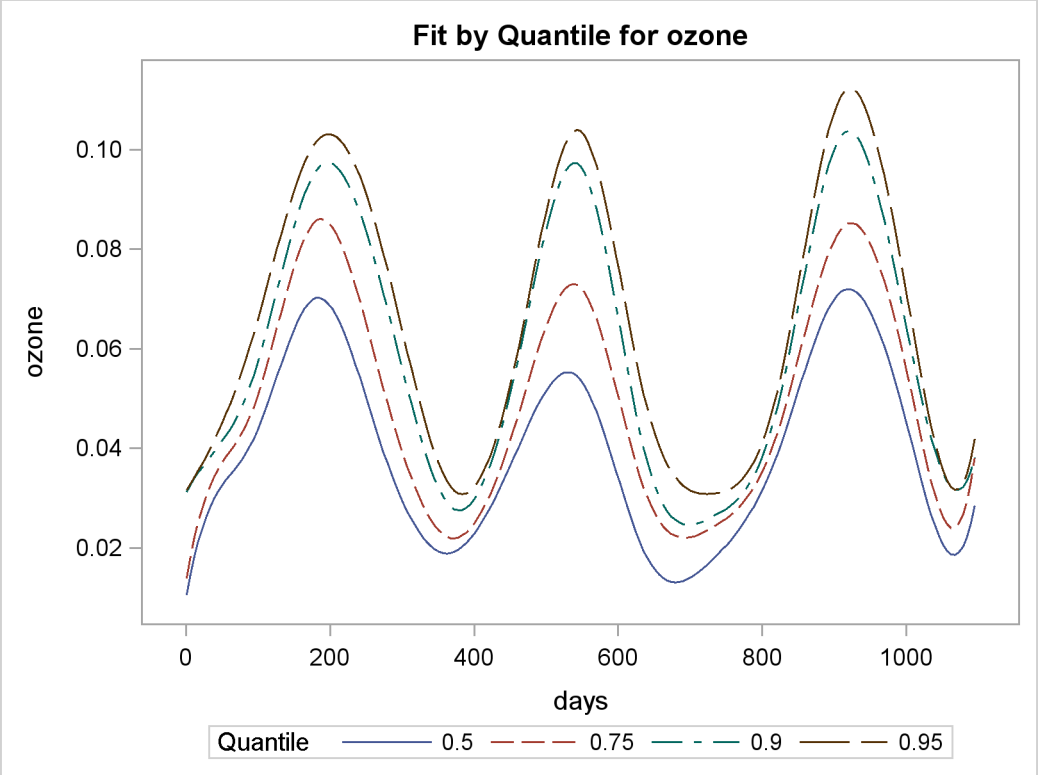
In this example, cubic B-splines are used to fit the seasonal effect. These splines are generated with 11 knots, which split the 3 years into 12 seasons. The following statements create the spline basis and fit multiple quantile regression spline curves:

```
ods graphics on;

proc quantreg data=ozone algorithm=smooth plot=fitplot(nodata);
   effect sp = spline( days / knotmethod = list
          (90 182 272 365 455 547 637 730 820 912 1002) );
   model ozone = sp / quantile = 0.5 0.75 0.90 0.95;
run;

ods graphics off;
```

Output 72.4.1 Time Series of Ozone Levels in Pittsburgh, Pennsylvania



The EFFECT statement creates spline bases for the variable days. The KNOTMETHOD=LIST option provides all internal knots for these bases. Cubic spline bases are generated by default. These bases are treated as components of the spline effect *sp*, which is used in the MODEL statement. Spline fits for four quantiles are requested with the QUANTILE= option.

When you enable ODS Graphics, the QUANTREG procedure automatically generates a fit plot, which includes all fitted curves.

Output 72.4.2 displays these curves obtained with the QUANTREG procedure. The curves show that peak ozone levels occur in the summer. For the three years (1989–1991), the median curve (labeled 50%) does not cross the 0.08 ppm line, which is the 1997 EPA 8-hour standard. The median curve and the 75% curve show a drop for the ozone concentration levels in 1990. However, with the 90% and 95% curves, peak ozone levels tend to increase. This indicates that there might have been more days with low ozone concentration in 1990, but the top 10% and 5% tend to have higher ozone concentration levels.

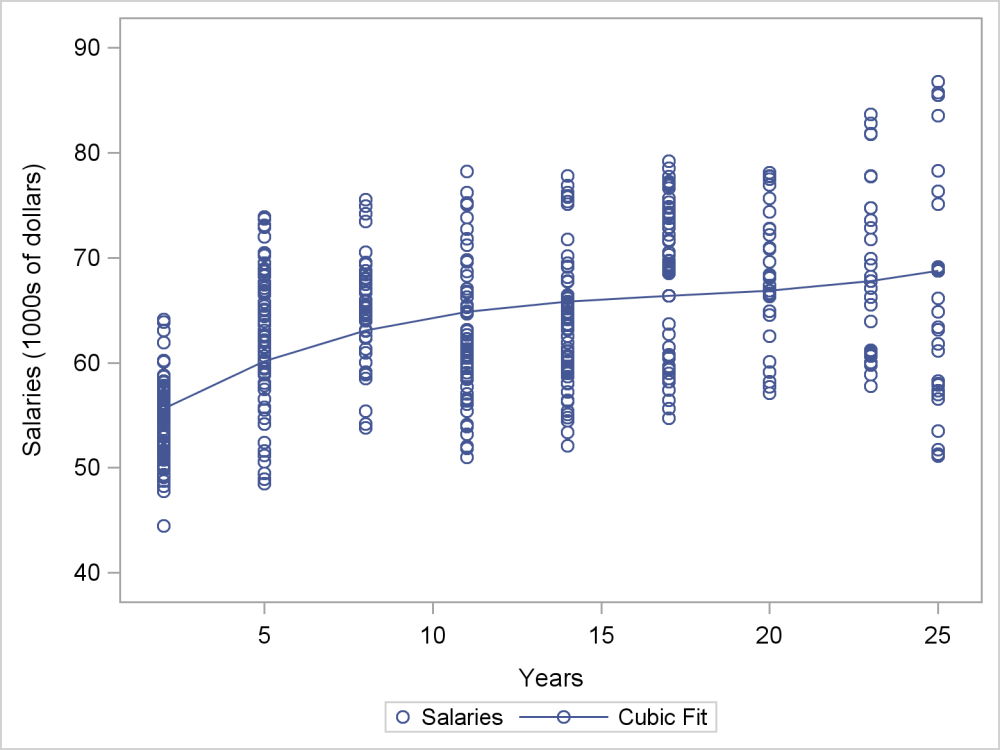
Output 72.4.2 Quantiles of Ozone Levels in Pittsburgh, Pennsylvania

The quantile curves also show that high ozone concentration in 1989 had a longer duration than in 1990 and 1991. This is indicated by the wider spread of the quantile curves in 1989.

Example 72.5: Quantile Polynomial Regression for Salary Data

This example uses the data set from a university union survey of salaries of professors in 1991. The survey covered departments in U.S. colleges and universities that list programs in statistics. The goal here is to examine the relationship between faculty salaries and years of service.

The data include salaries and years of service for 459 professors. The scatter plot in Output 72.5.1 shows that the relationship is not linear, and a quadratic or cubic regression curve is appropriate. Output 72.5.1 shows a cubic curve.



The curve in Output 72.5.1 does not adequately describe the conditional salary distributions and how they change with length of service. Output 72.5.2 shows the 25th, 50th, and 75th percentiles for each number of years, which gives a better picture of the conditional distributions.

```
data salary;
  label salaries='Salaries (1000s of dollars)'
        years   ='Years';
  input salaries years @@;

years*years*years   1   0.0034

                    Parameter Estimates

Parameter          DF Estimate

Intercept           1  51.0298
years               1   3.6513
years*years         1  -0.2390
years*years*years   1   0.0055
```

Output 72.5.4 displays the three cubic percentile curves.

Output 72.5.4 Salary with Years as Professor: Regression Quantiles

The three curves show that salary dispersion increases gradually with length of service. After 15 years, a salary over $70,000 is relatively high, while a salary less than $60,000 is relatively low. Note that percentile curves of this type are useful in medical science as reference curves; see Yu, Lu, and Stabder (2003).

Overview: REG Procedure

The REG procedure is one of many regression procedures in the SAS System. It is a general-purpose procedure for regression, while other SAS regression procedures provide more specialized applications.

Other SAS/STAT procedures that perform at least one type of regression analysis are the CATMOD, GENMOD, GLM, LOGISTIC, MIXED, NLIN, ORTHOREG, PROBIT, RSREG, and TRANSREG procedures. SAS/ETS procedures are specialized for applications in time series or simultaneous systems. These other SAS/STAT regression procedures are summarized in Chapter 4, "Introduction to Regression Procedures," which also contains an overview of regression techniques and defines many of the statistics computed by PROC REG and other regression procedures.

PROC REG provides the following capabilities:

- multiple MODEL statements
- nine model-selection methods
- interactive changes both in the model and the data used to fit the model
- linear equality restrictions on parameters
- tests of linear hypotheses and multivariate hypotheses
- collinearity diagnostics
- predicted values, residuals, studentized residuals, confidence limits, and influence statistics
- correlation or crossproduct input
- requested statistics available for output through output data sets
- ODS Graphics is now available. For more information, see the section "ODS Graphics" on page 5589. These plots are available in addition to the line printer and the traditional graphics currently available in PROC REG.

Nine model-selection methods are available in PROC REG. In the simplest method, PROC REG fits the complete model that you specify. The other eight methods involve various ways of including or excluding variables from the model. You specify these methods with the SELECTION= option in the MODEL statement.

The methods are identified in the following list and are explained in detail in the section "Model-Selection Methods" on page 5523.

NONE	no model selection. This is the default. The complete model specified in the MODEL statement is fit to the data.
FORWARD	forward selection. This method starts with no variables in the model and adds variables.
BACKWARD	backward elimination. This method starts with all variables in the model and deletes variables.
STEPWISE	stepwise regression. This is similar to the FORWARD method except that variables already in the model do not necessarily stay there.
MAXR	forward selection to fit the best one-variable model, the best two-variable model, and so on. Variables are switched so that R^2 is maximized.
MINR	similar to the MAXR method, except that variables are switched so that the increase in R^2 from adding a variable to the model is minimized.
RSQUARE	finds a specified number of models with the highest R^2 in a range of model sizes.
ADJRSQ	finds a specified number of models with the highest adjusted R^2 in a range of model sizes.
CP	finds a specified number of models with the lowest C_p in a range of model sizes.

Getting Started: REG Procedure

Simple Linear Regression

Suppose that a response variable Y can be predicted by a linear function of a regressor variable X. You can estimate β_0, the intercept, and β_1, the slope, in

$$Y_i = \beta_0 + \beta_1 X_i + \epsilon_i$$

for the observations $i = 1, 2, \ldots, n$. Fitting this model with the REG procedure requires only the following MODEL statement, where y is the outcome variable and x is the regressor variable.

```
proc reg;
   model y=x;
run;
```

For example, you might use regression analysis to find out how well you can predict a child's weight if you know that child's height. The following data are from a study of nineteen children. Height and weight are measured for each child.

```
title 'Simple Linear Regression';
data Class;
   input Name $ Height Weight Age @@;
   datalines;
Alfred  69.0 112.5 14  Alice   56.5  84.0 13  Barbara 65.3  98.0 13
Carol   62.8 102.5 14  Henry   63.5 102.5 14  James   57.3  83.0 12
Jane    59.8  84.5 12  Janet   62.5 112.5 15  Jeffrey 62.5  84.0 13

William 66.5 112.0 15
;
```

The equation of interest is

$$\text{Weight} = \beta_0 + \beta_1 \text{Height} + \epsilon$$

The variable Weight is the response or dependent variable in this equation, and β_0 and β_1 are the unknown parameters to be estimated. The variable Height is the regressor or independent variable, and ϵ is the unknown error. The following commands invoke the REG procedure and fit this model to the data.

```
ods graphics on;

proc reg;
   model Weight = Height;
run;

ods graphics off;
```

Figure 73.1 includes some information concerning model fit.

The F statistic for the overall model is highly significant (F=57.076, p<0.0001), indicating that the model explains a significant portion of the variation in the data.

The degrees of freedom can be used in checking accuracy of the data and model. The model degrees of freedom are one less than the number of parameters to be estimated. This model estimates two parameters, β_0 and β_1; thus, the degrees of freedom should be $2 - 1 = 1$. The corrected total degrees of freedom are always one less than the total number of observations in the data set, in this case $19 - 1 = 18$.

Several simple statistics follow the ANOVA table. The Root MSE is an estimate of the standard deviation of the error term. The coefficient of variation, or Coeff Var, is a unitless expression of the variation in the data. The R-square and Adj R-square are two statistics used in assessing the fit of the model; values close to 1 indicate a better fit. The R-square of 0.77 indicates that Height accounts for 77% of the variation in Weight.

Figure 73.1 ANOVA Table

Simple Linear Regression

The REG Procedure
Model: MODEL1
Dependent Variable: Weight

Analysis of Variance

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	1	7193.24912	7193.24912	57.08	<.0001
Error	17	2142.48772	126.02869		
Corrected Total	18	9335.73684			

Root MSE	11.22625	R-Square	0.7705
Dependent Mean	100.02632	Adj R-Sq	0.7570
Coeff Var	11.22330		

The "Parameter Estimates" table in Figure 73.2 contains the estimates of β_0 and β_1. The table also contains the t statistics and the corresponding p-values for testing whether each parameter is significantly different from zero. The p-values ($t = -4.43$, $p = 0.0004$ and $t = 7.55$, $p < 0.0001$) indicate that the intercept and Height parameter estimates, respectively, are highly significant.

From the parameter estimates, the fitted model is

$$\text{Weight} = -143.0 + 3.9 \times \text{Height}$$

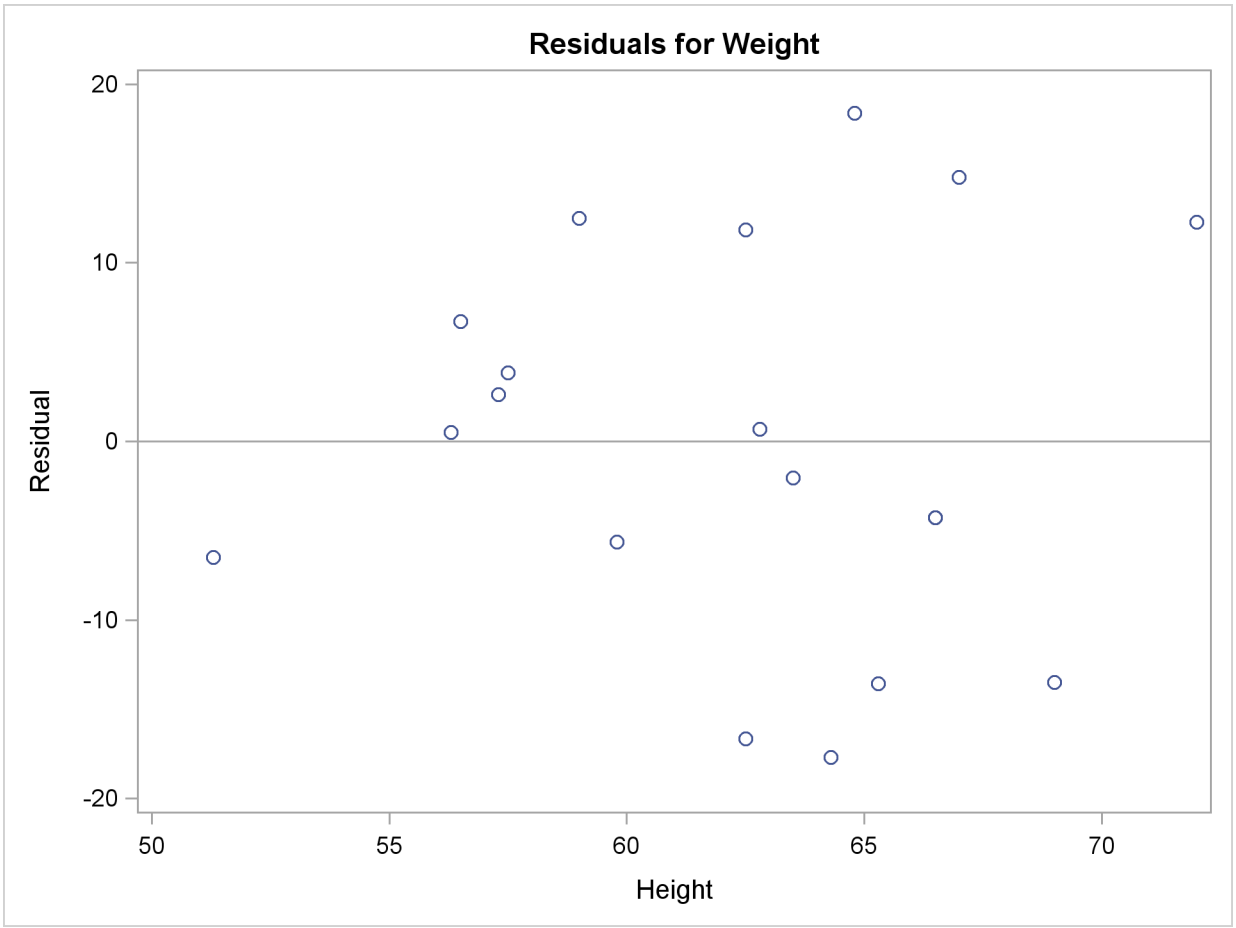
Figure 73.2 Parameter Estimates

Parameter Estimates

Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	1	-143.02692	32.27459	-4.43	0.0004
Height	1	3.89903	0.51609	7.55	<.0001

If you enable ODS Graphics with an ODS GRAPHICS statement, then PROC REG produces a variety of useful plots. Figure 73.3 shows a plot of the residuals versus the regressor and Figure 73.4 shows a panel of diagnostic plots.

Figure 73.3 Residuals vs. Regressor



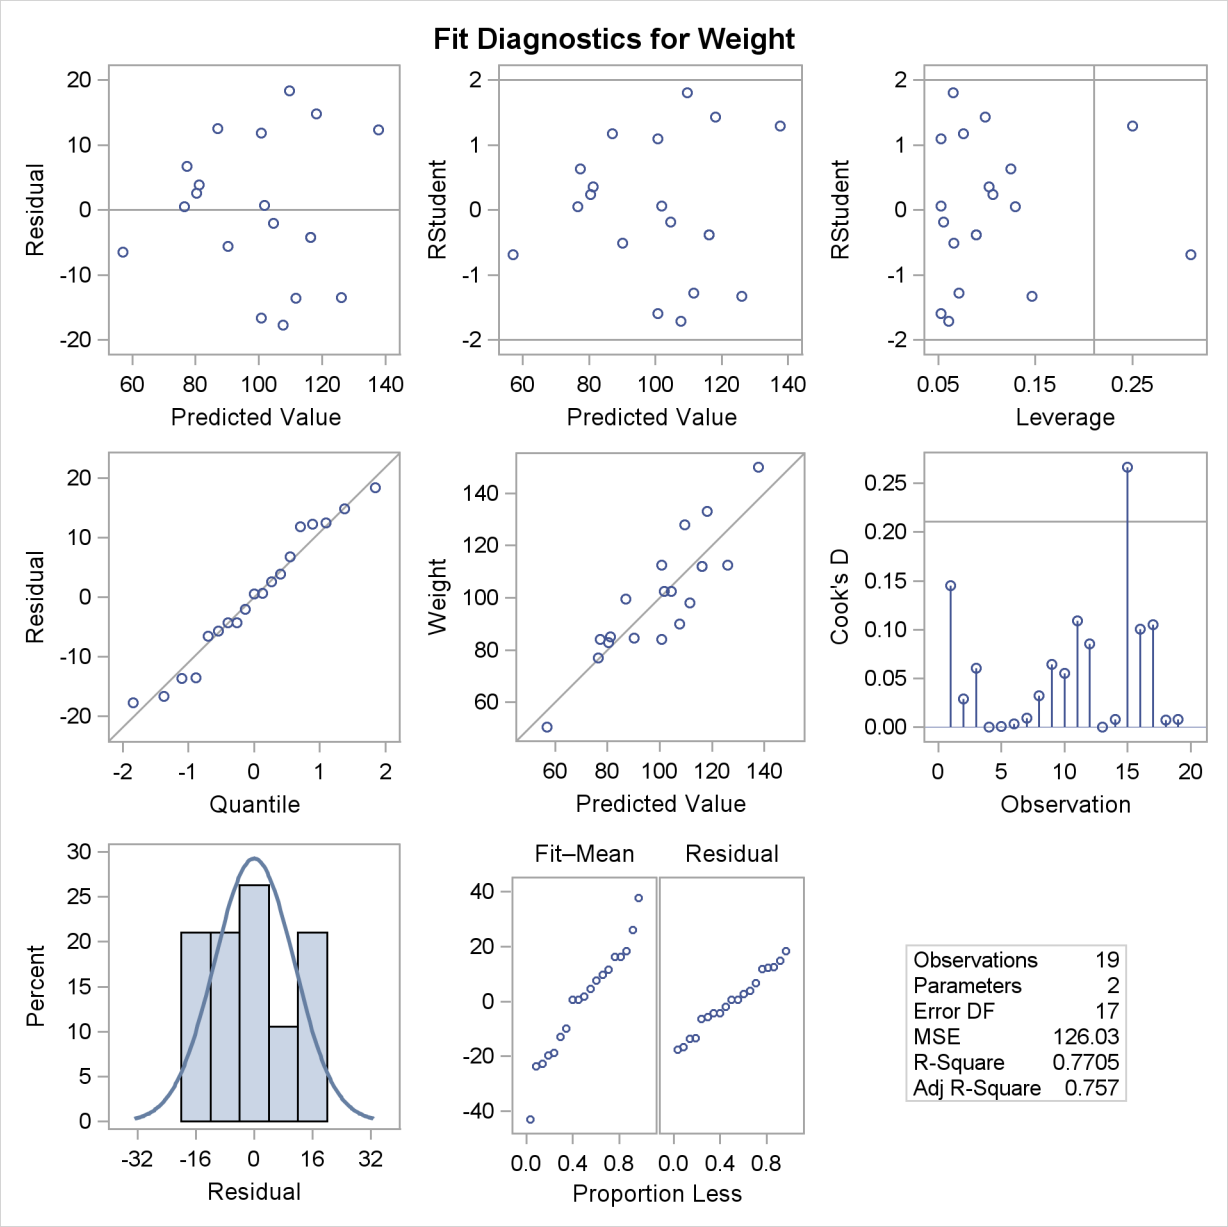


Figure 73.4 Fit Diagnostics

A trend in the residuals would indicate nonconstant variance in the data. The plot of residuals by predicted values in the upper-left corner of the diagnostics panel in Figure 73.4 might indicate a slight trend in the residuals; they appear to increase slightly as the predicted values increase. A fan-shaped trend might indicate the need for a variance-stabilizing transformation. A curved trend (such as a semicircle) might indicate the need for a quadratic term in the model. Since these residuals have no apparent trend, the analysis is considered to be acceptable.

Polynomial Regression

Consider a response variable Y that can be predicted by a polynomial function of a regressor variable X. You can estimate β_0, the intercept; β_1, the slope due to X; and β_2, the slope due to X^2, in

$$Y_i = \beta_0 + \beta_1 X_i + \beta_2 X_i^2 + \epsilon_i$$

for the observations $i = 1, 2, \ldots, n$.

Consider the following example on population growth trends. The population of the United States from 1790 to 2000 is fit to linear and quadratic functions of time. Note that the quadratic term, YearSq, is created in the DATA step; this is done since polynomial effects such as Year*Year cannot be specified in the MODEL statement in PROC REG. The data are as follows:

```
data USPopulation;
   input Population @@;
   retain Year 1780;
   Year       = Year+10;
   YearSq     = Year*Year;
   Population = Population/1000;
datalines;
3929 5308 7239 9638 12866 17069 23191 31443 39818 50155
62947 75994 91972 105710 122775 131669 151325 179323 203211
226542 248710 281422
;

ods graphics on;

proc reg data=USPopulation plots=ResidualByPredicted;
   var YearSq;
   model Population=Year / r clm cli;
run;
```

The DATA option ensures that the procedure uses the intended data set. Any variable that you might add to the model but that is not included in the first MODEL statement must appear in the VAR statement.

The "Analysis of Variance" and "Parameter Estimates" tables are displayed in Figure 73.5.

Figure 73.5 ANOVA Table and Parameter Estimates

The REG Procedure
Model: MODEL1
Dependent Variable: Population

Analysis of Variance

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	1	146869	146869	228.92	<.0001
Error	20	12832	641.58160		
Corrected Total	21	159700			

Root MSE	25.32946	R-Square	0.9197
Dependent Mean	94.64800	Adj R-Sq	0.9156
Coeff Var	26.76175		

Parameter Estimates

Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	1	-2345.85498	161.39279	-14.54	<.0001
Year	1	1.28786	0.08512	15.13	<.0001

The Model F statistic is significant (F=228.92, p<0.0001), indicating that the model accounts for a significant portion of variation in the data. The R-square indicates that the model accounts for 92% of the variation in population growth. The fitted equation for this model is

$$\text{Population} = -2345.85 + 1.29 \times \text{Year}$$

In the MODEL statement, three options are specified: R requests a residual analysis to be performed, CLI requests 95% confidence limits for an individual value, and CLM requests these limits for the expected value of the dependent variable. You can request specific $100(1-\alpha)\%$ limits with the ALPHA= option in the PROC REG or MODEL statement.

Figure 73.6 shows the "Output Statistics" table. The residual, its standard error, and the studentized residuals are displayed for each observation. The studentized residual is the residual divided by its standard error. The magnitude of each studentized residual is shown in a print plot. Studentized residuals follow a t distribution and can be used to identify outlying or extreme observations. Asterisks (*) extending beyond the dashed lines indicate that the residual is more than three standard errors from zero. Many observations having absolute studentized residuals greater than two might indicate an inadequate model. Cook's D is a measure of the change in the predicted values upon deletion of that observation from the data set; hence, it measures the influence of the observation on the estimated regression coefficients.

Figure 73.7 shows the residual statistics table. A fairly close agreement between the PRESS statistic (see Table 73.8) and the Sum of Squared Residuals indicates that the MSE is a reasonable measure of the predictive accuracy of the fitted model (Neter, Wasserman, and Kutner 1990).

Figure 73.7 Residual Statistics

Sum of Residuals	0
Sum of Squared Residuals	12832
Predicted Residual SS (PRESS)	16662

Graphical representations are very helpful in interporting the information in the "Output Statistics" table. When you enable ODS Graphics, the REG procedure produces a default set of diagnostic plots that are appropriate for the requested analysis.

Figure 73.8 displays a panel of diagnostics plots. These diagnostics indicate an inadequate model:

- The plots of residual and studentized residual versus predicted value show a clear quadratic pattern.
- The plot of studentized residual versus leverage seems to indicate that there are two outlying data points. However, the plot of Cook's D distance versus observation number reveals that these two points are just the data points for the endpoint years 1790 and 2000. These points show up as apparent outliers because the departure of the linear model from the underlying quadratic behavior in the data shows up most strongly at these endpoints.
- The normal quantile plot of the residuals and the residual histogram are not consistent with the assumption of Gaussian errors. This occurs as the residuals themselves still contain the quadratic behavior that is not captured by the linear model.
- The plot of the dependent variable versus the predicted value exhibits a quadratic form around the 45-degree line that represents a perfect fit.
- The "Residual-Fit" (or RF) plot consisting of side-by-side quantile plots of the centered fit and the residuals shows that the spread in the residuals is no greater than the spread in the centered fit. For inappropriate models, the spread of the residuals in such a plot is often greater than the spread of the centered fit. In this case, the RF plot shows that the linear model does indeed capture the increasing trend in the data, and hence accounts for much of the variation in the response.

Figure 73.8 Diagnostics Panel

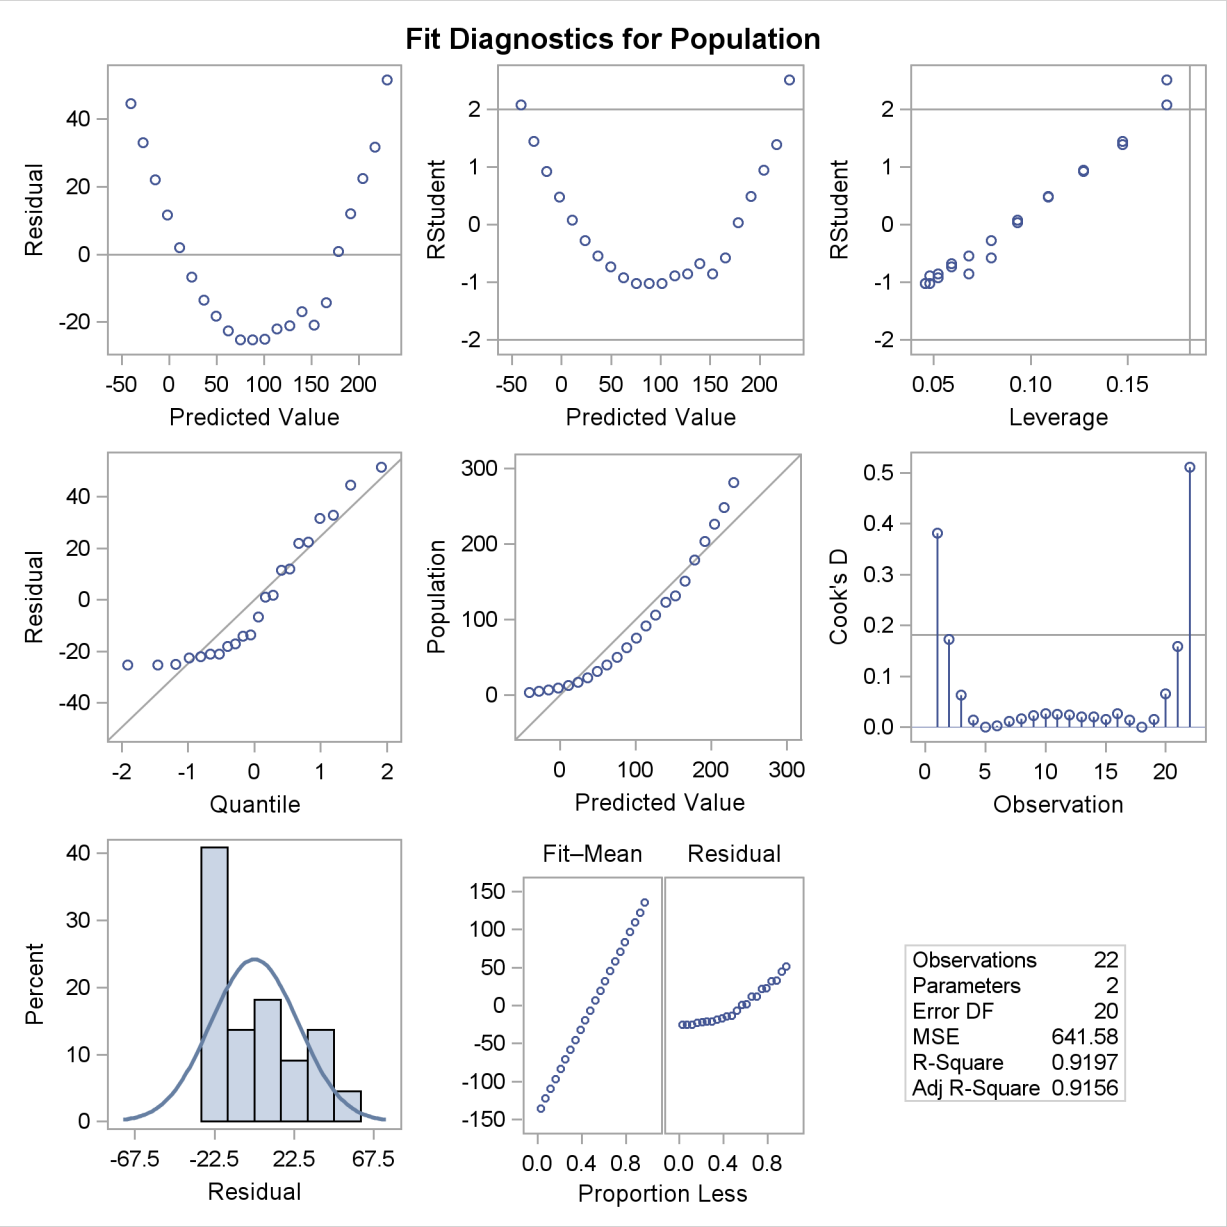

Figure 73.9 shows a plot of residuals versus Year. Again you can see the quadratic pattern that strongly indicates that a quadratic term should be added to the model.

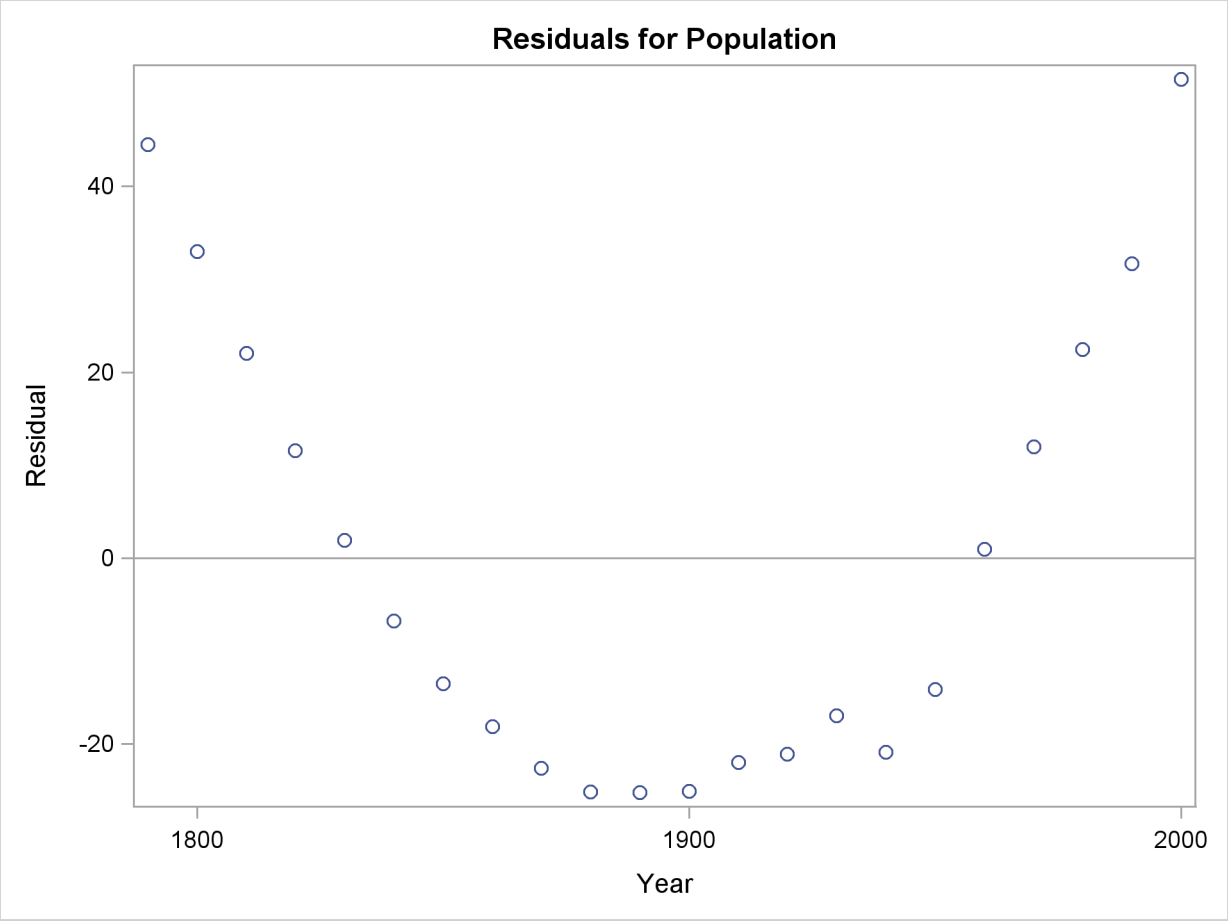
Figure 73.9 Residual Plot



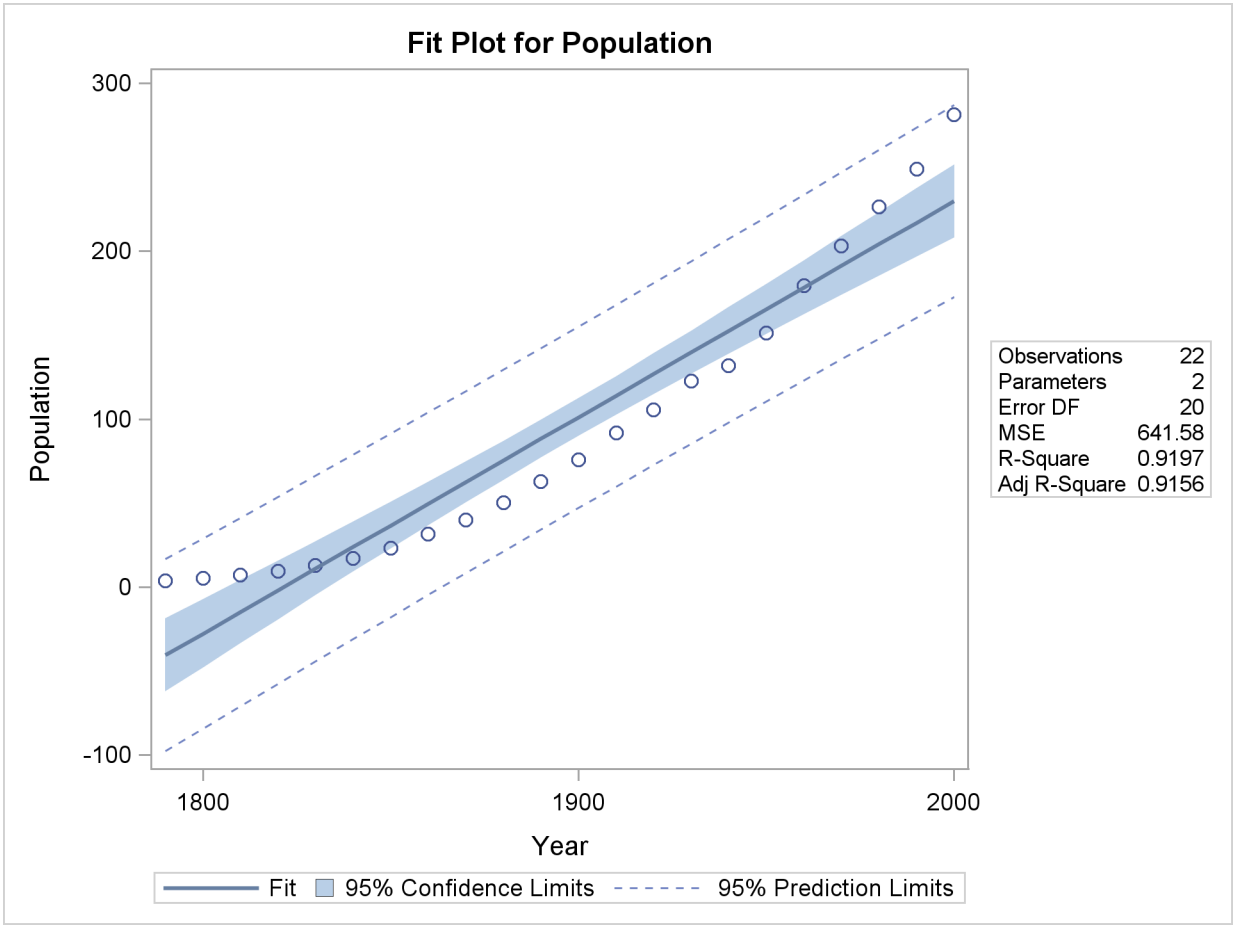


Figure 73.10 shows the "FitPlot" consisting of a scatter plot of the data overlaid with the regression line, and 95% confidence and prediction limits. Note that this plot also indicates that the model fails to capture the quadratic nature of the data. This plot is produced for models containing a single regressor. You can use the ALPHA= option in the model statement to change the significance level of the confidence band and prediction limits.

Figure 73.10 Fit Plot

These default plots provide strong evidence that the Yearsq needs to be added to the model. You can use the interactive feature of PROC REG to do this by specifying the following statements:

```
add YearSq;
print;
run;
```

The ADD statement requests that YearSq be added to the model, and the PRINT command causes the model to be refit and displays the ANOVA and parameter estimates for the new model. The print statement also produces updated ODS graphical displays.

Figure 73.11 displays the ANOVA table and parameter estimates for the new model.

Figure 73.11 ANOVA Table and Parameter Estimates

Analysis of Variance

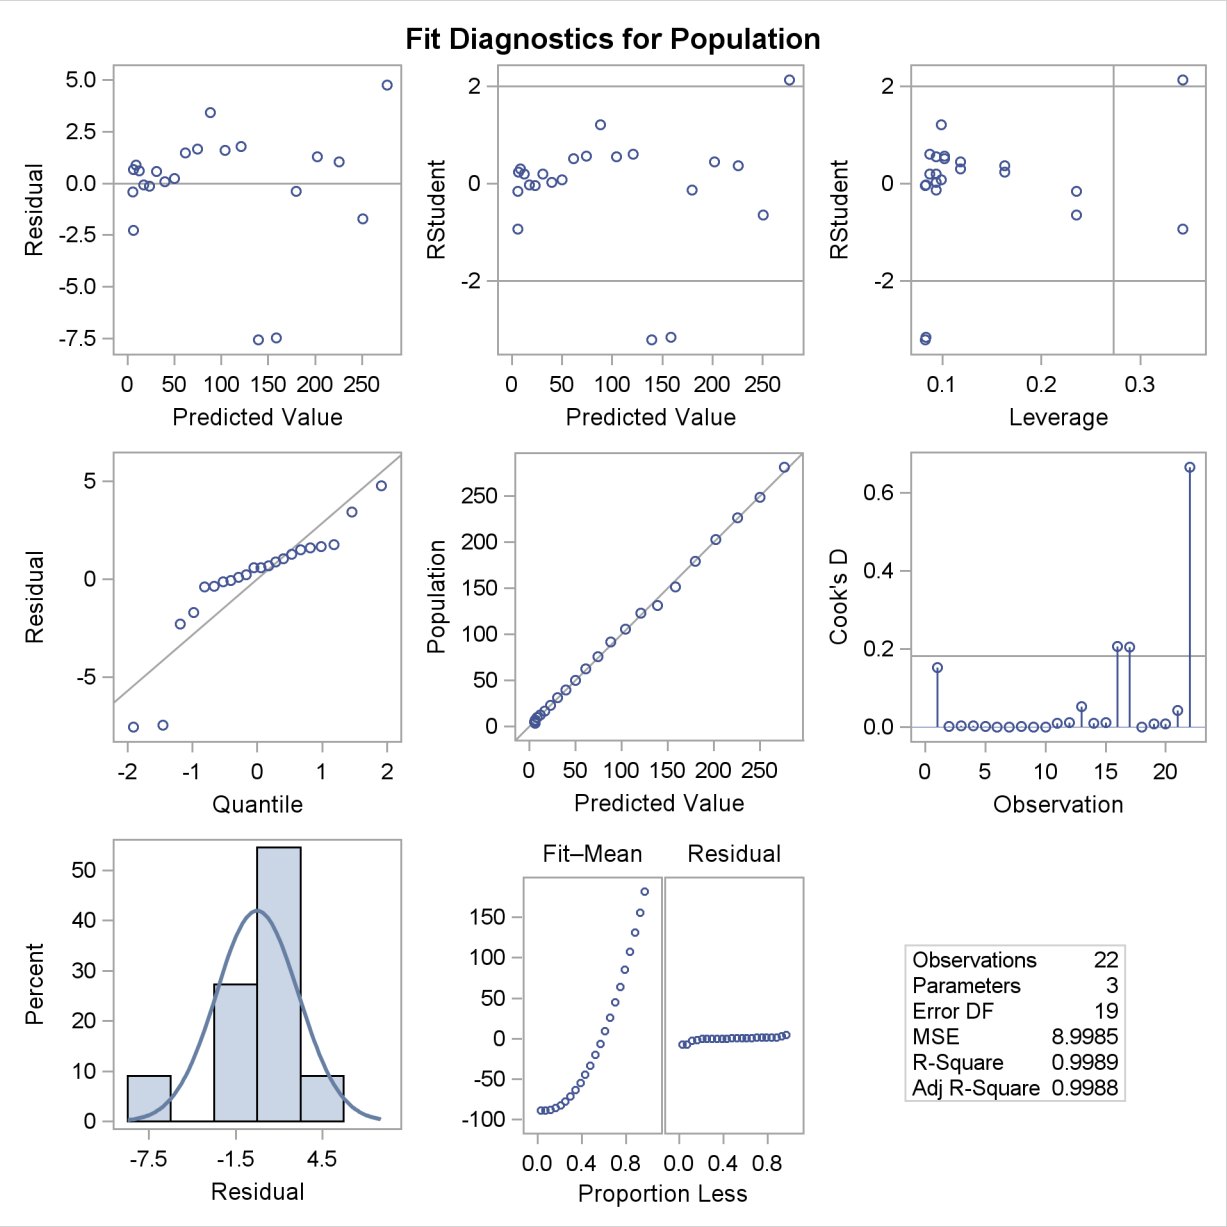
Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	2	159529	79765	8864.19	<.0001
Error	19	170.97193	8.99852		
Corrected Total	21	159700			

Root MSE	2.99975	R-Square	0.9989
Dependent Mean	94.64800	Adj R-Sq	0.9988
Coeff Var	3.16938		

Parameter Estimates

Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	1	21631	639.50181	33.82	<.0001
Year	1	-24.04581	0.67547	-35.60	<.0001
YearSq	1	0.00668	0.00017820	37.51	<.0001

The overall F statistic is still significant (F=8864.19, p<0.0001). The R-square has increased from 0.9197 to 0.9989, indicating that the model now accounts for 99.9% of the variation in Population. All effects are significant with p<0.0001 for each effect in the model.



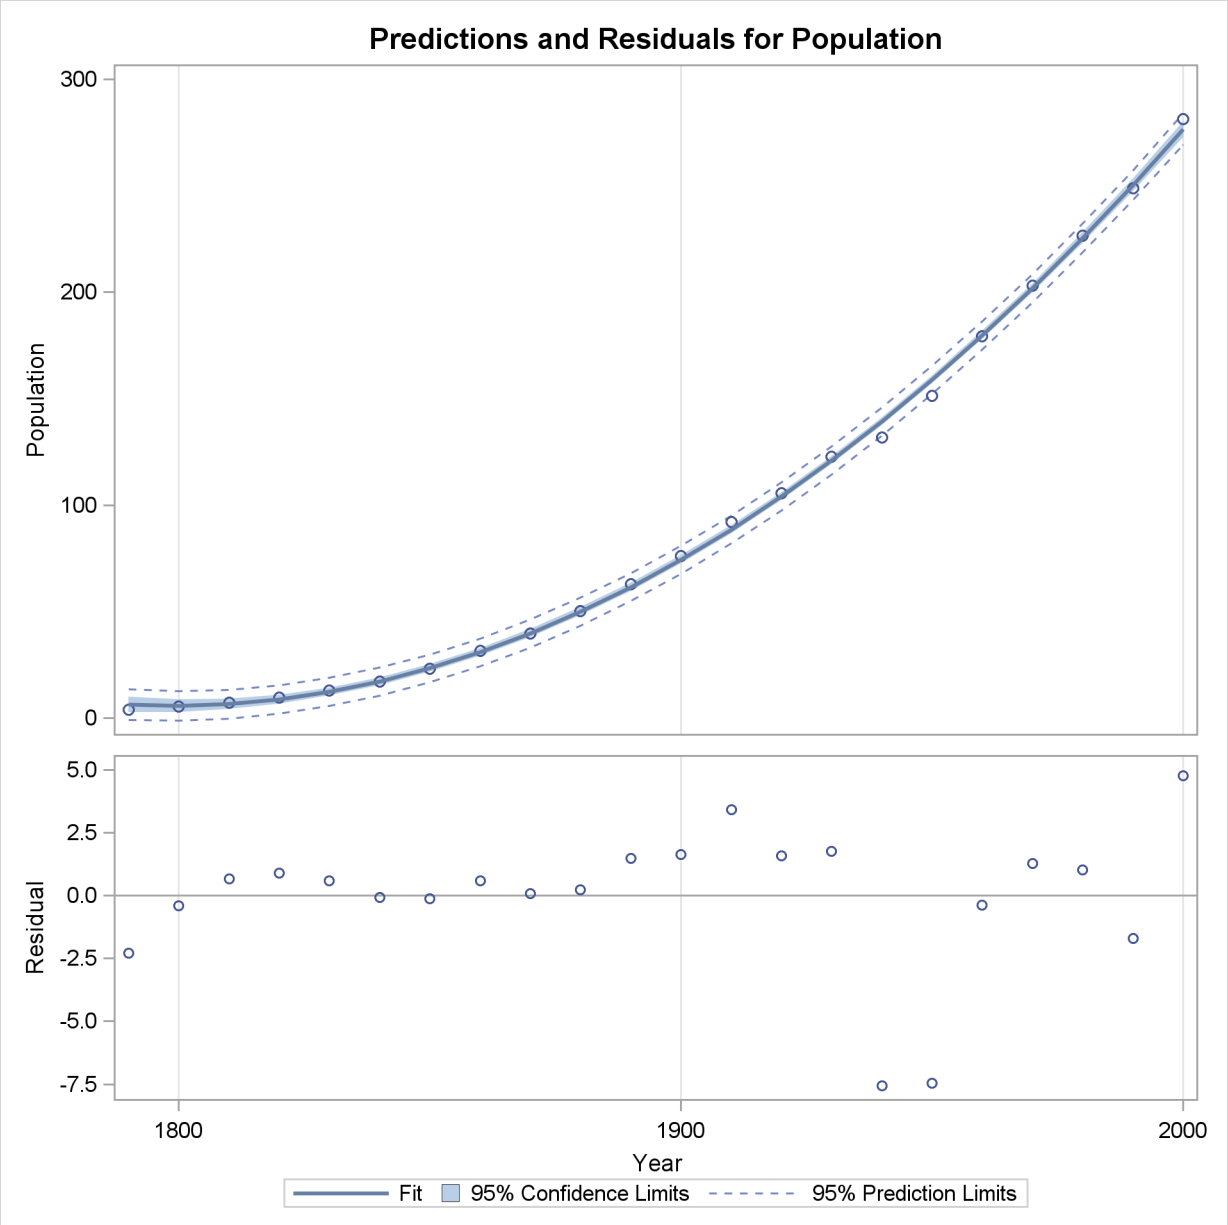
The fitted equation is now

$$\text{Population} = 21631 - 24.046 \times \text{Year} + 0.0067 \times \text{Yearsq}$$

Figure 73.12 show the panel of diagnostics for this quadratic polynomial model. These diagnostics indicate that this model is considerably more successful than the corresponding linear model:

- The plots of residuals and studentized residuals versus predicted values exhibit no obvious patterns.
- The points on the plot of the dependent variable versus the predicted values lie along a 45-degree line, indicating that the model successfully predicts the behavior of the dependent variable.
- The plot of studentized residual versus leverage shows that the years 1790 and 2000 are leverage points with 2000 showing up as an outlier. This is confirmed by the plot of Cook's D distance versus observation number. This suggests that while the quadratic model fits the current data well, the model might not be quite so successful over a wider range of data. You might want to investigate whether the population trend over the last couple of decades is growing slightly faster than quadratically.

Figure 73.12 Diagnostics Panel



When a model contains more than one regressor, PROC REG does not produce a fit plot. However, when all the regressors in the model are functions of a single variable, it is appropriate to plot predictions and residuals as a function of that variable. You request such plots by using the PLOTS=PREDICTIONS option in the PROC REG statement, as the following code illustrates:

```
proc reg data=USPopulation plots=predictions(X=Year);
   model Population=Year Yearsq;
quit;

ods graphics off;
```

Figure 73.13 shows the data, predictions, and residuals by Year. These plots confirm that the quadratic polynomial model successfully model the growth in U.S. population between the years 1780 and 2000.

Figure 73.13 Predictions and Residuals by Year

To complete an analysis of these data, you might want to examine influence statistics and, since the data are essentially time series data, examine the Durbin-Watson statistic.

Using PROC REG Interactively

The REG procedure can be used interactively. After you specify a model with a MODEL statement and run PROC REG with a RUN statement, a variety of statements can be executed without reinvoking PROC REG.

The section "Interactive Analysis" on page 5519 describes which statements can be used interactively. These interactive statements can be executed singly or in groups by following the single statement or group of statements with a RUN statement. Note that the MODEL statement can be repeated. This is an important difference from the GLM procedure, which supports only one MODEL statement.

If you use PROC REG interactively, you can end the REG procedure with a DATA step, another PROC step, an ENDSAS statement, or a QUIT statement. The syntax of the QUIT statement is

```
quit;
```

When you are using PROC REG interactively, additional RUN statements do not end PROC REG but tell the procedure to execute additional statements.

When a BY statement is used with PROC REG, interactive processing is not possible; that is, once the first RUN statement is encountered, processing proceeds for each BY group in the data set, and no further statements are accepted by the procedure.

When you use PROC REG interactively, you can fit a model, perform diagnostics, and then refit the model and perform diagnostics on the refitted model. Most of the interactive statements implicitly refit the model; for example, if you use the ADD statement to add a variable to the model, the regression equation is automatically recomputed. The two exceptions to this automatic recomputing are the PAINT and REWEIGHT statements. These two statements do not cause the model to be refitted. To refit the model, you can follow these statements either with a REFIT statement, which causes the model to be explicitly recomputed, or with another interactive statement that causes the model to be implicitly recomputed.

Syntax: REG Procedure

The following statements are available in PROC REG:

PROC REG < *options* > ;
< **label:** >**MODEL** *dependents*=< *regressors* > < / *options* > ;
BY *variables* ;
FREQ *variable* ;
ID *variables* ;
VAR *variables* ;
WEIGHT *variable* ;
ADD *variables* ;
DELETE *variables* ;
< **label:** >**MTEST** < *equation, . . . ,equation* > < / *options* > ;
OUTPUT < **OUT=***SAS-data-set* >< *keyword=names* > < . . . *keyword=names* > ;
PAINT < *condition* | **ALLOBS** > < / *options* > | < **STATUS** | **UNDO** > ;
RESTRICT *equation, . . . ,equation* ;
REWEIGHT < *condition* | **ALLOBS** > < / *options* > | < **STATUS** | **UNDO** > ;
PLOT < *yvariable*xvariable* > < =*symbol* > < . . . *yvariable*xvariable* > < =*symbol* > < / *options* > ;
PRINT < *options* > < **ANOVA** > < **MODELDATA** > ;
REFIT ;
RESTRICT *equation, . . . ,equation* ;
REWEIGHT < *condition* | **ALLOBS** > < / *options* > | < **STATUS** | **UNDO** > ;
< **label:** >**TEST** *equation,*< *,. . . ,equation* > < / *option* > ;

Although there are numerous statements and options available in PROC REG, many analyses use only a few of them. Often you can find the features you need by looking at an example or by scanning this section.

In the preceding list, brackets denote optional specifications, and vertical bars denote a choice of one of the specifications separated by the vertical bars. In all cases, *label* is optional.

The PROC REG statement is required. To fit a model to the data, you must specify the MODEL statement. If you want to use only the options available in the PROC REG statement, you do not need a MODEL statement, but you must use a VAR statement. (See the example in the section "OUTSSCP= Data Sets" on page 5518.) Several MODEL statements can be used. In addition, several MTEST, OUTPUT, PAINT, PLOT, PRINT, RESTRICT, and TEST statements can follow each MODEL statement.

The ADD, DELETE, and REWEIGHT statements are used interactively to change the regression model and the data used in fitting the model. The ADD, DELETE, MTEST, OUTPUT, PLOT, PRINT, RESTRICT, and TEST statements implicitly refit the model; changes made to the model are reflected in the results from these statements. The REFIT statement is used to refit the model explicitly and is most helpful when it follows PAINT and REWEIGHT statements, which do not refit the model.

The BY, FREQ, ID, VAR, and WEIGHT statements are optionally specified once for the entire PROC step, and they must appear before the first RUN statement.

When a TYPE=CORR, TYPE=COV, or TYPE=SSCP data set is used as an input data set to PROC REG, statements and options that require the original data are not available. Specifically, the OUTPUT, PAINT, PLOT, and REWEIGHT statements and the MODEL and PRINT statement options P, R, CLM, CLI, DW, DWPROB, INFLUENCE, PARTIAL, and PARTIALDATA are disabled.

You can specify the following statements with the REG procedure in addition to the PROC REG statement:

ADD	adds independent variables to the regression model.
BY	specifies variables to define subgroups for the analysis.
DELETE	deletes independent variables from the regression model.
FREQ	specifies a frequency variable.
ID	names a variable to identify observations in the tables.
MODEL	specifies the dependent and independent variables in the regression model, requests a model selection method, displays predicted values, and provides details on the estimates (according to which options are selected).
MTEST	performs multivariate tests across multiple dependent variables.
OUTPUT	creates an output data set and names the variables to contain predicted values, residuals, and other diagnostic statistics.
PAINT	paints points in scatter plots.
PLOT	generates scatter plots.
PRINT	displays information about the model and can reset options.
REFIT	refits the model.
RESTRICT	places linear equality restrictions on the parameter estimates.
REWEIGHT	excludes specific observations from analysis or changes the weights of observations used.
TEST	performs an F test on linear functions of the parameters.
VAR	lists variables for which crossproducts are to be computed, variables that can be interactively added to the model, or variables to be used in scatter plots.
WEIGHT	declares a variable to weight observations.

PROC REG Statement

PROC REG < *options* > **;**

The PROC REG statement is required. If you want to fit a model to the data, you must also use a MODEL statement. If you want to use only the PROC REG options, you do not need a MODEL statement, but you must use a VAR statement. If you do not use a MODEL statement, then the COVOUT and OUTEST= options are not available.

Table 73.1 lists the options you can use with the PROC REG statement. Note that any option specified in the PROC REG statement applies to all MODEL statements.

Table 73.1 PROC REG Statement Options

Option	Description
Data Set Options	
DATA=	names a data set to use for the regression
OUTEST=	outputs a data set that contains parameter estimates and other model fit summary statistics
OUTSSCP=	outputs a data set that contains sums of squares and crossproducts
COVOUT	outputs the covariance matrix for parameter estimates to the OUTEST= data set
EDF	outputs the number of regressors, the error degrees of freedom, and the model R^2 to the OUTEST= data set
OUTSEB	outputs standard errors of the parameter estimates to the OUTEST= data set
OUTSTB	outputs standardized parameter estimates to the OUTEST= data set. Use only with the RIDGE= or PCOMIT= option.
OUTVIF	outputs the variance inflation factors to the OUTEST= data set. Use only with the RIDGE= or PCOMIT= option.
PCOMIT=	performs incomplete principal component analysis and outputs estimates to the OUTEST= data set
PRESS	outputs the PRESS statistic to the OUTEST= data set
RIDGE=	performs ridge regression analysis and outputs estimates to the OUTEST= data set
RSQUARE	same effect as the EDF option
TABLEOUT	outputs standard errors, confidence limits, and associated test statistics of the parameter estimates to the OUTEST= data set
ODS Graphics Options	
PLOTS=	produces ODS graphical displays
Traditional Graphics Options	
ANNOTATE=	specifies an annotation data set
GOUT=	specifies the graphics catalog in which graphics output is saved
Display Options	
CORR	displays correlation matrix for variables listed in MODEL and VAR statements

Table 73.1 *continued*

Option	Description
SIMPLE	displays simple statistics for each variable listed in MODEL and VAR statements
USCCP	displays uncorrected sums of squares and crossproducts matrix
ALL	displays all statistics (CORR, SIMPLE, and USSCP)
NOPRINT	suppresses output
LINEPRINTER	creates plots requested as line printer plot
Other Options	
ALPHA=	sets significance value for confidence and prediction intervals and tests
SINGULAR=	sets criterion for checking for singularity

Following are explanations of the options that you can specify in the PROC REG statement (in alphabetical order).

Note that any option specified in the PROC REG statement applies to all MODEL statements.

ALL

requests the display of many tables. Using the ALL option in the PROC REG statement is equivalent to specifying ALL in every MODEL statement. The ALL option also implies the CORR, SIMPLE, and USSCP options.

ALPHA=*number*

sets the significance level used for the construction of confidence intervals. The value must be between 0 and 1; the default value of 0.05 results in 95% intervals. This option affects the PROC REG option TABLEOUT; the MODEL options CLB, CLI, and CLM; the OUTPUT statement keywords LCL, LCLM, UCL, and UCLM; the PLOT statement keywords LCL., LCLM., UCL., and UCLM.; and the PLOT statement options CONF and PRED.

ANNOTATE=*SAS-data-set*

ANNO=*SAS-data-set*

specifies an input data set containing annotate variables, as described in *SAS/GRAPH Software: Reference*. You can use this data set to add features to the traditional graphics that you request with the PLOT statement. Features provided in this data set are applied to all plots produced in the current run of PROC REG. To add features to individual plots, use the ANNOTATE= option in the PLOT statement. This option cannot be used if the LINEPRINTER option is specified.

CORR

displays the correlation matrix for all variables listed in the MODEL or VAR statement.

COVOUT

outputs the covariance matrices for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is also specified. See the section "OUTEST= Data Set" on page 5512.

DATA=*SAS-data-set*

names the SAS data set to be used by PROC REG. The data set can be an ordinary SAS data set or a TYPE=CORR, TYPE=COV, or TYPE=SSCP data set. If one of these special TYPE= data sets is used, the OUTPUT, PAINT, PLOT, and REWEIGHT statements, ODS Graphics, and some options in the MODEL and PRINT statements are not available. See Appendix A, "Special SAS Data Sets," for more information about TYPE= data sets. If the DATA= option is not specified, PROC REG uses the most recently created SAS data set.

EDF

outputs the number of regressors in the model excluding and including the intercept, the error degrees of freedom, and the model R^2 to the OUTEST= data set.

GOUT=*graphics-catalog*

specifies the graphics catalog in which traditional graphics output is saved. The default *graphics-catalog* is WORK.GSEG. The GOUT= option cannot be used if the LINEPRINTER option is specified.

LINEPRINTER | LP

creates plots requested as line printer plots. If you do not specify this option, requested plots are created on a high-resolution graphics device. This option is required if plots are requested and you do not have SAS/GRAPH software.

NOPRINT

suppresses the normal display of results. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, "Using the Output Delivery System," for more information.

OUTEST=*SAS-data-set*

requests that parameter estimates and optional model fit summary statistics be output to this data set. See the section "OUTEST= Data Set" on page 5512 for details. If you want to create a permanent SAS data set, you must specify a two-level name (refer to the section "SAS Files" in *SAS Language Reference: Concepts* for more information about permanent SAS data sets).

OUTSEB

outputs the standard errors of the parameter estimates to the OUTEST= data set. The value SEB for the variable _TYPE_ identifies the standard errors. If the RIDGE= or PCOMIT= option is specified, additional observations are included and identified by the values RIDGESEB and IPCSEB, respectively, for the variable _TYPE_. The standard errors for ridge regression estimates and IPC estimates are limited in their usefulness because these estimates are biased. This option is available for all model selection methods except RSQUARE, ADJRSQ, and CP.

OUTSSCP=*SAS-data-set*

requests that the sums of squares and crossproducts matrix be output to this TYPE=SSCP data set. See the section "OUTSSCP= Data Sets" on page 5518 for details. If you want to create a permanent SAS data set, you must specify a two-level name (refer to the section "SAS Files" in *SAS Language Reference: Concepts* for more information about permanent SAS data sets).

OUTSTB
outputs the standardized parameter estimates as well as the usual estimates to the OUTEST= data set when the RIDGE= or PCOMIT= option is specified. The values RIDGESTB and IPCSTB for the variable _TYPE_ identify ridge regression estimates and IPC estimates, respectively.

OUTVIF
outputs the variance inflation factors (VIF) to the OUTEST= data set when the RIDGE= or PCOMIT= option is specified. The factors are the diagonal elements of the inverse of the correlation matrix of regressors as adjusted by ridge regression or IPC analysis. These observations are identified in the output data set by the values RIDGEVIF and IPCVIF for the variable _TYPE_.

PCOMIT=*list*
requests an incomplete principal component (IPC) analysis for each value *m* in the list. The procedure computes parameter estimates by using all but the last *m* principal components. Each value of *m* produces a set of IPC estimates, which are output to the OUTEST= data set. The values of *m* are saved by the variable _PCOMIT_, and the value of the variable _TYPE_ is set to IPC to identify the estimates. Only nonnegative integers can be specified with the PCOMIT= option.

If you specify the PCOMIT= option, RESTRICT statements are ignored.

PLOTS <(*global-plot-options***)> <= *plot-request* <(***options***)>>**
PLOTS <(*global-plot-options***)> <= (***plot-request* <(***options***)>** **<... *plot-request* <(***options***)>>)>**
controls the plots produced through ODS Graphics. When you specify only one plot request, you can omit the parentheses around the plot request. Here are some examples:

```
plots         = none
plots         = diagnostics(unpack)
plots         = (all fit(stats)=none)
plots(label)  = (rstudentbyleverage cooksd)
plots(only)   = (diagnostics(stats=all) fit(nocli stats=(aic sbc)
```

You must enable ODS Graphics before requesting plots, as shown in the following example. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS."

```
ods graphics on;

proc reg;
   model y = x1-x10;
run;

proc reg plots=diagnostics(stats=(default aic sbc));
   model y = x1-x10;
run;

ods graphics off;
```

If you have enabled ODS Graphics but do not specify the PLOTS= option, then PROC REG produces a default set of plots. Table 73.2 lists the default set of plots produced.

Table 73.2 Default ODS Graphics Produced

Plot	Conditional On
DiagnosticsPanel	Unconditional
ResidualPlot	Unconditional
FitPlot	Model with one regressor (excluding intercept)
PartialPlot	PARTIAL option specified in MODEL statement
RidgePanel	RIDGE= option specified in PROC REG or MODEL statement

For models with multiple dependent variables, separate plots are produced for each dependent variable. For jobs with more than one MODEL statement, plots are produced for each model statement.

The *global-options* apply to all plots generated by the REG procedure, unless it is altered by a *specific-plot-option*. The following global plot options are available:

LABEL
specifies that the LABEL option be applied to each plot that supports a LABEL option. See the descriptions of the specific plots for details.

MAXPOINTS=NONE | *number*
specifies that plots with elements that require processing more than *number* points be suppressed. The default is MAXPOINTS=5000. This cutoff is ignored if you specify MAXPOINTS=NONE.

MODELLABEL
requests that the model label be displayed in the upper-left corner of all plots. This option is useful when you use more than one MODEL statement.

ONLY
suppress the default plots. Only plots specifically requested are displayed.

STATS=ALL | **DEFAULT** | **NONE** | (*plot-statistics*)
requests statistics that are included on the fit plot and diagnostics panel. Table 73.3 lists the statistics that you can request. STATS=ALL requests all these statistics; STATS=NONE suppresses them.

Table 73.3 Statistics Available on Plots

Keyword	Default	Description
ADJRSQ	x	adjusted R-square
AIC		Akaike's information criterion
BIC		Sawa's Bayesian information criterion
CP		Mallows' C_p statistic

Table 73.3 *continued*

Keyword	Default	Description
COEFFVAR		coefficient of variation
DEPMEAN		mean of dependent
DEFAULT		all default statistics
EDF	x	error degrees of freedom
GMSEP		estimated MSE of prediction, assuming multivariate normality
JP		final prediction error
MSE	x	mean squared error
NOBS	x	number of observations used
NPARM	x	number of parameters in the model (including the intercept)
PC		Amemiya's prediction criterion
RSQUARE	x	R-square
SBC		SBC statistic
SP		SP statistic
SSE		error sum of squares

You request statistics in addition to the default set by including the keyword DEFAULT in the *plot-statistics* list.

UNPACK
suppresses paneling.

USEALL
specifies that predicted values at data points with missing dependent variable(s) be included on appropriate plots. By default, only points used in constructing the SSCP matrix appear on plots.

The following specific plots are available:

ADJRSQ < (*adjrsq-options*) >
displays the adjusted R-square values for the models examined when you request variable selection with the SELECTION= option in the MODEL statement.

The following *adjrsq-options* are available for models where you request the RSQUARE, ADJRSQ, or CP selection method:

LABEL
requests that the model number corresponding to the one displayed in the "Subset Selection Summary" table be used to label the model with the largest adjusted R-square statistic at each value of the number of parameters.

LABELVARS
requests that the list (excluding the intercept) of the regressors in the relevant model be used to label the model with the largest adjusted R-square statistic at each value of the number of parameters.

AIC <(*aic-options*)>
displays Akaike's information criterion (AIC) for the models examined when you request variable selection with the SELECTION= option in the MODEL statement.

The following *aic-options* are available for models where you request the RSQUARE, ADJRSQ, or CP selection method:

LABEL
requests that the model number corresponding to the one displayed in the "Subset Selection Summary" table be used to label the model with the smallest AIC statistic at each value of the number of parameters.

LABELVARS
requests that the list (excluding the intercept) of the regressors in the relevant model be used to label the model with the smallest AIC statistic at each value of the number of parameters.

ALL
produces all appropriate plots.

BIC <(*bic-options*)>
displays Sawa's Bayesian information criterion (BIC) for the models examined when you request variable selection with the SELECTION= option in the MODEL statement.

The following *bic-options* are available for models where you request the RSQUARE, ADJRSQ, or CP selection method:

LABEL
requests that the model number corresponding to the one displayed in the "Subset Selection Summary" table be used to label the model with the smallest BIC statistic at each value of the number of parameters.

LABELVARS
requests that the list (excluding the intercept) of the regressors in the relevant model be used to label the model with the smallest BIC statistic at each value of the number of parameters.

COOKSD <(LABEL)>
plots Cook's D statistic by observation number. Observations whose Cook's D statistic lies above the horizontal reference line at value $4/n$, where n is the number of observations used, are deemed to be influential (Rawlings 1998). If you specify the LABEL option, then points deemed as influential are labeled. If you do not specify an ID variable, the observation number within the current BY group is used as the label. If you specify one or more ID variables in one or more ID statements, then the first ID variable you specify is used for the labeling.

CP <(*cp-options*)>
displays Mallow's C_p statistic for the models examined when you request variable selection with the SELECTION= option in the MODEL statement. For models where you request the RSQUARE, ADJRSQ, or CP selection, reference lines corresponding

to the equations $C_p = p$ and $C_p = 2p - p_{full}$, where p_{full} is the number of parameters in the full model (excluding the intercept) and p is the number of parameters in the subset model (including the intercept), are displayed on the plot of C_p versus p. For the purpose of parameter estimation, Hocking (1976) suggests selecting a model where $C_p \leq 2p - p_{full}$. For the purpose of prediction, Hocking suggests the criterion $C_p \leq p$. Mallows (1973) suggests that all subset models with C_p small and near p be considered for further study.

The following *cp-options* are available for models where you request the RSQUARE, ADJRSQ, or CP selection method:

LABEL

requests that the model number corresponding to the one displayed in the "Subset Selection Summary" table be used to label the model with the smallest C_p statistic at each value of the number of parameters.

LABELVARS

requests that the list (excluding the intercept) of the regressors in the relevant model be used to label the model with the smallest C_p statistic at each value of the number of parameters.

CRITERIA | CRITERIONPANEL < (*criteria-options*) >

produces a panel of fit criteria for the models examined when you request variable selection with the SELECTION= option in the MODEL statement. The fit criteria displayed are R-square, adjusted R-square, Mallow's C_p, Akaike's information criterion (AIC), Sawa's Bayesian information criterion (BIC), and Schwarz's Bayesian information criterion (SBC). For SELECTION=RSQUARE, SELECTION=ADJRSQ, or SELECTION=CP, scatter plots of these statistics versus the number of parameters (including the intercept) are displayed. For other selection methods, line plots of these statistics as function of the selection step number are displayed.

The following *criteria-options* are available:

LABEL

requests that the model number corresponding to the one displayed in the "Subset Selection Summary" table be used to label the best model at each value of the number of parameters. This option applies only to the RSQUARE, ADJRSQ, and CP selection methods.

LABELVARS

requests that the list (excluding the intercept) of the regressors in the relevant model be used to label the best model at each value of the number of parameters. Since these labels are typically long, LABELVARS is supported only when the panel is unpacked. This option applies only to the RSQUARE, ADJRSQ, and CP selection methods.

UNPACK

suppresses paneling. Separate plots are produced for each of the six fit statistics. For models where you request the RSQUARE, ADJRSQ, or CP selection, two reference lines corresponding to the equations $C_p = p$ and $C_p = 2p - p_{full}$,

where p_{full} is the number of parameters in the full model (excluding the intercept) and p is the number of parameters in the subset model (including the intercept), are displayed on the plot of C_p versus p. For the purpose of parameter estimation, Hocking (1976) suggests selecting a model where $C_p \leq 2p - p_{full}$. For the purpose of prediction, Hocking suggests the criterion $C_p \leq p$. Mallows (1973) suggests that all subset models with C_p small and near p be considered for further study.

DFBETAS < (*DFBETAS-options*) >

produces panels of DFBETAS by observation number for the regressors in the model. Note that each panel contains at most six plots, and multiple panels are used in the case where there are more than six regressors (including the intercept) in the model. Observations whose DFBETAS' statistics for a regressor are greater in magnitude than $2/\sqrt{n}$, where n is the number of observations used, are deemed to be influential for that regressor (Rawlings 1998).

The following *DFBETAS-options* are available:

COMMONAXES

specifies that the same DFBETAS axis be used in all panels when multiple panels are needed. By default, the DFBETAS axis is chosen independently for each panel. If you also specify the *UNPACK* option, then the same DFBETAS axis is used for each regressor.

LABEL

specifies that observations whose magnitude are greater than $2/\sqrt{n}$ be labeled. If you do not specify an ID variable, the observation number within the current BY group is used as the label. If you specify one or more ID variables on one or more ID statements, then the first ID variable you specify is used for the labeling.

UNPACK

suppresses paneling. The DFBETAS statistics for each regressor are displayed on separate plots.

DFFITS < (LABEL) >

plots the DFFITS statistic by observation number. Observations whose DFFITS' statistic is greater in magnitude than $2\sqrt{p/n}$, where n is the number of observations used and p is the number of regressors, are deemed to be influential (Rawlings 1998). If you specify the LABEL option, then these influential observations are labeled. If you do not specify an ID variable, the observation number within the current BY group is used as the label. If you specify one or more ID variables in one or more ID statements, then the first ID variable you specify is used for the labeling.

DIAGNOSTICS < (*diagnostics-options*) >
produces a summary panel of fit diagnostics:

- residuals versus the predicted values
- studentized residuals versus the predicted values
- studentized residuals versus the leverage
- normal quantile plot of the residuals
- dependent variable values versus the predicted values
- Cook's D versus observation number
- histogram of the residuals
- "Residual-Fit" (or RF) plot consisting of side-by-side quantile plots of the centered fit and the residuals
- box plot of the residuals if you specify the STATS=NONE suboption

You can specify the following *diagnostics-options*:

STATS=*stats-options*
determines which model fit statistics are included in the panel. See the global STATS= suboption for details. The PLOTS= suboption of the DIAGNOSTICSPANEL option overrides the global PLOTS= suboption.

UNPACK
produces the eight plots in the panel as individual plots. Note that you can also request individual plots in the panel by name without having to unpack the panel.

FITPLOT | FIT < (*fit-options*) >
produces a scatter plot of the data overlaid with the regression line, confidence band, and prediction band for models that depend on at most one regressor excluding the intercept.

You can specify the following *fit-options*:

NOCLI
suppresses the prediction limits.

NOCLM
suppresses the confidence limits.

NOLIMITS
suppresses the confidence and prediction limits.

STATS=*stats-options*
determines which model fit statistics are included in the panel. See the global STATS= suboption for details. The PLOTS= suboption of the FITPLOT option overrides the global PLOTS= suboption.

OBSERVEDBYPREDICTED < (LABEL) >
plots dependent variable values by the predicted values. If you specify the LABEL option, then points deemed as outliers or influential (see the RSTUDENTBYLEVERAGE option for details) are labeled.

NONE
suppresses all plots.

PARTIAL < (UNPACK) >
produces panels of partial regression plots for each regressor with at most six regressors per panel. If you specify the UNPACK option, then all partial plot panels are unpacked.

PREDICTIONS (X=*numeric-variable* **<** *prediction-options* **>)**
produces a panel of two plots whose horizontal axis is the variable you specify in the required X= suboption. The upper plot in the panel is a scatter plot of the residuals. The lower plot shows the data overlaid with the regression line, confidence band, and prediction band. This plot is appropriate for models where all regressors are known to be functions of the single variable that you specify in the X= suboption.

You can specify the following *prediction-options*:

NOCLI
suppresses the prediction limits.

NOCLM
suppresses the confidence limits

NOLIMITS
suppresses the confidence and prediction limits

SMOOTH
requests a nonparametric smooth of the residuals as a function of the variable you specify in the X= suboption. This nonparametric fit is a loess fit that uses local linear polynomials, linear interpolation, and a smoothing parameter selected that yields a local minimum of the corrected Akaike information criterion (AICC). See Chapter 50, "The LOESS Procedure," for details. The SMOOTH option is not supported when a FREQ statement is used.

UNPACK
suppresses paneling.

QQPLOT | QQ
produces a normal quantile plot of the residuals.

RESIDUALBOXPLOT | BOXPLOT < (LABEL) >
produces a box plot consisting of the residuals. If you specify label option, points deemed far-outliers are labeled. If you do not specify an ID variable, the observation number within the current BY group is used as the label. If you specify one or more ID variables in one or more ID statements, then the first ID variable you specify is used for the labeling.

RESIDUALBYPREDICTED < (LABEL) >
plots residuals by predicted values. If you specify the LABEL option, then points deemed as outliers or influential (see the RSTUDENTBYLEVERAGE option for details) are labeled.

RESIDUALS < *residual-options***) >**

produces panels of the residuals versus the regressors in the model. Note that each panel contains at most six plots, and multiple panels are used in the case where there are more than six regressors (including the intercept) in the model.

The following *residual-options* are available:

SMOOTH

requests a nonparametric smooth of the residuals for each regressor. Each nonparametric fit is a loess fit that uses local linear polynomials, linear interpolation, and a smoothing parameter selected that yields a local minimum of the corrected Akaike information criterion (AICC). See Chapter 50, "The LOESS Procedure," for details. The SMOOTH option is not supported when a FREQ statement is used.

UNPACK

suppresses paneling.

RESIDUALHISTOGRAM

produces a histogram of the residuals.

RFPLOT | RF

produces a "Residual-Fit" (or RF) plot consisting of side-by-side quantile plots of the centered fit and the residuals. This plot "shows how much variation in the data is explained by the fit and how much remains in the residuals" (Cleveland 1993).

RIDGE | RIDGEPANEL | RIDGEPLOT <(*ridge-options***)>**

creates panels of VIF values and standardized ridge estimates by ridge values for each coefficient. The VIF values for each coefficient are connected by lines and are displayed in the upper plot in each panel. The points corresponding to the standardized estimates of each coefficient are connected by lines and are displayed in the lower plot in each panel. By default, at most 10 coefficients are represented in a panel and multiple panels are produced for models with more than 10 regressors. For ridge estimates to be computed and plotted, the OUTEST= option must be specified in the PROC REG statement, and the RIDGE= list must be specified in either the PROC REG or the MODEL statement. (See Example 73.5.)

The following *ridge-options* are available:

COMMONAXES

specifies that the same VIF axis and the same standardized estimate axis are used in all panels when multiple panels are needed. By default, these axes are chosen independently for the regressors shown in each panel.

RIDGEAXIS=LINEAR | LOG

specifies the axis type used to display the ridge parameters. The default is RIDGEAXIS=LINEAR. Note that the point with the ridge parameter equal to zero is not displayed if you specify RIDGEAXIS=LOG.

UNPACK
suppresses paneling. The traces of the VIF statistics and standardized estimates are shown in separate plots.

VARSPERPLOT=ALL

VARSPERPLOT=*number*
specifies the maximum number of regressors displayed in each panel or in each plot if you additionally specify the *UNPACK* option. If you specify VARSPERPLOT=ALL, then the VIF values and ridge traces for all regressors are displayed in a single panel.

VIFAXIS=LINEAR | LOG
specifies the axis type used to display the VIF statistics. The default is VIFAXIS=LINEAR.

RSQUARE < (*rsquare-options***) >**
displays the R-square values for the models examined when you request variable selection with the SELECTION= option in the MODEL statement.

The following *rsquare-options* are available for models where you request the RSQUARE, ADJRSQ, or CP selection method:

LABEL
requests that the model number corresponding to the one displayed in the "Subset Selection Summary" table be used to label the model with the largest R-square statistic at each value of the number of parameters.

LABELVARS
requests that the list (excluding the intercept) of the regressors in the relevant model be used to label the model with the largest R-square statistic at each value of the number of parameters.

RSTUDENTBYLEVERAGE < (LABEL) >
plots studentized residuals by leverage. Observations whose studentized residuals lie outside the band between the reference lines RSTUDENT $= \pm 2$ are deemed outliers. Observations whose leverage values are greater than the vertical reference LEVERAGE $= 2p/n$, where p is the number of parameters excluding the intercept and n is the number of observations used, are deemed influential (Rawlings 1998). If you specify the LABEL option, then points deemed as outliers or influential are labeled. If you do not specify an ID variable, the observation number within the current BY group is used as the label. If you specify one or more ID variables in one or more ID statements, then the first ID variable you specify is used for the labeling.

RSTUDENTBYPREDICTED < (LABEL) >
plots studentized residuals by predicted values. If you specify the LABEL option, then points deemed as outliers or influential (see the RSTUDENTBYLEVERAGE option for details) are labeled.

SBC <(*sbc-options*)>
displays Schwarz's Bayesian information criterion (SBC) for the models examined when you request variable selection with the SELECTION= option in the MODEL statement.

The following *sbc-options* are available for models where you request the RSQUARE, ADJRSQ, or CP selection method:

LABEL
requests that the model number corresponding to the one displayed in the "Subset Selection Summary" table be used to label the model with the smallest SBC statistic at each value of the number of parameters.

LABELVARS
requests that the list (excluding the intercept) of the regressors in the relevant model be used to label the model with the smallest SBC statistic at each value of the number of parameters.

PRESS
outputs the PRESS statistic to the OUTEST= data set. The values of this statistic are saved in the variable _PRESS_. This option is available for all model selection methods except RSQUARE, ADJRSQ, and CP.

RIDGE=*list*
requests a ridge regression analysis and specifies the values of the ridge constant k (see the section "Computations for Ridge Regression and IPC Analysis" on page 5583). Each value of k produces a set of ridge regression estimates that are placed in the OUTEST= data set. The values of k are saved by the variable _RIDGE_, and the value of the variable _TYPE_ is set to RIDGE to identify the estimates.

Only nonnegative numbers can be specified with the RIDGE= option. Example 73.5 illustrates this option.

If ODS Graphics is in effect (see the section "ODS Graphics" on page 5589), then ridge regression plots are automatically produced. These plots consist of panels containing ridge traces for the regressors, with at most eight ridge traces per panel.

If you specify the RIDGE= option, RESTRICT statements are ignored.

RSQUARE
has the same effect as the EDF option.

SIMPLE
displays the sum, mean, variance, standard deviation, and uncorrected sum of squares for each variable used in PROC REG.

SINGULAR=*n*
tunes the mechanism used to check for singularities. The default value is machine dependent but is approximately 1E−7 on most machines. This option is rarely needed.

Singularity checking is described in the section "Computational Methods" on page 5584.

TABLEOUT

outputs the standard errors and $100(1-\alpha)\%$ confidence limits for the parameter estimates, the t statistics for testing if the estimates are zero, and the associated p-values to the OUTEST= data set. The _TYPE_ variable values STDERR, LnB, UnB, T, and PVALUE, where $n = 100(1-\alpha)$, identify these rows in the OUTEST= data set. The α level can be set with the ALPHA= option in the PROC REG or MODEL statement. The OUTEST= option must be specified in the PROC REG statement for this option to take effect.

USSCP

displays the uncorrected sums-of-squares and crossproducts matrix for all variables used in the procedure.

ADD Statement

ADD *variables* **;**

The ADD statement adds independent variables to the regression model. Only variables used in the VAR statement or used in MODEL statements before the first RUN statement can be added to the model. You can use the ADD statement interactively to add variables to the model or to include a variable that was previously deleted with a DELETE statement. Each use of the ADD statement modifies the MODEL label.

See the section "Interactive Analysis" on page 5519 for an example.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC REG to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in the order of the BY variables. The *variables* are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives.

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the REG procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

When a BY statement is used with PROC REG, interactive processing is not possible; that is, once the first RUN statement is encountered, processing proceeds for each BY group in the data set, and no further statements are accepted by the procedure. A BY statement that appears after the first RUN statement is ignored.

For more information about the BY statement, see *SAS Language Reference: Contents*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

DELETE Statement

DELETE *variables* **;**

The DELETE statement deletes independent variables from the regression model. The DELETE statement performs the opposite function of the ADD statement and is used in a similar manner. Each use of the DELETE statement modifies the MODEL label.

For an example of how the ADD statement is used (and how the DELETE statement can be used), see the section "Interactive Analysis" on page 5519.

FREQ Statement

FREQ *variable* **;**

When a FREQ statement appears, each observation in the input data set is assumed to represent n observations, where n is the value of the FREQ variable. The analysis produced when you use a FREQ statement is the same as an analysis produced by using a data set that contains n observations in place of each observation in the input data set. When the procedure determines degrees of freedom for significance tests, the total number of observations is considered to be equal to the sum of the values of the FREQ variable.

If the value of the FREQ variable is missing or is less than 1, the observation is not used in the analysis. If the value is not an integer, only the integer portion is used.

The FREQ statement must appear before the first RUN statement, or it is ignored.

ID Statement

ID *variables* **;**

When one of the MODEL statement options CLI, CLM, P, R, and INFLUENCE is requested, the variables listed in the ID statement are displayed beside each observation. These variables can be used to identify each observation. If the ID statement is omitted, the observation number is used to identify the observations.

Although there are no restrictions on the length of ID variables, PROC REG might truncate ID values to 16 characters for display purposes.

MODEL Statement

< *label:* > MODEL *dependents=< regressors > < / options >* **;**

After the keyword MODEL, the dependent (response) variables are specified, followed by an equal sign and the regressor variables. Variables specified in the MODEL statement must be numeric variables in the data set being analyzed. For example, if you want to specify a quadratic term for variable *X1* in the model, you cannot use X1*X1 in the MODEL statement but must create a new variable (for example, X1SQUARE=X1*X1) in a DATA step and use this new variable in the MODEL statement. The label in the MODEL statement is optional.

Table 73.4 lists the options available in the MODEL statement. Equations for the statistics available are given in the section "Model Fit and Diagnostic Statistics" on page 5557.

Table 73.4 MODEL Statement Options

Option	Description
Model Selection and Details of Selection	
SELECTION=	specifies model selection method
BEST=	specifies maximum number of subset models displayed or output to the OUTEST= data set
DETAILS	produces summary statistics at each step
DETAILS=	specifies the display details for FORWARD, BACKWARD, and STEPWISE methods
GROUPNAMES=	provides names for groups of variables
INCLUDE=	includes first n variables in the model
MAXSTEP=	specifies maximum number of steps that might be performed
NOINT	fits a model without the intercept term
PCOMIT=	performs incomplete principal component analysis and outputs estimates to the OUTEST= data set
RIDGE=	performs ridge regression analysis and outputs estimates to the OUTEST= data set
SLE=	sets criterion for entry into model
SLS=	sets criterion for staying in model
START=	specifies number of variables in model to begin the comparing and switching process
STOP=	stops selection criterion
Statistics	
ADJRSQ	computes adjusted R^2
AIC	computes Akaike's information criterion
B	computes parameter estimates for each model
BIC	computes Sawa's Bayesian information criterion
CP	computes Mallows' C_p statistic

Table 73.4 *continued*

Option	Description
GMSEP	computes estimated MSE of prediction assuming multivariate normality
JP	computes J_p, the final prediction error
MSE	computes MSE for each model
PC	computes Amemiya's prediction criterion
RMSE	displays root MSE for each model
SBC	computes the SBC statistic
SP	computes S_p statistic for each model
SSE	computes error sum of squares for each model
Data Set Options	
EDF	outputs the number of regressors, the error degrees of freedom, and the model R^2 to the OUTEST= data set
OUTSEB	outputs standard errors of the parameter estimates to the OUTEST= data set
OUTSTB	outputs standardized parameter estimates to the OUTEST= data set. Use only with the RIDGE= or PCOMIT= option.
OUTVIF	outputs the variance inflation factors to the OUTEST= data set. Use only with the RIDGE= or PCOMIT= option.
PRESS	outputs the PRESS statistic to the OUTEST= data set
RSQUARE	has same effect as the EDF option
Regression Calculations	
I	displays inverse of sums of squares and crossproducts
XPX	displays sums-of-squares and crossproducts matrix
Details on Estimates	
ACOV	displays heteroscedasticity- consistent covariance matrix of estimates and heteroscedasticity-consistent standard errors
ACOVMETHOD=	specifies method for computing the asymptotic heteroscedasticity-consistent covariance matrix
COLLIN	produces collinearity analysis
COLLINOINT	produces collinearity analysis with intercept adjusted out
CORRB	displays correlation matrix of estimates
COVB	displays covariance matrix of estimates
HCC	displays heteroscedasticity-consistent standard errors
HCCMETHOD=	specifies method for computing the asymptotic heteroscedasticity-consistent covariance matrix
LACKFIT	performs lack-of-fit test
PARTIALR2	displays squared semipartial correlation coefficients computed using Type I sums of squares
PCORR1	displays squared partial correlation coefficients computed using Type I sums of squares
PCORR2	displays squared partial correlation coefficients computed using Type II sums of squares

Table 73.4 *continued*

Option	Description
SCORR1	displays squared semipartial correlation coefficients computed using Type I sums of squares
SCORR2	displays squared semipartial correlation coefficients computed using Type II sums of squares
SEQB	displays a sequence of parameter estimates during selection process
SPEC	tests that first and second moments of model are correctly specified
SS1	displays the sequential sums of squares
SS2	displays the partial sums of squares
STB	displays standardized parameter estimates
TOL	displays tolerance values for parameter estimates
WHITE	displays heteroscedasticity-consistent standard errors
VIF	computes variance-inflation factors
Predicted and Residual Values	
CLB	computes $100(1-\alpha)\%$ confidence limits for the parameter estimates
CLI	computes $100(1-\alpha)\%$ confidence limits for an individual predicted value
CLM	computes $100(1-\alpha)\%$ confidence limits for the expected value of the dependent variable
DW	computes a Durbin-Watson statistic
DWPROB	computes a Durbin-Watson statistic and p-value
INFLUENCE	computes influence statistics
P	computes predicted values
PARTIAL	displays partial regression plots for each regressor
PARTIALDATA	displays partial regression data
R	produces analysis of residuals
Display Options and Other Options	
ALL	requests the following options: ACOV, CLB, CLI, CLM, CORRB, COVB, HCC, I, P, PCORR1, PCORR2, R, SCORR1, SCORR2, SEQB, SPEC, SS1, SS2, STB, TOL, VIF, XPX
ALPHA=	sets significance value for confidence and prediction intervals and tests
NOPRINT	suppresses display of results
SIGMA=	specifies the true standard deviation of error term for computing CP and BIC
SINGULAR=	sets criterion for checking for singularity

You can specify the following options in the MODEL statement after a slash (/).

ACOV

displays the estimated asymptotic covariance matrix of the estimates under the hypothesis of heteroscedasticity and heteroscedasticity-consistent standard errors of parameter estimates. See the HCCMETHOD= option and the HCC option and the section "Testing for Heteroscedasticity" on page 5575 for more information.

ACOVMETHOD=0,1,2, or 3

See the HCCMETHOD= option.

ADJRSQ

computes R^2 adjusted for degrees of freedom for each model selected (Darlington 1968; Judge et al. 1980).

AIC

outputs Akaike's information criterion for each model selected (Akaike 1969; Judge et al. 1980) to the OUTEST= data set. If SELECTION=ADJRSQ, SELECTION=RSQUARE, or SELECTION=CP is specified, then the AIC statistic is also added to the SubsetSelSummary table.

ALL

requests all these options: ACOV, CLB, CLI, CLM, CORRB, COVB, HCC, I, P, PCORR1, PCORR2, R, SCORR1, SCORR2, SEQB, SPEC, SS1, SS2, STB, TOL, VIF, and XPX.

ALPHA=*number*

sets the significance level used for the construction of confidence intervals for the current MODEL statement. The value must be between 0 and 1; the default value of 0.05 results in 95% intervals. This option affects the MODEL options CLB, CLI, and CLM; the OUTPUT statement keywords LCL, LCLM, UCL, and UCLM; the PLOT statement keywords LCL., LCLM., UCL., and UCLM.; and the PLOT statement options CONF and PRED. If you specify this option in the MODEL statement, it takes precedence over the ALPHA= option in the PROC REG statement.

B

is used with the RSQUARE, ADJRSQ, and CP model-selection methods to compute estimated regression coefficients for each model selected.

BEST=*n*

is used with the RSQUARE, ADJRSQ, and CP model-selection methods. If SELECTION=CP or SELECTION=ADJRSQ is specified, the BEST= option specifies the maximum number of subset models to be displayed or output to the OUTEST= data set. For SELECTION=RSQUARE, the BEST= option requests the maximum number of subset models for each size.

If the BEST= option is used without the B option (displaying estimated regression coefficients), the variables in each MODEL are listed in order of inclusion instead of the order in which they appear in the MODEL statement.

If the BEST= option is omitted and the number of regressors is less than 11, all possible subsets are evaluated. If the BEST= option is omitted and the number of regressors is greater

than 10, the number of subsets selected is, at most, equal to the number of regressors. A small value of the BEST= option greatly reduces the CPU time required for large problems.

BIC

outputs Sawa's Bayesian information criterion for each model selected (Sawa 1978; Judge et al. 1980) to the OUTEST= data set. If SELECTION=ADJRSQ, SELECTION=RSQUARE, or SELECTION=CP is specified, then the BIC statistic is also added to the SubsetSelSummary table.

CLB

requests the $100(1-\alpha)\%$ upper and lower confidence limits for the parameter estimates. By default, the 95% limits are computed; the ALPHA= option in the PROC REG or MODEL statement can be used to change the α level. If any of the MODEL statement options ACOV, HCC, or WHITE are in effect, then the CLB option also produces heteroscedasticity-consistent $100(1-\alpha)\%$ upper and lower confidence limits for the parameter estimates.

CLI

requests the $100(1-\alpha)\%$ upper and lower confidence limits for an individual predicted value. By default, the 95% limits are computed; the ALPHA= option in the PROC REG or MODEL statement can be used to change the α level. The confidence limits reflect variation in the error, as well as variation in the parameter estimates. See the section "Predicted and Residual Values" on page 5531 and Chapter 4, "Introduction to Regression Procedures," for more information.

CLM

displays the $100(1-\alpha)\%$ upper and lower confidence limits for the expected value of the dependent variable (mean) for each observation. By default, the 95% limits are computed; the ALPHA= in the PROC REG or MODEL statement can be used to change the α level. This is not a prediction interval (see the CLI option) because it takes into account only the variation in the parameter estimates, not the variation in the error term. See the section "Predicted and Residual Values" on page 5531 and Chapter 4, "Introduction to Regression Procedures," for more information.

COLLIN

requests a detailed analysis of collinearity among the regressors. This includes eigenvalues, condition indices, and decomposition of the variances of the estimates with respect to each eigenvalue. See the section "Collinearity Diagnostics" on page 5555.

COLLINOINT

requests the same analysis as the COLLIN option with the intercept variable adjusted out rather than included in the diagnostics. See the section "Collinearity Diagnostics" on page 5555.

CORRB

displays the correlation matrix of the estimates. This is the $(\mathbf{X}'\mathbf{X})^{-1}$ matrix scaled to unit diagonals.

COVB

displays the estimated covariance matrix of the estimates. This matrix is $(\mathbf{X}'\mathbf{X})^{-1}s^2$, where s^2 is the estimated mean squared error.

CP

outputs Mallows' C_p statistic for each model selected (Mallows 1973; Hocking 1976) to the OUTEST= data set. See the section "Criteria Used in Model-Selection Methods" on page 5526 for a discussion of the use of C_p. If SELECTION=ADJRSQ, SELECTION=RSQUARE, or SELECTION=CP is specified, then the C_p statistic is also added to the SubsetSelSummary table.

DETAILS

DETAILS=*name*

specifies the level of detail produced when the BACKWARD, FORWARD, or STEPWISE method is used, where *name* can be ALL, STEPS, or SUMMARY. The DETAILS or DETAILS=ALL option produces entry and removal statistics for each variable in the model building process, ANOVA and parameter estimates at each step, and a selection summary table. The option DETAILS=STEPS provides the step information and summary table. The option DETAILS=SUMMARY produces only the summary table. The default if the DETAILS option is omitted is DETAILS=STEPS.

DW

calculates a Durbin-Watson statistic to test whether or not the errors have first-order autocorrelation. (This test is appropriate only for time series data.) Note that your data should be sorted by the date/time ID variable before you use this option. The sample autocorrelation of the residuals is also produced. See the section "Autocorrelation in Time Series Data" on page 5581.

DWPROB

calculates a Durbin-Watson statistic and a p-value to test whether or not the errors have first-order autocorrelation. Note that it is not necessary to specify the DW option if the DWPROB option is specified. (This test is appropriate only for time series data.) Note that your data should be sorted by the date/time ID variable before you use this option. The sample autocorrelation of the residuals is also produced. See the section "Autocorrelation in Time Series Data" on page 5581.

EDF

outputs the number of regressors in the model excluding and including the intercept, the error degrees of freedom, and the model R^2 to the OUTEST= data set.

GMSEP

outputs the estimated mean square error of prediction assuming that both independent and dependent variables are multivariate normal (Stein 1960; Darlington 1968) to the OUTEST= data set. (Note that Hocking's formula (1976, eq. 4.20) contains a misprint: "$n - 1$" should read "$n - 2$.") If SELECTION=ADJRSQ, SELECTION=RSQUARE, or SELECTION=CP is specified, then the GMSEP statistic is also added to the SubsetSelSummary table.

GROUPNAMES=*'name1' 'name2' ...*

provides names for variable groups. This option is available only in the BACKWARD, FORWARD, and STEPWISE methods. The group name can be up to 32 characters. Subsets of independent variables listed in the MODEL statement can be designated as variable groups. This is done by enclosing the appropriate variables in braces. Variables in the same group are entered into or removed from the regression model at the same time. However, if the

tolerance of any variable (see the TOL option on page 5480) in a group is less than the setting of the SINGULAR= option, then the variable is not entered into the model with the rest of its group. If the GROUPNAMES= option is not used, then the names GROUP1, GROUP2, ..., GROUP*n* are assigned to groups encountered in the MODEL statement. Variables not enclosed by braces are used as groups of a single variable.

For example:

```
model y={x1 x2} x3 / selection=stepwise
  groupnames='x1 x2' 'x3';
```

Another example:

```
model y={ht wgt age} bodyfat / selection=forward
  groupnames='htwgtage' 'bodyfat';
```

HCC

requests heteroscedasticity-consistent standard errors of the parameter estimates. You can use the HCCMETHOD= option to specify the method used to compute the heteroscedasticity-consistent covariance matrix.

HCCMETHOD=0,1,2, or 3

specifies the method used to obtain a heteroscedasticity-consistent covariance matrix for use with the ACOV, HCC, or WHITE option in the MODEL statement and for heteroscedasticity-consistent tests with the TEST statement. The default is HCCMETHOD=0. See the section "Testing for Heteroscedasticity" on page 5575 for details.

I

displays the $(\mathbf{X}'\mathbf{X})^{-1}$ matrix. The inverse of the crossproducts matrix is bordered by the parameter estimates and SSE matrices.

INCLUDE=*n*

forces the first n independent variables listed in the MODEL statement to be included in all models. The selection methods are performed on the other variables in the MODEL statement. The INCLUDE= option is not available with SELECTION=NONE.

INFLUENCE

requests a detailed analysis of the influence of each observation on the estimates and the predicted values. See the section "Influence Statistics" on page 5559 for details.

JP

outputs J_p, the estimated mean square error of prediction for each model selected assuming that the values of the regressors are fixed and that the model is correct to the OUTEST= data set. The J_p statistic is also called the final prediction error (FPE) by Akaike (Nicholson 1948; Lord 1950; Mallows 1967; Darlington 1968; Rothman 1968; Akaike 1969; Hocking 1976; Judge et al. 1980). If SELECTION=ADJRSQ, SELECTION=RSQUARE, or SELECTION=CP is specified, then the J_p statistic is also added to the SubsetSelSummary table.

LACKFIT

performs a lack-of-fit test. See the section "Testing for Lack of Fit" on page 5576 for more information. Refer to Draper and Smith (1981) for a discussion of lack-of-fit tests.

MSE

computes the mean square error for each model selected (Darlington 1968).

MAXSTEP=*n*

specifies the maximum number of steps that are done when SELECTION=FORWARD, SELECTION=BACKWARD, or SELECTION=STEPWISE is used. The default value is the number of independent variables in the model for the FORWARD and BACKWARD methods and three times this number for the stepwise method.

NOINT

suppresses the intercept term that is otherwise included in the model.

NOPRINT

suppresses the normal display of regression results. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, "Using the Output Delivery System," for more information.

OUTSEB

outputs the standard errors of the parameter estimates to the OUTEST= data set. The value SEB for the variable _TYPE_ identifies the standard errors. If the RIDGE= or PCOMIT= option is specified, additional observations are included and identified by the values RIDGESEB and IPCSEB, respectively, for the variable _TYPE_. The standard errors for ridge regression estimates and incomplete principal components (IPC) estimates are limited in their usefulness because these estimates are biased. This option is available for all model-selection methods except RSQUARE, ADJRSQ, and CP.

OUTSTB

outputs the standardized parameter estimates as well as the usual estimates to the OUTEST= data set when the RIDGE= or PCOMIT= option is specified. The values RIDGESTB and IPCSTB for the variable _TYPE_ identify ridge regression estimates and IPC estimates, respectively.

OUTVIF

outputs the variance inflation factors (VIF) to the OUTEST= data set when the RIDGE= or PCOMIT= option is specified. The factors are the diagonal elements of the inverse of the correlation matrix of regressors as adjusted by ridge regression or IPC analysis. These observations are identified in the output data set by the values RIDGEVIF and IPCVIF for the variable _TYPE_.

P

calculates predicted values from the input data and the estimated model. The display includes the observation number, the ID variable (if one is specified), the actual and predicted values, and the residual. If the CLI, CLM, or R option is specified, the P option is unnecessary. See the section "Predicted and Residual Values" on page 5531 for more information.

PARTIAL

requests partial regression leverage plots for each regressor. You can use the PARTIALDATA option to obtain a tabular display of the partial regression leverage data. If ODS Graphics is in effect (see the section "ODS Graphics" on page 5589), then these partial plots are produced

in panels with up to six plots per panel. See the section "Influence Statistics" on page 5559 for more information.

PARTIALDATA

requests partial regression leverage data for each regressor. You can request partial regression leverage plots of these data with the PARTIAL option. See the section "Influence Statistics" on page 5559 for more information.

PARTIALR2 < (< TESTS > < SEQTESTS >) >

See the SCORR1 option.

PC

outputs Amemiya's prediction criterion for each model selected (Amemiya 1976; Judge et al. 1980) to the OUTEST= data set. If SELECTION=ADJRSQ, SELECTION=RSQUARE, or SELECTION=CP is specified, then the PC statistic is also added to the SubsetSelSummary table.

PCOMIT=*list*

requests an IPC analysis for each value m in the list. The procedure computes parameter estimates by using all but the last m principal components. Each value of m produces a set of IPC estimates, which is output to the OUTEST= data set. The values of m are saved by the variable _PCOMIT_, and the value of the variable _TYPE_ is set to IPC to identify the estimates. Only nonnegative integers can be specified with the PCOMIT= option.

If you specify the PCOMIT= option, RESTRICT statements are ignored. The PCOMIT= option is ignored if you use the SELECTION= option in the MODEL statement.

PCORR1

displays the squared partial correlation coefficients computed using Type I sum of squares (SS). This is calculated as SS/(SS+SSE), where SSE is the error sum of squares.

PCORR2

displays the squared partial correlation coefficients computed using Type II sums of squares. These are calculated the same way as with the PCORR1 option, except that Type II SS are used instead of Type I SS.

PRESS

outputs the PRESS statistic to the OUTEST= data set. The values of this statistic are saved in the variable _PRESS_. This option is available for all model-selection methods except RSQUARE, ADJRSQ, and CP.

R

requests an analysis of the residuals. The results include everything requested by the P option plus the standard errors of the mean predicted and residual values, the studentized residual, and Cook's D statistic to measure the influence of each observation on the parameter estimates. See the section "Predicted and Residual Values" on page 5531 for more information.

RIDGE=*list*

requests a ridge regression analysis and specifies the values of the ridge constant k (see the section "Computations for Ridge Regression and IPC Analysis" on page 5583). Each value

of k produces a set of ridge regression estimates that are placed in the OUTEST= data set. The values of k are saved by the variable _RIDGE_, and the value of the variable _TYPE_ is set to RIDGE to identify the estimates.

Only nonnegative numbers can be specified with the RIDGE= option. Example 73.5 illustrates this option.

If you specify the RIDGE= option, RESTRICT statements are ignored. The RIDGE= option is ignored if you use the SELECTION= option in the MODEL statement.

RMSE

displays the root mean square error for each model selected.

RSQUARE

has the same effect as the EDF option.

SBC

outputs the SBC statistic for each model selected (Schwarz 1978; Judge et al. 1980) to the OUTEST= data set. If SELECTION=ADJRSQ, SELECTION=RSQUARE, or SELECTION=CP is specified, then the SBC statistic is also added to the SubsetSelSummary table.

SCORR1 < (< TESTS > < SEQTESTS >) >

displays the squared semipartial correlation coefficients computed using Type I sums of squares. This is calculated as SS/SST, where SST is the corrected total SS. If the NOINT option is used, the uncorrected total SS is used in the denominator. The optional arguments TESTS and SEQTESTS request are sequentially added to a model. The F-test values are computed as the Type I sum of squares for the variable in question divided by a mean square error. If you specify the TESTS option, the denominator MSE is the residual mean square for the full model specified in the MODEL statement. If you specify the SEQTESTS option, the denominator MSE is the residual mean square for the model containing all the independent variables that have been added to the model up to and including the variable in question. The TESTS and SEQTESTS options are not supported if you specify model selection methods or the RIDGE or PCOMIT options. Note that the PARTIALR2 option is a synonym for the SCORR1 option.

SCORR2 < (TESTS) >

displays the squared semipartial correlation coefficients computed using Type II sums of squares. These are calculated the same way as with the SCORR1 option, except that Type II SS are used instead of Type I SS. The optional TEST argument requests F tests and p-values as variables are sequentially added to a model. The F-test values are computed as the Type II sum of squares for the variable in question divided by the residual mean square for the full model specified in the MODEL statement. The TESTS option is not supported if you specify model selection methods or the RIDGE or PCOMIT options.

SELECTION=*name*

specifies the method used to select the model, where *name* can be FORWARD (or F), BACKWARD (or B), STEPWISE, MAXR, MINR, RSQUARE, ADJRSQ, CP, or NONE (use the full model). The default method is NONE. See the section "Model-Selection Methods" on page 5523 for a description of each method.

SEQB

produces a sequence of parameter estimates as each variable is entered into the model. This is displayed as a matrix where each row is a set of parameter estimates.

SIGMA=*n*

specifies the true standard deviation of the error term to be used in computing the CP and BIC statistics. If the SIGMA= option is not specified, an estimate from the full model is used. This option is available in the RSQUARE, ADJRSQ, and CP model-selection methods only.

SINGULAR=*n*

tunes the mechanism used to check for singularities. If you specify this option in the MODEL statement, it takes precedence over the SINGULAR= option in the PROC REG statement. The default value is machine dependent but is approximately 1E−7 on most machines. This option is rarely needed. Singularity checking is described in the section "Computational Methods" on page 5584.

SLENTRY=*value*

SLE=*value*

specifies the significance level for entry into the model used in the FORWARD and STEPWISE methods. The defaults are 0.50 for FORWARD and 0.15 for STEPWISE.

SLSTAY=*value*

SLS=*value*

specifies the significance level for staying in the model for the BACKWARD and STEPWISE methods. The defaults are 0.10 for BACKWARD and 0.15 for STEPWISE.

SP

outputs the S_p statistic for each model selected (Hocking 1976) to the OUTEST= data set. If SELECTION=ADJRSQ, SELECTION=RSQUARE, or SELECTION=CP is specified, then the SP statistic is also added to the SubsetSelSummary table.

SPEC

performs a test that the first and second moments of the model are correctly specified. See the section "Testing for Heteroscedasticity" on page 5575 for more information.

SS1

displays the sequential sums of squares (Type I SS) along with the parameter estimates for each term in the model. See Chapter 15, "The Four Types of Estimable Functions," for more information about the different types of sums of squares.

SS2

displays the partial sums of squares (Type II SS) along with the parameter estimates for each term in the model. See the SS1 option also.

SSE

computes the error sum of squares for each model selected.

START=*s*
is used to begin the comparing-and-switching process in the MAXR, MINR, and STEPWISE methods for a model containing the first s independent variables in the MODEL statement, where s is the START value. For these methods, the default is START=0.

For the RSQUARE, ADJRSQ, and CP methods, START=s specifies the smallest number of regressors to be reported in a subset model. For these methods, the default is START=1.

The START= option cannot be used with model-selection methods other than the six described here.

STB
produces standardized regression coefficients. A standardized regression coefficient is computed by dividing a parameter estimate by the ratio of the sample standard deviation of the dependent variable to the sample standard deviation of the regressor.

STOP=*s*
causes PROC REG to stop when it has found the "best" s-variable model, where s is the STOP value. For the RSQUARE, ADJRSQ, and CP methods, STOP=s specifies the largest number of regressors to be reported in a subset model. For the MAXR and MINR methods, STOP=s specifies the largest number of regressors to be included in the model.

The default setting for the STOP= option is the number of variables in the MODEL statement. This option can be used only with the MAXR, MINR, RSQUARE, ADJRSQ, and CP methods.

TOL
produces tolerance values for the estimates. Tolerance for a variable is defined as $1 - R^2$, where R^2 is obtained from the regression of the variable on all other regressors in the model. See the section "Collinearity Diagnostics" on page 5555 for more details.

VIF
produces variance inflation factors with the parameter estimates. Variance inflation is the reciprocal of tolerance. See the section "Collinearity Diagnostics" on page 5555 for more detail.

WHITE
See the HCC option.

XPX
displays the $\mathbf{X}'\mathbf{X}$ crossproducts matrix for the model. The crossproducts matrix is bordered by the $\mathbf{X}'\mathbf{Y}$ and $\mathbf{Y}'\mathbf{Y}$ matrices.

MTEST Statement

< *label:* **>** **MTEST** < *equation* <, . . . , *equation* > > < / *options* > **;**

where each *equation* is a linear function composed of coefficients and variable names. The *label* is optional.

The MTEST statement is used to test hypotheses in multivariate regression models where there are several dependent variables fit to the same regressors. If no equations or options are specified, the MTEST statement tests the hypothesis that all estimated parameters except the intercept are zero.

The hypotheses that can be tested with the MTEST statement are of the form

$$(\mathbf{L}\boldsymbol{\beta} - \mathbf{cj})\mathbf{M} = 0$$

where $\mathbf{L}$ is a linear function on the regressor side, $\boldsymbol{\beta}$ is a matrix of parameters, $\mathbf{c}$ is a column vector of constants, $\mathbf{j}$ is a row vector of ones, and $\mathbf{M}$ is a linear function on the dependent side. The special case where the constants are zero is

$$\mathbf{L}\boldsymbol{\beta}\mathbf{M} = \mathbf{0}$$

See the section "Multivariate Tests" on page 5577 for more details.

Each linear function extends across either the regressor variables or the dependent variables. If the equation is across the dependent variables, then the constant term, if specified, must be zero. The equations for the regressor variables form the $\mathbf{L}$ matrix and $\mathbf{c}$ vector in the preceding formula; the equations for dependent variables form the $\mathbf{M}$ matrix. If no equations for the dependent variables are given, PROC REG uses an identity matrix for $\mathbf{M}$, testing the same hypothesis across all dependent variables. If no equations for the regressor variables are given, PROC REG forms a linear function corresponding to a test that all the nonintercept parameters are zero.

As an example, consider the following statements:

```
model y1 y2 y3=x1 x2 x3;
mtest x1,x2;
mtest y1-y2, y2 -y3, x1;
mtest y1-y2;
```

The first MTEST statement tests the hypothesis that the $X1$ and $X2$ parameters are zero for $Y1$, $Y2$, and $Y3$. In addition, the second MTEST statement tests the hypothesis that the $X1$ parameter is the same for all three dependent variables. For the same model, the third MTEST statement tests the hypothesis that all parameters except the intercept are the same for dependent variables $Y1$ and $Y2$.

You can specify the following options in the MTEST statement:

CANPRINT

displays the canonical correlations for the hypothesis combinations and the dependent variable combinations. If you specify

```
mtest / canprint;
```

the canonical correlations between the regressors and the dependent variables are displayed.

DETAILS

displays the $\mathbf{M}$ matrix and various intermediate calculations.

MSTAT=FAPPROX

MSTAT=EXACT

specifies the method of evaluating the multivariate test statistics. The default is MSTAT=FAPPROX, which specifies that the multivariate tests are evaluated by using the usual approximations based on the F distribution, as discussed in the "Multivariate Tests" section in Chapter 4, "Introduction to Regression Procedures." Alternatively, you can specify MSTAT=EXACT to compute exact p-values for three of the four tests (Wilks' lambda, the Hotelling-Lawley trace, and Roy's greatest root) and an improved F approximation for the fourth (Pillai's trace). While MSTAT=EXACT provides better control of the significance probability for the tests, especially for Roy's greatest root, computations for the exact p-values can be appreciably more demanding, and are in fact infeasible for large problems (many dependent variables). Thus, although MSTAT=EXACT is more accurate for most data, it is not the default method.

PRINT

displays the **H** and **E** matrices.

OUTPUT Statement

OUTPUT < **OUT=***SAS-data-set*>< *keyword=names*> < . . . *keyword=names*> **;**

The OUTPUT statement creates a new SAS data set that saves diagnostic measures calculated after fitting the model. The OUTPUT statement refers to the most recent MODEL statement. At least one *keyword=names* specification is required.

All the variables in the original data set are included in the new data set, along with variables created in the OUTPUT statement. These new variables contain the values of a variety of statistics and diagnostic measures that are calculated for each observation in the data set. If you want to create a permanent SAS data set, you must specify a two-level name (for example, *libref.data-set-name*).

For more information about permanent SAS data sets, refer to the section "SAS Files" in *SAS Language Reference: Concepts*.

The OUTPUT statement cannot be used when a TYPE=CORR, TYPE=COV, or TYPE=SSCP data set is used as the input data set for PROC REG. See the section "Input Data Sets" on page 5508 for more details.

The statistics created in the OUTPUT statement are described in this section. More details are given in the section "Predicted and Residual Values" on page 5531 and the section "Influence Statistics" on page 5559. Also see Chapter 4, "Introduction to Regression Procedures," for definitions of the statistics available from the REG procedure.

You can specify the following options in the OUTPUT statement:

OUT=*SAS data set*

gives the name of the new data set. By default, the procedure uses the DATA*n* convention to name the new data set.

keyword=names

specifies the statistics to include in the output data set and names the new variables that contain the statistics. Specify a keyword for each desired statistic (see the following list of keywords), an equal sign, and the variable or variables to contain the statistic.

In the output data set, the first variable listed after a keyword in the OUTPUT statement contains that statistic for the first dependent variable listed in the MODEL statement; the second variable contains the statistic for the second dependent variable in the MODEL statement, and so on. The list of variables following the equal sign can be shorter than the list of dependent variables in the MODEL statement. In this case, the procedure creates the new names in order of the dependent variables in the MODEL statement.

For example, the following SAS statements create an output data set named b:

```
proc reg data=a;
   model y z=x1 x2;
   output out=b
      p=yhat zhat
      r=yresid zresid;
run;
```

In addition to the variables in the input data set, b contains the following variables:

- yhat, with values that are predicted values of the dependent variable y
- zhat, with values that are predicted values of the dependent variable z
- yresid, with values that are the residual values of y
- zresid, with values that are the residual values of z

You can specify the following keywords in the OUTPUT statement. See the section "Model Fit and Diagnostic Statistics" on page 5557 for computational formulas.

Table 73.5 Keywords for OUTPUT Statement

Keyword	Description
COOKD=*names*	Cook's D influence statistic
COVRATIO=*names*	standard influence of observation on covariance of betas, as discussed in the section "Influence Statistics" on page 5559
DFFITS=*names*	standard influence of observation on predicted value
H=*names*	leverage, $x_i(\mathbf{X}'\mathbf{X})^{-1}x_i'$
LCL=*names*	lower bound of a $100(1-\alpha)\%$ confidence interval for an individual prediction. This includes the variance of the error, as well as the variance of the parameter estimates.
LCLM=*names*	lower bound of a $100(1-\alpha)\%$ confidence interval for the expected value (mean) of the dependent variable
PREDICTED | P=*names*	predicted values
PRESS=*names*	ith residual divided by $(1-h)$, where h is the leverage, and where the model has been refit without the ith observation
RESIDUAL | R=*names*	residuals, calculated as ACTUAL minus PREDICTED

Table 73.5 *continued*

Keyword	Description
RSTUDENT=*names*	a studentized residual with the current observation deleted
STDI=*names*	standard error of the individual predicted value
STDP=*names*	standard error of the mean predicted value
STDR=*names*	standard error of the residual
STUDENT=*names*	studentized residuals, which are the residuals divided by their standard errors
UCL=*names*	upper bound of a $100(1-\alpha)\%$ confidence interval for an individual prediction
UCLM=*names*	upper bound of a $100(1-\alpha)\%$ confidence interval for the expected value (mean) of the dependent variable

PAINT Statement

PAINT < *condition* | **ALLOBS** > < / *options* > **;**

PAINT < *STATUS* | *UNDO* > **;**

The PAINT statement selects observations to be *painted* or highlighted in a scatter plot on line printer output; the PAINT statement is ignored if the LINEPRINTER option is not specified in the PROC REG statement.

All observations that satisfy *condition* are painted using some specific symbol. The PAINT statement does not generate a scatter plot and must be followed by a PLOT statement, which does generate a scatter plot. Several PAINT statements can be used before a PLOT statement, and all prior PAINT statement requests are applied to all later PLOT statements.

The PAINT statement lists the observation numbers of the observations selected, the total number of observations selected, and the plotting symbol used to paint the points.

On a plot, paint symbols take precedence over all other symbols. If any position contains more than one painted point, the paint symbol for the observation plotted last is used.

The PAINT statement cannot be used when a TYPE=CORR, TYPE=COV, or TYPE=SSCP data set is used as the input data set for PROC REG. Also, the PAINT statement cannot be used for models with more than one dependent variable. Note that the syntax for the PAINT statement is the same as the syntax for the REWEIGHT statement.

For detailed examples of painting scatter plots, see the section "Painting Scatter Plots" on page 5543.

Specifying Condition

Condition is used to select observations to be painted. The syntax of *condition* is

variable compare value

or

variable compare value *logical* *variable compare value*

where

variable is one of the following:

- a variable name in the input data set
- OBS**.**, which is the observation number
- *keyword***.**, where *keyword* is a keyword for a statistic requested in the OUTPUT statement

compare is an operator that compares *variable* to *value*. *Compare* can be any one of the following: <, <=, >, >=, =, ^ =. The operators LT, LE, GT, GE, EQ, and NE, respectively, can be used instead of the preceding symbols. Refer to the "Expressions" section in *SAS Language Reference: Concepts* for more information about comparison operators.

value gives an unformatted value of *variable*. Observations are selected to be painted if they satisfy the condition created by *variable compare value*. *Value* can be a number or a character string. If *value* is a character string, it must be eight characters or less and must be enclosed in quotes. In addition, *value* is case-sensitive. In other words, the statements

```
paint name='henry';
```

and

```
paint name='Henry';
```

are not the same.

logical is one of two logical operators. Either AND or OR can be used. To specify AND, use AND or the symbol &. To specify OR, use OR or the symbol |.

Here are some examples of the *variable compare value* form:

```
paint name='Henry';
paint residual.>=20;
paint obs.=99;
```

Here are some examples of the *variable compare value* *logical* *variable compare value* form:

```
paint name='Henry'|name='Mary';
paint residual.>=20 or residual.<=10;
paint obs.>=11 and residual.<=20;
```

Using ALLOBS

Instead of specifying *condition*, the ALLOBS option can be used to select all observations. This is most useful when you want to unpaint all observations. For example,

```
paint allobs / reset;
```

resets the symbols for all observations.

Options in the PAINT Statement

The following options can be used when either a condition is specified, the ALLOBS option is specified, or nothing is specified before the slash. If only an option is listed, the option applies to the observations selected in the previous PAINT statement, *not* to the observations selected by reapplying the condition from the previous PAINT statement. For example, in the statements

```
paint r.>0 / symbol='a';
reweight r.>0;
refit;
paint / symbol='b';
```

the second PAINT statement paints only those observations selected in the first PAINT statement. No additional observations are painted even if, after refitting the model, there are new observations that meet the condition in the first PAINT statement.

NOTE: Options are not available when either the UNDO or STATUS option is used.

You can specify the following options after a slash (/).

NOLIST
suppresses the display of the selected observation numbers. If the NOLIST option is not specified, a list of observations selected is written to the log. The list includes the observation numbers and painting symbol used to paint the points. The total number of observations selected to be painted is also shown.

RESET
changes the painting symbol to the current default symbol, effectively unpainting the observations selected. If you set the default symbol by using the SYMBOL= option in the PLOT statement, the RESET option in the PAINT statement changes the painting symbol to the symbol you specified. Otherwise, the default symbol of '1' is used.

SYMBOL='character'
specifies a painting symbol. If the SYMBOL= option is omitted, the painting symbol is either the one used in the most recent PAINT statement or, if there are no previous PAINT statements, the symbol '@'. For example,

```
paint / symbol='#';
```

changes the painting symbol for the observations selected by the most recent PAINT statement to '#'. As another example,

```
paint temp lt 22 / symbol='c';
```

changes the painting symbol to 'c' for all observations with TEMP<22. In general, the numbers 1, 2, . . . , 9 and the asterisk are not recommended as painting symbols. These symbols are used as default symbols in the PLOT statement, where they represent the number of replicates at a point. If SYMBOL=" is used, no painting is done in the current plot. If SYMBOL=' ' is used, observations are painted with a blank and are no longer seen on the plot.

STATUS and UNDO

Instead of specifying *condition* or the ALLOBS option, you can use the STATUS or UNDO option as follows:

STATUS
lists (in the log) the observation number and plotting symbol of all currently painted observations.

UNDO
undoes changes made by the most recent PAINT statement. Observations might be, but are not necessarily, unpainted. For example:

```
paint obs. <=10 / symbol='a';
\Codecomment{...other interactive statements}
paint obs.=1 / symbol='b';
\Codecomment{...other interactive statements}
paint undo;
```

The last PAINT statement changes the plotting symbol used for observation 1 back to 'a'. If the statement

```
paint / reset;
```

is used instead, observation 1 is unpainted.

PLOT Statement

PLOT < *yvariable***xvariable* > < =*symbol* > < . . . *yvariable***xvariable* > < =*symbol* > < / *options* > ;

The PLOT statement in PROC REG displays scatter plots with *yvariable* on the vertical axis and *xvariable* on the horizontal axis. Line printer plots are generated if the LINEPRINTER option is specified in the PROC REG statement; otherwise, the traditional graphics are created. Points in line printer plots can be marked with *symbols*, while global graphics statements such as GOPTIONS and SYMBOL are used to enhance the traditional graphics. Note that the plots you request by using the PLOT statement are independent of the ODS graphical displays (see the section "ODS Graphics" on page 5589) that are now available in PROC REG.

As with most other interactive statements, the PLOT statement implicitly refits the model. For example, if a PLOT statement is preceded by a REWEIGHT statement, the model is recomputed, and the plot reflects the new model.

If there are multiple MODEL statements preceding a PLOT statement, then the PLOT statement refers to the latest MODEL statement.

The PLOT statement cannot be used when a TYPE=CORR, TYPE=COV, or TYPE=SSCP data set is used as input to PROC REG.

You can specify several PLOT statements for each MODEL statement, and you can specify more than one plot in each PLOT statement.

For detailed examples of using the PLOT statement and its options, see the section "Producing Scatter Plots" on page 5535.

Specifying Yvariables, Xvariables, and Symbol

More than one *yvariable*∗*xvariable* pair can be specified to request multiple plots. The *yvariables* and *xvariables* can be as follows:

- any variables specified in the VAR or MODEL statement before the first RUN statement
- *keyword*., where *keyword* is a regression diagnostic statistic available in the OUTPUT statement (see Table 73.6). For example,

```
plot predicted.*residual.;
```

  generates one plot of the predicted values by the residuals for each dependent variable in the MODEL statement. These statistics can also be plotted against any of the variables in the VAR or MODEL statements.

- the keyword OBS. (the observation number), which can be plotted against any of the preceding variables
- the keyword NPP. or NQQ., which can be used with any of the preceding variables to construct normal P-P or Q-Q plots, respectively (see the section "Construction of Q-Q and P-P Plots" on page 5583 and "Traditional Normal Quantile and Normal Probability Plots" on page 5551 for more information)
- keywords for model fit summary statistics available in the OUTEST= data set with _TYPE_= PARMS (see Table 73.6). A SELECTION= method (other than NONE) must be requested in the MODEL statement for these variables to be plotted. If one member of a *yvariable*∗*xvariable* pair is from the OUTEST= data set, the other member must also be from the OUTEST= data set.

The OUTPUT statement and the OUTEST= option are not required when their keywords are specified in the PLOT statement.

The *yvariable* and *xvariable* specifications can be replaced by a set of variables and statistics enclosed in parentheses. When this occurs, all possible combinations of *yvariable* and *xvariable* are generated. For example, the following two statements are equivalent:

```
plot (y1 y2)*(x1 x2);
plot y1*x1 y1*x2 y2*x1 y2*x2;
```

The statement

```
plot;
```

is equivalent to respecifying the most recent PLOT statement without any options. However, the line printer options COLLECT, HPLOTS=, SYMBOL=, and VPLOTS=, described in the section "Line Printer Plots" on page 5497, apply across PLOT statements and remain in effect if they have been previously specified.

Options used for the traditional graphics are described in the following section; see "Line Printer Plots" on page 5497 for more information.

Traditional Graphics

The display of traditional graphics is described in the following paragraphs, the options are summarized in Table 73.6 and described in the section "Dictionary of PLOT Statement Options" on page 5493, and the section "Traditional Graphics" on page 5547 contains several examples of the graphics output.

Several line printer statements and options are not supported for the traditional graphics. In particular the PAINT statement is disabled, as are the PLOT statement options CLEAR, COLLECT, HPLOTS=, NOCOLLECT, SYMBOL=, and VPLOTS=. To display more than one plot per page or to collect plots from multiple PLOT statements, use the PROC GREPLAY statement (refer to *SAS/GRAPH Software: Reference*). Also note that traditional graphics options are not recognized for line printer plots.

The fitted model equation and a label are displayed in the top margin of the plot; this display can be suppressed with the NOMODEL option. If the label is requested but cannot fit on one line, it is not displayed. The equation and label are displayed on one line when possible; if more lines are required, the label is displayed in the first line with the model equation in successive lines. If displaying the entire equation causes the plot to be unacceptably small, the equation is truncated. Table 73.7 lists options to control the display of the equation. The section "Traditional Graphics for Simple Linear Regression" on page 5547 illustrates the display of the model equation.

Four statistics are displayed by default in the right margin: the number of observations, R^2, the adjusted R^2, and the root mean square error. (See Figure 73.43.) The display of these statistics can be suppressed with the NOSTAT option. You can specify other options to request the display of various statistics in the right margin; see Table 73.7.

A default reference line at zero is displayed if residuals are plotted. If the dependent variable is plotted against the independent variable in a simple linear regression model, the fitted regression line is displayed by default. (See Figure 73.42.) Default reference lines can be suppressed with the NOLINE option; the lines are not displayed if the OVERLAY option is specified.

Specialized plots are requested with special options. For each coefficient, the RIDGEPLOT option plots the ridge estimates against the ridge values k; see the description of the RIDGEPLOT option in the section "Dictionary of PLOT Statement Options" on page 5493 for more details. The CONF option plots $100(1-\alpha)\%$ confidence intervals for the mean while the PRED option plots $100(1-\alpha)\%$ prediction intervals; see the description of these options in the section "Dictionary of PLOT Statement Options" on page 5493 for more details.

If a SELECTION= method is requested, the fitted model equation and the statistics displayed in the margin correspond to the selected model. For the ADJRSQ and CP methods, the selected model is treated as a submodel of the full model. If a CP.*NP. plot is requested, the CHOCKING= and CMALLOWS= options display model selection reference lines; see the descriptions of these options in the section "Dictionary of PLOT Statement Options" on page 5493 and "Traditional Graphics for Variable Selection" on page 5550 for more details.

PLOT Statement variable Keywords

The following table lists the keywords available as PLOT statement *xvariables* and *yvariables*. All keywords have a trailing dot; for example, "*COOKD.*" requests Cook's D statistic. Neither the OUTPUT statement nor the OUTEST= option needs to be specified.

Table 73.6 Keywords for PLOT Statement *xvariables*

Keyword	Description
Diagnostic Statistics	
COOKD.	Cook's D influence statistics
COVRATIO.	standard influence of observation on covariance of betas
DFFITS.	standard influence of observation on predicted value
H.	leverage
LCL.	lower bound of $100(1-\alpha)\%$ confidence interval for individual prediction
LCLM.	lower bound of $100(1-\alpha)\%$ confidence interval for the mean of the dependent variable
PREDICTED. | PRED. | P.	predicted values
PRESS.	residuals from refitting the model with current observation deleted
RESIDUAL. | R.	residuals
RSTUDENT.	studentized residuals with the current observation deleted
STDI.	standard error of the individual predicted value
STDP.	standard error of the mean predicted value
STDR.	standard error of the residual
STUDENT.	residuals divided by their standard errors
UCL.	upper bound of $100(1-\alpha)\%$ confidence interval for individual prediction
UCLM.	upper bound of $100(1-\alpha)\%$ confidence interval for the mean of the dependent variables
Other Keywords Used with Diagnostic Statistics	
NPP.	normal probability-probability plot
NQQ.	normal quantile-quantile plot

Table 73.6 *continued*

Keyword	Description
OBS.	observation number (cannot plot against OUTEST= statistics)
Model Fit Summary Statistics	
ADJRSQ.	adjusted R-square
AIC.	Akaike's information criterion
BIC.	Sawa's Bayesian information criterion
CP.	Mallows' C_p statistic
EDF.	error degrees of freedom
GMSEP.	estimated MSE of prediction, assuming multivariate normality
IN.	number of regressors in the model not including the intercept
JP.	final prediction error
MSE.	mean squared error
NP.	number of parameters in the model (including the intercept)
PC.	Amemiya's prediction criterion
RMSE.	root MSE
RSQ.	R-square
SBC.	SBC statistic
SP.	SP statistic
SSE.	error sum of squares

Summary of PLOT Statement Graphics Options

The following table lists the PLOT statement *options* by function. These *options* are available unless the LINEPRINTER option is specified in the PROC REG statement. For complete descriptions, see the section "Dictionary of PLOT Statement Options" on page 5493.

Table 73.7 Traditional Graphics Options

Option	Description
General Graphics Options	
ANNOTATE=*SAS-data-set*	specifies the annotate data set
CHOCKING=*color*	requests a reference line for C_p model selection criteria
CMALLOWS=*color*	requests a reference line for the C_p model selection criterion
CONF	requests plots of $100(1-\alpha)\%$ confidence intervals for the mean
DESCRIPTION='*string*'	specifies a description for graphics catalog member
NAME='*string*'	names the plot in the graphics catalog
OVERLAY	overlays plots from the same model
PRED	requests plots of $100(1-\alpha)\%$ prediction intervals for individual responses
RIDGEPLOT	requests the ridge trace for ridge regression
Axis and Legend Options	
LEGEND=*LEGENDn*	specifies LEGEND statement to be used
HAXIS=*values*	specifies tick mark values for horizontal axis
VAXIS=*values*	specifies tick mark values for vertical axis

Table 73.7 *continued*

Option	Description
Reference Line Options	
HREF=*values*	specifies reference lines perpendicular to horizontal axis
LHREF=*linetype*	specifies line style for HREF= lines
LLINE=*linetype*	specifies line style for lines displayed by default
LVREF=*linetype*	specifies line style for VREF= lines
NOLINE	suppresses display of any default reference line
VREF=*values*	specifies reference lines perpendicular to vertical axis
Color Options	
CAXIS=*color*	specifies color for axis line and tick marks
CFRAME=*color*	specifies color for frame
CHREF=*color*	specifies color for HREF= lines
CLINE=*color*	specifies color for lines displayed by default
CTEXT=*color*	specifies color for text
CVREF=*color*	specifies color for VREF= lines
Options for Displaying the Fitted Model Equation	
MODELFONT=*font*	specifies font of model equation and model label
MODELHT=*value*	specifies text height of model equation and model label
MODELLAB='*label*'	specifies model label
NOMODEL	suppresses display of the fitted model and the label
Options for Displaying Statistics in the Plot Margin	
AIC	displays Akaike's information criterion
BIC	displays Sawa's Bayesian information criterion
CP	displays Mallows' C_p statistic
EDF	displays the error degrees of freedom
GMSEP	displays the estimated MSE of prediction assuming multivariate normality
IN	displays the number of regressors in the model not including the intercept
JP	displays the J_p statistic
MSE	displays the mean squared error
NOSTAT	suppresses display of the default statistics: the number of observations, R-square, adjusted R-square, and root mean square error
NP	displays the number of parameters in the model including the intercept, if any
PC	displays the PC statistic
SBC	displays the SBC statistic
SP	displays the S_p statistic
SSE	displays the error sum of squares
STATFONT=*font*	specifies font of text displayed in the margin
STATHT=*value*	specifies height of text displayed in the margin

Dictionary of PLOT Statement Options

The following entries describe the PLOT statement *options* in detail. Note that these *options* are available unless you specify the LINEPRINTER option in the PROC REG statement.

AIC

displays Akaike's information criterion in the plot margin.

ANNOTATE=*SAS-data-set*

ANNO=*SAS-data-set*

specifies an input data set that contains appropriate variables for annotation. This applies only to displays created with the current PLOT statement. Refer to *SAS/GRAPH Software: Reference* for more information.

BIC

displays Sawa's Bayesian information criterion in the plot margin.

CAXIS=*color*

CAXES=*color*

CA=*color*

specifies the color for the axes, frame, and tick marks.

CFRAME=*color*

CFR=*color*

specifies the color for filling the area enclosed by the axes and the frame.

CHOCKING=*color*

requests reference lines corresponding to the equations $C_p = p$ and $C_p = 2p - p_{full}$, where p_{full} is the number of parameters in the full model (excluding the intercept) and p is the number of parameters in the subset model (including the intercept). The *color* must be specified; the $C_p = p$ line is solid and the $C_p = 2p - p_{full}$ line is dashed. Only PLOT statements of the form PLOT CP.*NP. produce these lines.

For the purpose of parameter estimation, Hocking (1976) suggests selecting a model where $C_p \leq 2p - p_{full}$. For the purpose of prediction, Hocking suggests the criterion $C_p \leq p$. You can request the single reference line $C_p = p$ with the CMALLOWS= option. If, for example, you specify both CHOCKING=RED and CMALLOWS=BLUE, then the $C_p = 2p - p_{full}$ line is red and the $C_p = p$ line is blue (see Figure 73.45).

CHREF=*color*

CH=*color*

specifies the color for lines requested with the HREF= option.

CLINE=*color*

CL=*color*

specifies the color for lines displayed by default. See the NOLINE option for details.

CMALLOWS=*color*

requests a $C_p = p$ reference line, where p is the number of parameters (including the intercept) in the subset model. The *color* must be specified; the line is solid. Only PLOT statements of the form PLOT CP.*NP. produce this line.

Mallows (1973) suggests that all subset models with C_p small and near p be considered for further study. See the CHOCKING= option for related model-selection criteria.

CONF

is a keyword used as a shorthand option to request plots that include $(100 - \alpha)\%$ confidence intervals for the mean response (see Figure 73.44). The ALPHA= option in the PROC REG or MODEL statement selects the significance level α, which is 0.05 by default. The CONF option is valid for simple regression models only, and is ignored for plots where confidence intervals are inappropriate. The CONF option replaces the CONF95 option; however, the CONF95 option is still supported when the ALPHA= option is not specified. The OVERLAY option is ignored when the CONF option is specified.

CP

displays Mallows' C_p statistic in the plot margin.

CTEXT=*color*

CT=*color*

specifies the color for text including tick mark labels, axis labels, the fitted model label and equation, the statistics displayed in the margin, and legends.

CVREF=*color*

CV=*color*

specifies the color for lines requested with the VREF= option.

DESCRIPTION='*string* **'**

DESC='*string* **'**

specifies a descriptive string, up to 40 characters, that appears in the description field of the PROC GREPLAY master menu.

EDF

displays the error degrees of freedom in the plot margin.

GMSEP

displays the estimated mean square error of prediction in the plot margin. Note that the estimate is calculated under the assumption that both independent and dependent variables have a multivariate normal distribution.

HAXIS=*values*

HA=*values*

specifies tick mark values for the horizontal axis.

HREF=*values*

specifies where reference lines perpendicular to the horizontal axis are to appear.

IN

displays the number of regressors in the model (not including the intercept) in the plot margin.

JP

displays the J_p statistic in the plot margin.

LEGEND=LEGEND*n*

specifies the LEGEND*n* statement to be used. The LEGEND*n* statement is a global graphics statement; refer to *SAS/GRAPH Software: Reference* for more information.

LHREF=*linetype*

LH=*linetype*

specifies the line style for lines requested with the HREF= option. The default *linetype* is 2. Note that LHREF=1 requests a solid line. Refer to *SAS/GRAPH Software: Reference* for a table of available line types.

LLINE=*linetype*

LL=*linetype*

specifies the line style for reference lines displayed by default; see the NOLINE option for details. The default *linetype* is 2. Note that LLINE=1 requests a solid line.

LVREF=*linetype*

LV=*linetype*

specifies the line style for lines requested with the VREF= option. The default *linetype* is 2. Note that LVREF=1 requests a solid line.

MODELFONT=*font*

specifies the font used for displaying the fitted model label and the fitted model equation. Refer to *SAS/GRAPH Software: Reference* for tables of software fonts.

MODELHT=*height*

specifies the text height for the fitted model label and the fitted model equation.

MODELLAB='*label* **'**

specifies the label to be displayed with the fitted model equation. By default, no label is displayed. If the label does not fit on one line, it is not displayed. See the section "Traditional Graphics" on page 5489 for more information.

MSE

displays the mean squared error in the plot margin.

NAME='*string* **'**

specifies a descriptive string, up to eight characters, that appears in the name field of the PROC GREPLAY master menu. The default *string* is REG.

NOLINE

suppresses the display of default reference lines. A default reference line at zero is displayed if residuals are plotted. If the dependent variable is plotted against the independent variable in a simple regression model, then the fitted regression line is displayed by default. Default reference lines are not displayed if the OVERLAY option is specified.

NOMODEL
suppresses the display of the fitted model equation.

NOSTAT
suppresses the display of statistics in the plot margin. By default, the number of observations, R-square, adjusted R-square, and root MSE are displayed.

NP
displays the number of regressors in the model including the intercept, if any, in the plot margin.

OVERLAY
overlays all plots specified in the PLOT statement from the same model on one set of axes. The variables for the first plot label the axes. The procedure automatically scales the axes to fit all of the variables unless the HAXIS= or VAXIS= option is used. Default reference lines are not displayed. A default legend is produced; the LEGEND= option can be used to customize the legend.

PC
displays the PC statistic in the plot margin.

PRED
is a keyword used as a shorthand option to request plots that include $(100-\alpha)\%$ prediction intervals for individual responses (see Figure 73.44). The ALPHA= option in the PROC REG or MODEL statement selects the significance level α, which is 0.05 by default. The PRED option is valid for simple regression models only, and is ignored for plots where prediction intervals are inappropriate. The PRED option replaces the PRED95 option; however, the PRED95 option is still supported when the ALPHA= option is not specified. The OVERLAY option is ignored when the PRED option is specified.

RIDGEPLOT
creates overlaid plots of ridge estimates against ridge values for each coefficient. The points corresponding to the estimates of each coefficient in the plot are connected by lines. For ridge estimates to be computed and plotted, the OUTEST= option must be specified in the PROC REG statement, and the RIDGE=list must be specified in either the PROC REG or MODEL statement.

SBC
displays the SBC statistic in the plot margin.

SP
displays the S_p statistic in the plot margin.

SSE
displays the error sum of squares in the plot margin.

STATFONT=*font*
specifies the font used for displaying the statistics that appear in the plot margin. Refer to *SAS/GRAPH Software: Reference* for tables of software fonts.

STATHT=*height*
specifies the text height of the statistics that appear in the plot margin.

USEALL
specifies that predicted values at data points with missing dependent variable(s) be included on appropriate plots. By default, only points used in constructing the SSCP matrix appear on plots.

VAXIS=*values*

VA=*values*
specifies tick mark values for the vertical axis.

VREF=*values*
specifies where reference lines perpendicular to the vertical axis are to appear.

Line Printer Plots

Line printer plots are requested with the LINEPRINTER option in the PROC REG statement. Points in line printer plots can be marked with *symbols*, which can be specified as a single character enclosed in quotes or the name of any variable in the input data set.

If a character variable is used for the symbol, the first (leftmost) nonblank character in the formatted value of the variable is used as the plotting symbol. If a character in quotes is specified, that character becomes the plotting symbol. If a character is used as the plotting symbol, and if there are different plotting symbols needed at the same point, the symbol '?' is used at that point.

If an unformatted numeric variable is used for the symbol, the symbols '1', '2', ..., '9' are used for variable values 1, 2, ..., 9. For noninteger values, only the integer portion is used as the plotting symbol. For values of 10 or greater, the symbol '*' is used. For negative values, a '?' is used. If a numeric variable is used, and if there is more than one plotting symbol needed at the same point, the sum of the variable values is used at that point. If the sum exceeds 9, the symbol '*' is used.

If a symbol is not specified, the number of replicates at the point is displayed. The symbol '*' is used if there are 10 or more replicates.

If the LINEPRINTER option is used, you can specify the following options in the PLOT statement after a slash (/):

CLEAR
clears any collected scatter plots before plotting begins but does not turn off the COLLECT option. Use this option when you want to begin a new collection with the plots in the current PLOT statement. For more information about collecting plots, see the COLLECT and NOCOLLECT options in this section.

COLLECT
specifies that plots begin to be collected from one PLOT statement to the next and that subsequent plots show an overlay of all collected plots. This option enables you to overlay plots before and after changes to the model or to the data used to fit the model. Plots collected before changes are unaffected by the changes and can be overlaid on later plots. You can

request more than one plot with this option, and you do not need to request the same number of plots in subsequent PLOT statements. If you specify an unequal number of plots, plots in corresponding positions are overlaid. For example, the statements

```
plot residual.*predicted. y*x / collect;
run;
```

produce two plots. If these statements are then followed by

```
plot residual.*x;
run;
```

two plots are again produced. The first plot shows residual against X values overlaid on residual against predicted values. The second plot is the same as that produced by the first PLOT statement.

Axes are scaled for the first plot or plots collected. The axes are not rescaled as more plots are collected.

Once specified, the COLLECT option remains in effect until the NOCOLLECT option is specified.

HPLOTS=*number*

sets the number of scatter plots that can be displayed across the page. The procedure begins with one plot per page. The value of the HPLOTS= option remains in effect until you change it in a later PLOT statement. See the VPLOTS= option for an example.

NOCOLLECT

specifies that the collection of scatter plots ends after adding the plots in the current PLOT statement. PROC REG starts with the NOCOLLECT option in effect. After you specify the NOCOLLECT option, any following PLOT statement produces a new plot that contains only the plots requested by that PLOT statement.

For more information, see the COLLECT option.

OVERLAY

enables requested scatter plots to be superimposed. The axes are scaled so that points on all plots are shown. If the HPLOTS= or VPLOTS= option is set to more than one, the overlaid plot occupies the first position on the page. The OVERLAY option is similar to the COLLECT option in that both options produce superimposed plots. However, OVERLAY superimposes only the plots in the associated PLOT statement; COLLECT superimposes plots across PLOT statements. The OVERLAY option can be used when the COLLECT option is in effect.

SYMBOL='*character***'**

changes the default plotting symbol used for all scatter plots produced in the current and in subsequent PLOT statements. Both SYMBOL=" and SYMBOL=' ' are allowed.

If the SYMBOL= option has not been specified, the default symbol is '1' for positions with one observation, '2' for positions with two observations, and so on. For positions with more than 9 observations, '*' is used. The SYMBOL= option (or a plotting symbol) is needed to avoid any confusion caused by this default convention. Specifying a particular symbol is especially important when either the OVERLAY or COLLECT option is being used.

If you specify the SYMBOL= option and use a number for *character*, that number is used for all points in the plot. For example, the statement

```
plot y*x / symbol='1';
```

produces a plot with the symbol '1' used for all points.

If you specify a plotting symbol and the SYMBOL= option, the plotting symbol overrides the SYMBOL= option. For example, in the statements

```
plot y*x y*v='.' / symbol='*';
```

the symbol used for the plot of Y against X is '*', and a '.' is used for the plot of Y against V.

If a paint symbol is defined with a PAINT statement, the paint symbol takes precedence over both the SYMBOL= option and the default plotting symbol for the PLOT statement.

VPLOTS=*number*

sets the number of scatter plots that can be displayed down the page. The procedure begins with one plot per page. The value of the VPLOTS= option remains in effect until you change it in a later PLOT statement.

For example, to specify a total of six plots per page, with two rows of three plots, use the HPLOTS= and VPLOTS= options as follows:

```
plot y1*x1 y1*x2 y1*x3 y2*x1 y2*x2 y2*x3 /
     hplots=3 vplots=2;
run;
```

PRINT Statement

PRINT < *options* > < *ANOVA* > < *MODELDATA* > **;**

The PRINT statement enables you to interactively display the results of MODEL statement options, produce an ANOVA table, display the data for variables used in the current model, or redisplay the options specified in a MODEL or a previous PRINT statement. In addition, like most other interactive statements in PROC REG, the PRINT statement implicitly refits the model; thus, effects of REWEIGHT statements are seen in the resulting tables. If ODS Graphics is in effect (see the section "ODS Graphics" on page 5589), the PRINT statement also requests the use of the ODS graphical displays associated with the current model.

The following specifications can appear in the PRINT statement:

options

interactively displays the results of MODEL statement options, where *options* is one or more of the following: ACOV, ALL, CLI, CLM, COLLIN, COLLINOINT, CORRB, COVB, DW, I, INFLUENCE, P, PARTIAL, PCORR1, PCORR2, R, SCORR1, SCORR2, SEQB, SPEC, SS1, SS2, STB, TOL, VIF, or XPX. See the section "MODEL Statement" on page 5469 for a description of these options.

ANOVA

produces the ANOVA table associated with the current model. This is either the model specified in the last MODEL statement or the model that incorporates changes made by ADD, DELETE, or REWEIGHT statements after the last MODEL statement.

MODELDATA
displays the data for variables used in the current model.

Use the statement

```
print;
```

to reprint options in the most recently specified PRINT or MODEL statement.

Options that require original data values, such as R or INFLUENCE, cannot be used when a TYPE=CORR, TYPE=COV, or TYPE=SSCP data set is used as the input data set to PROC REG. See the section "Input Data Sets" on page 5508 for more detail.

REFIT Statement

REFIT ;

The REFIT statement causes the current model and corresponding statistics to be recomputed immediately. No output is generated by this statement. The REFIT statement is needed after one or more REWEIGHT statements to cause them to take effect before subsequent PAINT or REWEIGHT statements. This is sometimes necessary when you are using statistical conditions in REWEIGHT statements. For example, consider the following statements:

```
paint student.>2;
plot student.*p.;
reweight student.>2;
refit;
paint student.>2;
plot student.*p.;
```

The second PAINT statement paints any additional observations that meet the condition after deleting observations and refitting the model. The REFIT statement is used because the REWEIGHT statement does not cause the model to be recomputed. In this particular example, the same effect could be achieved by replacing the REFIT statement with a PLOT statement.

Most interactive statements can be used to implicitly refit the model; any plots or statistics produced by these statements reflect changes made to the model and changes made to the data used to compute the model. The two exceptions are the PAINT and REWEIGHT statements, which do not cause the model to be recomputed.

RESTRICT Statement

RESTRICT *equation* < , . . . , *equation* > **;**

A RESTRICT statement is used to place restrictions on the parameter estimates in the MODEL preceding it. More than one RESTRICT statement can follow each MODEL statement. Each RE-

STRICT statement replaces any previous RESTRICT statement. To lift all restrictions on a model, submit a new MODEL statement. If there are several restrictions, separate them with commas. The statement

```
restrict equation1=equation2=equation3;
```

is equivalent to imposing the two restrictions

```
restrict equation1=equation2;
restrict equation2=equation3;
```

Each restriction is written as a linear equation and can be written as

equation

or

equation = equation

The form of each *equation* is

$$c_1 \times variable_1 \pm c_2 \times variable_2 \pm \cdots \pm c_n \times variable_n$$

where the c_j's are constants and the $variable_j$'s are any regressor variables.

When no equal sign appears, the linear combination is set equal to zero. Each variable name mentioned must be a variable in the MODEL statement to which the RESTRICT statement refers. The keyword INTERCEPT can also be used as a variable name, and it refers to the intercept parameter in the regression model.

Note that the parameters associated with the variables are restricted, not the variables themselves. Restrictions should be consistent and not redundant.

Examples of valid RESTRICT statements include the following:

```
restrict x1;
restrict a+b=1;
restrict a=b=c;
restrict a=b, b=c;
restrict 2*f=g+h, intercept+f=0;
restrict f=g=h=intercept;
```

The third and fourth statements in this list produce identical restrictions. You cannot specify

```
restrict f-g=0,
         f-intercept=0,
         g-intercept=1;
```

because the three restrictions are not consistent. If these restrictions are included in a RESTRICT statement, one of the restrict parameters is set to zero and has zero degrees of freedom, indicating that PROC REG is unable to apply a restriction.

The restrictions usually operate even if the model is not of full rank. Check to ensure that DF= -1 for each restriction. In addition, the model DF should decrease by 1 for each restriction.

The parameter estimates are those that minimize the quadratic criterion (SSE) subject to the restrictions. If a restriction cannot be applied, its parameter value and degrees of freedom are listed as zero.

The method used for restricting the parameter estimates is to introduce a Lagrangian parameter for each restriction (Pringle and Rayner 1971). The estimates of these parameters are displayed with test statistics. Note that the t statistic reported for the Lagrangian parameters does not follow a Student's t distribution, but its square follows a beta distribution (LaMotte 1994). The p-value for these parameters is computed using the beta distribution.

The Lagrangian parameter γ measures the sensitivity of the SSE to the restriction constant. If the restriction constant is changed by a small amount ϵ, the SSE is changed by $2\gamma\epsilon$. The t ratio tests the significance of the restrictions. If γ is zero, the restricted estimates are the same as the unrestricted estimates, and a change in the restriction constant in either direction increases the SSE.

RESTRICT statements are ignored if the PCOMIT= or RIDGE= option is specified in the PROC REG statement.

REWEIGHT Statement

REWEIGHT < *condition* | *ALLOBS* > < / *options* > **;**

REWEIGHT < *STATUS* | *UNDO* > **;**

The REWEIGHT statement interactively changes the weights of observations that are used in computing the regression equation. The REWEIGHT statement can change observation weights, or set them to zero, which causes selected observations to be excluded from the analysis. When a REWEIGHT statement sets observation weights to zero, the observations are not deleted from the data set. More than one REWEIGHT statement can be used. The requests from all REWEIGHT statements are applied to the subsequent statements. Each use of the REWEIGHT statement modifies the MODEL label.

The model and corresponding statistics are not recomputed after a REWEIGHT statement. For example, consider the following statements:

```
reweight r.>0;
reweight r.>0;
```

The second REWEIGHT statement does not exclude any additional observations since the model is not recomputed after the first REWEIGHT statement. Either use a REFIT statement to explicitly refit the model, or implicitly refit the model by following the REWEIGHT statement with any other interactive statement except a PAINT statement or another REWEIGHT statement.

The REWEIGHT statement cannot be used if a TYPE=CORR, TYPE=COV, or TYPE=SSCP data set is used as an input data set to PROC REG. Note that the syntax used in the REWEIGHT statement is the same as the syntax in the PAINT statement.

The syntax of the REWEIGHT statement is described in the following sections.

For detailed examples of using this statement, see the section "Reweighting Observations in an Analysis" on page 5569.

Specifying Condition

Condition is used to find observations to be reweighted. The syntax of *condition* is

variable compare value

or

variable compare value *logical* *variable compare value*

where

variable is one of the following:

- a variable name in the input data set
- OBS**.**, which is the observation number
- *keyword***.**, where *keyword* is a keyword for a statistic requested in the OUTPUT statement. The keyword specification is applied to all dependent variables in the model.

compare is an operator that compares *variable* to *value*. *Compare* can be any one of the following: <, <=, >, >=, =, ^ =. The operators LT, LE, GT, GE, EQ, and NE, respectively, can be used instead of the preceding symbols. Refer to the "Expressions" chapter in *SAS Language Reference: Concepts* for more information about comparison operators.

value gives an unformatted value of *variable*. Observations are selected to be reweighted if they satisfy the condition created by *variable compare value*. *Value* can be a number or a character string. If *value* is a character string, it must be eight characters or less and must be enclosed in quotes. In addition, *value* is case-sensitive. In other words, the following two statements are not the same:

```
reweight name='steve';

reweight name='Steve';
```

logical is one of two logical operators. Either AND or OR can be used. To specify AND, use AND or the symbol &. To specify OR, use OR or the symbol |.

Here are some examples of the *variable compare value* form:

```
reweight obs. le 10;
reweight temp=55;
reweight type='new';
```

Here are some example of the *variable compare value* *logical* *variable compare value* form:

```
reweight obs.<=10 and residual.<2;
reweight student.<-2 or student.>2;
reweight name='Mary' | name='Susan';
```

Using ALLOBS

Instead of specifying *condition*, you can use the ALLOBS option to select all observations. This is most useful when you want to restore the original weights of all observations. For example,

```
reweight allobs / reset;
```

resets weights for all observations and uses all observations in the subsequent analysis. Note that

```
reweight allobs;
```

specifies that all observations be excluded from analysis. Consequently, using ALLOBS is useful only if you also use one of the options discussed in the following section.

Options in the REWEIGHT Statement

The following options can be used when either a condition, ALLOBS, or nothing is specified before the slash. If only an option is listed, the option applies to the observations selected in the previous REWEIGHT statement, not to the observations selected by reapplying the condition from the previous REWEIGHT statement. For example, consider the following statements:

```
reweight r.>0 / weight=0.1;
refit;
reweight;
```

The second REWEIGHT statement excludes from the analysis only those observations selected in the first REWEIGHT statement. No additional observations are excluded even if there are new observations that meet the condition in the first REWEIGHT statement.

NOTE: Options are not available when either the UNDO or STATUS option is used.

NOLIST

suppresses the display of the selected observation numbers. If you omit the NOLIST option, a list of observations selected is written to the log.

RESET

resets the observation weights to their original values as defined by the WEIGHT statement or to WEIGHT=1 if no WEIGHT statement is specified. For example,

```
reweight / reset;
```

resets observation weights to the original weights in the data set. If previous REWEIGHT statements have been submitted, this REWEIGHT statement applies only to the observations selected by the previous REWEIGHT statement. Note that, although the RESET option does reset observation weights to their original values, it does not cause the model and corresponding statistics to be recomputed.

WEIGHT=*value*

changes observation weights to the specified nonnegative real number. If you omit the WEIGHT= option, the observation weights are set to zero, and observations are excluded from the analysis. For example:

```
reweight name='Alan';
\Codecomment{...other interactive statements}
reweight / weight=0.5;
```

The first REWEIGHT statement changes weights to zero for all observations with name='Alan', effectively deleting these observations. The subsequent analysis does not include these observations. The second REWEIGHT statement applies only to those observations selected by the previous REWEIGHT statement, and it changes the weights to 0.5 for all the observations with NAME='Alan'. Thus, the next analysis includes all original observations; however, those observations with NAME='Alan' have their weights set to 0.5.

STATUS and UNDO

If you omit *condition* and the ALLOBS options, you can specify one of the following options.

STATUS

writes to the log the observation's number and the weight of all reweighted observations. If an observation's weight has been set to zero, it is reported as deleted. However, the observation is not deleted from the data set, only from the analysis.

UNDO

undoes the changes made by the most recent REWEIGHT statement. Weights might be, but are not necessarily, reset. For example, consider the following statements:

```
reweight student.>2 / weight=0.1;
reweight;
reweight undo;
```

The first REWEIGHT statement sets the weights of observations that satisfy the condition to 0.1. The second REWEIGHT statement sets the weights of the same observations to zero. The third REWEIGHT statement undoes the second, changing the weights back to 0.1.

TEST Statement

< label: > TEST *equation,< ,. . . ,equation> < / option>* **;**

The TEST statement tests hypotheses about the parameters estimated in the preceding MODEL statement. It has the same syntax as the RESTRICT statement except that it supports an option. Each equation specifies a linear hypothesis to be tested. The rows of the hypothesis are separated by commas.

Variable names must correspond to regressors, and each variable name represents the coefficient of the corresponding variable in the model. An optional label is useful to identify each test with a name. The keyword INTERCEPT can be used instead of a variable name to refer to the model's intercept.

The REG procedure performs an F test for the joint hypotheses specified in a single TEST statement. More than one TEST statement can accompany a MODEL statement. The numerator is the usual quadratic form of the estimates; the denominator is the mean squared error. If hypotheses can be represented by

$$\mathbf{L}\boldsymbol{\beta} = \mathbf{c}$$

then the numerator of the F test is

$$\mathbf{Q} = (\mathbf{Lb} - \mathbf{c})'(\mathbf{L}(\mathbf{X}'\mathbf{X})^{-}\mathbf{L}')^{-1}(\mathbf{Lb} - \mathbf{c})$$

divided by degrees of freedom, where $\mathbf{b}$ is the estimate of $\boldsymbol{\beta}$. For example:

```
model y=a1 a2 b1 b2;
aplus: test a1+a2=1;
b1:    test b1=0, b2=0;
b2:    test b1, b2;
```

The last two statements are equivalent; since no constant is specified, zero is assumed.

Note that, when the ACOV, HCC, or WHITE option is specified in the MODEL statement, tests are recomputed using the heteroscedasticity-consistent covariance matrix specified with the HCCMETHOD= option in the MODEL statement (see the section "Testing for Heteroscedasticity" on page 5575).

One option can be specified in the TEST statement after a slash (/):

PRINT
displays intermediate calculations. This includes $\mathbf{L}(\mathbf{X}'\mathbf{X})^{-}\mathbf{L}'$ bordered by $\mathbf{Lb} - \mathbf{c}$, and $(\mathbf{L}(\mathbf{X}'\mathbf{X})^{-}\mathbf{L}')^{-1}$ bordered by $(\mathbf{L}(\mathbf{X}'\mathbf{X})^{-}\mathbf{L}')^{-1}(\mathbf{Lb} - \mathbf{c})$.

VAR Statement

VAR *variables* **;**

The VAR statement is used to include numeric variables in the crossproducts matrix that are not specified in the first MODEL statement.

Variables not listed in MODEL statements before the first RUN statement must be listed in the VAR statement if you want the ability to add them interactively to the model with an ADD statement, to include them in a new MODEL statement, or to plot them in a scatter plot with the PLOT statement.

In addition, if you want to use options in the PROC REG statement and do not want to fit a model to the data (with a MODEL statement), you must use a VAR statement.

WEIGHT Statement

WEIGHT *variable* **;**

A WEIGHT statement names a variable in the input data set with values that are relative weights for a weighted least squares fit. If the weight value is proportional to the reciprocal of the variance for each observation, then the weighted estimates are the best linear unbiased estimates (BLUE).

Values of the weight variable must be nonnegative. If an observation's weight is zero, the observation is deleted from the analysis. If a weight is negative or missing, it is set to zero, and the observation is excluded from the analysis. A more complete description of the WEIGHT statement can be found in Chapter 39, "The GLM Procedure."

Observation weights can be changed interactively with the REWEIGHT statement.

Details: REG Procedure

Missing Values

PROC REG constructs only one crossproducts matrix for the variables in all regressions. If any variable needed for any regression is missing, the observation is excluded from all estimates. If you include variables with missing values in the VAR statement, the corresponding observations are excluded from all analyses, even if you never include the variables in a model. PROC REG assumes that you might want to include these variables after the first RUN statement and deletes observations with missing values.

Input Data Sets

PROC REG does not compute new regressors. For example, if you want a quadratic term in your model, you should create a new variable when you prepare the input data. For example, the statement

```
model y=x1 x1*x1;
```

is not valid. Note that this MODEL statement is valid in the GLM procedure.

The input data set for most applications of PROC REG contains standard rectangular data, but special TYPE=CORR, TYPE=COV, and TYPE=SSCP data sets can also be used. TYPE=CORR and TYPE=COV data sets created by the CORR procedure contain means and standard deviations. In addition, TYPE=CORR data sets contain correlations and TYPE=COV data sets contain covariances. TYPE=SSCP data sets created in previous runs of PROC REG that used the OUTSSCP= option contain the sums of squares and crossproducts of the variables.

See Appendix A, "Special SAS Data Sets," and the "SAS Files" section in *SAS Language Reference: Concepts* for more information about special SAS data sets.

These summary files save CPU time. It takes nk^2 operations (where n=number of observations and k=number of variables) to calculate crossproducts; the regressions are of the order k^3. When n is in the thousands and k is less than 10, you can save 99% of the CPU time by reusing the SSCP matrix rather than recomputing it.

When you want to use a special SAS data set as input, PROC REG must determine the TYPE for the data set. PROC CORR and PROC REG automatically set the type for their output data sets. However, if you create the data set by some other means (such as a DATA step), you must specify its type with the TYPE= data set option. If the TYPE for the data set is not specified when the data set is created, you can specify TYPE= as a data set option in the DATA= option in the PROC REG statement. For example:

```
proc reg data=a(type=corr);
```

When a TYPE=CORR, TYPE=COV, or TYPE=SSCP data set is used with PROC REG, statements and options that require the original data values have no effect. The OUTPUT, PAINT, PLOT, and REWEIGHT statements and the MODEL and PRINT statement options P, R, CLM, CLI, DW, INFLUENCE, and PARTIAL are disabled since the original observations needed to calculate predicted and residual values are not present.

Example Using TYPE=CORR Data Set

The following statements use PROC CORR to produce an input data set for PROC REG. The fitness data for this analysis can be found in Example 73.2.

```
proc corr data=fitness outp=r noprint;
   var Oxygen RunTime Age Weight RunPulse MaxPulse RestPulse;
proc print data=r;
proc reg data=r;
```

```
    model Oxygen=RunTime Age Weight;
run;
```

Since the OUTP= data set from PROC CORR is automatically set to TYPE=CORR, the TYPE= data set option is not required in this example. The data set containing the correlation matrix is displayed by the PRINT procedure as shown in Figure 73.14. Figure 73.15 shows results from the regression that uses the TYPE=CORR data as an input data set.

Age	1	−0.17388	0.09955	−1.75	0.0921
Weight	1	−0.05444	0.06181	−0.88	0.3862

The following example uses the saved crossproducts matrix:

```
proc reg data=fitness outsscp=sscp noprint;
   model Oxygen=RunTime Age Weight RunPulse MaxPulse RestPulse;
proc print data=sscp;
proc reg data=sscp;
   model Oxygen=RunTime Age Weight;
run;
```

First, all variables are used to fit the data and create the SSCP data set. Figure 73.16 shows the PROC PRINT display of the SSCP data set. The SSCP data set is then used as the input data set for PROC REG, and a reduced model is fit to the data.

Figure 73.16 TYPE=SSCP Data Set Created by PROC REG

Age	1	−0.17388	0.09955	−1.75	0.0921
Weight	1	−0.05444	0.06181	−0.88	0.3862

In the preceding example, the TYPE= data set option is not required since PROC REG sets the OUTSSCP= data set to TYPE=SSCP.

Output Data Sets

OUTEST= Data Set

The OUTEST= specification produces a TYPE=EST output SAS data set containing estimates and optional statistics from the regression models. For each BY group on each dependent variable occurring in each MODEL statement, PROC REG outputs an observation to the OUTEST= data set. The variables output to the data set are as follows:

- the BY variables, if any
- _MODEL_, a character variable containing the label of the corresponding MODEL statement, or MODEL*n* if no label is specified, where *n* is 1 for the first MODEL statement, 2 for the second model statement, and so on
- _TYPE_, a character variable with the value 'PARMS' for every observation

- _DEPVAR_, the name of the dependent variable
- _RMSE_, the root mean squared error or the estimate of the standard deviation of the error term
- Intercept, the estimated intercept, unless the NOINT option is specified
- all the variables listed in any MODEL or VAR statement. Values of these variables are the estimated regression coefficients for the model. A variable that does not appear in the model corresponding to a given observation has a missing value in that observation. The dependent variable in each model is given a value of -1.

If you specify the COVOUT option, the covariance matrix of the estimates is output after the estimates; the _TYPE_ variable is set to the value 'COV' and the names of the rows are identified by the character variable, _NAME_.

If you specify the TABLEOUT option, the following statistics listed by _TYPE_ are added after the estimates:

- STDERR, the standard error of the estimate
- T, the t statistic for testing if the estimate is zero
- PVALUE, the associated p-value
- LnB, the $100(1-\alpha)$ lower confidence limit for the estimate, where n is the nearest integer to $100(1-\alpha)$ and α defaults to 0.05 or is set by using the ALPHA= option in the PROC REG or MODEL statement
- UnB, the $100(1-\alpha)$ upper confidence limit for the estimate

Specifying the option ADJRSQ, AIC, BIC, CP, EDF, GMSEP, JP, MSE, PC, RSQUARE, SBC, SP, or SSE in the PROC REG or MODEL statement automatically outputs these statistics and the model R^2 for each model selected, regardless of the model selection method. Additional variables, in order of occurrence, are as follows:

- _IN_, the number of regressors in the model not including the intercept
- _P_, the number of parameters in the model including the intercept, if any
- _EDF_, the error degrees of freedom
- _SSE_, the error sum of squares, if the SSE option is specified
- _MSE_, the mean squared error, if the MSE option is specified
- _RSQ_, the R^2 statistic
- _ADJRSQ_, the adjusted R^2, if the ADJRSQ option is specified
- _CP_, the C_p statistic, if the CP option is specified

- _SP_, the S_p statistic, if the SP option is specified
- _JP_, the J_p statistic, if the JP option is specified
- _PC_, the PC statistic, if the PC option is specified
- _GMSEP_, the GMSEP statistic, if the GMSEP option is specified
- _AIC_, the AIC statistic, if the AIC option is specified
- _BIC_, the BIC statistic, if the BIC option is specified
- _SBC_, the SBC statistic, if the SBC option is specified

The following statements produce and display the OUTEST= data set. This example uses the population data given in the section "Polynomial Regression" on page 5440. Figure 73.18 through Figure 73.20 show the regression equations and the resulting OUTEST= data set.

```
proc reg data=USPopulation outest=est;
   m1: model Population=Year;
   m2: model Population=Year YearSq;
proc print data=est;
run;
```

Figure 73.18 Regression Output for Model M1

The REG Procedure

Year	1	1.28786	0.08512	15.13	<.0001

Figure 73.19 Regression Output for Model M2

Analysis of Variance

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	2	159529	79765	8864.19	<.0001
Error	19	170.97193	8.99852		
Corrected Total	21	159700			

Root MSE	2.99975	R-Square	0.9989
Dependent Mean	94.64800	Adj R-Sq	0.9988
Coeff Var	3.16938		

Parameter Estimates

Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	1	21631	639.50181	33.82	<.0001
Year	1	-24.04581	0.67547	-35.60	<.0001
YearSq	1	0.00668	0.00017820	37.51	<.0001

Figure 73.20 OUTEST= Data Set

Obs	_MODEL_	_TYPE_	_DEPVAR_	_RMSE_	Intercept	Year	Population	YearSq
1	m1	PARMS	Population	25.3295	-2345.85	1.2879	-1	.
2	m2	PARMS	Population	2.9998	21630.89	-24.0458	-1	.006684346

The following modification of the previous example uses the TABLEOUT and ALPHA= options to obtain additional information in the OUTEST= data set:

```
proc reg data=USPopulation outest=est tableout alpha=0.1;
   m1: model Population=Year/noprint;
   m2: model Population=Year YearSq/noprint;
proc print data=est;
run;
```

Notice that the TABLEOUT option causes standard errors, t statistics, p-values, and confidence limits for the estimates to be added to the OUTEST= data set. Also note that the ALPHA= option is used to set the confidence level at 90%. The OUTEST= data set is shown in Figure 73.21.

Figure 73.21 The OUTEST= Data Set When TABLEOUT Is Specified

Obs	_MODEL_	_TYPE_	_DEPVAR_	_RMSE_	Intercept	Year	Population	YearSq

11	m2	L90B	Population	2.9998	20525.11	-25.2138	.	0.0064
12	m2	U90B	Population	2.9998	22736.68	-22.8778	.	0.0070

A slightly different OUTEST= data set is created when you use the RSQUARE selection method. The following statements request only the "best" model for each subset size but ask for a variety of model selection statistics, as well as the estimated regression coefficients. An OUTEST= data set is created and displayed. See Figure 73.22 and Figure 73.23 for the results.

```
proc reg data=fitness outest=est;
   model Oxygen=Age Weight RunTime RunPulse RestPulse MaxPulse
         / selection=rsquare mse jp gmsep cp aic bic sbc b best=1;
proc print data=est;
run;
```

OUTSSCP= Data Sets

The OUTSSCP= option produces a TYPE=SSCP output SAS data set containing sums of squares and crossproducts. A special row (observation) and column (variable) of the matrix called Intercept contain the number of observations and sums. Observations are identified by the character variable _NAME_. The data set contains all variables used in MODEL statements. You can specify additional variables that you want included in the crossproducts matrix with a VAR statement.

The SSCP data set is used when a large number of observations are explored in many different runs. The SSCP data set can be saved and used for subsequent runs, which are much less expensive since PROC REG never reads the original data again. If you run PROC REG once to create only a SSCP data set, you should list all the variables that you might need in a VAR statement or include all the variables that you might need in a MODEL statement.

The following statements use the fitness data from Example 73.2 to produce an output data set with the OUTSSCP= option. The resulting output is shown in Figure 73.24.

```
proc reg data=fitness outsscp=sscp;
   var Oxygen RunTime Age Weight RestPulse RunPulse MaxPulse;
proc print data=sscp;
run;
```

Since a model is not fit to the data and since the only request is to create the SSCP data set, a MODEL statement is not required in this example. However, since the MODEL statement is not used, the VAR statement is required.

Interactive Analysis

PROC REG enables you to change interactively both the model and the data used to compute the model, and to produce and highlight scatter plots. See the section "Using PROC REG Interactively" on page 5450 for an overview of interactive analysis that uses PROC REG. The following statements can be used interactively (without reinvoking PROC REG): ADD, DELETE, MODEL, MTEST, OUTPUT, PAINT, PLOT, PRINT, REFIT, RESTRICT, REWEIGHT, and TEST. All interactive features are disabled if there is a BY statement.

The ADD, DELETE, and REWEIGHT statements can be used to modify the current MODEL. Every use of an ADD, DELETE, or REWEIGHT statement causes the model label to be modified by attaching an additional number to it. This number is the cumulative total of the number of ADD, DELETE, or REWEIGHT statements following the current MODEL statement.

A more detailed explanation of changing the data used to compute the model is given in the section "Reweighting Observations in an Analysis" on page 5569. Extra features for line printer scatter plots are discussed in the section "Line Printer Scatter Plot Features" on page 5534.

The following statements illustrate the usefulness of the interactive features. First, the full regression model is fit to the Class data (see the section "Getting Started: REG Procedure" on page 5436), and Figure 73.25 is produced.

```
ods graphics on;

proc reg data=Class plots(modelLabel only)=ResidualByPredicted;
   model Weight=Age Height;
run;
```

Figure 73.25 Interactive Analysis: Full Model

The REG Procedure
Model: MODEL1
Dependent Variable: Weight

Analysis of Variance

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	2	7215.63710	3607.81855	27.23	<.0001
Error	16	2120.09974	132.50623		
Corrected Total	18	9335.73684			

Root MSE	11.51114	R-Square	0.7729
Dependent Mean	100.02632	Adj R-Sq	0.7445
Coeff Var	11.50811		

Parameter Estimates

Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	1	-141.22376	33.38309	-4.23	0.0006
Age	1	1.27839	3.11010	0.41	0.6865
Height	1	3.59703	0.90546	3.97	0.0011

Next, the regression model is reduced by the following statements, and Figure 73.26 is produced.

```
delete age;
print;
run;
```

Figure 73.26 Interactive Analysis: Reduced Model

Analysis of Variance

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	1	7193.24912	7193.24912	57.08	<.0001
Error	17	2142.48772	126.02869		
Corrected Total	18	9335.73684			

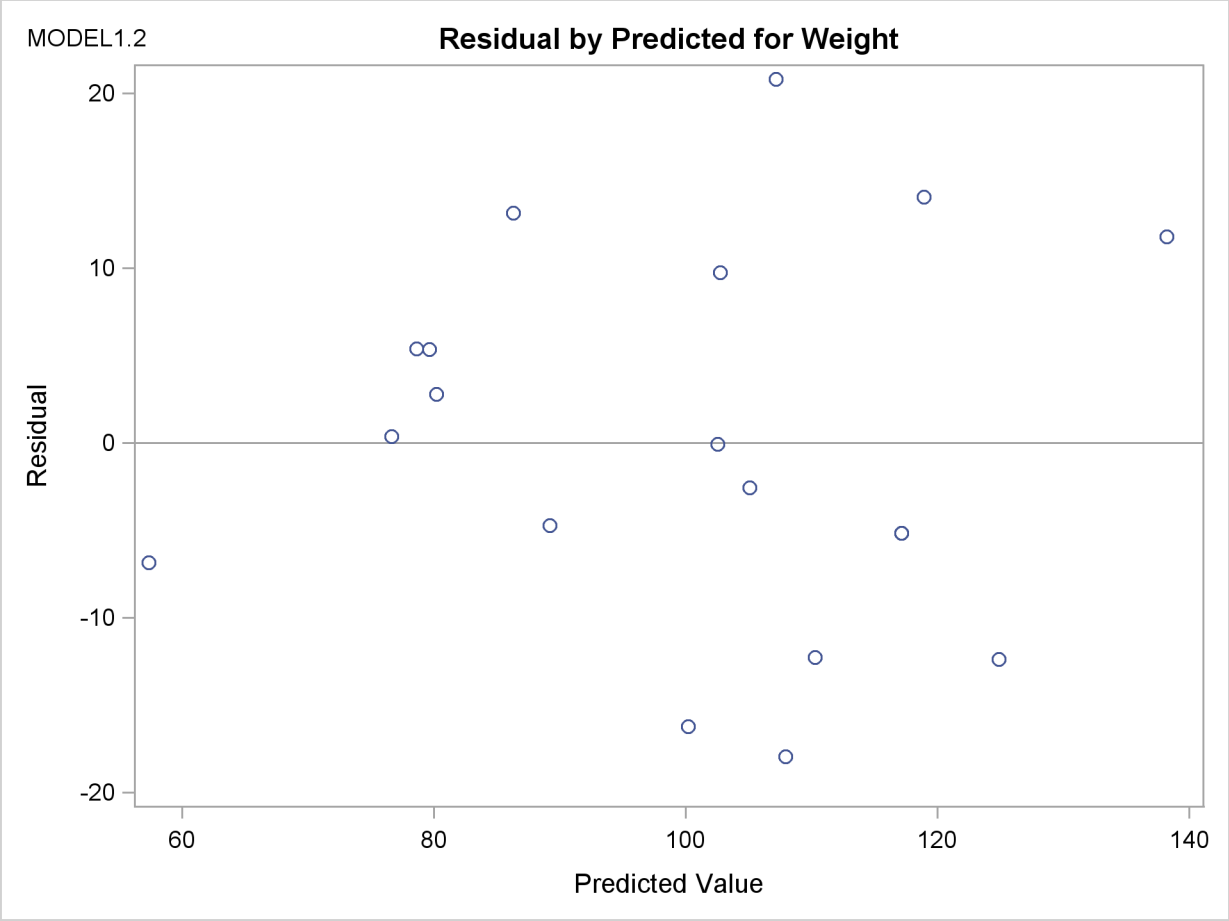
Root MSE	11.22625	R-Square	0.7705
Dependent Mean	100.02632	Adj R-Sq	0.7570
Coeff Var	11.22330		

Parameter Estimates

Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	1	-143.02692	32.27459	-4.43	0.0004
Height	1	3.89903	0.51609	7.55	<.0001

Note that the MODEL label has been changed from MODEL1 to MODEL1.1, since the original MODEL has been changed by the delete statement.

When ODS Graphics is enabled, updated plots are produced whenever a PRINT statement is used. The option



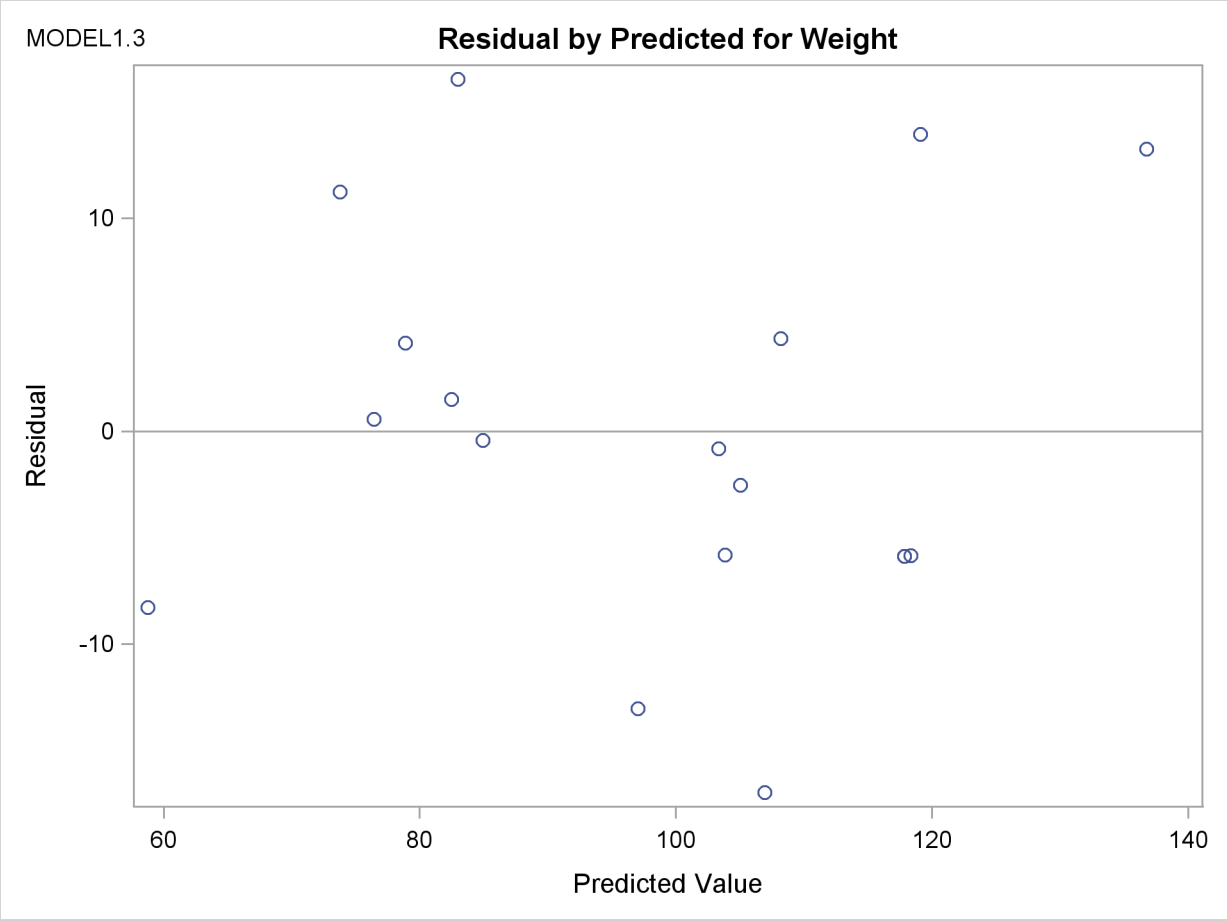
```
plots(modelLabel only)=ResidualByPredicted
```

in the PROC REG statement specifies that the only plot produced is a scatter plot of residuals by predicted values. The MODELLABEL option specifies that the current model label is added to the plot.

The following statements generate a scatter plot of the residuals against the predicted values from the full model. Figure 73.27 is produced, and the scatter plot shows a possible outlier.

```
add age;
print;
run;
```

Figure 73.27 Interactive Analysis: Scatter Plot



The following statements delete the observation with the largest residual, refit the regression model, and produce a scatter plot of residuals against predicted values for the refitted model. Figure 73.28 shows the new scatter plot.

```
reweight r.>20;
print;
run;

ods graphics off;
```

Figure 73.28 Interactive Analysis: Scatter Plot

Model-Selection Methods

The nine methods of model selection implemented in PROC REG are specified with the SELECTION= option in the MODEL statement. Each method is discussed in this section.

Full Model Fitted (NONE)

This method is the default and provides no model selection capability. The complete model specified in the MODEL statement is used to fit the model. For many regression analyses, this might be the only method you need.

Forward Selection (FORWARD)

The forward-selection technique begins with no variables in the model. For each of the independent variables, the FORWARD method calculates F statistics that reflect the variable's contribution to the model if it is included. The p-values for these F statistics are compared to the SLENTRY=

value that is specified in the MODEL statement (or to 0.50 if the SLENTRY= option is omitted). If no F statistic has a significance level greater than the SLENTRY= value, the FORWARD selection stops. Otherwise, the FORWARD method adds the variable that has the largest F statistic to the model. The FORWARD method then calculates F statistics again for the variables still remaining outside the model, and the evaluation process is repeated. Thus, variables are added one by one to the model until no remaining variable produces a significant F statistic. Once a variable is in the model, it stays.

Backward Elimination (BACKWARD)

The backward elimination technique begins by calculating F statistics for a model, including all of the independent variables. Then the variables are deleted from the model one by one until all the variables remaining in the model produce F statistics significant at the SLSTAY= level specified in the MODEL statement (or at the 0.10 level if the SLSTAY= option is omitted). At each step, the variable showing the smallest contribution to the model is deleted.

Stepwise (STEPWISE)

The stepwise method is a modification of the forward-selection technique and differs in that variables already in the model do not necessarily stay there. As in the forward-selection method, variables are added one by one to the model, and the F statistic for a variable to be added must be significant at the SLENTRY= level. After a variable is added, however, the stepwise method looks at all the variables already included in the model and deletes any variable that does not produce an F statistic significant at the SLSTAY= level. Only after this check is made and the necessary deletions are accomplished can another variable be added to the model. The stepwise process ends when none of the variables outside the model has an F statistic significant at the SLENTRY= level and every variable in the model is significant at the SLSTAY= level, or when the variable to be added to the model is the one just deleted from it.

Maximum R^2 Improvement (MAXR)

The maximum R^2 improvement technique does not settle on a single model. Instead, it tries to find the "best" one-variable model, the "best" two-variable model, and so forth, although it is not guaranteed to find the model with the largest R^2 for each size.

The MAXR method begins by finding the one-variable model producing the highest R^2. Then another variable, the one that yields the greatest increase in R^2, is added. Once the two-variable model is obtained, each of the variables in the model is compared to each variable not in the model. For each comparison, the MAXR method determines if removing one variable and replacing it with the other variable increases R^2. After comparing all possible switches, the MAXR method makes the switch that produces the largest increase in R^2. Comparisons begin again, and the process continues until the MAXR method finds that no switch could increase R^2. Thus, the two-variable model achieved is considered the "best" two-variable model the technique can find. Another variable is then added to the model, and the comparing-and-switching process is repeated to find the "best" three-variable model, and so forth.

The difference between the STEPWISE method and the MAXR method is that all switches are evaluated before any switch is made in the MAXR method. In the STEPWISE method, the "worst" variable might be removed without considering what adding the "best" remaining variable might accomplish. The MAXR method might require much more computer time than the STEPWISE method.

Minimum R^2 (MINR) Improvement

The MINR method closely resembles the MAXR method, but the switch chosen is the one that produces the smallest increase in R^2. For a given number of variables in the model, the MAXR and MINR methods usually produce the same "best" model, but the MINR method considers more models of each size.

R^2 Selection (RSQUARE)

The RSQUARE method finds subsets of independent variables that best predict a dependent variable by linear regression in the given sample. You can specify the largest and smallest number of independent variables to appear in a subset and the number of subsets of each size to be selected. The RSQUARE method can efficiently perform all possible subset regressions and display the models in decreasing order of R^2 magnitude within each subset size. Other statistics are available for comparing subsets of different sizes. These statistics, as well as estimated regression coefficients, can be displayed or output to a SAS data set.

The subset models selected by the RSQUARE method are optimal in terms of R^2 for the given sample, but they are not necessarily optimal for the population from which the sample is drawn or for any other sample for which you might want to make predictions. If a subset model is selected on the basis of a large R^2 value or any other criterion commonly used for model selection, then all regression statistics computed for that model under the assumption that the model is given a priori, including all statistics computed by PROC REG, are biased.

While the RSQUARE method is a useful tool for exploratory model building, no statistical method can be relied on to identify the "true" model. Effective model building requires substantive theory to suggest relevant predictors and plausible functional forms for the model.

The RSQUARE method differs from the other selection methods in that RSQUARE always identifies the model with the largest R^2 for each number of variables considered. The other selection methods are not guaranteed to find the model with the largest R^2. The RSQUARE method requires much more computer time than the other selection methods, so a different selection method such as the STEPWISE method is a good choice when there are many independent variables to consider.

Adjusted R^2 Selection (ADJRSQ)

This method is similar to the RSQUARE method, except that the adjusted R^2 statistic is used as the criterion for selecting models, and the method finds the models with the highest adjusted R^2 within the range of sizes.

Mallows' C_p Selection (CP)

This method is similar to the ADJRSQ method, except that Mallows' C_p statistic is used as the criterion for model selection. Models are listed in ascending order of C_p.

Additional Information about Model-Selection Methods

If the RSQUARE or STEPWISE procedure (as documented in *SAS User's Guide: Statistics, Version 5 Edition*) is requested, PROC REG with the appropriate model-selection method is actually used.

Reviews of model-selection methods by Hocking (1976) and Judge et al. (1980) describe these and other variable-selection methods.

Criteria Used in Model-Selection Methods

When many significance tests are performed, each at a level of, for example, 5%, the overall probability of rejecting at least one true null hypothesis is much larger than 5%. If you want to guard against including any variables that do not contribute to the predictive power of the model in the population, you should specify a very small SLE= significance level for the FORWARD and STEPWISE methods and a very small SLS= significance level for the BACKWARD and STEPWISE methods.

In most applications, many of the variables considered have some predictive power, however small. If you want to choose the model that provides the best prediction computed using the sample estimates, you need only to guard against estimating more parameters than can be reliably estimated with the given sample size, so you should use a moderate significance level, perhaps in the range of 10% to 25%.

In addition to R^2, the C_p statistic is displayed for each model generated in the model-selection methods. The C_p statistic is proposed by Mallows (1973) as a criterion for selecting a model. It is a measure of total squared error defined as

$$C_p = \frac{SSE_p}{s^2} - (N - 2p)$$

where s^2 is the MSE for the full model, and SSE_p is the sum-of-squares error for a model with p parameters including the intercept, if any. If C_p is plotted against p, Mallows recommends the model where C_p first approaches p. When the right model is chosen, the parameter estimates are unbiased, and this is reflected in C_p near p. For further discussion, refer to Daniel and Wood (1980).

The adjusted R^2 statistic is an alternative to R^2 that is adjusted for the number of parameters in the model. The adjusted R^2 statistic is calculated as

$$\text{ADJRSQ} = 1 - \frac{(n-i)(1-R^2)}{n-p}$$

where n is the number of observations used in fitting the model, and i is an indicator variable that is 1 if the model includes an intercept, and 0 otherwise.

Limitations in Model-Selection Methods

The use of model-selection methods can be time-consuming in some cases because there is no built-in limit on the number of independent variables, and the calculations for a large number of independent variables can be lengthy. The recommended limit on the number of independent variables for the MINR method is $20 + i$, where i is the value of the INCLUDE= option.

For the RSQUARE, ADJRSQ, or CP method, with a large value of the BEST= option, adding one more variable to the list from which regressors are selected might significantly increase the CPU time. Also, the time required for the analysis is highly dependent on the data and on the values of the BEST=, START=, and STOP= options.

Parameter Estimates and Associated Statistics

The following example uses the fitness data from Example 73.2. Figure 73.30 shows the parameter estimates and the tables from the SS1, SS2, STB, CLB, COVB, and CORRB options:

```
proc reg data=fitness;
   model Oxygen=RunTime Age Weight RunPulse MaxPulse RestPulse
         / ss1 ss2 stb clb covb corrb;
run;
```

The procedure first displays an analysis of variance table (Figure 73.29). The F statistic for the overall model is significant, indicating that the model explains a significant portion of the variation in the data.

Figure 73.29 ANOVA Table

The REG Procedure
Model: MODEL1
Dependent Variable: Oxygen

Analysis of Variance

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	6	722.54361	120.42393	22.43	<.0001
Error	24	128.83794	5.36825		
Corrected Total	30	851.38154			

Root MSE	2.31695	R-Square	0.8487
Dependent Mean	47.37581	Adj R-Sq	0.8108
Coeff Var	4.89057		

The procedure next displays parameter estimates and some associated statistics (Figure 73.30). First, the estimates are shown, followed by their standard errors. The next two columns of the table contain the t statistics and the corresponding probabilities for testing the null hypothesis that the parameter is not significantly different from zero. These probabilities are usually referred to as p-values. For example, the Intercept term in the model is estimated to be 102.9 and is significantly different from zero. The next two columns of the table are the result of requesting the SS1 and SS2 options, and they show sequential and partial sums of squares (SS) associated with each variable. The standardized estimates (produced by the STB option) are the parameter estimates that result when all variables are standardized to a mean of 0 and a variance of 1. These estimates are computed by multiplying the original estimates by the standard deviation of the regressor (independent) variable and then dividing by the standard deviation of the dependent variable. The CLB option adds the upper and lower 95% confidence limits for the parameter estimates; the α level can be changed by specifying the ALPHA= option in the PROC REG or MODEL statement.

Figure 73.30 SS1, SS2, STB, CLB, COVB, and CORRB Options: Parameter Estimates

Parameter Estimates

Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|	Type I SS

For further discussion of the parameters and statistics, see the section "Displayed Output" on page 5584, and Chapter 4, "Introduction to Regression Procedures."

Predicted and Residual Values

The display of the predicted values and residuals is controlled by the P, R, CLM, and CLI options in the MODEL statement. The P option causes PROC REG to display the observation number, the ID value (if an ID statement is used), the actual value, the predicted value, and the residual. The R, CLI, and CLM options also produce the items under the P option. Thus, P is unnecessary if you use one of the other options.

The R option requests more detail, especially about the residuals. The standard errors of the mean predicted value and the residual are displayed. The studentized residual, which is the residual divided by its standard error, is both displayed and plotted. A measure of influence, Cook's D, is displayed. Cook's D measures the change to the estimates that results from deleting each observation (Cook 1977, 1979). This statistic is very similar to DFFITS.

The CLM option requests that PROC REG display the $100(1-\alpha)\%$ lower and upper confidence limits for the mean predicted values. This accounts for the variation due to estimating the parameters only. If you want a $100(1-\alpha)\%$ confidence interval for observed values, then you can use the CLI option, which adds in the variability of the error term. The α level can be specified with the ALPHA= option in the PROC REG or MODEL statement.

You can use these statistics in PLOT and PAINT statements. This is useful in performing a variety of regression diagnostics. For definitions of the statistics produced by these options, see Chapter 4, "Introduction to Regression Procedures."

The following statements use the U.S. population data found in the section "Polynomial Regression" on page 5440. The results are shown in Figure 73.32 and Figure 73.33.

```

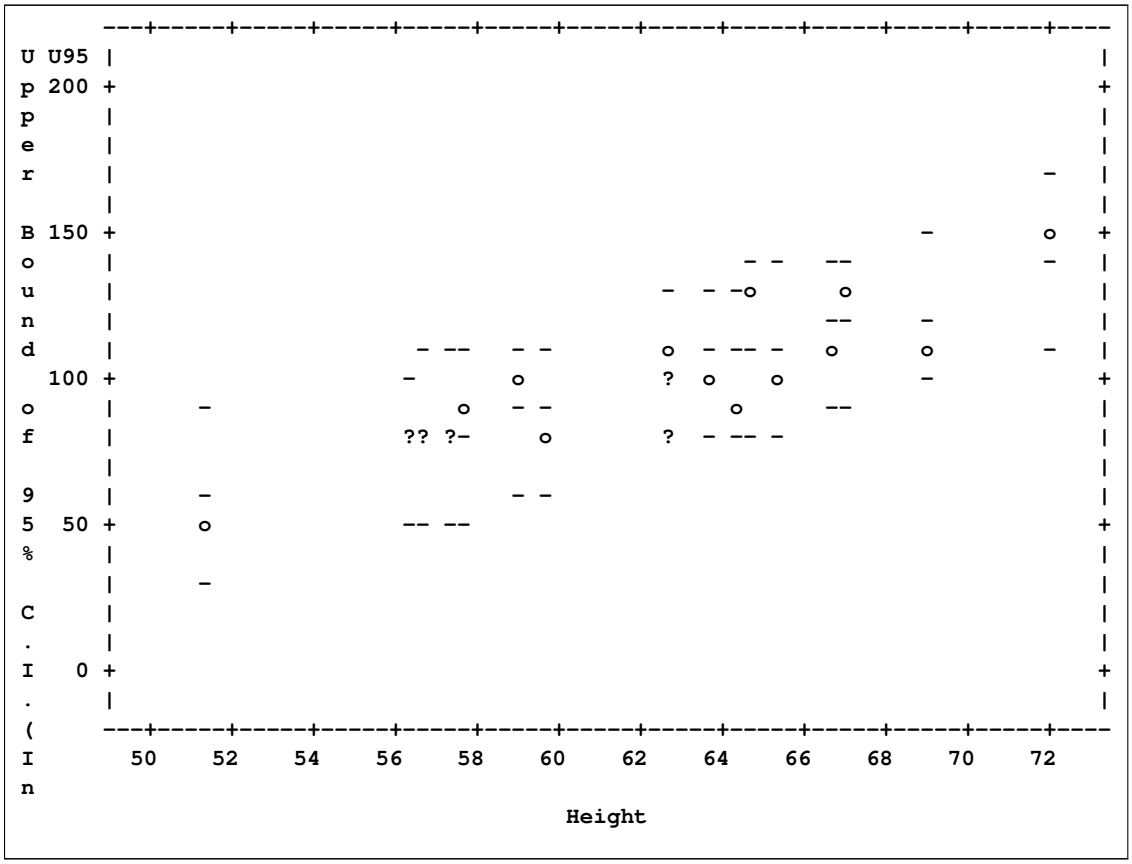
After producing the usual analysis of variance and parameter estimates tables (Figure 73.32), the procedure displays the results of requesting the options for predicted and residual values (Figure 73.33). For each observation, the requested information is shown. Note that the ID variable is used to identify each observation. Also note that, for observations with missing dependent variables, the predicted value, standard error of the predicted value, and confidence intervals for the predicted value are still available.

The columnar print plot of studentized residuals and Cook's D statistics are displayed as a result of requesting the R option. In the plot of studentized residuals, the large number of observations with absolute values greater than two indicates an inadequate model. You can use ODS Graphics to obtain high-resolution plots of studentized residuals by predicted values or leverage; see Example 73.1 for a similar example.

Line Printer Scatter Plot Features

This section discusses the special options available with line printer scatter plots. Detailed examples of traditional graphics and options are given in the section "Traditional Graphics" on page 5547.

Producing Scatter Plots



The interactive PLOT statement available in PROC REG enables you to look at scatter plots of data and diagnostic statistics. These plots can help you to evaluate the model and detect outliers in your data. Several options enable you to place multiple plots on a single page, superimpose plots, and collect plots to be overlaid by later plots. The PAINT statement can be used to highlight points on a plot. See the section "Painting Scatter Plots" on page 5543 for more information about painting.

The Class data set introduced in the section "Simple Linear Regression" on page 5436 is used in the following examples.

You can superimpose several plots with the OVERLAY option. With the following statements, a plot of Weight against Height is overlaid with plots of the predicted values and the 95% prediction intervals. The model on which the statistics are based is the full model including Height and Age. These statements produce the plot in Figure 73.34:

```
proc reg data=Class lineprinter;
   model Weight=Height Age / noprint;
   plot (ucl. lcl. p.)*Height='-' Weight*Height
        / overlay symbol='o';
run;
```

Figure 73.34 Scatter Plot Showing Data, Predicted Values, and Confidence Limits

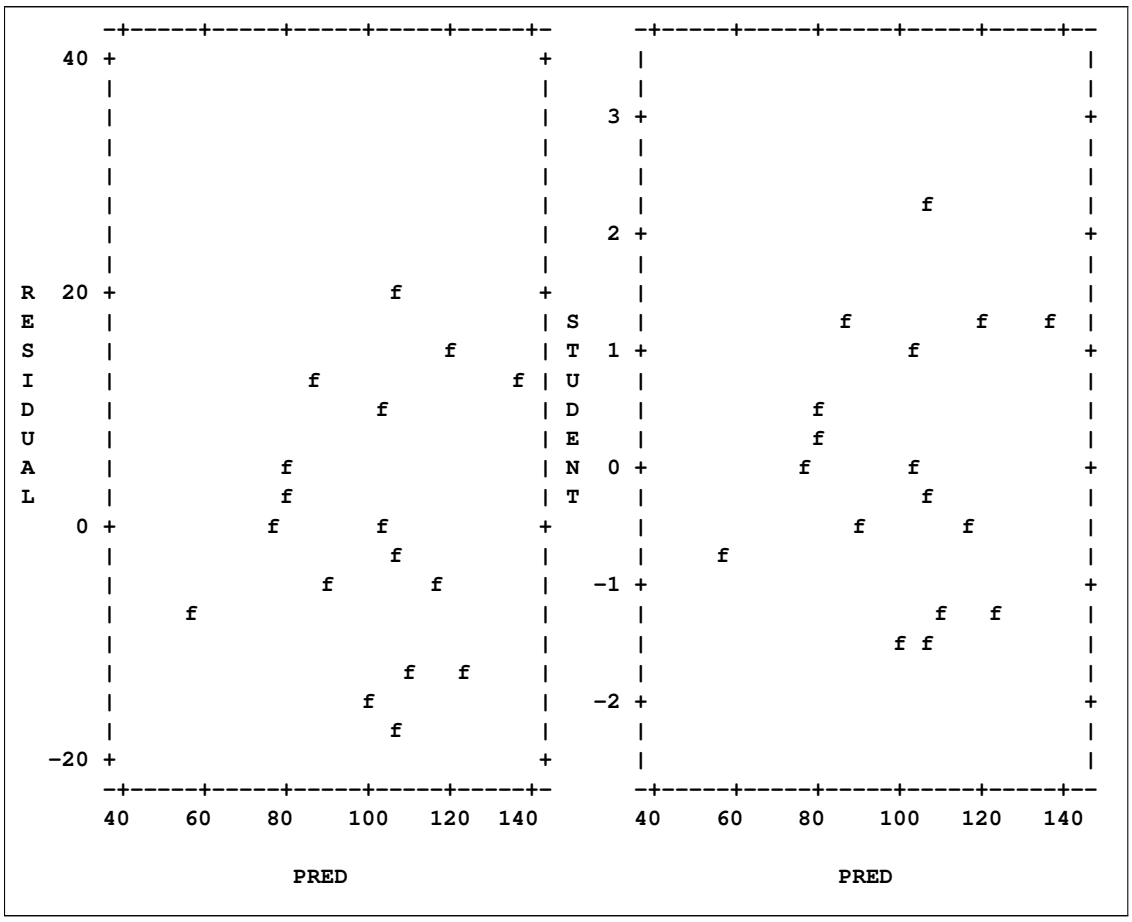
In this plot, the data values are marked with the symbol 'o' and the predicted values and prediction interval limits are labeled with the symbol '-'. The plot is scaled to accommodate the points from all plots. This is an important difference from the COLLECT option, which does not rescale plots after the first plot or plots are collected. You could separate the overlaid plots by using the following statements:

```
plot;
run;
```

This places each of the four plots on a separate page, while the statements

```
plot / overlay;
run;
```

repeat the previous overlaid plot. In general, the statement



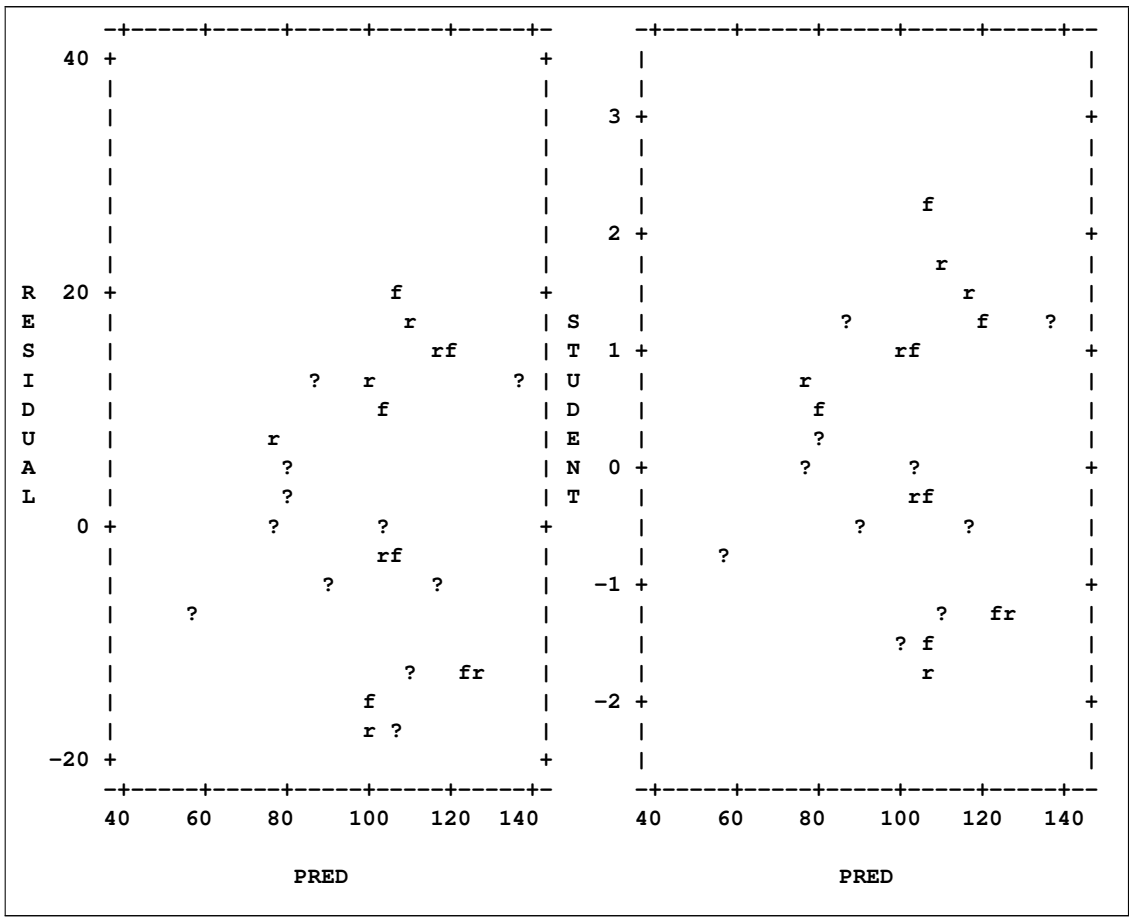
```
plot;
```

is equivalent to respecifying the most recent PLOT statement without any options. However, the COLLECT, HPLOTS=, SYMBOL=, and VPLOTS= options apply across PLOT statements and remain in effect.

The next example shows how you can overlay plots of statistics before and after a change in the model. For the full model involving Height and Age, the ordinary residuals and the studentized residuals are plotted against the predicted values. The COLLECT option causes these plots to be collected or retained for redisplay later. The option HPLOTS=2 enables the two plots to appear side by side on one page. The symbol 'f' is used on these plots to identify them as resulting from the full model. These statements produce Figure 73.35:

```
plot r.*p. student.*p. / collect hplots=2 symbol='f';
run;
```

Figure 73.35 Collecting Residual Plots for the Full Model

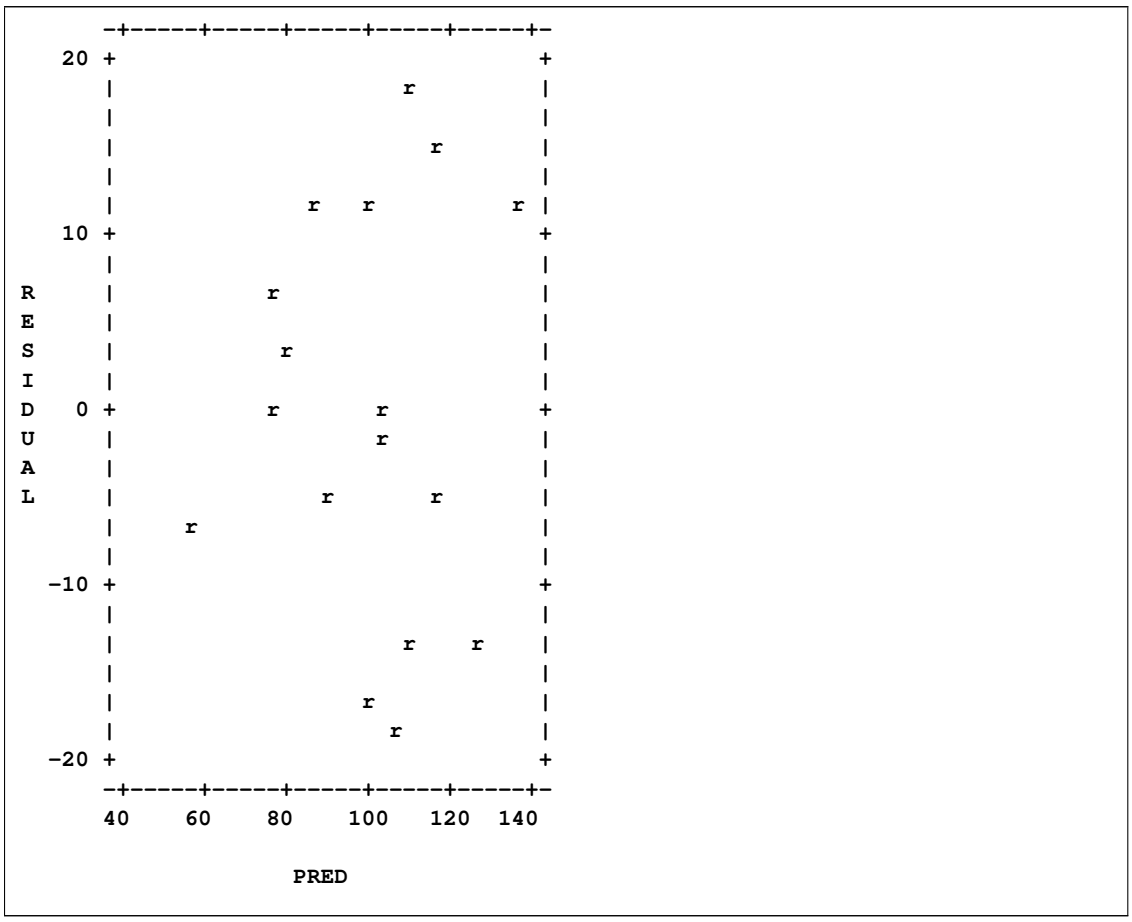


Note that these plots are not overlaid. The COLLECT option does not overlay the plots in one PLOT statement but retains them so that they can be overlaid by later plots. When the COLLECT option appears in a PLOT statement, the plots in that statement become the first plots in the collection.

Next, the model is reduced by deleting the Age variable. The PLOT statement requests the same plots as before but labels the points with the symbol 'r' denoting the reduced model. The following statements produce Figure 73.36:

```
delete Age;
plot r.*p. student.*p. / symbol='r';
run;
```

Figure 73.36 Overlaid Residual Plots for Full and Reduced Models



Notice that the COLLECT option causes the corresponding plots to be overlaid. Also notice that the DELETE statement causes the model label to be changed from MODEL1 to MODEL1.1. The points labeled 'f' are from the full model, and the points labeled 'r' are from the reduced model. Positions labeled '?' contain at least one point from each model. In this example, the OVERLAY option cannot be used because all of the plots to be overlaid cannot be specified in one PLOT statement. With the COLLECT option, any changes to the model or the data used to fit the model do not affect plots collected before the changes. Collected plots are always reproduced exactly as they first appear. (Similarly, a PAINT statement does not affect plots collected before the PAINT statement is issued.)

The previous example overlays the residual plots for two different models. You might prefer to see them side by side on the same page. This can also be done with the COLLECT option by using a blank plot. Continuing from the last example, the COLLECT, HPLOTS=2, and SYMBOL='r' options are still in effect. In the following PLOT statement, the CLEAR option deletes the collected plots and enables the specified plot to begin a new collection. The plot created is the residual plot for the reduced model. These statements produce Figure 73.37:

```
plot r.*p. / clear;
run;
```

Figure 73.37 Residual Plot for Reduced Model Only

The next statements add the variable AGE to the model and place the residual plot for the full model next to the plot for the reduced model. Notice that a blank plot is created in the first plot request by placing nothing between the quotes. Since the COLLECT option is in effect, this plot is superimposed on the residual plot for the reduced model. The residual plot for the full model is created by the second request. The result is the desired side-by-side plots. The NOCOLLECT option turns off the collection process after the specified plots are added and displayed. Any PLOT statements that follow show only the newly specified plots. These statements produce Figure 73.38:

```
add Age;
plot r.*p.='' r.*p.='f' / nocollect;
run;
```

Figure 73.38 Side-by-Side Residual Plots for the Full and Reduced Models

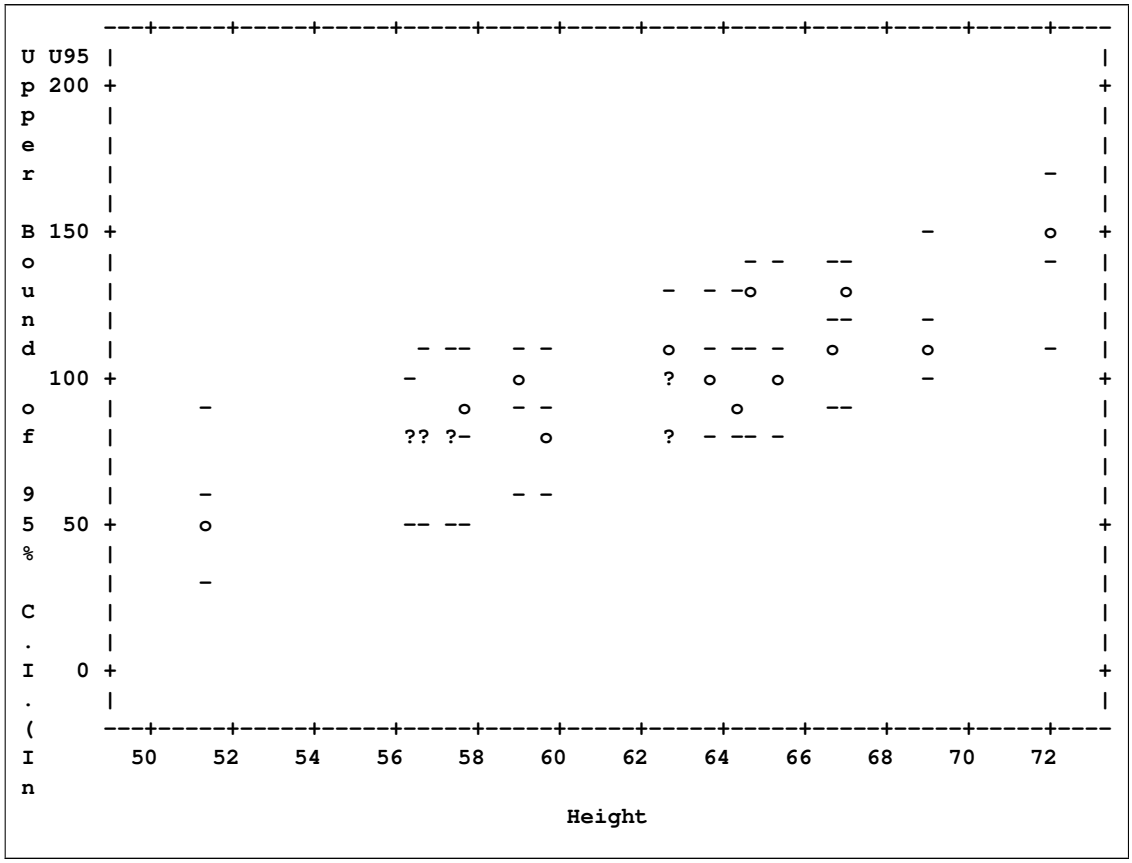


Figure 73.38 *continued*

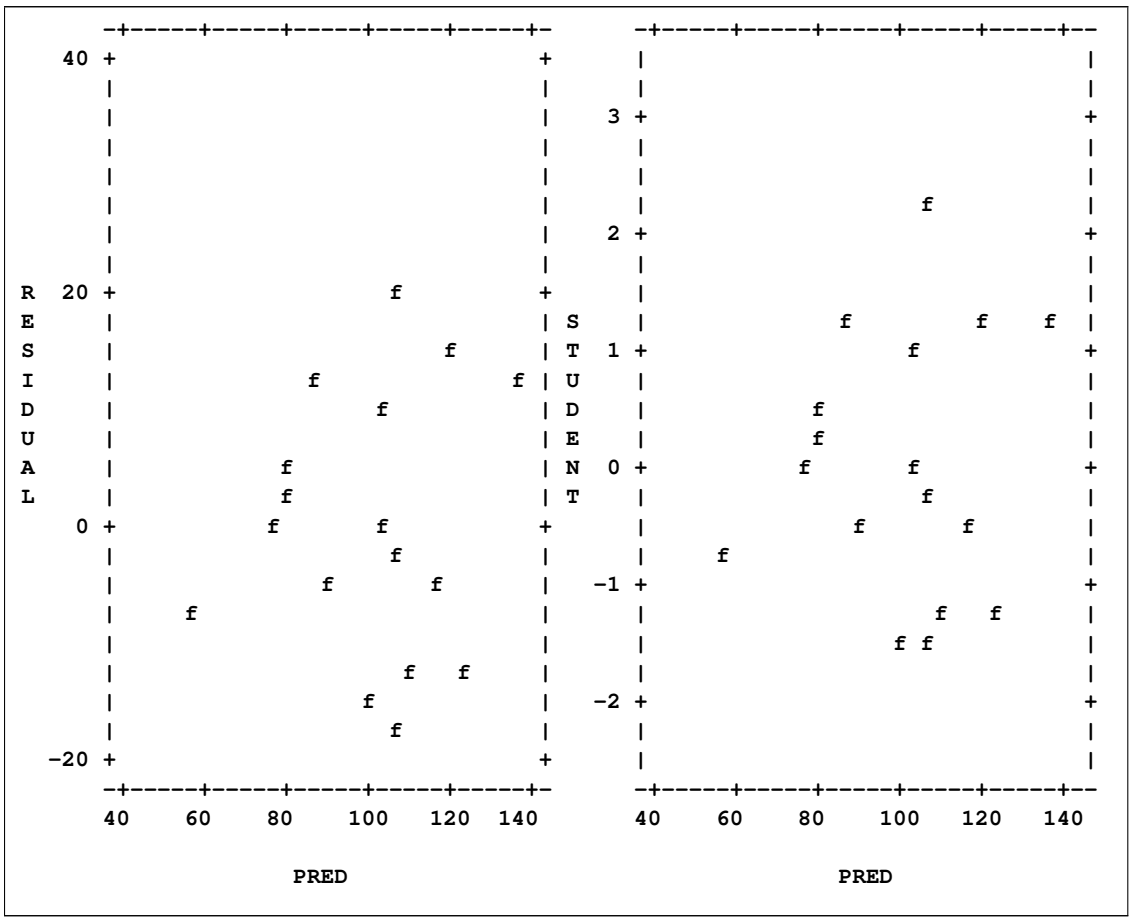

Figure 73.38 *continued*

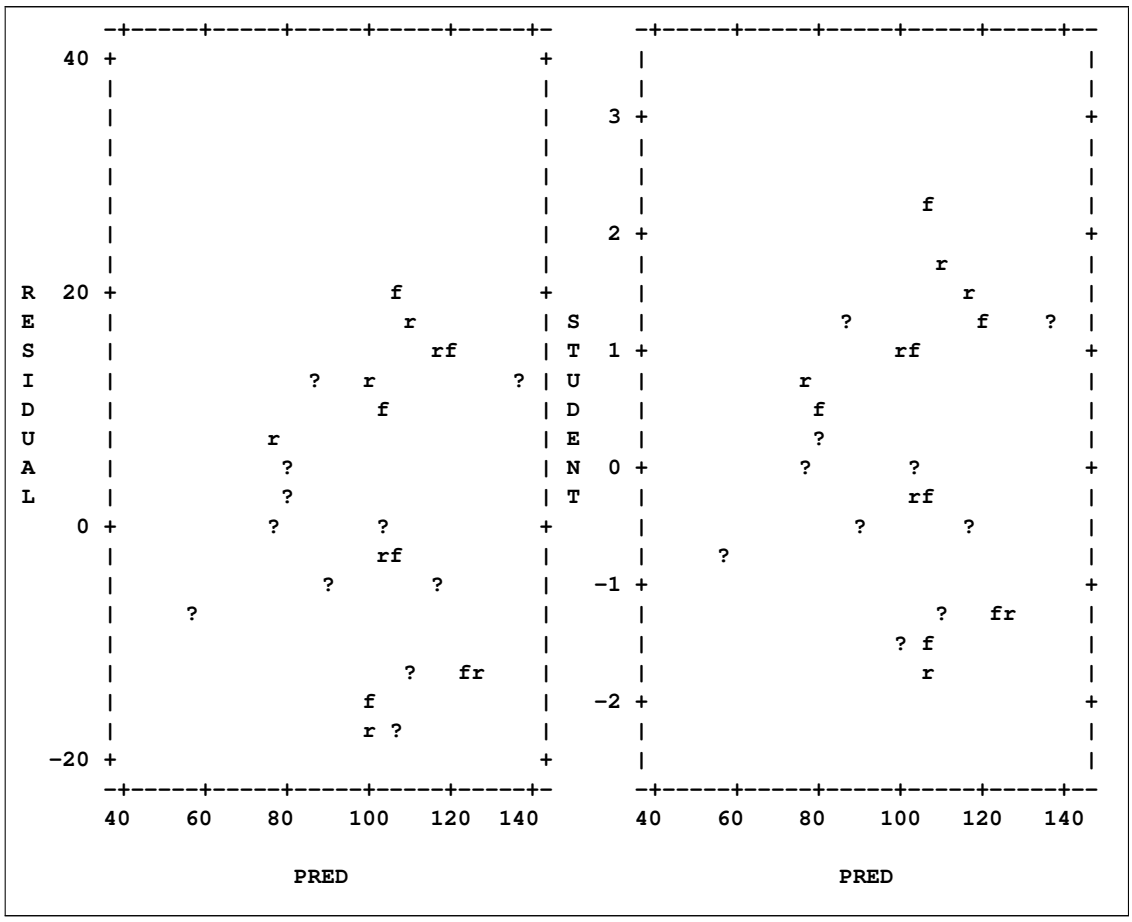

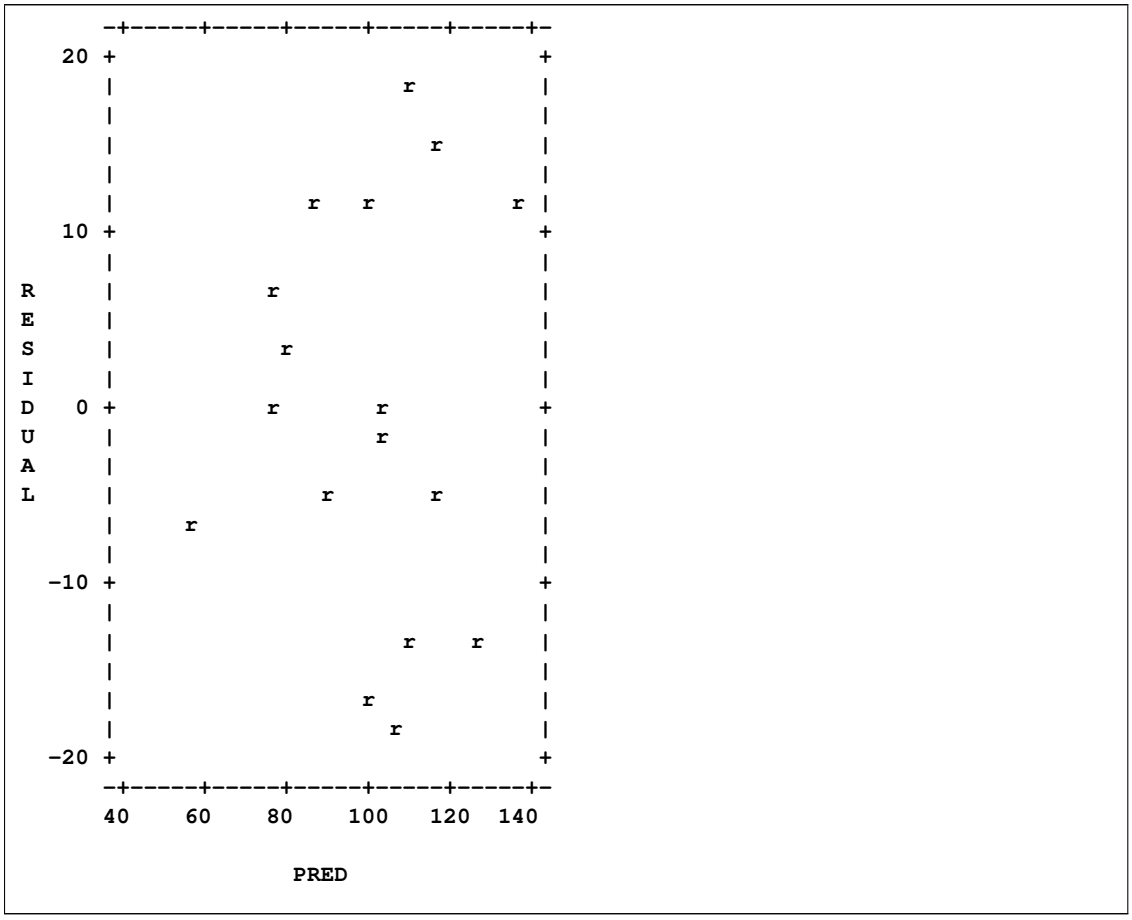

Figure 73.38 *continued*

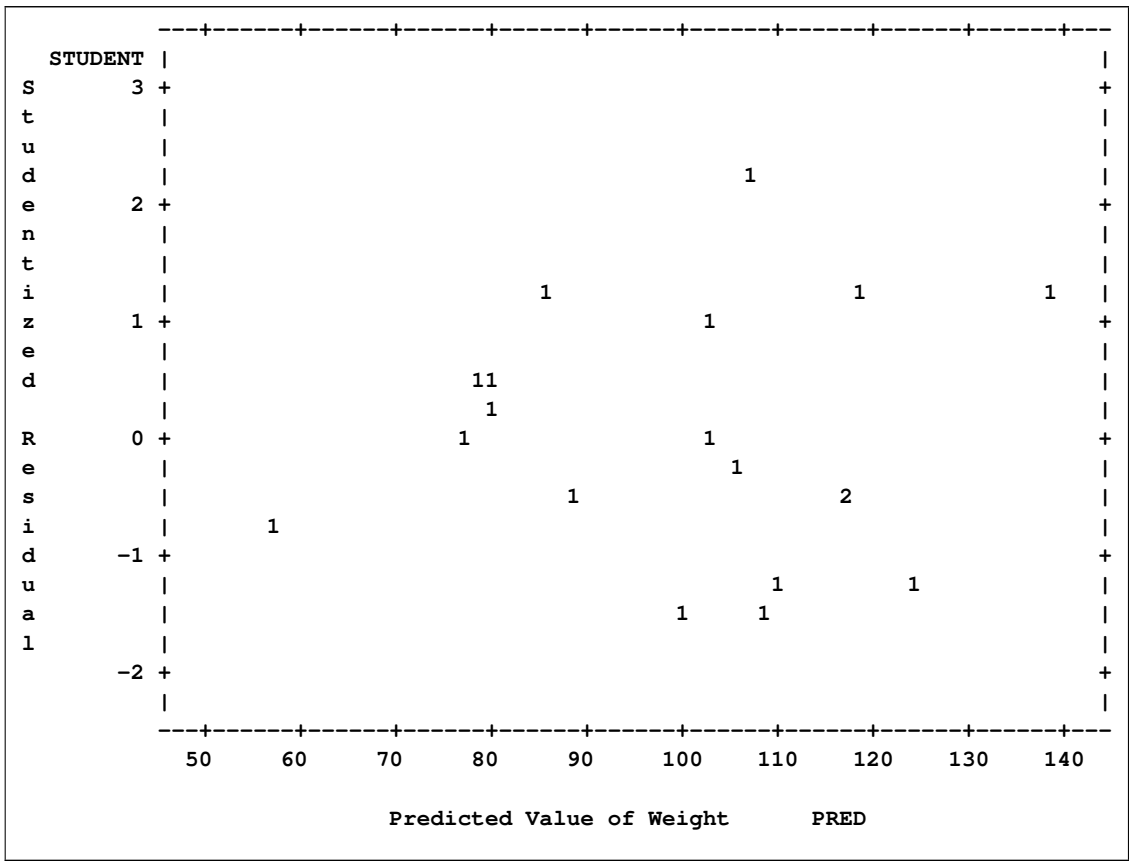
Frequently, when the COLLECT option is in effect, you want the current and following PLOT statements to show only the specified plots. To do this, use both the CLEAR and NOCOLLECT options in the current PLOT statement.



Painting Scatter Plots

Painting scatter plots is a useful interactive tool that enables you to mark points of interest in scatter plots. Painting can be used to identify extreme points in scatter plots or to reveal the relationship between two scatter plots. The Class data (from the section "Simple Linear Regression" on page 5436) is used to illustrate some of these applications.

The following statements produce the scatter plot of the studentized residuals against the predicted values in Figure 73.39.

```
proc reg data=Class lineprinter;
   model Weight=Age Height / noprint;
   plot student.*p.;
run;
```

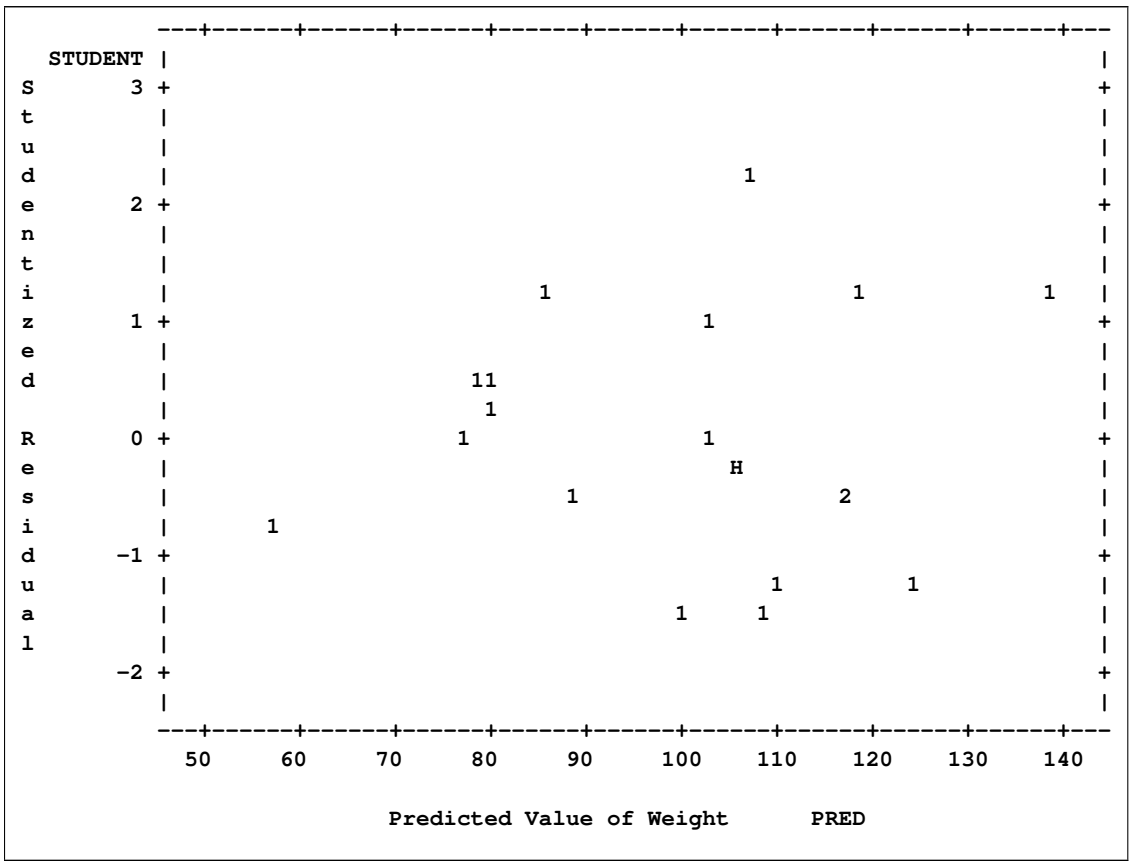


Figure 73.39 Plotting Studentized Residuals against Predicted Values

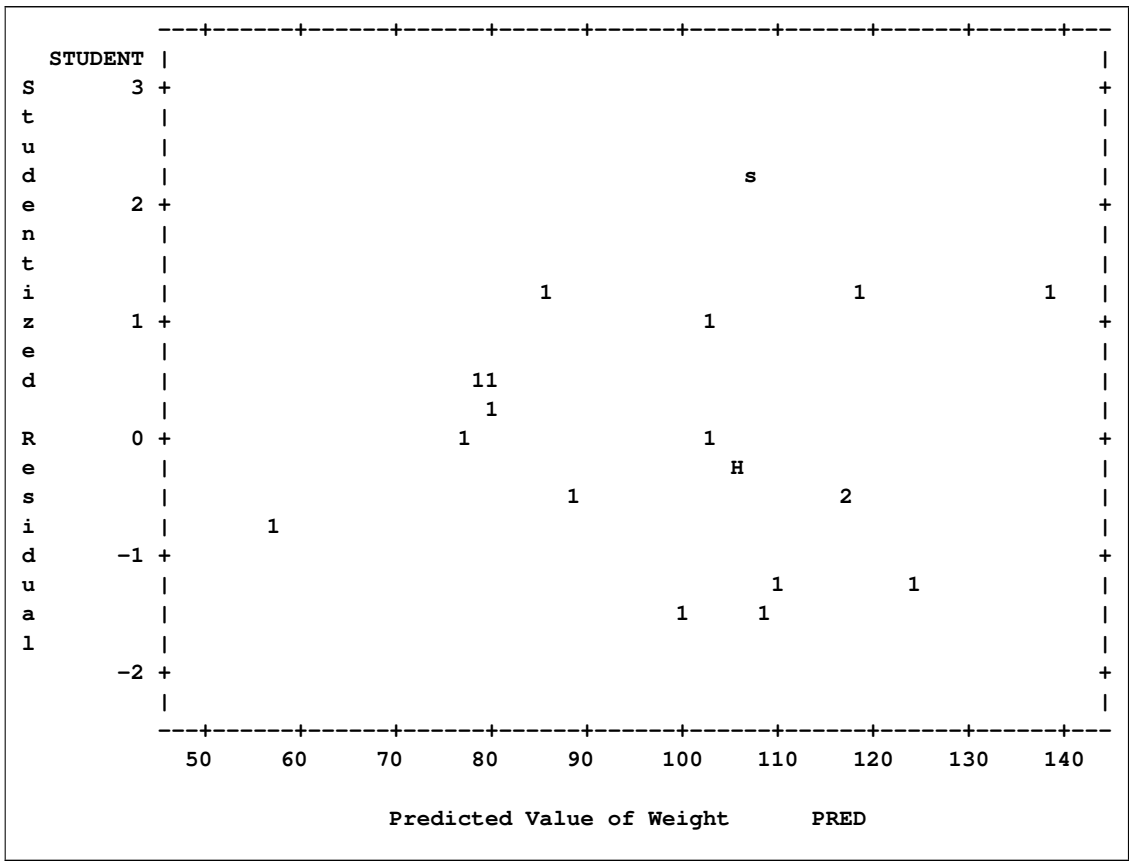
Then, the following statements identify the observation 'Henry' in the scatter plot and produce the plot in Figure 73.40:

```
paint Name='Henry' / symbol = 'H';
plot;
run;
```

Figure 73.40 Painting One Observation



Next, the following statements identify observations with large absolute residuals:

```
paint student.>=2 or student.<=-2 / symbol='s';
plot;
run;
```

The log shows the observation numbers found with these conditions and gives the painting symbol and the number of observations found. Note that the previous PAINT statement is also used in the PLOT statement. Figure 73.41 shows the scatter plot produced by the preceding statements.

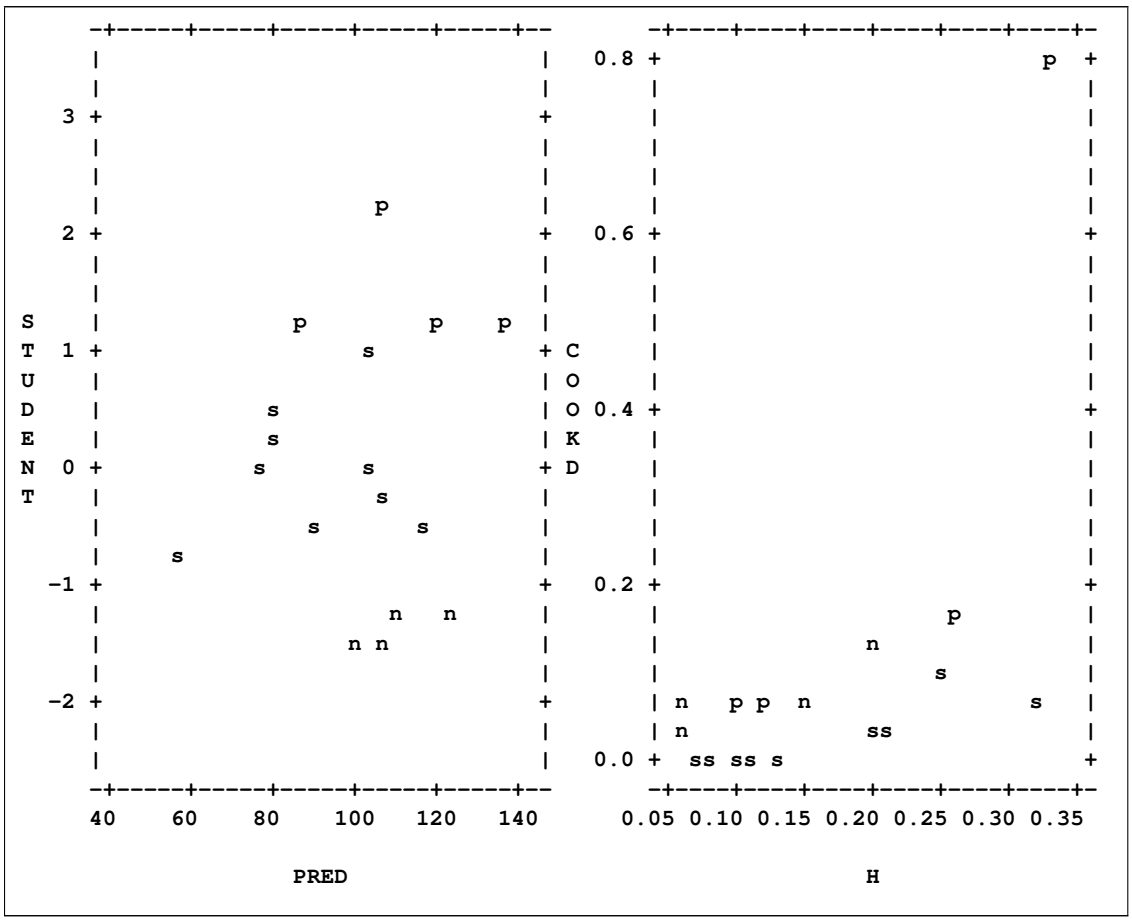


Figure 73.41 Painting Several Observations

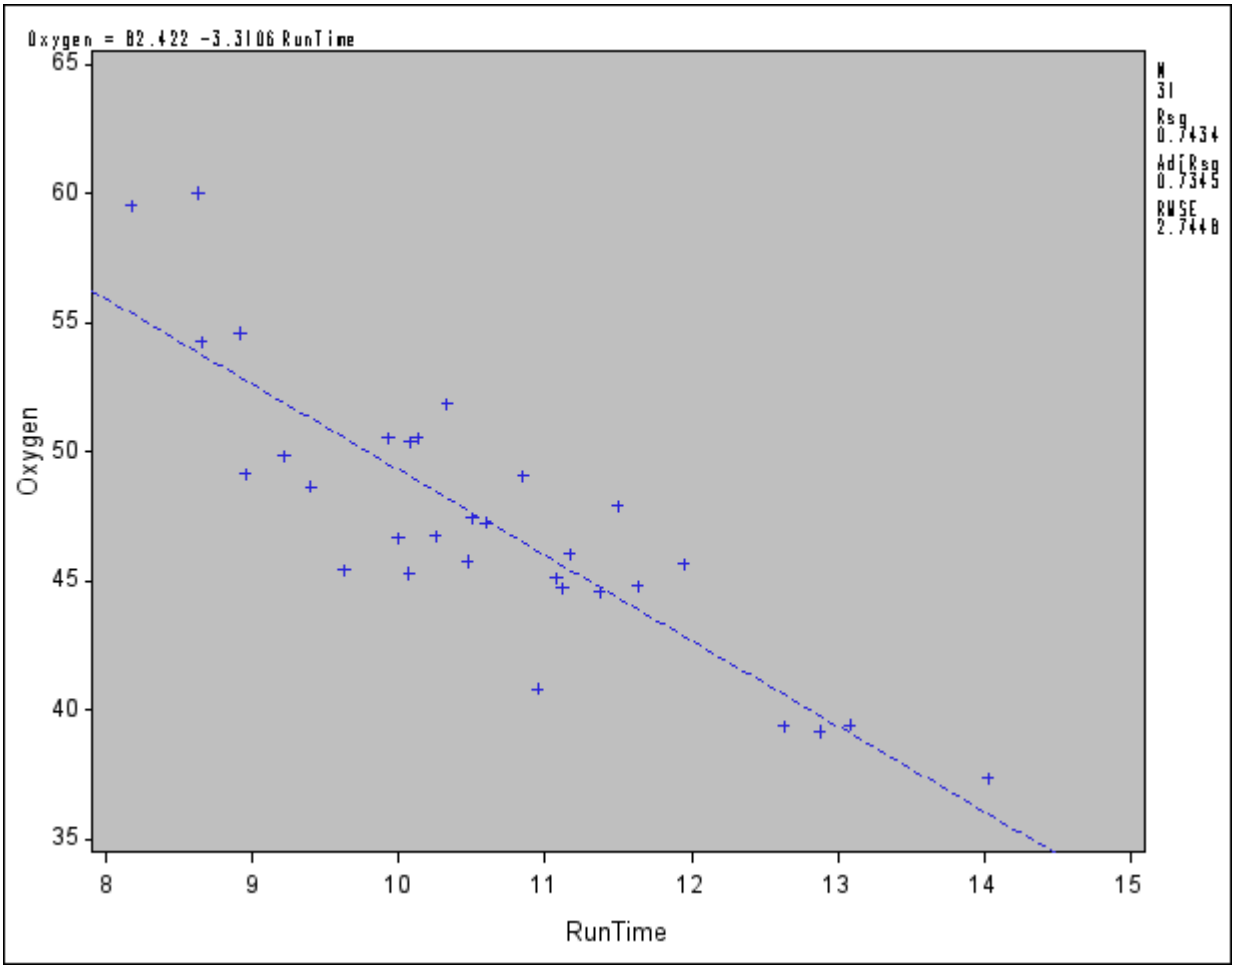
The following statements relate two different scatter plots. These statements produce the plot in Figure 73.42.

```
paint student.>=1 / symbol='p';
paint student.<1 and student.>-1 / symbol='s';
paint student.<=-1 / symbol='n';
plot student. * p. cookd. * h. / hplots=2;
run;
```

Figure 73.42 Painting Observations on More Than One Plot

Traditional Graphics



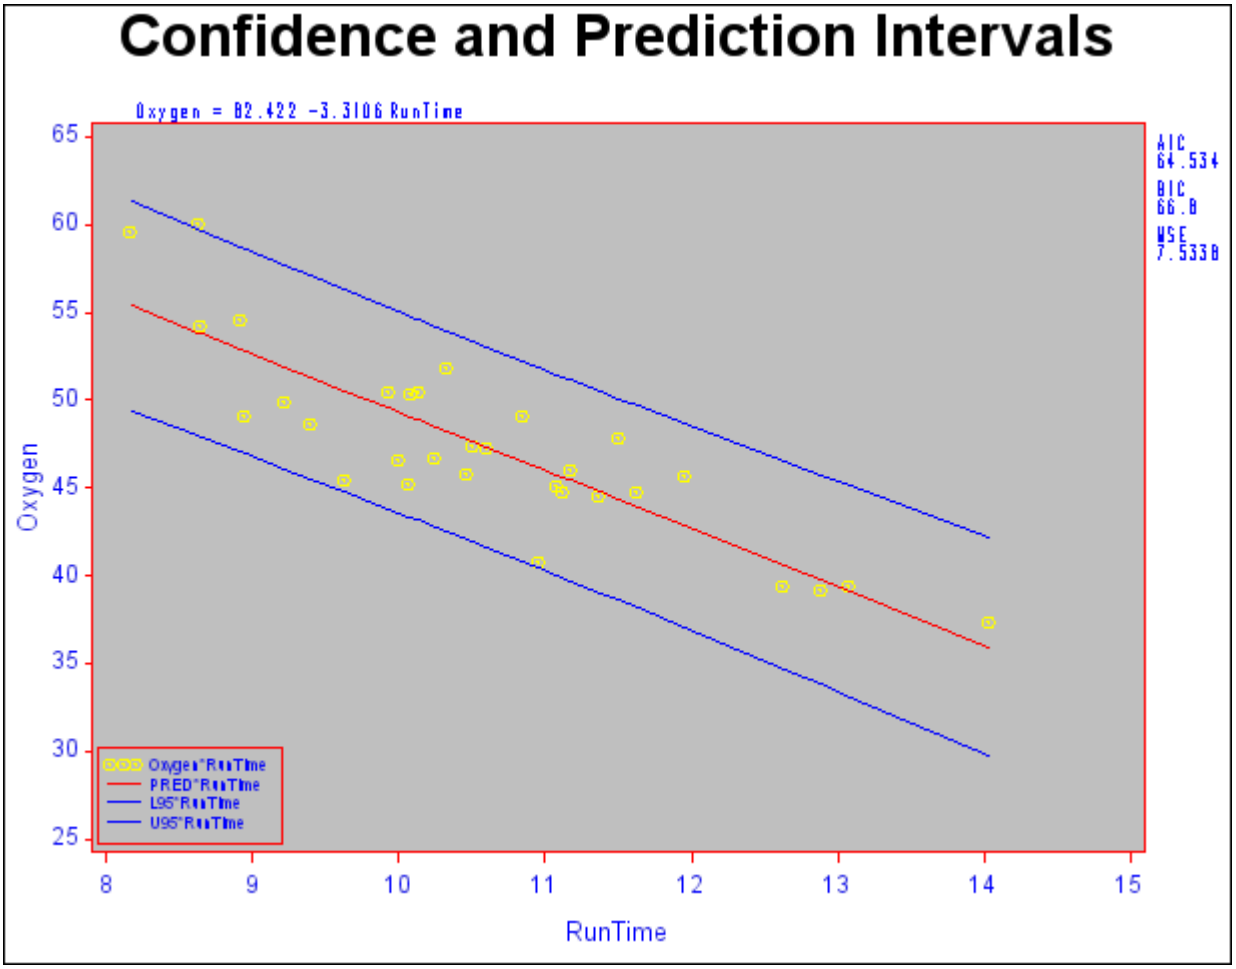
This section provides examples of using options available with the traditional graphics that you request with the PLOT statement. An alternative is to use ODS Graphics to obtain plots relevant to the analysis. See Example 73.1, Example 73.2, and Example 73.5 for examples of obtaining graphical displays with ODS Graphics. Examples in this section use the Fitness data set that is described in Example 73.2.

Traditional Graphics for Simple Linear Regression

The following statements introduce the basic PLOT statement graphics syntax. A simple linear regression of Oxygen on RunTime is performed, and a plot of Oxygen∗RunTime is requested. The fitted model, the regression line, and the four default statistics are also displayed in Figure 73.43.

```
proc reg data=fitness;
   model Oxygen=RunTime;
   plot Oxygen*RunTime / cframe=ligr;
run;
```

Figure 73.43 Simple Linear Regression



You can use shorthand commands to plot the dependent variable, the predicted value, and the 95% confidence or prediction intervals against a regressor. The following statements use the CONF and PRED options to create a plot with confidence and prediction intervals. Results are displayed in Figure 73.44. Note that the statistics displayed by default in the margin are suppressed while three other statistics are exhibited. Furthermore, global graphics LEGEND and SYMBOL statements and PLOT statement options are used to control the appearance of the plot. For more information about the global graphics statements, see *SAS/GRAPH Software: Reference*.

```
legend1 position=(bottom left inside)
        across=1 cborder=red offset=(0,0)
        shape=symbol(3,1) label=none
        value=(height=.8);
title 'Confidence and Prediction Intervals';
symbol1 c=yellow v=- h=1;
symbol2 c=red;
symbol3 c=blue;
symbol4 c=blue;

proc reg data=fitness;
   model Oxygen=RunTime / noprint;
   plot Oxygen*RunTime / pred nostat mse aic bic
        caxis=red ctext=blue cframe=ligr
        legend=legend1 modellab='          ';
run;
```

Figure 73.44 Simple Linear Regression

Traditional Graphics for Variable Selection

When you use the SELECTION= option in the MODEL statement, you can produce plots showing model fit summary statistics for the models examined. The following statements produce the plot shown in Figure 73.45 of the C_p statistic for model selection plotted against the number of parameters in the model; the CHOCKING= and CMALLOWS= options draw useful reference lines.

```
goptions ctitle=black   htitle=3.5pct ftitle=swiss
         ctext =magenta htext =3.0pct ftext =swiss
         cback =ligr    border;
symbol1 v=circle c=red h=1 w=2;
title 'Cp Plot with Reference Lines';
symbol1 c=green;
proc reg data=fitness;
   model Oxygen=Age Weight RunTime RunPulse RestPulse MaxPulse
         / selection=rsquare noprint;
   plot cp.*np.
        / chocking=red  cmallows=blue
          vaxis=0 to 15 by 5;
run;
```

In the GOPTIONS statement,

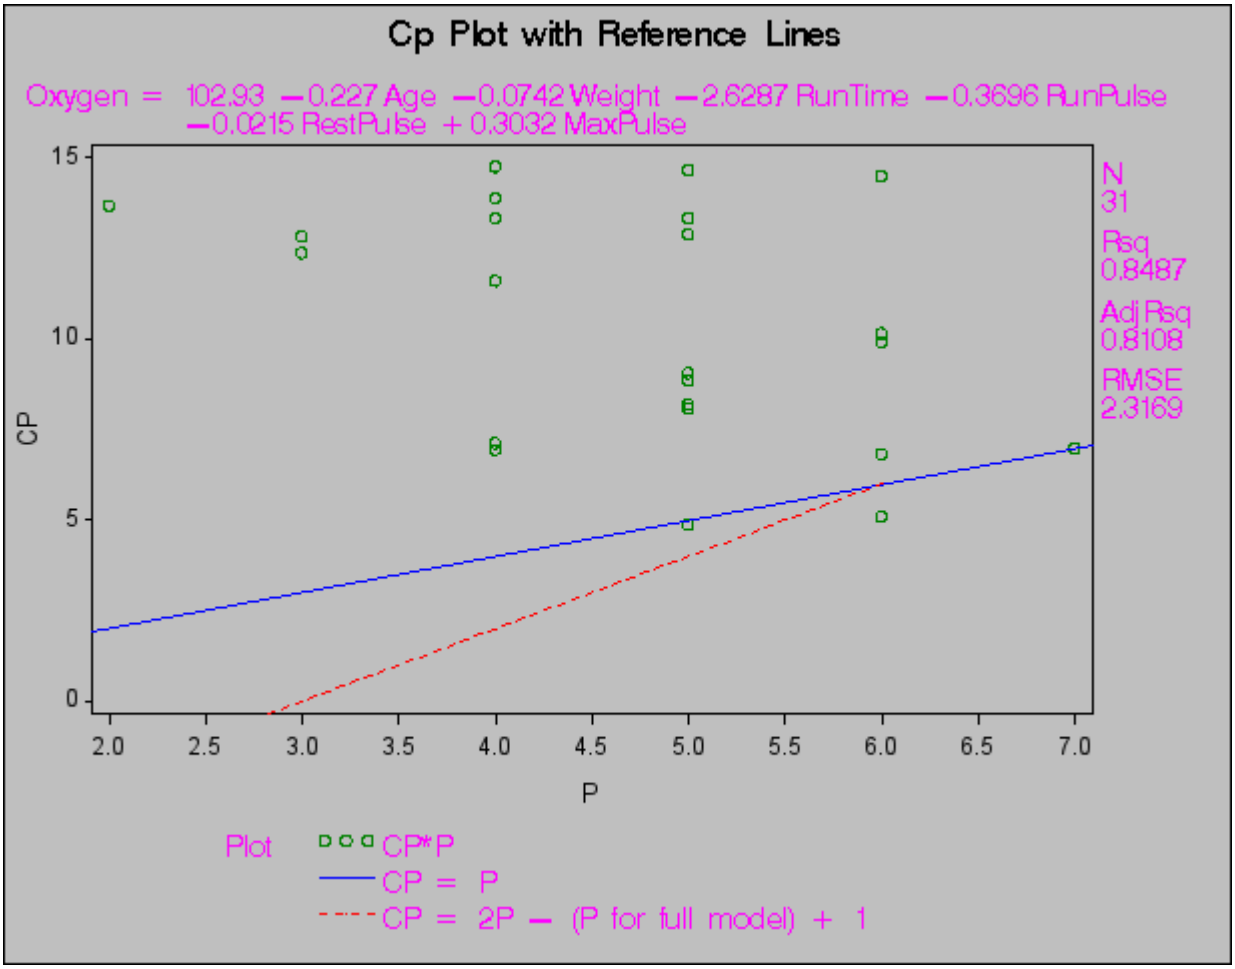
BORDER frames the entire display.

CBACK= specifies the background color.

CTEXT= selects the default color for the border and all text, including titles, footnotes, and notes.

CTITLE= specifies the title, footnote, note, and border color.

HTEXT= specifies the height for all text in the display.



HTITLE= specifies the height for the first title line.

FTEXT= selects the default font for all text, including titles, footnotes, notes, the model label and equation, the statistics, the axis labels, the tick values, and the legend.

FTITLE= specifies the first title font.

For more information about the GOPTIONS statement and other global graphics statements, see *SAS/GRAPH Software: Reference*.

Figure 73.45 C_p Plot with Reference Lines

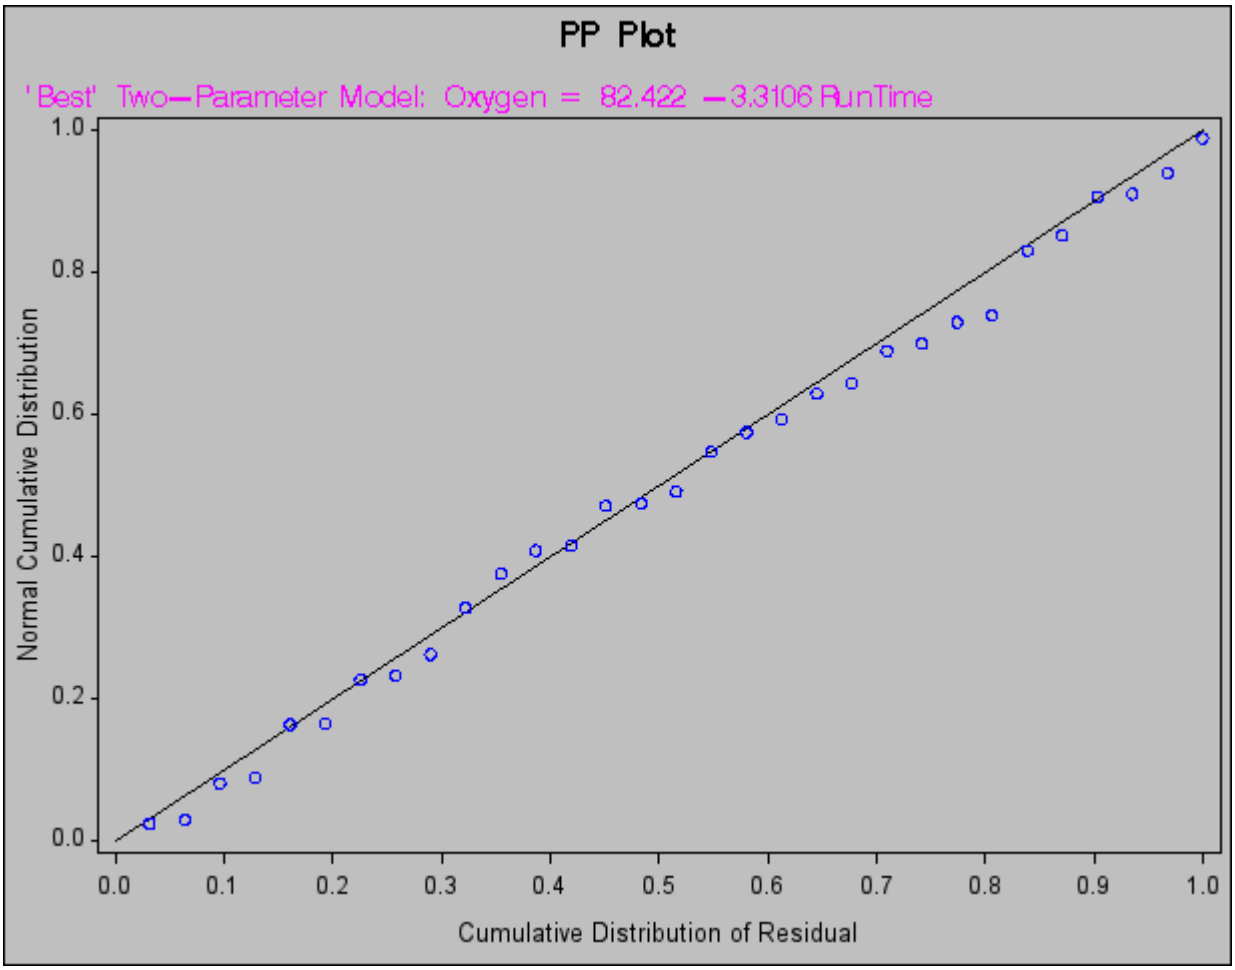
Traditional Normal Quantile and Normal Probability Plots

The following statements create probability-probability plots and quantile-quantile plots of the residuals (Figure 73.46 and Figure 73.47, respectively). An annotation data set is created to produce the (0,0)−(1,1) reference line for the P-P plot. Note that the NOSTAT option for the P-P plot suppresses the statistics that would be displayed in the margin.

```
data annote1;
   length function color $8;
   retain ysys xsys '2' color 'black';
   function='move';
      x=0;
      y=0;
      output;
   function='draw';
      x=1;
      y=1;
      output;
run;
```

```
symbol1 c=blue;
proc reg data=fitness;
   title 'PP Plot';
   model Oxygen=RunTime / noprint;
   plot npp.*r.
        / annotate=annote1 nostat cframe=ligr
          modellab="'Best' Two-Parameter Model:";
run;
   title 'QQ Plot';
   plot r.*nqq.
        / noline mse cframe=ligr
          modellab="'Best' Two-Parameter Model:";
run;
```

Figure 73.46 Normal Probability-Probability Plot for the Residuals



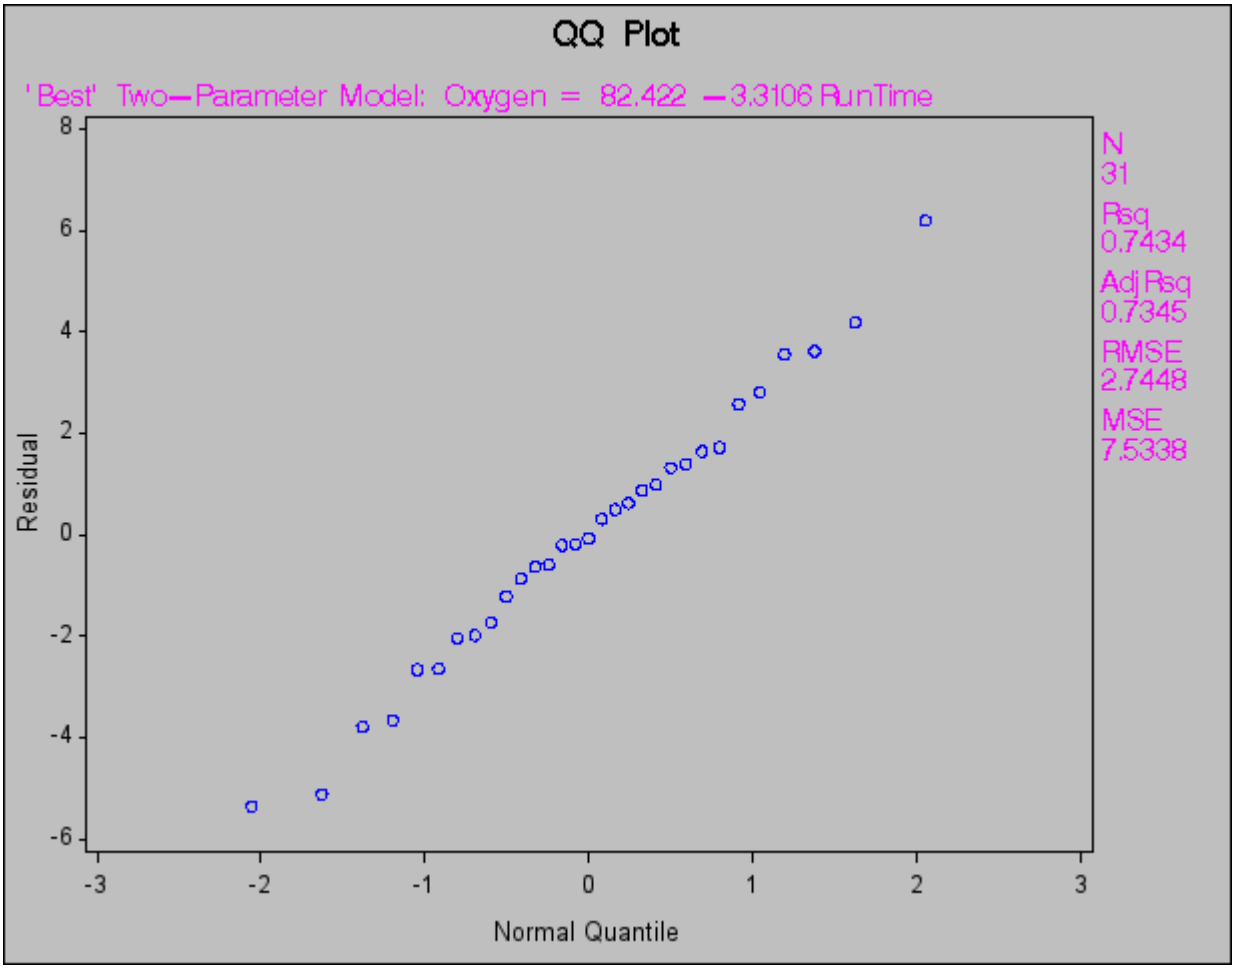


Figure 73.47 Normal Quantile-Quantile Plot for the Residuals

Models of Less Than Full Rank

If the model is not full rank, there are an infinite number of least squares solutions for the estimates. PROC REG chooses a nonzero solution for all variables that are linearly independent of previous variables and a zero solution for other variables. This solution corresponds to using a generalized inverse in the normal equations, and the expected values of the estimates are the Hermite normal form of $\mathbf{X}$ multiplied by the true parameters:

$$E(\mathbf{b}) = (\mathbf{X}'\mathbf{X})^{-}(\mathbf{X}'\mathbf{X})\boldsymbol{\beta}$$

Degrees of freedom for the zeroed estimates are reported as zero. The hypotheses that are not testable have t tests reported as missing. The message that the model is not full rank includes a display of the relations that exist in the matrix.

The following statements use the fitness data from Example 73.2. The variable Dif=RunPulse−RestPulse is created. When this variable is included in the model along with RunPulse and RestPulse, there is a linear dependency (or exact collinearity) between the independent variables. Figure 73.48 shows how this problem is diagnosed.

```
data fit2;
   set fitness; Dif=RunPulse-RestPulse;
proc reg data=fit2;
   model Oxygen=RunTime Age Weight RunPulse MaxPulse RestPulse Dif;
run;
```

RestPulse	B	−0.02153	0.06605	−0.33	0.7473
Dif	0	0	.	.	.

PROC REG produces a message informing you that the model is less than full rank. Parameters with DF=0 are not estimated, and parameters with DF=B are biased. In addition, the form of the linear dependency among the regressors is displayed.

Collinearity Diagnostics

When a regressor is nearly a linear combination of other regressors in the model, the affected estimates are unstable and have high standard errors. This problem is called *collinearity* or *multicollinearity*. It is a good idea to find out which variables are nearly collinear with which other variables. The approach in PROC REG follows that of Belsley, Kuh, and Welsch (1980). PROC REG provides several methods for detecting collinearity with the COLLIN, COLLINOINT, TOL, and VIF options.

The COLLIN option in the MODEL statement requests that a collinearity analysis be performed. First, $\mathbf{X}'\mathbf{X}$ is scaled to have 1s on the diagonal. If you specify the COLLINOINT option, the intercept variable is adjusted out first. Then the eigenvalues and eigenvectors are extracted. The analysis in PROC REG is reported with eigenvalues of $\mathbf{X}'\mathbf{X}$ rather than singular values of $\mathbf{X}$. The eigenvalues of $\mathbf{X}'\mathbf{X}$ are the squares of the singular values of $\mathbf{X}$.

The condition indices are the square roots of the ratio of the largest eigenvalue to each individual eigenvalue. The largest condition index is the condition number of the scaled $\mathbf{X}$ matrix. Belsey, Kuh, and Welsch (1980) suggest that, when this number is around 10, weak dependencies might be starting to affect the regression estimates. When this number is larger than 100, the estimates might have a fair amount of numerical error (although the statistical standard error almost always is much greater than the numerical error).

For each variable, PROC REG produces the proportion of the variance of the estimate accounted for by each principal component. A collinearity problem occurs when a component associated with a high condition index contributes strongly (variance proportion greater than about 0.5) to the variance of two or more variables.

The VIF option in the MODEL statement provides the variance inflation factors (VIF). These factors measure the inflation in the variances of the parameter estimates due to collinearities that exist among the regressor (independent) variables. There are no formal criteria for deciding if a VIF is large enough to affect the predicted values.

The TOL option requests the tolerance values for the parameter estimates. The tolerance is defined as $1/VIF$.

For a complete discussion of the preceding methods, refer to Belsley, Kuh, and Welsch (1980). For a more detailed explanation of using the methods with PROC REG, refer to Freund and Littell (1986).

This example uses the COLLIN option on the fitness data found in Example 73.2. The following statements produce Figure 73.49.

```
proc reg data=fitness;
   model Oxygen=RunTime Age Weight RunPulse MaxPulse RestPulse
         / tol vif collin;
run;
```

Model Fit and Diagnostic Statistics

This section gathers the formulas for the statistics available in the MODEL, PLOT, and OUTPUT statements. The model to be fit is $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$, and the parameter estimate is denoted by $\mathbf{b} = (\mathbf{X}'\mathbf{X})^{-}\mathbf{X}'\mathbf{Y}$. The subscript i denotes values for the ith observation, the parenthetical subscript (i) means that the statistic is computed by using all observations except the ith observation, and the subscript jj indicates the jth diagonal matrix entry. The ALPHA= option in the PROC REG or MODEL statement is used to set the α value for the t statistics.

Table 73.8 contains the summary statistics for assessing the fit of the model.

Table 73.8 Formulas and Definitions for Model Fit Summary Statistics

MODEL Option or Statistic	Definition or Formula
n	the number of observations
p	the number of parameters including the intercept
i	1 if there is an intercept, 0 otherwise
$\hat{\sigma}^2$	the estimate of pure error variance from the SIGMA= option or from fitting the full model
SST_0	the uncorrected total sum of squares for the dependent variable

Table 73.8 *continued*

MODEL Option or Statistic	Definition or Formula
SST_1	the total sum of squares corrected for the mean for the dependent variable
SSE	the error sum of squares
MSE	$\frac{SSE}{n-p}$
R^2	$1-\frac{SSE}{SST_i}$
ADJRSQ	$1-\frac{(n-i)(1-R^2)}{n-p}$
AIC	$n\ln\left(\frac{SSE}{n}\right)+2p$
BIC	$n\ln\left(\frac{SSE}{n}\right)+2(p+2)q-2q^2$ where $q=\frac{n\hat{\sigma}^2}{SSE}$
CP (C_p)	$\frac{SSE}{\hat{\sigma}^2}+2p-n$
GMSEP	$\frac{MSE(n+1)(n-2)}{n(n-p-1)}=\frac{1}{n}S_p(n+1)(n-2)$
JP (J_p)	$\frac{n+p}{n}MSE$
PC	$\frac{n+p}{n-p}(1-R^2)=J_p\left(\frac{n}{SST_i}\right)$
PRESS	the sum of squares of $predr_i$ (see Table 73.9)
RMSE	$\sqrt{MSE}$
SBC	$n\ln\left(\frac{SSE}{n}\right)+p\ln(n)$
SP (S_p)	$\frac{MSE}{n-p-1}$

Table 73.9 contains the diagnostic statistics and their formulas; these formulas and further information can be found in Chapter 4, "Introduction to Regression Procedures," and in the section "Influence Statistics" on page 5559. Each statistic is computed for each observation.

Table 73.9 Formulas and Definitions for Diagnostic Statistics

MODEL Option or Statistic	Formula
PRED ($\widehat{\mathbf{Y}}_i$)	$\mathbf{X}_i\mathbf{b}$
RES (r_i)	$\mathbf{Y}_i-\widehat{\mathbf{Y}}_i$
H (h_i)	$\mathbf{x}_i(\mathbf{X}'\mathbf{X})^{-}\mathbf{x}_i'$
STDP	$\sqrt{h_i\widehat{\sigma}^2}$

Table 73.9 *continued*

MODEL Option or Statistic	Formula
STDI	$\sqrt{(1+h_i)\widehat{\sigma}^2}$
STDR	$\sqrt{(1-h_i)\widehat{\sigma}^2}$
LCL	$\widehat{Y}_i - t_{\frac{\alpha}{2}}\text{STDI}$
LCLM	$\widehat{Y}_i - t_{\frac{\alpha}{2}}\text{STDP}$
UCL	$\widehat{Y}_i + t_{\frac{\alpha}{2}}\text{STDI}$
UCLM	$\widehat{Y}_i + t_{\frac{\alpha}{2}}\text{STDP}$
STUDENT	$\frac{r_i}{\text{STDR}_i}$
RSTUDENT	$\frac{r_i}{\hat{\sigma}_{(i)}\sqrt{1-h_i}}$
COOKD	$\frac{1}{p}\text{STUDENT}^2\frac{\text{STDP}^2}{\text{STDR}^2}$
COVRATIO	$\frac{\det(\hat{\sigma}^2_{(i)}(\mathbf{x}'_{(i)}\mathbf{x}_{(i)})^{-1}}{\det(\hat{\sigma}^2(\mathbf{X}'\mathbf{X})^{-1})}$
DFFITS	$\frac{(\widehat{\mathbf{Y}}_i - \widehat{\mathbf{Y}}_{(i)})}{(\hat{\sigma}_{(i)}\sqrt{h_i})}$
DFBETAS$_j$	$\frac{\mathbf{b}_j - \mathbf{b}_{(i)j}}{\hat{\sigma}_{(i)}\sqrt{(\mathbf{X}'\mathbf{X})_{jj}}}$
PRESS(predr$_i$)	$\frac{r_i}{1-h_i}$

Influence Statistics

This section discusses the INFLUENCE option, which produces several influence statistics, and the PARTIAL option, which produces partial regression leverage plots.

The INFLUENCE Option

The INFLUENCE option (in the MODEL statement) requests the statistics proposed by Belsley, Kuh, and Welsch (1980) to measure the influence of each observation on the estimates. Influential observations are those that, according to various criteria, appear to have a large influence on the parameter estimates.

Let $\mathbf{b}(i)$ be the parameter estimates after deleting the ith observation; let $s(i)^2$ be the variance estimate after deleting the ith observation; let $\mathbf{X}(i)$ be the $\mathbf{X}$ matrix without the ith observation; let $\hat{y}(i)$ be the ith value predicted without using the ith observation; let $r_i = y_i - \hat{y}_i$ be the ith

residual; and let h_i be the ith diagonal of the projection matrix for the predictor space, also called the *hat matrix*:

$$h_i = \mathbf{x}_i(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i'$$

Belsley, Kuh, and Welsch (1980) propose a cutoff of $2p/n$, where n is the number of observations used to fit the model and p is the number of parameters in the model. Observations with h_i values above this cutoff should be investigated.

For each observation, PROC REG first displays the residual, the studentized residual (RSTUDENT), and the h_i. The studentized residual RSTUDENT differs slightly from STUDENT since the error variance is estimated by $s^2_{(i)}$ without the ith observation, not by s^2. For example,

$$\text{RSTUDENT} = \frac{r_i}{s_{(i)}\sqrt{(1-h_i)}}$$

Observations with RSTUDENT larger than 2 in absolute value might need some attention.

The COVRATIO statistic measures the change in the determinant of the covariance matrix of the estimates by deleting the ith observation:

$$\text{COVRATIO} = \frac{\det\left(s^2(i)(\mathbf{X}'_{(i)}\mathbf{X}_{(i)})^{-1}\right)}{\det\left(s^2(\mathbf{X}'\mathbf{X})^{-1}\right)}$$

Belsley, Kuh, and Welsch (1980) suggest that observations with

$$|\text{COVRATIO} - 1| \geq \frac{3p}{n}$$

where p is the number of parameters in the model and n is the number of observations used to fit the model, are worth investigation.

The DFFITS statistic is a scaled measure of the change in the predicted value for the ith observation and is calculated by deleting the ith observation. A large value indicates that the observation is very influential in its neighborhood of the $\mathbf{X}$ space.

$$\text{DFFITS} = \frac{\hat{y}_i - \hat{y}_{(i)}}{s_{(i)}\sqrt{h_{(i)}}}$$

Large values of DFFITS indicate influential observations. A general cutoff to consider is 2; a size-adjusted cutoff recommended by Belsley, Kuh, and Welsch (1980) is $2\sqrt{p/n}$, where n and p are as defined previously.

The DFFITS statistic is very similar to Cook's D, defined in the section "Predicted and Residual Values" on page 5531.

The DFBETAS statistics are the scaled measures of the change in each parameter estimate and are calculated by deleting the ith observation:

$$\text{DFBETAS}_j = \frac{b_j - b_{(i)j}}{s_{(i)}\sqrt{(\mathbf{X}'\mathbf{X})_{jj}}}$$

where $(\mathbf{X}'\mathbf{X})_{jj}$ is the (j, j)th element of $(\mathbf{X}'\mathbf{X})^{-1}$.

In general, large values of DFBETAS indicate observations that are influential in estimating a given parameter. Belsley, Kuh, and Welsch (1980) recommend 2 as a general cutoff value to indicate influential observations and $2/\sqrt{n}$ as a size-adjusted cutoff.

The following statements use the population example in the section "Polynomial Regression" on page 5440. See Figure 73.32 for the fitted regression equation. The INFLUENCE option produces the tables shown in Figure 73.50 and Figure 73.51.

```
proc reg data=USPopulation;
   model Population=Year YearSq / influence;
run;
```

Figure 73.51 Residual Statistics

Sum of Residuals	-4.7569E-11
Sum of Squared Residuals	170.97193
Predicted Residual SS (PRESS)	237.71229

In Figure 73.50, observations 16, 17, and 19 exceed the cutoff value of 2 for RSTUDENT. None of the observations exceeds the general cutoff of 2 for DFFITS or the DFBETAS, but observations 16, 17, and 19 exceed at least one of the size-adjusted cutoffs for these statistics. Observations 1 and 19 exceed the cutoff for the hat diagonals, and observations 1, 2, 16, 17, and 18 exceed the cutoffs for COVRATIO. Taken together, these statistics indicate that you should look first at observations 16, 17, and 19 and then perhaps investigate the other observations that exceeded a cutoff.

When you enable ODS Graphics, you can request influence diagnostic plots by using the PLOTS= option in the PROC REG statement as shown in the following statements:

```
ods graphics on;

proc reg data=USPopulation
      plots(label)=(CooksD RStudentByLeverage DFFITS DFBETAS);
   id Year;
   model Population=Year YearSq;
run;

ods graphics off;
```

The LABEL suboption specified in the PLOTS(LABEL)= option requests that observations that exceed the relevant cutoffs for the statistics being plotted are labeled. Since Year has been named in an ID statement, the value of Year is used for the labels. The requested plots are shown in Figure 73.52.

Figure 73.52 Influence Diagnostics

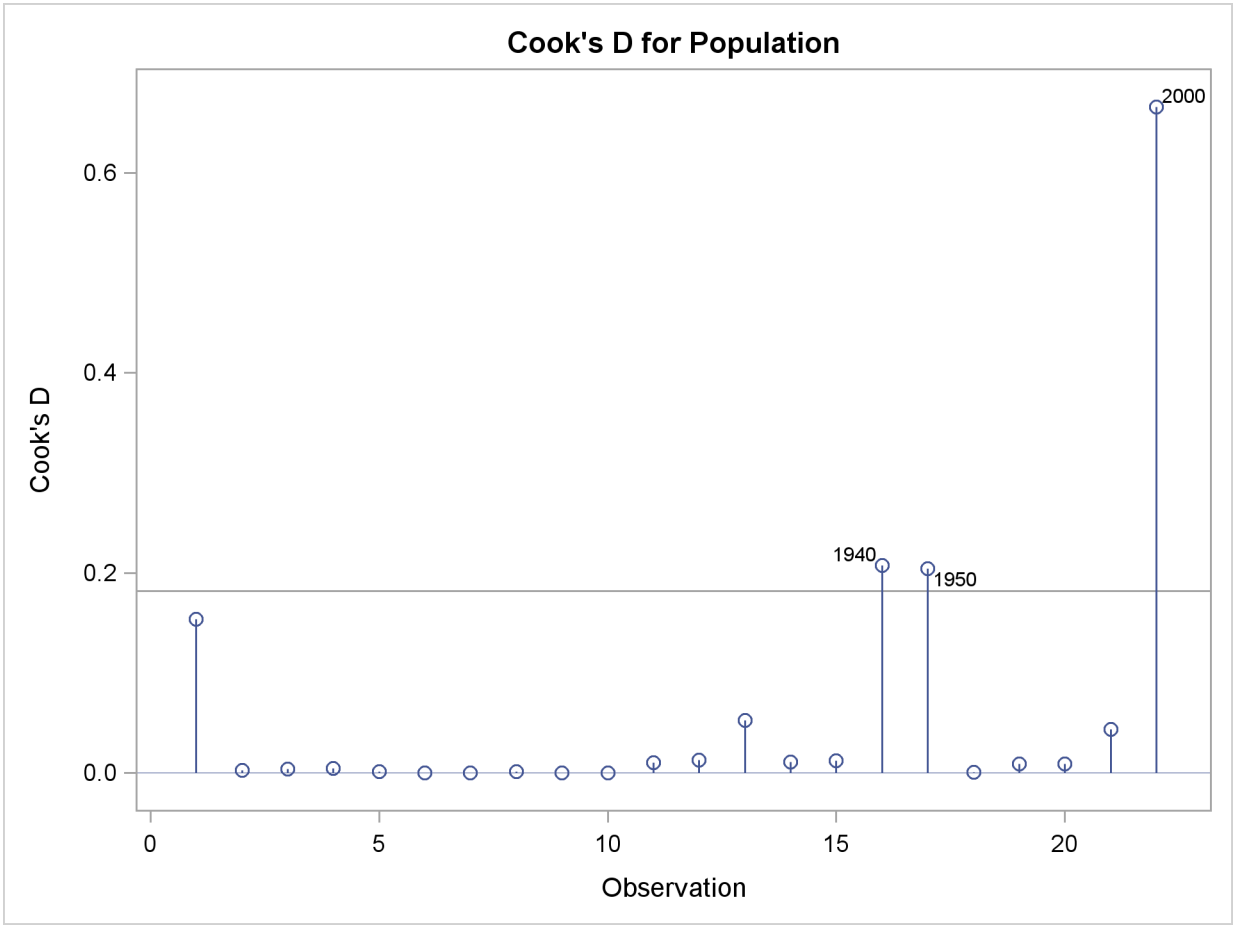

Figure 73.52 *continued*

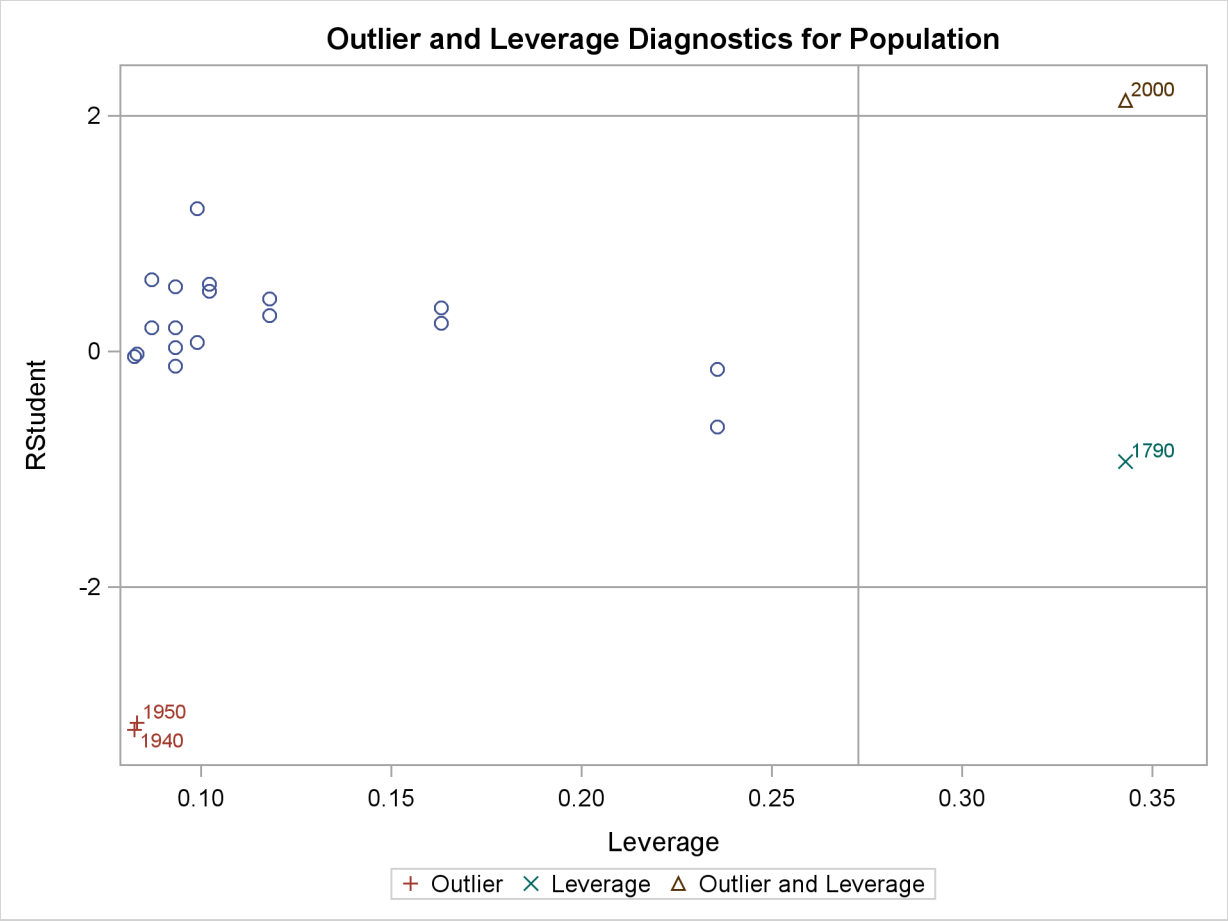

Figure 73.52 *continued*

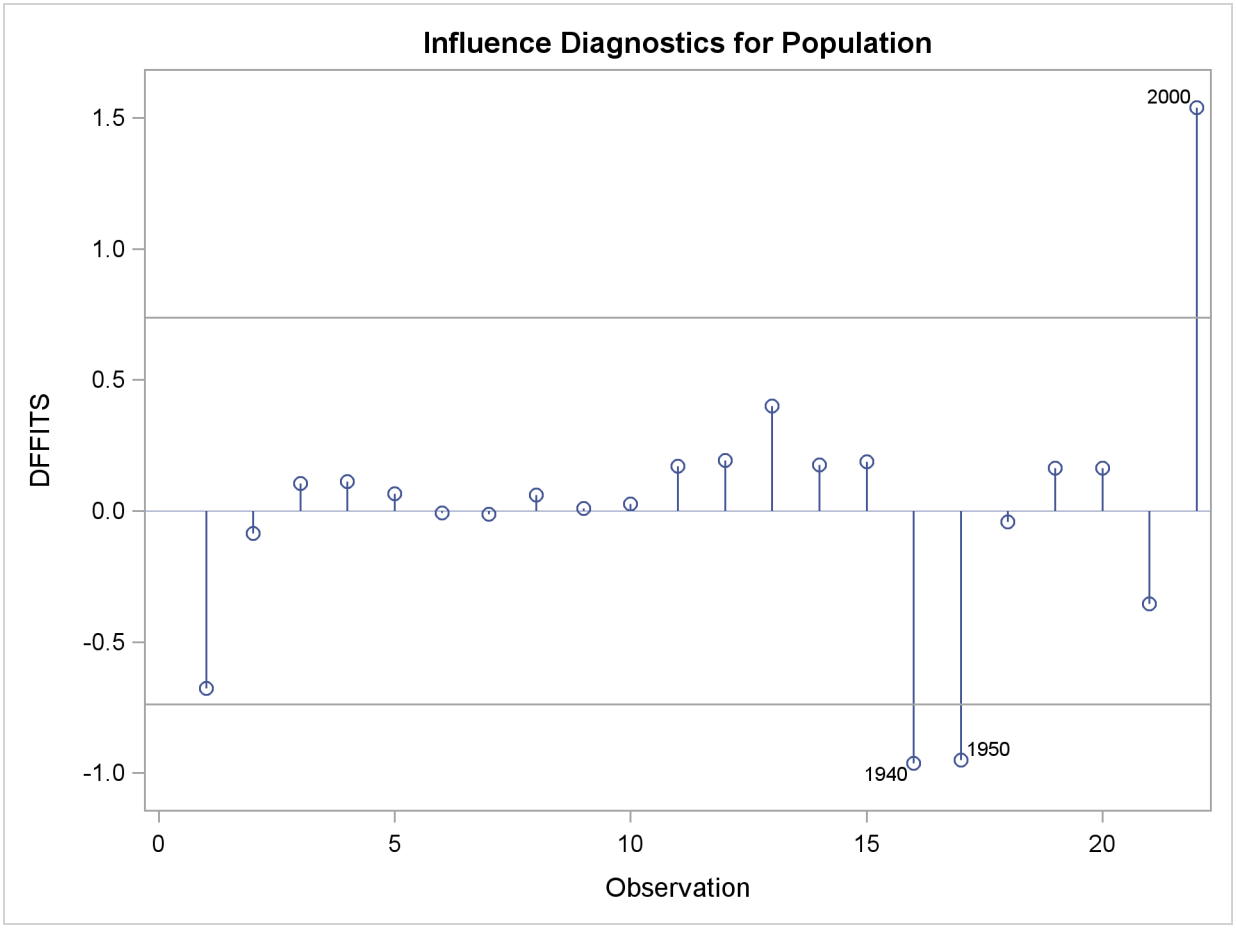

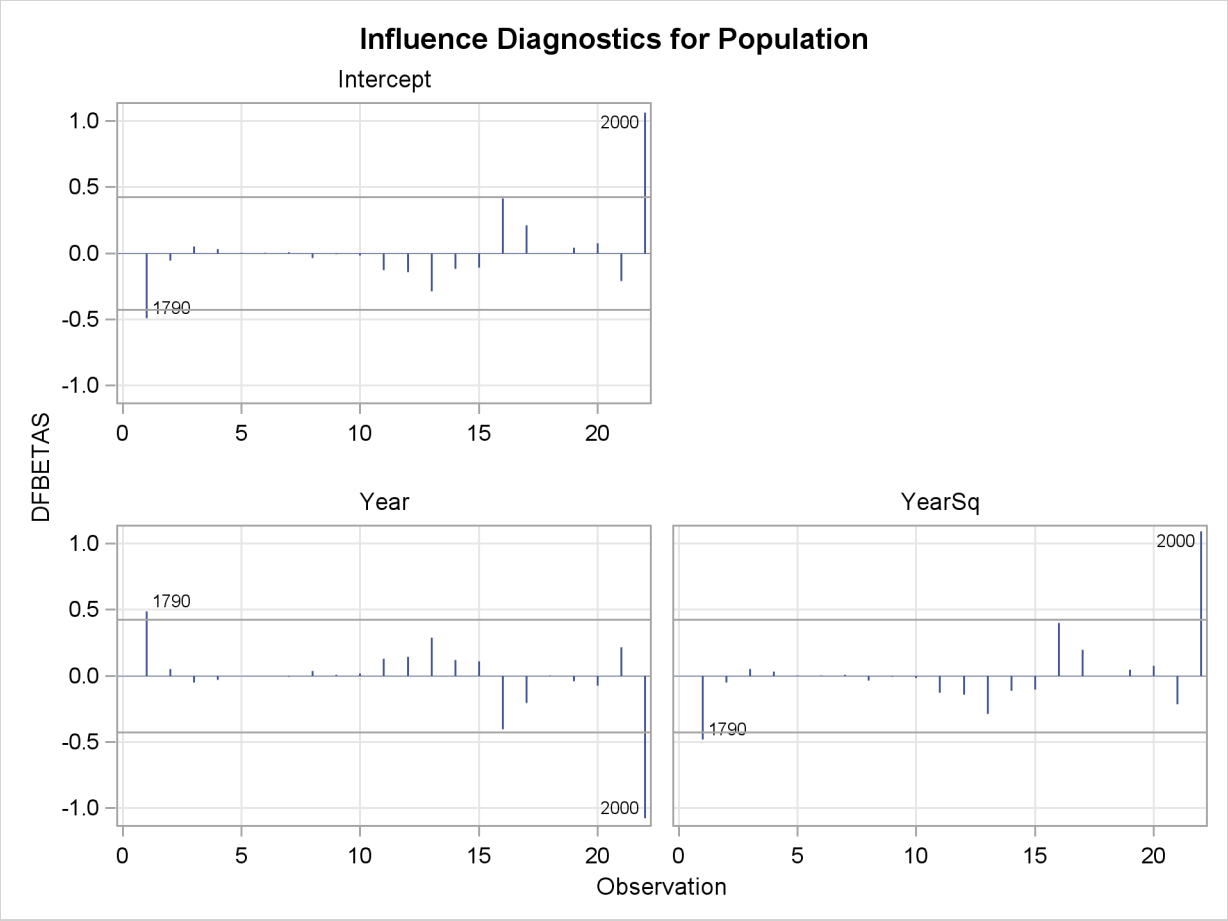

Figure 73.52 *continued*

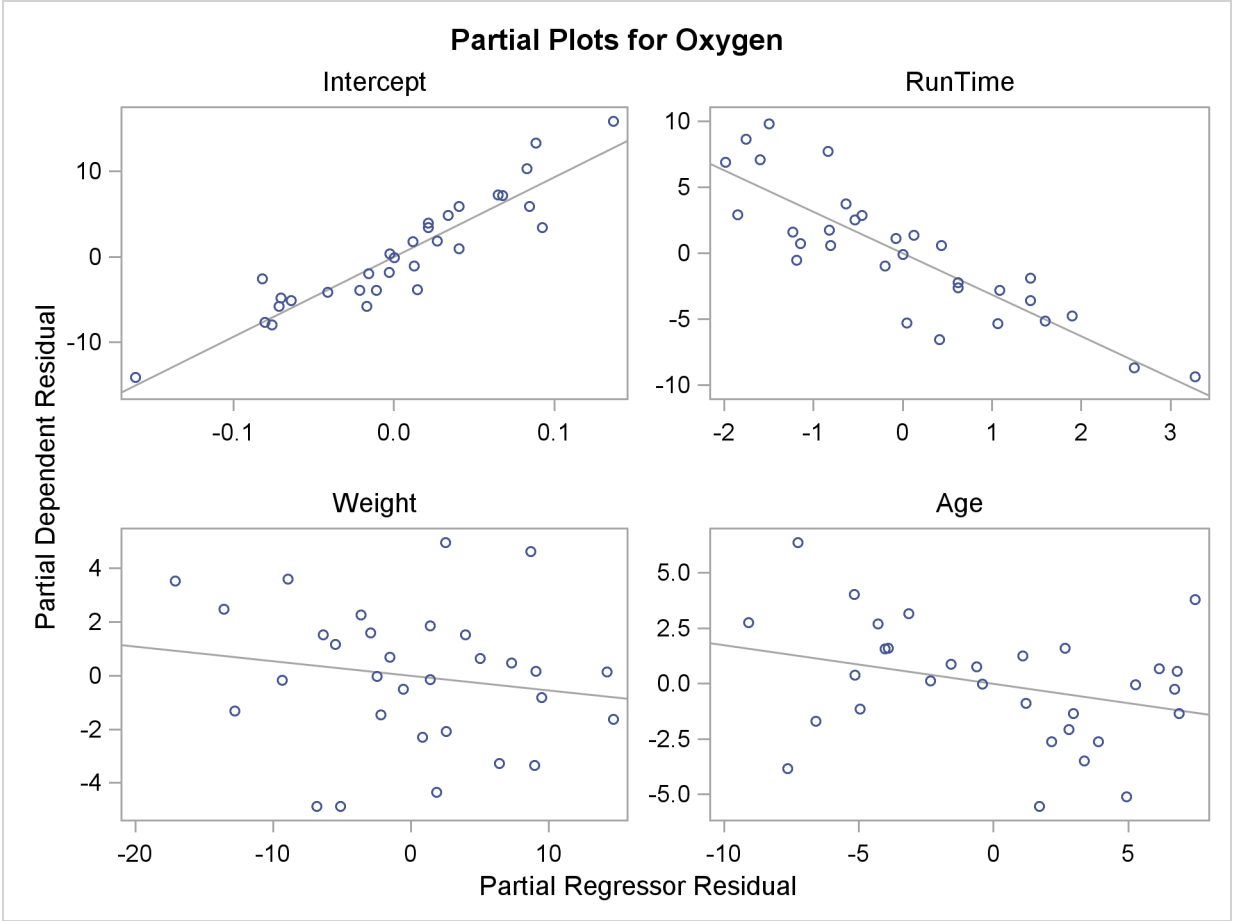
The PARTIAL and PARTIALDATA Options

The PARTIAL option in the MODEL statement produces partial regression leverage plots. If ODS Graphics is not in effect, this option requires the use of the LINEPRINTER option in the PROC REG statement. One plot is created for each regressor in the current full model. For example, plots are produced for regressors included by using ADD statements; plots are not produced for interim models in the various model-selection methods but only for the full model. If you use a model-selection method and the final model contains only a subset of the original regressors, the PARTIAL option still produces plots for all regressors in the full model. If ODS Graphics is in effect, these plots are produced as high-resolution graphics, in panels with a maximum of six partial regression leverage plots per panel. Multiple panels are displayed for models with more than six regressors.

For a given regressor, the partial regression leverage plot is the plot of the dependent variable and the regressor after they have been made orthogonal to the other regressors in the model. These can be obtained by plotting the residuals for the dependent variable against the residuals for the selected regressor, where the residuals for the dependent variable are calculated with the selected regressor omitted, and the residuals for the selected regressor are calculated from a model where the selected regressor is regressed on the remaining regressors. A line fit to the points has a slope equal to the parameter estimate in the full model.

When ODS Graphics is not in effect, points in the plot are marked by the number of replicates appearing at one position. The symbol '*' is used if there are 10 or more replicates. If an ID statement is specified, the leftmost nonblank character in the value of the ID variable is used as the plotting symbol.

The PARTIALDATA option in the MODEL statement produces a table that contains the partial regression data that are displayed in the partial regression leverage plots. You can request partial regression data even if you do not requests plots with the PARTIAL option.



The following statements use the fitness data in Example 73.2 with the PARTIAL option and the ODS GRAPHICS statement to produce the partial regression leverage plots. The plots are shown in Figure 73.53.

```
ods graphics on;

proc reg data=fitness;
   model Oxygen=RunTime Weight Age / partial;
run;

ods graphics off;
```

Figure 73.53 Partial Regression Leverage Plots

Reweighting Observations in an Analysis

Reweighting observations is an interactive feature of PROC REG that enables you to change the weights of observations used in computing the regression equation. Observations can also be deleted from the analysis (not from the data set) by changing their weights to zero. In the following statements, the Class data (in the section "Getting Started: REG Procedure" on page 5436) are used to illustrate some of the features of the REWEIGHT statement. First, the full model is fit, and the residuals are displayed in Figure 73.54.

```
proc reg data=Class;
   model Weight=Age Height / p;
   id Name;
run;
```

Sum of Squared Residuals	2120.09974
Predicted Residual SS (PRESS)	3272.72186

Upon examining the data and residuals, you realize that observation 17 (Ronald) was mistakenly included in the analysis. Also, you would like to examine the effect of reweighting to 0.5 those observations with residuals that have absolute values greater than or equal to 17. The following statements show how you request this reweighting:

```
reweight obs.=17;
reweight r. le -17 or r. ge 17 / weight=0.5;
print p;
run;
```

At this point, a message appears (in the log) that tells you which observations have been reweighted and what the new weights are. Figure 73.55 is produced.

Sum of Residuals	0
Sum of Squared Residuals	1500.61194
Predicted Residual SS (PRESS)	2287.57621

The first REWEIGHT statement excludes observation 17, and the second REWEIGHT statement reweights observations 12 and 16 to 0.5. An important feature to note from this example is that the model is not refit until after the PRINT statement. REWEIGHT statements do not cause the model to be refit. This is so that multiple REWEIGHT statements can be applied to a subsequent model.

In this example, since the intent is to reweight observations with large residuals, the observation that was mistakenly included in the analysis should be deleted; then the model should be fit for those remaining observations, and the observations with large residuals should be reweighted. To accomplish this, use the REFIT statement. Note that the model label has been changed from MODEL1 to MODEL1.2 since two REWEIGHT statements have been used. The following statements produce Figure 73.56:

```
reweight allobs / weight=1.0;
reweight obs.=17;
refit;
reweight r. le -17 or r. ge 17 / weight=.5;
print;
run;
```

Predicted Residual SS (PRESS)	2473.87984

Notice that this results in a slightly different model than the previous set of statements: only observation 16 is reweighted to 0.5. Also note that the model label is now MODEL1.5 since five REWEIGHT statements have been used for this model.

Another important feature of the REWEIGHT statement is the ability to nullify the effect of a previous or all REWEIGHT statements. First, assume that you have several REWEIGHT statements in effect and you want to restore the original weights of all the observations. The following REWEIGHT statement accomplishes this and produces Figure 73.57:

```
reweight allobs / reset;
print;
run;
```

Figure 73.57 Restoring Weights of All Observations

The REG Procedure

The resulting model is identical to the original model specified at the beginning of this section. Notice that the model label is now MODEL1.6. Note that the Weight column does not appear, since all observations have been reweighted to have weight=1.

Now suppose you want only to undo the changes made by the most recent REWEIGHT statement. Use REWEIGHT UNDO for this. The following statements produce Figure 73.58:

```
reweight r. le -12 or r. ge 12 / weight=.75;
reweight r. le -17 or r. ge 17 / weight=.5;
reweight undo;
print;
run;
```

Sum of Residuals	0
Sum of Squared Residuals	1694.87114
Predicted Residual SS (PRESS)	2547.22751

The resulting model reflects changes made only by the first REWEIGHT statement since the third REWEIGHT statement negates the effect of the second REWEIGHT statement. Observations 1, 3, 9, 10, 12, 16, and 17 have their weights changed to 0.75. Note that the label MODEL1.9 reflects the use of nine REWEIGHT statements for the current model.

Now suppose you want to reset the observations selected by the most recent REWEIGHT statement to their original weights. Use the REWEIGHT statement with the RESET option to do this. The following statements produce Figure 73.59:

```
reweight r. le -12 or r. ge 12 / weight=.75;
reweight r. le -17 or r. ge 17 / weight=.5;
reweight / reset;
print;
run;
```

Figure 73.59 REWEIGHT Statement with RESET option

Predicted Residual SS (PRESS)	2959.57279

Note that observations that meet the condition of the second REWEIGHT statement (residuals with an absolute value greater than or equal to 17) now have weights reset to their original value of 1. Observations 1, 3, 9, 10, and 17 have weights of 0.75, but observations 12 and 16 (which meet the condition of the second REWEIGHT statement) have their weights reset to 1.

Notice how the last three examples show three ways to change weights back to a previous value. In the first example, ALLOBS and the RESET option are used to change weights for all observations back to their original values. In the second example, the UNDO option is used to negate the effect of a previous REWEIGHT statement, thus changing weights for observations selected in the previous REWEIGHT statement to the weights specified in still another REWEIGHT statement. In the third example, the RESET option is used to change weights for observations selected in a pre-

vious REWEIGHT statement back to their original values. Finally, note that the label MODEL1.12 indicates that 12 REWEIGHT statements have been applied to the original model.

Testing for Heteroscedasticity

The regression model is specified as $y_i = \mathbf{x}_i\boldsymbol{\beta} + \epsilon_i$, where the ϵ_i's are identically and independently distributed: $E(\boldsymbol{\epsilon}) = 0$ and $E(\boldsymbol{\epsilon}'\boldsymbol{\epsilon}) = \sigma^2\mathbf{I}$. If the ϵ_i's are not independent or their variances are not constant, the parameter estimates are unbiased, but the estimate of the covariance matrix is inconsistent.

In the case of heteroscedasticity, if the regression data are from a simple random sample, then White (1980), showed that matrix

$$\mathrm{HC}_0 = (\mathbf{X}'\mathbf{X})^{-1}(\mathbf{X}'\mathrm{diag}(e_i^2)\mathbf{X})(\mathbf{X}'\mathbf{X})^{-1}$$

where

$$e_i = y_i - \mathbf{x}_i\mathbf{b}$$

is an asymptotically consistent estimate of the covariance matrix. MacKinnon and White (1985) introduced three alternative heteroscedasticity-consistent covariance matrix estimators that are all asymptotically equivalent to the estimator HC_0 but that typically have better small sample behavior. These estimators labeled HC_1, HC_2, and HC_3 are defined as follows:

$$\mathrm{HC}_1 = \frac{n}{n-p}\mathrm{HC}_0$$

where n is the number of observations and p is the number of regressors including the intercept.

$$\mathrm{HC}_2 = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathrm{diag}\left(\frac{e_i^2}{1-h_{ii}}\right)\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}$$

where

$$h_{ii} = \mathbf{x}_i(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i'$$

is the leverage of the ith observation.

$$\mathrm{HC}_3 = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathrm{diag}\left(\frac{e_i^2}{(1-h_{ii})^2}\right)\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}$$

Long and Ervin (2000) studied the performance of these estimators and recommend using the HC_3 estimator if the sample size is less than 250.

You can use the HCCMETHOD=0,1,2, or 3 in the MODEL statement to select a heteroscedasticity-consistent covariance matrix estimator, with HC_0 being the default. The ACOV option in the MODEL statement displays the heteroscedasticity-consistent covariance matrix estimator in effect and adds heteroscedasticity-consistent standard errors, also known as White standard errors, to the parameter estimates table. If you specify the HCC or WHITE option in the MODEL statement, but do not also specify the ACOV option, then the heteroscedasticity-consistent standard errors are added to the parameter estimates table but the heteroscedasticity- consistent covariance matrix is not displayed.

The SPEC option performs a model specification test. The null hypothesis for this test maintains that the errors are homoscedastic and independent of the regressors and that several technical assumptions about the model specification are valid. For details, see theorem 2 and assumptions 1–7 of White (1980). When the model is correctly specified and the errors are independent of the regressors, the rejection of this null hypothesis is evidence of heteroscedasticity. In implementing this test, an estimator of the average covariance matrix (White 1980, p. 822) is constructed and inverted. The nonsingularity of this matrix is one of the assumptions in the null hypothesis about the model specification. When PROC REG determines this matrix to be numerically singular, a generalized inverse is used and a note to this effect is written to the log. In such cases, care should be taken in interpreting the results of this test.

When you specify the SPEC, ACOV, HCC, or WHITE option in the MODEL statement, tests listed in the TEST statement are performed with both the usual covariance matrix and the heteroscedasticity-consistent covariance matrix requested with the HCCMETHOD= option. Tests performed with the consistent covariance matrix are asymptotic. For more information, refer to White (1980).

Both the ACOV and SPEC options can be specified in a MODEL or PRINT statement.

Testing for Lack of Fit

The test for lack of fit compares the variation around the model with "pure" variation within replicated observations. This measures the adequacy of the specified model. In particular, if there are n_i replicated observations $Y_{i1}, \ldots, Y_{in_i}$ of the response all at the same values $\mathbf{x}_i$ of the regressors, then you can predict the true response at $\mathbf{x}_i$ either by using the predicted value $\hat{Y}_i$ based on the model or by using the mean $\bar{Y}_i$ of the replicated values. The test for lack of fit decomposes the residual error into a component due to the variation of the replications around their mean value (the "pure" error) and a component due to the variation of the mean values around the model prediction (the "bias" error):

$$\sum_i \sum_{j=1}^{n_i} \left(Y_{ij} - \hat{Y}_i\right)^2 = \sum_i \sum_{j=1}^{n_i} \left(Y_{ij} - \bar{Y}_i\right)^2 + \sum_i n_i \left(\bar{Y}_i - \hat{Y}_i\right)^2$$

If the model is adequate, then both components estimate the nominal level of error; however, if the bias component of error is much larger than the pure error, then this constitutes evidence that there is significant lack of fit.

If some observations in your design are replicated, you can test for lack of fit by specifying the LACKFIT option in the MODEL statement (see Example 73.6). Note that, since all other tests use total error rather than pure error, you might want to hand-calculate the tests with respect to pure error if the lack of fit is significant. On the other hand, significant lack of fit indicates that the specified model is inadequate, so if this is a problem you can also try to refine the model.

Multivariate Tests

The MTEST statement described in the section "MTEST Statement" on page 5480 can test hypotheses involving several dependent variables in the form

$$(\mathbf{L}\boldsymbol{\beta} - \mathbf{cj})\mathbf{M} = 0$$

where $\mathbf{L}$ is a linear function on the regressor side, $\boldsymbol{\beta}$ is a matrix of parameters, $\mathbf{c}$ is a column vector of constants, $\mathbf{j}$ is a row vector of ones, and $\mathbf{M}$ is a linear function on the dependent side. The special case where the constants are zero is

$$\mathbf{L}\boldsymbol{\beta}\mathbf{M} = 0$$

To test this hypothesis, PROC REG constructs two matrices called $\mathbf{H}$ and $\mathbf{E}$ that correspond to the numerator and denominator of a univariate F test:

$$\begin{aligned} \mathbf{H} &= \mathbf{M}'(\mathbf{LB} - \mathbf{cj})'(\mathbf{L}(\mathbf{X}'\mathbf{X})^{-}\mathbf{L}')^{-1}(\mathbf{LB} - \mathbf{cj})\mathbf{M} \\ \mathbf{E} &= \mathbf{M}'(\mathbf{Y}'\mathbf{Y} - \mathbf{B}'(\mathbf{X}'\mathbf{X})\mathbf{B})\mathbf{M} \end{aligned}$$

These matrices are displayed for each MTEST statement if the PRINT option is specified.

Four test statistics based on the eigenvalues of $\mathbf{E}^{-1}\mathbf{H}$ or $(\mathbf{E}+\mathbf{H})^{-1}\mathbf{H}$ are formed. These are Wilks' lambda, Pillai's trace, the Hotelling-Lawley trace, and Roy's greatest root. These test statistics are discussed in Chapter 4, "Introduction to Regression Procedures."

The following code creates MANOVA data from Morrison (1976):

```
* Manova Data from Morrison (1976, 190);
data a;
input sex $ drug $ @;
do rep=1 to 4;
   input y1 y2 @;
   sexcode=(sex='m')-(sex='f');
   drug1=(drug='a')-(drug='c');
   drug2=(drug='b')-(drug='c');
   sexdrug1=sexcode*drug1;
   sexdrug2=sexcode*drug2;
   output;
end;
datalines;
m a  5  6  5  4  9  9  7  6
m b  7  6  7  7  9 12  6  8
m c 21 15 14 11 17 12 12 10
f a  7 10  6  6  9  7  8 10
f b 10 13  8  7  7  6  6  9
f c 16 12 14  9 14  8 10  5
;
```

The following statements perform a multivariate analysis of variance and produce Figure 73.60 through Figure 73.63:

```
proc reg;
   model y1 y2=sexcode drug1 drug2 sexdrug1 sexdrug2;
   y1y2drug: mtest y1=y2, drug1,drug2;
   drugshow: mtest drug1, drug2 / print canprint;
run;
```

NOTE: F Statistic for Roy's Greatest Root is an upper bound.
NOTE: F Statistic for Wilks' Lambda is exact.

The four multivariate test statistics are all highly significant, giving strong evidence that the coefficients of drug1 and drug2 are not zero for both dependent variables.

Autocorrelation in Time Series Data

When regression is performed on time series data, the errors might not be independent. Often errors are autocorrelated; that is, each error is correlated with the error immediately before it. Autocorrelation is also a symptom of systematic lack of fit. The DW option provides the Durbin-Watson d statistic to test that the autocorrelation is zero:

$$d = \frac{\sum_{i=2}^{n}(e_i - e_{i-1})^2}{\sum_{i=1}^{n} e_i^2}$$

The value of d is close to 2 if the errors are uncorrelated. The distribution of d is reported by Durbin and Watson (1951). Tables of the distribution are found in most econometrics textbooks, such as Johnston (1972) and Pindyck and Rubinfeld (1981).

The sample autocorrelation estimate is displayed after the Durbin-Watson statistic. The sample is computed as

$$r = \frac{\sum_{i=2}^{n} e_i e_{i-1}}{\sum_{i=1}^{n} e_i^2}$$

This autocorrelation of the residuals might not be a very good estimate of the autocorrelation of the true errors, especially if there are few observations and the independent variables have certain patterns. If there are missing observations in the regression, these measures are computed as though the missing observations did not exist.

Positive autocorrelation of the errors generally tends to make the estimate of the error variance too small, so confidence intervals are too narrow and true null hypotheses are rejected with a higher probability than the stated significance level. Negative autocorrelation of the errors generally tends to make the estimate of the error variance too large, so confidence intervals are too wide and the power of significance tests is reduced. With either positive or negative autocorrelation, least squares parameter estimates are usually not as efficient as generalized least squares parameter estimates. For more details, refer to Judge et al. (1985, Chapter 8) and the *SAS/ETS User's Guide*.

The following SAS statements request the DWPROB option for the U.S. population data (see Figure 73.64). If you use the DW option instead of the DWPROB option, then p-values are not produced.

```
proc reg data=USPopulation;
   model Population=Year YearSq / dwProb;
run;
```

Computations for Ridge Regression and IPC Analysis

In ridge regression analysis, the crossproduct matrix for the independent variables is centered (the NOINT option is ignored if it is specified) and scaled to one on the diagonal elements. The ridge constant k (specified with the RIDGE= option) is then added to each diagonal element of the crossproduct matrix. The ridge regression estimates are the least squares estimates obtained by using the new crossproduct matrix.

Let $\mathbf{X}$ be an $n \times p$ matrix of the independent variables after centering the data, and let $\mathbf{Y}$ be an $n \times 1$ vector corresponding to the dependent variable. Let $\mathbf{D}$ be a $p \times p$ diagonal matrix with diagonal elements as in $\mathbf{X}'\mathbf{X}$. The ridge regression estimate corresponding to the ridge constant k can be computed as

$$\mathbf{D}^{-\frac{1}{2}}(\mathbf{Z}'\mathbf{Z} + k\mathbf{I}_p)^{-1}\mathbf{Z}'\mathbf{Y}$$

where $\mathbf{Z} = \mathbf{X}\mathbf{D}^{-\frac{1}{2}}$ and $\mathbf{I}_p$ is a $p \times p$ identity matrix.

For IPC analysis, the smallest m eigenvalues of $\mathbf{Z}'\mathbf{Z}$ (where m is specified with the PCOMIT= option) are omitted to form the estimates.

For information about ridge regression and IPC standardized parameter estimates, parameter estimate standard errors, and variance inflation factors, refer to Rawlings (1988), Neter, Wasserman, and Kutner (1990), and Marquardt and Snee (1975). Unlike Rawlings (1988), the REG procedure uses the mean squared errors of the submodels instead of the full model MSE to compute the standard errors of the parameter estimates.

Construction of Q-Q and P-P Plots

If a normal probability-probability or quantile-quantile plot for the variable x is requested, the n nonmissing values of x are first ordered from smallest to largest:

$$x_{(1)} \leq x_{(2)} \leq \cdots \leq x_{(n)}$$

If a Q-Q plot is requested (with a PLOT statement of the form PLOT *yvariable*∗NQQ.), the ith-ordered value $x_{(i)}$ is represented by a point with y-coordinate $x_{(i)}$ and x-coordinate $\Phi^{-1}\left(\frac{i-0.375}{n+0.25}\right)$, where $\Phi(\cdot)$ is the standard normal distribution.

If a P-P plot is requested (with a PLOT statement of the form PLOT *yvariable*∗NPP.), the ith-ordered value $x_{(i)}$ is represented by a point with y-coordinate $\frac{i}{n}$ and x-coordinate $\Phi\left(\frac{x_{(i)}-\mu}{\sigma}\right)$, where μ is the mean of the nonmissing x-values and σ is the standard deviation. If an x-value has multiplicity k (that is, $x_{(i)} = \cdots = x_{(i+k-1)}$), then only the point $\left(\Phi\left(\frac{x_{(i)}-\mu}{\sigma}\right), \frac{i+k-1}{n}\right)$ is displayed.

Computational Methods

The REG procedure first composes a crossproducts matrix. The matrix can be calculated from input data, reformed from an input correlation matrix, or read in from an SSCP data set. For each model, the procedure selects the appropriate crossproducts from the main matrix. The normal equations formed from the crossproducts are solved by using a sweep algorithm (Goodnight 1979). The method is accurate for data that are reasonably scaled and not too collinear.

The mechanism that PROC REG uses to check for singularity involves the diagonal (pivot) elements of $\mathbf{X}'\mathbf{X}$ as it is being swept. If a pivot is less than SINGULAR*CSS, then a singularity is declared and the pivot is not swept (where CSS is the corrected sum of squares for the regressor and SINGULAR is machine dependent but is approximately 1E−7 on most machines or reset in the PROC REG statement).

The sweep algorithm is also used in many places in the model-selection methods. The RSQUARE method uses the leaps-and-bounds algorithm by Furnival and Wilson (1974).

Computer Resources in Regression Analysis

The REG procedure is efficient for ordinary regression; however, requests for optional features can greatly increase the amount of time required.

The major computational expense in the regression analysis is the collection of the crossproducts matrix. For p variables and n observations, the time required is proportional to np^2. For each model run, PROC REG needs time roughly proportional to k^3, where k is the number of regressors in the model. Include an additional nk^2 for the R, CLM, or CLI option and another nk^2 for the INFLUENCE option.

Most of the memory that PROC REG needs to solve large problems is used for crossproducts matrices. PROC REG requires $4p^2$ bytes for the main crossproducts matrix plus $4k^2$ bytes for the largest model. If several output data sets are requested, memory is also needed for buffers.

See the section "Input Data Sets" on page 5508 for information about how to use TYPE=SSCP data sets to reduce computing time.

Displayed Output

Many of the more specialized tables are described in detail in previous sections. Most of the formulas for the statistics are in Chapter 4, "Introduction to Regression Procedures," while other formulas can be found in the section "Model Fit and Diagnostic Statistics" on page 5557 and the section "Influence Statistics" on page 5559.

The analysis-of-variance table includes the following:

- the Source of the variation, Model for the fitted regression, Error for the residual error, and C Total for the total variation after correcting for the mean. The Uncorrected Total Variation is produced when the NOINT option is used.
- the degrees of freedom (DF) associated with the source
- the Sum of Squares for the term
- the Mean Square, the sum of squares divided by the degrees of freedom
- the F Value for testing the hypothesis that all parameters are zero except for the intercept. This is formed by dividing the mean square for Model by the mean square for Error.
- the Prob>F, the probability of getting a greater F statistic than that observed if the hypothesis is true. This is the significance probability.

Other statistics displayed include the following:

- Root MSE is an estimate of the standard deviation of the error term. It is calculated as the square root of the mean square error.
- Dep Mean is the sample mean of the dependent variable.
- C.V. is the coefficient of variation, computed as 100 times Root MSE divided by Dep Mean. This expresses the variation in unitless values.
- R-square is a measure between 0 and 1 that indicates the portion of the (corrected) total variation that is attributed to the fit rather than left to residual error. It is calculated as SS(Model) divided by SS(Total). It is also called the *coefficient of determination*. It is the square of the multiple correlation—in other words, the square of the correlation between the dependent variable and the predicted values.
- Adj R-square, the adjusted R^2, is a version of R^2 that has been adjusted for degrees of freedom. It is calculated as

$$\bar{R}^2 = 1 - \frac{(n-i)(1-R^2)}{n-p}$$

  where i is equal to 1 if there is an intercept and 0 otherwise, n is the number of observations used to fit the model, and p is the number of parameters in the model.

The parameter estimates and associated statistics are then displayed, and they include the following:

- the Variable used as the regressor, including the name Intercept to represent the estimate of the intercept parameter
- the degrees of freedom (DF) for the variable. There is one degree of freedom unless the model is not full rank.

- the Parameter Estimate
- the Standard Error, the estimate of the standard deviation of the parameter estimate
- T for H0: Parameter=0, the t test that the parameter is zero. This is computed as the Parameter Estimate divided by the Standard Error.
- the Prob > |T|, the probability that a t statistic would obtain a greater absolute value than that observed given that the true parameter is zero. This is the two-tailed significance probability.

If model-selection methods other than NONE, RSQUARE, ADJRSQ, and CP are used, the analysis-of-variance table and the parameter estimates with associated statistics are produced at each step. Also displayed are the following:

- C(p), which is Mallows' C_p statistic
- bounds on the condition number of the correlation matrix for the variables in the model (Berk 1977)

After statistics for the final model are produced, the following is displayed when the method chosen is FORWARD, BACKWARD, or STEPWISE:

- a Summary table listing Step number, Variable Entered or Removed, Partial and Model R-square, and C(p) and F statistics

The RSQUARE method displays its results beginning with the model containing the fewest independent variables and producing the largest R^2. Results for other models with the same number of variables are then shown in order of decreasing R^2, and so on, for models with larger numbers of variables. The ADJRSQ and CP methods group models of all sizes together and display results beginning with the model having the optimal value of adjusted $R^2$and C_p, respectively.

For each model considered, the RSQUARE, ADJRSQ, and CP methods display the following:

- Number in Model or IN, the number of independent variables used in each model
- R-square or RSQ, the squared multiple correlation coefficient

If the B option is specified, the RSQUARE, ADJRSQ, and CP methods produce the following:

- Parameter Estimates, the estimated regression coefficients

If the B option is not specified, the RSQUARE, ADJRSQ, and CP methods display the following:

- Variables in Model, the names of the independent variables included in the model

ODS Table Names

PROC REG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 73.10 ODS Tables Produced by PROC REG

ODS Table Name	Description	Statement	Option
ACovEst	Consistent covariance of estimates matrix	MODEL	ALL, ACOV
ACovTestANOVA	Test ANOVA using ACOV estimates	TEST	ACOV (MODEL statement)
ANOVA	Model ANOVA table	MODEL	default
CanCorr	Canonical correlations for hypothesis combinations	MTEST	CANPRINT
CollinDiag	Collinearity Diagnostics table	MODEL	COLLIN
CollinDiagNoInt	Collinearity Diagnostics for no intercept model	MODEL	COLLINOINT
ConditionBounds	Bounds on condition number	MODEL	(SELECTION=BACKWARD | FORWARD | STEPWISE | MAXR | MINR) and DETAILS
Corr	Correlation matrix for analysis variables	PROC	ALL, CORR
CorrB	Correlation of estimates	MODEL	CORRB
CovB	Covariance of estimates	MODEL	COVB
CrossProducts	Bordered model **X'X** matrix	MODEL	ALL, XPX
DWStatistic	Durbin-Watson statistic	MODEL	ALL, DW
DependenceEquations	Linear dependence equations	MODEL	default if needed
Eigenvalues	MTest eigenvalues	MTEST	CANPRINT
Eigenvectors	MTest eigenvectors	MTEST	CANPRINT
EntryStatistics	Entry statistics for selection methods	MODEL	(SELECTION=BACKWARD | FORWARD | STEPWISE | MAXR | MINR) and DETAILS
ErrorPlusHypothesis	MTest error plus hypothesis matrix **H+E**	MTEST	PRINT
ErrorSSCP	MTest error matrix **E**	MTEST	PRINT
FitStatistics	Model fit statistics	MODEL	default
HypothesisSSCP	MTest hypothesis matrix	MTEST	PRINT
InvMTestCov	Inv(**L** Ginv(**X'X**) **L'**) and Inv(**Lb-c**)	MTEST	DETAILS

USSCP	Uncorrected SSCP matrix for analysis variables	PROC	ALL, USSCP

ODS Graphics

This section describes the use of ODS for creating statistical graphs with the REG procedure. To request these graphs you must specify the ODS GRAPHICS statement. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS." The following sections describe the ODS graphical displays produced by PROC REG.

Diagnostics Panel

The "Diagnostics Panel" provides a display that you can use to get an overall assessment of your model. See Figure 73.8 for an example.

The panel contains the following plots:

- residuals versus the predicted values
- externally studentized residuals (RSTUDENT) versus the predicted values
- externally studentized residuals versus the leverage
- normal quantile-quantile plot (Q-Q plot) of the residuals
- dependent variable values versus the predicted values
- Cook's D versus observation number
- histogram of the residuals
- "Residual-Fit" (or RF) plot consisting of side-by-side quantile plots of the centered fit and the residuals
- box plot of the residuals if you specify the STATS=NONE suboption

Patterns in the plots of residuals or studentized residuals versus the predicted values, or spread of the residuals being greater than the spread of the centered fit in the RF plot, are indications of an inadequate model. Patterns in the spread about the 45-degree reference line in the plot of the dependent variable values versus the predicted values are also indications of an inadequate model.

The Q-Q plot, residual histogram, and box plot of the residuals are useful for diagnosing violations of the normality and homoscedasticity assumptions. If the data in a Q-Q plot come from a normal distribution, the points will cluster tightly around the reference line. A normal density is overlaid on the residual histogram to help in detecting departures form normality.

Following Rawlings (1998), reference lines are shown on the relevant plots to identify observations deemed outliers or influential. Observations whose externally studentized residual magnitudes exceed 2 are deemed outliers. Observations whose leverage value exceeds $2p/n$ or whose Cook's D value exceeds $4/n$ are deemed influential (p is the number of regressors including the intercept, and n is the number of observations used in the analysis). If you specify the LABEL suboption of

the PLOTS=DIAGNOSTICS option, then the points deemed outliers or influential are labeled on the appropriate plots.

Fit statistics are shown in the lower right of the plot and can be customized or suppressed by using the STATS= suboption of the PLOTS=DIAGNOSTICS option.

Residuals by Regressor Plots

Panels of plots of the residuals versus each of the regressors in the model are produced by default. Patterns in these plots are indications of an inadequate model. To help in detecting patterns, you can use the SMOOTH= suboption of the PLOTS=RESIDUALS option to add loess fits to these residual plots. See Figure 73.1.6 for an example.

Fit and Prediction Plots

A fit plot consisting of a scatter plot of the data overlaid with the regression line, as well as confidence and prediction limits, is produced for models depending on a single regressor. Fit statistics are shown to the right of the plot and can be customized or suppressed by using the STATS= suboption of the PLOTS=FIT option.

When a model contains more than one regressor, a fit plot is not appropriate. However, if all the regressors in the model are transformations of a single variable in the input data set, then you can request a scatter plot of the dependent variable overlaid with a fit line and confidence and prediction limits versus this variable. You can also plot residuals versus this variable. You request these plots, shown in a panel, with the PLOTS=PREDICTION option. See Figure 73.13 for an example.

Influence Plots

In addition to the "Cook's D Plot" and the "RStudent By Leverage Plot," you can request plots of the DFBETAS and DFFITS statistics versus observation number by using the PLOTS=DFBETAS and PLOTS=DFFITS options. You can also obtain partial regression leverage plots by using the PLOTS=PARTIAL option. See the section "Influence Statistics" on page 5559 for examples of these plots and details about their interpretation.

Ridge and VIF Plots

When you use ridge regression, you can request plots of the variance inflation factor (VIF) values and standardized ridge estimates by ridge values for each coefficient with the PLOTS=RIDGE option. See Example 73.5 for examples.

Variable Selection Plots

When you request variable selection by using the SELECTION= option in the MODEL statement, you can request plots of fit criteria for the models examined by using the PLOTS=CRITERIA

option. The fit criteria are displayed versus the step number for the FORWARD, BACKWARD, and STEPWISE selection methods and the step at which the optimal value of each criterion is obtained is indicated using a "Star" marker. For the all-subset-based selection methods (SELECTION=RSQUARE|ADJRSQ|CP), the fit criteria are displayed versus the number of observations in the model.

The criteria are shown in a panel, but you can use the UNPACK suboption of the PLOTS=CRITERIA option to obtain separate plots for each criterion. You can also use the LABEL suboption of the PLOTS=CRITERIA option to request that optimal models be labeled on the plots. Example 73.2 provides several examples.

ODS Graph Names

PROC REG assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 73.11.

To request these graphs you must specify the ODS GRAPHICS statement. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

Table 73.11 ODS Graphical Displays Produced by PROC REG

ODS Graph Name	Plot Description	PLOTS Option
AdjrsqPlot	Adjusted R-square statistic for models examined doing variable selection	ADJRSQ
AICPlot	AIC statistic for models examined doing variable selection	AIC
BICPlot	BIC statistic for models examined doing variable selection	BIC
CooksDPlot	Cook's D statistic versus observation number	COOKSD

Examples: REG Procedure

Example 73.1: Modeling Salaries of Major League Baseball Players

This example features the use of ODS Graphics in the process of building models by using the REG procedure and highlights the use of fit and influence diagnostics.

The following data set contains salary and performance information for Major League Baseball players who played at least one game in both the 1986 and 1987 seasons, excluding pitchers. The salaries (*Sports Illustrated,* April 20, 1987) are for the 1987 season and the performance measures are from 1986 (Collier Books, *The 1987 Baseball Encyclopedia Update*).

```

;
```

Suppose you want to investigate whether you can model the players' salaries for the 1987 season based on batting statistics for the previous season and lifetime batting performance. Since the variation in salaries is much greater for higher salaries, it is appropriate to apply a log transformation for this analysis. The following statements begin the analysis:

```
ods graphics on;

proc reg data=baseball;
   id name team league;
   model logSalary = no_hits no_runs no_rbi no_bb yr_major cr_hits;
run;
```

Output 73.1.1 shows the default output produced by PROC REG. The number of observations table shows that 59 observations are excluded because they have missing values for at least one of the variables used in the analysis. The analysis of variance and parameter estimates tables provide details about the fitted model.

Output 73.1.1 Default Output from PROC REG

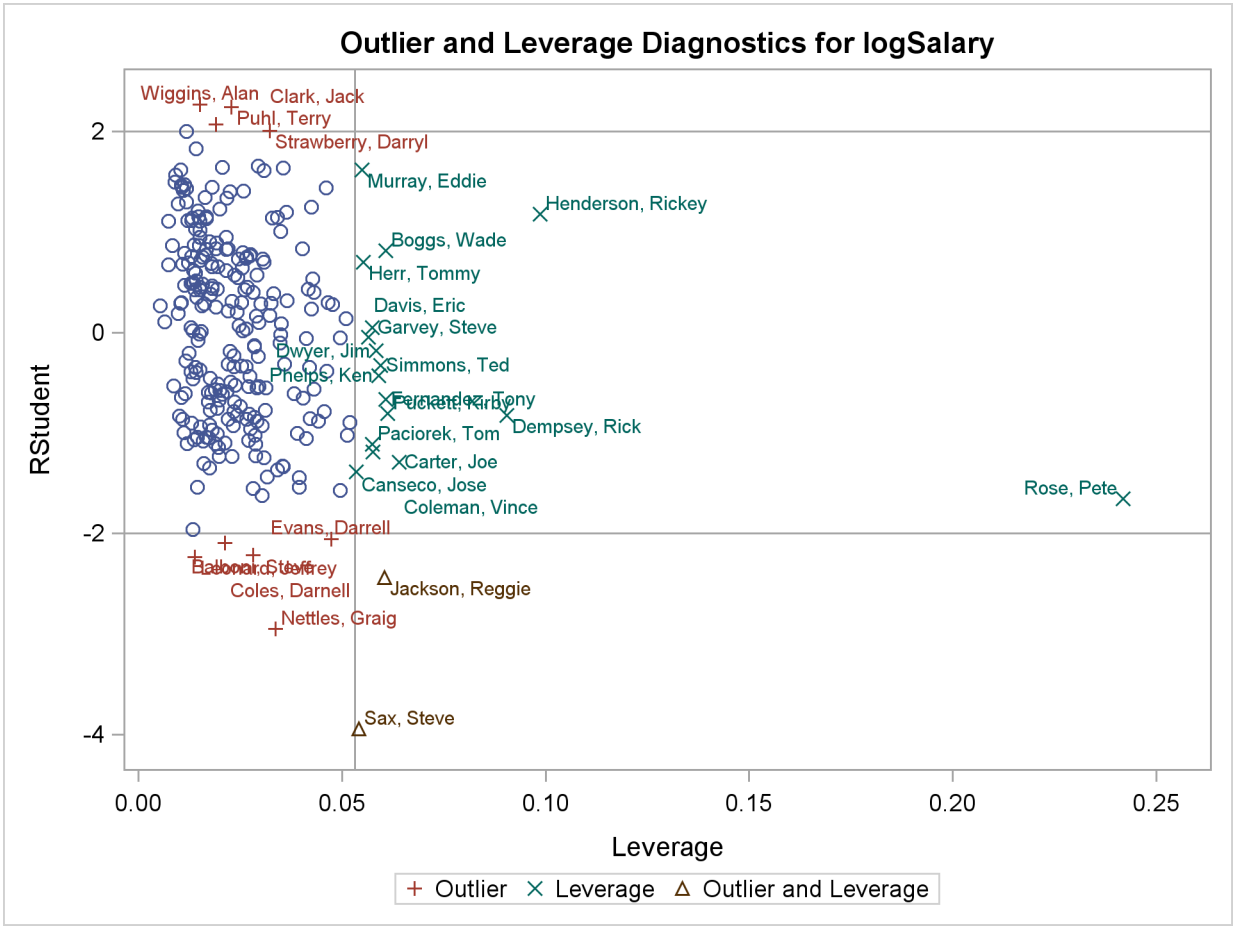
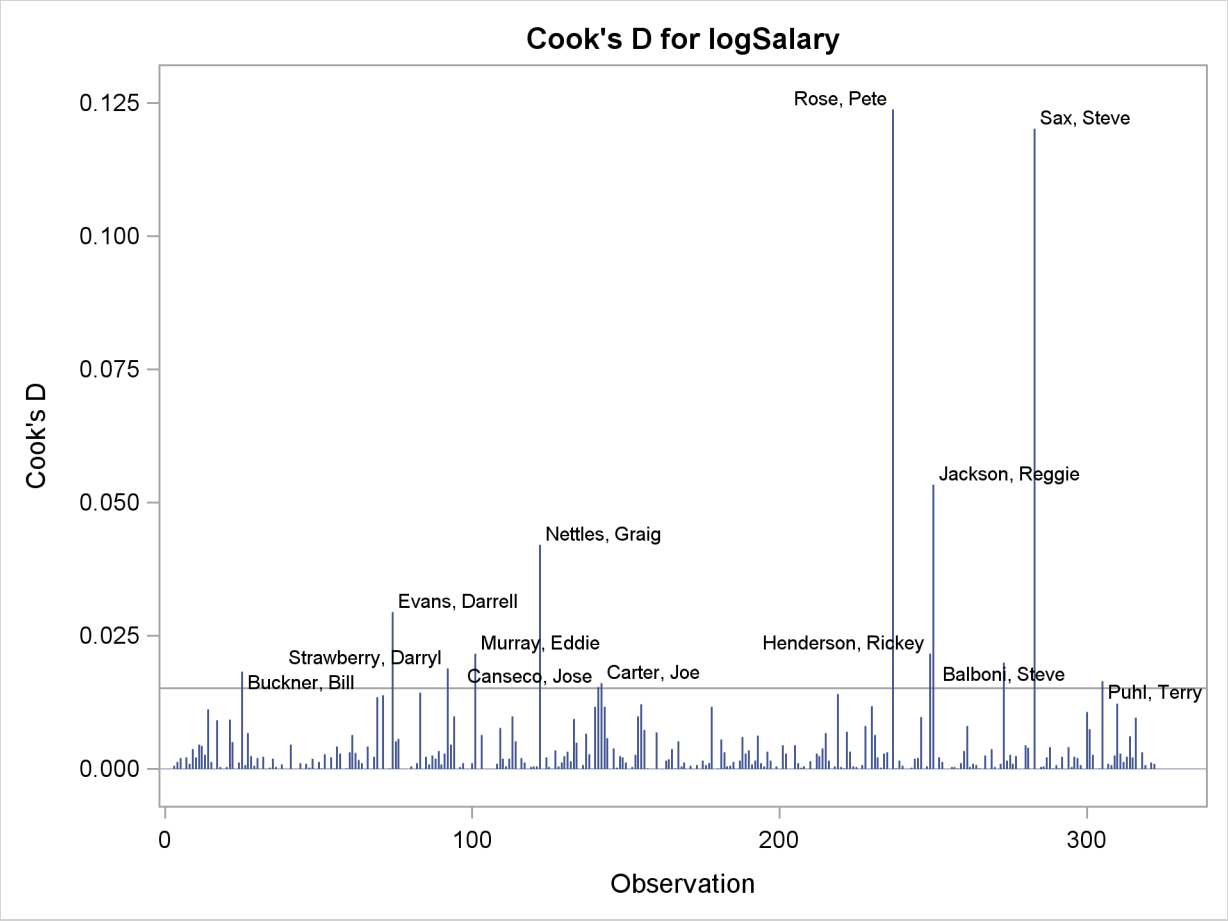
Before you accept a regression model, it is important to examine influence and fit diagnostics to see whether the model might be unduly influenced by a few observations and whether the data support the assumptions that underlie the linear regression. To facilitate such investigations, you can obtain diagnostic plots by enabling ODS Graphics.

Output 73.1.2 Fit Diagnostics



Output 73.1.2 shows a panel of diagnostic plots. The plot of externally studentized residuals (RStudent) by leverage values reveals that there is one observation with very high leverage that might be overly influencing the fit produced. The plot of Cook's D by observation also indicates two highly influential observations. To investigate further, you can use the PLOTS= option in the PROC REG statement as follows to produce labeled versions of these plots:

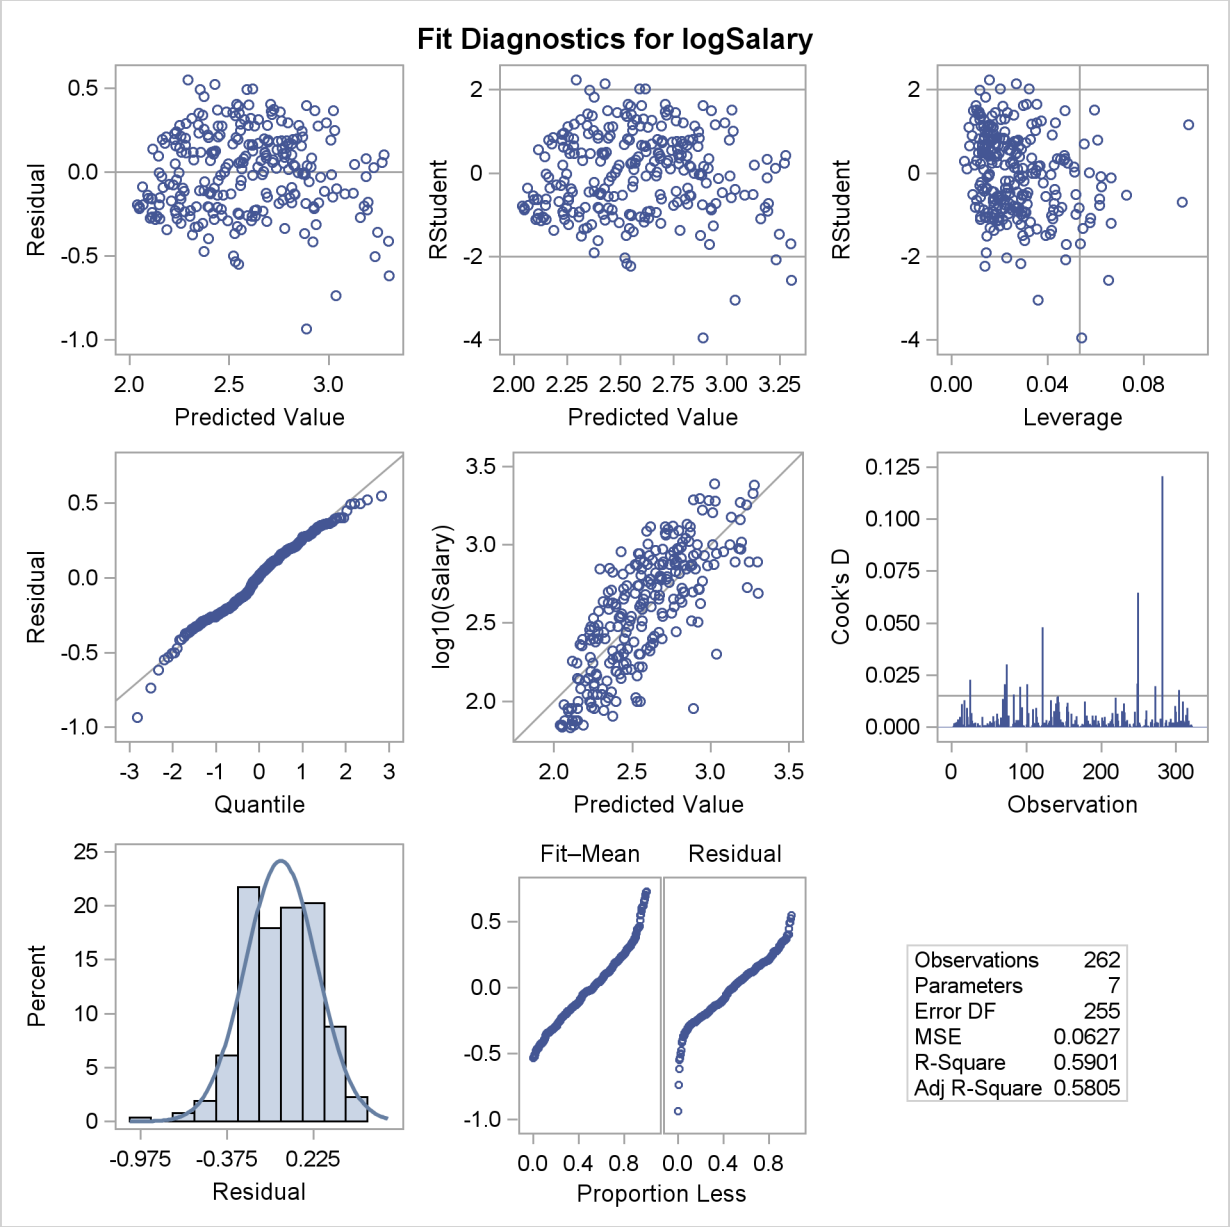


```
proc reg data=baseball
         plots(only label)=(RStudentByLeverage CooksD);
   id name team league;
   model logSalary = no_hits no_runs no_rbi no_bb yr_major cr_hits;
run;
```

Output 73.1.3 and Output 73.1.4 reveal that Pete Rose is the highly influential observation. You might obtain a better fit to the remaining data if you omit his statistics when building the model.

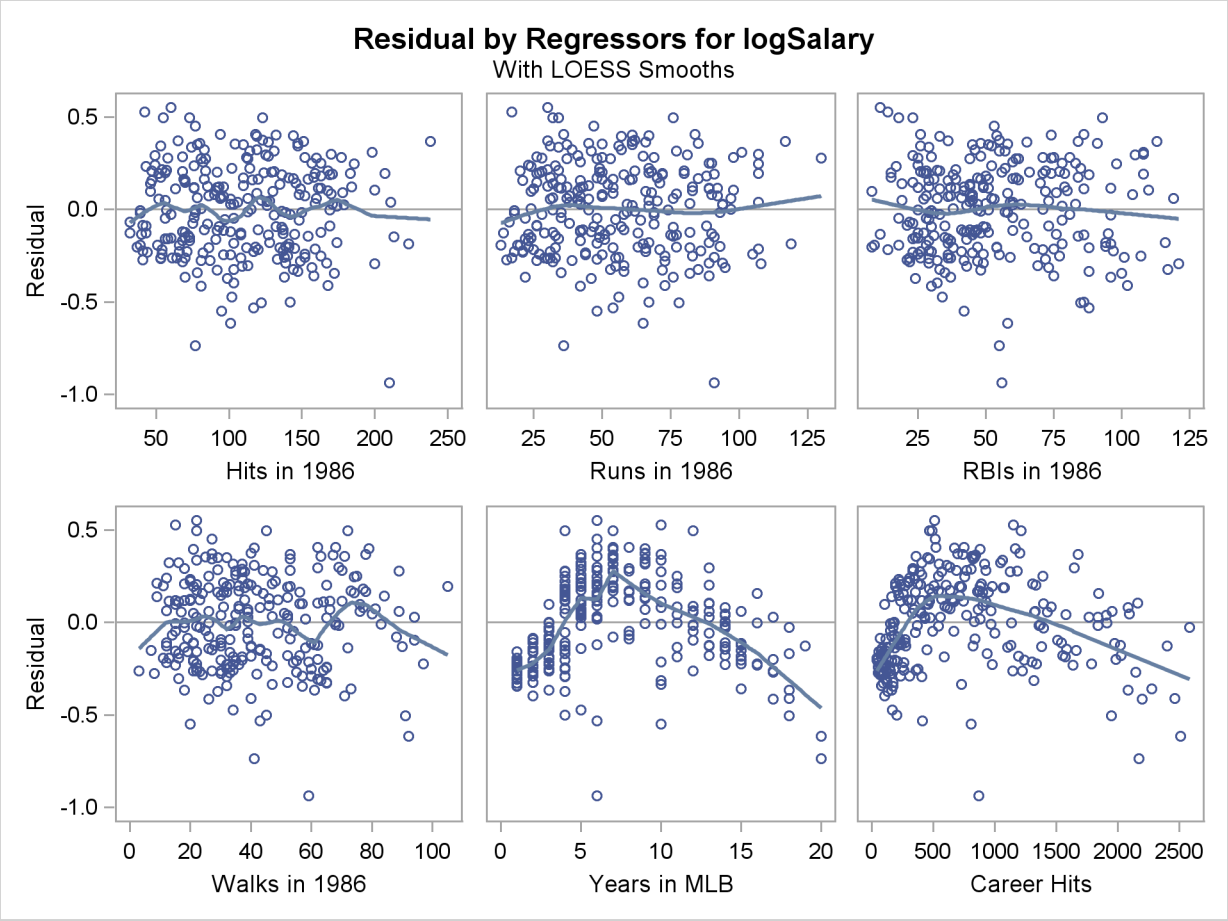
Output 73.1.3 Outlier and Leverage Diagnostics

Output 73.1.4 Cook's D



The following statements use a WHERE statement to omit Pete Rose's statistics when building the model. An alternative way to do this within PROC REG is to use a REWEIGHT statement. See "Reweighting Observations in an Analysis" on page 5569 for details about reweighting.

```
proc reg data=baseball
         plots=(RStudentByLeverage(label) residuals(smooth));
   where name^="Rose, Pete";
   id name team league;
   model logSalary = no_hits no_runs no_rbi no_bb yr_major cr_hits;
run;
```



Output 73.1.5 shows the new fit diagnostics panel. You can see that there are still several influential and outlying observations. One possible reason for observing outliers is that the linear model specified is not appropriate to capture the variation in this data. You can often see evidence of an inappropriate model by observing patterns in plots of residuals.

Output 73.1.5 Fit Diagnostics

Output 73.1.6 shows plots of the residuals by the regressors in the model. When you specify the RESIDUALS(SMOOTH) suboption of the PLOTS option in the PROC REG statement, a loess fit is overlaid on each of these plots. You can see the same clear pattern in the residual plots for yr_major and cr_hits. Players near the start of their careers and players near the end of their careers get paid less than the model predicts.

Output 73.1.6 Residuals by Regressors

You can address this lack of fit by using polynomials of degree 2 for these two variables as shown in the following statements:

```
data baseball;
   set baseball(where=(name^="Rose, Pete")) ;
   yr_major2 = yr_major*yr_major;
   cr_hits2  = cr_hits*cr_hits;
run;

proc reg data=baseball
      plots=(diagnostics(stats=none) RStudentByLeverage(label)
             CooksD(label) Residuals(smooth)
             DFFITS(label) DFBETAS ObservedByPredicted(label));
   id name team league;
   model logSalary = no_hits no_runs no_rbi no_bb yr_major cr_hits
                     yr_major2 cr_hits2;
run;
ods graphics off;
```

Output 73.1.7 shows the analysis of variance and parameter estimates for this model. Note that the R-square value of 0.787 for this model is considerably larger than the R-square value of 0.587 for the initial model shown in Output 73.1.1.

Output 73.1.7 Output from PROC REG

The REG Procedure
Model: MODEL1
Dependent Variable: logSalary log10(Salary)

Analysis of Variance

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F

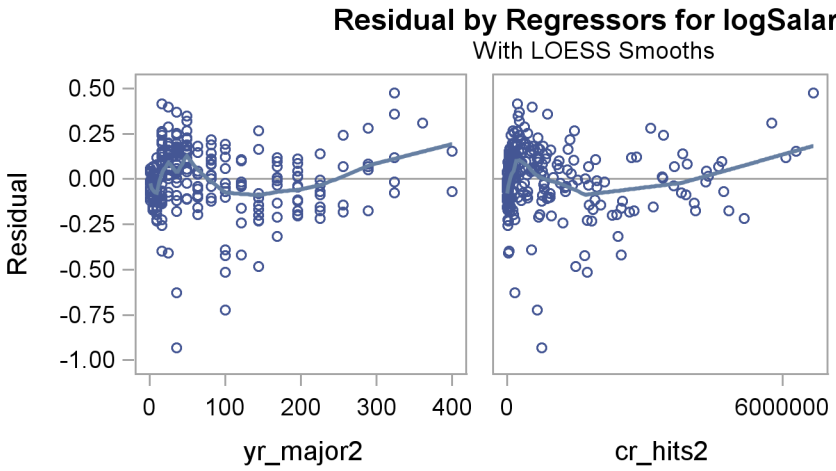
Root MSE	0.18098	R-Square	0.7874
Dependent Mean	2.57301	Adj R-Sq	0.7807
Coeff Var	7.03393		

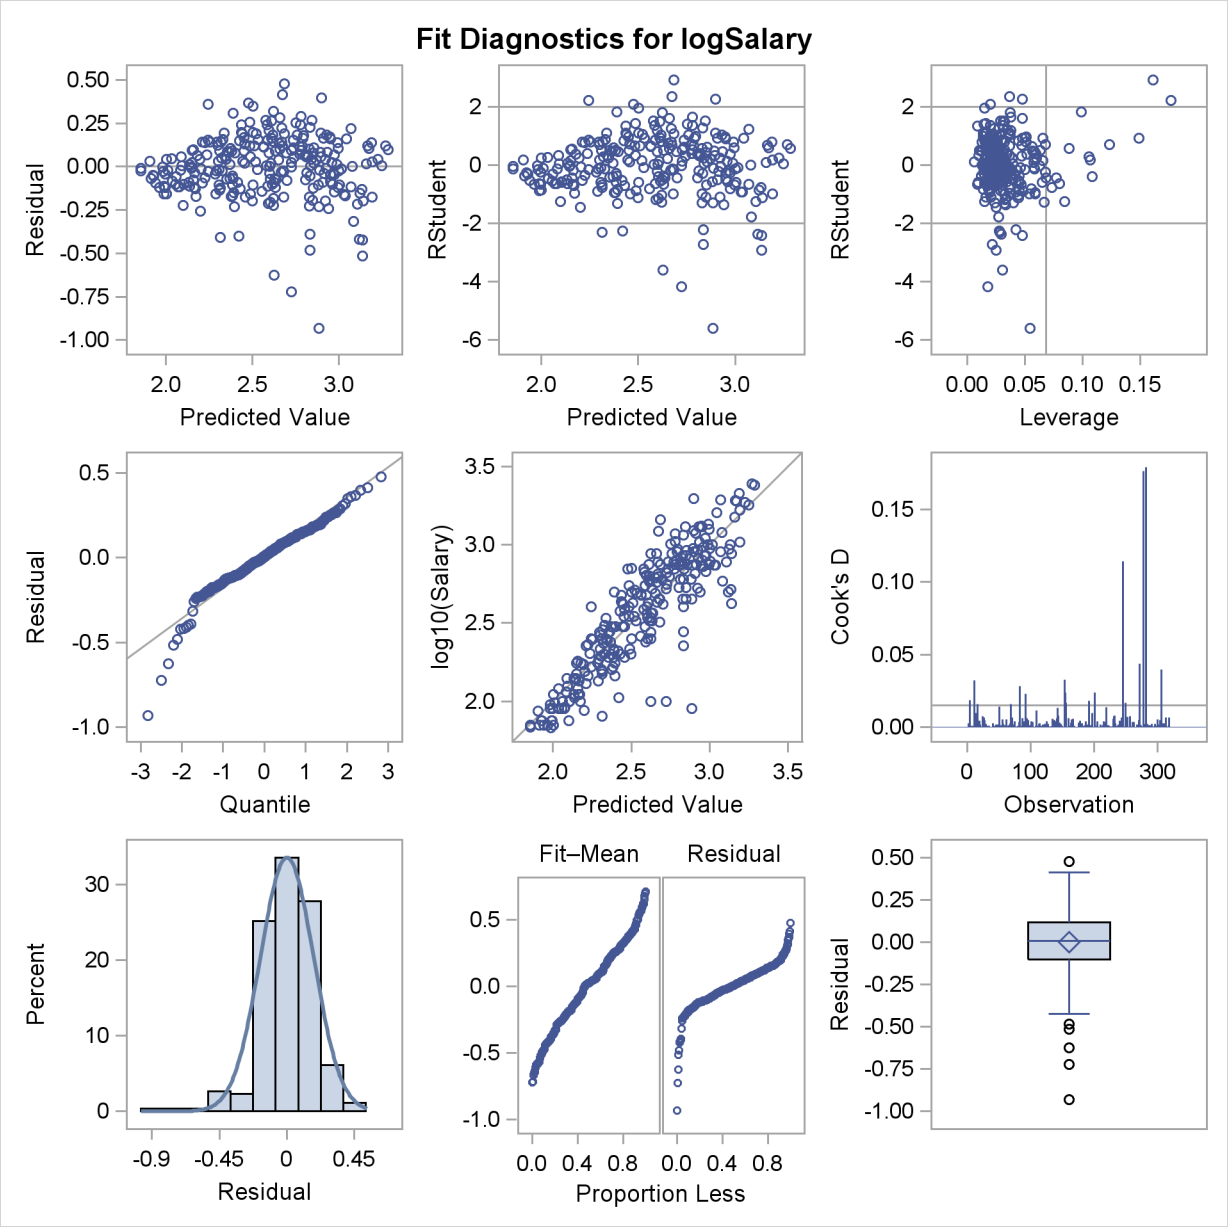
Parameter Estimates



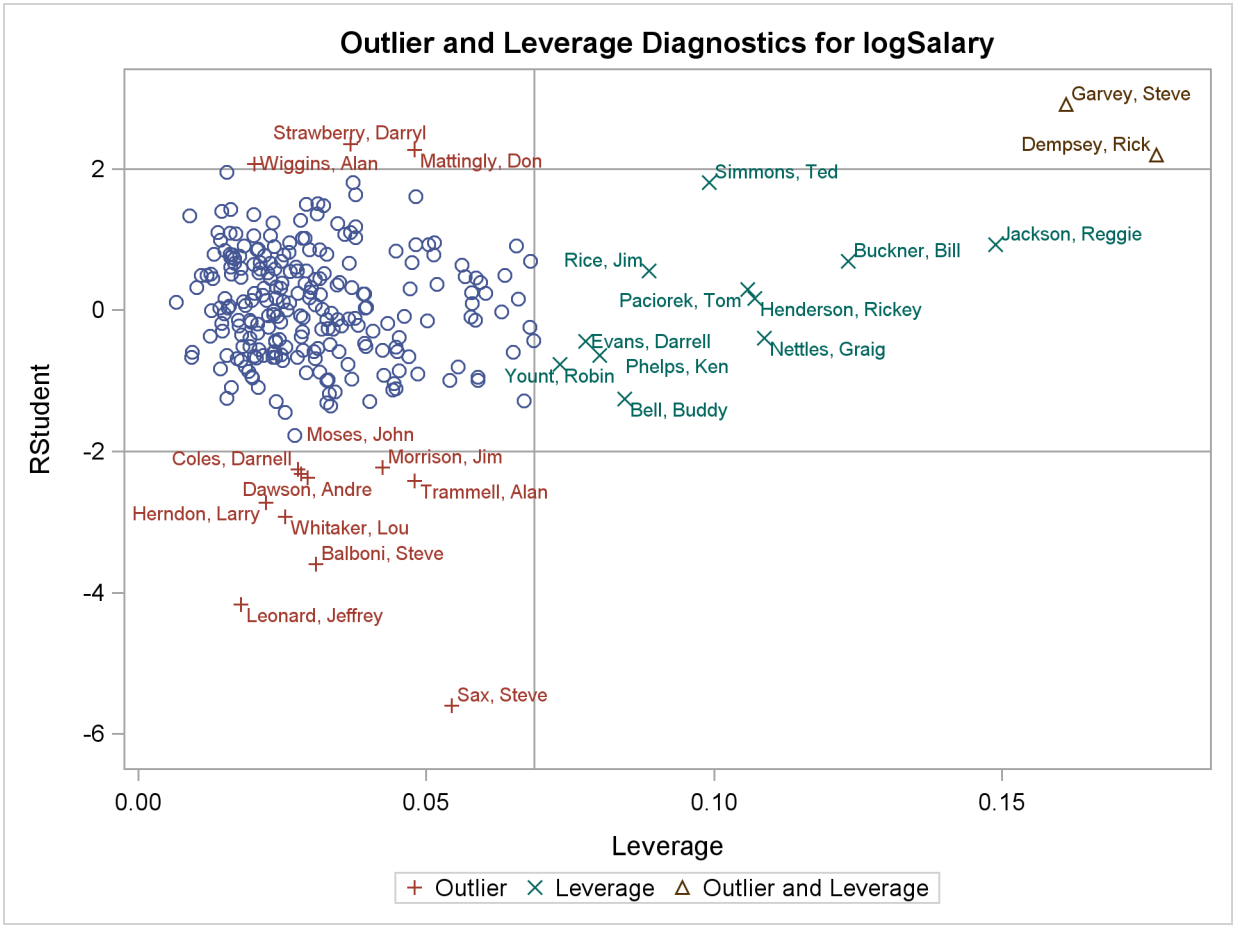
Variable	Label	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	Intercept	1	1.64564	0.05030	32.72	<.0001
no_hits	Hits in 1986	1	-0.00005539	0.00069200	-0.08	0.9363
no_runs	Runs in 1986	1	0.00093586	0.00125	0.75	0.4549
no_rbi	RBIs in 1986	1	0.00187	0.00074649	2.51	0.0127
no_bb	Walks in 1986	1	0.00218	0.00075057	2.90	0.0040
yr_major	Years in MLB	1	0.10383	0.01495	6.94	<.0001
cr_hits	Career Hits	1	0.00073955	0.00011970	6.18	<.0001
yr_major2		1	-0.00625	0.00071687	-8.73	<.0001
cr_hits2		1	-1.44072E-7	4.348471E-8	-3.31	0.0011

The plots of residuals by regressors in Output 73.1.8 and Output 73.1.9 show that the strong pattern in the plots for cr_majors and cr_hits has been reduced, although there is still some indication of a pattern remaining in these residuals. This suggests that a quadratic function might be insufficient to capture dependence of salary on these regressors.

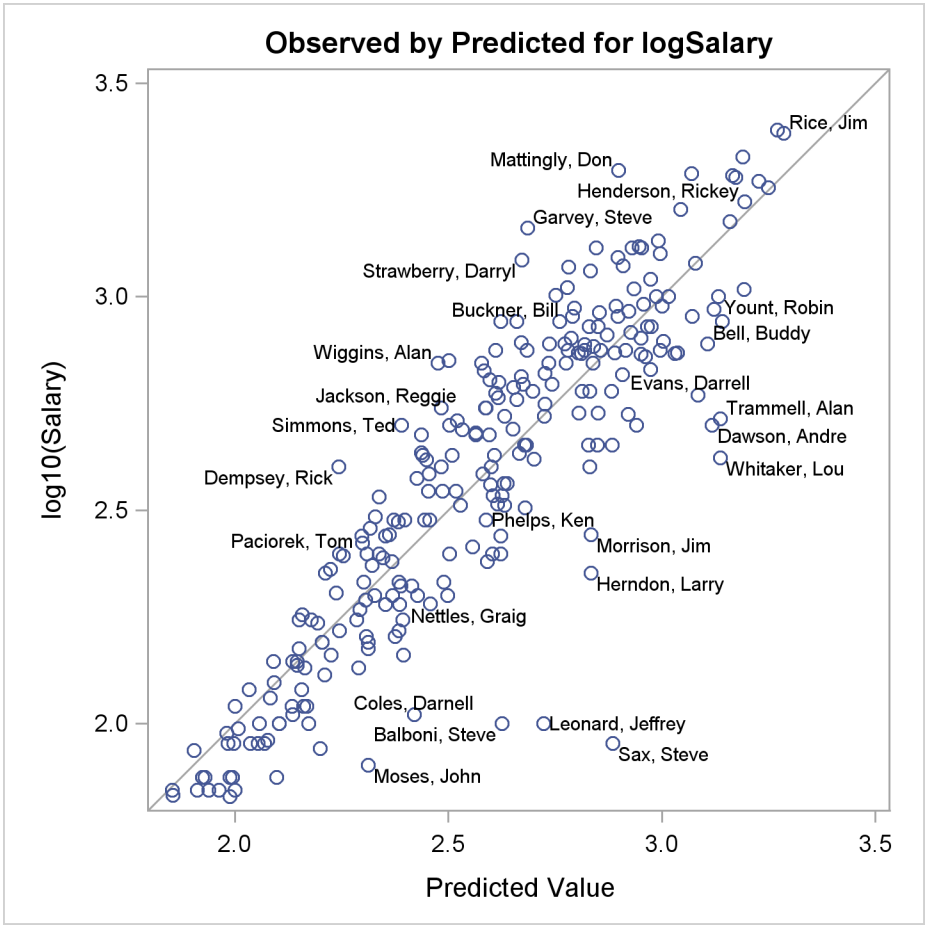
Output 73.1.8 Residuals by Regressors



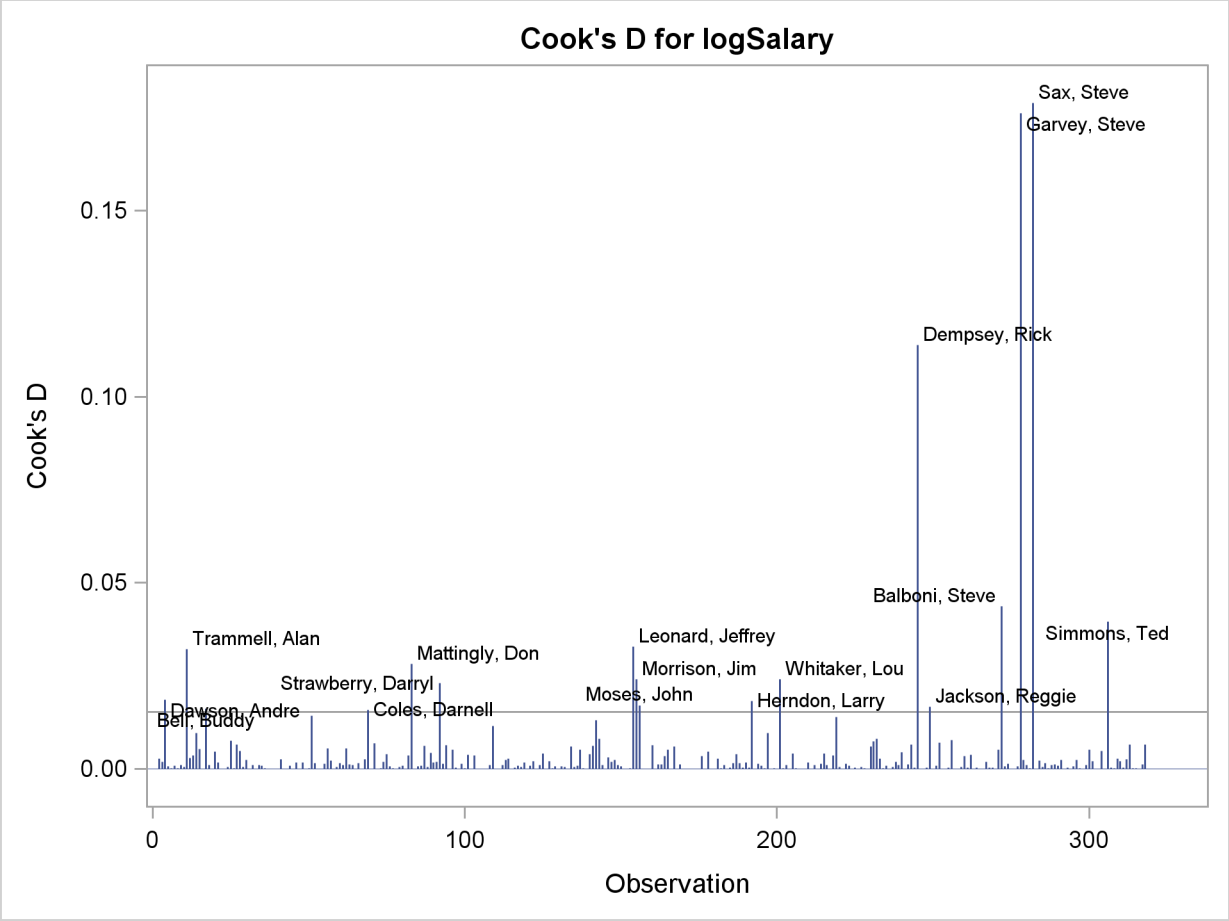
Output 73.1.9 Residuals by Regressors



Output 73.1.10 show the diagnostics plots; three of the plots, with points of interest labeled, are shown individually in Output 73.1.11, Output 73.1.12, and Output 73.1.13. The STATS=NONE suboption specified in the PLOTS=DIAGNOSTICS option replaces the inset of statistics with a box plot of the residuals in the fit diagnostics panel. The observed by predicted value plot reveals a reasonably successful model for explaining the variation in salary for most of the players. However, the model tends to overpredict the salaries of several players near the lower end of the salary range. This bias can also be seen in the distribution of the residuals that you can see in the histogram, Q-Q plot, and box plot in Output 73.1.10.

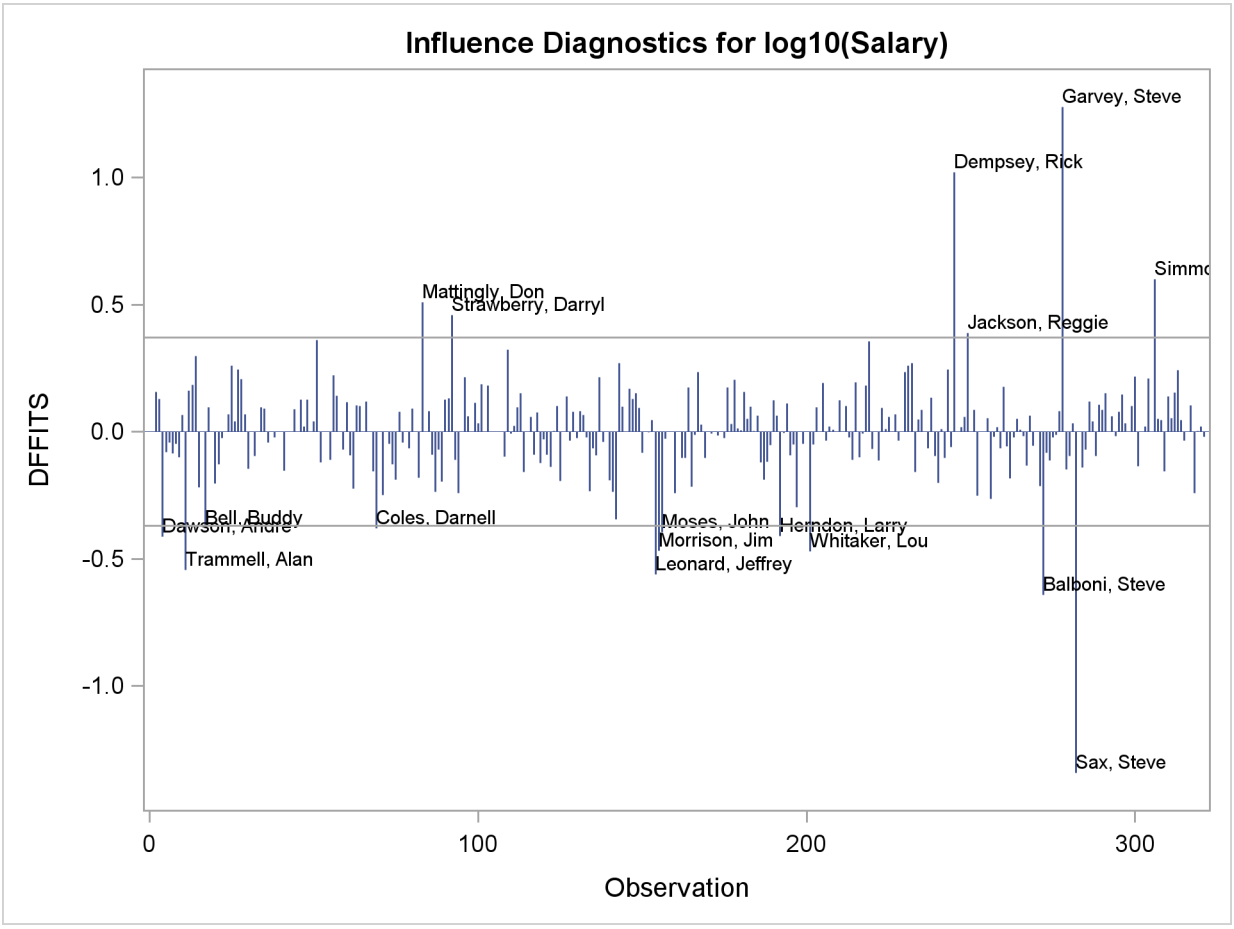


Output 73.1.10 Fit Diagnostics

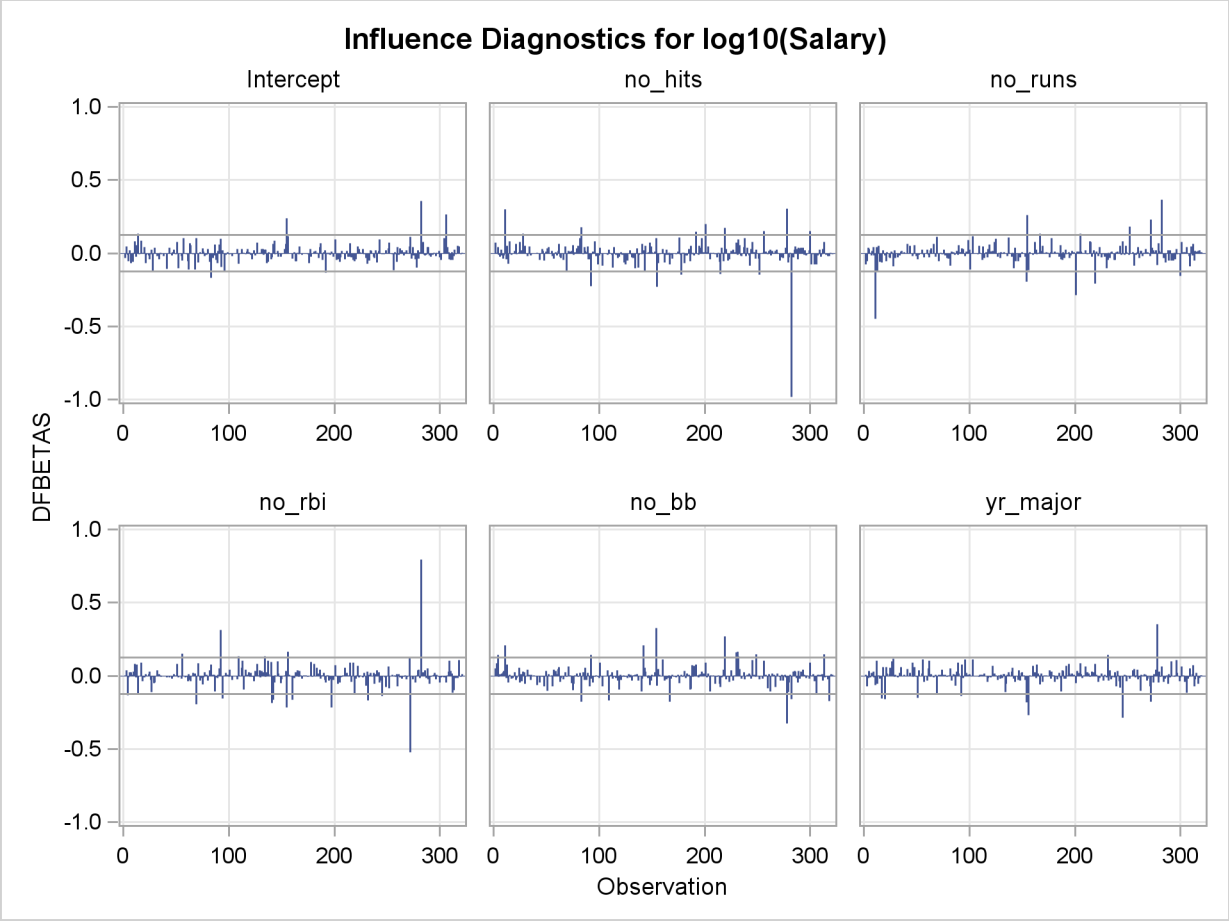


Output 73.1.11 Outlier and Leverage Diagnostics

Output 73.1.12 Observed by Predicted Values



Output 73.1.13 Cook's D



The RStudent by leverage plot in Output 73.1.11 and the Cook's *D* plot in Output 73.1.13 show that there are still a number of influential observations. By specifying the DFFITS and DFBETAS suboptions of the PLOTS= option, you obtain additional influence diagnostics plots shown in Output 73.1.14 and Output 73.1.15. See "Influence Statistics" on page 5559 for details about the interpretation DFFITS and DFBETAS statistics.

Output 73.1.14 DFFITS

Output 73.1.15 DFBETAS

You can continue this analysis by investigating how the influential observations identified in the various influence plots affect the fit. You can also use PROC ROBUSTREG to obtain a fit that is resistant to the presence of high leverage points and outliers.

Example 73.2: Aerobic Fitness Prediction

Aerobic fitness (measured by the ability to consume oxygen) is fit to some simple exercise tests. The goal is to develop an equation to predict fitness based on the exercise tests rather than on expensive and cumbersome oxygen consumption measurements. Three model-selection methods are used: forward selection, backward selection, and MAXR selection. Here are the data:

```
*------------------Data on Physical Fitness------------------*
| These measurements were made on men involved in a physical  |
| fitness course at N.C.State Univ. The variables are Age     |
| (years), Weight (kg), Oxygen intake rate (ml per kg body    |
| weight per minute), time to run 1.5 miles (minutes), heart  |
| rate while resting, heart rate while running (same time     |
| Oxygen rate measured), and maximum heart rate recorded while |
| running.                                                    |
| ***Certain values of MaxPulse were changed for this analysis.|
*-------------------------------------------------------------*;

52 82.78 47.467 10.50 53 170 172
;
```

The following statements demonstrate the FORWARD, BACKWARD, and MAXR model selection methods:

```
proc reg data=fitness;
   model Oxygen=Age Weight RunTime RunPulse RestPulse MaxPulse
         / selection=forward;
   model Oxygen=Age Weight RunTime RunPulse RestPulse MaxPulse
         / selection=backward;
   model Oxygen=Age Weight RunTime RunPulse RestPulse MaxPulse
         / selection=maxr;
run;
```

Output 73.2.1 shows the sequence of models produced by the FORWARD model-selection method.

Output 73.2.1 Forward Selection Method: PROC REG

Bounds on condition number: 8.7312, 104.83

The final variable available to add to the model, RestPulse, is not added since it does not meet the 50% (the default value of the SLE option is 0.5 for FORWARD selection) significance-level criterion for entry into the model.

The BACKWARD model-selection method begins with the full model. Output 73.2.2 shows the steps of the BACKWARD method. RestPulse is the first variable deleted, followed by Weight. No other variables are deleted from the model since the variables remaining (Age, RunTime, RunPulse, and MaxPulse) are all significant at the 10% (the default value of the SLS option is 0.1 for the BACKWARD elimination method) significance level.

Output 73.2.2 Backward Selection Method: PROC REG

Backward Elimination: Step 0

All Variables Entered: R-Square = 0.8487 and C(p) = 7.0000

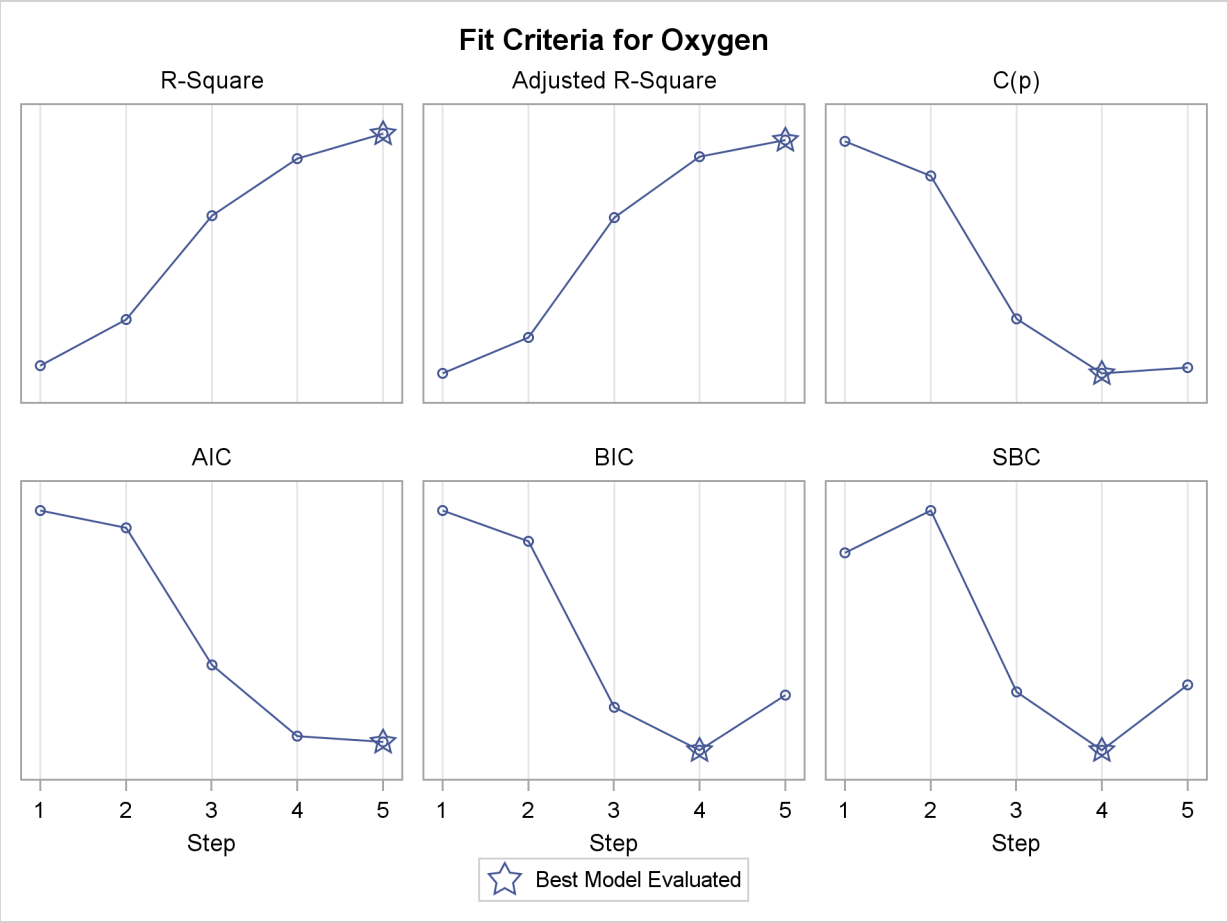
Note that for all three of these methods, RestPulse contributes least to the model. In the case of forward selection, it is not added to the model. In the case of backward selection, it is the first variable to be removed from the model. In the case of MAXR selection, RestPulse is included only for the full model.

For the STEPWISE, BACKWARD, and FORWARD selection methods, you can control the amount of detail displayed by using the DETAILS option, and you can use ODS Graphics to produce plots that show how selection criteria progress as the selection proceeds. For example, the following statements display only the selection summary table for the FORWARD selection method (Output 73.2.4) and produce the plots shown in Output 73.2.5 and Output 73.2.6.

```
ods graphics on;

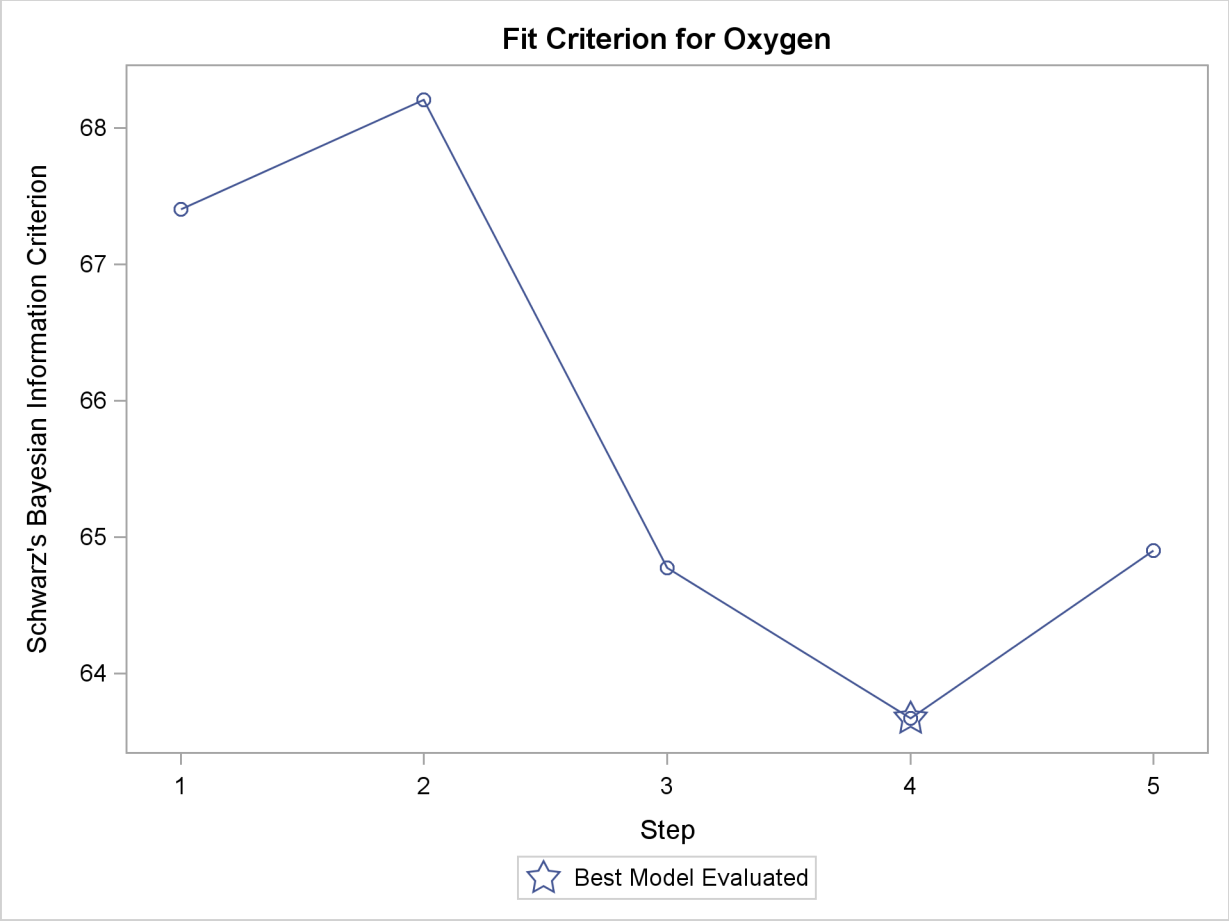
proc reg data=fitness plots=(criteria sbc);
   model Oxygen=Age Weight RunTime RunPulse RestPulse MaxPulse
         / selection=forward details=summary;
run;
```

Output 73.2.4 Forward Selection Summary



The REG Procedure
Model: MODEL1
Dependent Variable: Oxygen

Summary of Forward Selection



Step	Variable Entered	Number Vars In	Partial R-Square	Model R-Square	C(p)	F Value	Pr > F
1	RunTime	1	0.7434	0.7434	13.6988	84.01	<.0001
2	Age	2	0.0209	0.7642	12.3894	2.48	0.1267
3	RunPulse	3	0.0468	0.8111	6.9596	6.70	0.0154
4	MaxPulse	4	0.0257	0.8368	4.8800	4.10	0.0533
5	Weight	5	0.0112	0.8480	5.1063	1.84	0.1871

Output 73.2.5 show how six fit criteria progress as the forward selection proceeds. The step at which each criterion achieves its best value is indicated. For example, the BIC criterion achieves its minimum value for the model at step 4. Note that this does not mean that the model at step 4 achieves the smallest BIC criterion among all possible models that use a subset of the regressors; the model at step 4 yields the smallest BIC statistic among the models at each step of the forward selection. Output 73.2.6 show the progression of the SBC statistic in its own plot. If you want to see six of the selection criteria in individual plots, you can specify the UNPACK suboption of the PLOTS=CRITERIA option in the PROC REG statement.

Output 73.2.5 Fit Criteria

Output 73.2.6 SBC Criterion

Next, the RSQUARE model-selection method is used to request R^2 and C_p statistics for all possible combinations of the six independent variables. The following statements produce Output 73.2.7:

```
proc reg data=fitness plots=(criteria(label) cp);
   model Oxygen=Age Weight RunTime RunPulse RestPulse MaxPulse
         / selection=rsquare cp;
   title 'Physical fitness data: all models';
run;
```

Output 73.2.7 All Models by the RSQUARE Method: PROC REG

Physical fitness data: all models

The REG Procedure
Model: MODEL1
Dependent Variable: Oxygen

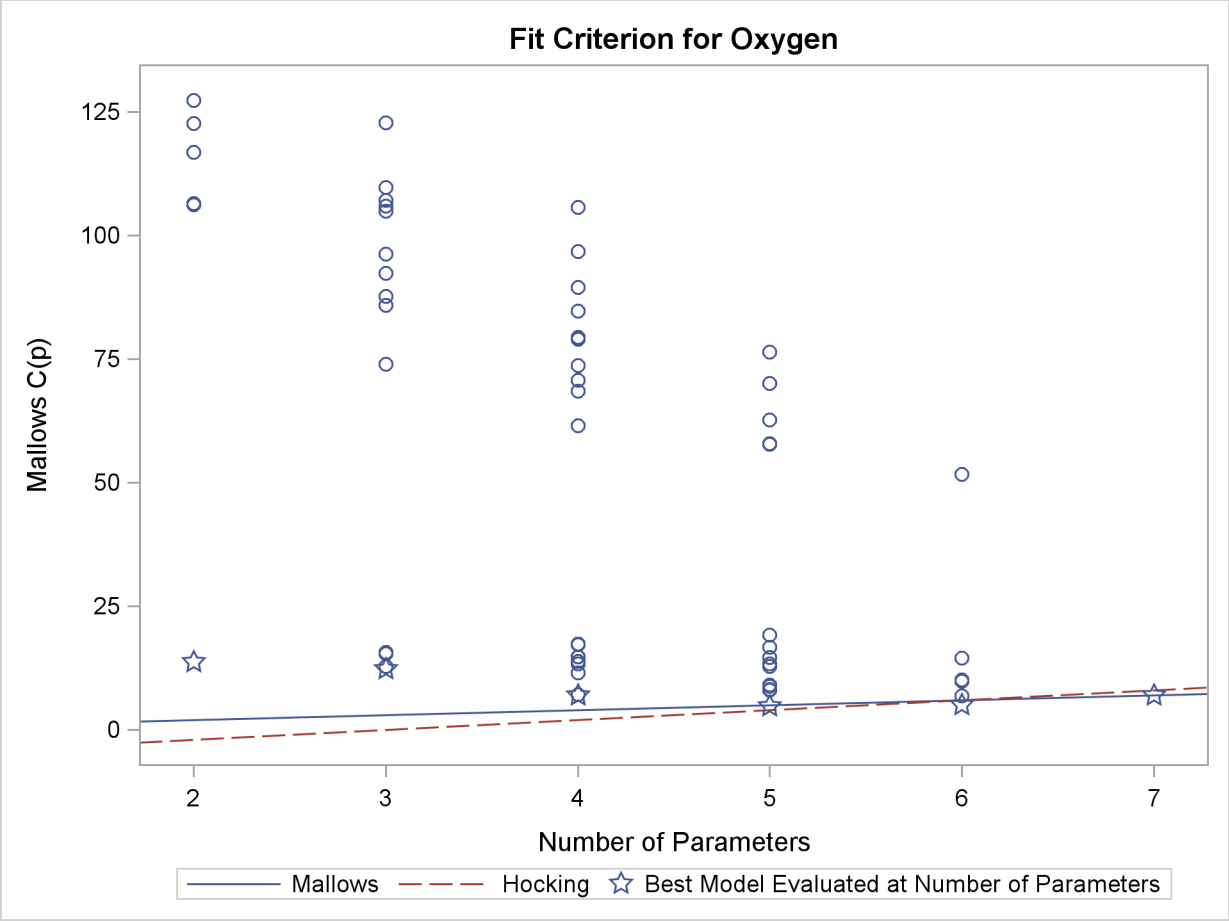
The models in Output 73.2.7 are arranged first by the number of variables in the model and then by the magnitude of R^2 for the model.



Output 73.2.8 shows the panel of fit criteria for the RSQUARE selection method. The best models (based on the R-square statistic) for each subset size are indicated on the plots. The LABEL suboption specifies that these models are labeled by the model number that appears in the summary table shown in Output 73.2.7.

Output 73.2.8 Fit Criteria

Output 73.2.9 shows the plot of the C_p criterion by number of regressors in the model. Useful reference lines suggested by Mallows (1973) and Hocking (1976) are included on the plot. However, because all possible subset models are included on this plot, the better models are all compressed near the bottom of the plot.

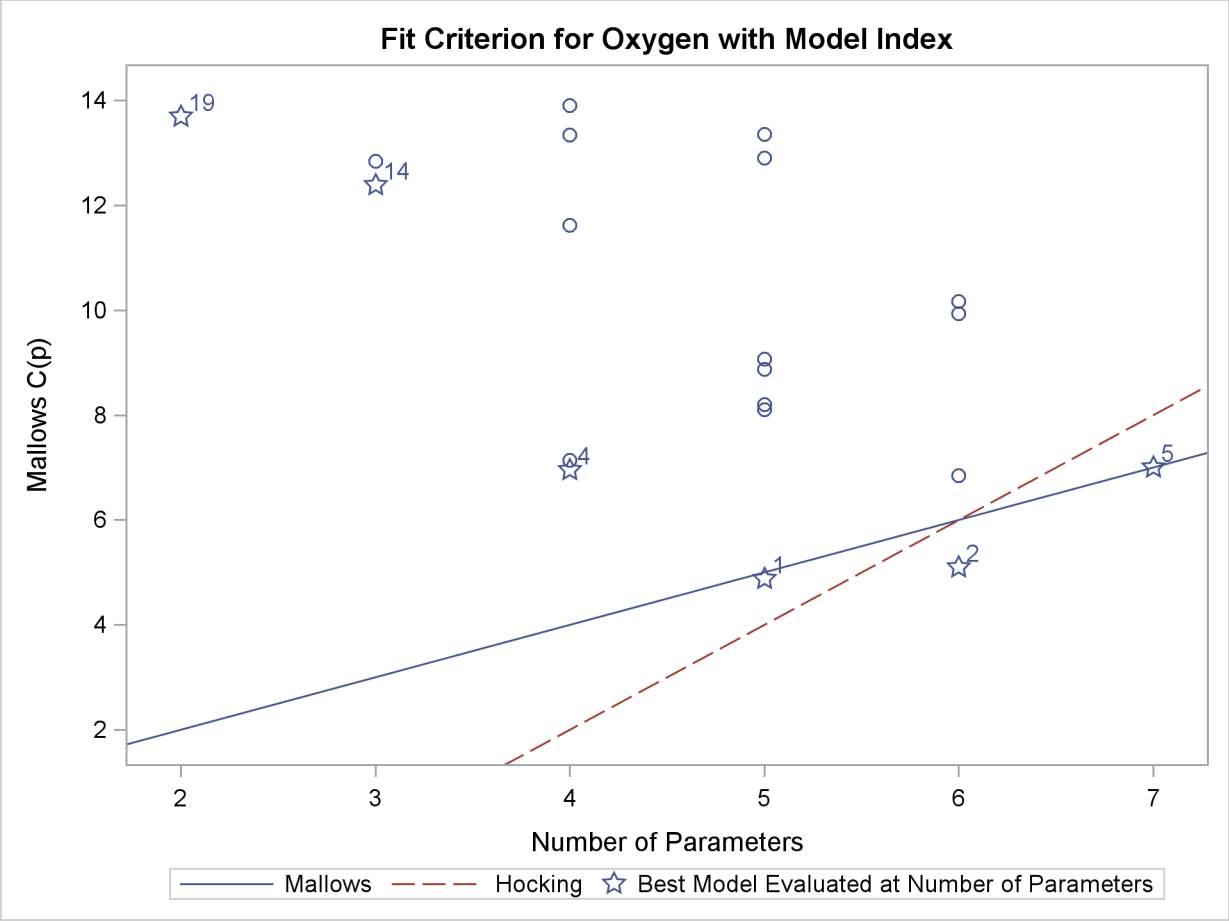
Output 73.2.9 C_p Criterion

The following statements use the BEST=20 option in the model statement and SELECTION=CP to restrict attention to the models that yield the 20 smallest values of the C_p statistic:

```
proc reg data=fitness plots(only)=cp(label);
   model Oxygen=Age Weight RunTime RunPulse RestPulse MaxPulse
         / selection=cp best=20;
run;

ods graphics off;
```

Output 73.2.10 shows the summary table listing the regressors in the 20 models that yield the smallest C_p values, and Output 73.2.11 presents the results graphically. Reference lines $C_p = 2p - p_{full}$ and $C_p = p$ are shown on this plot. See the PLOTS=CP option on page 5459 for interpretations of these lines. For the Fitness data, these lines indicate that a six-variable model is a reasonable choice for doing parameter estimation, while a five-variable model might be suitable for doing prediction.



Output 73.2.10 C_p Selection Summary: PROC REG

The REG Procedure
Model: MODEL1
Dependent Variable: Oxygen

C(p) Selection Method

Model Index	Number in Model	C(p)	R-Square	Variables in Model

Output 73.2.11 C_p Criterion

Before making a final decision about which model to use, you would want to perform collinearity diagnostics. Note that, since many different models have been fit and the choice of a final model is based on R^2, the statistics are biased and the p-values for the parameter estimates are not valid.

Example 73.3: Predicting Weight by Height and Age

In this example, the weights of schoolchildren are modeled as a function of their heights and ages. The example shows the use of a BY statement with PROC REG, multiple MODEL statements, and the OUTEST= and OUTSSCP= options, which create data sets. Here are the data:

```
*------------Data on Age, Weight, and Height of Children-------*
| Age (months), height (inches), and weight (pounds) were      |
| recorded for a group of school children.                     |
| From Lewis and Taylor (1967).                                |
*--------------------------------------------------------------*;

data htwt;
   input sex $ age :3.1 height weight @@;
   datalines;
f 143 56.3  85.0 f 155 62.3 105.0 f 153 63.3 108.0 f 161 59.0  92.0

m 151 59.3  87.0
;
```

Modeling is performed separately for boys and girls. Since the BY statement is used, interactive processing is not possible in this example; no statements can appear after the first RUN statement.

The following statements produce Output 73.3.1 through Output 73.3.4:

```
proc reg outest=est1 outsscp=sscp1 rsquare;
   by sex;
   eq1: model  weight=height;
   eq2: model  weight=height age;

proc print data=sscp1;
   title2 'SSCP type data set';

proc print data=est1;
   title2 'EST type data set';
run;
```

Output 73.3.1 Height and Weight Data: Submodel for Female Children

```

For both female and male children, the overall F statistics for both models are significant, indicating that the model explains a significant portion of the variation in the data. For females, the full model is

$$\text{weight} = -150.57 + 3.60 \times \text{height} + 1.91 \times \text{age}$$

and for males, the full model is

$$\text{weight} = -113.71 + 2.68 \times \text{height} + 3.08 \times \text{age}$$

The OUTSSCP= data set is shown in Output 73.3.5. Note how the BY groups are separated. Observations with _TYPE_='N' contain the number of observations in the associated BY group. Observations with _TYPE_='SSCP' contain the rows of the uncorrected sums of squares and crossproducts matrix. The observations with _NAME_='Intercept' contain crossproducts for the intercept.

Output 73.3.5 SSCP Matrix

Obs	sex	_TYPE_	_NAME_	Intercept	height	weight	age
1	f	SSCP	Intercept	111.0	6718.40	10975.50	1824.90
2	f	SSCP	height	6718.4	407879.32	669469.85	110818.32
3	f	SSCP	weight	10975.5	669469.85	1123360.75	182444.95
4	f	SSCP	age	1824.9	110818.32	182444.95	30363.81
5	f	N		111.0	111.00	111.00	111.00
6	m	SSCP	Intercept	126.0	7825.00	13034.50	2072.10

8	m	SSCP	weight	13034.5	817919.60	1398238.75	217717.45
9	m	SSCP	age	2072.1	129432.57	217717.45	34515.95
10	m	N		126.0	126.00	126.00	126.00

The OUTEST= data set is displayed in Output 73.3.6; again, the BY groups are separated. The _MODEL_ column contains the labels for models from the MODEL statements. If no labels are specified, the defaults MODEL1 and MODEL2 would appear as values for _MODEL_. Note that _TYPE_='PARMS' for all observations, indicating that all observations contain parameter estimates. The _DEPVAR_ column displays the dependent variable, and the _RMSE_ column gives the root mean square error for the associated model. The Intercept column gives the estimate for the intercept for the associated model, and variables with the same name as variables in the original data set (height, age) give parameter estimates for those variables. The dependent variable, weight, is shown with a value of −1. The _IN_ column contains the number of regressors in the model not including the intercept; _P_ contains the number of parameters in the model; _EDF_ contains the error degrees of freedom; and _RSQ_ contains the R^2 statistic. Finally, note that the _IN_, _P_, _EDF_, and _RSQ_ columns appear in the OUTEST= data set since the RSQUARE option is specified in the PROC REG statement.

Output 73.3.6 OUTEST Data Set

Example 73.4: Regression with Quantitative and Qualitative Variables

At times it is desirable to have independent variables in the model that are qualitative rather than quantitative. This is easily handled in a regression framework. Regression uses qualitative variables to distinguish between populations. There are two main advantages of fitting both populations in one model. You gain the ability to test for different slopes or intercepts in the populations, and more degrees of freedom are available for the analysis.

Regression with qualitative variables is different from analysis of variance and analysis of covariance. Analysis of variance uses qualitative independent variables only. Analysis of covariance uses quantitative variables in addition to the qualitative variables in order to account for correlation in the data and reduce MSE; however, the quantitative variables are not of primary interest and merely improve the precision of the analysis.

Consider the case where Y_i is the dependent variable, $\mathbf{X1}_i$ is a quantitative variable, $\mathbf{X2}_i$ is a qualitative variable taking on values 0 or 1, and $\mathbf{X1}_i\mathbf{X2}_i$ is the interaction. The variable $\mathbf{X2}_i$ is called a dummy, binary, or indicator variable. With values 0 or 1, it distinguishes between two populations. The model is of the form

$$\mathbf{Y}_i = \beta_0 + \beta_1\mathbf{X1}_i + \beta_2\mathbf{X2}_i + \beta_3\mathbf{X1}_i\mathbf{X2}_i + \boldsymbol{\epsilon}_i$$

for the observations $i = 1, 2, \ldots, n$. The parameters to be estimated are β_0, β_1, β_2, and β_3. The number of dummy variables used is one less than the number of qualitative levels. This yields a nonsingular $\mathbf{X}'\mathbf{X}$ matrix. See Chapter 10 of Neter, Wasserman, and Kutner (1990) for more details.

An example from Neter, Wasserman, and Kutner (1990) follows. An economist is investigating the relationship between the size of an insurance firm and the speed at which it implements new insurance innovations. He believes that the type of firm might affect this relationship and suspects that there might be some interaction between the size and type of firm. The dummy variable in the model enables the two firms to have different intercepts. The interaction term enables the firms to have different slopes as well.

In this study, $\mathbf{Y}_i$ is the number of months from the time the first firm implemented the innovation to the time it was implemented by the ith firm. The variable $\mathbf{X1}_i$ is the size of the firm, measured in total assets of the firm. The variable $\mathbf{X2}_i$ denotes the firm type; it is 0 if the firm is a mutual fund company and 1 if the firm is a stock company. The dummy variable enables each firm type to have a different intercept and slope.

The previous model can be broken down into a model for each firm type by plugging in the values for $\mathbf{X2}_i$. If $\mathbf{X2}_i = 0$, the model is

$$\mathbf{Y}_i = \beta_0 + \beta_1\mathbf{X1}_i + \boldsymbol{\epsilon}_i$$

This is the model for a mutual company. If $\mathbf{X2}_i = 1$, the model for a stock firm is

$$\mathbf{Y}_i = (\beta_0 + \beta_2) + (\beta_1 + \beta_3)\mathbf{X1}_i + \boldsymbol{\epsilon}_i$$

This model has intercept $\beta_0 + \beta_2$ and slope $\beta_1 + \beta_3$.

The data[1] follow. Note that the interaction term is created in the DATA step since polynomial effects such as size*type are not allowed in the MODEL statement in the REG procedure.

```
title 'Regression With Quantitative and Qualitative Variables';
data insurance;
   input time size type @@;
   sizetype=size*type;
   datalines;

;
run;
```

The following statements begin the analysis:

```
proc reg data=insurance;
   model time = size type sizetype;
run;
```

The ANOVA table is displayed in Output 73.4.1.

Output 73.4.1 ANOVA Table and Parameter Estimates

Regression With Quantitative and Qualitative Variables

The REG Procedure
Model: MODEL1
Dependent Variable: time

Analysis of Variance

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	3	1504.41904	501.47301	45.49	<.0001
Error	16	176.38096	11.02381		
Corrected Total	19	1680.80000			

Root MSE	3.32021	R-Square	0.8951
Dependent Mean	19.40000	Adj R-Sq	0.8754
Coeff Var	17.11450		

[1] From Neter, J., et al., *Applied Linear Statistical Models*, Third Edition, Copyright (c) 1990, Richard D. Irwin. Reprinted with permission of The McGraw-Hill Companies.

Output 73.4.1 *continued*

Parameter Estimates

Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	1	33.83837	2.44065	13.86	<.0001
size	1	−0.10153	0.01305	−7.78	<.0001
type	1	8.13125	3.65405	2.23	0.0408
sizetype	1	−0.00041714	0.01833	−0.02	0.9821

The overall F statistic is significant (F=45.490, p<0.0001). The interaction term is not significant (t=−0.023, p=0.9821). Hence, this term should be removed and the model refitted, as shown in the following statements:

```
   delete sizetype;
   print;
run;
```

The DELETE statement removes the interaction term (sizetype) from the model. The new ANOVA and parameter estimates tables are shown in Output 73.4.2.

Output 73.4.2 ANOVA Table and Parameter Estimates

Analysis of Variance

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	2	1504.41333	752.20667	72.50	<.0001
Error	17	176.38667	10.37569		
Corrected Total	19	1680.80000			

Root MSE	3.22113	R-Square	0.8951
Dependent Mean	19.40000	Adj R-Sq	0.8827
Coeff Var	16.60377		

Parameter Estimates

Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	1	33.87407	1.81386	18.68	<.0001
size	1	−0.10174	0.00889	−11.44	<.0001
type	1	8.05547	1.45911	5.52	<.0001

The overall F statistic is still significant (F=72.497, p<0.0001). The intercept and the coefficients associated with size and type are significantly different from zero (t=18.675, p<0.0001; t=−11.443, p<0.0001; t=5.521, p<0.0001, respectively). Notice that the R^2 did not change with the omission of the interaction term.

The fitted model is

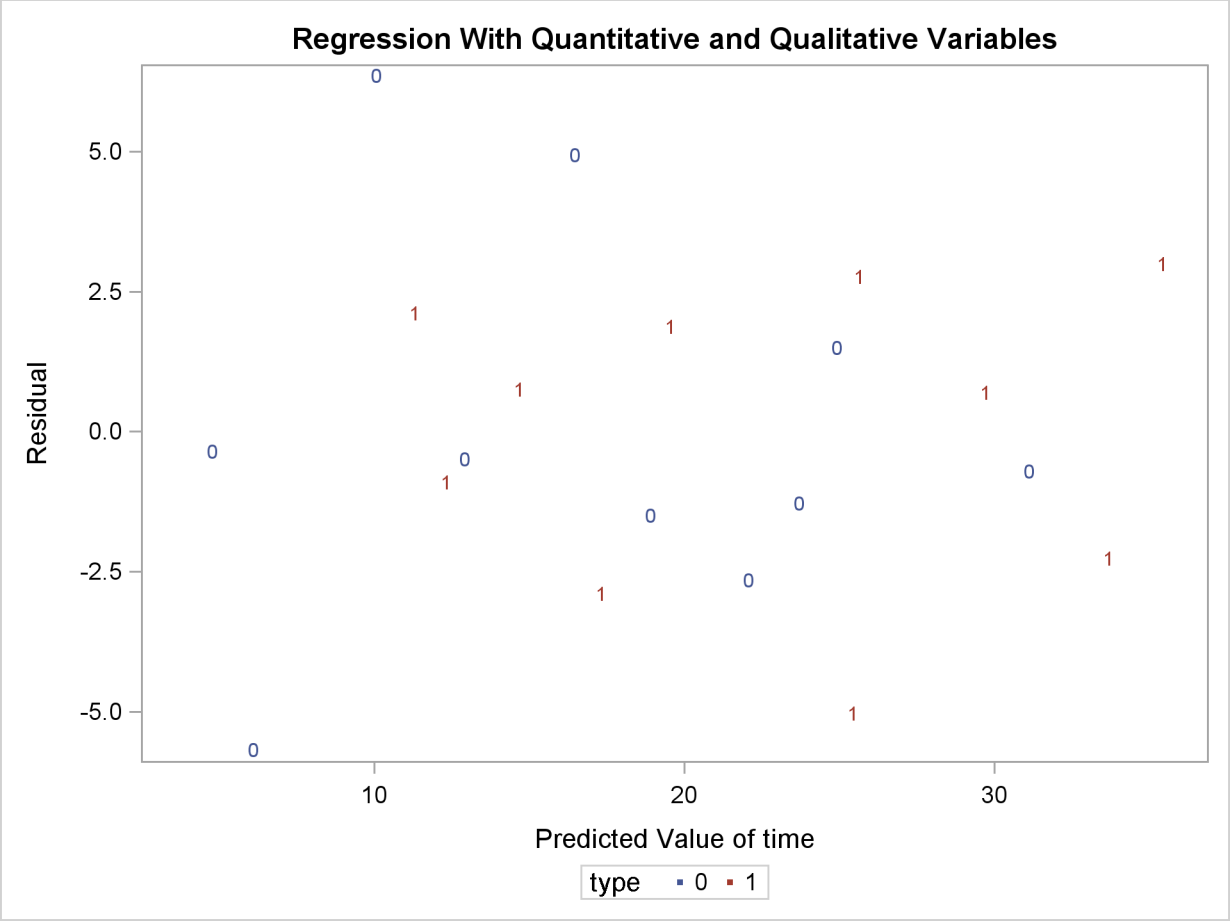
$$\text{time} = 33.87 - 0.102 \times \text{size} + 8.055 \times \text{type}$$

The fitted model for a mutual fund company ($X2_i = 0$) is

$$\text{time} = 33.87 - 0.102 \times \text{size}$$

and the fitted model for a stock company ($X2_i = 1$) is

$$\text{time} = (33.87 + 8.055) - 0.102 \times \text{size}$$



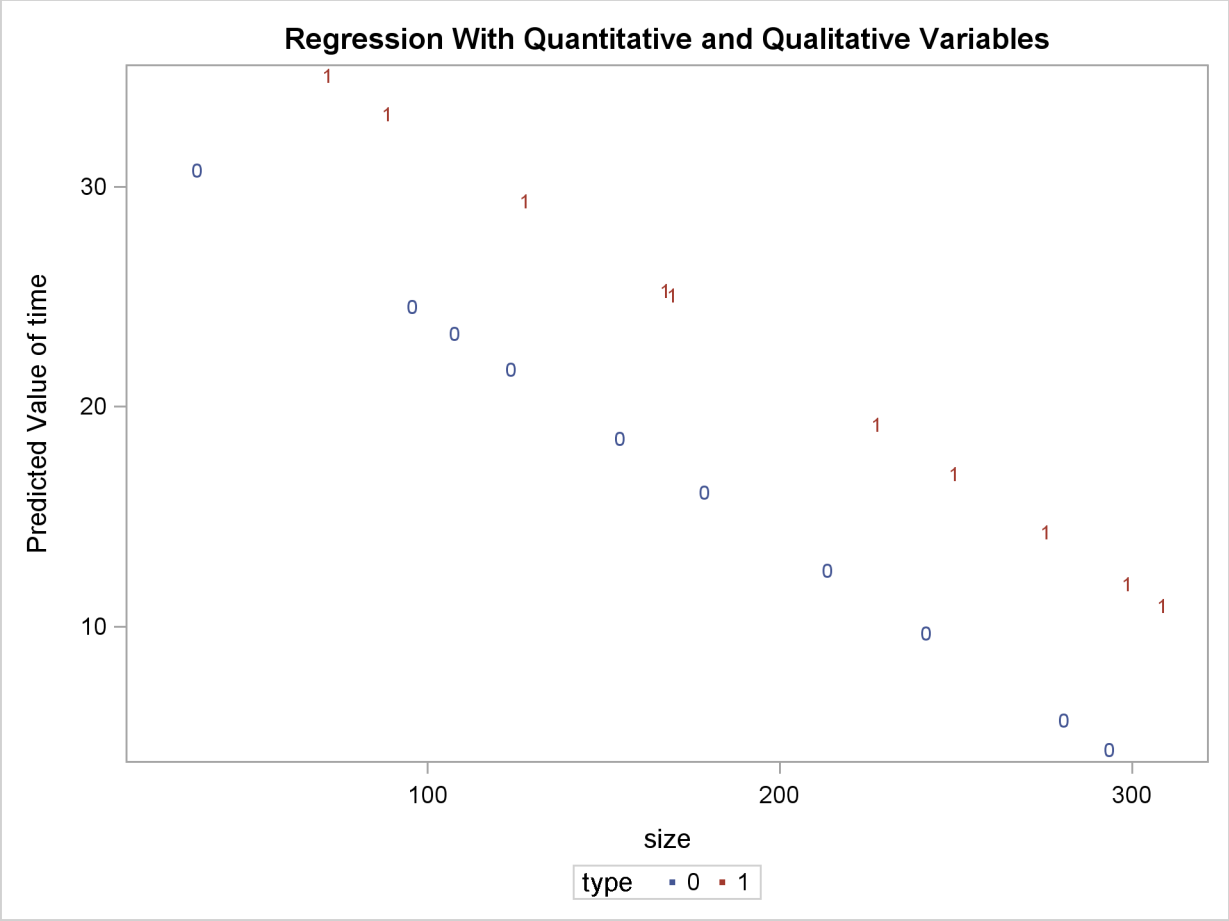
So the two models have different intercepts but the same slope.

The following statements first use an OUTPUT statement to save the residuals and predicted values from the new model in the OUT= data set. Next PROC SGPLOT is used to produce Output 73.4.3, which plots residuals versus predicted values. The firm type is used as the plot symbol; this can be useful in determining if the firm types have different residual patterns.

```
   output out=out r=r p=p;
run;

proc sgplot data=out;
  scatter x=p y=r / markerchar=type group=type;
run;
```

Output 73.4.3 Plot of Residual vs. Predicted Values



The residuals show no major trend. Neither firm type by itself shows a trend either. This indicates that the model is satisfactory.

The following statements produce the plot of the predicted values versus size that appears in Output 73.4.4, where the firm type is again used as the plotting symbol:

```
proc sgplot data=out;
  scatter x=size y=p / markerchar=type group=type;
run;
```

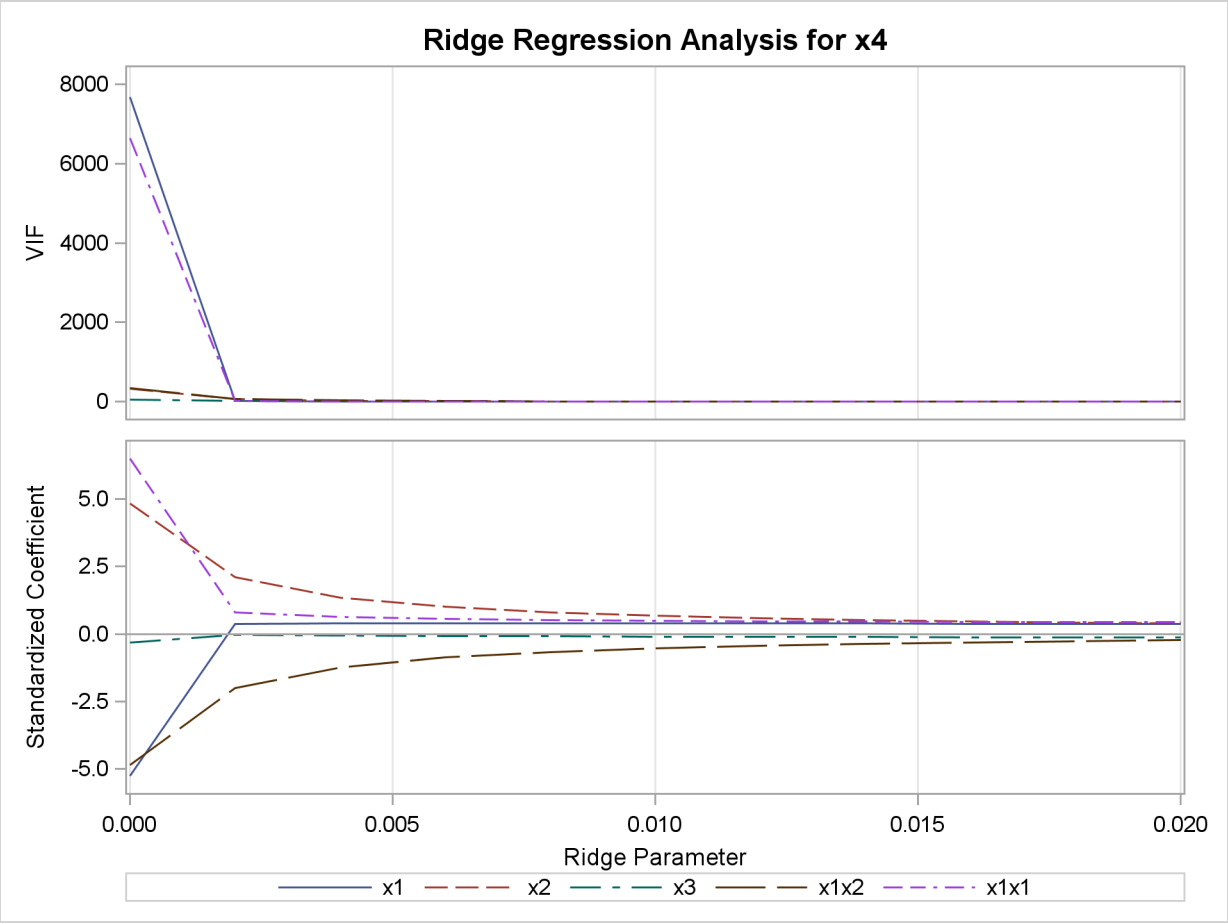
Output 73.4.4 Plot of Predicted vs. Size

The different intercepts are very evident in this plot.

Example 73.5: Ridge Regression for Acetylene Data

This example uses the acetylene data in Marquardt and Snee (1975) to illustrate the RIDGEPLOT and OUTVIF options. Here are the data:

```
data acetyl;
   input x1-x4 @@;
   x1x2 = x1 * x2;
   x1x1 = x1 * x1;
   label x1   = 'reactor temperature(celsius)'
         x2   = 'h2 to n-heptone ratio'
         x3   = 'contact time(sec)'
         x4   = 'conversion percentage'
         x1x2= 'temperature-ratio interaction'
         x1x1= 'squared temperature';
   datalines;
```



```
1300  7.5 .012 49   1300  9   .012  50.2 1300 11 .0115 50.5
1300 13.5 .013 48.5 1300 17   .0135 47.5 1300 23 .012  44.5
1200  5.3 .04  28   1200  7.5 .038  31.5 1200 11 .032  34.5
1200 13.5 .026 35   1200 17   .034  38   1200 23 .041  38.5
1100  5.3 .084 15   1100  7.5 .098  17   1100 11 .092  20.5
1100 17   .086 29.5
;

ods graphics on;

proc reg data=acetyl outvif
         outest=b ridge=0 to 0.02 by .002;
   model x4=x1 x2 x3 x1x2 x1x1;
run;
proc print data=b;
run;
```

When you enable ODS Graphics and you request ridge regression by using the RIDGE= option in the PROC REG statement, PROC REG produces a panel showing variance inflation factors (VIF) in the upper plot in the panel and ridge traces in the lower plot. This panel is shown in Output 73.5.1.

Output 73.5.1 Ridge Regression and VIF Traces

The OUTVIF option outputs the variance inflation factors to the OUTEST= data set that is shown in Output 73.5.2.

Output 73.5.2 OUTEST Data Set Showing VIF Values

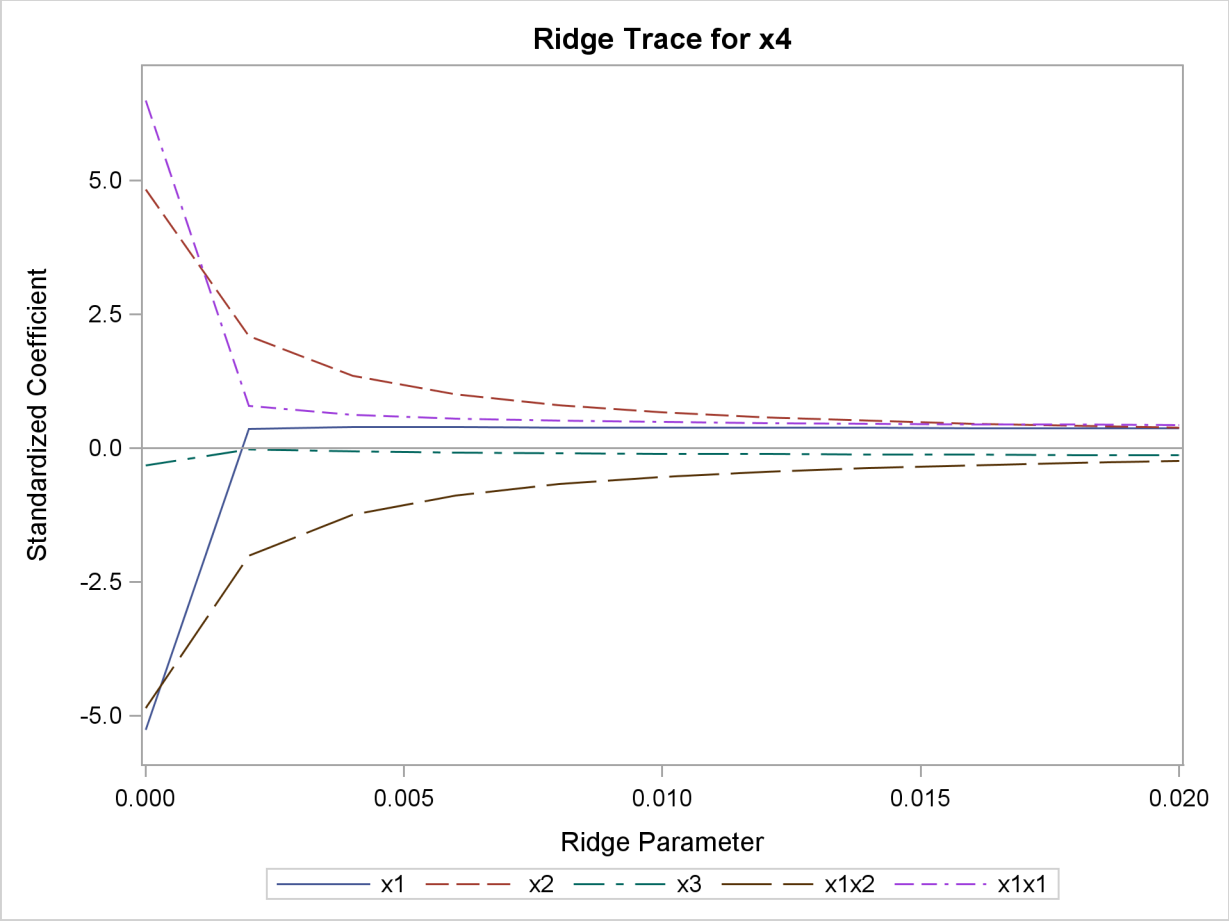
If you want to obtain separate plots containing the ridge traces and VIF traces, you can specify the UNPACK suboption in the PLOTS=RIDGE option. You can also request that one or both of the VIF axis and ridge parameter axis be displayed on a logarithmic scale. You can see in Output 73.5.1 that the VIF traces for several of the parameters are nearly indistinguishable when displayed on a linear scale. The following code illustrates how you obtain separate VIF and ridge traces with the VIF values displayed on a logarithmic scale. Note that you can obtain plots of VIF values even though you do not specify the OUTVIF option in the PROC REG statement.

```
proc reg data=acetyl plots(only)=ridge(unpack VIFaxis=log)
         outest=b ridge=0 to 0.02 by .002;
   model x4=x1 x2 x3 x1x2 x1x1;
run;



ods graphics off;
```

The requested plots are shown in Output 73.5.3 and Output 73.5.4.

Output 73.5.3 VIF Traces

Output 73.5.4 Ridge Traces

Example 73.6: Chemical Reaction Response

This example shows how you can use lack-of-fit tests with the REG procedure. See the section "Testing for Lack of Fit" on page 5576 for details about lack-of-fit tests.

In a study of the percentage of raw material that responds in a reaction, researchers identified the following five factors:

- the feed rate of the chemicals (FeedRate), ranging from 10 to 15 liters per minute
- the percentage of the catalyst (Catalyst), ranging from 1% to 2%
- the agitation rate of the reactor (AgitRate), ranging from 100 to 120 revolutions per minute
- the temperature (Temperature), ranging from 140 to 180 degrees Celsius
- the concentration (Concentration), ranging from 3% to 6%

The following data set contains the results of an experiment designed to estimate main effects for all factors:

```
data reaction;
  input FeedRate Catalyst AgitRate Temperature
        Concentration ReactionPercentage;
datalines;
10.0   1.0  100   140  6.0   37.5
10.0   1.0  120   180  3.0   28.5
10.0   2.0  100   180  3.0   40.4
10.0   2.0  120   140  6.0   48.2
15.0   1.0  100   180  6.0   50.7
15.0   1.0  120   140  3.0   28.9
15.0   2.0  100   140  3.0   43.5
15.0   2.0  120   180  6.0   64.5
12.5   1.5  110   160  4.5   39.0
12.5   1.5  110   160  4.5   40.3
12.5   1.5  110   160  4.5   38.7
12.5   1.5  110   160  4.5   39.7
;
```

The first eight runs of this experiment enable orthogonal estimation of the main effects for all factors. The last four comprise four replicates of the centerpoint.

The following statements fit a linear model. Because this experiment includes replications, you can test for lack of fit by using the LACKFIT option in the MODEL statement.

```
proc reg data=reaction;
   model  ReactionPercentage=FeedRate Catalyst AgitRate
                             Temperature Concentration / lackfit;
run;
```

Output 73.6.1 shows that the lack of fit for the linear model is significant, indicating that a more complex model is required. Models that include interactions should be investigated. In this case, this will require additional experimentation to obtain appropriate data for estimating the effects.

Output 73.6.1 Analysis of Variance

The REG Procedure
Model: MODEL1
Dependent Variable: ReactionPercentage

Overview: ROBUSTREG Procedure

The main purpose of robust regression is to detect outliers and provide resistant (stable) results in the presence of outliers. In order to achieve this stability, robust regression limits the influence of outliers. Historically, three classes of problems have been addressed with robust regression techniques:

- problems with outliers in the y-direction (response direction)
- problems with multivariate outliers in the x-space (i.e., outliers in the covariate space, which are also referred to as leverage points)
- problems with outliers in both the y-direction and the x-space

Many methods have been developed in response to these problems. However, in statistical applications of outlier detection and robust regression, the methods most commonly used today are Huber M estimation, high breakdown value estimation, and combinations of these two methods. The ROBUSTREG procedure in SAS 9.2 provides four such methods: M estimation, LTS estimation, S estimation, and MM estimation.

1. M estimation was introduced by Huber (1973), and it is the simplest approach both computationally and theoretically. Although it is not robust with respect to leverage points, it is still used extensively in analyzing data for which it can be assumed that the contamination is mainly in the response direction.
2. Least trimmed squares (LTS) estimation is a high breakdown value method introduced by Rousseeuw (1984). The breakdown value is a measure of the proportion of contamination that an estimation method can withstand and still maintain its robustness. The performance of this method was improved by the FAST-LTS algorithm of Rousseeuw and Van Driessen (2000).
3. S estimation is a high breakdown value method introduced by Rousseeuw and Yohai (1984). With the same breakdown value, it has a higher statistical efficiency than LTS estimation.
4. MM estimation, introduced by Yohai (1987), combines high breakdown value estimation and M estimation. It has both the high breakdown property and a higher statistical efficiency than S estimation.

Features

The main features of the ROBUSTREG procedure are as follows:

- offers four estimation methods: M, LTS, S, and MM

- provides 10 weight functions for M estimation
- provides robust R^2 and deviance for all estimates
- provides asymptotic covariance and confidence intervals for regression parameter with the M, S, and MM methods
- provides robust Wald and F tests for regression parameters with the M and MM methods
- provides outlier and leverage-point diagnostics
- supports parallel computing for S and LTS estimates
- produces fit plots and diagnostic plots by using ODS Graphics

Getting Started: ROBUSTREG Procedure

The following examples demonstrate how you can use the ROBUSTREG procedure to fit a linear regression model and obtain outlier and leverage-point diagnostics.

M Estimation

This example shows how you can use the ROBUSTREG procedure to do M estimation, which is a commonly used method for outlier detection and robust regression when contamination is mainly in the response direction.

```
data stack;
   input  x1 x2 x3 y exp$ @@;
datalines;
80  27   89  42   e1   80  27   88  37   e2
75  25   90  37   e3   62  24   87  28   e4
62  22   87  18   e5   62  23   87  18   e6
62  24   93  19   e7   62  24   93  20   e8
58  23   87  15   e9   58  18   80  14  e10
58  18   89  14  e11   58  17   88  13  e12
58  18   82  11  e13   58  19   93  12  e14

70  20   91  15  e21
;
```

The data set stack is the well-known stackloss data set presented by Brownlee (1965). The data describe the operation of a plant for the oxidation of ammonia to nitric acid and consist of 21 four-dimensional observations. The explanatory variables for the response stackloss (y) are the rate of operation (x1), the cooling water inlet temperature (x2), and the acid concentration (x3).

The following ROBUSTREG statements analyze the data:

```
proc robustreg data=stack;
   model y = x1 x2 x3 / diagnostics leverage;
   id    exp;
   test  x3;
run;
```

By default, the procedure does M estimation with the bisquare weight function, and it uses the median method for estimating the scale parameter. The MODEL statement specifies the covariate effects. The DIAGNOSTICS option requests a table for outlier diagnostics, and the LEVERAGE option adds leverage-point diagnostic results to this table for continuous covariate effects. The ID statement specifies that the variable exp is used to identify each observation (experiment) in this table. If the ID statement is omitted, the observation number is used to identify the observations. The TEST statement requests a test of significance for the covariate effects specified. The results of this analysis are displayed in the following figures.

Figure 74.1 Model Fitting Information and Summary Statistics

The ROBUSTREG Procedure

Model Information

Data Set	WORK.STACK
Dependent Variable	y
Number of Independent Variables	3
Number of Observations	21
Method	M Estimation

Summary Statistics

Variable	Q1	Median	Q3	Mean	Standard Deviation	MAD
x1	53.0000	58.0000	62.0000	60.4286	9.1683	5.9304
x2	18.0000	20.0000	24.0000	21.0952	3.1608	2.9652
x3	82.0000	87.0000	89.5000	86.2857	5.3586	4.4478
y	10.0000	15.0000	19.5000	17.5238	10.1716	5.9304

Figure 74.1 displays the model fitting information and summary statistics for the response variable and the continuous covariates. The columns labeled Q1, Median, and Q3 provide the lower quantile, median, and upper quantile, respectively. The column labeled MAD provides a robust estimate of the univariate scale, which is computed as the standardized median absolute deviation (MAD). See Huber (1981, p. 108) for more details about the standardized MAD. The columns labeled Mean and Standard Deviation provide the usual mean and standard deviation. A large difference between the standard deviation and the MAD for a variable indicates some extreme values for this variable. In the stackloss data, the stackloss (response y) has the biggest difference between the standard deviation and the MAD.

Figure 74.2 Model Parameter Estimates

Parameter Estimates

Parameter	DF	Estimate	Standard Error	95% Confidence Limits		Chi-Square	Pr > ChiSq
Intercept	1	-42.2854	9.5045	-60.9138	-23.6569	19.79	<.0001
x1	1	0.9276	0.1077	0.7164	1.1387	74.11	<.0001
x2	1	0.6507	0.2940	0.0744	1.2270	4.90	0.0269
x3	1	-0.1123	0.1249	-0.3571	0.1324	0.81	0.3683
Scale	1	2.2819					

Figure 74.2 displays the table of robust parameter estimates, standard errors, and confidence limits. The row labeled Scale provides a point estimate of the scale parameter in the linear regression model, which is obtained by the median method. See the section "M Estimation" on page 5672 for more information about scale estimation methods. For the stackloss data, M estimation yields the fitted linear model:

$$\hat{y} = -42.2845 + 0.9276\text{x1} + 0.6507\text{x2} - 0.1123\text{x3}$$

Figure 74.3 Diagnostics

Diagnostics

Obs	exp	Mahalanobis Distance	Robust MCD Distance	Leverage	Standardized Robust Residual	Outlier
1	e1	2.2536	5.5284	*	1.0995	
2	e2	2.3247	5.6374	*	-1.1409	
3	e3	1.5937	4.1972	*	1.5604	
4	e4	1.2719	1.5887		3.0381	*
21	e21	2.1768	3.6573	*	-4.5733	*

Figure 74.3 displays outlier and leverage-point diagnostics. Standardized robust residuals are computed based on the estimated parameters. Both the Mahalanobis distance and the robust MCD distance are displayed. Outliers and leverage points, identified with asterisks, are defined by the standardized robust residuals and robust MCD distances that exceed the corresponding cutoff values displayed in the diagnostics summary. Observations 4 and 21 are outliers because their standardized robust residuals exceed the cutoff value in absolute value. The procedure detects 4 observations with high leverage. Leverage points (points with high leverage) with smaller standardized robust residuals than the cutoff value in absolute value are called good leverage points; others are called bad leverage points. Observation 21 is a bad leverage point.

Two particularly useful plots for revealing outliers and leverage points are a scatter plot of the standardized robust residuals against the robust distances (RDPLOT) and a scatter plot of the robust distances against the classical Mahalanobis distances (DDPLOT).

For the stackloss data, the following statements produce the RDPLOT in Figure 74.4 and the DDPLOT in Figure 74.5. The histogram and the normal quantile-quantile plots for the standardized robust residuals are also created with the HISTOGRAM and QQPLOT options in the PROC ROBUSTREG statement. See Figure 74.6 and Figure 74.7.

```
ods graphics on;

proc robustreg data=stack
        plots=(rdplot ddplot reshistogram resqqplot);
   model y = x1 x2 x3;
run;

ods graphics off;
```

Figure 74.4 RDPLOT for Stackloss Data

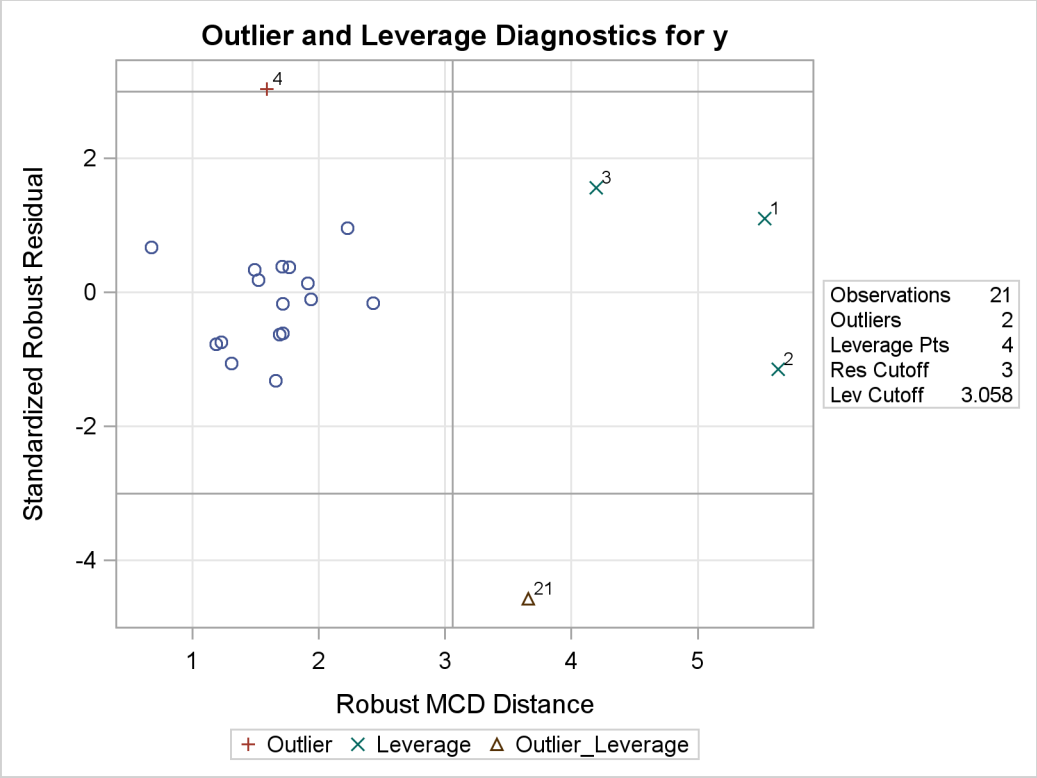

Figure 74.5 DDPLOT for Stackloss Data

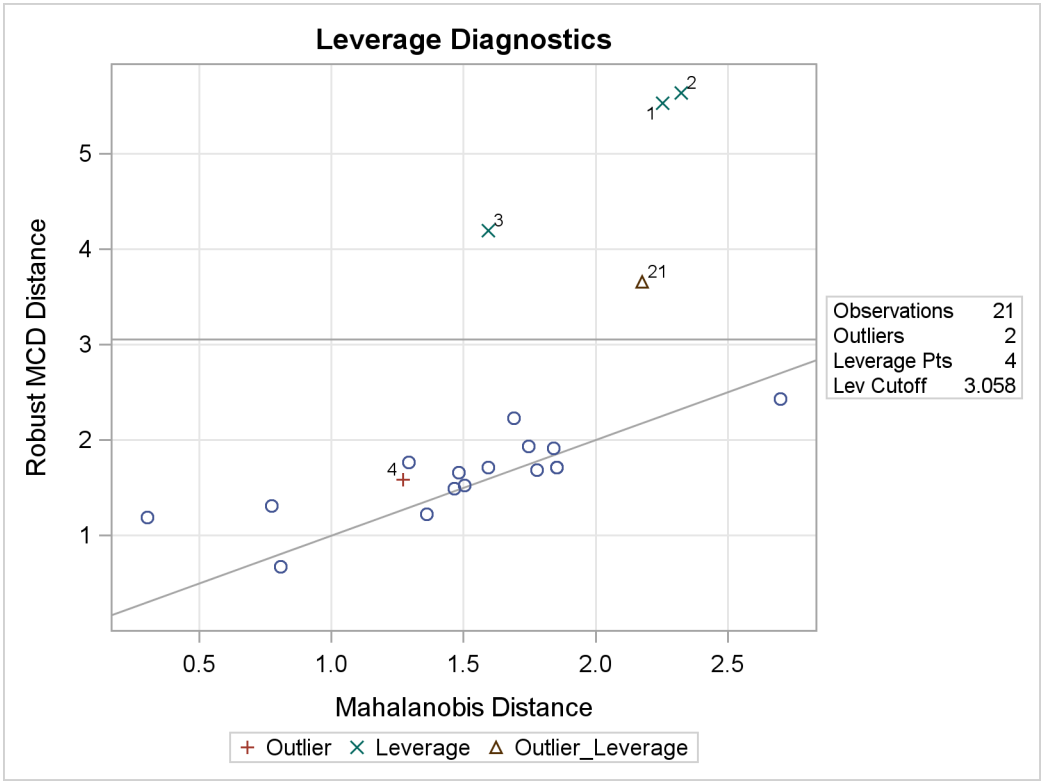

Figure 74.6 Histogram

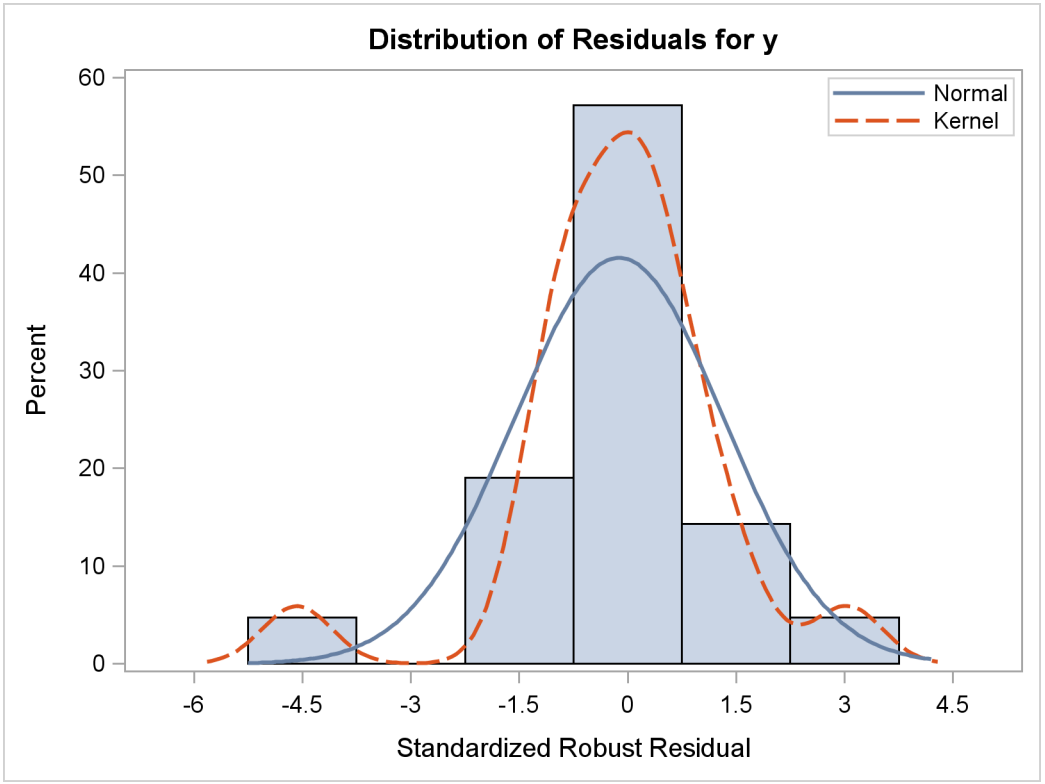

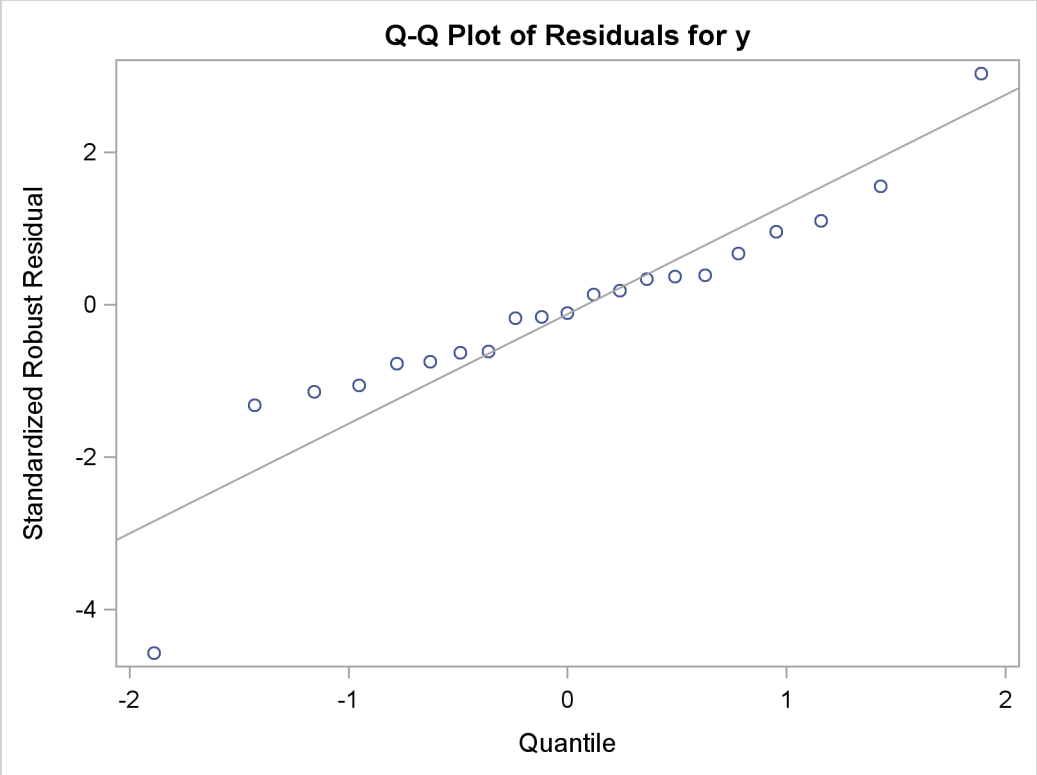

Figure 74.7 Q-Q Plot

These plots are helpful in identifying outliers as well as good and bad high leverage points.

These graphical displays are requested by specifying the ODS GRAPHICS statement and the PLOTS= option in the PROC statement. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." For specific information about the graphics available in the ROBUSTREG procedure, see the section "ODS Graphics" on page 5692.

Figure 74.8 Goodness-of-Fit Statistics

Goodness-of-Fit

Statistic	Value
R-Square	0.6659
AICR	29.5231
BICR	36.3361
Deviance	125.7905

Figure 74.8 displays robust versions of goodness-of-fit statistics for the model. You can use the robust information criteria, AICR and BICR, for model selection and comparison. For both AICR and BICR, the lower the value, the more desirable the model.

Figure 74.9 Test of Significance

Robust Linear Tests

Test

Test	Test Statistic	Lambda	DF	Chi-Square	Pr > ChiSq
Rho	0.9378	0.7977	1	1.18	0.2782
Rn2	0.8092		1	0.81	0.3683

Figure 74.9 displays the test results requested by the TEST statement. The ROBUSTREG procedure conducts two robust linear tests, the ρ test and the R_n^2 test. See the section "Linear Tests" on page 5678 for information about how the procedure computes test statistics and the correction factor lambda. Due to the large p-values for both tests, you can conclude that the effect x3 is not significant at the 5% level.

For the bisquare weight function, the default tuning constant, $c = 4.685$, is chosen to yield a 95% asymptotic efficiency of the M estimates with the Gaussian distribution. See the section "M Estimation" on page 5672 for details. The smaller the constant c, the lower the asymptotic efficiency but the sharper the M estimate as an outlier detector. For the stackloss data set, you could consider using a sharper outlier detector.

In the following invocation of the ROBUSTREG procedure, a smaller constant, $c = 3.5$, is used. This tuning constant corresponds to an efficiency close to 85%. See Chen and Yin (2002) for relations between the tuning constant and asymptotic efficiency of M estimates.

```
proc robustreg method=m(wf=bisquare(c=3.5)) data=stack;
   model y = x1 x2 x3 / diagnostics leverage;
   id    exp;
   test  x3;
run;
```

Figure 74.10 Model Parameter Estimates

The ROBUSTREG Procedure

Parameter Estimates

Parameter	DF	Estimate	Standard Error	95% Confidence Limits		Chi-Square	Pr > ChiSq
Intercept	1	-37.1076	5.4731	-47.8346	-26.3805	45.97	<.0001
x1	1	0.8191	0.0620	0.6975	0.9407	174.28	<.0001
x2	1	0.5173	0.1693	0.1855	0.8492	9.33	0.0022
x3	1	-0.0728	0.0719	-0.2138	0.0681	1.03	0.3111
Scale	1	1.4265					

Figure 74.10 displays the table of robust parameter estimates, standard errors, and confidence limits with the constant $c = 3.5$.

The refitted linear model is

$$\hat{y} = -37.1076 + 0.8191x1 + 0.5173x2 - 0.0728x3$$

1	e1	2.2536	5.5284	*	4.2719	*
2	e2	2.3247	5.6374	*	0.7158	
3	e3	1.5937	4.1972	*	4.4142	*
4	e4	1.2719	1.5887		5.7792	*
21	e21	2.1768	3.6573	*	-6.2727	*

Figure 74.11 displays outlier and leverage-point diagnostics with the constant $c = 3.5$. Besides observations 4 and 21, observations 1 and 3 are also detected as outliers.

LTS Estimation

If the data are contaminated in the x-space, M estimation does not do well. The following example shows how you can use LTS estimation to deal with this situation.

```
data hbk;
   input index$ x1 x2 x3 y @@;
datalines;
1   10.1  19.6  28.3   9.7     39  2.1  0.0  1.2  -0.7
2    9.5  20.5  28.9  10.1     40  0.5  2.0  1.2  -0.5
3   10.7  20.2  31.0  10.3     41  3.4  1.6  2.9  -0.1
4    9.9  21.5  31.7   9.5     42  0.3  1.0  2.7  -0.7

38   1.5   1.2   0.2   0.9
;
```

The data set hbk is an artificial data set generated by Hawkins, Bradu, and Kass (1984). Both ordinary least squares (OLS) estimation and M estimation (not shown here) suggest that observations 11 to 14 are outliers. However, these four observations were generated from the underlying model, whereas observations 1 to 10 were contaminated. The reason that OLS estimation and M estimation do not pick up the contaminated observations is that they cannot distinguish good leverage points (observations 11 to 14) from bad leverage points (observations 1 to 10). In such cases, the LTS method identifies the true outliers.

The following statements invoke the ROBUSTREG procedure with the LTS estimation method:

```
proc robustreg data=hbk fwls method=lts;
   model y = x1 x2 x3 / diagnostics leverage;
   id index;
run;
```

Figure 74.12 Model Fitting Information and Summary Statistics

The ROBUSTREG Procedure

Model Information

Data Set	WORK.HBK
Dependent Variable	y
Number of Independent Variables	3
Number of Observations	75
Method	LTS Estimation

Figure 74.12 *continued*

Summary Statistics

Variable	Q1	Median	Q3	Mean	Standard Deviation	MAD
x1	0.8000	1.8000	3.1000	3.2067	3.6526	1.9274
x2	1.0000	2.2000	3.3000	5.5973	8.2391	1.6309
x3	0.9000	2.1000	3.0000	7.2307	11.7403	1.7791
y	−0.5000	0.1000	0.7000	1.2787	3.4928	0.8896

Figure 74.12 displays the model fitting information and summary statistics for the response variable and independent covariates.

Figure 74.13 LTS Profile

LTS Profile

Total Number of Observations	75
Number of Squares Minimized	57
Number of Coefficients	4
Highest Possible Breakdown Value	0.2533

Figure 74.13 displays information about the LTS fit, which includes the breakdown value of the LTS estimate. The breakdown value is a measure of the proportion of contamination that an estimation method can withstand and still maintain its robustness. In this example the LTS estimate minimizes the sum of 57 smallest squares of residuals. It can still estimate the true underlying model if the remaining 18 observations are contaminated. This corresponds to the breakdown value around 0.25, which is set as the default.

Figure 74.14 LTS Parameter Estimates

LTS Parameter Estimates

Parameter	DF	Estimate
Intercept	1	−0.3431
x1	1	0.0901
x2	1	0.0703
x3	1	−0.0731
Scale (sLTS)	0	0.7451
Scale (Wscale)	0	0.5749

Figure 74.14 displays parameter estimates for covariates and scale. Two robust estimates of the scale parameter are displayed. See the section "Final Weighted Scale Estimator" on page 5681 for how these estimates are computed. The weighted scale estimator (Wscale) is a more efficient estimator of the scale parameter.

Figure 74.15 Diagnostics

Diagnostics

Obs	index	Mahalanobis Distance	Robust MCD Distance	Leverage	Standardized Robust Residual	Outlier
1	1	1.9168	29.4424	*	17.0868	*
3	2	1.8558	30.2054	*	17.8428	*
5	3	2.3137	31.8909	*	18.3063	*
7	4	2.2297	32.8621	*	16.9702	*
9	5	2.1001	32.2778	*	17.7498	*
11	6	2.1462	30.5892	*	17.5155	*
13	7	2.0105	30.6807	*	18.8801	*
15	8	1.9193	29.7994	*	18.2253	*
17	9	2.2212	31.9537	*	17.1843	*
19	10	2.3335	30.9429	*	17.8021	*
21	11	2.4465	36.6384	*	0.0406	
23	12	3.1083	37.9552	*	−0.0874	
25	13	2.6624	36.9175	*	1.0776	
27	14	6.3816	41.0914	*	−0.7875	

Figure 74.15 displays outlier and leverage-point diagnostics. The ID variable index is used to identify the observations. If you do not specify this ID variable, the observation number is used to identify the observations. However, the observation number depends on how the data are read. The first 10 observations are identified as outliers, and observations 11 to 14 are identified as good leverage points.

Figure 74.16 Final Weighted LS Estimates

Parameter Estimates for Final Weighted Least Squares Fit

Parameter	DF	Estimate	Standard Error	95% Confidence Limits		Chi-Square	Pr > ChiSq
Intercept	1	−0.1805	0.1044	−0.3852	0.0242	2.99	0.0840
x1	1	0.0814	0.0667	−0.0493	0.2120	1.49	0.2222
x2	1	0.0399	0.0405	−0.0394	0.1192	0.97	0.3242
x3	1	−0.0517	0.0354	−0.1210	0.0177	2.13	0.1441
Scale	0	0.5572					

Figure 74.16 displays the final weighted least squares estimates. These estimates are least squares estimates computed after deleting the detected outliers.

Syntax: ROBUSTREG Procedure

The following statements are available in PROC ROBUSTREG:

PROC ROBUSTREG < *options* > **;**
BY *variables* **;**
CLASS *variables* **;**
ID *variables* **;**
MODEL *response*=< *effects* > < / *options* > **;**
OUTPUT < *OUT=SAS-data-set* > < *options* > **;**
PERFORMANCE < *options* > **;**
TEST *effects* **;**
WEIGHT *variable* **;**

The PROC ROBUSTREG statement invokes the procedure. The METHOD= option in the PROC ROBUSTREG statement selects one of the four estimation methods, M, LTS, S, and MM. By default, Huber M estimation is used. The MODEL statement is required and specifies the variables used in the regression. Main effects and interaction terms can be specified in the MODEL statement, as in the GLM procedure (Chapter 39, "The GLM Procedure.") The CLASS statement specifies which explanatory variables are treated as categorical. These variables are allowed in the MODEL statement only for M estimation and not for other estimation methods. The ID statement names variables to identify observations in the outlier diagnostics tables. The WEIGHT statement identifies a variable in the input data set whose values are used to weight the observations. The OUTPUT statement creates an output data set containing final weights, predicted values, and residuals. The TEST statement requests robust linear tests for the model parameters. The PERFORMANCE statement tunes the performance of the procedure by using single or multiple processors available on the hardware. In one invocation of PROC ROBUSTREG, multiple OUTPUT and TEST statements are allowed.

PROC ROBUSTREG Statement

PROC ROBUSTREG < *options* > **;**

The PROC ROBUSTREG statement invokes the procedure. You can specify the following options in the PROC ROBUSTREG statement.

COVOUT
saves the estimated covariance matrix in the OUTEST= data set. This option is not supported for LTS estimation.

DATA=*SAS-data-set*
specifies the input SAS data set used by PROC ROBUSTREG. By default, the most recently created SAS data set is used.

FWLS

requests that final weighted least squares estimates be computed. These estimates are equivalent to the least squares estimates after the detected outliers are deleted.

INEST=*SAS-data-set*

specifies an input SAS data set that contains initial estimates for all the parameters in the model. See the section "INEST= Data Set" on page 5689 for a detailed description of the contents of the INEST= data set.

ITPRINT

displays the iteration history for the iteratively reweighted least squares algorithm used by M and MM estimation. You can also use this option in the MODEL statement.

NAMELEN=*n*

specifies the length of effect names in tables and output data sets to be *n* characters, where *n* is a value between 20 and 200. The default length is 20 characters.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sorting order for the levels of the classification variables (specified in the CLASS statement). This ordering determines which parameters in the model correspond to each level in the data. The following table explains how PROC ROBUSTREG interprets values of the ORDER= option.

Table 74.1 Options for Order

Value of ORDER=	Levels Sorted By
DATA	order of appearance in the input data set
FORMATTED	formatted value
FREQ	descending frequency count; levels with the most observations come first in the order
INTERNAL	unformatted value

By default, ORDER=FORMATTED. For FORMATTED and INTERNAL, the sort order is machine dependent. For more information about sorting order, refer to the chapter titled "The SORT Procedure" in the *Base SAS Procedures Guide*.

OUTEST=*SAS-data-set*

specifies an output SAS data set containing the parameter estimates, and, if the COVOUT option is specified, the estimated covariance matrix. See the section "OUTEST= Data Set" on page 5690 for a detailed description of the contents of the OUTEST= data set.

PLOT | PLOTS <(*global-plot-options***)> <=***plot-request***>**

PLOT | PLOTS<(*global-plot-options***)> <=(***plot-request* **<...***plot-request***>)>**

specifies options that control details of the plots. If you have enabled ODS GRAPHICS but do not specify the PLOTS= option, then PROC ROBUSTREG produces the robust fit plot by default when the model includes a single continuous independent variable.

The *global-plot-options* apply to all plots generated by the ROBUSTREG procedure. The following global plot option is available:

ONLY
suppresses the default robust fit plot. Only plots specifically requested are displayed.

You can specify more than one plot request within the parentheses after PLOTS=. For a single plot request, you can omit the parentheses. The following plot requests are available.

ALL
creates all appropriate plots.

DDPLOT<(LABEL=ALL | LEVERAGE | NONE | OUTLIER)>
creates a plot of robust distance against Mahalanobis distance. See the section "Leverage Point and Outlier Detection" on page 5689 for details about robust distance. The LABEL= option specifies how the points on this plot are to be labeled, as summarized by the following table.

Table 74.2 Options for Label

Value of LABEL=	Label Method
ALL	label all points
LEVERAGE	label leverage points
NONE	no labels
OUTLIERS	label outliers

By default, the ROBUSTREG procedure labels both outliers and leverage points.

If you specify ID variables in the ID statement, the values of the first ID variable are used as labels; otherwise, observation numbers are used as labels.

FITPLOT<(NOLIMITS)>
creates a plot of robust fit against the single independent continuous variable specified in the model. You can request this plot when only a single independent continuous variable is specified in the model. Confidence limits are added on the plot by default. The NOLIMITS option suppresses these limits.

HISTOGRAM
creates a histogram for the standardized robust residuals. The histogram is superimposed with a normal density curve and a kernel density curve.

NONE
suppresses all plots.

QQPLOT
creates the normal quantile-quantile plot for the standardized robust residuals.

RDPLOT<(LABEL=ALL | LEVERAGE | NONE | OUTLIER)>
creates the plot of standardized robust residual against robust distance. See the section "Leverage Point and Outlier Detection" on page 5689 for details about robust distance. The LABEL= option specifies a label method for points on this plot. These label methods are described in Table 74.2.

If you specify ID variables in the ID statement, the values of the first ID variable are used as labels; otherwise, observation numbers are used as labels.

SEED=*number*

specifies the seed for the random number generator used to randomly select the subgroups and subsets for LTS and S estimation. By default or if you specify zero, the ROBUSTREG procedure generates a random seed.

METHOD=*method type* **<(** *options* **)>**

specifies the estimation method and *options* specify some additional options for the estimation method. PROC ROBUSTREG provides four estimation methods: M estimation, LTS estimation, S estimation, and MM estimation. The default method is M estimation.

NOTE: Since the LTS and S methods use subsampling algorithms, these methods are not suitable in an analysis with categorical independent variables specified in the CLASS statement. These methods are not suitable in an analysis with continuous independent variables that have only a few unequal values or a few unequal values within one BY group. This also applies to the initial LTS and S estimates in the MM method. In summary, if the model includes categorical independent variables or continuous independent variables with a few unequal values, the M method is recommended.

Options with METHOD=M

With METHOD=M, you can specify the following additional *options*:

ASYMPCOV=*H1* | *H2* | *H3*

specifies the type of asymptotic covariance computed for the M estimate. The three types are described in the section "Asymptotic Covariance and Confidence Intervals" on page 5677. By default, ASYMPCOV= H1.

CONVERGENCE=*criterion***<(EPS=***value***)>**

specifies a convergence criterion for the M estimate. The three criteria listed in the following table are available.

Table 74.3 Options to Specify Convergence Criteria

Type	Option
coefficient	CONVERGENCE=COEF
residual	CONVERGENCE=RESID
weight	CONVERGENCE=WEIGHT

By default, CONVERGENCE = COEF. You can specify the precision of the convergence criterion with the EPS= option. By default, EPS=1.E−8.

MAXITER=*n*

sets the maximum number of iterations during the parameter estimation. By default, MAXITER=1000.

SCALE=*scale type | value*

specifies the scale parameter or a method for estimating the scale parameter. These methods and options are summarized in the following table.

Table 74.4 Options to Specify Scale

Scale	Option	Default d
Fixed constant	SCALE=*value*	
Huber estimate	SCALE=HUBER<(D=d)>	2.5
Median estimate	SCALE=MED	
Tukey estimate	SCALE=TUKEY<(D=d)>	2.5

By default, SCALE = MED.

WF | WEIGHTFUNCTION=*function type*

specifies the weight function used for the M estimate. The ROBUSTREG procedure provides 10 weight functions, which are listed in the following table. You can specify the parameters in these functions with the A=, B=, and C= options. These functions are described in the section "M Estimation" on page 5672. The default weight function is bisquare.

Table 74.5 Options to Specify Weight Functions

Weight Function	Option	Default a, b, c
andrews	WF=ANDREWS<(C=c)>	1.339
bisquare	WF=BISQUARE<(C=c)>	4.685
cauchy	WF=CAUCHY<(C=c)>	2.385
fair	WF=FAIR<(C=c)>	1.4
hampel	WF=HAMPEL<(<A=a> <B=b> <C=c>)>	2, 4, 8
huber	WF=HUBER<(C=c)>	1.345
logistic	WF=LOGISTIC<(C=c)>	1.205
median	WF=MEDIAN<(C=c)>	0.01
talworth	WF=TALWORTH<(C=c)>	2.795
welsch	WF=WELSCH<(C=c)>	2.985

Options with METHOD=LTS

With METHOD=LTS, you can specify the following additional *options*:

CSTEP=*n*

specifies the number of C-steps for the LTS estimate. See the section "LTS Estimate" on page 5679 for how the default value is determined.

IADJUST=ALL | NONE

requests (IADJUST=ALL) or suppresses (IADJUST=NONE) the intercept adjustment for all estimates in the LTS algorithm. By default, the intercept adjustment is used for data sets with less than 10000 observations. See the section "Algorithm" on page 5680 for details.

H=*n*

specifies the quantile for the LTS estimate. See the section "LTS Estimate" on page 5679 for how the default value is determined.

NBEST=*n*

specifies the number of best solutions kept for each subgroup during the computation of the LTS estimate. The default number is 10, which is the maximum number allowed.

NREP=*n*

specifies the number of repeats of least squares fit in subgroups during the computation of the LTS estimate. See the section "LTS Estimate" on page 5679 for how the default number is determined.

SUBANALYSIS

requests a display of the subgrouping information and parameter estimates within subgroups. This option generates the following ODS tables.

Table 74.6 ODS Tables Available with SUBANALYSIS Option

ODS Table Name	Description
BestEstimates	Best final estimates for LTS
BestSubEstimates	Best estimates for each subgroup
CStep	C-step information for LTS
Groups	Grouping information for LTS

SUBGROUPSIZE=*n*

specifies the data set size of the subgroups in the computation of the LTS estimate. The default number is 300.

Options with METHOD=S

With METHOD=S, you can specify the following additional *options*:

ASYMPCOV=*H1* | *H2* | *H3* | *H4*

specifies the type of asymptotic covariance computed for the S estimate. The four types are described in the section "Asymptotic Covariance and Confidence Intervals" on page 5684. By default, ASYMPCOV= H4.

CHIF= TUKEY | YOHAI

specifies the χ function for the S estimate. PROC ROBUSTREG provides two χ functions, Tukey's bisquare function and Yohai's optimal function, which you can request with CHIF=TUKEY and CHIF=YOHAI, respectively. The default is Tukey's bisquare function.

EFF=*value*

specifies the efficiency (as a fraction) for the S estimate. The parameter k_0 in the χ function is determined by this efficiency. The default efficiency is determined such that

the consistent S estimate has the breakdown value of 25%. This option is overwritten by the K0= option if both of them are used.

K0=*value*
specifies the $k0$ parameter in the χ function of the S estimate. For CHIF=TUKEY, the default is 1.548. For CHIF=YOHAI, the default is 0.66. These default values correspond to a 50% breakdown value of the consistent S estimate.

MAXITER=*n*
sets the maximum number of iterations for computing the scale parameter of the S estimate. By default, MAXITER=1000.

NREP=*n*
specifies the number of repeats of subsampling in the computation of the S estimate. See the section "Algorithm" on page 5682 for how the default number of repeats is determined.

NOREFINE
suppresses the refinement for the S estimate. See the section "Algorithm" on page 5682 for details.

SUBSETSIZE=*n*
specifies the size of the subset for the S estimate. See the section "Algorithm" on page 5682 for how its default value is determined.

TOLERANCE=*value*
specifies the tolerance for the S estimate of the scale. The default value is 0.001.

Options with METHOD=MM

With METHOD=MM, you can specify the following additional *options*:

ASYMPCOV=*H1* | *H2* | *H3* | *H4*
specifies the type of asymptotic covariance computed for the MM estimate. The four types are described in the section "Details: ROBUSTREG Procedure" on page 5672. By default, ASYMPCOV= H4.

BIASTEST< (ALPHA=*number***) >**
requests the bias test for the final MM estimate. See the section "Bias Test" on page 5686 for details about this test.

CHIF= TUKEY | YOHAI
selects the χ function for the MM estimate. PROC ROBUSTREG provides two χ functions: Tukey's bisquare function and Yohai's optimal function, which you can request with CHIF=TUKEY and CHIF=YOHAI, respectively. The default is Tukey's bisquare function. This χ function is also used by the initial S estimate if you specify the INITEST=S option.

CONVERGENCE=*criterion***<(EPS=***number***)>**

specifies a convergence criterion for the MM estimate. The three criteria listed in the following table are available.

Table 74.7 Options to Specify Convergence Criteria

Type	Option
coefficient	CONVERGENCE=COEF
residual	CONVERGENCE=RESID
weight	CONVERGENCE=WEIGHT

By default, CONVERGENCE = COEF. You can specify the precision of the convergence criterion with the EPS= option. By default, EPS=1.E−8.

EFF=*value*

specifies the efficiency (as a fraction) for the MM estimate. The parameter k_1 in the χ function is determined by this efficiency. The default efficiency is set to 0.85, which corresponds to $k_1 = 3.440$ for CHIF=TUKEY or $k_1 = 0.868$ for CHIF=YOHAI.

INITH=*n*

specifies the integer h for the initial LTS estimate used by the MM estimator. See the section "Algorithm" on page 5686 for how to specify h and how the default is determined.

INITEST=LTS | S

specifies the initial estimator for the MM estimator. By default, the LTS estimator with its default settings is used as the initial estimator for the MM estimator.

K0=*number*

specifies the parameter k_0 in the χ function for the MM estimate. For CHIF=TUKEY, the default is $k_0 = 2.9366$. For CHIF=YOHAI, the default is $k_0 = 0.7405$. These default values correspond to the 25% breakdown value of the MM estimator.

MAXITER=*n*

sets the maximum number of iterations during the parameter estimation. By default, MAXITER=1000.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC ROBUSTREG to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the ROBUSTREG procedure. The NOTSORTED option does not mean that the data are unsorted, but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variables* **;**

Explanatory variables that are classification variables rather than quantitative numeric variables must be listed in the CLASS statement. For each explanatory variable listed in the CLASS statement, indicator variables are generated for the levels assumed by the CLASS variable. If the CLASS statement is used, it must appear before the MODEL statement.

ID Statement

ID *variables* **;**

When the diagnostics table is requested with the DIAGNOSTICS option in the MODEL statement, the variables listed in the ID statement are displayed in addition to the observation number. These variables can be used to identify each observation. If the ID statement is omitted, the observation number is used to identify the observations.

MODEL Statement

<label:> **MODEL** *response = < effects > < / options >* **;**

Main effects and interaction terms can be specified in the MODEL statement, as in the GLM procedure (Chapter 39, "The GLM Procedure.") Classification variables are not allowed in the MODEL statement when you specify MM estimation or LTS estimation by using the METHOD= option in the PROC statement.

The optional *label*, which must be a valid SAS name, is used to label the model in the OUTEST data set.

You can specify the following options for the model fit.

ALPHA=*value*
specifies the significance level for the confidence intervals for regression parameters. The value must be between 0 and 1. By default, ALPHA=0.05.

CORRB
produces the estimated correlation matrix of the parameter estimates.

COVB
produces the estimated covariance matrix of the parameter estimates.

CUTOFF=*value*
specifies the multiplier of the cutoff value for outlier detection. By default, CUTOFF=3.

DIAGNOSTICS<(ALL)>
requests the outlier diagnostics. By default, only observations identified as outliers or leverage points are displayed. To request that all observations be displayed, specify the ALL option.

ITPRINT
displays the iteration history for the iteratively reweighted least squares algorithm used by M and MM estimation. You can also use this option in the PROC statement.

LEVERAGE<(<CUTOFF=*value* | **CUTOFFALPHA=***value***> <QUANTILE=***n***>)>**

requests an analysis of leverage points for the continuous covariates. The results are added to the diagnostics table, which you can request with the DIAGNOSTICS option in the MODEL statement. You can specify the cutoff value for leverage-point detection with the CUTOFF= option. The default cutoff value is $\sqrt{\chi^2_{p;1-\alpha}}$, where α can be specified with the CUTOFFALPHA= option. By default, $\alpha = 0.025$. You can use the QUANTILE= option to specify the quantile to be minimized for the MCD algorithm used for the leverage-point analysis. By default, QUANTILE=$[(3n + p + 1)/4]$, where n is the number of observations and p is the number of independent variables. The LEVERAGE option is ignored if the model includes classification variables as covariates.

Since the MCD algorithm uses subsampling, it is not suitable to apply the leverage-point analysis to continuous variables that have only a few nonzero values or a few nonzero values within one BY group.

NOGOODFIT
suppresses the computation of goodness-of-fit statistics.

NOINT
specifies no-intercept regression.

SINGULAR=*value*
specifies the tolerance for testing singularity of the information matrix and the crossproducts matrix for the initial least squares estimates. Roughly, the test requires that a pivot be at least this value times the original diagonal value. By default, SINGULAR=1.E−12.

OUTPUT Statement

OUTPUT < *OUT=SAS-data-set* > *keyword=name* < . . . *keyword=name* > **;**

The OUTPUT statement creates an output SAS data set containing statistics calculated after fitting the model. At least one specification of the form *keyword=name* is required.

All variables in the original data set are included in the new data set, along with the variables created with *keyword* options in the OUTPUT statement. These new variables contain fitted values and estimated quantiles. If you want to create a permanent SAS data set, you must specify a two-level name (refer to *SAS Language Reference: Concepts* for more information about permanent SAS data sets).

The following specifications can appear in the OUTPUT statement:

OUT=*SAS-data-set* specifies the new data set. By default, the procedure uses the DATA*n* convention to name the new data set.

keyword=name specifies the statistics to include in the output data set and gives names to the new variables. Specify a keyword for each desired statistic (see the following list), an equal sign, and the variable to contain the statistic.

The keywords allowed and the statistics they represent are as follows:

LEVERAGE specifies a variable to indicate leverage points. To include this variable in the OUTPUT data set, you must specify the LEVERAGE option in the PROC statement. See the section "Leverage Point and Outlier Detection" on page 5689 for how to define LEVERAGE.

OUTLIER specifies a variable to indicate outliers. See the section "Leverage Point and Outlier Detection" on page 5689 for how to define OUTLIER.

PREDICTED | P specifies a variable to contain the estimated response.

RESIDUAL | R specifies a variable to contain the unstandardized residuals

$$y_i - \mathbf{x}_i^T \hat{\theta}$$

SRESIDUAL | SR specifies a variable to contain the standardized residuals

$$\frac{y_i - \mathbf{x}_i^T \hat{\theta}}{\hat{\sigma}}$$

STDP specifies a variable to contain the estimates of the standard errors of the estimated response.

WEIGHT specifies a variable to contain the computed final weights.

PERFORMANCE Statement

The PERFORMANCE statement is used to change default options that affect the performance of PROC ROBUSTREG and to request tables that show the performance options in effect and timing details. See Chen (2002) for some empirical results.

PERFORMANCE < *options* > **;**

The following options are available:

CPUCOUNT=*1-1024*

CPUCOUNT=*ACTUAL*

specifies the number of processors to use for forming crossproduct matrices. CPUCOUNT=ACTUAL sets CPUCOUNT to be the number of physical processors available. Note that this can be less than the physical number of CPUs if the SAS process has been restricted by system administration tools. Setting CPUCOUNT= to a number greater than the actual number of available CPUs might result in reduced performance. This option overrides the SAS system option CPUCOUNT=. If CPUCOUNT=1, then NOTHREADS is in effect, and PROC ROBUSTREG uses singly threaded code.

DETAILS

requests the "PerfSettings" table that shows the performance settings in effect and the "Timing" table that provides a broad timing breakdown of the PROC ROBUSTREG step.

THREADS

enables multithreaded computation. This option overrides the SAS system option THREADS | NOTHREADS.

NOTHREADS

disables multithreaded computation. This option overrides the SAS system option THREADS | NOTHREADS.

TEST Statement

<*label:*> **TEST** *effects* **;**

With M estimation and MM estimation, the TEST statement provides a means of obtaining a test for the canonical linear hypothesis concerning the parameters of the tested effects:

$$\theta_j = 0, \quad j = i_1, \ldots, i_q$$

where q is the total number of parameters of the tested effects.

PROC ROBUSTREG provides two kinds of robust tests: the ρ test and the R_n^2 test. They are described in the section "Details: ROBUSTREG Procedure" on page 5672. No test is available for LTS and S estimation.

The optional *label*, which must be a valid SAS name, is used to label output from the corresponding TEST statement.

WEIGHT Statement

WEIGHT *variable* **;**

The WEIGHT statement specifies a weight variable in the input data set.

If you want to use fixed weights for each observation in the input data set, place the weights in a variable in the data set and specify the name in a WEIGHT statement. The values of the WEIGHT variable can be nonintegral and are not truncated. Observations with nonpositive or missing values for the weight variable do not contribute to the fit of the model.

Details: ROBUSTREG Procedure

This section describes the statistical and computational aspects of the ROBUSTREG procedure. The following notation is used throughout this section.

Let $X = (x_{ij})$ denote an $n \times p$ matrix, $y = (y_1, \ldots, y_n)^T$ denote a given n-vector of responses, and $\theta = (\theta_1, \ldots, \theta_p)^T$ denote an unknown p-vector of parameters or coefficients whose components are to be estimated. The matrix X is called the design matrix. Consider the usual linear model

$$y = X\theta + e$$

where $e = (e_1, \ldots, e_n)^T$ is an n-vector of unknown errors. It is assumed that (for a given X) the components e_i of e are independent and identically distributed according to a distribution $L(\cdot/\sigma)$, where σ is a scale parameter (usually unknown). Often $L(\cdot) \approx \Phi(\cdot)$, the standard normal distribution function. The vector of residuals for a given value of $\hat{\theta}$ is denoted by $r = (r_1, \ldots, r_n)^T$ and the ith row of the matrix X is denoted by x_i^T.

M Estimation

M estimation in the context of regression was first introduced by Huber (1973) as a result of making the least squares approach robust. Although M estimators are not robust with respect to leverage points, they are popular in applications where leverage points are not an issue.

Instead of minimizing a sum of squares of the residuals, a Huber-type M estimator $\hat{\theta}_M$ of θ minimizes a sum of less rapidly increasing functions of the residuals:

$$Q(\theta) = \sum_{i=1}^{n} \rho(\frac{r_i}{\sigma})$$

where $r = y - X\theta$. For the ordinary least squares estimation, ρ is the square function, $\rho(z) = z^2$.

If σ is known, then by taking derivatives with respect to θ, $\hat{\theta}_{\boldsymbol{M}}$ is also a solution of the system of p equations:

$$\sum_{i=1}^{n} \psi(\frac{r_i}{\sigma}) x_{ij} = 0, \ j = 1, \ldots, p$$

where $\psi = \frac{\partial \rho}{\partial z}$. If ρ is convex, $\hat{\theta}_{\boldsymbol{M}}$ is the unique solution.

The ROBUSTREG procedure solves this system by using iteratively reweighted least squares (IRLS). The weight function $w(x)$ is defined as

$$w(z) = \frac{\psi(z)}{z}$$

The ROBUSTREG procedure provides 10 kinds of weight functions through the WEIGHTFUNCTION= option in the MODEL statement. Each weight function corresponds to a ρ function. See the section "Weight Functions" on page 5674 for a complete discussion. You can specify the scale parameter σ with the SCALE= option in the PROC statement.

If σ is unknown, both θ and σ are estimated by minimizing the function

$$Q(\theta, \sigma) = \sum_{i=1}^{n} [\rho(\frac{r_i}{\sigma}) + a]\sigma, \ a > 0$$

The algorithm proceeds by alternately improving $\hat{\theta}$ in a location step and $\hat{\sigma}$ in a scale step.

For the scale step, three methods are available to estimate σ, which you can select with the SCALE= option.

1. (SCALE=HUBER<(D=d)>) Compute $\hat{\sigma}$ by the iteration

$$(\hat{\sigma}^{(m+1)})^2 = \frac{1}{nh} \sum_{i=1}^{n} \chi_d(\frac{r_i}{\hat{\sigma}^{(m)}})(\hat{\sigma}^{(m)})^2$$

where

$$\chi_d(x) = \begin{cases} x^2/2 & \text{if } |x| < d \\ d^2/2 & \text{otherwise} \end{cases}$$

is the Huber function and $h = \frac{n-p}{n}(d^2 + (1-d^2)\Phi(d) - 0.5 - d\sqrt{2\pi}e^{-\frac{1}{2}d^2})$ is the Huber constant (refer to Huber 1981, p. 179). You can specify d with the D= option. By default, $d = 2.5$.

2. (SCALE=TUKEY<(D=d)>) Compute $\hat{\sigma}$ by solving the supplementary equation

$$\frac{1}{n-p}\sum_{i=1}^{n}\chi_d(\frac{r_i}{\sigma}) = \beta$$

where

$$\chi_d(x) = \begin{cases} \frac{3x^2}{d^2} - \frac{3x^4}{d^4} + \frac{x^6}{d^6} & \text{if } |x| < d \\ 1 & \text{otherwise} \end{cases}$$

Here $\psi = \frac{1}{6}\chi_1'$ is Tukey's bisquare function, and $\beta = \int \chi_d(s)d\Phi(s)$ is the constant such that the solution $\hat{\sigma}$ is asymptotically consistent when $L(\cdot/\sigma) = \Phi(\cdot)$ (refer to Hampel et al. 1986, p. 149). You can specify d with the D= option. By default, $d = 2.5$.

3. (SCALE=MED) Compute $\hat{\sigma}$ by the iteration

$$\hat{\sigma}^{(m+1)} = \text{median}\{|y_i - x_i^T\hat{\theta}^{(m)}|/\beta_0, i = 1, \ldots, n\}$$

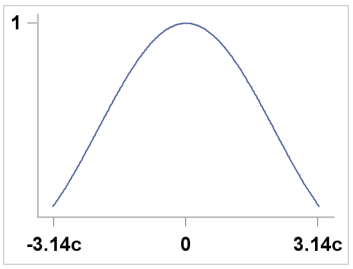
where $\beta_0 = \Phi^{-1}(.75)$ is the constant such that the solution $\hat{\sigma}$ is asymptotically consistent when $L(\cdot/\sigma) = \Phi(\cdot)$ (refer to Hampel et al. 1986, p. 312).

Note that SCALE = MED is the default.

Algorithm

The basic algorithm for computing M estimates for regression is iteratively reweighted least squares (IRLS). As the name suggests, a weighted least squares fit is carried out inside an iteration loop. For each iteration, a set of weights for the observations is used in the least squares fit. The weights are constructed by applying a weight function to the current residuals. Initial weights are based on residuals from an initial fit. The ROBUSTREG procedure uses the unweighted least squares fit as a default initial fit. The iteration terminates when a convergence criterion is satisfied. The maximum number of iterations is set to 1000. You can specify the weight function and the convergence criteria.

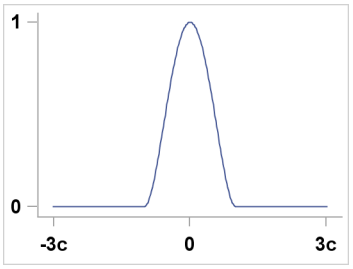
Weight Functions



You can specify the weight function for M estimation with the WEIGHTFUNCTION= option. The ROBUSTREG procedure provides 10 weight functions. By default, the procedure uses the bisquare

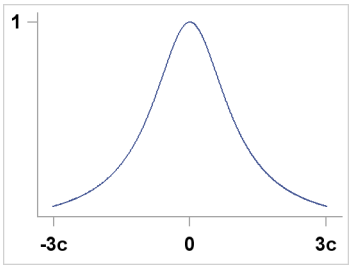
weight function. In most cases, M estimates are more sensitive to the parameters of these weight functions than to the type of the weight function. The median weight function is not stable and is seldom recommended in data analysis; it is included in the procedure for completeness. You can specify the parameters for these weight functions. Except for the hampel and median weight functions, default values for these parameters are defined such that the corresponding M estimates have 95% asymptotic efficiency in the location model with the Gaussian distribution (see Holland and Welsch 1977).

The following list shows the weight functions available. See Table 74.5 for the default values of the constants in these weight functions.



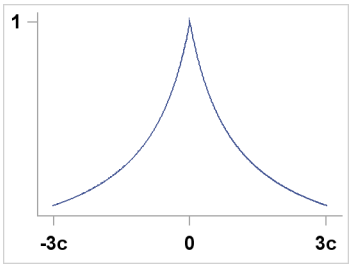
andrews

$$W(x,c) = \begin{cases} \frac{\sin(\frac{x}{c})}{\frac{x}{c}} & \text{if } |x| \leq \pi c \\ 0 & \text{otherwise} \end{cases}$$



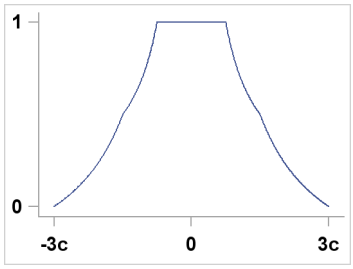
bisquare

$$W(x,c) = \begin{cases} (1-(\frac{x}{c})^2)^2 & \text{if } |x| < c \\ 0 & \text{otherwise} \end{cases}$$

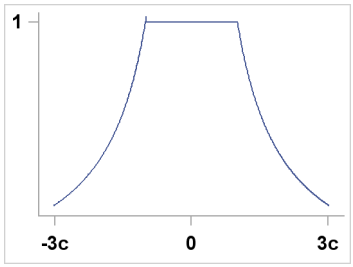


cauchy

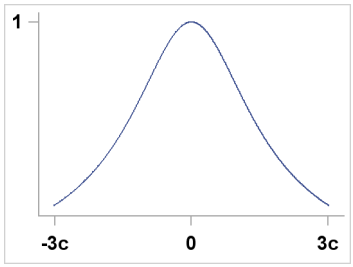
$$W(x,c) = \frac{1}{1+(\frac{|x|}{c})^2}$$



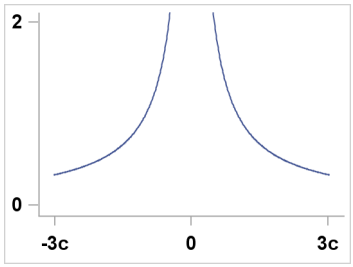
fair



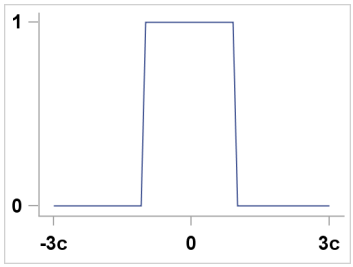
$$W(x,c) = \frac{1}{(1+\frac{|x|}{c})}$$



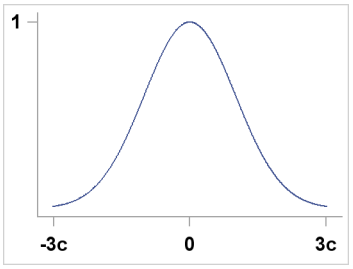
hampel $$W(x,a,b,c) = \begin{cases} 1 & |x| < a \\ \frac{a}{|x|} & a < |x| \le b \\ \frac{a}{|x|}\frac{c-|x|}{c-b} & b < |x| \le c \\ 0 & \text{otherwise} \end{cases}$$



huber $$W(x,c) = \begin{cases} 1 & \text{if } |x| < c \\ \frac{c}{|x|} & \text{otherwise} \end{cases}$$



logistic $$W(x,c) = \frac{\tanh(\frac{x}{c})}{\frac{x}{c}}$$



median $$W(x,c) = \begin{cases} \frac{1}{c} & \text{if } x = 0 \\ \frac{1}{|x|} & \text{otherwise} \end{cases}$$

talworth $$W(x,c) = \begin{cases} 1 & \text{if } |x| < c \\ 0 & \text{otherwise} \end{cases}$$

welsch $W(x,c) = \exp(-\frac{1}{2}(\frac{x}{c})^2)$

Convergence Criteria

The following convergence criteria are available in PROC ROBUSTREG:

- relative change in the coefficients (CONVERGENCE= COEF)
- relative change in the scaled residuals (CONVERGENCE= RESID)
- relative change in weights (CONVERGENCE= WEIGHT)

You can specify the criteria with the CONVERGENCE= option in the PROC statement. The default is CONVERGENCE= COEF.

You can specify the precision of the convergence criterion with the EPS= suboption. The default is EPS=1.E−8.

In addition to these convergence criteria, a convergence criterion based on scale-independent measure of the gradient is always checked. See Coleman et al. (1980) for more details. A warning is issued if this criterion is not satisfied.

Asymptotic Covariance and Confidence Intervals

The following three estimators of the asymptotic covariance of the robust estimator are available in PROC ROBUSTREG:

H1: $K^2 \dfrac{[1/(n-p)]\sum(\psi(r_i))^2}{[(1/n)\sum(\psi'(r_i))]^2}(X^TX)^{-1}$

H2: $K \dfrac{[1/(n-p)]\sum(\psi(r_i))^2}{[(1/n)\sum(\psi'(r_i))]}W^{-1}$

H3: $K^{-1}\dfrac{1}{(n-p)}\sum(\psi(r_i))^2 W^{-1}(X^TX)W^{-1}$

where $K = 1 + \frac{p}{n}\frac{\mathrm{Var}(\psi')}{(E\psi')^2}$ is a correction factor and $W_{jk} = \sum \psi'(r_i)x_{ij}x_{ik}$. Refer to Huber (1981, p. 173) for more details.

You can specify the asymptotic covariance estimate with the option ASYMPCOV= option. The ROBUSTREG procedure uses H1 as the default because of its simplicity and stability. Confidence intervals are computed from the diagonal elements of the estimated asymptotic covariance matrix.

R Square and Deviance

The robust version of R^2 is defined as

$$R^2 = \frac{\sum \rho(\frac{y_i-\hat{\mu}}{\hat{s}}) - \sum \rho(\frac{y_i-x_i^T\hat{\theta}}{\hat{s}})}{\sum \rho(\frac{y_i-\hat{\mu}}{\hat{s}})}$$

and the robust deviance is defined as the optimal value of the objective function on the σ^2 scale:

$$D = 2(\hat{s})^2 \sum \rho(\frac{y_i - x_i^T\hat{\theta}}{\hat{s}})$$

where $\rho' = \psi$, $\hat{\theta}$ is the M estimator of θ, $\hat{\mu}$ is the M estimator of location, and $\hat{s}$ is the M estimator of the scale parameter in the full model.

Linear Tests

Two tests are available in PROC ROBUSTREG for the canonical linear hypothesis

$$H_0: \quad \theta_j = 0, \quad j = i_1, \ldots, i_q$$

where q is the total number of parameters of the tested effects. The first test is a robust version of the F test, which is referred to as the ρ test. Denote the M estimators in the full and reduced model as $\hat{\theta}(0) \in \Omega_0$ and $\hat{\theta}(1) \in \Omega_1$, respectively. Let

$$\begin{aligned} Q_0 &= Q(\hat{\theta}(0)) = \min\{Q(\theta)|\theta \in \Omega_0\} \\ Q_1 &= Q(\hat{\theta}(1)) = \min\{Q(\theta)|\theta \in \Omega_1\} \end{aligned}$$

with

$$Q = \sum_{i=1}^{n} \rho(\frac{r_i}{\sigma})$$

The robust F test is based on the test statistic

$$S_n^2 = \frac{2}{q}[Q_1 - Q_0]$$

Asymptotically $S_n^2 \sim \lambda\chi_q^2$ under H_0, where the standardization factor is $\lambda = \int \psi^2(s)d\Phi(s) / \int \psi'(s)\ d\Phi(s)$ and Φ is the cumulative distribution function of the standard normal distribution. Large values of S_n^2 are significant. This test is a special case of the general τ test of Hampel et al. (1986, Section 7.2).

The second test is a robust version of the Wald test, which is referred to as R_n^2 test. The test uses a test statistic

$$R_n^2 = n(\hat{\theta}_{i_1}, \ldots, \hat{\theta}_{i_q}) H_{22}^{-1} (\hat{\theta}_{i_1}, \ldots, \hat{\theta}_{i_q})^T$$

where $\frac{1}{n}H_{22}$ is the $q \times q$ block (corresponding to $\theta_{i_1}, \ldots, \theta_{i_q}$) of the asymptotic covariance matrix of the M estimate $\hat{\theta}_M$ of θ in a p-parameter linear model.

Under H_0, the statistic R_n^2 has an asymptotic χ^2 distribution with q degrees of freedom. Large values of R_n^2 are significant. Refer to Hampel et al. (1986, Chapter 7) for more details.

Model Selection

When M estimation is used, two criteria are available in PROC ROBUSTREG for model selection. The first criterion is a counterpart of the Akaike (1974) AIC criterion for robust regression, and it is defined as

$$AICR = 2\sum_{i=1}^{n}\rho(r_{i:p}) + \alpha p$$

where $r_{i:p} = (y_i - x_i^T\hat{\theta})/\hat{\sigma}$, $\hat{\sigma}$ is a robust estimate of σ and $\hat{\theta}$ is the M estimator with p-dimensional design matrix.

As with AIC, α is the weight of the penalty for dimensions. The ROBUSTREG procedure uses $\alpha = 2E\psi^2/E\psi'$ (Ronchetti 1985) and estimates it by using the final robust residuals.

The second criterion is a robust version of the Schwarz information criteria (BIC), and it is defined as

$$BICR = 2\sum_{i=1}^{n}\rho(r_{i:p}) + p\log(n)$$

High Breakdown Value Estimation

The *breakdown value* of an estimator is defined as the smallest fraction of contamination that can cause the estimator to take on values arbitrarily far from its value on the uncontamined data. The breakdown value of an estimator can be used as a measure of the robustness of the estimator. Rousseeuw and Leroy (1987) and others introduced the following high breakdown value estimators for linear regression.

LTS Estimate

The least trimmed squares (LTS) estimate proposed by Rousseeuw (1984) is defined as the p-vector

$$\hat{\theta}_{LTS} = \arg\min_{\theta} Q_{LTS}(\theta)$$

where

$$Q_{LTS}(\theta) = \sum_{i=1}^{h} r_{(i)}^2$$

$r_{(1)}^2 \le r_{(2)}^2 \le \ldots \le r_{(n)}^2$ are the ordered squared residuals $r_i^2 = (y_i - x_i^T\theta)^2$, $i = 1, \ldots, n$, and h is defined in the range $\frac{n}{2} + 1 \le h \le \frac{3n+p+1}{4}$.

You can specify the parameter h with the H= option in the PROC statement. By default, $h = [\frac{3n+p+1}{4}]$. The breakdown value is $\frac{n-h}{n}$ for the LTS estimate.

The ROBUSTREG procedure computes LTS estimates by using the FAST-LTS algorithm of Rousseeuw and Van Driessen (2000). The estimates are often used to detect outliers in the data, which are then downweighted in the resulting weighted LS regression.

Algorithm

Least trimmed squares (LTS) regression is based on the subset of h observations (out of a total of n observations) whose least squares fit possesses the smallest sum of squared residuals. The coverage h can be set between $\frac{n}{2}$ and n. The LTS method was proposed by Rousseeuw (1984, p. 876) as a highly robust regression estimator with breakdown value $\frac{n-h}{n}$. The ROBUSTREG procedure uses the FAST-LTS algorithm given by Rousseeuw and Van Driessen (2000). The intercept adjustment technique is also used in this implementation. However, because this adjustment is expensive to compute, it is optional. You can use the IADJUST option in the PROC statement to request or suppress the intercept adjustment. By default, PROC ROBUSTREG does intercept adjustment for data sets with fewer than 10000 observations. The steps of the algorithm are described briefly as follows. Refer to Rousseeuw and Van Driessen (2000) for details.

1. The default h is $[\frac{3n+p+1}{4}]$, where p is the number of independent variables. You can specify any integer h with $[\frac{n}{2}] + 1 \leq h \leq [\frac{3n+p+1}{4}]$ with the H= option in the MODEL statement. The breakdown value for LTS, $\frac{n-h}{n}$, is reported. The default h is a good compromise between breakdown value and statistical efficiency.

2. If $p = 1$ (single regressor), the procedure uses the exact algorithm of Rousseeuw and Leroy (1987, p. 172).

3. If $p \geq 2$, the procedure uses the following algorithm. If $n < 2ssubs$, where *ssubs* is the size of the subgroups (you can specify *ssubs* by using the SUBGROUPSIZE= option in the PROC statement; by default, $ssubs = 300$), draw a random p-subset and compute the regression coefficients by using these p points (if the regression is degenerate, draw another p-subset). Compute the absolute residuals for all observations in the data set, and select the first h points with smallest absolute residuals. From this selected h-subset, carry out *nsteps* C-steps (Concentration step; see Rousseeuw and Van Driessen (2000) for details. You can specify *nsteps* with the CSTEP= option in the PROC statement; by default, $nsteps = 2$). Redraw p-subsets and repeat the preceding computing procedure *nrep* times, and then find the *nbsol* (at most) solutions with the lowest sums of h squared residuals. *nrep* can be specified with the NREP= option in the PROC statement. By default, NREP=min$\{500, \binom{n}{p}\}$. For small n and p, all $\binom{n}{p}$ subsets are used and the NREP= option is ignored (Rousseeuw and Hubert 1996). *nbsol* can be specified with the NBEST= option in the PROC statement. By default, NBEST=10. For each of these *nbsol* best solutions, take C-steps until convergence and find the best final solution.

4. If $n \geq 5ssubs$, construct 5 disjoint random subgroups with size *ssubs*. If $2ssubs < n < 5ssubs$, the data are split into at most four subgroups with *ssubs* or more observations in each subgroup, so that each observation belongs to a subgroup and the subgroups have roughly the same size. Let *nsubs* denote the number of subgroups. Inside each subgroup, repeat the procedure in step 3 $[\frac{nrep}{nsubs}]$ times and keep the *nbsol* best solutions. Pool the subgroups, yielding the merged set of size n_{merged}. In the merged set, for each of the $nsubs \times nbsol$ best solutions, carry out *nsteps* C-steps by using n_{merged} and $h_{merged} = [n_{merged}\frac{h}{n}]$ and keep the *nbsol* best solutions. In the full data set, for each of these *nbsol* best solutions, take C-steps by using n and h until convergence and find the best final solution.

R^2

The robust version of R^2 for the LTS estimate is defined as

$$R^2_{LTS} = 1 - \frac{s^2_{LTS}(X, y)}{s^2_{LTS}(\mathbf{1}, y)}$$

for models with the intercept term and as

$$R^2_{LTS} = 1 - \frac{s^2_{LTS}(X, y)}{s^2_{LTS}(\mathbf{0}, y)}$$

for models without the intercept term, where

$$s_{LTS}(X, y) = d_{h,n}\sqrt{\frac{1}{h}\sum_{i=1}^{h} r^2_{(i)}}$$

s_{LTS} is a preliminary estimate of the parameter σ in the distribution function $L(\cdot/\sigma)$.

Here $d_{h,n}$ is chosen to make s_{LTS} consistent, assuming a Gaussian model. Specifically,

$$\begin{aligned} d_{h,n} &= 1/\sqrt{1 - \frac{2n}{hc_{h,n}}\phi(1/c_{h,n})} \\ c_{h,n} &= 1/\Phi^{-1}(\frac{h+n}{2n}) \end{aligned}$$

with Φ and ϕ being the distribution function and the density function of the standard normal distribution, respectively.

Final Weighted Scale Estimator

The ROBUSTREG procedure displays two scale estimators, s_{LTS} and Wscale. The estimator Wscale is a more efficient scale estimator based on the preliminary estimate s_{LTS}, and it is defined as

$$\text{Wscale} = \sqrt{\frac{\sum_i w_i r_i^2}{\sum_i w_i - p}}$$

where

$$w_i = \begin{cases} 0 & \text{if } |r_i|/s_{LTS} > k \\ 1 & \text{otherwise} \end{cases}$$

You can specify k with the CUTOFF= option in the MODEL statement. By default, $k = 3$.

S Estimate

The S estimate proposed by Rousseeuw and Yohai (1984) is defined as the p-vector

$$\hat{\theta}_S = \arg\min_{\theta} S(\theta)$$

where the dispersion $S(\theta)$ is the solution of

$$\frac{1}{n-p}\sum_{i=1}^{n}\chi\left(\frac{y_i - x_i^T\theta}{S}\right) = \beta$$

Here β is set to $\int \chi(s)d\Phi(s)$ such that $\hat{\theta}_S$ and $S(\hat{\theta}_S)$ are asymptotically consistent estimates of θ and σ for the Gaussian regression model. The breakdown value of the S estimate is

$$\frac{\beta}{\max_s \chi(s)}$$

The ROBUSTREG procedure provides two choices for χ: Tukey's bisquare function and Yohai's optimal function.

Tukey's bisquare function, which you can specify with the option CHIF=TUKEY, is

$$\chi_{k_0}(s) = \begin{cases} 3(\frac{s}{k_0})^2 - 3(\frac{s}{k_0})^4 + (\frac{s}{k_0})^6, & \text{if } |s| \le k_0 \\ 1 & \text{otherwise} \end{cases}$$

The constant k_0 controls the breakdown value and efficiency of the S estimate. If you specify the efficiency by using the EFF= option, you can determine the corresponding k_0. The default k_0 is 2.9366 such that the breakdown value of the S estimate is 0.25 with a corresponding asymptotic efficiency for the Gaussian model of 75.9%.

The Yohai function, which you can specify with the option CHIF=YOHAI, is

$$\chi_{k_0}(s) = \begin{cases} \frac{s^2}{2} & \text{if } |s| \le 2k_0 \\ k_0^2[b_0 + b_1(\frac{s}{k_0})^2 + b_2(\frac{s}{k_0})^4 & \\ \quad +b_3(\frac{s}{k_0})^6 + b_4(\frac{s}{k_0})^8] & \text{if } 2k_0 < |s| \le 3k_0 \\ 3.25k_0^2 & \text{if } |s| > 3k_0 \end{cases}$$

where $b_0 = 1.792$, $b_1 = -0.972$, $b_2 = 0.432$, $b_3 = -0.052$, and $b_4 = 0.002$. If you specify the efficiency by using the EFF= option, you can determine the corresponding k_0. By default, k_0 is set to 0.7405 such that the breakdown value of the S estimate is 0.25 with a corresponding asymptotic efficiency for the Gaussian model of 72.7%.

Algorithm

The ROBUSTREG procedure implements the algorithm by Marazzi (1993) for the S estimate, which is a refined version of the algorithm proposed by Ruppert (1992). The refined algorithm is briefly described as follows.

Initialize iter $= 1$.

1. Draw a random q-subset of the total n observations and compute the regression coefficients by using these q observations (if the regression is degenerate, draw another q-subset), where $q \geq p$ can be specified with the SUBSIZE= option. By default, $q = p$.

2. Compute the residuals: $r_i = y_i - \sum_{j=1}^{p} x_{ij}\theta_j$ for $i = 1, \ldots, n$. If iter $= 1$, set $s^* = 2\text{median}\{|r_i|, i = 1, \ldots, n\}$; if $s^* = 0$, set $s^* = \min\{|r_i|, i = 1, \ldots, n\}$;
while $\sum_{i=1}^{n} \chi(r_i/s^*) > (n-p)\beta$, set $s^* = 1.5s^*$; go to step 3.
If iter > 1 and $\sum_{i=1}^{n} \chi(r_i/s^*) <= (n-p)\beta$, go to step 3; otherwise, go to step 5.

3. Solve for s the equation

$$\frac{1}{n-p}\sum_{i=1}^{n}\chi(r_i/s) = \beta$$

using an iterative algorithm.

4. If iter > 1 and $s > s^*$, go to step 5. Otherwise, set $s^* = s$ and $\theta^* = \theta$. If $s^* < TOLS$, return s^* and θ^*; otherwise, go to step 5.

5. If iter $< NREP$, set iter $=$ iter $+ 1$ and return to step 1; otherwise, return s^* and θ^*.

The ROBUSTREG procedure does the following refinement step by default. You can request that this refinement not be done by using the NOREFINE option in the PROC statement.

6. Let $\psi = \chi'$. Using the values s^* and θ^* from the previous steps, compute M estimates θ_M and σ_M of θ and σ with the setup for M estimation in the section "M Estimation" on page 5672. If $\sigma_M > s^*$, give a warning and return s^* and θ^*; otherwise, return σ_M and θ_M.

You can specify $TOLS$ with the TOLERANCE= option; by default, TOLERANCE=0.001. Alternately, you can specify $NREP$ with the NREP= option. You can also use the options NREP=NREP0 or NREP=NREP1 to determine $NREP$ according to the following table. NREP=NREP0 is set as the default.

Table 74.9 Default NREP

P	NREP0	NREP1
1	150	500
2	300	1000
3	400	1500
4	500	2000
5	600	2500
6	700	3000
7	850	3000
8	1250	3000
9	1500	3000
>9	1500	3000

R^2 and Deviance

The robust version of R^2 for the S estimate is defined as

$$R_S^2 = 1 - \frac{(n-p)S_p^2}{(n-1)S_\mu^2}$$

for the model with the intercept term and

$$R_S^2 = 1 - \frac{(n-p)S_p^2}{nS_0^2}$$

for the model without the intercept term, where S_p is the S estimate of the scale in the full model, S_μ is the S estimate of the scale in the regression model with only the intercept term, and S_0 is the S estimate of the scale without any regressor. The deviance D is defined as the optimal value of the objective function on the σ^2 scale:

$$D = S_p^2$$

Asymptotic Covariance and Confidence Intervals

Since the S estimate satisfies the first-order necessary conditions as the M estimate, it has the same asymptotic covariance as that of the M estimate. All three estimators of the asymptotic covariance for the M estimate in the section "Asymptotic Covariance and Confidence Intervals" on page 5677 can be used for the S estimate. Besides, the weighted covariance estimator H4 described in the section "Asymptotic Covariance and Confidence Intervals" on page 5687 is also available and is set as the default. Confidence intervals for estimated parameters are computed from the diagonal elements of the estimated asymptotic covariance matrix.

MM Estimation

MM estimation is a combination of high breakdown value estimation and efficient estimation, which was introduced by Yohai (1987). It has the following three steps.

1. Compute an initial (consistent) high breakdown value estimate $\hat{\theta}'$. The ROBUSTREG procedure provides two kinds of estimates as the initial estimate: the LTS estimate and the S estimate. By default, the LTS estimate is used because of its speed and high breakdown value. The breakdown value of the final MM estimate is decided by the breakdown value of the initial LTS estimate and the constant k_0 in the χ function. To use the S estimate as the initial estimate, you specify the INITEST=S option in the PROC statement. In this case, the breakdown value of the final MM estimate is decided only by the constant k_0. Instead of computing the LTS estimate or the S estimate as the initial estimate, you can also specify the initial estimate explicitly by using the INEST= option in the PROC statement. See the section "INEST= Data Set" on page 5689 for details.

2. Find $\hat{\sigma}'$ such that

$$\frac{1}{n-p}\sum_{i=1}^{n}\chi(\frac{y_i - x_i^T\hat{\theta}'}{\hat{\sigma}'}) = \beta$$

where $\beta = \int \chi(s)d\Phi(s)$.

The ROBUSTREG procedure provides two choices for χ: Tukey's bisquare function and Yohai's optimal function.

Tukey's bisquare function, which you can specify with the option CHIF=TUKEY, is

$$\chi_{k_0}(s) = \begin{cases} 3(\frac{s}{k_0})^2 - 3(\frac{s}{k_0})^4 + (\frac{s}{k_0})^6, & \text{if } |s| \le k_0 \\ 1 & \text{otherwise} \end{cases}$$

where k_0 can be specified with the K0= option. The default k_0 is 2.9366 such that the asymptotically consistent scale estimate $\hat{\sigma}'$ has the breakdown value of 25%.

Yohai's optimal function, which you can specify with the option CHIF=YOHAI, is

$$\chi_{k_0}(s) = \begin{cases} \frac{s^2}{2} & \text{if } |s| \le 2k_0 \\ k_0^2[b_0 + b_1(\frac{s}{k_0})^2 + b_2(\frac{s}{k_0})^4 & \\ \quad +b_3(\frac{s}{k_0})^6 + b_4(\frac{s}{k_0})^8] & \text{if } 2k_0 < |s| \le 3k_0 \\ 3.25k_0^2 & \text{if } |s| > 3k_0 \end{cases}$$

where $b_0 = 1.792$, $b_1 = -0.972$, $b_2 = 0.432$, $b_3 = -0.052$, and $b_4 = 0.002$. You can specify k_0 with the K0= option. The default k_0 is 0.7405 such that the asymptotically consistent scale estimate $\hat{\sigma}'$ has the breakdown value of 25%.

3. Find a local minimum $\hat{\theta}_{MM}$ of

$$Q_{MM} = \sum_{i=1}^{n}\rho(\frac{y_i - x_i^T\theta}{\hat{\sigma}'})$$

such that $Q_{MM}(\hat{\theta}_{MM}) \le Q_{MM}(\hat{\theta}')$. The algorithm for M estimation is used here.

The ROBUSTREG procedure provides two choices for ρ: Tukey's bisquare function and Yohai's optimal function.

Tukey's bisquare function, which you can specify with the option CHIF=TUKEY, is

$$\rho(s) = \chi_{k_1}(s) = \begin{cases} 3(\frac{s}{k_1})^2 - 3(\frac{s}{k_1})^4 + (\frac{s}{k_1})^6, & \text{if } |s| \le k_1 \\ 1 & \text{otherwise} \end{cases}$$

where k_1 can be specified with the K1= option. The default k_1 is 3.440 such that the MM estimate has 85% asymptotic efficiency with the Gaussian distribution.

Yohai's optimal function, which you can specify with the option CHIF=YOHAI, is

$$\rho(s) = \chi_{k_1}(s) = \begin{cases} \frac{s^2}{2} & \text{if } |s| \le 2k_1 \\ k_1^2[b_0 + b_1(\frac{s}{k_1})^2 + b_2(\frac{s}{k_1})^4 & \\ \quad +b_3(\frac{s}{k_1})^6 + b_4(\frac{s}{k_1})^8] & \text{if } 2k_1 < |s| \le 3k_1 \\ 3.25k_1^2 & \text{if } |s| > 3k_1 \end{cases}$$

where k_1 can be specified with the K1= option. The default k_1 is 0.868 such that the MM estimate has 85% asymptotic efficiency with the Gaussian distribution.

Algorithm

The initial LTS estimate is computed using the algorithm described in the section "LTS Estimate" on page 5679. You can control the quantile of the LTS estimate with the option INITH=h, where h is an integer between $[\frac{n}{2}] + 1$ and $[\frac{3n+p+1}{4}]$. By default, $h = [\frac{3n+p+1}{4}]$, which corresponds to a breakdown value of around 25%.

The initial S estimate is computed using the algorithm described in the section "S Estimate" on page 5682. You can control the breakdown value and efficiency of this initial S estimate by the constant k_0, which can be specified with the K0 option.

The scale parameter σ is solved by an iterative algorithm

$$(\sigma^{(m+1)})^2 = \frac{1}{(n-p)\beta} \sum_{i=1}^{n} \chi_{k_0}(\frac{r_i}{\sigma^{(m)}})(\sigma^{(m)})^2$$

where $\beta = \int \chi_{k_0}(s) d\Phi(s)$.

Once the scale parameter is computed, the iteratively reweighted least squares (IRLS) algorithm with fixed scale parameter is used to compute the final MM estimate.

Convergence Criteria

In the iterative algorithm for the scale parameter, the relative change of the scale parameter controls the convergence.

In the iteratively reweighted least squares algorithm, the same convergence criteria for the M estimate used before are used here.

Bias Test

Although the final MM estimate inherits the high breakdown value property, its bias due to the distortion of the outliers can be high. Yohai, Stahel, and Zamar (1991) introduced a bias test. The ROBUSTREG procedure implements this test when you specify the BIASTEST option in the PROC statement. This test is based on the initial scale estimate $\hat{\sigma}'$ and the final scale estimate $\hat{\sigma}'_1$, which is the solution of

$$\frac{1}{n-p} \sum_{i=1}^{n} \chi(\frac{y_i - x_i^T \hat{\theta}_{MM}}{\hat{\sigma}'_1}) = \beta$$

Let $\psi_{k_0}(z) = \frac{\partial \chi_{k_0}(z)}{\partial z}$ and $\psi_{k_1}(z) = \frac{\partial \chi_{k_1}(z)}{\partial z}$. Compute

$$\begin{aligned} \tilde{r}_i &= (y_i - x_i^T \hat{\theta}')/\hat{\sigma}' \quad \text{for } i = 1, \ldots, n \\ v_0 &= \frac{(1/n) \sum \psi'_{k_0}(\tilde{r}_i)}{(\hat{\sigma}'_1/n) \sum \psi_{k_0}(\tilde{r}_i)\tilde{r}_i} \end{aligned}$$

$$
\begin{aligned}
p_i^{(0)} &= \frac{\psi_{k_0}(\tilde{r}_i)}{(1/n)\sum \psi'_{k_0}(\tilde{r}_i)} \quad \text{for } i = 1, \ldots, n \\
p_i^{(1)} &= \frac{\psi_{k_1}(\tilde{r}_i)}{(1/n)\sum \psi'_{k_1}(\tilde{r}_i)} \quad \text{for } i = 1, \ldots, n \\
d^2 &= \frac{1}{n}\sum (p_i^{(1)} - p_i^{(0)})^2
\end{aligned}
$$

Let

$$T = \frac{2n(\hat{\sigma}'_1 - \hat{\sigma}')}{v_0 d^2 (\hat{\sigma}')^2}$$

Standard asymptotic theory shows that T approximately follows a χ^2 distribution with p degrees of freedom. If T exceeds the α quantile χ^2_α of the χ^2 distribution with p degrees of freedom, then the ROBUSTREG procedure gives a warning and recommends that you use other methods. Otherwise the final MM estimate and the initial scale estimate are reported. You can specify α with the ALPHA= option following the BIASTEST option. By default, ALPHA=0.99.

Asymptotic Covariance and Confidence Intervals

Since the MM estimate is computed as a M estimate with a fixed scale in the last step, the asymptotic covariance for the M estimate can be used here for the asymptotic covariance of the MM estimate. Besides the three estimators H1, H2, and H3 as described in the section "Asymptotic Covariance and Confidence Intervals" on page 5677, a weighted covariance estimator H4 is available:

$$\text{H4: } K^2 \frac{[1/(n-p)]\sum(\psi(r_i))^2}{[(1/n)\sum(\psi'(r_i))]^2} W^{-1}$$

where $K = 1 + \frac{p}{n}\frac{\text{Var}(\psi')}{(E\psi')^2}$ is the correction factor and $W_{jk} = \frac{1}{\bar{w}}\sum w_i x_{ij} x_{ik}$, $\bar{w} = \frac{1}{n}\sum w_i$.

You can specify these estimators with the option ASYMPCOV= [H1 | H2 | H3 | H4]. The ROBUSTREG procedure uses H4 as the default. Confidence intervals for estimated parameters are computed from the diagonal elements of the estimated asymptotic covariance matrix.

R Square and Deviance

The robust version of R^2 for the MM estimate is defined as

$$R^2 = \frac{\sum \rho(\frac{y_i - \hat{\mu}}{\hat{s}}) - \sum \rho(\frac{y_i - x_i^T\hat{\theta}}{\hat{s}})}{\sum \rho(\frac{y_i - \hat{\mu}}{\hat{s}})}$$

and the robust deviance is defined as the optimal value of the objective function on the σ^2 scale:

$$D = 2(\hat{s})^2 \sum \rho(\frac{y_i - x_i^T\hat{\theta}}{\hat{s}})$$

where $\rho' = \psi$, $\hat{\theta}$ is the MM estimator of θ, $\hat{\mu}$ is the MM estimator of location, and $\hat{s}$ is the MM estimator of the scale parameter in the full model.

Linear Tests

For MM estimation, the same ρ test and R_n^2 test used for M estimation can be used. See the section "Linear Tests" on page 5678 for details.

Model Selection

For MM estimation, the same two model selection methods used for M estimation can be used. See the section "Model Selection" on page 5679 for details.

Robust Distance

The ROBUSTREG procedure uses the robust multivariate location and scale estimates for leverage-point detection. The procedure computes a robust version of the Mahalanobis distance by using the minimum covariance determinant (MCD) method of Rousseeuw (1984).

Algorithm

PROC ROBUSTREG implements the algorithm given by Rousseeuw and Van Driessen (1999) for MCD, which is similar to the algorithm for LTS.

Robust Distance

The Mahalanobis distance is defined as

$$MD(x_i) = [(x_i - \bar{x})^T \bar{C}(X)^{-1}(x_i - \bar{x})]^{1/2}$$

where $\bar{x} = \frac{1}{n}\sum_{i=1}^{n} x_i$ and $\bar{C}(X) = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^T(x_i - \bar{x})$ are the empirical multivariate location and scale. Here $x_i = (x_{i1}, \ldots, x_{i(p-1)})^T$ does not include the intercept. The relation between the Mahalanobis distance $MD(x_i)$ and the hat matrix $H = (h_{ij}) = X(X^TX)^{-1}X^T$ is

$$h_{ii} = \frac{1}{n-1}MD_i^2 + \frac{1}{n}$$

The robust distance is defined as

$$RD(x_i) = [(x_i - T(X))^T C(X)^{-1}(x_i - T(X))]^{1/2}$$

where $T(X)$ and $C(X)$ are the robust multivariate location and scale obtained by MCD.

These distances are used to detect leverage points.

Leverage Point and Outlier Detection

Let $C(p) = \sqrt{\chi^2_{p;1-\alpha}}$ be the cutoff value. The variable LEVERAGE is defined as

$$\text{LEVERAGE} = \begin{cases} 0 & \text{if } RD(x_i) \leq C(p) \\ 1 & \text{otherwise} \end{cases}$$

You can specify a cutoff value with the LEVERAGE option in the MODEL statement.

Residuals $r_i, i = 1, \ldots, n$, based on robust regression estimates are used to detect vertical outliers. The variable OUTLIER is defined as

$$\text{OUTLIER} = \begin{cases} 0 & \text{if } |r_i| \leq k\hat{\sigma} \\ 1 & \text{otherwise} \end{cases}$$

You can specify the multiplier k of the cutoff value by using the CUTOFF= option in the MODEL statement. By default, $k = 3$. $\hat{\sigma}$ is estimated scale in the model.

An ODS table called DIAGNOSTICS contains these two variables.

INEST= Data Set

When you use the M or MM estimation, you can use the INEST= data set to specify initial estimates for all the parameters in the model. The INEST= option is ignored if you specify LTS or S estimation by using the METHOD=LTS or METHOD=S option or if you specify the INITEST= option after the METHOD=MM option in the PROC statement. The INEST= data set must contain the intercept variable (named Intercept) and all independent variables in the MODEL statement.

If BY processing is used, the INEST= data set should also include the BY variables, and there must be at least one observation for each BY group. If there is more than one observation in a BY group, the first one read is used for that BY group.

If the INEST= data set also contains the _TYPE_ variable, only observations with _TYPE_ value "PARMS" are used as starting values.

You can specify starting values for the iteratively reweighted least squares algorithm in the INEST= data set. The INEST= data set has the same structure as the OUTEST= data set but is not required to have all the variables or observations that appear in the OUTEST= data set. One simple use of the INEST= option is passing the previous OUTEST= data set directly to the next model as an INEST= data set, assuming that the two models have the same parameterization.

OUTEST= Data Set

The OUTEST= data set contains parameter estimates for the model. You can specify a label in the MODEL statement to distinguish between the estimates for different models used by the ROBUSTREG procedure. If the COVOUT option is specified, the OUTEST= data set also contains the estimated covariance matrix of the parameter estimates. Note that, if the ROBUSTREG procedure does not converge, the parameter estimates are set to missing in the OUTEST data set.

The OUTEST= data set contains all variables specified in the MODEL statement and the BY statement. One observation consists of parameter values for the model with the dependent variable having the value -1. If the COVOUT option is specified, there are additional observations containing the rows of the estimated covariance matrix. For these observations, the dependent variable contains the parameter estimate for the corresponding row variable. The following variables are also added to the data set:

MODEL	is a character variable containing the label of the MODEL statement, if present. Otherwise, the variable's value is blank.
NAME	is a character variable containing the name of the dependent variable for the parameter estimates or the name of the row for the covariance matrix estimates.
TYPE	is a character variable containing the type of the observation, either PARMS for parameter estimates or COV for covariance estimates.
METHOD	is a character variable containing the type of estimation method, either M estimation, LTS estimation, S estimation, or MM estimation.
STATUS	is a character variable containing the status of model fitting, either Converged, Warning, or Failed.
INTERCEPT	is a numeric variable containing the intercept parameter estimates and covariances.
SCALE	is a numeric variable containing the scale parameter estimates.

Any BY variables specified are also added to the OUTEST= data set.

Computational Resources

The algorithms for the various estimation methods need a different amount of memory for working space. Let p be the number of parameters estimated and n be the number of observations used in the model estimation.

For M estimation, the minimum working space (in bytes) needed is

$$3n + 2p^2 + 30p$$

If sufficient space is available, the input data set is also kept in memory; otherwise, the input data set is reread for computing the iteratively reweighted least squares estimates and the execution

time of the procedure increases substantially. For each reweighted least squares, $O(np^2 + p^3)$ multiplications and additions are required for computing the crossproduct matrix and its inverse. The $O(v)$ notation means that, for large values of the argument, v, $O(v)$ is approximately a constant times v.

Since the iteratively reweighted least squares algorithm converges very quickly (normally within fewer than 20 iterations), the computation of M estimates is fast.

LTS estimation is more expensive in computation. The minimum working space (in bytes) needed is

$$np + 12n + 4p^2 + 60p$$

The memory is mainly used to store the current data used by LTS for modeling. The LTS algorithm uses subsampling and spends much of its computing time on resampling and computing estimates for subsamples. Since it resamples if singularity is detected, it might take more time if the data set has serious singularities.

The MCD algorithm for leverage-point diagnostics is similar to the LTS algorithm.

ODS Table Names

The ROBUSTREG procedure assigns a name to each table it creates. You can specify these names when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 74.10 ODS Tables Produced by PROC ROBUSTREG

ODS Table Name	Description	Statement	Option
BestEstimates	Best final estimates for LTS	PROC	SUBANALYSIS
BestSubEstimates	Best estimates for each subgroup	PROC	SUBANALYSIS
BiasTest	Bias test for MM estimation	PROC	BIASTEST
ClassLevels	Classification variable levels	CLASS	default

ODS Graphics

Graphical displays are important in robust regression and outlier detection. This section provides information about the basic ODS statistical graphics produced by the ROBUSTREG procedure.

If the model includes a single continuous independent variable, a plot of robust fit against this variable (FITPLOT) is provided by default. For diagnostics, two plots are particularly useful in revealing outliers and leverage points. The first is a scatter plot of the standardized robust residuals against the robust distances (RDPLOT). The second is a scatter plot of the robust distances against the classical Mahalanobis distances (DDPLOT). In addition to these two plots, a histogram and a quantile-quantile plot of the standardized robust residuals are also helpful.

These plots are controlled by the PLOTS= option in the PROC statement. You can specify more than one plot request with the PLOTS= option. Table 74.11 summarizes these requests.

In addition to the PLOTS= option, you must specify the ODS GRAPHICS statement. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

The names of the graphs that PROC ROBUSTREG generates are listed in Table 74.12, along with the required statements and options. The following subsections provide information about these graphs.

Table 74.11 Options for Plots

Option	Plot
ALL	All appropriate plots
DDPLOT	Robust distance vs. Mahalanobis distance
FITPLOT	Robust fit vs. independent variable
HISTOGRAM	Histogram of standardized robust residuals
NONE	No plot
QQPLOT	Q-Q plot of standardized robust residuals
RDPLOT	Standardized robust residual vs. robust distance

Fit Plot

When the model has a single independent continuous variable (with or without the intercept), the ROBUSTREG procedure automatically creates a plot of robust fit against this independent variable.

The following simple example is used to show the fit plot. The data, from Rousseeuw and Leroy (1987, Table 3), include the logarithm of surface temperature and the logarithm of light intensity for 47 stars in the direction of the constellation Cygnus.

```
data star;
   input index x y @@;
   label x = 'Log Temperature'
         y = 'Log Light Intensity';
datalines;
1   4.37  5.23     25  4.38  5.02
2   4.56  5.74     26  4.42  4.66
3   4.26  4.93     27  4.29  4.66
4   4.56  5.74     28  4.38  4.90

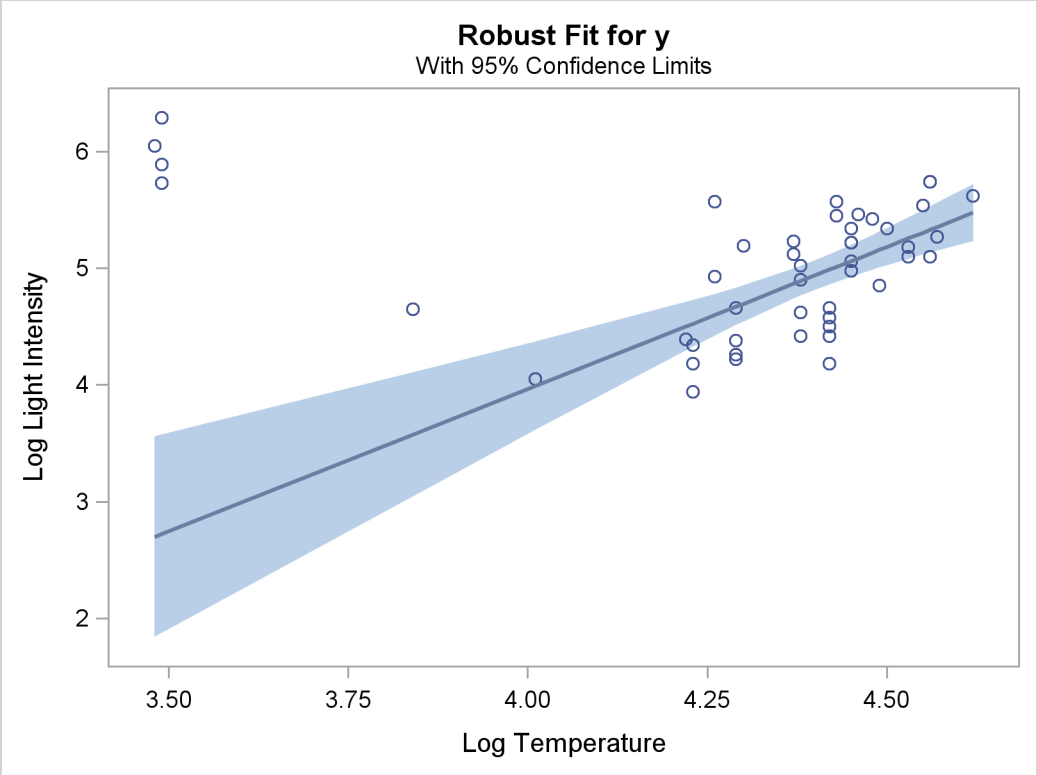
;
```

The fit plot in Figure 74.17, created with the following statements, plots the robust fit of the logarithm of light intensity with the MM method against the logarithm of the surface temperature.



```
ods graphics on;

proc robustreg data=star method=mm ;
    model y = x;
run;

ods graphics off;
```

Confidence limits are added on the plot by default. The NOLIMITS option suppresses these limits.

Figure 74.17 Robust Fit

```
ods graphics on;

proc robustreg data=star method=mm plot=fitplot(nolimits);
    model y = x;
run;

ods graphics off;
```

Distance-Distance Plot

The distance-distance plot (DDPLOT) is mainly used for leverage-point diagnostics. It is a scatter plot of the robust distances against the classical Mahalanobis distances for the continuous independent variables. See the section "Leverage Point and Outlier Detection" on page 5689 for details about the robust distance. If there is a classification variable specified in the model, this plot is not created.

You can use the PLOT=DDPLOT option to request this plot. The following statements use the stack data set in the section "M Estimation" on page 5649 to create the single plot shown in Figure 74.5.

```
ods graphics on;

proc robustreg data=stack plot=ddplot;
   model y = x1 x2 x3;
run;

ods graphics off;
```

The reference lines represent the cutoff values. The diagonal line is also drawn to show the distribution of the distances. By default, all outliers and leverage points are labeled with observation numbers. To change the default, you can use the LABEL= option as described in Table 74.2.

If you specify ID variables in the ID statement, instead of observation numbers, the values of the first ID variable are used as labels.

Residual-Distance Plot

The residual-distance plot (RDPLOT) is used for both outlier and leverage-point diagnostics. It is a scatter plot of the standardized robust residuals against the robust distances. See the section "Leverage Point and Outlier Detection" on page 5689 for details about the robust distance. If there is a classification variable specified in the model, this plot is not created.

You can use the PLOT=RDPLOT option to request this plot. The following statements use the stack data set in the section "M Estimation" on page 5649 to create a single plot shown in Figure 74.4.

```
ods graphics on;

proc robustreg data=stack plot=rdplot;
   model y = x1 x2 x3;
run;

ods graphics off;
```

The reference lines represent the cutoff values. By default, all outliers and leverage points are labeled with observation numbers. To change the default, you can use the LABEL= option as described in Table 74.2.

If you specify ID variables in the ID statement instead of observation numbers, the values of the first ID variable are used as labels.

Histogram and Q-Q Plot

PROC ROBUSTREG produces a histogram and a Q-Q plot for the standardized robust residuals. The histogram is superimposed with a normal density curve and a kernel density curve. Using the stack data set in the section "M Estimation" on page 5649, the following statements create the plots in Figure 74.6 and Figure 74.7.

```
ods graphics on;

proc robustreg data=stack plots=(histogram qqplot);
   model y = x1 x2 x3;
run;

ods graphics off;
```

ODS Graph Names

PROC ROBUSTREG assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 74.12.

To request these graphs you must specify the ODS GRAPHICS statement in addition to the PLOTS= option described in Table 74.11. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

Table 74.12 ODS Graphics Produced by PROC ROBUSTREG

ODS Graph Name	Plot Description	Statement	PLOTS= Option
DDPlot	Robust distance vs. Mahalanobis distance	PROC	DDPLOT
FitPlot	Robust fit vs. independent variable	PROC	FITPLOT
Histogram	Histogram of standardized robust residuals	PROC	HISTOGRAM
QQPlot	Q-Q plot of standardized robust residuals	PROC	QQPLOT
RDPlot	Standardized robust residual vs. robust distance	PROC	RDPLOT

Examples: ROBUSTREG Procedure

Example 74.1: Comparison of Robust Estimates

This example contrasts several of the robust methods available in the ROBUSTREG procedure.

The following statements generate 1000 random observations. The first 900 observations are from a linear model, and the last 100 observations are significantly biased in the y-direction. In other words, 10% of the observations are contaminated with outliers.

```
data a (drop=i);
   do i=1 to 1000;
      x1=rannor(1234);
      x2=rannor(1234);
      e=rannor(1234);
      if i > 900 then y=100 + e;
      else y=10 + 5*x1 + 3*x2 + .5 * e;
      output;
   end;
run;
```

The following statements invoke PROC REG and PROC ROBUSTREG with the data set a.

```
proc reg data=a;
   model y = x1 x2;
run;
proc robustreg data=a method=m ;
   model y = x1 x2;
run;
proc robustreg data=a method=mm;
   model y = x1 x2;
run;
proc robustreg data=a method=s ;
   model y = x1 x2;
run;
proc robustreg data=a method=lts ;
   model y = x1 x2;
run;
```

The tables of parameter estimates generated with the ROBUSTREG procedure by using M estimation, MM estimation, S estimation, and LTS estimation are shown in Output 74.1.2, Output 74.1.3, Output 74.1.4, and Output 74.1.5, respectively. For comparison, the ordinary least squares (OLS) estimates produced by the REG procedure (Chapter 73, "The REG Procedure") are shown in Output 74.1.1. The four robust methods, M, MM, S, and LTS, correctly estimate the regression coefficients for the underlying model (10, 5, and 3), but the OLS estimate does not.

The next statements demonstrate that if the percentage of contamination is increased to 40%, the M method and the MM method with default options fail to estimate the underlying model. Output 74.1.6 and Output 74.1.7 display these estimates. However, by tuning the constant c for the M method and the constants INITH and K0 for the MM method, you can increase the breakdown values of the estimates and capture the right model. Output 74.1.8 and Output 74.1.9 display these estimates. Similarly, you can tune the constant EFF for the S method and the constant H for the LTS method and correctly estimate the underlying model with these methods. Results are not presented.

```
data b (drop=i);

When there are bad leverage points, the M method fails to estimate the underlying model no matter what constant c you use. In this case, other methods (LTS, S, and MM) in PROC ROBUSTREG, which are robust to bad leverage points, will correctly estimate the underlying model.

The following statements generate 1000 observations with 1% bad high leverage points.

```
data c (drop=i);
   do i=1 to 1000;
      x1=rannor(1234);
      x2=rannor(1234);
      e=rannor(1234);
      if i > 600 then y=100 + e;
      else y=10 + 5*x1 + 3*x2 + .5 * e;
      if i < 11 then x1=200 * rannor(1234);
      if i < 11 then x2=200 * rannor(1234);
      if i < 11 then y= 100*e;
      output;
   end;
run;
proc robustreg data=c method=mm(inith=502 k0=1.8);
   model y = x1 x2;
run;
proc robustreg data=c method=s(k0=1.8);
   model y = x1 x2;
run;
proc robustreg data=c method=lts(h=502);

Example 74.2: Robust ANOVA

The classical analysis of variance (ANOVA) technique based on least squares assumes that the underlying experimental errors are normally distributed. However, data often contain outliers due to recording or other errors. In other cases, extreme responses occur when control variables in the experiments are set to extremes. It is important to distinguish these extreme points and determine

whether they are outliers or important extreme cases. You can use the ROBUSTREG procedure for robust analysis of variance based on M estimation. Typically, there are no high leverage points in a well-designed experiment, so M estimation is appropriate.

The following example shows how to use the ROBUSTREG procedure for robust ANOVA.

An experiment was carried out to study the effects of two successive treatments (T1, T2) on the recovery time of mice with certain diseases. Sixteen mice were randomly assigned into four groups for the four different combinations of the treatments. The recovery times (time) were recorded (in hours) as shown in the following data set recover.

```
data recover;
   input  T1 $ T2 $ time @@;
datalines;
0 0 20.2  0 0 23.9  0 0 21.9  0 0 42.4
1 0 27.2  1 0 34.0  1 0 27.4  1 0 28.5
0 1 25.9  0 1 34.5  0 1 25.1  0 1 34.2
1 1 35.0  1 1 33.9  1 1 38.3  1 1 39.9
;
```

The following statements invoke the GLM procedure (Chapter 39, "The GLM Procedure") for a standard ANOVA.

```
proc glm data=recover;
    class T1 T2;
    model time = T1 T2 T1*T2;
run;
```

Output 74.2.1 Overall ANOVA

The GLM Procedure

Dependent Variable: time

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	3	209.9118750	69.9706250	1.86	0.1905
Error	12	451.9225000	37.6602083		
Corrected Total	15	661.8343750			

R-Square	Coeff Var	Root MSE	time Mean

Example 74.3: Growth Study of De Long and Summers

Robust regression and outlier detection techniques have considerable applications to econometrics. The following example from Zaman, Rousseeuw, and Orhan (2001) shows how these techniques substantially improve the ordinary least squares (OLS) results for the growth study of De Long and Summers.

De Long and Summers (1991) studied the national growth of 61 countries from 1960 to 1985 by using OLS with the following data set growth.

```
data growth;
   input country$ GDP LFG EQP NEQ GAP @@;
datalines;
Argentin  0.0089 0.0118 0.0214 0.2286 0.6079

The regression equation they used is

$$GDP = \beta_0 + \beta_1 LFG + \beta_2 GAP + \beta_3 EQP + \beta_4 NEQ + \epsilon$$

where the response variable is the growth in gross domestic product per worker (GDP) and the regressors are labor force growth (LFG), relative GDP gap (GAP), equipment investment (EQP), and nonequipment investment (NEQ).

The following statements invoke the REG procedure (Chapter 73, "The REG Procedure") for the OLS analysis:

```
proc reg data=growth;
   model GDP  = LFG GAP EQP NEQ ;
run;
```

Output 74.3.1 OLS Estimates

The REG Procedure
Model: MODEL1
Dependent Variable: GDP

Parameter Estimates

Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	1	−0.01430	0.01028	−1.39	0.1697
LFG	1	−0.02981	0.19838	−0.15	0.8811
GAP	1	0.02026	0.00917	2.21	0.0313
EQP	1	0.26538	0.06529	4.06	0.0002
NEQ	1	0.06236	0.03482	1.79	0.0787

The OLS analysis shown in Output 74.3.1 indicates that GAP and EQP have a significant influence on GDP at the 5% level.

The following statements invoke the ROBUSTREG procedure with the default M estimation.

```
ods graphics on;

proc robustreg data=growth plots=all;
   model GDP  = LFG GAP EQP NEQ / diagnostics leverage;
   id country;
run;

ods graphics off;
```

Output 74.3.2 displays model information and summary statistics for variables in the model.

Output 74.3.2 Model Fitting Information and Summary Statistics

The ROBUSTREG Procedure

Model Information

Data Set	WORK.GROWTH

GAP	0.5796	0.8015	0.8863	0.7258	0.2181	0.1778
EQP	0.0265	0.0433	0.0720	0.0523	0.0296	0.0325
NEQ	0.0956	0.1356	0.1812	0.1399	0.0570	0.0624
GDP	0.0121	0.0231	0.0310	0.0224	0.0155	0.0150

Output 74.3.3 displays the M estimates. Besides GAP and EQP, the robust analysis also indicates that NEQ is significant. This new finding is explained by Output 74.3.4, which shows that Zambia, the 60th country in the data, is an outlier. Output 74.3.4 also identifies leverage points based on the robust MCD distances; however, there are no serious high-leverage points in this data set.

Output 74.3.3 M Estimates

Overview: RSREG Procedure

The RSREG procedure uses the method of least squares to fit quadratic response surface regression models. Response surface models are a kind of general linear model in which attention focuses on characteristics of the fit response function and in particular, where optimum estimated response values occur.

In addition to fitting a quadratic function, you can use the RSREG procedure to do the following:

- test for lack of fit
- test for the significance of individual factors
- analyze the canonical structure of the estimated response surface
- compute the ridge of optimum response
- predict new values of the response

The RSREG procedure uses ODS Graphics to display the response surfaces, residuals, fit diagnostics, and ridges of optimum response. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS."

Comparison to Other SAS Software

Other SAS/STAT procedures can be used to fit the response surface, but the RSREG procedure is more specialized. PROC RSREG uses a much more compact model syntax than other procedures; for example, the following statements model a three-factor response surface in the REG, GLM, and RSREG procedures:

```
proc reg;
   model y=x1 x1*x1
            x2 x1*x2 x2*x2
            x3 x1*x3 x2*x3 x3*x3;
run;

proc glm;
   model y=x1|x2|x3@2;
run;

proc rsreg;
   model y=x1 x2 x3;
run;
```

Additionally, PROC RSREG includes specialized methodology for analyzing the fitted response surface, such as canonical analysis and optimum response ridges.

Note that the ADX Interface in SAS/QC software provides an *interactive* environment for constructing and analyzing many different kinds of experiments, including response surface experiments. The ADX Interface is the preferred interactive SAS System tool for analyzing experiments,

since it includes facilities for checking underlying assumptions and graphically optimizing the response surface; see *Getting Started with the SAS ADX Interface* for more information. The RSREG procedure is appropriate for analyzing experiments in a batch environment.

Terminology

Variables are referred to according to the following conventions:

factor variables	independent variables used to construct the quadratic response surface. To estimate the necessary parameters, each variable must have at least three distinct values in the data. Independent variables must be numeric.
response variables	the dependent variables to which the quadratic response surfaces are fit. Dependent variables must be numeric.
covariates	additional independent variables for use in the regression but not in the formation of the quadratic response surface. Covariates must be numeric.
WEIGHT variable	a variable for weighting the observations in the regression. The WEIGHT variable must be numeric.
ID variables	variables not previously described that are transferred to an output data set containing statistics for each observation in the input data set. This data set is created by using the OUT= option in the PROC RSREG statement. ID variables can be either character or numeric.
BY variables	variables for grouping observations. Separate analyses are obtained for each BY group. BY variables can be either character or numeric.

Getting Started: RSREG Procedure

A Response Surface with a Simple Optimum

This example uses the three-factor quadratic model discussed in John (1971). Settings of the temperature, gas–liquid ratio, and packing height are controlled factors in the production of a certain chemical; Schneider and Stockett (1963) performed an experiment in order to determine the values of these three factors that minimize the unpleasant odor of the chemical. The following statements input the SAS data set smell; the variable Odor is the response, while the variables T, R, and H are the independent factors.

```
title 'Response Surface with a Simple Optimum';
data smell;
   input Odor T R H @@;
   label
      T = "Temperature"
      R = "Gas-Liquid Ratio"
      H = "Packing Height";
   datalines;
 66 40 .3 4     39 120 .3 4     43 40 .7 4     49 120 .7  4
 58 40 .5 2     17 120 .5 2     -5 40 .5 6    -40 120 .5  6
 65 80 .3 2      7  80 .7 2     43 80 .3 6    -22  80 .7  6
-31 80 .5 4    -35  80 .5 4    -26 80 .5 4
;
```

The following statements invoke PROC RSREG on the data set smell. Figure 75.1 through Figure 75.3 display the results of the analysis, including a lack-of-fit test requested with the LACKFIT option.

```
proc rsreg data=smell;
   model Odor = T R H / lackfit;
run;
```

Figure 75.1 displays the coding coefficients for the transformation of the independent variables to lie between −1 and 1, simple statistics for the response variable, hypothesis tests for linear, quadratic, and crossproduct terms, and the lack-of-fit test. The hypothesis tests can be used to gain a rough idea of importance of the effects; here the crossproduct terms are not significant. However, the lack of fit for the model is significant, so more complicated modeling or further experimentation with additional variables should be performed before firm conclusions are made concerning the underlying process.

Figure 75.1 Summary Statistics and Analysis of Variance

Figure 75.1 *continued*

Regression	DF	Type I Sum of Squares	R-Square	F Value	Pr > F
Linear	3	7143.250000	0.3337	4.71	0.0641
Quadratic	3	11445	0.5346	7.55	0.0264
Crossproduct	3	293.500000	0.0137	0.19	0.8965
Total Model	9	18882	0.8820	4.15	0.0657

Residual	DF	Sum of Squares	Mean Square	F Value	Pr > F
Lack of Fit	3	2485.750000	828.583333	40.75	0.0240
Pure Error	2	40.666667	20.333333		
Total Error	5	2526.416667	505.283333		

Parameter estimates and the factor ANOVA are shown in Figure 75.2. Looking at the parameter estimates, you can see that the crossproduct terms are not significantly different from zero, as noted previously. The Estimate column contains estimates based on the raw data, and the Parameter Estimate from Coded Data column contains estimates based on the coded data. The factor ANOVA table displays tests for all four parameters corresponding to each factor—the parameters corresponding to the linear effect, the quadratic effect, and the effects of the crossproducts with each of the other two factors. The only factor with a significant overall effect is R, indicating that the level of noise left unexplained by the model is still too high to estimate the effects of T and H accurately. This might be due to the lack of fit.

Figure 75.2 Parameter Estimates and Hypothesis Tests

Parameter	DF	Estimate	Standard Error	t Value	Pr > |t|	Parameter Estimate from Coded Data
Intercept	1	568.958333	134.609816	4.23	0.0083	-30.666667
T	1	-4.102083	1.489024	-2.75	0.0401	-12.125000
R	1	-1345.833333	335.220685	-4.01	0.0102	-17.000000
H	1	-22.166667	29.780489	-0.74	0.4902	-21.375000
T*T	1	0.020052	0.007311	2.74	0.0407	32.083333
R*T	1	1.031250	1.404907	0.73	0.4959	8.250000
R*R	1	1195.833333	292.454665	4.09	0.0095	47.833333
H*T	1	0.018750	0.140491	0.13	0.8990	1.500000
H*R	1	-4.375000	28.098135	-0.16	0.8824	-1.750000
H*H	1	1.520833	2.924547	0.52	0.6252	6.083333

Factor	DF	Sum of Squares	Mean Square	F Value	Pr > F	Label
T	4	5258.016026	1314.504006	2.60	0.1613	Temperature
R	4	11045	2761.150641	5.46	0.0454	Gas-Liquid Ratio
H	4	3813.016026	953.254006	1.89	0.2510	Packing Height

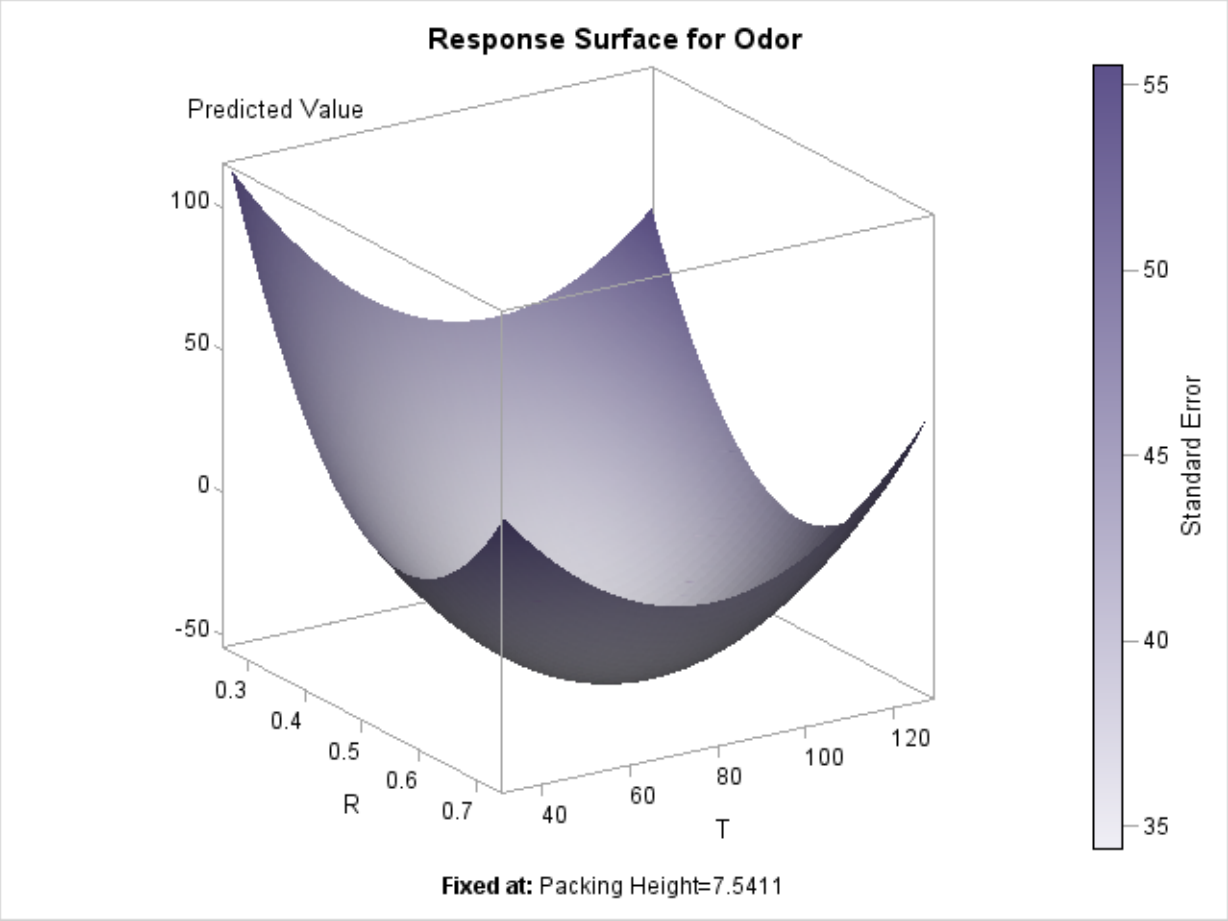
Figure 75.3 displays the canonical analysis and eigenvectors. The canonical analysis indicates that the directions of principal orientation for the predicted response surface are along the axes associated with the three factors, confirming the small interaction effect in the regression ANOVA (Figure 75.1). The largest eigenvalue (48.8588) corresponds to the eigenvector $\{0.238091,\ 0.971116,\ -0.015690\}$, the largest component of which (0.971116) is associated with R; similarly, the second-largest eigenvalue (31.1035) is associated with T. The third eigenvalue (6.0377), associated with H, is quite a bit smaller than the other two, indicating that the response surface is relatively insensitive to changes in this factor. The coded form of the canonical analysis indicates that the estimated response surface is at a minimum when T and R are both near the middle of their respective ranges (that is, the coded critical values for T and R are both near 0) and H is relatively high; in uncoded terms, the model predicts that the unpleasant odor is minimized when T = 84.876502, R = 0.539915, and H = 7.541050.

Figure 75.3 Canonical Analysis and Eigenvectors

	Critical Value		
Factor	Coded	Uncoded	Label
T	0.121913	84.876502	Temperature
R	0.199575	0.539915	Gas-Liquid Ratio
H	1.770525	7.541050	Packing Height

Predicted value at stationary point: -52.024631

	Eigenvectors		
Eigenvalues	T	R	H
48.858807	0.238091	0.971116	-0.015690
31.103461	0.970696	-0.237384	0.037399
6.037732	-0.032594	0.024135	0.999177



Stationary point is a minimum.

To plot the response surface with respect to two of the factor variables, fix H, the least significant factor variable, at its estimated optimum value. The following statements use ODS Graphics to display the surface:

```
ods graphics on;
proc rsreg data=smell
           plots(unpack)=surface(3d at(H=7.541050));
   model Odor = T R H;
   ods select 'T * R = Pred';
run;
ods graphics off;
```

Note that the ODS SELECT statement is specified to select the plot of interest.

Figure 75.4 The Response Surface at the Optimum H

Alternatively, the following statements produce an output data set containing the surface information, which you can then use for plotting surfaces or searching for optima. The first DATA step fixes H, the least significant factor variable, at its estimated optimum value (7.541), and generates a grid of points for T and R. To ensure that the grid data do not affect parameter estimates, the response variable (Odor) is set to missing. (See the section "Missing Values" on page 5738.) The second DATA step concatenates these grid points to the original data. Then PROC RSREG computes predictions for the combined data. The last DATA step subsets the predicted values over just the grid points, which excludes the predictions at the original data.

```
data grid;
   do;
      Odor =  .  ;
      H    = 7.541;
      do T = 20 to 140 by 5;
         do R = .1 to .9 by .05;
            output;
         end;
      end;
   end;
```

```
data grid;
   set smell grid;
run;

proc rsreg data=grid out=predict noprint;
   model Odor = T R H / predict;
run;

data grid;
   set predict;
   if H = 7.541;
run;
```

Syntax: RSREG Procedure

The following statements are available in PROC RSREG.

PROC RSREG < *options* > ;
MODEL *responses= independents* < / *options* > ;
RIDGE < *options* > ;
WEIGHT *variable* ;
ID *variables* ;
BY *variables* ;

The PROC RSREG and MODEL statements are required.

The BY, ID, MODEL, RIDGE, and WEIGHT statements are described after the PROC RSREG statement, and they can appear in any order.

PROC RSREG Statement

PROC RSREG < *options* > ;

The PROC RSREG statement invokes the procedure. You can specify the following options in the PROC RSREG statement.

DATA=*SAS-data-set*
specifies the input SAS data set that contains the data to be analyzed. By default, PROC RSREG uses the most recently created SAS data set.

NOPRINT
suppresses the normal display of results when only the output data set is required.

For more information, see the description of the NOPRINT option in the MODEL and RIDGE statements.

Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, "Using the Output Delivery System," for more information.

OUT=*SAS-data-set*

creates an output SAS data set that contains statistics for each observation in the input data set. In particular, this data set contains the BY variables, the ID variables, the WEIGHT variable, the variables in the MODEL statement, and the output options requested in the MODEL statement. You must specify output statistic options in the MODEL statement; otherwise, the output data set is created but contains no observations. To create a permanent SAS data set, you must specify a two-level name (see *SAS Language Reference: Concepts* for more information about permanent SAS data sets). For more details, see the section "OUT=SAS-data-set" on page 5743.

PLOTS <(*global-plot-option***) >=***plot-request*< *(options)*>

PLOTS <(*global-plot-option***) >=(***plot-request*< *(options)*>< . . . *plot-request*< *(options)*> >)**

controls the plots produced through ODS Graphics. When you specify only one *plot-request*, you can omit the parentheses from around the *plot-request*. For example:

```
plots = all
plots = (diagnostics ridge surface(unpack))
plots(unpack) = surface(overlaypairs)
```

In order to produce plots, you must enable ODS Graphics and specify a *plot-request*, as shown in the following statements:

```
ods graphics on;
proc rsreg plots=all;
   model y=x;
run;
ods graphics off;
```

See Figure 75.4, Output 75.1.5, Output 75.1.6, Output 75.2.3, and Output 75.2.4 for examples of the ODS graphical displays. For general information about ODS graphics, see Chapter 21, "Statistical Graphics Using ODS."

The following *global-plot-option* is available.

UNPACKPANELS | UNPACK

suppresses paneling. By default, multiple plots can appear in some output *panels*. Specify the UNPACK option to display each plot separately.

The following *plot-requests* are available.

ALL

produces all appropriate plots. You can specify other options with ALL; for example, to display all plots and unpack the SURFACE contours you can specify `plots=(all surface(unpack))`.

DIAGNOSTICS <(LABEL | UNPACK)>

displays a panel of summary fit diagnostic plots. The plots produced and their usage are discussed in Table 75.1.

Table 75.1 Diagnostic Plots

Diagnostic Plot	Usage
Cook's *D* statistic versus observation number	Evaluate influence of an observation on the entire parameter estimate vector
Dependent variable values versus predicted values	Evaluate adequacy of fit and detect influential observations
Externally studentized residuals (RStudent) versus leverage	Detect outliers and influential (high-leverage) observations
Externally studentized residuals versus predicted values	Evaluate adequacy of fit and detect outliers
Histogram of residuals	Confirm normality of error terms
Normal quantile plot of residuals	Confirm normality and homogeneity of error terms, and detect outliers
Residuals versus predicted values	Evaluate adequacy of fit and detect outliers
Residual-fit (RF) spread plot	side-by-side quantile plots of the centered fit and the residuals show "how much variation in the data is explained by the fit and how much remains in the residuals" (Cleveland 1993)

Observations satisfying RStudent > 2 or RStudent < –2 are called *outliers*, and observations with leverage > $2p/n$ are called *influential*, where n is the number of observations used in fitting the model and p is the number of parameters used in the model (Rawlings, Pantula, and Dickey 1998). Specifying the LABEL option labels the influential and outlying observations—the label is the first ID variable if the ID statement is specified; otherwise, it is the observation number. Note in the Cook's *D* plot that only observations with *D* exceeding $4/n$ are labeled; these are also called influential observations. The UNPACK option displays each diagnostic plot separately. See Output 75.2.3 for an example of the diagnostics panel.

FIT < (GRIDSIZE=*number*) >

plots the predicted values against a single predictor when you have only one factor or only one covariate in the model. The GRIDSIZE= option specifies the number of points at which the fitted values are computed; by default, GRIDSIZE=200.

NONE

suppresses all plots.

RESIDUALS < (UNPACK | SMOOTH) >

displays plots of residuals against each factor and covariate. The UNPACK option displays each residual plot separately. The SMOOTH option overlays a loess smooth on each residual plot; see Chapter 50, "The LOESS Procedure," for more information. See Output 75.1.5 for an example of this plot.

RIDGE <(UNPACK)>
displays the maximum and/or minimum ridge plots. This option is available only when a MAXIMUM or MINIMUM option is specified in the RIDGE statement. The UNPACK option displays the estimated response and factor level ridge plots separately. See Output 75.1.5 for an example of this plot.

SURFACE <(*surface-options*)>
displays the response surface for each response variable and each pair of factors with all other factors and covariates fixed at their means. By default a panel of contour plots is produced; see Output 75.1.6 for an example of this plot. The following *surface-options* can be specified:

3D displays three-dimensional surface plots instead of contour plots. See Figure 75.4 for an example of this plot.

AT <*keyword*><(*variable=value-list* | *keyword* <...*variable=value-list* | *keyword*>)>
specifies fixed values for factors and covariates. You can specify one or more numbers in the *value-list* or one of the following *keywords*:

MIN	sets the variable to its minimum value.
MEAN	sets the variable to its mean value.
MIDRANGE	sets the variable to the middle value: $\frac{\max + \min}{2}$.
MAX	sets the variable to its maximum value.

Specifying a keyword immediately after AT sets the default value of all variables; for example, **`AT MIN`** sets all variables not displayed on an axis to their minimum values. By default, continuous variables are set to their means (**`AT MEAN`**) when they are not used on an axis. For example, if your model contains variables X1, X2, and X3, then specifying **`AT(X1=7 9)`** produces a contour plot of X2 versus X3 fixing X1 $= 7$ and then another contour plot with X1 $= 9$, along with contour plots of X1 versus X2 fixing X3 at its mean, and X1 versus X3 fixing X2 at its mean.

EXTEND=*value* extends the surface *value*-times the range of each factor in each direction, which enables you to see more of the fitted surface. For example, if factor A has range $[0, 10]$, then specifying **`EXTEND=0.1`** will compute and display the surface for A in $[-1, 11]$. You can specify $value \geq 0$; by default, $value = 0.1$.

FILL=PRED | SE | NONE produces a filled contour plot for either the predicted values or the standard errors. FILL=SE is the default. If the 3D option is also specified, then the contour plot is projected onto the surface.

GRIDSIZE=*n* creates an $n \times n$ grid of points at which the estimated values for the surface and standard errors are computed, for $n \geq 1$. By default, $n = 50$.

LINE<=PRED | SE | NONE> produces a contour line plot for either the predicted values or the standard errors. LINE=PRED is the default. If the 3D option is also specified, then specifying LINE displays a grid on the surface, and the other LINE= specifications are ignored.

NODESIGN suppresses the display of the design points on the contour surface plots and the overlaid contour-line plots.

OVERLAYPAIRS produces overlaid contour line plots for all pairs of response variables in addition to the contour surface plots. See Figure 75.6 for an example of this plot.

ROTATE=*angle* rotates the 3D surface plots *angle* degrees, –180 < *angle* < 180. By default, *angle* = 57.

TILT=*angle* tilts the 3D surface plots *angle* degrees, –180 < *angle* < 180. By default, *angle* = 20.

UNPACKPANELS | UNPACK suppresses paneling, and displays each surface plot separately.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC RSREG to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the RSREG procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

ID Statement

ID *variables* **;**

The ID statement names variables that are to be transferred to the data set created by the OUT= option in the PROC RSREG statement.

MODEL Statement

MODEL *responses=independents* < / *options* > **;**

In the MODEL statement, you specify the response (dependent) variables followed by an equal sign and then the independent variables, some of which can be covariates.

Table 75.2 summarizes the *options* available in the MODEL statement. The *statistic options* specify which statistics are output to the OUT= data set. If none of the *statistic options* are selected, the data set is created but contains no observations. The *statistic option* keywords become values of the special variable _TYPE_ in the output data set.

Table 75.2 MODEL Statement Options

Task	Options
Analyze original data	NOCODE
Fit model to first BY group only	BYOUT
Declare covariates	COVAR=
Request additional statistics	PRESS
Request additional tests	LACKFIT
Suppress displayed output	NOANOVA
	NOOPTIMAL
	NOPRINT
Task	**Statistic Options**
Output statistics	ACTUAL
	PREDICT
	RESIDUAL
	L95
	U95
	L95M
	U95M
	D

The following list describes these options in alphabetical order.

ACTUAL
specifies that the observed response values from the input data set be written to the output data set.

BYOUT
uses only the first BY group to estimate the model. Subsequent BY groups have scoring statistics computed in the output data set only. The BYOUT option is used only when a BY statement is specified.

COVAR=*n*

declares that the first *n* variables on the right side of the model are simple linear regressors (covariates) and not factors in the quadratic response surface. By default, PROC RSREG forms quadratic and crossproduct effects for all regressor variables in the MODEL statement.

See the section "Handling Covariates" on page 5741 for more details and Example 75.2 for an example that uses covariates.

D

specifies that Cook's *D* influence statistic be written to the output data set.

See Chapter 4, "Introduction to Regression Procedures," for details and formulas.

LACKFIT

performs a lack-of-fit test.

See Draper and Smith (1981) for a discussion of lack-of-fit tests.

L95

specifies that the lower bound of a 95% confidence interval for an individual predicted value be written to the output data set. The variance used in calculating this bound is a function of both the mean square error and the variance of the parameter estimates.

See Chapter 4, "Introduction to Regression Procedures," for details and formulas.

L95M

specifies that the lower bound of a 95% confidence interval for the expected value of the dependent variable be written to the output data set. The variance used in calculating this bound is a function of the variance of the parameter estimates.

See Chapter 4, "Introduction to Regression Procedures," for details and formulas.

NOANOVA

NOAOV

suppresses the display of the analysis of variance and parameter estimates from the model fit.

NOCODE

performs the canonical and ridge analyses with the parameter estimates derived from fitting the response to the original values of the factor variables, rather than their coded values (see the section "Coding the Factor Variables" on page 5738 for more details). Use this option if the data are already stored in a coded form.

NOOPTIMAL

NOOPT

suppresses the display of the canonical analysis for the quadratic response surface.

NOPRINT

suppresses the display of both the analysis of variance and the canonical analysis.

PREDICT
specifies that the values predicted by the model be written to the output data set.

PRESS
computes and displays the predicted residual sum of squares (PRESS) statistic for each dependent variable in the model. The PRESS statistic is added to the summary information at the beginning of the analysis of variance, so if the NOANOVA or NOPRINT option is specified, then the PRESS option has no effect.

See Chapter 4, "Introduction to Regression Procedures," for details and formulas.

RESIDUAL
specifies that the residuals, calculated as ACTUAL − PREDICTED, be written to the output data set.

U95
specifies that the upper bound of a 95% confidence interval for an individual predicted value be written to the output data set. The variance used in calculating this bound is a function of both the mean square error and the variance of the parameter estimates.

See Chapter 4, "Introduction to Regression Procedures," for details and formulas.

U95M
specifies that the upper bound of a 95% confidence interval for the expected value of the dependent variable be written to the output data set. The variance used in calculating this bound is a function of the variance of the parameter estimates.

See Chapter 4, "Introduction to Regression Procedures," for details and formulas.

RIDGE Statement

RIDGE < *options* > **;**

A RIDGE statement computes the ridge of optimum response. The ridge starts at a given point $\mathbf{x}_0$, and the point on the ridge at radius r from $\mathbf{x}_0$ is the collection of factor settings that optimizes the predicted response at this radius. You can think of the ridge as climbing or falling as fast as possible on the surface of predicted response. Thus, the ridge analysis can be used as a tool to help interpret an existing response surface or to indicate the direction in which further experimentation should be performed.

The default starting point, $\mathbf{x}_0$, has each coordinate equal to the point midway between the highest and lowest values of the factor in the design. The default radii at which the ridge is computed are 0, 0.1, . . ., 0.9, 1. If the ridge analysis is based on the response surface fit to coded values for the factor variables (see the section "Coding the Factor Variables" on page 5738 for details), then this results in a ridge that starts at the point with a coded zero value for each coordinate and extends toward, but not beyond, the edge of the range of experimentation. Alternatively, both the center point of the ridge and the radii at which it is to be computed can be specified.

You can specify the following options in the RIDGE statement:

CENTER=*uncoded-factor-values*
gives the coordinates of the point $\mathbf{x}_0$ from which to begin the ridge. The coordinates should be given in the original (uncoded) factor variable values and should be separated by commas. There must be as many coordinates specified as there are factors in the model, and the order of the coordinates must be the same as that used in the MODEL statement. This starting point should be well inside the range of experimentation. The default sets each coordinate equal to the value midway between the highest and lowest values for the associated factor.

MAXIMUM
MAX
computes the ridge of maximum response. Both the MIN and MAX options can be specified; at least one must be specified.

MINIMUM
MIN
computes the ridge of minimum response. Both the MIN and MAX options can be specified; at least one must be specified.

NOPRINT
suppresses the display of the ridge analysis when only an output data set is required.

OUTR=*SAS-data-set*
creates an output SAS data set containing the computed optimum ridge.

For details, see the section "OUTR=SAS-data-set" on page 5743.

RADIUS=*coded-radii*
gives the distances from the ridge starting point at which to compute the optima. The values in the list represent distances between coded points. The list can take any of the following forms or can be composed of mixtures of them:

$m_1, m_2, \ldots, m_n$	specifies several values.
m TO n	specifies a sequence where m equals the starting value, n equals the ending value, and the increment equals 1.
m TO n BY i	specifies a sequence where m equals the starting value, n equals the ending value, and i equals the increment.

Mixtures of the preceding forms should be separated by commas. The default list runs from 0 to 1 by increments of 0.1. The following are examples of valid lists.

```
radius=0 to 5 by .5;
radius=0, .2, .25, .3, .5 to 1.0 by .1;
```

WEIGHT Statement

WEIGHT *variable* **;**

When a WEIGHT statement is specified, a weighted residual sum of squares

$$\sum_i w_i (y_i - \hat{y}_i)^2$$

is minimized, where w_i is the value of the variable specified in the WEIGHT statement, y_i is the observed value of the response variable, and $\hat{y}_i$ is the predicted value of the response variable.

The observation is used in the analysis only if the value of the WEIGHT statement variable is greater than zero. The WEIGHT statement has no effect on degrees of freedom or number of observations. If the weights for the observations are proportional to the reciprocals of the error variances, then the weighted least squares estimates are best linear unbiased estimators (BLUE).

Details: RSREG Procedure

Introduction to Response Surface Experiments

Many industrial experiments are conducted to discover which values of given factor variables optimize a response. If each factor is measured at three or more values, a quadratic response surface can be estimated by least squares regression. The predicted optimal value can be found from the estimated surface if the surface is shaped like a simple hill or valley. If the estimated surface is more complicated, or if the predicted optimum is far from the region of experimentation, then the shape of the surface can be analyzed to indicate the directions in which new experiments should be performed.

Suppose that a response variable y is measured at combinations of values of two factor variables, x_1 and x_2. The quadratic response surface model for this variable is written as

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_1^2 + \beta_4 x_2^2 + \beta_5 x_1 x_2 + \epsilon$$

The steps in the analysis for such data are as follows:

1. model fitting and analysis of variance, including lack-of-fit testing, to estimate parameters
2. canonical analysis to investigate the shape of the predicted response surface
3. ridge analysis to search for the region of optimum response

Model Fitting and Analysis of Variance

The first task in analyzing the response surface is to estimate the parameters of the model by least squares regression and to obtain information about the fit in the form of an analysis of variance. The estimated surface is typically curved: a *hill* with the peak occurring at the unique estimated point of maximum response, a *valley,* or a *saddle surface* with no unique minimum or maximum. Use the results of this phase of the analysis to answer the following questions:

- What is the contribution of each type of effect—linear, quadratic, and crossproduct—to the statistical fit? The ANOVA table with sources labeled "Regression" addresses this question.
- What part of the residual error is due to lack of fit? Does the quadratic response model adequately represent the true response surface? If you specify the LACKFIT option in the MODEL statement, then the ANOVA table with sources labeled "Residual" addresses this question. See the section "Lack-of-Fit Test" on page 5736 for details.
- What is the contribution of each factor variable to the statistical fit? Can the response be predicted accurately if the variable is removed? The ANOVA table with sources labeled "Factor" addresses this question.
- What are the predicted responses for a grid of factor values? (See the section "Plotting the Surface" on page 5738 and the section "Searching for Multiple Response Conditions" on page 5739.)

Lack-of-Fit Test

The lack-of-fit test compares the variation around the model with *pure* variation within replicated observations. This measures the adequacy of the quadratic response surface model. In particular, if there are n_i replicated observations $Y_{i1}, \ldots, Y_{in_i}$ of the response all at the same values $\mathbf{x}_i$ of the factors, then you can predict the true response at $\mathbf{x}_i$ either by using the predicted value $\hat{Y}_i$ based on the model or by using the mean $\bar{Y}_i$ of the replicated values. The lack-of-fit test decomposes the residual error into a component due to the variation of the replications around their mean value (the *pure* error) and a component due to the variation of the mean values around the model prediction (the *bias* error):

$$\sum_i \sum_{j=1}^{n_i} \left(Y_{ij} - \hat{Y}_i\right)^2 = \sum_i \sum_{j=1}^{n_i} \left(Y_{ij} - \bar{Y}_i\right)^2 + \sum_i n_i \left(\bar{Y}_i - \hat{Y}_i\right)^2$$

If the model is adequate, then both components estimate the nominal level of error; however, if the bias component of error is much larger than the pure error, then this constitutes evidence that there is significant lack of fit.

If some observations in your design are replicated, you can test for lack of fit by specifying the LACKFIT option in the MODEL statement. Note that, since all other tests use total error rather than pure error, you might want to hand-calculate the tests with respect to pure error if the lack of fit is significant. On the other hand, significant lack of fit indicates that the quadratic model is inadequate, so if this is a problem you can also try to refine the model, possibly by using PROC GLM for general

polynomial modeling; see Chapter 39, "The GLM Procedure," for more information. Example 75.1 illustrates the use of the LACKFIT option.

Canonical Analysis

The second task in analyzing the response surface is to examine the overall shape of the curve and determine whether the estimated stationary point is a maximum, a minimum, or a saddle point. The canonical analysis can be used to answer the following questions:

- Is the surface shaped like a hill, a valley, or a saddle, or is it flat?
- If there is a unique optimum combination of factor values, where is it?
- To which factor or factors are the predicted responses most sensitive?

The eigenvalues and eigenvectors in the matrix of second-order parameters characterize the shape of the response surface. The eigenvectors point in the directions of principal orientation for the surface, and the signs and magnitudes of the associated eigenvalues give the shape of the surface in these directions. Positive eigenvalues indicate directions of upward curvature, and negative eigenvalues indicate directions of downward curvature. The larger an eigenvalue is in absolute value, the more pronounced is the curvature of the response surface in the associated direction. Often, all the coefficients of an eigenvector except for one are relatively small, indicating that the vector points roughly along the axis associated with the factor corresponding to the single large coefficient. In this case, the canonical analysis can be used to determine the relative sensitivity of the predicted response surface to variations in that factor. (See the section "Getting Started: RSREG Procedure" on page 5721 for an example.)

Ridge Analysis

If the estimated surface is found to have a simple optimum well within the range of experimentation, the analysis performed by the preceding two steps might be sufficient. In more complicated situations, further search for the region of optimum response is required. The method of ridge analysis computes the estimated ridge of optimum response for increasing radii from the center of the original design. The ridge analysis answers the following question:

- If there is not a unique optimum of the response surface within the range of experimentation, in which direction should further searching be done in order to locate the optimum?

You can use the RIDGE statement to compute the ridge of maximum or minimum response.

Coding the Factor Variables

For the results of the canonical and ridge analyses to be interpretable, the values of different factor variables should be comparable. This is because the canonical and ridge analyses of the response surface are not invariant with respect to differences in scale and location of the factor variables. The analysis of variance is not affected by these changes. Although the actual predicted surface does not change, its parameterization does. The usual solution to this problem is to code each factor variable so that its minimum in the experiment is -1 and its maximum is 1 and to carry through the analysis with the coded values instead of the original ones. This practice has the added benefit of making 1 a reasonable boundary radius for the ridge analysis since 1 represents approximately the edge of the experimental region. By default, PROC RSREG computes the linear transformation to perform this coding as the data are initially read in, and the canonical and ridge analyses are performed on the model fit to the coded data. The actual form of the coding operation for each value of a variable is

$$coded\ value = (original\ value - M)/S$$

where M is the average of the highest and lowest values for the variable in the design and S is half their difference.

Missing Values

If an observation has missing data for any of the variables used by the procedure, then that observation is not used in the estimation process. If one or more response variables are missing, but no factor or covariate variables are missing, then predicted values and confidence limits are computed for the output data set, but the residual and Cook's D statistic are missing.

Plotting the Surface

Specifying the PLOTS=SURFACE option in the PROC RSREG statement displays contour plots for all pairs of factors in the model (see Example 75.1), while specifying the PLOTS=SURFACE(3D) option displays a three-dimensional surface as shown in Figure 75.4.

You can also generate predicted values for a grid of points with the PREDICT option (see the section "Getting Started: RSREG Procedure" on page 5721 for an example) and then use these values to create a contour plot or a three-dimensional plot of the response surface over a two-dimensional grid. Any two factor variables can be chosen to form the grid for the plot. Several plots can be generated by using different pairs of factor variables.

Searching for Multiple Response Conditions

Suppose you have the following data with two factors and three responses, and you want to find the factor setting that produces responses in a certain region:

```
data a;
   input x1 x2 y1 y2 y3;
   datalines;
-1      -1         1.8 1.940  3.6398
-1       1         2.6 1.843  4.9123
 1      -1         5.4 1.063  6.0128
 1       1         0.7 1.639  2.3629
 0       0         8.5 0.134  9.0910
 0       0         3.0 0.545  3.7349
 0       0         9.8 0.453 10.4412
 0       0         4.1 1.117  5.0042
 0       0         4.8 1.690  6.6245
 0       0         5.9 1.165  6.9420
 0       0         7.3 1.013  8.7442
 0       0         9.3 1.179 10.2762
 1.4142  0         3.9 0.945  5.0245
-1.4142  0         1.7 0.333  2.4041
 0       1.4142    3.0 1.869  5.2695
 0      -1.4142    5.7 0.099  5.4346
;
```

You want to find the values of x1 and x2 that maximize y1 subject to y2<2 and y3<y2+y1. The exact answer is not easy to obtain analytically, but you can obtain a practically feasible solution by checking conditions across a grid of values in the range of interest. First, append a grid of factor values to the observed data, with missing values for the responses:

```
data b;
   set a end=eof;
   output;
   if eof then do;
      y1=.;
      y2=.;
      y3=.;
      do x1=-2 to 2 by .1;
         do x2=-2 to 2 by .1;
            output;
         end;
      end;
   end;
run;
```

Next, use PROC RSREG to fit a response surface model to the data and to compute predicted values for both the observed data and the grid, putting the predicted values in a data set c:

```
proc rsreg data=b out=c;
   model y1 y2 y3=x1 x2 / predict;
run;
```

Finally, find the subset of predicted values that satisfy the constraints, sort by the unconstrained variable, and display the top five predictions:

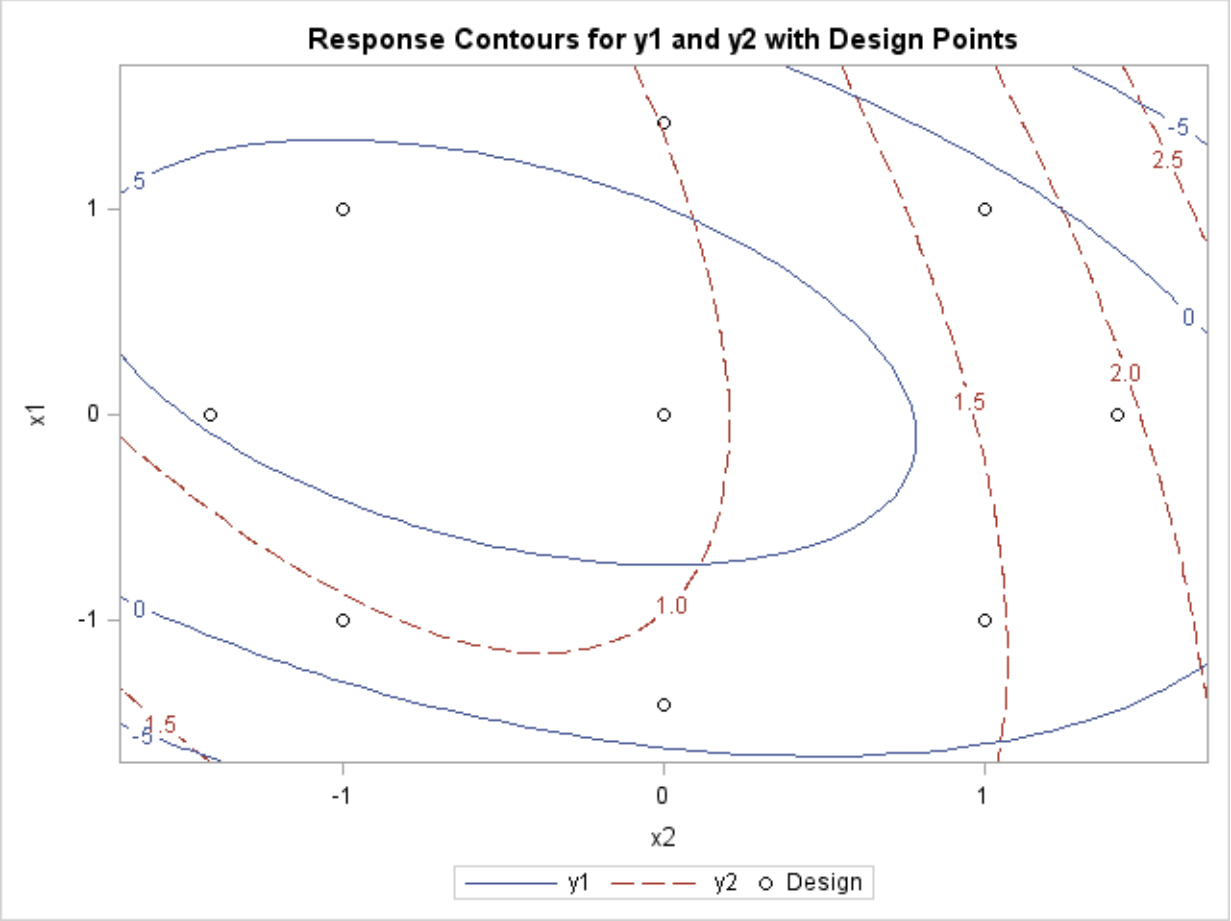
```
data d;
   set c;
   if y2<2;
   if y3<y2+y1;

proc sort data=d;
   by descending y1;
run;

data d; set d;
   if (_n_ <= 5);
proc print;
run;
```

The results are displayed in Figure 75.5. They indicate that optimal values of the factors are around 0.3 for x1 and around –0.5 for x2.

Figure 75.5 Top Five Predictions



Obs	x1	x2	_TYPE_	y1	y2	y3
1	0.3	−0.5	PREDICT	6.92570	0.75784	7.60471
2	0.3	−0.6	PREDICT	6.91424	0.74174	7.54194
3	0.3	−0.4	PREDICT	6.91003	0.77870	7.64341
4	0.4	−0.6	PREDICT	6.90769	0.73357	7.51836
5	0.4	−0.5	PREDICT	6.90540	0.75135	7.56883

If you are also interested in simultaneously optimizing y1 and y2, you can specify the following statements to make a visual comparison of the two response surfaces by overlaying their contour plots:

```
ods graphics on;
proc rsreg data=a plots=surface(overlaypairs);
   model y1 y2=x1 x2;
run;
ods graphics off;
```

Figure 75.6 shows that you have to make some compromises in any attempt to maximize both y1 and y2; however, you might be able to maximize y1 while minimizing y2.

Figure 75.6 Overlaid Line Contours of Predicted Responses

Handling Covariates

Covariate regressors are added to a response surface model because they are believed to account for a sizable yet relatively uninteresting portion of the variation in the data. What the experimenter is really interested in is the response corrected for the effect of the covariates. A common example is the block effect in a block design. In the canonical and ridge analyses of a response surface, which estimate responses at hypothetical levels of the factor variables, the actual value of the predicted response is computed by using the average values of the covariates. The estimated response values do optimize the estimated surface of the response corrected for covariates, but true prediction of the response requires actual values for the covariates. You can use the COVAR= option in the MODEL statement to include covariates in the response surface model. Example 75.2 illustrates the use of this option.

Computational Method

Canonical Analysis

For each response variable, the model can be written in the form

$$y_i = \mathbf{x}_i' \mathbf{A} \mathbf{x}_i + \mathbf{b}' \mathbf{x}_i + \mathbf{c}' \mathbf{z}_i + \epsilon_i$$

where

y_i is the ith observation of the response variable.

$\mathbf{x}_i$ $= (x_{i1}, x_{i2}, \ldots, x_{ik})'$ are the k factor variables for the ith observation.

$\mathbf{z}_i$ $= (z_{i1}, z_{i2}, \ldots, z_{iL})'$ are the L covariates, including the intercept term.

$\mathbf{A}$ is the $k \times k$ symmetrized matrix of quadratic parameters, with diagonal elements equal to the coefficients of the pure quadratic terms in the model and off-diagonal elements equal to half the coefficient of the corresponding crossproduct.

$\mathbf{b}$ is the $k \times 1$ vector of linear parameters.

$\mathbf{c}$ is the $L \times 1$ vector of covariate parameters, one of which is the intercept.

ϵ_i is the error associated with the ith observation. Tests performed by PROC RSREG assume that errors are independently and normally distributed with mean zero and variance σ^2.

The parameters in $\mathbf{A}$, $\mathbf{b}$, and $\mathbf{c}$ are estimated by least squares. To optimize $\mathbf{y}$ with respect to $\mathbf{x}$, take partial derivatives, set them to zero, and solve:

$$\frac{\partial y}{\partial \mathbf{x}} = 2\mathbf{x}'\mathbf{A} + \mathbf{b}' = \mathbf{0} \quad \Longrightarrow \quad \mathbf{x} = -\frac{1}{2}\mathbf{A}^{-1}\mathbf{b}$$

You can determine if the solution is a maximum or minimum by looking at the eigenvalues of $\mathbf{A}$:

If the eigenvalues...	then the solution is...
are all negative	a maximum
are all positive	a minimum
have mixed signs	a saddle point
contain zeros	in a flat area

Ridge Analysis

If the largest eigenvalue is positive, its eigenvector gives the direction of steepest ascent from the stationary point; if the largest eigenvalue is negative, its eigenvector gives the direction of steepest descent. The eigenvectors corresponding to small or zero eigenvalues point in directions of relative flatness.

The point on the optimum response ridge at a given radius R from the ridge origin is found by optimizing

$$(\mathbf{x}_0 + \mathbf{d})'\mathbf{A}(\mathbf{x}_0 + \mathbf{d}) + \mathbf{b}'(\mathbf{x}_0 + \mathbf{d})$$

over $\mathbf{d}$ satisfying $\mathbf{d}'\mathbf{d} = R^2$, where $\mathbf{x}_0$ is the $k \times 1$ vector containing the ridge origin and $\mathbf{A}$ and $\mathbf{b}$ are as previously discussed. By the method of Lagrange multipliers, the optimal $\mathbf{d}$ has the form

$$\mathbf{d} = -(\mathbf{A} - \mu\mathbf{I})^{-1}(\mathbf{A}\mathbf{x}_0 + 0.5\mathbf{b})$$

where $\mathbf{I}$ is the $k \times k$ identity matrix and μ is chosen so that $\mathbf{d}'\mathbf{d} = R^2$. There can be several values of μ that satisfy this constraint; the correct one depends on which sort of response ridge is of interest. If you are searching for the ridge of maximum response, then the appropriate μ is the unique one that satisfies the constraint and is greater than all the eigenvalues of $\mathbf{A}$. Similarly, the appropriate μ for the ridge of minimum response satisfies the constraint and is less than all the eigenvalues of $\mathbf{A}$. (See Myers and Montgomery (1995) for details.)

Output Data Sets

OUT=SAS-data-set

An output data set containing statistics requested with options in the MODEL statement for each observation in the input data set is created whenever the OUT= option is specified in the PROC RSREG statement. The data set contains the following variables:

- the BY variables
- the ID variables
- the WEIGHT variable
- the independent variables in the MODEL statement
- the variable _TYPE_, which identifies the observation type in the output data set. _TYPE_ is a character variable with a length of eight, and it takes on the values 'ACTUAL', 'PREDICT', 'RESIDUAL', 'U95M', 'L95M', 'U95', 'L95', and 'D', corresponding to the options specified.
- the response variables containing special output values identified by the _TYPE_ variable

All confidence limits use the two-tailed Student's t value.

OUTR=SAS-data-set

An output data set containing the optimum response ridge is created when the OUTR= option is specified in the RIDGE statement. The data set contains the following variables:

- the current values of the BY variables
- a character variable _DEPVAR_ containing the name of the dependent variable

- a character variable _TYPE_ identifying the type of ridge being computed, MINIMUM or MAXIMUM. If both MAXIMUM and MINIMUM are specified, the data set contains observations for the minimum ridge followed by observations for the maximum ridge.
- a numeric variable _RADIUS_ giving the distance from the ridge starting point
- the values of the model factors at the estimated optimum point at distance _RADIUS_ from the ridge starting point
- a numeric variable _PRED_, which is the estimated expected value of the dependent variable at the optimum
- a numeric variable _STDERR_, which is the standard error of the estimated expected value

Displayed Output

All estimates and hypothesis tests assume that the model is correctly specified and the errors are distributed according to classical statistical assumptions.

The output displayed by PROC RSREG includes the following.

Estimation and Analysis of Variance

- The actual form of the coding operation for each value of a variable is

$$coded\ value = \frac{1}{S}(original\ value - M)$$

  where M is the average of the highest and lowest values for the variable in the design and S is half their difference. The Subtracted off column contains the M values for this formula for each factor variable, and S is found in the Divided by column.

- The summary table for the response variable contains the following information.
  - "Response Mean" is the mean of the response variable in the sample. When a WEIGHT statement is specified, the mean $\bar{y}$ is calculated by

$$\bar{y} = \frac{\sum_i w_i y_i}{\sum_i w_i}$$

  - "Root MSE" estimates the standard deviation of the response variable and is calculated as the square root of the "Total Error" mean square.
  - The "R-Square" value is R^2, or the coefficient of determination. R^2 measures the proportion of the variation in the response that is attributed to the model rather than to random error.
  - The "Coefficient of Variation" is 100 times the ratio of the "Root MSE" to the "Response Mean."

- A table analyzing the significance of the terms of the regression is displayed. Terms are brought into the regression in four steps: (1) the "Intercept" and any covariates in the model, (2) "Linear" terms like X1 and X2, (3) pure "Quadratic" terms like X1*X1 or X2*X2, and (4) "Crossproduct" terms like X1*X2. The table displays the following information:
  - the degrees of freedom in the DF column, which should be the same as the number of corresponding parameters unless one or more of the parameters are not estimable
  - Type I Sum of Squares, also called the sequential sums of squares, which measures the reduction in the error sum of squares as sets of terms (Linear, Quadratic, and so forth) are added to the model
  - R-Square, which measures the portion of total R^2 contributed as each set of terms (Linear, Quadratic, and so forth) is added to the model
  - F Value, which tests the null hypothesis that all parameters in the term are zero by using the Total Error mean square as the denominator. This is a test of a Type I hypothesis, containing the usual F test numerator, conditional on the effects of subsequent variables not being in the model.
  - Pr > F, which is the significance value or probability of obtaining at least as great an F ratio given that the null hypothesis is true.
- The Sum of Squares column partitions the "Total Error" into "Lack of Fit" and "Pure Error." When "Lack of Fit" is significant, there is variation around the model other than random error (such as cubic effects of the factor variables).
  - The "Total Error" Mean Square estimates σ^2, the variance.
  - F Value tests the null hypothesis that the variation is adequately described by random error.
- A table containing the parameter estimates from the model is displayed.
  - The Estimate column contains the parameter estimates based on the *uncoded* values of the factor variables. If an effect is a linear combination of previous effects, the parameter for the effect is not estimable. When this happens, the degrees of freedom are zero, the parameter estimate is set to zero, and estimates and tests on other parameters are conditional on this parameter being zero.
  - The Standard Error column contains the estimated standard deviations of the parameter estimates based on *uncoded* data.
  - The t Value column contains t values of a test of the null hypothesis that the true parameter is zero when the *uncoded* values of the factor variables are used.
  - The Pr > |T| column gives the significance value or probability of a greater absolute t ratio given that the true parameter is zero.
  - The Parameter Estimate from Coded Data column contains the parameter estimates based on the *coded* values of the factor variables. These are the estimates used in the subsequent canonical and ridge analyses.
- The sum of squares are partitioned by the factors in the model, and an analysis table is displayed. The test on a factor is a joint test on all the parameters involving that factor. For example, the test for the factor X1 tests the null hypothesis that the true parameters for X1, X1*X1, and X1*X2 are all zero.

Canonical Analysis

- The Critical Value columns contain the values of the factor variables that correspond to the stationary point of the fitted response surface. The critical values can be at a minimum, maximum, or saddle point.
- The eigenvalues and eigenvectors are from the matrix of quadratic parameter estimates based on the coded data. They characterize the shape of the response surface.

Ridge Analysis

- The Coded Radius column contains the distance from the coded version of the associated point to the coded version of the origin of the ridge. The origin is given by the point at radius zero.
- The Estimated Response column contains the estimated value of the response variable at the associated point. The standard error of this estimate is also given. This quantity is useful for assessing the relative credibility of the prediction at a given radius. Typically, this standard error increases rapidly as the ridge moves up to and beyond the design perimeter, reflecting the inherent difficulty of making predictions beyond the range of experimentation.
- The Uncoded Factor Values columns contain the values of the uncoded factor variables that give the optimum response at this radius from the ridge origin.

ODS Table Names

PROC RSREG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 75.3. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 75.3 ODS Tables Produced by PROC RSREG

ODS Table Name	Description	Statement
Coding	Coding coefficients for the independent variables	default
ErrorANOVA	Error analysis of variance	default
FactorANOVA	Factor analysis of variance	default
FitStatistics	Overall statistics for fit	default
ModelANOVA	Model analysis of variance	default
ParameterEstimates	Estimated linear parameters	default
Ridge	Ridge analysis for optimum response	RIDGE
Spectral	Spectral analysis	default
StationaryPoint	Stationary point of response surface	default

ODS Graphics

PROC RSREG assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 75.4.

To request these graphs you must specify the ODS GRAPHICS statement in addition to the PLOTS= option and any other options indicated in Table 75.4. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

Table 75.4 ODS Graphics Produced by PROC RSREG

ODS Graph Name	Plot Description	PLOTS= Option
FitPlot	Fit plot for 1 predictor	FIT
DiagnosticsPanel	Panel of fit diagnostics	DIAGNOSTICS
CooksDPlot	Cook's *D* plot	DIAGNOSTICS(UNPACK)
ObservedByPredicted	Observed by predicted	DIAGNOSTICS(UNPACK)
QQPlot	Residual Q-Q plot	DIAGNOSTICS(UNPACK)
ResidualByPredicted	Residual by predicted values	DIAGNOSTICS(UNPACK)
ResidualHistogram	Residual histogram	DIAGNOSTICS(UNPACK)
RFPlot	RF plot	DIAGNOSTICS(UNPACK)
RStudentByPredicted	Studentized residuals by predicted	DIAGNOSTICS(UNPACK)
RStudentByLeverage	RStudent by hat diagonals	DIAGNOSTICS(UNPACK)
ResidualPlots	Panel of residuals by predictors	RESIDUALS
	Residuals by predictors	RESIDUALS(UNPACK)
RidgePlots	Panel of ridge plot and factors	RIDGE (with RIDGE MAX or MIN)
	Ridge plot	RIDGE(UNPACK) (with RIDGE MAX or MIN)

	Contour plots	SURFACE(UNPACK)
Surface	Panel of 3D surface plots	SURFACE(3D)
	3D surface plots	SURFACE(3D UNPACK)
ContourOverlay	Panel of overlaid line-contour plots	SURFACE(OVERLAYPAIRS)
	Overlaid line-contour plots	SURFACE(OVERLAYPAIRS UNPACK)

Examples: RSREG Procedure

Example 75.1: A Saddle Surface Response Using Ridge Analysis

Myers (1976) analyzes an experiment reported by Frankel (1961) aimed at maximizing the yield of mercaptobenzothiazole (MBT) by varying processing time and temperature. Myers (1976) uses a two-factor model in which the estimated surface does not have a unique optimum. A ridge analysis is used to determine the region in which the optimum lies. The objective is to find the settings of time and temperature in the processing of a chemical that maximize the yield. The following statements produce Output 75.1.1 through Output 75.1.5:

```
data d;
   input Time Temp MBT;
   label Time = "Reaction Time (Hours)"
         Temp = "Temperature (Degrees Centigrade)"
         MBT  = "Percent Yield Mercaptobenzothiazole";
   datalines;
 4.0   250   83.8
20.0   250   81.7
12.0   250   82.4
12.0   250   82.9
12.0   220   84.7
12.0   280   57.9
12.0   250   81.2
 6.3   229   81.3
 6.3   271   83.1
17.7   229   85.3
17.7   271   72.7
 4.0   250   82.0
;
ods graphics on;
proc rsreg data=d plots=(ridge surface);
   model MBT=Time Temp / lackfit;
   ridge max;
run;
ods graphics off;
```

Output 75.1.1 displays the coding coefficients for the transformation of the independent variables to lie between −1 and 1 and some simple statistics for the response variable.

Output 75.1.1 Coding and Response Variable Information

The RSREG Procedure

Coding Coefficients for the Independent Variables

Factor	Subtracted off	Divided by
Time	12.000000	8.000000
Temp	250.000000	30.000000

Response Surface for Variable MBT: Percent Yield Mercaptobenzothiazole

Response Mean	79.916667
Root MSE	4.615964
R-Square	0.8003
Coefficient of Variation	5.7760

Output 75.1.2 shows that the lack of fit for the model is highly significant. Since the quadratic model does not fit the data very well, firm statements about the underlying process should not be based only on the current analysis. Note from the analysis of variance for the model that the test for the time factor is not significant. If further experimentation is undertaken, it might be best to fix Time at a moderate to high value and to concentrate on the effect of temperature. In the actual experiment discussed here, extra runs were made that confirmed the results of the following analysis.

Output 75.1.2 Analyses of Variance

Regression	DF	Type I Sum of Squares	R-Square	F Value	Pr > F
Linear	2	313.585803	0.4899	7.36	0.0243

Output 75.1.2 *continued*

Factor	DF	Sum of Squares	Mean Square	F Value	Pr > F
Time	3	61.290957	20.430319	0.96	0.4704
Temp	3	461.250925	153.750308	7.22	0.0205

Factor	Label
Time	Reaction Time (Hours)
Temp	Temperature (Degrees Centigrade)

The canonical analysis (Output 75.1.3) indicates that the predicted response surface is shaped like a saddle. The eigenvalue of 2.5 shows that the valley orientation of the saddle is less curved than the hill orientation, with an eigenvalue of −9.99. The coefficients of the associated eigenvectors show that the valley is more aligned with Time and the hill with Temp. Because the canonical analysis resulted in a saddle point, the estimated surface does not have a unique optimum.

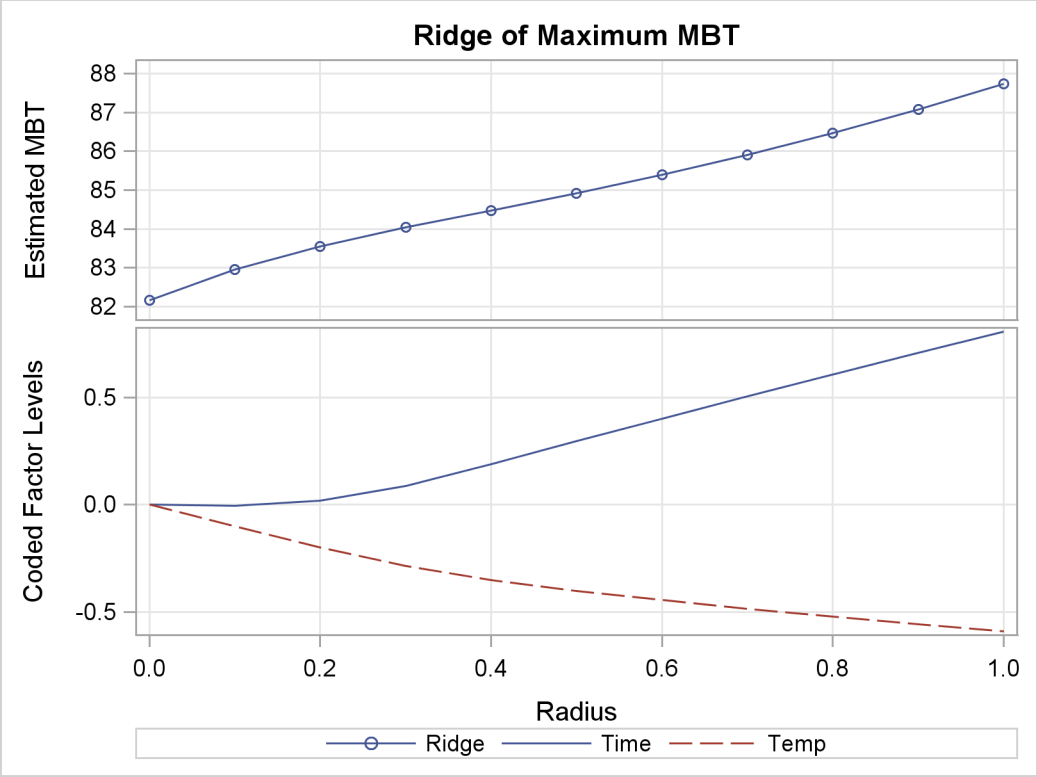
Output 75.1.3 Canonical Analysis

Factor	Critical Value Coded	Uncoded	Label
Time	−0.441758	8.465935	Reaction Time (Hours)
Temp	−0.309976	240.700718	Temperature (Degrees Centigrade)

Predicted value at stationary point: 83.741940

Eigenvalues	Eigenvectors Time	Temp
2.528816	0.953223	−0.302267
−9.996940	0.302267	0.953223

Stationary point is a saddle point.



However, the ridge analysis in Output 75.1.4 and the ridge plot in Output 75.1.5 indicate that maximum yields result from relatively high reaction times and low temperatures. A contour plot of the predicted response surface, shown in Output 75.1.6, confirms this conclusion.

Output 75.1.4 Ridge Analysis

Output 75.1.6 Contour Plot of Predicted Response Surface

Example 75.2: Response Surface Analysis with Covariates

One way of viewing covariates is as extra sources of variation in the dependent variable that can mask the variation due to primary factors. This example demonstrates the use of the COVAR= option in PROC RSREG to fit a response surface model to the dependent variables corrected for the covariates.

You have a chemical process with a yield that you hypothesize to be dependent on three factors: reaction time, reaction temperature, and reaction pressure. You perform an experiment to measure this dependence. You are willing to include up to 20 runs in your experiment, but you can perform no more than 8 runs on the same day, so the design for the experiment is composed of three blocks. Additionally, you know that the grade of raw material for the reaction has a significant impact on the yield. You have no control over this, but you keep track of it. The following statements create a SAS data set containing the results of the experiment:

```
data Experiment;
   input Day Grade Time Temp Pressure Yield;
   datalines;
1 67      -1     -1     -1         32.98
1 68      -1      1      1         47.04
1 70       1     -1      1         67.11
1 66       1      1     -1         26.94
1 74       0      0      0        103.22
1 68       0      0      0         42.94
2 75      -1     -1      1        122.93
2 69      -1      1     -1         62.97
2 70       1     -1     -1         72.96
2 71       1      1      1         94.93
2 72       0      0      0         93.11
2 74       0      0      0        112.97
3 69       1.633  0      0         78.88
3 67      -1.633  0      0         52.53
3 68       0      1.633  0         68.96
3 71       0     -1.633  0         92.56
3 70       0      0      1.633     88.99
3 72       0      0     -1.633    102.50
3 70       0      0      0         82.84
3 72       0      0      0        103.12
;
```

Your first analysis neglects to take the covariates into account. The following statements use PROC RSREG to fit a response surface to the observed yield, but note that Day and Grade are omitted:

```
proc rsreg data=Experiment;
   model Yield = Time Temp Pressure;
run;
```

The ANOVA results shown in Output 75.2.1 indicate that *no* process variable effects are significantly larger than the background noise.

Output 75.2.1 Analysis of Variance Ignoring Covariates

The RSREG Procedure

Regression	DF	Type I Sum of Squares	R-Square	F Value	Pr > F
Linear	3	1880.842426	0.1353	0.67	0.5915
Quadratic	3	2370.438681	0.1706	0.84	0.5023
Crossproduct	3	241.873250	0.0174	0.09	0.9663
Total Model	9	4493.154356	0.3233	0.53	0.8226

Residual	DF	Sum of Squares	Mean Square
Total Error	10	9405.129724	940.512972

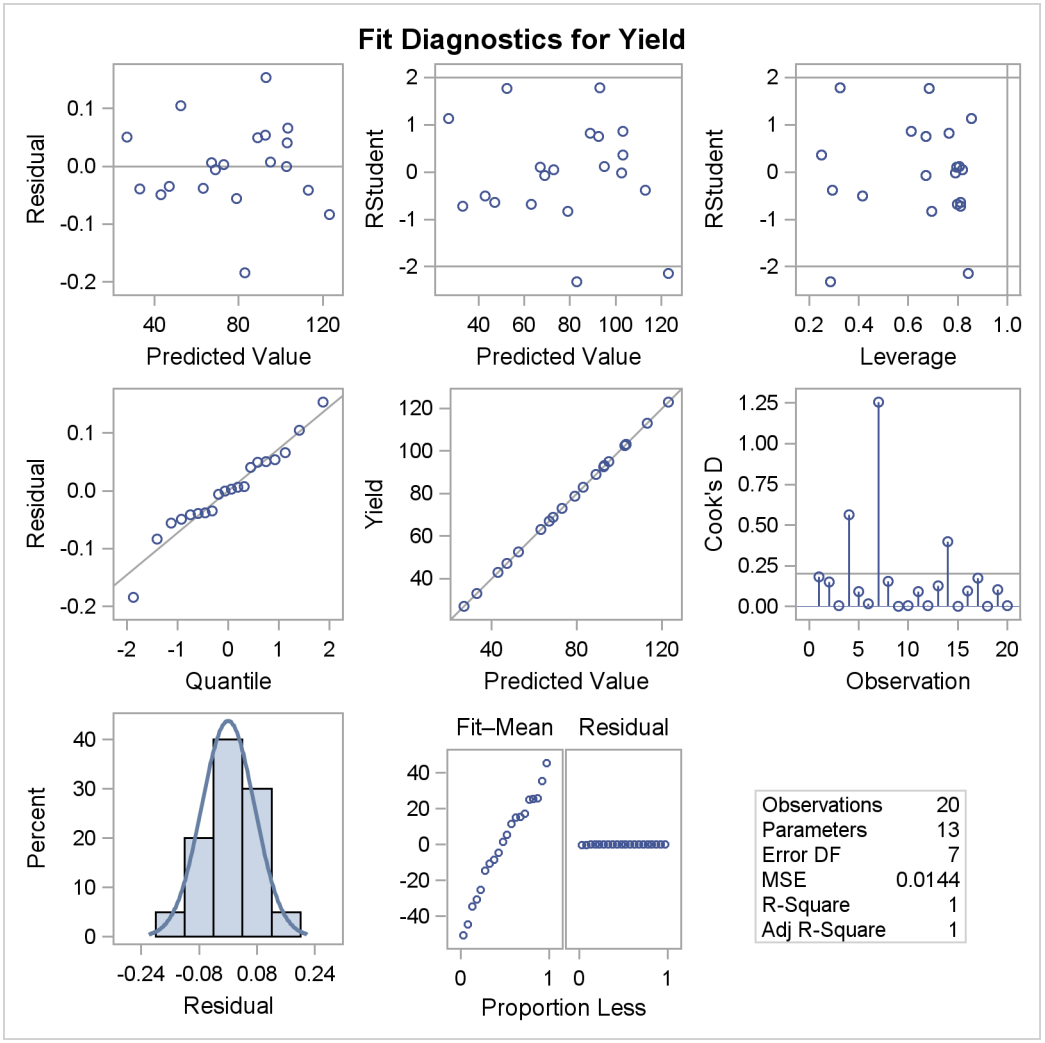
However, when the yields are adjusted for covariate effects of day and grade of raw material, very strong process variable effects are revealed. The following statements produce the ANOVA results in Output 75.2.2. Note that in order to include the effects of the classification factor Day as covariates, you need to create dummy variables indicating each day separately.

```
data Experiment;
   set Experiment;
   d1 = (Day = 1);
   d2 = (Day = 2);
   d3 = (Day = 3);

ods graphics on;
proc rsreg data=Experiment plots=all;
   model Yield = d1-d3 Grade Time Temp Pressure / covar=4;
run;
ods graphics off;
```

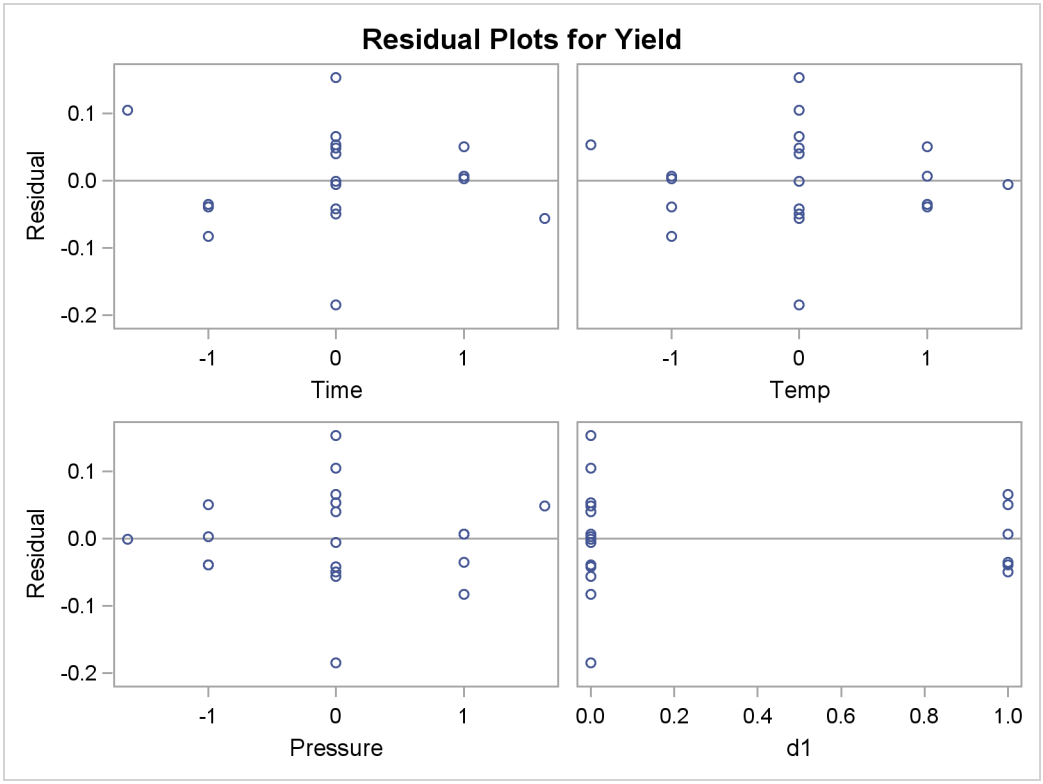
The results show very strong effects due to both the covariates and the process variables.

Output 75.2.2 Analysis of Variance Including Covariates

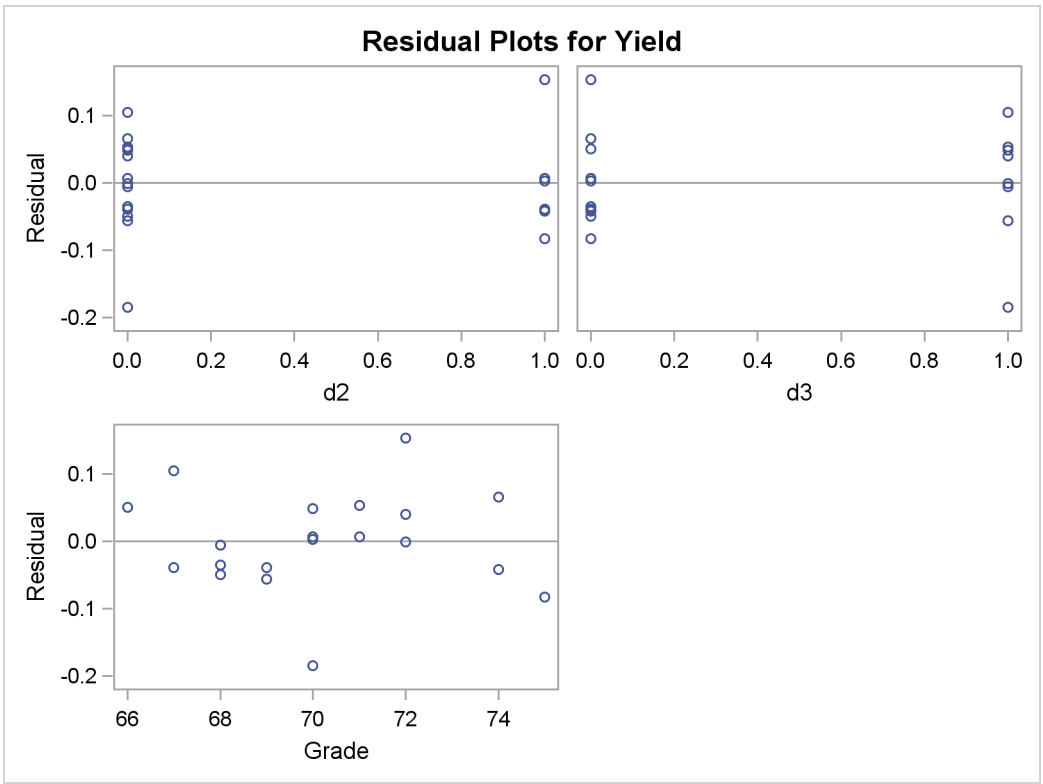


The RSREG Procedure

Regression	DF	Type I Sum of Squares	R-Square	F Value	Pr > F
Covariates	3	13695	0.9854	316957	<.0001
Linear	3	156.524497	0.0113	3622.53	<.0001
Quadratic	3	22.989775	0.0017	532.06	<.0001
Crossproduct	3	23.403614	0.0017	541.64	<.0001
Total Model	12	13898	1.0000	80413.2	<.0001



Residual	DF	Sum of Squares	Mean Square
Total Error	7	0.100820	0.014403



The number of observations in the data set might be too small for the diagnostic plots in Output 75.2.3 to dependably identify problems; however, some outliers are indicated. The residual plots in Output 75.2.4 do not display any obvious structure.

Output 75.2.3 Fit Diagnostics

Output 75.2.4 Residual Plots

Overview: SCORE Procedure

The SCORE procedure multiplies values from two SAS data sets, one containing coefficients (for example, factor-scoring coefficients or regression coefficients) and the other containing raw data to be scored using the coefficients from the first data set. The result of this multiplication is a SAS data set containing linear combinations of the coefficients and the raw data values.

Many statistical procedures output coefficients that PROC SCORE can apply to raw data to produce scores. The new score variable is formed as a linear combination of raw data and scoring coefficients. For each observation in the raw data set, PROC SCORE multiplies the value of a variable in the raw data set by the matching scoring coefficient from the data set of scoring coefficients. This

multiplication process is repeated for each variable in the VAR statement. The resulting products are then summed to produce the value of the new score variable. This entire process is repeated for each observation in the raw data set. In other words, PROC SCORE cross multiplies part of one data set with another.

Raw Data Set

The raw data set can contain the original data used to calculate the scoring coefficients, or it can contain an entirely different data set. The raw data set must contain all the variables needed to produce scores. In addition, the scoring coefficients and the variables in the raw data set that are used in scoring must have the same names. See the section "Getting Started: SCORE Procedure" on page 5762 for more information.

Scoring Coefficients Data Set

The data set containing scoring coefficients must contain two special variables: the _TYPE_ variable and the _NAME_ or _MODEL_ variable.

- The _TYPE_ variable identifies the observations that contain scoring coefficients.
- The _NAME_ or _MODEL_ variable provides a SAS name for the new score variable.

PROC SCORE first looks for a _NAME_ variable in the SCORE= input data set. If there is such a variable, the variable's value is what SCORE uses to name the new score variable. If the SCORE= data set does not have a _NAME_ variable, then PROC SCORE looks for a _MODEL_ variable.

For example, PROC FACTOR produces an output data set that contains factor-scoring coefficients. In this output data set, the scoring coefficients are identified by _TYPE_='SCORE'. For _TYPE_='SCORE', the _NAME_ variable has values of 'Factor1', 'Factor2', and so forth. PROC SCORE gives the new score variables the names Factor1, Factor2, and so forth.

As another example, the REG procedure produces an output data set that contains parameter estimates. In this output data set, the parameter estimates are identified by _TYPE_='PARMS'. The _MODEL_ variable contains the label used in the MODEL statement in PROC REG, or it uses MODEL*n* if no label is specified. This label is the name PROC SCORE gives to the new score variable.

Standardization of Raw Data

PROC SCORE automatically standardizes or centers the DATA= variables for you, based on information from the original variables and analysis from the SCORE= data set.

If the SCORE= scoring coefficients data set contains observations with _TYPE_='MEAN' and _TYPE_='STD', then PROC SCORE standardizes the raw data before scoring. For example, this type of SCORE= data set can come from PROC PRINCOMP without the COV option.

If the SCORE= scoring coefficients data set contains observations with _TYPE_='MEAN' but _TYPE_='STD' is absent, then PROC SCORE centers the raw data (the means are subtracted) before scoring. For example, this type of SCORE= data set can come from PROC PRINCOMP with the COV option.

If the SCORE= scoring coefficients data set does not contain observations with _TYPE_='MEAN' and _TYPE_='STD', or if you use the NOSTD option, then PROC SCORE does not center or standardize the raw data.

If the SCORE= scoring coefficients are obtained from observations with _TYPE_='USCORE', then PROC SCORE "standardizes" the raw data by using the uncorrected standard deviations identified by _TYPE_='USTD', and the means are not subtracted from the raw data. For example, this type of SCORE= data set can come from PROC PRINCOMP with the NOINT option. For more information about _TYPE_='USCORE' scoring coefficients in TYPE=UCORR or TYPE=UCOV output data sets, see Appendix A, "Special SAS Data Sets."

You can use PROC SCORE to score the data that were also used to generate the scoring coefficients, although more typically, scoring results are directly obtained from the OUT= data set in a procedure that computes scoring coefficients. When scoring new data, it is important to realize that PROC SCORE assumes that the new data have approximately the same scales as the original data. For example, if you specify the COV option with PROC PRINCOMP for the original analysis, the scoring coefficients in the PROC PRINCOMP OUTSTAT= data set are not appropriate for standardized data. With the COV option, PROC PRINCOMP will not output _TYPE_='STD' observations to the OUTSTAT= data set, and PROC SCORE will only subtract the means of the original (not new) variables from the new variables before multiplying. Without the COV option in PROC PRINCOMP, both the original variable means and standard deviations will be in the OUTSTAT= data set, and PROC SCORE will subtract the original variable means from the new variables and divide them by the original variable standard deviations before multiplying.

In general, procedures that output scoring coefficients in their OUTSTAT= data sets provide the necessary information for PROC SCORE to determine the appropriate standardization. However, if you use PROC SCORE with a scoring coefficients data set that you constructed without _TYPE_='MEAN' and _TYPE_='STD' observations, you might have to do the relevant centering or standardization of the new data first. If you do this, you must use the means and standard deviations of the original variables—that is, the variables that were used to generate the coefficients—not the means and standard deviations of the variables to be scored.

See the section "Getting Started: SCORE Procedure" on page 5762 for further illustration.

Getting Started: SCORE Procedure

The SCORE procedure multiplies the values from two SAS data sets and creates a new data set to contain the results of the multiplication. The variables in the new data set are linear combinations of the variables in the two input data sets. Typically, one of these data sets contains raw data that you want to score, and the other data set contains scoring coefficients.

The following example demonstrates how to use the SCORE procedure to multiply values from two SAS data sets, one containing factor-scoring coefficients and the other containing raw data to be scored using the scoring coefficients.

Suppose you are interested in the performance of three different types of schools: private schools, state-run urban schools, and state-run rural schools. You want to compare the schools' performances as measured by student grades on standard tests in English, mathematics, and biology. You administer these tests and record the scores for each of the three types of schools.

The following DATA step creates the SAS data set Schools. The data are provided by Chaseling (1996).

```
data Schools;
   input Type $ English Math Biology @@;
   datalines;
p  52  55  45  p  42  49  40  p  63  64  54
p  47  50  51  p  64  69  47  p  63  67  54
p  59  63  42  p  56  61  41  p  41  44  72

... more lines ...

r  50  47  49  r  55  48  46  r  38  36  51
;
```

The data set Schools contains the character variable Type, which represents the type of school. Valid values are p (private schools), r (state-run rural schools), and u (state-run urban schools).

The three numeric variables in the data set are English, Math, and Biology, which represent the student scores for English, mathematics, and biology, respectively. The double trailing at sign (@@) in the INPUT statement specifies that observations are input from each line until all values are read.

The following statements invoke the FACTOR procedure to compute the data set of factor scoring coefficients. The statements perform a principal components factor analysis that uses all three numeric variables in the SAS data set Schools. The OUTSTAT= option requests that PROC FACTOR output the factor scores to the data set Scores. The NOPRINT option suppresses display of the output.

```
proc factor data=Schools score outstat=Scores noprint;
   var english math biology;
run;

proc score data=schools score=Scores out=New;
   var english math biology;
   id type;
run;
```

The SCORE procedure is then invoked using Schools as the raw data set to be scored and Scores as the scoring data set. The OUT= option creates the SAS data set New to contain the linear combinations.

The VAR statement specifies that the variables English, Math, and Biology are used in computing scores. The ID statement copies the variable Type from the Schools data set to the output data set New.

The following statements print the SAS output data set Scores, the first two observations from the original data set Schools, and the first two observations of the resulting data set New.

```
title 'OUTSTAT= Data Set from PROC FACTOR';
proc print data=Scores;
run;

title 'First Two Observations of the DATA= Data Set from PROC SCORE';
proc print data=Schools(obs=2);
run;

title 'First Two Observations of the OUT= Data Set from PROC SCORE';
proc print data=New(obs=2);
run;
```

Figure 76.1 displays the output data set Scores produced by the FACTOR procedure. The last observation (number 11) contains the scoring coefficients (_TYPE_='SCORE'). Only one factor has been retained.

Figure 76.2 lists the first two observations of the original SAS data set (Schools).

Figure 76.2 First Two Observations of the Schools Data Set

First Two Observations of the DATA= Data Set from PROC SCORE

Obs	Type	English	Math	Biology
1	p	52	55	45
2	p	42	49	40

Figure 76.3 lists the first two observations of the output data set New created by PROC SCORE.

Figure 76.3 Listing of the New Data Set

First Two Observations of the OUT= Data Set from PROC SCORE

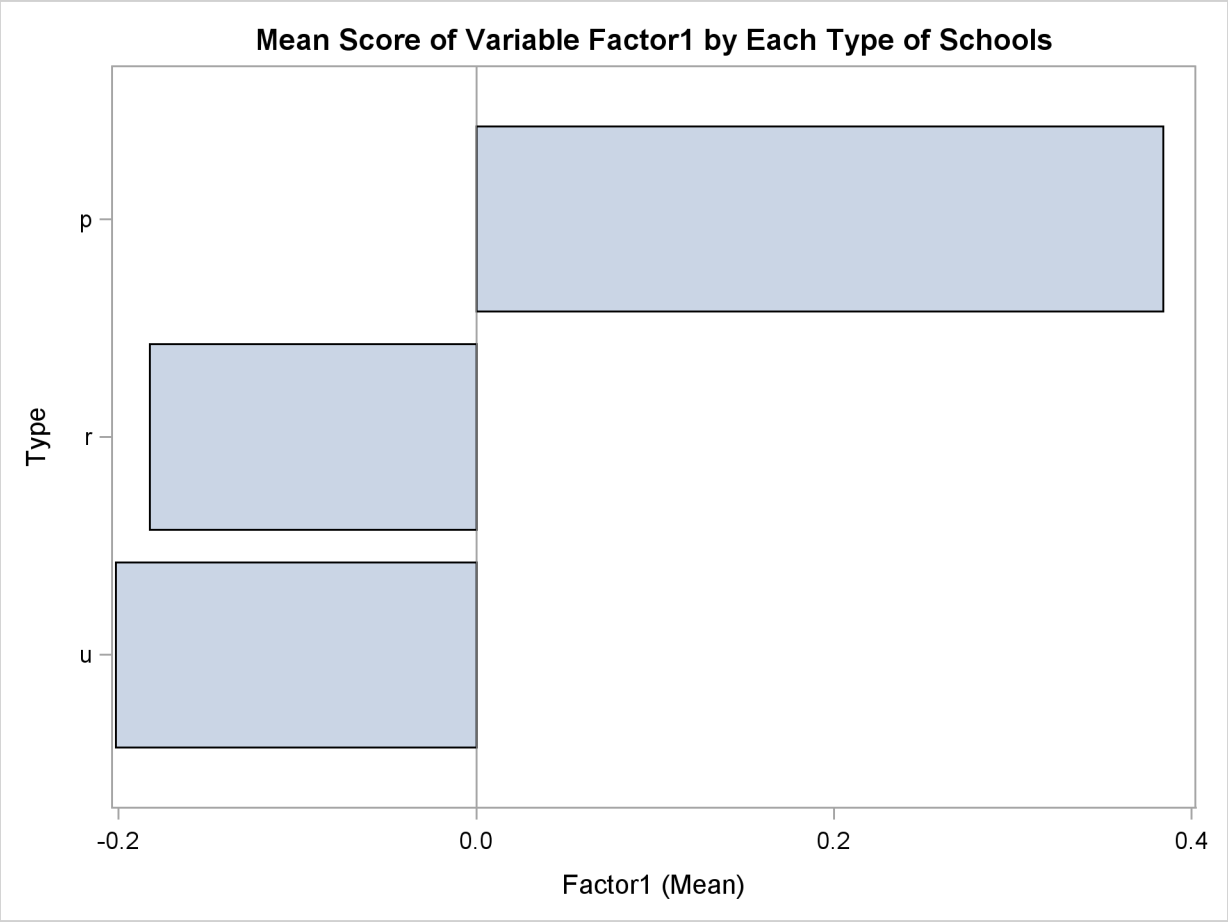
Obs	Type	Factor1
1	p	-0.17604
2	p	-0.80294

The score variable Factor1 in the New data set is named according to the value of the _NAME_ variable in the Scores data set. The values of the variable Factor1 are computed as follows: the DATA= data set variables are standardized using the same means and standard deviations that PROC FACTOR used when extracting the factors because the Scores data set contains observations with _TYPE_='MEAN' and _TYPE_='STD'.

Note that in order to correctly use standardized scoring coefficients created by other procedures such as PROC FACTOR in this example, the data to be scored must be standardized in the same way that the data were standardized when the scoring coefficients were computed. Otherwise, the resulting scores might be incorrect. PROC SCORE does this automatically if the SCORE= data set is the original OUTSTAT= data set output from the procedure creating the scoring coefficients.

These standardized variables are then multiplied by their respective standardized scoring coefficients from the data set Scores. These products are summed over all three variables, and the sum is the value of the new variable Factor1. The first two values of the scored variable Factor1 are obtained as follows:

$$\left(\frac{(52-55.525)}{12.949}\times 0.390\right)+\left(\frac{(55-52.325)}{12.356}\times 0.378\right)+\left(\frac{(45-50.350)}{12.239}\times 0.347\right)=-0.17604$$



$$\left(\frac{(42-55.525)}{12.949}\times 0.390\right)+\left(\frac{(49-52.325)}{12.356}\times 0.378\right)+\left(\frac{(40-50.350)}{12.239}\times 0.347\right)=-0.80294$$

The following statements request that the SGPLOT procedure produce a horizontal bar chart of the variable Type. The length of each bar represents the mean of the variable Factor1.

```
title 'Mean Score of Variable Factor1 by Each Type of Schools';
proc sgplot data=New;
   hbar type / stat = mean response=Factor1;
run;
```

Figure 76.4 displays the mean score of the variable Factor1 for each of the three school types. For private schools (Type=p), the average value of the variable Factor1 is 0.384, while for state-run schools the average values are much lower. The state-run urban schools (Type=u) have the lowest mean value of –0.202, and the state-run rural schools (Type=r) have a mean value of –0.183.

Figure 76.4 Bar Chart of School Type

Syntax: SCORE Procedure

The following statements are available in the SCORE procedure:

PROC SCORE DATA=SAS-data-set< *options* > **;**
BY *variables* **;**
ID *variables* **;**
VAR *variables* **;**

The only required statement is the PROC SCORE statement. The BY, ID, and VAR statements are described following the PROC SCORE statement.

PROC SCORE Statement

PROC SCORE DATA= *SAS-data-set* < *options* > **;**

You can specify the following options in the PROC SCORE statement.

DATA=*SAS-data-set*
names the input SAS data set containing the raw data to score. This option is required.

NOSTD
suppresses centering and scaling of the raw data. Ordinarily, if PROC SCORE finds _TYPE_='MEAN', _TYPE_= 'USCORE', _TYPE_='USTD', or _TYPE_='STD' observations in the SCORE= data set, the procedure uses these to standardize the raw data before scoring.

OUT=*SAS-data-set*
specifies the name of the SAS data set created by PROC SCORE. If you want to create a permanent SAS data set, you must specify a two-level name. See *SAS Language Reference: Concepts* for more information about permanent SAS data sets. If the OUT= option is omitted, PROC SCORE still creates an output data set and automatically names it according to the DATA*n* convention, as if you omitted a data set name in a DATA statement.

PREDICT
specifies that PROC SCORE should treat coefficients of −1 in the SCORE= data set as 0. In regression applications, the dependent variable is coded with a coefficient of −1. Applied directly to regression results, PROC SCORE produces negative residuals (see the description of the RESIDUAL option, which follows); the PREDICT option produces predicted values instead.

RESIDUAL
reverses the sign of each score. Applied directly to regression results, PROC SCORE produces negative residuals (PREDICT−ACTUAL); the RESIDUAL option produces positive residuals (ACTUAL−PREDICT) instead.

SCORE=*SAS-data-set*

names the data set containing the scoring coefficients. If you omit the SCORE= option, the most recently created SAS data set is used. This data set must have two special variables: _TYPE_ and either _NAME_ or _MODEL_.

TYPE=*name* **or** *'string'*

specifies the observations in the SCORE= data set that contain scoring coefficients. The TYPE= procedure option is unrelated to the data set option that has the same name. PROC SCORE examines the values of the special variable _TYPE_ in the SCORE= data set. When the value of _TYPE_ matches TYPE=*name*, the observation in the SCORE= data set is used to score the raw data in the DATA= data set.

If you omit the TYPE= option, scoring coefficients are read from observations with either _TYPE_='SCORE' or _TYPE_='USCORE'. Because the default for PROC SCORE is TYPE=SCORE, you need not specify the TYPE= option for factor scoring or for computing scores from OUTSTAT= data sets from the CANCORR, CANDISC, PRINCOMP, or VARCLUS procedure. When you use regression coefficients from PROC REG, specify TYPE=PARMS.

The maximum length of the argument specified in the TYPE= option depends on the length defined by the VALIDVARNAME= SAS system option. For additional information, see *SAS Language Reference: Dictionary*.

Note that the TYPE= option setting is not case sensitive. For example, the two option settings TYPE='MyScore' and TYPE='myscore' are equivalent.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC SCORE to obtain separate scoring for observations in groups defined by the BY variables. You can also specify a BY statement to apply separate groups of scoring coefficients to the entire DATA= data set.

If your SCORE= input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for PROC SCORE. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide.*

If the DATA= data set does not contain any of the BY variables, the entire DATA= data set is scored by each BY group of scoring coefficients in the SCORE= data set.

If the DATA= data set contains some but not all of the BY variables, or if some BY variables do not have the same type or length in the DATA= data set as in the SCORE= data set, then PROC SCORE prints an error message and stops.

If all the BY variables appear in the DATA= data set with the same type and length as in the SCORE= data set, then each BY group in the DATA= data set is scored using scoring coefficients from the corresponding BY group in the SCORE= data set. The BY groups in the DATA= data set must be in the same order as in the SCORE= data set. All BY groups in the DATA= data set must also appear in the SCORE= data set. If you do not specify the NOTSORTED option, some BY groups can appear in the SCORE= data set but not in the DATA= data set; such BY groups are not used in computing scores.

ID Statement

ID *variables* **;**

The ID statement identifies variables from the DATA= data set to be included in the OUT= data set. If there is no ID statement, all variables from the DATA= data set are included in the OUT= data set. The ID variables can be character or numeric.

VAR Statement

VAR *variables* **;**

The VAR statement specifies the variables to be used in computing scores. These variables must be in both the DATA= and SCORE= input data sets and must be numeric. If you do not specify a VAR statement, the procedure uses all numeric variables in the SCORE= data set. You should almost always specify a VAR statement with PROC SCORE because you would rarely use all the numeric variables in your data set to compute scores.

Details: SCORE Procedure

Missing Values

If one of the scoring variables in the DATA= data set has a missing value for an observation, all the scores have missing values for that observation. The exception to this criterion is that if the PREDICT option is specified, the variable with a coefficient of −1 can tolerate a missing value and still produce a prediction score. Also, a variable with a coefficient of 0 can tolerate a missing value.

If a scoring coefficient in the SCORE= data set has a missing value for an observation, the coefficient is not used in creating the new score variable for the observation. In other words, missing values of scoring coefficients are treated as zeros. This treatment affects only the observation in which the missing value occurs.

Regression Parameter Estimates from PROC REG

If the SCORE= data set is an OUTEST= data set produced by PROC REG and if you specify TYPE=PARMS, the interpretation of the new score variables depends on the PROC SCORE options chosen and the variables listed in the VAR statement. If the VAR statement contains only the independent variables used in a model in PROC REG, the new score variables give the predicted values. If the VAR statement contains the dependent variables and the independent variables used in a model in PROC REG, the interpretation of the new score variables depends on the PROC SCORE options chosen. If you omit both the PREDICT and the RESIDUAL options, the new score variables give negative residuals (PREDICT−ACTUAL). If you specify the RESIDUAL option, the new score variables give positive residuals (ACTUAL−PREDICT). If you specify the PREDICT option, the new score variables give predicted values.

Unless you specify the NOINT option for PROC REG, the OUTEST= data set contains the variable Intercept. The SCORE procedure uses the intercept value in computing the scores.

Output Data Set

PROC SCORE produces an output data set but displays no output. The output OUT= data set contains the following variables:

- the ID variables, if any
- all variables from the DATA= data set, if no ID variables are specified
- the BY variables, if any

- the new score variables, named from the _NAME_ or _MODEL_ values in the SCORE= data set

Computational Resources

Let

v = number of variables used in computing scores
s = number of new score variables
b = maximum number of new score variables in a BY group
n = original input value

Memory

The array storage required is approximately $8(4v + (3 + v)b + s)$ bytes. When you do not use BY processing, the array storage required is approximately $8(4v + (4 + v)s)$ bytes.

Time

The time required to construct the scoring matrix is roughly proportional to vs, and the time needed to compute the scores is roughly proportional to nvs.

Examples: SCORE Procedure

The following three examples use a subset of the Fitness data set. The complete data set is given in Chapter 73, "The REG Procedure."

Example 76.1: Factor Scoring Coefficients

This example shows how to use PROC SCORE with factor scoring coefficients. First, the FACTOR procedure produces an output data set containing scoring coefficients in observations identified by _TYPE_='SCORE'. These data, together with the original data set Fitness, are supplied to PROC SCORE, resulting in a data set containing scores Factor1 and Factor2. The following statements produce Output 76.1.1 through Output 76.1.3:

```
   /* This data set contains only the first 12 observations   */
   /* from the full data set used in the chapter on PROC REG. */
data Fitness;
   input Age Weight Oxygen RunTime RestPulse RunPulse @@;
   datalines;

Since the PROC SCORE statement does not contain the NOSTD option, the data in the Fitness data set are standardized before scoring. For each variable specified in the VAR statement, the mean and standard deviation are obtained from the FactOut data set. For each observation in the Fitness data set, the variables are then standardized. For example, for observation 1 in the Fitness data set, the variable Age is standardized to $0.5569 = [(44 - 42.4167)/2.8431]$.

After the data in the Fitness data set are standardized, the standardized values of the variables in the VAR statement are multiplied by the matching coefficients in the FactOut data set, and the resulting products are summed. This sum is output as a value of the new score variable.

Output 76.1.3 displays the FScore data set produced by PROC SCORE. This data set contains the variables Age, Weight, Oxygen, RunTime, RestPulse, and RunPulse from the Fitness data set. It also contains Factor1 and Factor2, the two new score variables.

Output 76.1.3 OUT= Data Set from PROC SCORE Reproduced with PROC PRINT

Example 76.2: Regression Parameter Estimates

In this example, PROC REG computes regression parameter estimates for the Fitness data. (See Example 76.1 to for more information about how to create the Fitness data set.) The parameter estimates are output to a data set and used as scoring coefficients. For the first part of this example, PROC SCORE is used to score the Fitness data, which are the same data used in the regression.

In the second part of this example, PROC SCORE is used to score a new data set, Fitness2. For PROC SCORE, the TYPE= specification is PARMS, and the names of the score variables are found in the variable _MODEL_, which gets its values from the model label. The following code produces Output 76.2.1 through Output 76.2.3:

```
proc reg data=Fitness outest=RegOut;

OxyHat: model Oxygen=Age Weight RunTime RunPulse RestPulse;
   title 'REGRESSION SCORING EXAMPLE';
run;

proc print data=RegOut;
   title2 'OUTEST= Data Set from PROC REG';
run;

proc score data=Fitness score=RegOut out=RScoreP type=parms;
   var Age Weight RunTime RunPulse RestPulse;
run;

proc print data=RScoreP;
   title2 'Predicted Scores for Regression';
run;
```

```
proc score data=Fitness score=RegOut out=RScoreR type=parms;
   var Oxygen Age Weight RunTime RunPulse RestPulse;
run;

proc print data=RScoreR;
   title2 'Negative Residual Scores for Regression';
run;
```

Output 76.2.1 shows the PROC REG output. The column labeled "Parameter Estimates" lists the parameter estimates. These estimates are output to the RegOut data set.

Output 76.2.1 Creating an OUTEST= Data Set with PROC REG

RestPulse	1	-0.17910	0.13005	-1.38	0.2176

Output 76.2.2 lists the RegOut data set. Note that _TYPE_='PARMS' and _MODEL_='OXYHAT', which are from the label in the MODEL statement in PROC REG.

Output 76.2.2 OUTEST= Data Set from PROC REG Reproduced with PROC PRINT

REGRESSION SCORING EXAMPLE
OUTEST= Data Set from PROC REG

Obs	_MODEL_	_TYPE_	_DEPVAR_	_RMSE_	Intercept	Age
1	OxyHat	PARMS	Oxygen	2.53970	151.916	-0.63045

Obs	Weight	RunTime	RunPulse	Rest Pulse	Oxygen
1	-0.10586	-1.75698	-0.22891	-0.17910	-1

Output 76.2.3 lists the data sets created by PROC SCORE. Since the SCORE= data set does not contain observations with _TYPE_='MEAN' or _TYPE_='STD', the data in the Fitness data set are not standardized before scoring. The SCORE= data set contains the variable Intercept, so this intercept value is used in computing the score. To produce the RScoreP data set, the VAR statement in PROC SCORE includes only the independent variables from the model in PROC REG. As a result, the OxyHat variable contains predicted values. To produce the RScoreR data set, the VAR statement in PROC SCORE includes both the dependent variables and the independent variables from the model in PROC REG. As a result, the OxyHat variable contains negative residuals (PREDICT−ACTUAL) as shown in Output 76.2.4. If the RESIDUAL option is specified, the variable OxyHat contains positive residuals (ACTUAL−PREDICT). If the PREDICT option is specified, the OxyHat variable contains predicted values.

Output 76.2.3 Predicted Scores from the OUT= Data Set Created by PROC SCORE

proc print data=NewPred;
   title2 'Predicted Scores for Regression';
   title3 'for Additional Data from FITNESS2';
run;
```

Output 76.2.5 lists the Fitness2 data set.

Output 76.2.5 Listing of the Fitness2 Data Set

REGRESSION SCORING EXAMPLE
New Raw Data Set to be Scored

Obs	Age	Weight	Oxygen	Run Time	Rest Pulse	Run Pulse
1	45	66.45	44.754	11.12	51	176
2	47	79.15	47.273	10.60	47	162
3	54	83.12	51.855	10.33	50	166
4	49	81.42	49.156	8.95	44	180

PROC SCORE scores the Fitness2 data set by using the parameter estimates in the RegOut data set. These parameter estimates result from fitting a regression equation to the Fitness data set. The NOSTD option is specified, so the raw data are not standardized before scoring. (However, the NOSTD option is not necessary here. The SCORE= data set does not contain observations with _TYPE_='MEAN' or _TYPE_='STD', so standardization is not performed.) The VAR statement contains the dependent variables and the independent variables used in PROC REG. In addition, the PREDICT option is specified. This combination gives predicted values for the new score variable. The name of the new score variable is OxyHat, from the value of the _MODEL_ variable in the SCORE= data set. Output 76.2.6 shows the data set produced by PROC SCORE.

Output 76.2.6 Predicted Scores from the OUT= Data Set Created by PROC SCORE and Reproduced Using PROC PRINT

REGRESSION SCORING EXAMPLE
Predicted Scores for Regression
for Additional Data from FITNESS2

Obs	Age	Weight	Oxygen	Run Time	Rest Pulse	Run Pulse	OxyHat
1	45	66.45	44.754	11.12	51	176	47.5507
2	47	79.15	47.273	10.60	47	162	49.7802
3	54	83.12	51.855	10.33	50	166	43.9682
4	49	81.42	49.156	8.95	44	180	47.5949

Example 76.3: Custom Scoring Coefficients

This example uses a specially created custom scoring data set and produces Output 76.3.1 and Output 76.3.2. The first scoring coefficient creates a variable that is Age−Weight; the second scoring coefficient evaluates the variable RunPulse−RstPulse; and the third scoring coefficient totals all six variables. Since the scoring coefficients data set (data set A) does not contain any observations with _TYPE_='MEAN' or _TYPE_='STD', the data in the Fitness data set (see Example 76.1) are not standardized before scoring.

The following statements produce Output 76.3.1 and Output 76.3.2:

```
data A;
   input _type_ $ _name_ $
         Age Weight RunTime RunPulse RestPulse;
   datalines;
SCORE  AGE_WGT  1 -1  0  0  0
SCORE  RUN_RST  0  0  0  1 -1
SCORE  TOTAL    1  1  1  1  1
;

proc print data=A;
   title 'CONSTRUCTED SCORING EXAMPLE';
   title2 'Scoring Coefficients';
run;

proc score data=Fitness score=A out=B;
   var Age Weight RunTime RunPulse RestPulse;
run;

proc print data=B;
   title2 'Scored Data';
run;
```

Output 76.3.1 Custom Scoring Data Set and Scored Fitness Data: PROC PRINT

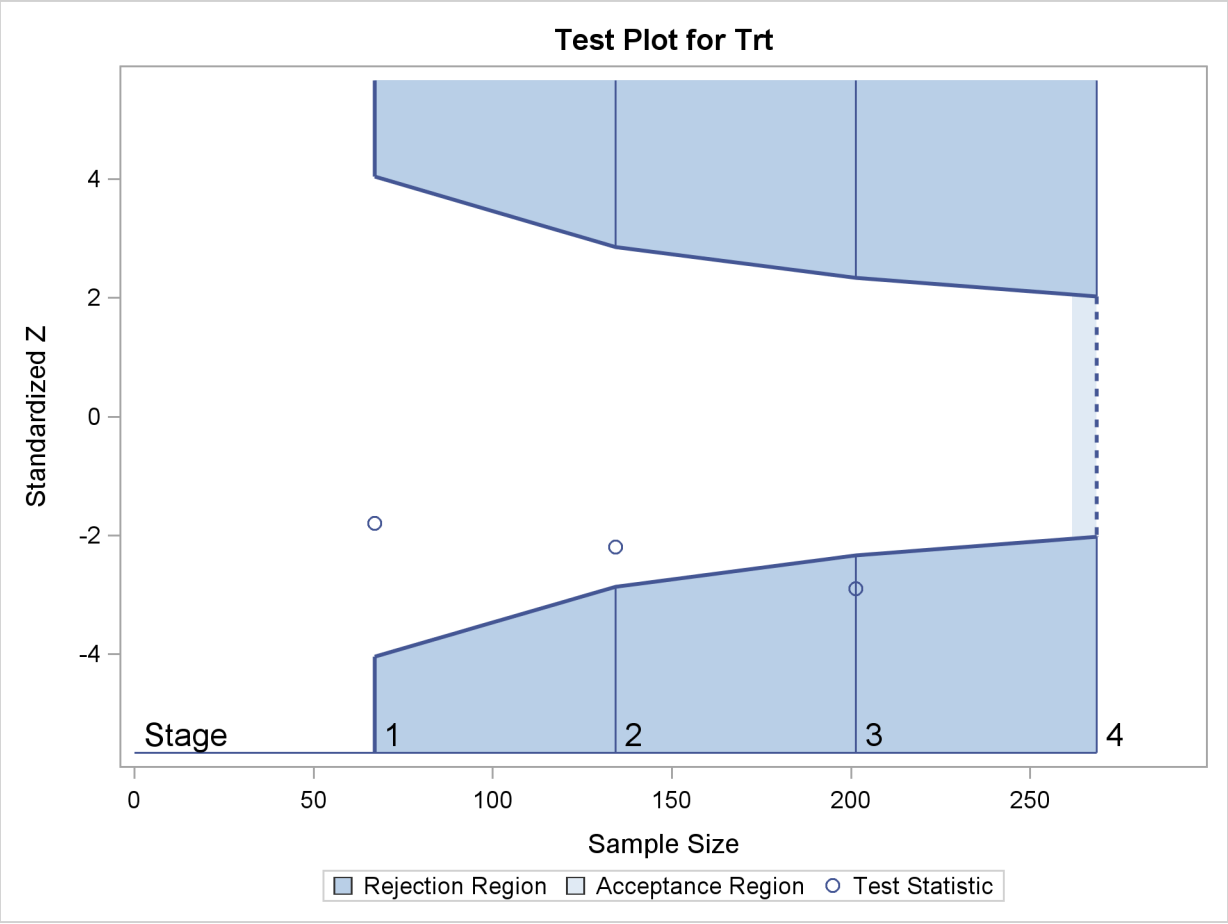
Overview: SEQDESIGN Procedure

The purpose of the SEQDESIGN procedure is to design interim analyses for clinical trials. Clinical trials are experiments on human subjects to demonstrate the efficacy and safety of new drugs or treatments. A simple example is a trial to test the effectiveness of a new drug in humans by comparing the outcomes in a group of patients who receive the new drug with the outcomes in a comparable group of patients who receive a placebo.

A clinical trial is conducted according to a plan called a *protocol*. A protocol details the objectives of the trial, the data collection process, and the analysis. The protocol specifies the null hypothesis and an alternative hypothesis, a test statistic, the probability α of a Type I error, the probability β of a Type II error, the sample size needed to attain a specified power of $1 - \beta$ at an alternative reference, and critical values that are associated with the test statistic.

In a fixed-sample trial, data about all individuals are first collected and then examined at the end of the study. Most major trials have committees that periodically monitor safety and efficacy data during the trial and recommend that a trial be stopped for safety concerns such as an unacceptable toxicity level. In certain situations, the committee might recommend that a trial be stopped for efficacy. In contrast to a fixed-sample trial, a group sequential trial provides for interim analyses before the completion of the trial while maintaining the specified overall Type I and Type II error probabilities.

A group sequential trial is most useful in situations where it is important to monitor the trial to prevent unnecessary exposure of patients to an unsafe new drug, or alternatively to a placebo treatment if the new drug shows significant improvement. In most cases, if a group sequential trial stops early



for safety concerns, fewer patients are exposed to the new treatment than in the fixed-sample trial. If a trial stops early for efficacy reasons, the new treatment is available sooner than it would be in a fixed-sample trial. Early stopping can also save time and resources.

A group sequential design provides detailed specifications for a group sequential trial. In addition to the usual specification for a fixed-sample design, it provides the total number of stages (the number of interim stages plus a final stage) and a stopping criterion to reject, to accept, or to either reject or accept the null hypothesis at each interim stage. It also provides critical values and the sample size at each stage for the trial.

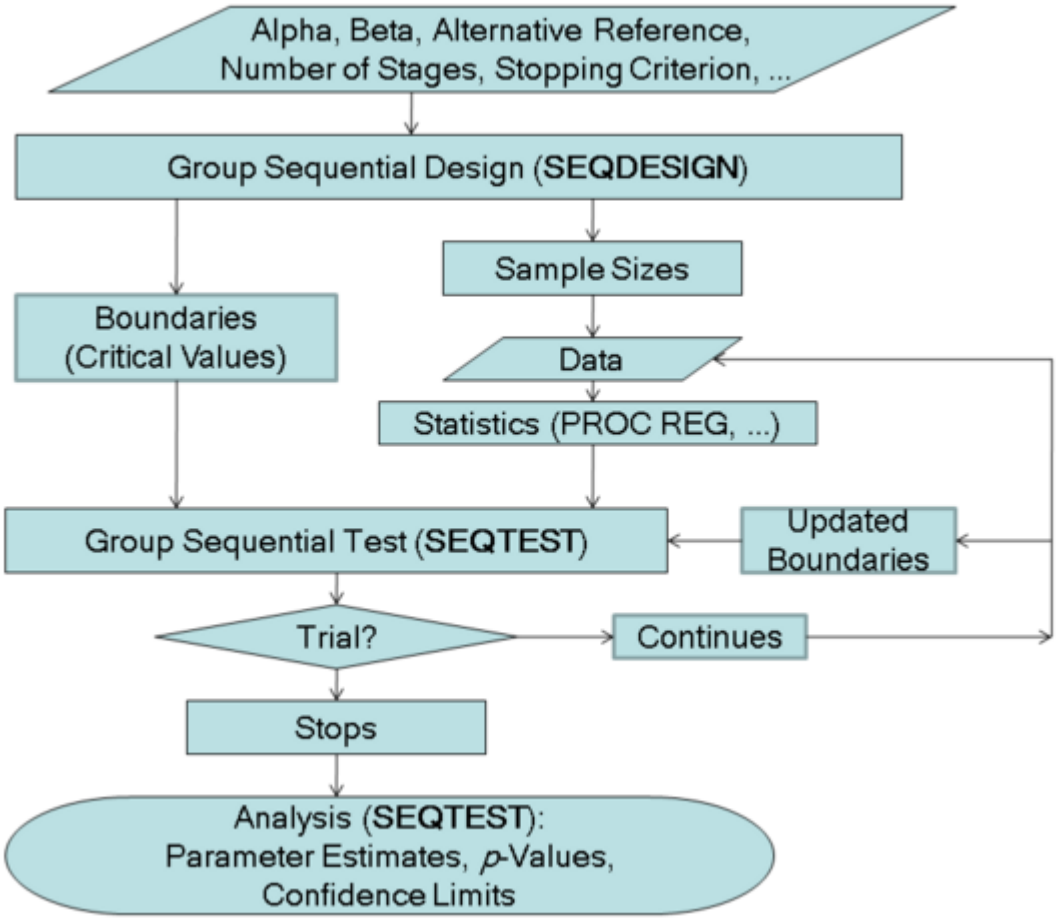
At each interim stage, the data collected at the current stage in addition to the data collected at previous stages are analyzed, and statistics such as a maximum likelihood test statistic and its associated standard error are computed. The test statistic is then compared with critical values that are generated from the sequential design, and the trial is stopped or continued. If a trial continues to the final stage, the null hypothesis is either rejected or accepted. The critical values for each stage are chosen in such a way that the overall α and β are maintained at the specified levels.

Figure 77.1 shows a two-sided symmetric group sequential trial that stops early to reject the null hypothesis that the parameter Trt is zero.

Figure 77.1 Sequential Plot for Two-Sided Test

The trial has four stages, which are indicated by the vertical lines labeled 1, 2, 3, and 4. With early stopping to reject the null hypothesis, the lower rejection boundary is constructed by connecting the lower critical values for the stages. Similarly, the upper rejection boundary is constructed by connecting the upper critical values for the stages. The horizontal axis indicates the sample size for the group sequential trial, and the vertical axis indicates the values of the test statistic on the standardized Z scale.

At each interim stage, if the test statistic falls into a rejection region (the darker shaded areas in Figure 77.1), the trial stops and the null hypothesis is rejected. Otherwise, the trial continues to the next stage. At the final stage (stage 4), the null hypothesis is rejected if Z falls into a rejection region. Otherwise, the null hypothesis is not rejected. In Figure 77.1, the test statistic does not fall into the rejection regions for stages 1 and 2, and so the trial continues to stage 3. At stage 3, the test statistic falls into the rejection region, and the null hypothesis is rejected.



A group sequential trial usually involves six steps:

1. You specify the statistical details of the design, including the null and alternative hypotheses, a test statistic for the hypothesis test, the Type I and II error probabilities, a stopping criterion, the total number of stages, and the relative information level at each stage.
2. You compute the boundary values for the trial based on the specifications in Step 1. You also compute the sample size required at each stage for the specified hypothesis test.
3. At each stage, you collect additional data with the required sample sizes. The data available at each stage include the data collected at previous stages in addition to the data collected at the current stage.
4. At each stage, you analyze the available data with a procedure such as the REG procedure, and you compute the test statistic.
5. At each stage, you compare the test statistic with the corresponding boundary values. You stop the trial to reject or accept the hypothesis, or you continue the trial to the next stage. If you continue the trial to the final stage, you either accept or reject the hypothesis.
6. After the trial stops, you compute parameter estimates, confidence limits for the parameter, and a p-value for the hypothesis test.

You use the SEQDESIGN procedure at Step 2 to compute the initial boundary values and required sample sizes for the trial. You use the companion SEQTEST procedure at Step 5 to compare the test statistic with its boundary values. At stage 1, the boundary values are derived by using the boundary information tables created by the SEQDESIGN procedure. These boundary information tables are structured for input to the SEQTEST procedure. At each subsequent stage, the boundary values are derived by using the test information tables are created by the SEQTEST procedure at the previous stage. These test information tables are also structured for input to the SEQTEST procedure. You also use the SEQTEST procedure at Step 6 to compute parameter estimates, confidence limits, and p-values after the trial stops.

The flowchart in Figure 77.2 summarizes the steps in a typical group sequential trial and the relevant SAS procedures.

Figure 77.2 Group Sequential Trial

Features of the SEQDESIGN Procedure

The SEQDESIGN procedure assumes that the standardized Z test statistics for the null hypothesis $H_0 : \theta = 0$ at the stages have the joint canonical distribution with the information levels at the stages for the parameter θ. This implies that these test statistics are normally distributed. If the test statistic is not normally distributed, then it is assumed that the test statistic is computed from a large sample such that the statistic has an approximately normal distribution. See the section "Statistical Assumptions for Group Sequential Designs" on page 5829 for a detailed description of the joint canonical distribution.

You can use the SEQDESIGN procedure to compute required sample sizes for commonly used hypothesis tests. Note that for a fixed-sample design, you should use the POWER and GLMPOWER procedures to compute sample sizes.

The applicable tests include tests for binomial proportions and the log-rank test for two survival distributions. See the section "Applicable One-Sample Tests and Sample Size Computation" on page 5858, the section "Applicable Two-Sample Tests and Sample Size Computation" on page 5860, and the section "Applicable Regression Parameter Tests and Sample Size Computation" on page 5868 for examples of applicable tests in group sequential trials.

At each stage, the data are analyzed with a statistical procedure such as the REG procedure, and a test statistic and its associated information level are computed. The information level is the amount of information available about the unknown parameter. For a maximum likelihood statistic, the information level is the inverse of its variance.

At each stage, you use the SEQTEST procedure to derive the boundary values that correspond to the information level associated with the test statistic. You then use the SEQTEST procedure to compare the test statistic with these boundary values. When a trial is stopped at an interim stage or at the final stage, the SEQTEST procedure also derives parameter estimates, confidence limits for the parameter, and a p-value for hypothesis testing.

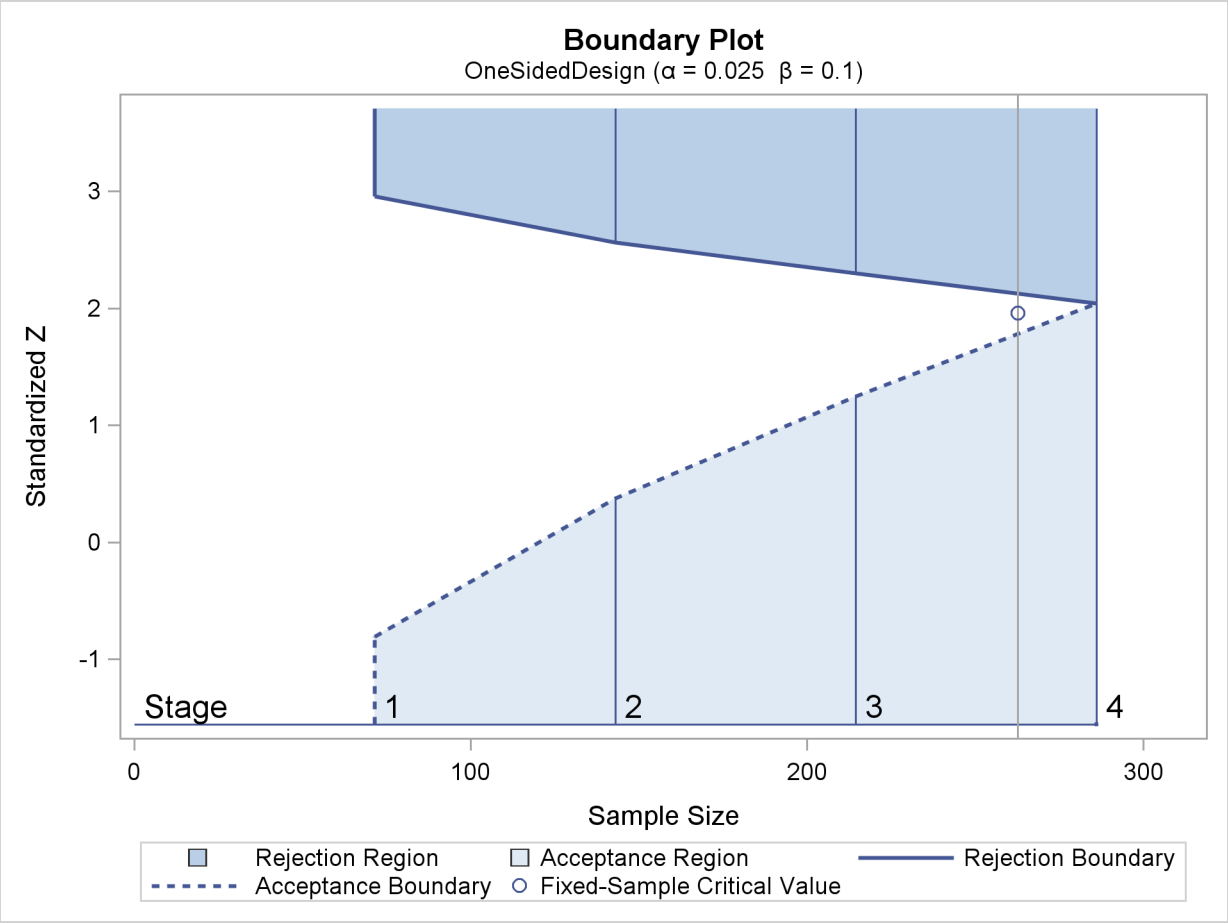
Output from the SEQDESIGN Procedure

In addition to computing the boundary values for a group sequential design, the SEQDESIGN procedure computes the following quantities:

- maximum sample size (as a percentage of the corresponding fixed-sample size) if the trial does not stop at an interim stage
- average sample numbers (as percentages of the corresponding fixed-sample sizes for nonsurvival data or fixed-sample numbers of events for survival data) under various hypothetical references, including the null and alternative references
- stopping probabilities at each stage under various hypothetical references to indicate how likely it is that the trial will stop at that stage
- sample sizes required at each stage for the specified hypothesis test
- numbers of events required at each stage for the specified hypothesis test with survival data

You can create more than one design with multiple DESIGN statements in the SEQDESIGN procedure and then choose the design with the most desirable features. The next two subsections introduce some basic aspects of group sequential designs that are useful for getting started with the SEQDESIGN procedure.

Boundaries for Group Sequential Designs



A one-sided test is a test of a hypothesis with either a lower alternative ($H_1 : \theta < 0$) or an upper alternative ($H_1 : \theta > 0$), and a two-sided test is a test with a two-sided alternative ($H_1 : \theta \neq 0$). The number of critical values for a test depends on whether the alternative is one-sided or two-sided, and it also depends on whether the trial is conducted with a fixed-sample design or a group sequential design.

For a fixed-sample trial, a one-sided test has one critical value and a two-sided test has two critical values. These critical values are computed with the specified Type I error probability α. In contrast, at each interim stage of a group sequential trial, a one-sided test has up to two critical values and a two-sided group sequential test has up to four critical values. Thus, there are two or four possible

boundaries for a group sequential design, and each boundary is a set of critical values, one from each stage.

Figure 77.3 illustrates the boundaries for a one-sided test with an upper alternative that allows for early stopping to either reject or accept the null hypothesis.

Figure 77.3 Boundary Plot for One-Sided Design

With an upper alternative, as in this example, the design has the following two boundaries: an upper α (rejection) boundary for the rejection region that consists of upper rejection critical values and an upper β (acceptance) boundary for the acceptance region that consists of upper acceptance critical values. The stages are indicated by vertical lines with accompanying stage numbers. In Figure 77.3, the horizontal axis indicates the cumulative sample size for the group sequential trial. The vertical axis indicates the critical values at each stage on the standardized Z scale. Other scales can be used for the vertical axis, including the MLE scale, score statistic scale, and p-value scale.

At each interim stage, if the test statistic is in the rejection region (darker shaded area in Figure 77.3), the trial stops and the null hypothesis is rejected. If the test statistic is in the acceptance region (lightly shaded area in Figure 77.3), the trial stops and the hypothesis is accepted. Otherwise, the trial continues to the next stage. If the trial proceeds to the final stage (stage 4), the upper α and upper β critical values are identical, and the trial stops to either reject or accept the null hypothesis.

Group Sequential Methods

For a group sequential design, there are two possible boundaries for a one-sided test and four possible boundaries for a two-sided test. Each boundary consists of one boundary value (critical value) for each stage. The SEQDESIGN procedure provides various methods for computing the boundary values.

The boundary value for a fixed-sample test cannot be applied to each stage of sequential design because, as shown by Armitage, McPherson, and Rowe (1969), repeated significance tests at a fixed level on accumulating data increase the probability of a Type I error. For example, with a fixed-sample two-sided test, the critical values ± 1.96 for a standardized Z statistic produce a Type I error probability level $\alpha = 0.05$. But for a two-sided group sequential test with two equally spaced stages, if the same critical values ± 1.96 are used to reject the null hypothesis at these two stages, the Type I error probability level is $\alpha = 0.083$, larger than the fixed-sample α.

Numerous methods are available for deriving the critical values for each boundary in a sequential design. Pocock (1977) applies repeated significance tests to group sequential trials with equal-size groups and derives a constant critical value on the standardized normal Z scale across all stages that maintains the specified Type I error probability level. O'Brien and Fleming (1979) propose a sequential procedure that has boundary values (in absolute value) decrease over the stages on the standardized normal Z scale.

The SEQDESIGN procedure provides the following three types of methods:

- fixed boundary shape methods, which derive boundaries with specified boundary shapes
- Whitehead methods, which adjust boundaries derived for continuous monitoring so that they apply to discrete monitoring
- error spending methods

Each type of methods uses a distinct approach to derive the boundary values for a group sequential trial. Whitehead methods require much less computation with resulting Type I error probability and power that are close but differ slightly from the specified values due to the approximations used in deriving the tests (Jennison and Turnbull 2000, p. 106). Fixed boundary shape methods derive boundary values by estimating a fixed number of parameters and require more computation. Error spending methods derive boundary values at each stage sequentially and require much more computation than other types of methods for group sequential trials with a large number of stages.

Within each type of methods, you can choose methods that creating boundary values range from conservative stopping boundary values at early stages to liberal stopping boundary values at very early stages.

You can use the SEQDESIGN procedure to specify methods from the same type for each design. A different method can be specified for each boundary separately, but all methods in a design must be of the same type.

Fixed Boundary Shape Methods

The fixed boundary shape methods include the unified family methods and the Haybittle-Peto method. The unified family methods (Kittelson and Emerson 1999) derive boundaries from specified boundary shapes. These methods include Pocock's method (Pocock 1977) and the O'Brien-Fleming method (O'Brien and Fleming 1979) as special cases.

The Haybittle-Peto method (Haybittle 1971; Peto et al. 1976) uses a value of 3 for the critical values in interim stages, so the critical value at the final stage is close to the critical value for the fixed-sample design. In the SEQDESIGN procedure, the Haybittle-Peto method has been generalized to allow for different boundary values at interim stages.

Whitehead Methods

Whitehead and Stratton (1983) and Whitehead (1997, 2001) develop triangular and straight-line boundaries by adapting tests constructed for continuous monitoring to discrete monitoring of group sequential tests. With continuous monitoring, the values for each boundary fall in a straight line when plotted on the score statistic scale. The discrete boundary is derived by subtracting the expected overshoot from the continuous boundary to obtain the desired Type I and Type II error probabilities. For a design with early stopping to either reject or accept the null hypothesis, the boundaries form a triangle when plotted on the score statistic scale. See the section "Score Statistic" on page 5819 for a detailed description of the score statistic.

Error Spending Methods

For every sequential design, the α and β errors at each stage can be computed from the boundary values. On the other hand, you can derive the boundary values from specified α and β errors for each stage. The error spending function approach (Lan and DeMets 1983) uses an error spending function to specify the errors at each stage for each boundary and then derives the boundary values.

Getting Started: SEQDESIGN Procedure

This section illustrates a clinical study design that uses a two-sided O'Brien-Fleming design (O'Brien and Fleming 1979) to stop the trial early for ethical concerns about possible harm or for unexpectedly strong efficacy of the new drug.

Suppose that a pharmaceutical company is conducting a clinical trial to test the efficacy of a new cholesterol-lowering drug. The primary focus is low-density lipoprotein (LDL), the so-called bad cholesterol, which is a risk factor for coronary heart disease. LDL is measured in mg/dL, milligrams per deciliter of blood.

The trial consists of two groups of equally allocated patients with elevated LDL levels: an experimental group given the new drug and a placebo control group. Suppose the changes in LDL level

after the treatment for individuals in the experimental and control groups are normally distributed with means μ_e and μ_c, respectively, and have a common variance σ^2. Then the null hypothesis of no effect for the new drug is $H_0 : \theta = 0$, where $\theta = \mu_e - \mu_c$.

For a fixed-sample design with a total sample size N, the MLE for θ is computed as $\hat{\theta} = \hat{\mu}_e - \hat{\mu}_c$, where $\hat{\mu}_e$ and $\hat{\mu}_c$ are the sample means of the decreases in LDL level in the experimental and control groups, respectively.

Following the derivation in the section "Test for the Difference between Two Normal Means" on page 5860, the statistic $\hat{\theta}$ has a normal distribution

$$\hat{\theta} \sim N\left(\theta, \frac{4\sigma^2}{N}\right)$$

Thus, under the null hypothesis $H_0 : \theta = 0$, the standardized statistic

$$Z = \frac{\hat{\theta}}{\sqrt{\frac{4\sigma^2}{N}}} \sim N(0, 1)$$

The Z statistic can be used to test the null hypothesis H_0. If the variance σ^2 is unknown, the sample variance can be used to compute the test statistic if it is assumed that the sample variance is computed from a large sample such that the Z statistic has an approximately standard normal distribution.

With a Type I error probability $\alpha = 0.05$, the critical values for the Z statistic are given by $\Phi^{-1}(\alpha/2) = -1.96$ and $\Phi^{-1}(1-\alpha/2) = 1.96$, where Φ is the cumulative standard normal distribution function. At the end of study, if $Z \geq 1.96$, the null hypothesis is rejected for harmful drug effect, and if $Z \leq -1.96$, the null hypothesis is rejected for efficacy of the new drug. Otherwise, the null hypothesis is not rejected and the drug effect is not significant.

Also suppose that for the trial, the alternative reference $\theta = -10$ is the clinically meaningful difference that the trial should detect with a high probability (power). Further suppose that a good estimate of the standard deviation for the changes in LDL level is $\hat{\sigma} = 20$. The following statements invoke the SEQDESIGN procedure and request a four-stage O'Brien-Fleming design for standardized normal test statistics:

```
ods graphics on;
 proc seqdesign altref=-10
                plots=boundary(hscale=samplesize)
                ;
   TwoSidedOBrienFleming: design nstages=4
                          method=obf
                          ;
   samplesize model=twosamplemean(stddev=20);
ods output Boundary=Bnd_LDL;
run;
ods graphics off;
```

The ALTREF= option specifies the alternative reference, and the actual maximum information is derived in the SEQDESIGN procedure. With the specified ODS GRAPHICS ON statement, the PLOTS=BOUNDARY option displays a boundary plot with the rejection and acceptance regions.

In the DESIGN statement, the label `TwoSidedOBrienFleming` identifies the design in the output tables. The default ALT=TWOSIDED option specifies a two-sided alternative hypothesis. The default STOP=REJECT option specifies early stopping in the interim stages only for the purpose of rejecting the null hypothesis. That is, at each interim stage, the trial will either be stopped to reject the null hypothesis or continue to the next stage.

The NSTAGES=4 option in the DESIGN statement specifies the total number of stages in the group sequential trial, including three interim stages and a final stage. In the SEQDESIGN procedure, the null hypothesis for the design is $H_0 : \theta = 0$. The default ALPHA=0.05 option specifies a Type I error probability $\alpha = 0.05$, and the default BETA=0.10 option specifies a Type II error probability $\beta = 0.10$, which corresponds to a power of $1-\beta = 0.90$ at the alternative reference $H_1 : \theta = -10$.

For a two-sided design with early stopping to reject the null hypothesis, there are two boundaries for the design: an upper α boundary that consists of upper rejection critical values and a lower α boundary that consists of lower rejection critical values. Each boundary is a set of critical values, one from each stage. With the METHOD=OBF option in the DESIGN statement, the O'Brien-Fleming method is used for the two boundaries for the design; see Figure 77.7.

A property of the boundaries constructed with the O'Brien-Fleming design is that the null hypothesis is more difficult to reject in the early stages than in the later stages. That is, the trial is rejected in the early stages only with overwhelming evidence, because in these stages there might not be a sufficient number of responses for a reliable estimate of the treatment effect.

The SAMPLESIZE statement with the MODEL=TWOSAMPLEMEAN option uses the derived maximum information to compute required sample sizes for a two-sample test for mean difference. The ODS OUTPUT statement with the BOUNDARY=BND_LDL option creates an output data set named BND_LDL which contains the resulting boundary information.

In a clinical trial, the amount of information about an unknown parameter available from the data can be measured by the Fisher information. For a maximum likelihood statistic, the information level is the inverse of its variance. See the section "Maximum Likelihood Estimator" on page 5818 for a detailed description of Fisher information. At each stage of the trial, data are collected and analyzed with a statistical procedure, and a test statistic and its corresponding information level are computed.

In this example, you can use the REG procedure to compute the maximum likelihood estimate $\hat{\theta}$ for the drug effect and the corresponding standard error for $\hat{\theta}$. At stage 1, you can use the SEQTEST procedure to compare the test statistic with adjusted boundaries derived from the boundary information stored in the BOUND_LDL data set. At each subsequent stage, you can use the SEQTEST procedure to compare the test statistic with adjusted boundaries derived from the boundary information stored in the test information table created by the SEQTEST procedure at the previous stage. The test information tables are structured for input to the SEQTEST procedure.

At each interim stage, the trial will either be stopped to reject the null hypothesis or continue to the next stage. At the final stage, the null hypothesis is either rejected or accepted.

By default, the SEQDESIGN procedure derives boundary values with equally spaced information levels for all stages—that is, the same information increment between successive stages. The "Design Information," "Method Information," and "Boundary Information" tables are displayed by default, as shown in Figure 77.4, Figure 77.5, and Figure 77.6, respectively.

The "Design Information" table in Figure 77.4 displays design specifications and four derived statistics: the actual maximum information, the maximum information, the average sample number under the null hypothesis (Null Ref ASN), and the average sample number under the alternative hypothesis (Alt Ref ASN). Except for the actual maximum information, each statistic is expressed as a percentage of the identical statistic for the corresponding fixed-sample information. The average sample number is the expected sample size (for nonsurvival data) or expected number of events (for survival data). Note that for a symmetric two-sided design, the ALTREF=−10 option implies a lower alternative reference of −10 and an upper alternative reference of 10.

Figure 77.4 O'Brien-Fleming Design Information

The SEQDESIGN Procedure
Design: TwoSidedOBrienFleming

Design Information

Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	-10
Number of Stages	4
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	102.2163
Max Information	0.107403
Null Ref ASN (Percent of Fixed Sample)	101.5728
Alt Ref ASN (Percent of Fixed Sample)	76.7397

The maximum information is the information level at the final stage of the group sequential trial. The Max Information (Percent Fixed-Sample) is the maximum information for the sequential design expressed as a percentage of the information for the corresponding fixed-sample design. In Figure 77.4, the Max Information (Percent Fixed-Sample) is 102.22%, which means that the information needed for the group sequential trial is 2.22% more than that of the corresponding fixed-sample design if the trial does not stop at any interim stage.

The Null Ref ASN (Percent Fixed-Sample) is the average sample number (expected sample size) required under the null hypothesis for the group sequential design expressed as a percentage of the sample size for the corresponding fixed-sample design. In Figure 77.4, the Null Ref ASN is 101.57%, which means that the expected sample size for the group sequential trial is 1.57% greater than the corresponding fixed-sample size.

Similarly, the Alt Ref ASN (Percent Fixed-Sample) is the average sample number (expected sample size) required under the alternative hypothesis for the group sequential design expressed as a percentage of the sample size for the corresponding fixed-sample design. In Figure 77.4, the Alt Ref ASN is 76.74%, which means that the expected sample size for the group sequential trial is 76.74% of the corresponding fixed-sample size. That is, if the alternative hypothesis is true, then on average, only 76.74% of the fixed-sample size is needed for the group sequential trial.

In this example, the O'Brien-Fleming design requires only a slight increase in sample size if the trial proceeds to the final stage. On the other hand, if the alternative hypothesis is correct, this design provides a substantial saving in sample size on average.

The "Method Information" table in Figure 77.5 displays the computed Type I and Type II error probabilities α and β, and the derived drift parameter for the design. For a two-sided test with early stopping to reject the null hypothesis, both lower and upper α boundaries are created. With the specified ALTREF= option, the alternative references are also included.

With the zero null reference, the drift parameter is the standardized alternative reference at the final stage $\theta_1\sqrt{I_X}$, where θ_1 is the alternative reference and I_X is the maximum information. See the section "Specified and Derived Parameters" on page 5851 for a detailed description of the drift parameter. The drift parameters for the design are derived in the SEQDESIGN procedure even if the alternative reference is not specified or derived in the procedure.

Figure 77.5 Method Information

Method Information

Boundary	Method	Alpha	Beta	Unified Family Rho	Unified Family Tau	Unified Family C
Upper Alpha	O'Brien-Fleming	0.02500	0.10000	0.5	0	2.02429
Lower Alpha	O'Brien-Fleming	0.02500	0.10000	0.5	0	2.02429

Method Information

Boundary	Alternative Reference	Drift
Upper Alpha	10	3.277238
Lower Alpha	-10	-3.27724

The O'Brien-Fleming method belongs to the unified family of designs, which is parameterized by two parameters, ρ and τ, as implemented in the SEQDESIGN procedure. See Table 77.3 for parameter values of commonly used methods in the unified family. The "Method Information" table in Figure 77.5 displays the values of $\rho = 0.5$ and $\tau = 0$, which are the parameters for the O'Brien-Fleming method. The table also displays the derived parameter $C_\alpha = 2.0243$, which is used in the construction of symmetric lower and upper α boundaries; see the section "Unified Family Methods" on page 5839.

The "Boundary Information" table in Figure 77.6 displays the information level, including the proportion, actual level, and corresponding sample size (N) at each stage. The table also displays the lower and upper alternative references, and the lower and upper boundary values at each stage. By default, equally spaced information levels for all stages are used to derive boundary values.

Figure 77.6 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0

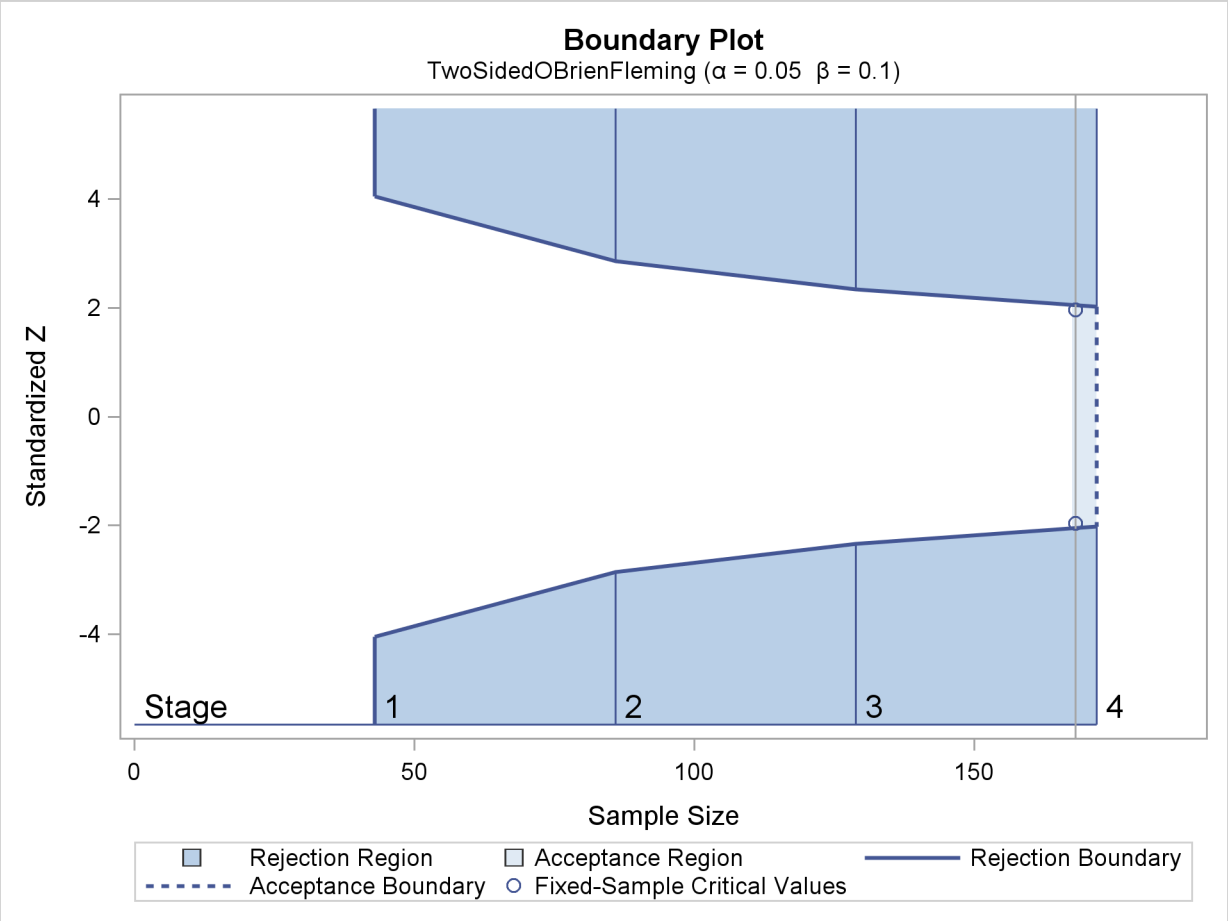
	Information Level			Alternative Reference	
Stage	Proportion	Actual	N	Lower	Upper
1	0.2500	0.026851	42.96116	−1.63862	1.63862
2	0.5000	0.053701	85.92233	−2.31736	2.31736
3	0.7500	0.080552	128.8835	−2.83817	2.83817
4	1.0000	0.107403	171.8447	−3.27724	3.27724

Boundary Information (Standardized Z Scale)
Null Reference = 0

	Boundary Values	
	Lower	Upper
Stage	Alpha	Alpha
1	−4.04859	4.04859
2	−2.86278	2.86278
3	−2.33745	2.33745
4	−2.02429	2.02429

The information proportion is the proportion of maximum information available at each stage and N is the corresponding sample size. The default BOUNDARYSCALE=STDZ option specifies that the standardized Z scale be used to display the boundary values in the boundary information table and the boundary plot. The alternative reference on the standardized Z scale at stage k is given by $\theta_1\sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information available at stage k, $k = 1, 2, 3, 4$. These standardized alternative references for the design are derived in the SEQDESIGN procedure even if the alternative reference is not specified or derived in the procedure.

In this example, a standardized Z statistic is computed by standardizing the parameter estimate of the effect in LDL level. A lower Z test statistic indicates a beneficial effect. Consequently, at each interim stage, if the standardized Z test statistic is less than or equal to the corresponding lower α boundary value, the hypothesis $H_0 : \theta = 0$ is rejected for efficacy. If the test statistic is greater than or equal to the corresponding upper α boundary value, the hypothesis H_0 is rejected for harmful effect. Otherwise, the process continues to the next stage. At the final stage (stage 4), the hypothesis H_0 is rejected for efficacy if the Z statistic is less than or equal to the corresponding lower α boundary value -2.0243, and the hypothesis H_0 is rejected for harmful effect if the Z statistic is greater than or equal to the corresponding upper α boundary value 2.0243. Otherwise, the hypothesis of no significant difference is accepted.



Note that in a typical trial, the actual information levels do not match the information levels specified in the design. The SEQTEST procedure modifies the boundary values stored in the BOUND_LDL data set to adjust for these new information levels.

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Figure 77.7. This plot displays the boundary values in the "Boundary Information" table in Figure 77.6. The stages are indicated by vertical lines

with accompanying stage numbers. The horizontal axis indicates the sample sizes for the stages. Note that comparing with a fixed-sample design, only a small increase in sample size is needed for the O'Brien-Fleming design, as shown in Figure 77.7.

If a test statistic at an interim stage is in the rejection region (shaded area), the trial stops and the null hypothesis is rejected. If the statistic is not in any rejection region, the trial continues to the next stage.

Figure 77.7 Boundary Plot

The boundary plot also displays critical values for the corresponding fixed-sample design. The symbol "∘" identifies the fixed-sample critical values of -1.96 and 1.96, and the accompanying vertical line indicates the required sample size for the fixed-sample design at the horizontal axis. Note that the boundary values ± 2.0243 at the final stage are close to the fixed-sample critical values ± 1.96.

When you specify the SAMPLESIZE statement, the maximum information (either explicitly specified or derived in the SEQDESIGN procedure) is used to compute the required sample sizes for the study. The MODEL=TWOSAMPLEMEAN(STDDEV=20) option specifies the test for the difference between two normal means. See the section "Test for the Difference between Two Normal Means" on page 5860 for a detailed derivation of these required sample sizes.

The "Sample Size Summary" table in Figure 77.8 displays the parameters for the sample size computation and the resulting maximum and expected sample sizes.

Figure 77.8 Sample Size Summary

Sample Size Summary

Test	Two-Sample Means
Mean Difference	-10
Standard Deviation	20
Max Sample Size	171.8447
Expected Sample Size (Null Ref)	170.7627
Expected Sample Size (Alt Ref)	129.0137

The "Sample Sizes (N)" table in Figure 77.9 displays the required sample sizes at each stage for the trial, in both fractional and integer numbers. The derived fractional sample sizes are displayed under the heading "Fractional N." These sample sizes are rounded up to integers under the heading "Ceiling N." With the default WEIGHT=1 option in the SAMPLESIZE statement, the sample sizes for the two groups are equal for the two-sample test.

Figure 77.9 Derived Sample Sizes

Sample Sizes (N)
Two-Sample Z Test for Mean Difference

	Fractional N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	42.96	21.48	21.48	0.0269
2	85.92	42.96	42.96	0.0537
3	128.88	64.44	64.44	0.0806
4	171.84	85.92	85.92	0.1074

Sample Sizes (N)
Two-Sample Z Test for Mean Difference

	Ceiling N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	44	22	22	0.0275
2	86	43	43	0.0538
3	130	65	65	0.0812
4	172	86	86	0.1075

In practice, integer sample sizes are used in the trial, and the resulting information levels increase slightly. Thus, 22, 43, 65, and 86 individuals are needed in each of the two groups for the four stages, respectively.

Syntax: SEQDESIGN Procedure

The following statements are available in PROC SEQDESIGN:

PROC SEQDESIGN < *options* > **;**
  < *label:* > **DESIGN** *options* **;**
  SAMPLESIZE < *MODEL= option* > **;**

The PROC SEQDESIGN statement and the DESIGN statement are required for the SEQDESIGN procedure. Each DESIGN statement requests a new group sequential design, and multiple DESIGN statements can be used to create more than one design for comparison of features. The label, which must be a valid SAS name, is used to identify the design in the output tables and graphics. The SAMPLESIZE statement computes the required sample sizes for the design specified in each DESIGN statement. With a selected design, the SAMPLESIZE statement computes the required sample sizes for the trial.

PROC SEQDESIGN Statement

PROC SEQDESIGN < *options* > **;**

Table 77.1 summarizes the options in the PROC SEQDESIGN statement.

Table 77.1 Summary of PROC SEQDESIGN Options

Option	Description
Design Parameters	
ALTREF=	specifies alternative reference
BOUNDARYSCALE=	specifies statistic scale for the boundary
MAXINFO=	specifies maximum information level
Table Output	
ERRSPEND	displays cumulative error spending at each stage
PSS	displays powers and expected sample sizes
STOPPROB	displays expected cumulative stopping probabilities
Graphics Output	
PLOTS=ASN	displays expected sample numbers plot
PLOTS=BOUNDARY	displays detailed boundary plot
PLOTS=COMBINEDBOUNDARY	displays combined boundary plot
PLOTS=ERRSPEND	displays error spending plot
PLOTS=POWER	displays powers plot

By default, the SEQDESIGN procedure displays tables of design information, method information, and boundary information for each specified design. If the ODS GRAPHICS ON statement is specified, it also displays a detailed boundary plot.

In addition, you can use output options to display output tables such as expected cumulative stopping probability at each stage under various hypothetical references. If the ODS GRAPHICS ON statement is specified, you can also use output options to display plots such as powers and expected sample sizes under various hypothetical references.

The following options can be used in the PROC SEQDESIGN statement to derive boundary values for all sequential designs in the procedure. They are listed in alphabetical order.

ALTREF=θ_1 < (< LOWER=θ_{1l} > < UPPER=θ_{1u} >) >

specifies the alternative reference—that is, the hypothetical reference under the alternative hypothesis at which the power is computed. The LOWER= and UPPER= options are applicable only for a two-sided design with different lower and upper alternative references.

For a one-sided design, $\theta_{1l} = -|\theta_1|$ is the lower alternative reference and $\theta_{1u} = |\theta_1|$ is the upper alternative reference. For a two-sided design, the specified θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. If the LOWER= option is not specified, $\theta_{1l} = -|\theta_1|$, and if the UPPER= option is not specified, $\theta_{1u} = |\theta_1|$.

The specification of the ALTREF= option depends on the hypothesis used in the clinical trial. For example, suppose the null hypothesis $H_0 : \theta = 0$ with an alternative hypothesis $H_1 : \theta = \theta_1$ is used to compare two binomial populations, $p_a = p_b$. Then θ_1 is the proportion difference under H_1 if $\theta = p_a - p_b$, and θ_1 is the log odds ratio under H_1 if $\theta = \log\left(\frac{p_a(1-p_b)}{p_b(1-p_a)}\right)$.

If the ALTREF= option is not specified, the alternative reference θ_1 can also be specified or derived in the SAMPLESIZE statement. If θ_1 is specified or derived in the SAMPLESIZE statement, $\theta_{1l} = -|\theta_1|$ and $\theta_{1u} = |\theta_1|$ are the lower and upper alternative references, respectively.

Note that if the SAMPLESIZE statement is specified with a two-sided design, the sample sizes derived by using the lower and upper alternatives might be different. If θ_1 is specified or derived in the SAMPLESIZE statement, it is used to compute the sample sizes. Otherwise, the θ_1 specified in the ALTREF= option is used.

BOUNDARYSCALE=MLE | SCORE | STDZ | PVALUE

BSCALE=MLE | SCORE | STDZ | PVALUE

specifies the scale for the statistic that is displayed in the boundary table and boundary plots. The keywords MLE, SCORE, STDZ, and PVALUE correspond to the boundary with the maximum likelihood estimate scale, the score statistic scale, the standardized normal Z scale, and the p-value scale, respectively. The default is BOUNDARYSCALE=STDZ.

With the BOUNDARYSCALE=MLE or BOUNDARYSCALE=SCORE option, the maximum information must be either explicitly specified with the MAXINFO= option or derived in the SEQDESIGN procedure to provide the necessary information level at each stage to compute the boundary values. See the section "Boundary Scales" on page 5832 for a detailed description of the statistic scale for the boundary values.

Note that for a two-sided design, the p-value scale displays the one-sided fixed-sample p-value under the null hypothesis with a lower alternative hypothesis.

MAXINFO=*number*

specifies the maximum information level for the design. If the MAXINFO=option is specified and the alternative reference is either specified explicitly with the ALTREF= option or derived from the SAMPLESIZE statement, then the Type I and Type II error probability levels cannot be met simultaneously. In this case, the ALPHA= option in the DESIGN statement is applicable only with the default BOUNDARYKEY=ALPHA option in the DESIGN statement, and the Type II error probability β is derived. The BETA= option in the DESIGN statement is applicable only with the BOUNDARYKEY=BETA option in the DESIGN statement, and the Type I error probability α is derived.

Table Output Options

The following options can be used in the PROC SEQDESIGN statement to display addition table output. They are listed in alphabetical order.

ERRSPEND

displays the error spending at each stage for each boundary in the design.

PSS < (CREF= *numbers* **) >**

displays powers and expected sample sizes under various hypothetical references, where the numbers $c_i \geq 0$.

For a one-sided design, the power and expected sample sizes under hypotheses $\theta = c_i\,\theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, the power and expected sample sizes under hypotheses $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The default is CREF= 0 0.5 1.0 1.5.

Note that for a symmetric two-sided design, only the power and expected sample sizes under hypotheses $\theta = c_i\,\theta_{1u}$ are derived. See the section "Type I and Type II Errors" on page 5836 for a detailed description of the power computation. See the section "Powers and Expected Sample Sizes" on page 5878 for a detailed description of the expected sample size computation.

STOPPROB < (CREF= *numbers* **) >**

displays expected cumulative stopping probabilities under various hypothetical references, where the numbers $c_i \geq 0$.

For a one-sided design, expected cumulative stopping probabilities at each stage under hypotheses $\theta = c_i\,\theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, expected cumulative stopping probabilities at each stage under hypotheses $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only expected cumulative stopping probabilities under hypotheses $\theta = c_i\,\theta_{1u}$ are derived. The default is CREF= 0 0.5 1.0 1.5.

Graphics Output Options

This section describes the options for using ODS Graphics with the SEQDESIGN procedure to create plots. To request these graphs, you must specify the ODS GRAPHICS ON statement in addition to the following options in the PROC SEQDESIGN statement. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

The following options can be used in the PROC SEQDESIGN statement to display graphs with ODS Graphics. They are listed in alphabetical order.

PLOTS < (ONLY) > < = *plot-request* >

PLOTS < (ONLY) > < = (*plot-request* < . . . *plot-request* >) >

specifies options that control the details of the plots. The default is PLOTS=BOUNDARY. The global plot option ONLY suppresses the default plots and displays only plots specifically requested.

The plot request options are as follows.

ALL

produces all appropriate plots.

ASN < (CREF= *numbers*) >

displays a plot of the average sample numbers (expected sample sizes for nonsurvival data or expected numbers of events for survival data) under various hypothetical references, where the numbers $c_i \geq 0$. These average sample numbers are displayed as percentages of the average sample numbers for the corresponding fixed-sample design.

For a one-sided design, expected sample numbers under hypotheses $\theta = c_i\ \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, expected sample numbers under hypotheses $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only the average sample numbers under hypotheses $\theta = c_i\ \theta_{1u}$ are derived. The default is CREF= 0 to 1.5 by 0.01.

BOUNDARY < (HSCALE=INFO | SAMPLESIZE) >

displays a plot of the resulting sequential boundaries with the acceptance and rejection regions for each design. Either the information level (HSCALE=INFO) or the sample size (HSCALE=SAMPLESIZE) is displayed on the horizontal axis. If the maximum information is not available for the design, the information in percentage of its corresponding fixed-sample design are used in the plot. The stage number for each stage is displayed inside the plot. The default is HSCALE=INFO.

If the HSCALE=SAMPLESIZE option is specified. the SAMPLESIZE statement must also be specified. The options MODEL=INPUTNEVENTS, MODEL=TWOSAMPLESURVIVAL, and MODEL=PHREG in the SAMPLESIZE statement indicate survival data. For a sample that does not contain survival data, the sample size at each stage is displayed on the horizontal axis. For survival data, the number of events is displayed on the horizontal axis at each stage. The critical values for the corresponding fixed-sample design are also displayed in the plot.

COMBINEDBOUNDARY < (HSCALE=INFO | SAMPLESIZE | STAGE) >

displays a plot of the resulting sequential boundaries for all designs simultaneously. You can

display the information level (HSCALE=INFO), the sample size (HSCALE=SAMPLESIZE), or the stage number (HSCALE=STAGE) on the horizontal axis. The default is HSCALE=INFO. With HSCALE=INFO, if the maximum information is not available for the design, then the information in percentage of its corresponding fixed-sample design is used in the plot.

If the HSCALE=SAMPLESIZE option is specified, the SAMPLESIZE statement must also be specified. The options MODEL=INPUTNEVENTS, MODEL=TWOSAMPLESURVIVAL, and MODEL=PHREG in the SAMPLESIZE statement indicate survival data. For a sample that does not contain survival data, the sample size at each stage is displayed on the horizontal axis. For survival data, the number of events is displayed on the horizontal axis at each stage.

ERRSPEND < (HSCALE=INFO | STAGE) >

displays a plot of the error spending for all sequential boundaries in the designs simultaneously. You can display the information level (HSCALE=INFO) or the stage number (HSCALE=STAGE) on the horizontal axis. With HSCALE=INFO, the information fractions are used in the plot. The default is HSCALE=STAGE.

NONE

suppresses all plots.

POWER < (CREF= *numbers* **) >**

displays a plot of the power curves under various hypothetical references, where the numbers $c_i \geq 0$.

For a one-sided design, powers under hypotheses $\theta = c_i\,\theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, powers under hypotheses $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only powers under hypotheses $\theta = c_i\,\theta_{1u}$ are derived. The default is CREF= 0 to 1.5 by 0.01.

DESIGN Statement

< label: > **DESIGN** *< options >* **;**

The DESIGN statement requests a new group sequential design. You can use multiple DESIGN statements, and each DESIGN statement corresponds to a separate group sequential design.

Table 77.2 lists the options available in the DESIGN statement.

Table 77.2 Design Statement Options

Option	Description
Design Parameters	
ALPHA=	specifies Type I error probability level α
ALT=	specifies type of alternative hypothesis
BETA=	specifies Type II error probability level β

Table 77.2 *continued*

Option	Description
BETAOVERLAP=	checks for overlapping of the lower and upper β boundaries in a two-sided design with error spending methods
BOUNDARYKEY=	specifies type of error probability to maintain
INFO=	specifies information levels
NSTAGES=	specifies number of stages
STOP=	specifies condition for early stopping
Boundary Methods	
METHOD=	specifies methods for boundary values

The required NSTAGES= option specifies the number of stages. The METHOD= option is required if the number of stages specified in the NSTAGES= option is greater than one. The following options can be used in the DESIGN statement. They are listed in alphabetical order.

ALPHA=α < (< LOWER=α_l > < UPPER=α_u >) >

specifies the Type I error probability α. The default is $\alpha = 0.05$. The LOWER= and UPPER= options are applicable only for the two-sided design. The LOWER= option specifies the lower Type I error probability α_l, and the upper Type I error probability is computed as $\alpha_u = \alpha - \alpha_l$. The UPPER= option specifies the upper Type I error probability α_u, and the lower Type I error probability is computed as $\alpha_l = \alpha - \alpha_u$. If both LOWER= and UPPER= options are not specified, $\alpha_l = \alpha_u = \alpha/2$.

If both the MAXINFO= and ALTREF= options are specified, then the Type I and Type II error probability levels cannot be met simultaneously. In this case, the ALPHA= option is applicable only with the default BOUNDARYKEY=ALPHA option, and the Type II error probability β is derived.

ALT=LOWER | UPPER | TWOSIDED

specifies the type of alternative hypothesis in the design. For a test of $H_0 : \theta = 0$, the keywords LOWER, UPPER, and TWOSIDED correspond to the alternatives of $\theta < 0$, $\theta > 0$, and $\theta \neq 0$, respectively. The default is ALT=TWOSIDED.

BETA=β < (< LOWER=β_l > < UPPER=β_u >) >

specifies the Type II error probability level β. The default is $\beta = 0.10$. The LOWER= and UPPER= options are applicable only for the two-sided design. The LOWER= option specifies the lower Type II error probability level β_l, and the UPPER= option specifies the upper Type II error probability level β_u. If the LOWER= or UPPER= option is not specified, β is used.

If both the MAXINFO= and ALTREF= options are specified, then the Type I and Type II error probability levels cannot be met simultaneously. In this case, the BETA= option is applicable only with the BOUNDARYKEY=BETA option, and the Type I error probability α is derived.

BETAOVERLAP=ADJUST | NOADJUST

OVERLAP=ADJUST | NOADJUST

specifies whether to check for overlapping of the lower and upper β boundaries for the two corresponding one-sided tests. This option applies to two-sided designs with STOP=ACCEPT or STOP=BOTH that are constructed with error spending methods, and this

type of overlapping might result from a small β spending at an interim stage. When you specify BETAOVERLAP=ADJUST, the procedure checks for this type of overlapping. If such overlapping is found, the β boundaries for the two-sided design at that stage are set to missing, and the β spending values at subsequent stages are adjusted, as described in the section "Boundary Adjustments for Overlapping Lower and Upper β Boundaries" on page 5850".

You can specify BETAOVERLAP=NOADJUST to request that no adjustment be made. The default is BETAOVERLAP=ADJUST.

BOUNDARYKEY=ALPHA | BETA | BOTH | NONE

specifies types of errors to be maintained in the resulting boundary. The default is BOUNDARYKEY=ALPHA if both ALTREF= and MAXINFO= options are specified. Otherwise, the default is BOUNDARYKEY=NONE for Whitehead methods with the STOP=BOTH option, and it is BOUNDARYKEY=BOTH for others.

See the section "Applicable Boundary Keys" on page 5853 for a detailed description of applicable boundary keys.

INFO=EQUAL

INFO=CUM(*numbers* **)**

specifies relative information levels for all stages in the design. The INFO=EQUAL option specifies equally spaced information levels, and the INFO=CUM option specifies cumulative relative information levels. The default is INFO=EQUAL.

If the number of information levels specified in the INFO=CUM option is less than the number of stages specified in the NSTAGES= option, the last available information increment is used as the information increment for each subsequent stage.

METHOD=WHITEHEAD < (TAU=τ < (<LOWER=τ_l > <UPPER=τ_u >) >) >

METHOD=*method*

METHOD(*boundary***) =** *method*

specifies the methods for the boundaries in the design, where $0 \leq \tau < 0.5$.

For a one-sided design, an α boundary is created with the STOP=REJECT or STOP=BOTH option, and a β boundary is created with the STOP=ACCEPT or STOP=BOTH option. For a two-sided design, lower and upper α boundaries are created with the STOP=REJECT or STOP=BOTH option, and lower and upper β boundaries are created with the STOP=ACCEPT or STOP=BOTH option.

There are three types of methods available in the SEQDESIGN procedure. The unified family methods and Haybittle-Peto methods derive boundary values with fixed boundary shape; the Whitehead methods derive boundary values by adjusting the boundary values generated from continuous monitoring; and the error spending methods derive the boundary values from the specified errors used at each stage. You can specify different methods for the same design, but all methods must be from the same group.

For a design with early stopping to reject or accept the null hypothesis, the METHOD=WHITEHEAD option uses Whitehead's triangular design and double-triangular design for a one-sided design and two-sided design, respectively (Whitehead and Stratton 1983; Whitehead 1997, 2001). For a design with early stopping only to reject the null hypothesis or only to accept the null hypothesis, you can specify the slope of the boundary line in the score statistic scale with the TAU= τ option. The default is TAU=0.25. See the section "Whitehead Methods" on page 5845 for a detailed description of the Whitehead methods.

The following options specify available error spending methods for the boundary. Each of these methods can be specified with the METHOD= option for all boundaries, or with the METHOD(*boundary*) = option for an individual boundary. See the section "Error Spending Methods" on page 5848 for a detailed description of these error spending methods.

ERRFUNCGAMMA < (GAMMA= γ **) >**
specifies a gamma cumulative error spending function for the boundary (Hwang, Shih, and DeCani 1990). The GAMMA= option specifies the gamma parameter γ in the function, where $\gamma \leq 3$. The boundaries created with $\gamma = 1$ are similar to the boundaries from the Pocock method, and the boundaries created with $\gamma = -4$ or $\gamma = -5$ are similar to the boundaries from the O'Brien-Fleming method. The default is GAMMA=−2, which is the average of $\gamma = 1$ and $\gamma = -5$.

ERRFUNCOBF
specifies the O'Brien-Fleming-type cumulative error spending function for the boundary (Lan and DeMets 1983).

ERRFUNCPOC
specifies the Pocock-type cumulative error spending function for the boundary (Lan and DeMets 1983).

ERRFUNCPOW < (RHO=ρ **) >**
specifies a power cumulative error spending function for the boundary (Jennison and Turnbull 2000, p. 148). The RHO= option specifies the power parameter ρ in the function, where $\rho \geq 0.25$. The boundaries created with $\rho = 1$ are similar to the boundaries from the Pocock method, and the boundaries created with $\rho = 3$ are similar to the boundaries from the O'Brien-Fleming method. The default is RHO=2, which is the average of $\rho = 1$ and $\rho = 3$.

ERRSPEND (*numbers* **)**
specifies the relative cumulative error spending at each stage.

With a fixed boundary shape, you can use the following available Haybittle-Peto methods and unified family methods to derive the boundary. You can specify each of these methods in the METHOD= option for all boundaries, or in the METHOD(*boundary*) = option for an individual boundary. See the section "Haybittle-Peto Method" on page 5844 for a detailed description of the Haybittle-Peto methods, and see the section "Unified Family Methods" on page 5839 for a detailed description of unified family methods.

HP | HAYBITTLE | PETO < (Z= *numbers* **| PVALUE=** *numbers* **) >**
specifies the Haybittle-Peto method (Haybittle 1971; Peto et al. 1976). The values specified are used to create the boundary values. The boundary value at the final stage

can be derived in the procedure to maintain the Type I and Type II error probability levels. The default is Z=3.

OBF | OBRIENFLEMING
specifies the O'Brien-Fleming method (O'Brien and Fleming 1979). The O'Brien-Fleming method is equivalent to a power family method with RHO=0.5.

POC | POCOCK
specifies the Pocock method (Pocock 1977). The Pocock method is equivalent to a power family method with RHO=0.

POW | POWER < (RHO=ρ) >
specifies a power family method (Wang and Tsiatis 1987; Emerson and Fleming 1989; Pampallona and Tsiatis 1994). The RHO= option specifies the power parameter ρ in the power family method, where $\rho \geq -0.25$. The power family method with $\rho = 0$ corresponds to the Pocock method, and the power family method with $\rho = 0.5$ corresponds to the O'Brien-Fleming method. The default is RHO=0.25, a value halfway between the Pocock and O'Brien-Fleming methods. A power family method is equivalent to a unified family method with RHO=ρ and TAU=0.

TRI | TRIANGULAR < (TAU=τ) >
specifies a unified family triangular method (Kittelson and Emerson 1999), where $0 \leq \tau \leq 1$. The default is TAU=1.0. The triangular method is identical to the unified family method with RHO=0.5 and TAU=τ. Note that this unified family triangular method is different from Whitehead's triangular method.

UNI | UNIFIED < (< TAU=τ > < RHO=ρ >) >
specifies a unified family method (Kittelson and Emerson 1999). The TAU= and RHO= options specify the τ and ρ parameters in a unified family method, respectively, where $\rho \geq 0$ and $0 \leq \tau \leq 2\rho$. The defaults are TAU=0 and RHO=0.25. See the section "Unified Family Methods" on page 5839 for a detailed description of the unified family methods.

The O'Brien-Fleming, Pocock, power family, and triangular methods are all special cases of the unified family methods. Table 77.3 summarizes the corresponding parameters in the unified family for these methods.

Table 77.3 Parameters in the Unified Family for Various Methods

Method	Option	Unified Family	
		Rho	Tau
Pocock	POC	0	0
O'Brien-Fleming	OBF	0.5	0
Power family	POW (RHO=ρ)	ρ	0
Triangular	TRI (TAU=τ)	0.5	τ

Note that the power parameter $\rho = 1/2-\Delta = \rho^*-1/2$, where Δ is the power parameter used in Jennison and Turnbull (2000) and Wang and Tsiatis (1987) and ρ^* is the power parameter used in Kittelson and Emerson (1999).

If a method with specified parameters is used for all boundaries in the design, you can use the METHOD= option to specify the method. Otherwise, you can use the following METHOD(*boundary*)= options to specify different methods from the same group for the boundaries.

METHOD(ALPHA)=*method*

METHOD(REJECT)=*method*

specifies the method for the α boundary of a one-sided design or the lower and upper α boundaries for a two-sided design.

METHOD(LOWERALPHA)=*method*

METHOD(LOWERREJECT)=*method*

specifies the method for the lower α boundary of a two-sided design.

METHOD(UPPERALPHA)=*method*

METHOD(UPPERREJECT)=*method*

specifies the method for the upper α boundary of a two-sided design.

METHOD(BETA)=*method*

METHOD(ACCEPT)=*method*

specifies the method for the β boundary of a one-sided design or the lower and upper β boundaries for a two-sided design.

METHOD(LOWERBETA)=*method*

METHOD(LOWERACCEPT)=*method*

specifies the method for the lower β boundary of a two-sided design.

METHOD(UPPERBETA)=*method*

METHOD(UPPERACCEPT)=*method*

specifies the method for the upper β boundary of a two-sided design.

NSTAGES=*number*

specifies the number of stages for the design. This option is required in the DESIGN statement, and the maximum allowed number of stages is 25.

STOP=ACCEPT | REJECT | BOTH

specifies the condition of early stopping for the design. The keywords ACCEPT, REJECT, and BOTH correspond to early stopping only to accept, only to reject, and either to accept or reject the null hypothesis H_0, respectively. The default is STOP=REJECT.

SAMPLESIZE Statement

SAMPLESIZE < *MODEL= option* > **;**

If each observation in the data set provides one unit of information in a hypothesis testing such as a one-sample test for the mean, the SAMPLESIZE statement computes the required sample sizes for the sequential design specified in each DESIGN statement. However, for a survival analysis, an individual in the survival time data might provide only partial information because of censoring. For this hypothesis, the SAMPLESIZE statement computes the required numbers of events. With additional accrual information in a survival analysis, the sample sizes can also be computed.

Only one SAMPLESIZE statement can be specified. For each specified group sequential design, the SAMPLESIZE statement computes the required sample sizes or numbers of events. The SAMPLESIZE statement is not required if the SEQDESIGN procedure is used only to compare features among different designs. Table 77.4 lists the options available in the SAMPLESIZE statement.

Table 77.4 SAMPLESIZE Statement Options

Option	Description
Fixed-Sample Models	
INPUTNOBS	specifies sample size for fixed-sample design
INPUTNEVENTS	specifies number of events for fixed-sample design
One-Sample Models	
ONESAMPLEMEAN	specifies one-sample Z test for mean
ONESAMPLEFREQ	specifies one-sample test for binomial proportion
Two-Sample Models	
TWOSAMPLEMEAN	specifies two-sample Z test for mean difference
TWOSAMPLEFREQ	specifies two-sample test for binomial proportions
TWOSAMPLESURVIVAL	specifies log-rank test for two survival distributions
Regression Models	
REG	specifies test for a regression parameter
LOGISTIC	specifies test for a logistic regression parameter
PHREG	specifies test for a proportional hazards regression parameter

The MODEL= option specifies the input sample size or number of events from a fixed-sample study, or it specifies a statistical model to compute the required sample size. The MODEL=INPUTNOBS option specifies the input sample size from a fixed-sample study of nonsurvival data, and the MODEL=INPUTNEVENTS option specifies the number of events from a fixed-sample study of survival data. The remaining MODEL= options specify the statistical models used to compute the required sample size. The default is MODEL=TWOSAMPLEMEAN, the two-sample Z test for the mean difference.

With the MODEL=INPUTNOBS or MODEL=INPUTNEVENTS option, the required sample size or number of events for the group sequential trial is computed by multiplying the input sample size or number of events by the ratio between the design information level and its corresponding fixed-sample information level. This ratio can be obtained by dividing the Max Information (Percent

Fixed-Sample) in the "Design Information" table by 100. See the section "Design Information" on page 5877 for a description of the "Design Information" table.

Fixed-Sample Models

The following two options compute the required sample size or number of events for a group sequential trial by using the sample size or number of events for the fixed-sample design.

MODEL=INPUTNOBS < (*options*) >
specifies the sample size information for a fixed-sample design. The available options are as follows:

- N= n
- SAMPLE= ONE | TWO
- WEIGHT= w_a < w_b >
- MATCHNOBS= YES | NO

The required N=n option specifies the sample size n for the fixed-sample design. The SAMPLE=ONE option specifies a one-sample test, and the SAMPLE=TWO option specifies a two-sample test. The default is SAMPLE=ONE.

With a two-sample test, the WEIGHT= option specifies the sample size allocation weights for the two groups. If w_b is not specified, $w_b = 1$ is used. The default is WEIGHT=1, equal allocation for the two groups. The derived fractional sample sizes are rounded up to integers, and the MATCHNOBS=YES option requests these integer sample sizes to match the sample size allocation.

See the section "Input Sample Size for Fixed-Sample Design" on page 5856 for a detailed description of the input sample size for the fixed-sample design in sample size computation.

MODEL=INPUTNEVENTS < (*options*) >
specifies the number of events D for a fixed-sample survival test. The available options are as follows:

- D= d
- SAMPLE= ONE | TWO

The required D=d option specifies the fixed-sample number of events d. The SAMPLE=ONE option specifies a one-sample test, and the SAMPLE=TWO option specifies a two-sample test. The default is SAMPLE=ONE.

In order to derive the sample size, addition options are needed. The available options for the sample size computation are as follows:

- HAZARD= h_a < h_b >
- MEDSURVTIME= t_a < t_b >
- WEIGHT= w_a < w_b >
- ACCRATE= r_a
- ACCTIME= T_a

- FOLTIME= T_f
- TOTALTIME= T

The hazard rates are needed for the sample size computation. For a one-sample test, the HAZARD= h_a option specifies the hazard rate h_a explicitly, and the MEDSURVTIME=t_a option specifies the hazard rate implicitly through the median survival time t_a. Similarly, for a two-sample test, the HAZARD= h_a h_b option specifies the hazard rates h_a and h_b for groups A and B explicitly, and the MEDSURVTIME=t_a t_b option specifies hazard rates for groups A and B implicitly through the median survival times t_a and t_b. Also, for a two-sample test, $h_b = h_a$ if h_b is not specified and $t_b = t_a$ if t_b is not specified.

With a two-sample test, the WEIGHT= option specifies the sample size allocation weights for the two groups. If w_b is not specified, $w_b = 1$ is used. The default is WEIGHT=1.

Assuming that the hazard rates are constant and the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a, the sample size and study time can be derived.

The ACCRATE= option specifies the constant accrual rate r_a, and the ACCTIME= and FOLTIME= options specify the accrual time T_a and follow-up time T_f, respectively. The TOTALTIME= option specifies the total study time, $T = T_a + T_f$.

If the ACCRATE= option is specified, then one of the ACCTIME=, FOLTIME, and TOTALTIME options is required for the sample size computation. Otherwise, two of the ACCTIME=, FOLTIME, and TOTALTIME options are required to compute the accrual rate and sample size.

See the section "Input Number of Events for Fixed-Sample Design" on page 5856 for a detailed description of the input number of events for the fixed-sample design in sample size computation.

One-Sample Models

The following two options compute the required sample size for a one-sample group sequential test.

MODEL=ONESAMPLEMEAN < (*options*) >

specifies the one-sample Z test for mean. The available options are as follows:

- MEAN= μ_1
- STDDEV= σ

The MEAN= option specifies the alternative reference μ_1 and is required if the alternative reference is not specified or derived in the procedure. If the MEAN=option is not specified, the specified or derived alternative reference is used.

The STDDEV= option specifies the standard deviation σ. The default is STDDEV=1. See the section "Test for a Normal Mean" on page 5858 for a detailed description of the one-sample Z test for mean.

Note that the one-sample Z test for mean also includes the paired difference in two-treatment comparison (Jennison and Turnbull 2000, pp. 51–52), where μ_1 is the mean of differences within pairs under the alternative hypothesis and σ is the standard deviation for the mean of differences within pairs.

MODEL=ONESAMPLEFREQ < (*options*) >

specifies the one-sample test for binomial proportion with the null hypothesis $H_0 : \theta = 0$ and the alternative hypothesis $H_1 : \theta = \theta_1$, where $\theta = p - p_0$ and $\theta_1 = p_1 - p_0$. The available options are as follows:

- NULLPROP= p_0
- PROP= p_1
- REF= NULLPROP | PROP

The NULLPROP= and PROP= options specify the proportions under the null and alternative hypotheses, respectively. The default for the null reference is NULLPROP=0.5. The PROP= option is required if the alternative reference is not specified or derived in the procedure. If the PROP= option is not specified, the specified or derived alternative reference θ_1 is used to compute the alternative reference $p_1 = p_0 + \theta_1$.

The REF= option specifies the hypothesis under which the proportion is used in the sample size computation. The REF=NULLPROP option uses the null hypothesis, and the REF=PROP option uses the alternative hypothesis to compute the sample size. The default is REF=PROP. See the section "Test for a Binomial Proportion" on page 5859 for a detailed description of the one-sample tests for proportion.

Two-Sample Models

The following three options compute the required sample size or number of events for a two-sample group sequential trial.

MODEL=TWOSAMPLEMEAN < (*options*) >

specifies the two-sample Z test for mean difference. The available options are as follows:

- MEANDIFF= θ_1
- STDDEV= σ_a $< \sigma_b >$
- WEIGHT= w_a $< w_b >$
- MATCHNOBS= YES | NO

The MEANDIFF= option specifies the alternative reference θ_1 and is required if the alternative reference is not specified or derived in the procedure. If the MEANDIFF= option is not specified, the specified or derived alternative reference is used.

The STDDEV= option specifies the standard deviations σ_a and σ_b. If σ_b is not specified, $\sigma_b = \sigma_a$. The default is STDDEV=1.

The WEIGHT= option specifies the sample size allocation weights for the two groups. If w_b is not specified, $w_b = 1$ is used. The default is WEIGHT=1, equal sample size for the two groups. The derived fractional sample sizes are rounded up to integers, and the MATCHNOBS=YES option requests these integer sample sizes to match the sample size allocation. The default is MATCHNOBS=NO.

See the section "Test for the Difference between Two Normal Means" on page 5860 for a detailed description of the two-sample Z test for mean difference.

MODEL=TWOSAMPLEFREQ < (*options*) >

specifies the two-sample test for binomial proportions. The available options are as follows:

- NULLPROP= $p_{0a} < p_{0b} >$
- PROP= p_{1a}
- TEST= PROP | LOGOR | LOGRR
- REF= NULLPROP | PROP | AVGNULLPROP | AVGPROP
- WEIGHT= $w_a < w_b >$
- MATCHNOBS= YES | NO

The NULLPROP= option specifies proportions $p_a = p_{0a}$ and $p_b = p_{0b}$ in groups A and B, respectively, under the null hypothesis. If p_{0b} is not specified, $p_{0b} = p_{0a}$. The default is NULLPROP=0.5.

The PROP= option specifies proportion $p_a = p_{1a}$ in group A under the alternative hypothesis. The proportion p_{1b} in group B under the alternative hypothesis is given by $p_{1b} = p_{0b}$. The PROP= option is required if the alternative reference is not specified or derived in the procedure. If the PROP= option is not specified, the specified or derived alternative reference is used to compute p_{1a}, the proportion in group A under the alternative hypothesis.

The TEST= option specified the null hypothesis $H_0 : \theta = 0$ in the test. The TEST=PROP option uses the difference in proportions $\theta = (p_a - p_b) - (p_{0a} - p_{0b})$, the TEST=LOGOR option uses the log odds-ratio test $\theta = \delta - \delta_0$, where

$$\delta = \log\left(\frac{p_a(1-p_b)}{p_b(1-p_a)}\right) \qquad \delta_0 = \log\left(\frac{p_{0a}(1-p_{0b})}{p_{0b}(1-p_{0a})}\right)$$

and the TEST=LOGRR option uses the log relative risk test with $\theta = \delta - \delta_0$, where

$$\delta = \log\left(\frac{p_a}{p_b}\right) \qquad \delta_0 = \log\left(\frac{p_{0a}}{p_{0b}}\right)$$

The default is TEST=LOGOR.

The REF= option specifies the hypothesis under which the proportions are used in the sample size computation. The REF=NULLPROP option uses the null proportions p_{0a} and p_{0b}, the REF=PROP option uses the alternative proportions p_{1a} and p_{1b}, the REF=AVGNULLPROP option uses the average null proportion, and the REF=AVGPROP option uses the average alternative proportion. The default is REF=PROP.

The WEIGHT= option specifies the sample size allocation weights for the two groups. If w_b is not specified, $w_b = 1$ is used. The default is WEIGHT=1, equal sample size for the two groups. The derived fractional sample sizes are also rounded up to integers, and the MATCHNOBS=YES option requests that these integer sample sizes match the sample size allocation.

See the section "Test for the Difference between Two Binomial Proportions" on page 5862, the section "Test for Two Binomial Proportions with a Log Odds Ratio Statistic" on page 5864, and the section "Test for Two Binomial Proportions with a Log Relative Risk Statistic" on page 5865 for a detailed description of the two-sample tests for proportions.

MODEL=TWOSAMPLESURVIVAL < (*options*) >

MODEL=TWOSAMPLESURV < (*options*) >

specifies the log-rank test for two survival distributions with the null hypothesis $H_0 : \theta = \delta - \delta_0 = 0$, where the parameter $\delta = -\log(h_a/h_b)$, δ_0 is the value of δ under the null hypothesis and the values h_a and h_b are the hazard rates for groups A and B, respectively.

The available options for the number of events are as follows:

- NULLHAZARD= $h_{0a} < h_{0b} >$
- NULLMEDSURVTIME= $t_{0a} < t_{0b} >$
- HAZARD= h_{1a}
- MEDSURVTIME= t_{1a}
- HAZARDRATIO= λ_1

The NULLHAZARD= option specifies hazard rates $h_a = h_{0a}$ and $h_b = h_{0b}$ for groups A and B, respectively, under the null hypothesis. If h_{0b} is not specified, $h_{0b} = h_{0a}$. The NULLMEDSURVTIME= option specifies the median survival times $t_a = t_{0a}$ and $t_b = t_{0b}$ under the null hypothesis. If t_{0b} is not specified, $t_{0b} = t_{0a}$. If both NULLHAZARD= and NULLMEDSURVTIME= option are not specified, NULLHAZARD=0.06931, which corresponds to NULLMEDSURVTIME=10, is used.

The hazard rate for group B under the alternative hypothesis $h_{1b} = h_{0b}$, as the hazard rate under the null hypothesis. The HAZARD=, MEDSURVTIME=, and HAZARDRATIO= options specify the group A hazard rate h_{1a}, the group A median survival time t_{1a}, and the hazard ratio $\lambda_1 = h_{1a}/h_{1b}$, respectively, under the alternative hypothesis. The HAZARD=, MEDSURVTIME=, or HAZARDRATIO= option is required if the alternative reference is not specified or derived in the procedure. If these three options are not specified, the specified or derived alternative reference θ_1 is used to compute h_{1a} from the equation:

$$\theta_1 = -\log(\frac{h_{1a}}{h_{1b}}) - (-\log(\frac{h_{0a}}{h_{0b}})) = -\log(\frac{h_{1a}}{h_{0a}})$$

In order to derive the sample size, additional options are needed. The available options for the sample size computation are as follows:

- REF= NULLHAZARD | HAZARD
- WEIGHT= $w_a < w_b >$
- ACCRATE= r_a
- ACCTIME= T_a
- FOLTIME= T_f
- TOTALTIME= T

The REF= option specifies the hypothesis under which the hazard is used in the sample size computation. The REF=NULLHAZARD option uses the null hypothesis, and the REF=HAZARD option uses the alternative hypothesis. The default is REF=HAZARD.

The WEIGHT= option specifies the sample size allocation weights for the two groups. If w_b is not specified, $w_b = 1$ is used. The default is WEIGHT=1, equal sample size for the two groups.

With the available maximum information, the number of events can be derived for the specified hypothesis. Assuming that the hazard rates are constant and the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a, the sample size and study time can be derived.

The ACCRATE= option specifies the constant accrual rate r_a, and the ACCTIME= and FOLTIME= options specify the accrual time T_a and follow-up time T_f, respectively. The TOTALTIME= option specifies the total study time, $T = T_a + T_f$.

If the ACCRATE= option is specified, then one of the ACCTIME=, FOLTIME=, and TOTALTIME= options is required for the sample size computation. Otherwise, two of the ACCTIME=, FOLTIME=, and TOTALTIME= options are required to compute the accrual rate and sample size.

See the section "Test for Two Survival Distributions with a Log-Rank Test" on page 5866 for a detailed description of the two-sample log-rank test for survival data.

Regression Models

The following three options compute the required sample size or number of events for group sequential tests on a regression parameter.

MODEL=REG < (*options*) >

specifies the Z test for a normal regression parameter. The available options are as follows:

- BETA= β_1
- VARIANCE= σ_y^2
- XVARIANCE= σ_x^2
- XRSQUARE= r_x^2

The BETA= option specifies the alternative reference β_1 and is required if the alternative reference is not specified or derived in the procedure. If the BETA= option is not specified, $\beta_1 = \theta_1$, the specified or derived alternative reference.

The VARIANCE= and XVARIANCE= options specify the variances for the response variable Y and covariate X, respectively. The defaults are VARIANCE=1 and XVARIANCE=1. For a model with more than one covariate, the XRSQUARE= option can be used to derive the variance of X after adjusting for other covariates. The default is XRSQUARE=0.

See the section "Test for a Parameter in the Regression Model" on page 5869 for a detailed description of the Z test for the regression parameter.

MODEL=LOGISTIC < (*options*) >

specifies the Z test for a logistic regression parameter. The available options are as follows:

- BETA= β_1
- PROP= p
- XVARIANCE= σ_x^2
- XRSQUARE= r_x^2

The BETA= option specifies the alternative reference β_1 and is required if the alternative reference is not specified or derived in the procedure. If the BETA= option is not specified, $\beta_1 = \theta_1$, the specified or derived alternative reference.

The PROP= option specifies the proportion of the binary response variable Y. The default is PROP=0.5. The XVARIANCE= option specifies the variance of the covariate X. The default is XVARIANCE=1. For a model with more than one covariate, the XRSQUARE= option can be used to derive the variance of X after adjusting for other covariates. The default is XRSQUARE=0.

See the section "Test for a Parameter in the Logistic Regression Model" on page 5870 for a detailed description of the Z test for the logistic regression parameter.

MODEL=PHREG < (*options*) >

specifies the Z test for a proportional hazards regression parameter. The available options for the number of events are as follows:

- BETA= β_1
- XVARIANCE= σ_x^2
- XRSQUARE= r_x^2

The BETA= option specifies the alternative reference β_1 and is required if the alternative reference is not specified or derived in the procedure. If the BETA= option is not specified, $\beta_1 = \theta_1$, the specified or derived alternative reference.

The XVARIANCE= option specifies the variance of the covariate X. The default is XVARIANCE=1. For a model with more than one covariate, the XRSQUARE= option can be used to derive the variance of X after adjusting for other covariates. The default is XRSQUARE=0.

In order to derive the sample size, additional options are needed. The available options for the sample size computation are as follows:

- HAZARD= h_a
- MEDSURVTIME= t_a
- ACCRATE= r_a
- ACCTIME= T_a
- FOLTIME= T_f
- TOTALTIME= T

The hazard rate is required for the sample size computation. The HAZARD= h_a option specifies the hazard rate h_a explicitly, and the MEDSURVTIME=t_a option specifies the hazard rate implicitly through the median survival time t_a.

Assuming that the hazard rates are constant and the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a, the sample size and study time can be derived.

The ACCRATE= option specifies the constant accrual rate r_a, the ACCTIME= option specifies the accrual time T_a, and the FOLTIME= option specifies the follow-up time T_f. The TOTALTIME= option specifies the total study time, $T = T_a + T_f$.

If the ACCRATE= option is specified, then one of the ACCTIME=, FOLTIME=, and TOTALTIME= options is required for the sample size computation. Otherwise, two of the ACCTIME=, FOLTIME=, and TOTALTIME= options are required to compute the accrual rate and sample size.

See the section "Test for a Parameter in the Proportional Hazards Regression Model" on page 5871 for a detailed description of the Z test for the proportional hazards regression parameter.

Details: SEQDESIGN Procedure

Fixed-Sample Clinical Trials

A clinical trial is a research study in consenting human beings to answer specific health questions. One type of trial is a treatment trial, which tests the effectiveness of an experimental treatment. An example is a planned experiment designed to assess the efficacy of a treatment in humans by comparing the outcomes in a group of patients who receive the test treatment with the outcomes in a comparable group of patients who receive a placebo control treatment, where patients in both groups are enrolled, treated, and followed over the same time period.

A clinical trial is conducted according to a plan called a protocol. The protocol provides detailed description of the study. For a fixed-sample trial, the study protocol contains detailed information such as the null hypothesis, the one-sided or two-sided test, and the Type I and II error probability levels. It also includes the test statistic and its associated critical values in the hypothesis testing.

Generally, the efficacy of a new treatment is demonstrated by testing a hypothesis $H_0 : \theta = 0$ in a clinical trial, where θ is the parameter of interest. For example, to test whether a population mean μ is greater than a specified value μ_0, $\theta = \mu - \mu_0$ can be used with an alternative $\theta > 0$.

A one-sided test is a test of the hypothesis with either an upper (greater) or a lower (lesser) alternative, and a two-sided test is a test of the hypothesis with a two-sided alternative. The drug industry often prefers to use a one-sided test to demonstrate clinical superiority based on the argument that a study should not be run if the test drug would be worse (Chow, Shao, and Wang 2003, p. 28). But in practice, two-sided tests are commonly performed in drug development (Senn 1997, p. 161). For a fixed Type I error probability α, the sample sizes required by one-sided and two-sided tests are

different. Refer to Senn (1997, pp. 161–167) for a detailed description of issues involving one-sided and two-sided tests.

For independent and identically distributed observations $y_1, y_2, \ldots, y_n$ of a random variable, the likelihood function for θ is

$$L(\theta) = \prod_{j=1}^{n} L_i(\theta)$$

where θ is the population parameter and $L_i(\theta)$ is the probability or probability density of y_i. Using the likelihood function, two statistics can be derived that are useful for inference: the maximum likelihood estimator and the score statistic.

Maximum Likelihood Estimator

The maximum likelihood estimate (MLE) of θ is the value $\hat{\theta}$ that maximizes the likelihood function for θ. Under mild regularity conditions, $\hat{\theta}$ is an asymptotically unbiased estimate of θ with variance $1/E_\theta(I(\theta))$, where $I(\theta)$ is the Fisher information

$$I(\theta) = -\frac{\partial^2 \log(L(\theta))}{\partial \theta^2}$$

and $E_\theta(I(\theta))$ is the expected Fisher information (Diggle et al. 2002, p. 340)

$$E_\theta(I(\theta)) = -E_\theta\left(\frac{\partial^2 \log(L(\theta))}{\partial \theta^2}\right)$$

The score function for θ is defined as

$$S(\theta) = \frac{\partial \log(L(\theta))}{\partial \theta}$$

and usually, the MLE can be derived by solving the likelihood equation $S(\theta) = 0$. Asymptotically, the MLE is normally distributed (Lindgren 1976, p. 272):

$$\hat{\theta} \sim N\left(\theta, \frac{1}{E_\theta(I(\theta))}\right)$$

If the Fisher information $I(\theta)$ does not depend on θ, then $I(\theta)$ is known. Otherwise, either the expected information evaluated at the MLE $\hat{\theta}$ ($E_{\theta=\hat{\theta}}(I(\theta))$) or the observed information $I(\hat{\theta})$ can be used for the Fisher information (Cox and Hinkley, 1974, p. 302; Efron and Hinkley, 1978, p. 458), where the observed Fisher information

$$I(\hat{\theta}) = -\left(\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} \mid \theta = \hat{\theta}\right)$$

If the Fisher information $I(\theta)$ does depend on θ, the observed Fisher information is recommended for the variance of the maximum likelihood estimator (Efron and Hinkley, 1978, p. 457).

Thus, asymptotically, for large n,

$$\hat{\theta} \sim N\left(\theta, \frac{1}{I}\right)$$

where I is the information, either the expected Fisher information $E_{\theta=0}(I(\theta))$ or the observed Fisher information $I\hat{\theta})$.

So to test $H_0 : \theta = 0$ versus $H_1 : \theta \neq 0$, you can use the standardized Z test statistic

$$Z = \frac{\hat{\theta}}{\sqrt{\text{Var}(\hat{\theta})}} = \hat{\theta}\sqrt{I} \sim N\,(0,\ 1)$$

and the two-sided p-value is given by

$$\text{Prob}(|Z| > |z_0|) = 1 - 2\Phi(|z_0|)$$

where Φ is the cumulative standard normal distribution function and z_0 is the observed Z statistic.

If the BOUNDARYSCALE=SCORE is specified in the SEQDESIGN procedure, the boundary values for the test statistic are displayed in the score statistic scale. With the standardized Z statistic, the score statistic $S = Z\sqrt{I} = \hat{\theta}I$ and

$$S \sim N\,(0,\ I)$$

Score Statistic

The score statistic is based on the score function for θ,

$$S(\theta) = \frac{\partial \log(L(\theta))}{\partial\theta}$$

Under the null hypothesis $H_0 : \theta = 0$, the score statistic $S(0)$ is the first derivative of the log likelihood evaluated at the null reference 0:

$$S(0) = \frac{\partial \log(L(\theta))}{\partial\theta} \,|\, \theta = 0$$

Under regularity conditions, $S(0)$ is asymptotically normally distributed with mean zero and variance $E_{\theta=0}(I(\theta))$, the expected Fisher information evaluated at the null hypothesis $\theta = 0$ (Kalbfleisch and Prentice, 1980, p. 45), where $I(\theta)$ is the Fisher information

$$I(\theta) = -E\left(\frac{\partial^2 \log(L(\theta))}{\partial\theta^2}\right)$$

That is, for large n,

$$S(0) \sim N\,(0,\ E_{\theta=0}(I(\theta)))$$

Asymptotically, the variance of the score statistic $S(0)$, $E_{\theta=0}(I(\theta))$, can also be replaced by the expected Fisher information evaluated at the MLE $\theta = \hat{\theta}$ ($E_{\theta=\hat{\theta}}(I(\theta))$), the observed Fisher information evaluated at the null hypothesis $\theta = 0$ ($I(0)$), or the observed Fisher information evaluated at the MLE $\theta = \hat{\theta}$ ($I(\hat{\theta})$) (Kalbfleisch and Prentice, 1980, p. 46), where

$$I(0) = -\left(\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} \mid \theta = 0\right)$$

$$I(\hat{\theta}) = -\left(\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} \mid \theta = \hat{\theta}\right)$$

Thus, asymptotically, for large n,

$$S(0) \sim N\,(0,\ I)$$

where I is the information, either an expected Fisher information ($E_{\theta=0}(I(\theta))$ or $E_{\theta=\hat{\theta}}(I(\theta))$) or a observed Fisher information ($I(0)$ or $I(\hat{\theta})$).

So to test $H_0 : \theta = 0$ versus $H_1 : \theta \neq 0$, you can use the standardized Z test statistic

$$Z = \frac{S(0)}{\sqrt{I}}$$

If the BOUNDARYSCALE=MLE is specified in the SEQDESIGN procedure, the boundary values for the test statistic are displayed in the MLE scale. With the standardized Z statistic, the MLE statistic $\hat{\theta} = Z/\sqrt{I} = U(0)/I$ and

$$\hat{\theta} \sim N\left(0,\ \frac{1}{I}\right)$$

One-Sample Test for Mean

The following one-sample test for mean is used to demonstrate fixed-sample clinical trials in the section "One-Sided Fixed-Sample Tests in Clinical Trials" on page 5821 and the section "Two-Sided Fixed-Sample Tests in Clinical Trials" on page 5824.

Suppose $y_1, y_2, \ldots, y_n$ are n observations of a response variable Y from a normal distribution

$$y_i \sim N\left(\theta,\ \sigma^2\right)$$

where θ is the unknown mean and σ^2 is the known variance.

Then the log likelihood function for θ is

$$\log(L(\theta)) = \sum_{j=1}^{n} -\frac{1}{2}\frac{(y_j - \theta)^2}{\sigma^2} + c$$

where c is a constant. The first derivative is

$$\frac{\partial \log(L(\theta))}{\partial \theta} = \frac{1}{\sigma^2}\sum_{j=1}^{n}(y_j - \theta) = \frac{n}{\sigma^2}(\overline{y} - \theta)$$

where $\overline{y}$ is the sample mean.

Setting the first derivative to zero, the MLE of θ is $\hat{\theta} = \overline{y}$, the sample mean. The variance for $\hat{\theta}$ can be derived from the Fisher information

$$I(\theta) = -\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} = \frac{n}{\sigma^2}$$

Since the Fisher information $I_0 = I(\theta)$ does not depend on θ in this case, $1/I_0$ is used as the variance for $\hat{\theta}$. Thus the sample mean $\overline{y}$ has a normal distribution with mean θ and variance σ^2/n:

$$\hat{\theta} = \overline{y} \sim N\left(\theta, \frac{1}{I_0}\right) = N\left(\theta, \frac{\sigma^2}{n}\right)$$

Under the null hypothesis $H_0 : \theta = 0$, the score statistic

$$S(0) = \frac{\partial \log(L(\theta))}{\partial \theta} | \theta = 0 = \frac{n}{\sigma^2}\overline{y}$$

has a mean zero and variance

$$I(\theta) = -\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} = \frac{n}{\sigma^2}$$

With the MLE $\hat{\theta}$, the corresponding standardized statistic is computed as $Z = \hat{\theta}\sqrt{I_0} = \overline{y}/(\sigma/\sqrt{n})$, which has a normal distribution with variance 1:

$$Z \sim N\left(\theta\sqrt{I_0}, 1\right) = N\left(\frac{\theta}{\sigma/\sqrt{n}}, 1\right)$$

Also, the corresponding score statistic is computed as $S = \hat{\theta} I_0 = n\overline{y}/\sigma^2$ and

$$S \sim N\left(\theta I_0, I_0\right) = N\left(\frac{n\theta}{\sigma^2}, \frac{n}{\sigma^2}\right)$$

which is identical to $S(0)$ computed under the null hypothesis $H_0 : \theta = 0$.

Note that if the variable Y does not have a normal distribution, then it is assumed that the sample size n is large such that the sample mean has an approximately normal distribution.

One-Sided Fixed-Sample Tests in Clinical Trials

A one-sided test has either an upper (greater) or a lower (lesser) alternative. This section describes one-sided tests with upper alternatives only. Corresponding results for one-sided tests with lower alternatives can be derived similarly.

For a one-sided test of $H_0 : \delta \leq \delta_0$ with an upper alternative $H_1 : \delta > \delta_0$, an equivalent null hypothesis is $H_0 : \theta \leq 0$ with an upper alternative $H_1 : \theta > 0$, where $\theta = \delta - \delta_0$. A fixed-sample test rejects H_0 if the standardized test statistic $Z_0 = \hat{\theta}\sqrt{I_0} \geq C_\alpha$, where $\hat{\theta}$ is the sample estimate of θ and $C_\alpha = \Phi^{-1}(1-\alpha)$ is the critical value.

The p-value of the test is given by $1 - \Phi(Z_0)$, and the hypothesis H_0 is rejected if the p-value is less than α. An upper $(1-\alpha)$ confidence interval has the lower limit

$$\theta_l = \hat{\theta} - \frac{\Phi^{-1}(1-\alpha)}{\sqrt{I_0}} = \frac{Z_0 - \Phi^{-1}(1-\alpha)}{\sqrt{I_0}}$$

The hypothesis H_0 is rejected if the confidence interval for the parameter θ does not contain zero—that is, if the lower limit θ_l is greater than 0.

With an alternative reference $\theta = \theta_1$, $\theta_1 > 0$, a Type II error probability is defined as

$$\beta = P_{\theta=\theta_1}(Z_0 < C_\alpha)$$

which is equivalent to

$$\beta = P_{\theta=\theta_1}\left(Z_0 - \theta_1\sqrt{I_0} \; < \; C_\alpha - \theta_1\sqrt{I_0}\right) = \Phi\left(C_\alpha - \theta_1\sqrt{I_0}\right)$$

Thus, $\Phi^{-1}(\beta) = C_\alpha - \theta_1\sqrt{I_0}$. Then, with $C_\alpha = \Phi^{-1}(1-\alpha)$,

$$\theta_1\sqrt{I_0} = \Phi^{-1}(1-\alpha) + \Phi^{-1}(1-\beta)$$

The drift parameter $\theta_1\sqrt{I_0}$ can be computed for specified α and β and the maximum information is given by

$$I_0 = \left(\frac{\Phi^{-1}(1-\alpha) + \Phi^{-1}(1-\beta)}{\theta_1}\right)^2$$

If the maximum information is available, then the required sample size can be derived. For example, in a one-sample test for the mean with a specific standard deviation σ, the sample size n required for the test is

$$n = \sigma^2 I_0 = \sigma^2\left(\frac{\Phi^{-1}(1-\alpha) + \Phi^{-1}(1-\beta)}{\theta_1}\right)^2$$

On the other hand, if the alternative reference θ_1, standard deviation σ, and sample size n are all specified, then α can be derived for a given β and, similarly, β can be derived for a given α.

With an alternative reference $\theta = \theta_1$, $\theta_1 > 0$, the power $1 - \beta$ is the probability of correctly rejecting the null hypothesis H_0 at θ_1:

$$1 - \beta = 1 - P_{\theta=\theta_1}(Z_0 < C_\alpha) = \Phi\left(\theta_1\sqrt{I_0} - C_\alpha\right)$$

Superiority Trials

A superiority trial that tests the response to a new drug is clinically superior to a comparative placebo control or active control therapy. If a positive value indicates a beneficial effect, a test for superiority has

$$H_0 : \theta \leq 0 \qquad H_1 : \theta > 0$$

where H_0 is the hypothesis of nonsuperiority and H_1 is the alternative hypothesis of superiority.

The superiority test rejects the hypothesis H_0 and declares superiority if the standardized statistic $Z_0 = \hat{\theta}\sqrt{I_0} \geq C_\alpha$, where the critical value $C_\alpha = \Phi^{-1}(1-\alpha)$.

For example, if θ is the response difference between the treatment and placebo control groups, then a superiority trial can be

$$H_0 : \theta \leq 0 \qquad H_1 : \theta = 6$$

with a Type I error probability level $\alpha = 0.025$ and a power $1 - \beta = 0.90$ at $\theta_1 = 6$.

Noninferiority Trials

A noninferiority trial does not compare the response to a new treatment with the response to a placebo. Instead, it demonstrates the effectiveness of a new treatment compared with that of a nonexisting placebo by showing that the response of a new treatment is not clinically inferior to the response of a standard therapy with an established effect. That is, this type of trial attempts to demonstrate that the new treatment effect is not worse than the standard therapy effect by an acceptable margin. These trials are often performed when there is an existing effective therapy for a serious disease, and therefore a placebo control group cannot be ethically included.

It can be difficult to specify an appropriate noninferiority margin. One practice is to choose with reference to the effect of the active control in historical placebo-controlled trials (Snapinn 2000, p. 20). With this practice, there is some basis to imply that the new treatment is better than the placebo for a positive noninferiority trial.

If a positive value indicates a beneficial effect, a test for noninferiority has a null hypothesis $\delta \leq -\delta_0$ and an alternative hypothesis $\delta = \delta_1 > -\delta_0$, where $\delta_0 > 0$ is the specified noninferiority margin.

An equivalent test has

$$H_0 : \theta \leq 0 \qquad H_1 : \theta = \theta_1 > 0$$

where the parameter $\theta = \delta + \delta_0$, H_0 is the null hypothesis of inferiority, and H_1 is the alternative hypothesis of noninferiority,

The noninferiority test rejects the hypothesis H_0 and declares noninferiority if the standardized statistic $Z_0 = \hat{\theta}\sqrt{I_0} = (\hat{\delta} + \delta_0)\sqrt{I_0} \geq C_\alpha$, where the critical value $C_\alpha = \Phi^{-1}(1-\alpha)$.

For example, if δ is the response difference between the treatment and active control groups and $\delta_0 = 2$ is the noninferiority margin, then a noninferiority trial with a power $1-\beta = 0.90$ at $\delta_1 = 1$ might be

$$H_0 : \theta \leq 0 \qquad H_1 : \theta = 3$$

where $\theta = \delta + \delta_0 = \delta + 2$.

Two-Sided Fixed-Sample Tests in Clinical Trials

A two-sided test is a test of a hypothesis with a two-sided alternative. Two-sided tests include simple symmetric tests and more complicated asymmetric tests that might have distinct lower and upper alternative references.

Symmetric Two-Sided Tests for Equality

For a symmetric two-sided test with the null hypothesis $\delta = \delta_0$ against the alternative $\delta \neq \delta_0$, an equivalent null hypothesis is $H_0 : \theta = 0$ with a two-sided alternative $H_1 : \theta \neq 0$, where $\theta = \delta - \delta_0$. A fixed-sample test rejects H_0 if $|\hat{\theta}\sqrt{I_0}| \geq C_{\alpha/2}$, where $\hat{\theta}$ is a sample estimate of θ and $C_{\alpha/2} = \Phi^{-1}(1-\alpha/2)$ is the critical value.

A common two-sided test is the test for the response difference between a treatment group and a control group. The null and alternative hypotheses are $H_0 : \theta = 0$ and $H_1 : \theta \neq 0$, respectively, where θ is the response difference between the two groups. If a greater value indicates a beneficial effect, then there are three possible results:

- The test rejects the hypothesis H_0 of equality and indicates that the treatment is significantly better if the standardized statistic $Z_0 = \hat{\theta}\sqrt{I_0} \geq C_{\alpha/2}$.
- The test rejects the hypothesis H_0 and indicates the treatment is significantly worse if the standardized statistic $Z_0 = \hat{\theta}\sqrt{I_0} \leq -C_{\alpha/2}$.
- The test indicates no significant difference between the two responses if $-C_{\alpha/2} < \hat{\theta}\sqrt{I_0} < C_{\alpha/2}$.

The p-value of the test is $2(1-\Phi(Z_0))$ if $Z_0 > 0$ and $2\Phi(Z_0)$ if $Z_0 \leq 0$. The hypothesis H_0 is rejected if the p-value of the test is less than α—that is, if $1-\Phi(Z_0) < \alpha/2$ or $\Phi(Z_0) < \alpha/2$. A symmetric $(1-\alpha)$ confidence interval for θ has lower and upper limits

$$\left(\hat{\theta} - \frac{C_{\alpha/2}}{\sqrt{I_0}}\,,\ \hat{\theta} + \frac{C_{\alpha/2}}{\sqrt{I_0}}\right)$$

which is

$$\left(\frac{1}{\sqrt{I_0}}\left(Z_0 - C_{\alpha/2}\right)\,,\ \frac{1}{\sqrt{I_0}}\left(Z_0 + C_{\alpha/2}\right)\right)$$

The hypothesis H_0 is rejected if the confidence interval for the parameter θ does not contain zero. That is, the lower limit is greater than zero or the upper limit is less than zero.

With an alternative reference $\theta = \theta_1 > 0$, a Type II error probability is defined as

$$\beta = P_{\theta=\theta_1}(-C_{\alpha/2} \ < \ Z_0 \ < \ C_{\alpha/2})$$

which is

$$\beta = P_{\theta=\theta_1}\left((-C_{\alpha/2} - \theta_1\sqrt{I_0}) \ < \ (Z_0 - \theta_1\sqrt{I_0}) \ < \ (C_{\alpha/2} - \theta_1\sqrt{I_0})\right)$$

Thus

$$\beta = \Phi\left(C_{\alpha/2} - \theta_1\sqrt{I_0}\right) - \Phi\left(-C_{\alpha/2} - \theta_1\sqrt{I_0}\right)$$

The resulting power $1 - \beta$ is the probability of correctly rejecting the null hypothesis, which includes the probability for the lower alternative and the probability for the upper alternative. The SEQDESIGN procedure uses only the probability of correctly rejecting the null hypothesis for the correct alternative in the power computation.

Thus, under the upper alternative hypothesis, the power in the SEQDESIGN procedure is computed as the probability of rejecting the null hypothesis for the upper alternative, $1. - \Phi\left(C_{\alpha/2} - \theta_1\sqrt{I_0}\right) = \Phi\left(\theta_1\sqrt{I_0} - C_{\alpha/2}\right)$, and a very small probability of rejecting the null hypothesis for the lower alternative, $\Phi\left(-C_{\alpha/2} - \theta_1\sqrt{I_0}\right)$, is ignored. This power computation is more rational than the power based on the probability of correctly rejecting the null hypothesis (Whitehead 1997, p. 75).

That is,

$$\beta = P_{\theta=\theta_1}\left((Z_0 - \theta_1\sqrt{I_0}) \ < \ (C_{\alpha/2} - \theta_1\sqrt{I_0})\right) = \Phi\left(C_{\alpha/2} - \theta_1\sqrt{I_0}\right)$$

Then with $\Phi^{-1}(\beta) = C_{\alpha/2} - \theta_1\sqrt{I_0}$,

$$\theta_1\sqrt{I_0} = C_{\alpha/2} - \Phi^{-1}(\beta) = \Phi^{-1}(1-\alpha/2) + \Phi^{-1}(1-\beta)$$

The drift parameter $\theta_1\sqrt{I_0}$ can be derived for specified α and β, and the maximum information is given by

$$I_0 = \left(\frac{\Phi^{-1}(1-\alpha/2) + \Phi^{-1}(1-\beta)}{\theta_1}\right)^2$$

If the maximum information is available, then the required sample size can be derived. For example, in a one-sample test for mean, if the standard deviation σ is known, the sample size n required for the test is

$$n = \sigma^2 I_0 = \sigma^2\left(\frac{\Phi^{-1}(1-\alpha/2) + \Phi^{-1}(1-\beta)}{\theta_1}\right)^2$$

On the other hand, if the alternative reference θ_1, standard deviation σ, and sample size n are all known, then α can be derived with a given β and, similarly, β can be derived with a given α.

Generalized Two-Sided Tests for Equality

For a generalized two-sided test with the null hypothesis $\delta = \delta_0$ against the alternative $\delta \neq \delta_0$, an equivalent null hypothesis is $H_0 : \theta \leq 0$ with a two-sided alternative $H_1 : \theta \neq 0$, where $\theta = \delta - \delta_0$. A fixed-sample test rejects H_0 if the standardized statistic $Z_0 = \hat{\theta}\sqrt{I_0} < -C_{\alpha_l}$ or $Z_0 = \hat{\theta}\sqrt{I_0} > C_{\alpha_u}$, where the critical values $C_{\alpha_l} = \Phi^{-1}(1-\alpha_l)$ and $C_{\alpha_u} = \Phi^{-1}(1-\alpha_u)$.

With the lower alternative reference $\theta_{1l} < 0$, a lower Type II error probability is defined as

$$\beta_l = P_{\theta=\theta_{1l}}\left(-C_{\alpha_l} \leq Z_{0l}\sqrt{I_0}\right) = P_{\theta=\theta_{1l}}\left(-C_{\alpha_l} - \theta_{1l}\sqrt{I_0} \leq Z_{0l}\sqrt{I_0} - \theta_{1l}\sqrt{I_0}\right)$$

This implies

$$\beta_l = 1 - \Phi(-C_{\alpha_l} - \theta_{1l}\sqrt{I_0})$$

and the power is the probability of correctly rejecting the null hypothesis for the lower alternative,

$$1 - \beta_l = \Phi(-C_{\alpha_l} - \theta_{1l}\sqrt{I_0})$$

The lower drift parameter is derived as

$$\theta_{1l}\sqrt{I_0} = -\left(\Phi^{-1}(1-\alpha_l) + \Phi^{-1}(1-\beta_l)\right)$$

Then, with specified α_l and β_l, if the maximum information is known, the lower alternative reference θ_{1l} can be derived. If the maximum information is unknown, then with the specified lower alternative reference θ_{1l}, the maximum information required is

$$I_{0l} = \left(\frac{\Phi^{-1}(1-\alpha_l) + \Phi^{-1}(1-\beta_l)}{-\theta_{1l}}\right)^2$$

Similarly, the upper drift parameter is derived as

$$\theta_{1u}\sqrt{I_0} = \Phi^{-1}(1-\alpha_u) + \Phi^{-1}(1-\beta_u)$$

For a given α_u, β_u, and the upper alternative reference θ_{1u}, the maximum information required is

$$I_{0u} = \left(\frac{\Phi^{-1}(1-\alpha_u) + \Phi^{-1}(1-\beta_u)}{\theta_{1u}}\right)^2$$

Thus, the maximum information required for the design is given by

$$I_0 = \max\left(I_{0l},\ I_{0u}\right)$$

Note that with the maximum information level I_0, if $I_{0l} < I_0$, then the derived power from the lower alternative is larger than the specified $1-\beta_l$. Similarly, if $I_{0u} < I_0$, then the derived power from the upper alternative is larger than the specified $1-\beta_u$.

If maximum information is available, the required sample size can be derived. For example, in a one-sample test for mean, if the standard deviation σ is known, the sample size n required for the test is $n = \sigma^2 I_0$.

On the other hand, if the alternative references, Type I error probabilities α_l and α_u, standard deviation σ, and sample size n are all specified, then the Type II error probabilities β_l and β_u and the corresponding powers can be derived.

Group Sequential Methods

A group sequential design provides interim analyses before the formal completion of a trial. The monitoring process provides possible early stopping for either positive or negative results and thus reduces the time to complete the trial. With a specified number of stages, the design creates critical values such that at each interim analysis, a hypothesis can be rejected, accepted, or continued to the next time point. At the final stage, a hypothesis is either rejected or accepted. Usually, the critical values are derived such that the specified overall Type I and Type II error probability levels are maintained in the design.

For example, to test a null hypothesis H_0 with an upper alternative in a fixed-sample design, a critical value c_α is created. The null hypothesis H_0 is rejected if the test statistic is greater than or equal to the critical value c_α. Otherwise, H_0 is accepted. But, for a group sequential design with early stopping to reject or accept the null hypothesis H_0, there are two critical values created at each interim analysis: an α critical value $c_{\alpha k}$ to reject the null hypothesis and a β critical value $c_{\beta k}$ to accept the null hypothesis. The null hypothesis H_0 is rejected if the test statistic is greater than or equal to the α critical value $c_{\alpha k}$, and H_0 is accepted if the test statistic is less than the β critical value $c_{\beta k}$. If the test statistic is between these two critical values, the process continues to the next stage. At the final stage, the two critical values are equal, and the hypothesis is either rejected or accepted.

Armitage, McPherson, and Rowe (1969) showed that repeated significance tests at a fixed level on accumulating data increase the probability of obtaining a significant result under the null hypothesis. For example, with a significance level 0.05 in a two-sided fixed-sample test, the critical value is 1.96. If this value is used in a five-stage group sequential trial with early stopping to reject the null hypothesis, then the probability of rejecting the null hypothesis at or before the fifth stage is 0.14169, much larger than the nominal value 0.05 (Armitage, McPherson, and Rowe 1969, p. 239).

Pocock (1977) applied these repeated significance tests to group sequential trials with equally spaced information levels and derives a constant critical value on the standardized normal Z scale across all stages that maintains the Type I error probability level. For example, with a significance level 0.05 in a two-sided test, the derived critical value at each stage is 2.413 on the standardized normal Z scale, larger than the fixed-sample critical value 1.96. The corresponding nominal p-value is 0.0158, which is smaller than the fixed-sample p-value 0.025 (Pocock 1977, p. 193).

O'Brien and Fleming (1979) proposed a sequential procedure that has boundary values decrease over the stages on the standardized normal Z scale to make the early stop less likely. The procedure has conservative stopping boundary values at very early stages, and boundary values at the final stage are close to the fixed-sample design. For example, with a significance level 0.05 in a two-sided test, the derived critical values at these five stages on the standardized normal Z scale are 4.562, 3.226, 2.634, 2.281, and 2.040.

Wang and Tsiatis (1987), Emerson and Fleming (1989) and Pampallona and Tsiatis (1994) generalized the Pocock and O'Brien-Fleming methods to the power family, where a power parameter is used to allow a continuous set of designs between the Pocock and O'Brien-Fleming methods.

Kittelson and Emerson (1999) extended the methods in the power family even further to the unified family, which also includes the exact triangular method. The shape and location of each of the four boundaries can be independently specified in the unified family methods.

Whitehead and Stratton (1983) and Whitehead (1997, 2001) developed triangular methods by adapting tests for continuous monitoring to discrete monitoring. With early stopping to reject or accept the null hypothesis in a one-sided test, the derived continuation region has a triangular shape for the score-scaled boundaries. Only elementary calculations are needed to derive the boundary values for Whitehead's triangular methods.

For a sequential design, you can derive the α and β error probabilities at each stage from the boundaries. On the other hand, you can derive the boundaries from specified α and β error probabilities at each stage. The error spending function approach (Lan and DeMets 1983) uses the error spending function to specify the error probabilities at each stage and then uses these probabilities to derive the boundaries. You can specify α and β explicitly or implicitly with an error spending function for the cumulative probabilities.

Refer to Jennison and Turnbull (2000, pp. 5–11) for a more detailed history of group sequential methods.

The following three types of methods are available in the SEQDESIGN procedure to derive boundaries in a sequential design:

- fixed boundary shape methods, which derive boundaries with specified boundary shapes. These include the unified family method and Haybittle-Peto method.
- Whitehead methods, which adjust the boundaries from continuous monitoring for discrete monitoring
- error spending methods

You can use the SEQDESIGN procedure to specify methods from the same group for each design. A different method can be specified for each boundary separately, but all methods in a design must be from the same group.

Fixed Boundary Shape Methods

The fixed boundary shape methods include the unified family method (Kittelson and Emerson 1999) and the Haybittle-Peto method (Haybittle 1971; Peto et al. 1976). The unified family methods derive the boundary values with the specified boundary shape. The unified family methods include the Pocock method (Pocock 1977), the O'Brien-Fleming method (O'Brien and Fleming 1979), the power family method (Wang and Tsiatis 1987; Emerson and Fleming 1989; Pampallona and Tsiatis 1994), and the triangular method (Kittelson and Emerson 1999). See the section "Unified Family Methods" on page 5839 for a detailed description of the methods that use the unified family approach.

The Haybittle-Peto method uses a value of 3 for the critical values in interim stages, so that the critical value at the final stage is close to the original design without interim monitoring. In the SEQDESIGN procedure, the Haybittle-Peto method has been generalized to allow for different boundary values at different stages. See the section "Haybittle-Peto Method" on page 5844 for a detailed description of the Haybittle-Peto method.

Whitehead Methods

The Whitehead methods (Whitehead and Stratton 1983; Whitehead 1997, 2001) derive the boundary values by adapting the continuous monitoring tests to the discrete monitoring of group sequential tests. The Type I error probability and power corresponding to the resulting boundaries are extremely close but differ slightly from the specified values because of the approximations used in deriving the tests (Jennison and Turnbull 2000, p. 106). The SEQDESIGN procedure provides the BOUNDARYKEY= option to adjust the boundary value at the final stage for the exact Type I or Type II error probability level. See the section "Whitehead Methods" on page 5845 for a detailed description of Whitehead's methods.

Error Spending Methods

An error spending method (Lan and DeMets 1983) uses the error spending function to specify the error spending at each stage and then uses these error probabilities to derive the boundary values. You can specify these errors explicitly or with an error spending function for these cumulative errors. See the section "Error Spending Methods" on page 5848 for a detailed description of the error spending methods.

Error spending methods derive boundary values at each stage sequentially and require much more computation than other types of methods for group sequential trials with a large number of stages, especially for a two-sided asymmetric design with early stopping to accept H_0, or to reject or accept H_0.

The sample size requirement for some applicable tests can also be computed in the procedure. After the actual data from a clinical trial are collected, you can then use the boundary information created in the SEQDESIGN procedure to perform a group sequential test in the SEQTEST procedure.

Statistical Assumptions for Group Sequential Designs

The SEQDESIGN procedure assumes that with a total number of stages K, the sequence of the standardized test statistics $\{Z_1, Z_2, \ldots, Z_K\}$ has the canonical joint distribution with information levels $\{I_1, I_2, \ldots, I_K\}$ for the parameter θ (Jennison and Turnbull 2000, p. 49):

- $(Z_1, Z_2, \ldots, Z_K)$ is multivariate normal
- $Z_k \sim N\left(\theta\sqrt{I_k}, 1\right), \; k = 1, 2, \ldots, K$
- $\mathrm{Cov}(Z_{k_1}, Z_{k_2}) = \sqrt{(I_{k_1}/I_{k_2})}, \quad 1 \le k_1 \le k_2 \le K$

In terms of the maximum likelihood estimator, $\hat{\theta}_k = Z_k/\sqrt{I_k}, k = 1, 2, \ldots, K$, the canonical joint distribution can be expressed as follows:

- $(\hat{\theta}_1, \hat{\theta}_2, \ldots, \hat{\theta}_K)$ is multivariate normal
- $\hat{\theta}_k \sim N\left(\theta,\ 1/I_k\right),\ k = 1, 2, \ldots, K$
- $\mathrm{Cov}(\hat{\theta}_{k_1}, \hat{\theta}_{k_2}) = 1/I_{k_2},\quad 1 \le k_1 \le k_2 \le K$

Furthermore, in terms of the score statistics $S_k = Z_k\sqrt{I_k}, k = 1, 2, \ldots, K$, the canonical joint distribution can be expressed as follows:

- $(S_1, S_2, \ldots, S_K)$ is multivariate normal
- $S_k \sim N\left(\theta\, I_k,\ I_k\right),\ k = 1, 2, \ldots, K$
- $\mathrm{Cov}(S_{k_1}, S_{k_2}) = \mathrm{Var}(S_{k_1}) = I_{k_1},\quad 1 \le k_1 \le k_2 \le K$

That is, the increments S_1, $S_2 - S_1$, …, and $S_K - S_{(K-1)}$ are independently distributed.

If the test statistic is computed from the data that are not from a normal distribution, such as a binomial distribution, then it is assumed that the test statistic is computed from a large sample such that the statistic has an approximately normal distribution.

If the increments S_1, $S_2 - S_1$, …, and $S_K - S_{(K-1)}$ are not independently distributed, then it is inappropriate to use group sequential methods in the SEQDESIGN procedure. One such example is the Gehan statistic, which is a weighted log-rank statistic for censored data. Refer to Jennison and Turnbull (2000 pp. 232–233, 276–277) and Proschan, Lan, and Wittes (2006 pp. 150–151) for a description of statistics with nonindependent increments.

If a trial stops at an early interim stage with only a small number of responses observed, it can lead to a distrust of the statistical findings, which rely on the assumption that the sample is large (Whitehead 1997, p. 167). A group sequential design can be specified such that at the first interim analysis, there are a sufficient number of responses to ensure that the analysis to be conducted is both reliable and persuasive (Whitehead 1997, p. 167).

Alternatively, a method such as the O'Brien-Fleming method can be used to derive conservative stopping boundary values at very early stages to make the early stop less likely. That is, the trial is stopped in early stages only with overwhelming evidence.

A simple example of the group sequential tests is the test for a normal mean, $\mu = \mu_0$. Suppose $y_1, y_2, \ldots, y_n$ are n observations of a response variable Y in a data set from a normal distribution with an unknown mean μ and a known variance σ^2. Then the maximum likelihood estimate of μ is the sample mean

$$\overline{y} = \frac{1}{n}\sum_{j=1}^{n} y_j$$

The sample mean has a normal distribution with mean μ and variance σ^2/n:

$$\overline{y} \sim N\left(\mu,\ \frac{\sigma^2}{n}\right)$$

An equivalent hypothesis for $\mu = \mu_0$ is $H_0 : \theta = 0$, where $\theta = \mu - \mu_0$. The MLE statistic for θ,

$$\hat{\theta} = \overline{y} - \mu_0 \sim N\left(\theta,\ {I_0}^{-1}\right)$$

where the information $I_0 = n/\sigma^2$.

For a group sequential test with K stages, there are $N_1, N_2, \ldots, N_K$ observations available at these stages. At stage k, the sample mean is computed as

$$\overline{y}_k = \frac{1}{N_k} \sum_{j=1}^{N_k} y_{kj}$$

where y_{kj} is the value of the jth observation available at the kth stage and N_k is the cumulative sample size at stage k, which includes the N_{k-1} observations collected at previous stages and the $N_k - N_{k-1}$ observations collected at the current stage.

The maximum likelihood estimate

$$\hat{\theta}_k = \overline{y}_k - \mu_0 \sim N\left(\theta,\ {I_k}^{-1}\right)$$

where the information

$$I_k = \frac{1}{\mathrm{Var}(\overline{y}_k)} = \frac{N_k}{\sigma^2}$$

is the inverse of the variance.

Thus, the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} = (\overline{y}_k - \mu_0)\sqrt{I_k} \sim N\left(\theta \sqrt{I_k},\ 1\right)$$

The covariance of Z_{k_1} and Z_{k_2}, $1 \le k_1 \le k_2 \le K$ can be expressed as

$$\mathrm{Cov}(Z_{k_1}, Z_{k_2}) = \frac{1}{\sqrt{(I_{k_1} I_{k_2})}} \mathrm{Cov}(S_{k_1}, S_{k_2})$$

where $S_{k_1} = Z_{k_1}\sqrt{I_{k_1}}$ and $S_{k_2} = Z_{k_2}\sqrt{I_{k_2}}$.

Since $S_{k_2} - S_{k_1}$ is independent of S_{k_1}, $\mathrm{Cov}(S_{k_1}, S_{k_2}) = \mathrm{Var}(S_{k_1}) = I_{k_1}$ and

$$\mathrm{Cov}(Z_{k_1}, Z_{k_2}) = \frac{1}{\sqrt{(I_{k_1} I_{k_2})}} I_{k_1} = \sqrt{I_{k_1}/I_{k_2}}$$

Thus the statistics $\{Z_1, Z_2, \ldots, Z_K\}$ has the canonical joint distribution with information levels $\{I_1, I_2, \ldots, I_K\}$ for the parameter μ. See the section "Applicable One-Sample Tests and Sample Size Computation" on page 5858, the section "Applicable Two-Sample Tests and Sample Size Computation" on page 5860, and the section "Applicable Regression Parameter Tests and Sample Size Computation" on page 5868 for more examples of applicable tests in group sequential trials.

Boundary Scales

The boundaries computed by the SEQDESIGN procedure are applied to test statistics computed during the analysis, and so generally, the scale you select for the boundaries is determined by the scale of the statistics that you will be using.

The following scales are available in the SEQDESIGN procedure:

- MLE, maximum likelihood estimate
- standardized Z
- score statistic S
- p-value

These scales are all equivalent for a given set of boundary values—that is, there exists a unique transformation between any two of these scales. If you know the boundary values in terms of statistics from one scale, you can uniquely derive the boundary values of statistics for other scales. You can specify the scale with the BOUNDARYSCALE= option, and the default is the standardized Z scale.

You can also select the boundary scale to better examine the features of an individual group sequential design or to compare features among multiple designs. For example, with the standardized Z scale, the boundary values for the Pocock design are identical across all stages, and the O'Brien-Fleming design has boundary values (in absolute value) that decrease over the stages.

The remaining section demonstrates the transformations from one scale to the other scales. If the maximum likelihood estimate $\hat{\theta}$ is computed by the analysis, then

$$\hat{\theta} \sim N\left(\theta,\ \frac{1}{I}\right)$$

where I is the Fisher information if it does not depend on θ. Otherwise, I is either the expected Fisher information evaluated at $\hat{\theta}$ or the observed Fisher information. See the section "Maximum Likelihood Estimator" on page 5818 for a detailed description of these statistics.

With the MLE statistic $\hat{\theta}$, the corresponding standardized Z statistic is computed as

$$Z = \hat{\theta}\sqrt{I} \sim N\left(\theta\sqrt{I},\ 1\right)$$

and the corresponding score statistic is computed as

$$S = \hat{\theta}\, I \sim N\left(\theta\, I,\ I\right)$$

Similarly, if a score statistic S is computed by the analysis, then with

$$S \sim N\left(\theta\, I,\ I\right)$$

where I is the information, either an expected Fisher information ($E_{\theta=0}(I(\theta))$ or $E_{\theta=\hat{\theta}}(I(\theta))$) or an observed Fisher information ($I(0)$ or $I(\hat{\theta})$).

The corresponding standardized Z statistic is computed as

$$Z = \frac{S}{\sqrt{I}} \sim N\left(\theta\sqrt{I},\ 1\right)$$

and the corresponding MLE-scaled statistic is computed as

$$\hat{\theta} = \frac{S}{I} \sim N\left(\theta,\ \frac{1}{I}\right)$$

With a standardized normal Z statistic, the corresponding fixed-sample nominal p-value depends on the type of alternative hypothesis. With an upper alternative, the nominal p-value is defined as the one-sided p-value under the null hypothesis $H_0 : \theta = 0$ with an upper alternative:

$$p_k = 1 - \Phi(Z)$$

With a lower alternative or a two-sided alternative, the nominal p-value is defined as the one-sided p-value under the null hypothesis $H_0 : \theta = 0$ with a lower alternative:

$$p_k = \Phi(Z)$$

which is an increasing function of the standardized Z statistic (Emerson, Kittelson, and Gillen 2005, p. 12).

The BOUNDARYSCALE= MLE, STDZ, SCORE, and PVALUE options display the boundary values in the MLE, standardize Z, score, and p-value scales, respectively. For example, suppose $y_{k1}, y_{k2}, \ldots, y_{kn_k}$ are n_k observations of a response variable Y in a data set from a normal distribution with an unknown mean μ and a known variance σ^2. Then

$$y_{kj} \sim N\left(\mu,\ \sigma^2\right)$$

for $k = 1, 2, \ldots, K$, where K is the number of groups and n_k is the number of observations at group k.

If N_k is the cumulative number of observations for the first k groups, then the sample mean from these N_k observations

$$\overline{y}_k = \frac{1}{N_k} \sum_{j=1}^{N_k} y_{kj}$$

has a normal distribution with mean θ and variance σ^2/N_k:

$$\overline{y}_k \sim N\left(\theta,\ \frac{\sigma^2}{N_k}\right)$$

To test the null hypothesis $\mu = \mu_0$, $H_0 : \theta = 0$, where $\theta = \mu - \mu_0$ can be used. The MLE of θ is $\hat{\theta}_k = \overline{y}_k - \mu_0$ and

$$\hat{\theta}_k \sim N\left(\theta,\ \frac{1}{I_k}\right)$$

where the information is the inverse of the variance of $\overline{y}_k$,

$$I_k = \frac{N_k}{\sigma^2}$$

The corresponding standardized Z statistic is

$$Z_k = \hat{\theta}_k \, I_k^{\frac{1}{2}} \sim N\left(\theta \, I_k^{\frac{1}{2}}, \, 1\right)$$

The score statistic in the SEQDESIGN procedure is then given by

$$S_k = \hat{\theta}_k \, I_k = Z_k \, I_k^{\frac{1}{2}} \sim N\left(\theta \, I_k, \, I_k\right)$$

For a null hypothesis $H_0 : \theta = 0$ with an upper alternative, the nominal p-value of the standardized Z statistic is $p_k = 1 - \Phi(Z_k)$. For a null hypothesis $H_0 : \theta = 0$ with a lower alternative or a two-sided alternative, the nominal p-value of the standardized Z statistic is $p_k = \Phi(Z_k)$.

Boundary Variables

The boundaries created in group sequential trials depend on the type of the alternative hypothesis and the early stopping criterion. Table 77.5 shows the boundaries created with various design specifications.

Table 77.5 Boundary Variables

Specifications		Boundary Variables			
Alternative		**Lower**		**Upper**	
Hypothesis	**Early Stopping**	**Alpha**	**Beta**	**Beta**	**Alpha**
Lower	Accept H_0		X		
	Reject H_0	X			
	Accept/Reject H_0	X	X		
Upper	Accept H_0			X	
	Reject H_0				X
	Accept/Reject H_0			X	X
Two-sided	Accept H_0		X	X	
	Reject H_0	X			X
	Accept/Reject H_0	X	X	X	X

Up to four boundaries can be generated in a group sequential design:

- the upper α boundary, to reject the null hypothesis for the upper alternative
- the upper β boundary, to accept the null hypothesis with an upper alternative

- the lower β boundary, to accept the null hypothesis with a lower alternative
- the lower α boundary, to reject the null hypothesis for the lower alternative

For a two-sided design, the null hypothesis is accepted only if both the hypothesis is accepted with an upper alternative and the hypothesis is accepted with a lower alternative.

For a one-sided design with a lower alternative, only the lower boundaries are created. Similarly, for a one-sided design with an upper alternative, only the upper boundaries are created. For example, Figure 77.10 shows the boundary plot for a one-sided test with an upper alternative.

Figure 77.10 Boundary Plot for One-Sided Test

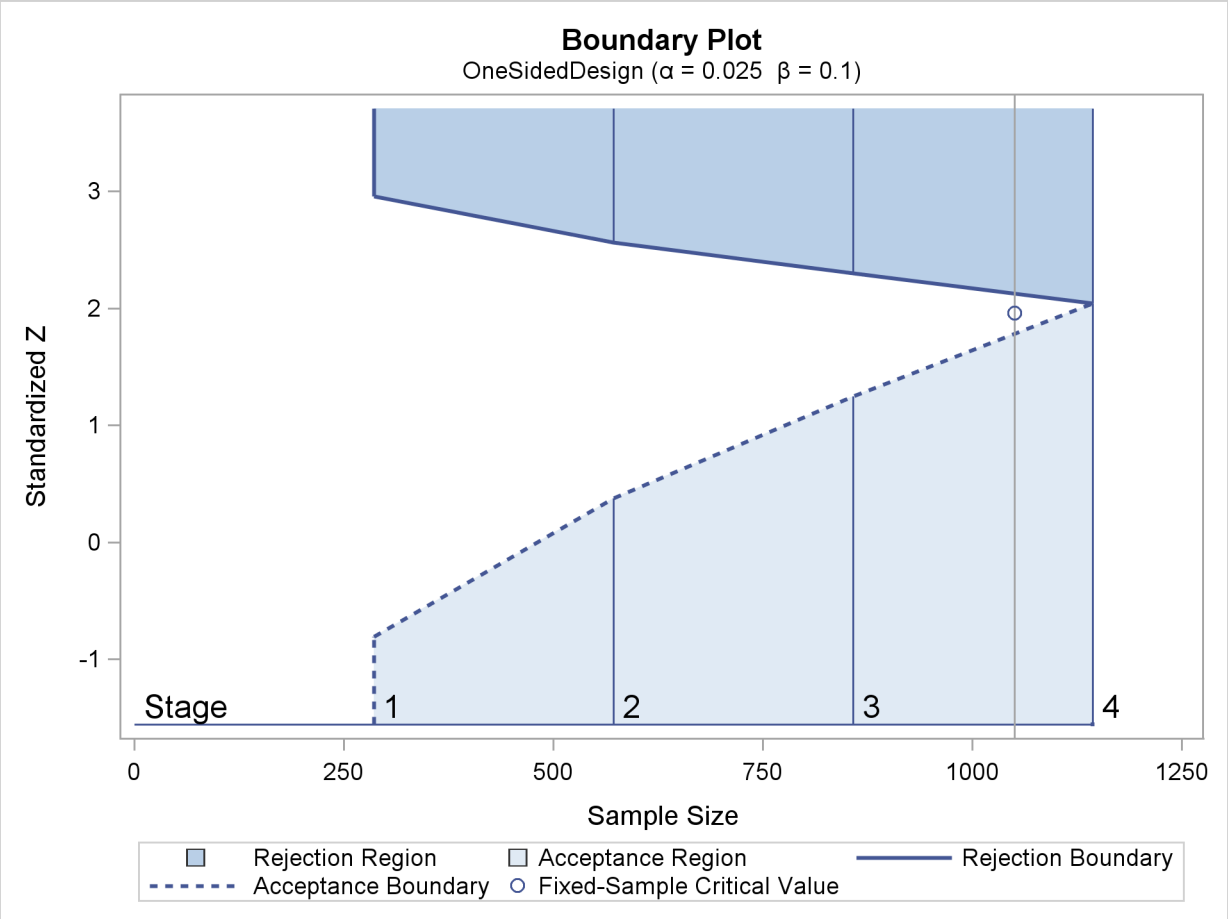


Figure 77.10 corresponds to a one-sided sequential design with early stopping to reject or accept the null hypothesis. For a sequential test with early stopping only to reject the null hypothesis, there are no acceptance boundary values at interim stages. The acceptance boundary value and its associated acceptance region are displayed only at the final stage. Similarly, for a sequential test with early stopping only to accept the null hypothesis, there are no rejection boundary values at interim stages. The rejection boundary value and its associated rejection region are displayed only at the final stage.

For a two-sided design, both the lower and upper boundaries are created. For a design with early stopping to reject the null hypothesis, α boundaries are created. Similarly, for a design with early

stopping to accept the null hypothesis, β boundaries are created. For a design with early stopping to accept or reject the null hypothesis, both the α and β boundaries are created.

For example, Figure 77.11 shows the boundary plot for a two-sided test.

Figure 77.11 Boundary Plot for Two-Sided Test

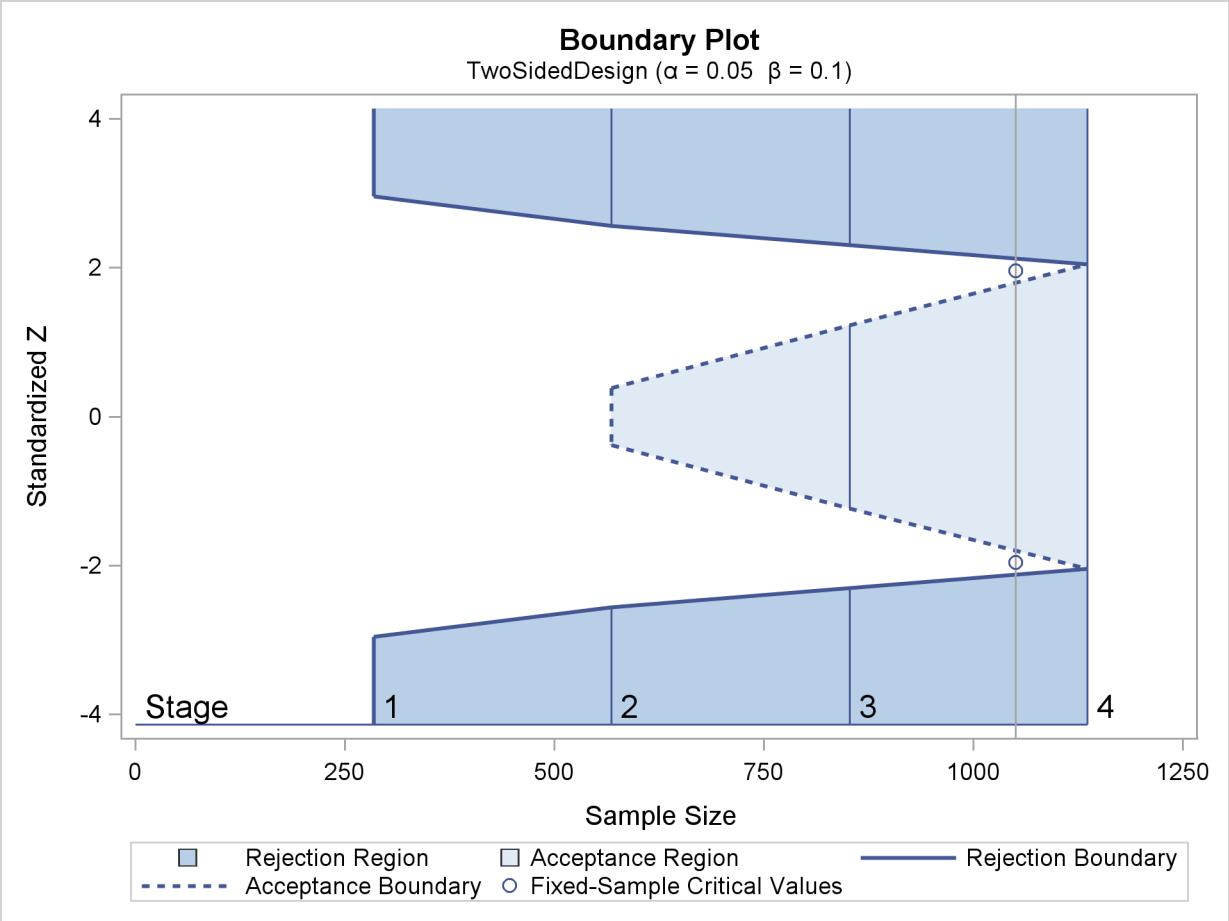

Figure 77.11 corresponds to a two-sided sequential design with early stopping to reject or accept the null hypothesis. For a sequential test with early stopping only to reject the null hypothesis, there are no acceptance boundary values at interim stages. The acceptance boundary value and its associated acceptance region are displayed only at the final stage. Similarly, for a sequential test with early stopping only to accept the null hypothesis, there are no rejection boundary values at interim stages. The rejection boundary value and its associated rejection region are displayed only at the final stage.

Type I and Type II Errors

The Type I error is the error of rejecting the null hypothesis when the null hypothesis is correct, and the Type II error is the error of not rejecting the null hypothesis when the null hypothesis is incorrect. The level of significance α is the probability of making a Type I error. The Type II error depends

on the hypothetical reference of the alternative hypothesis, and the Type II error probability β is defined as the probability of not rejecting the null hypothesis when a specific alternative reference is true. The power $1 - \beta$ is then defined as the probability of rejecting the null hypothesis at the alternative reference.

In a sequential design, if the maximum information and alternative reference are not both specified, the critical values are created such that both the specified Type I and the specified Type II error probability levels are maintained in the design. Otherwise, the critical values are created such that either the specified Type I error probability or the specified Type II error probability is maintained.

One-Sided Tests

For a K-stage group sequential design with an upper alternative hypothesis $H_1 : \theta = \theta_1$ and early stopping to reject or accept the null hypothesis $H_0 : \theta = 0$, the boundaries contain the upper α critical values a_k and upper β critical values $b_k, k = 1, 2, \ldots, K$. At each interim stage, $b_k < a_k$, the null hypothesis H_0 is rejected if the observed statistic $z_k \geq a_k$, H_0 is accepted if $z_k < b_k$, or the process is continued to the next stage if $b_k \leq z_k < a_k$. At the final stage $b_K = a_K$, the hypothesis is either rejected or accepted.

The overall Type I error probability α is given by

$$\alpha = \sum_{k=1}^{K} \alpha_k$$

where α_k is the α spending at stage k. That is, at stage 1,

$$\alpha_1 = P_{\theta=0}(z_1 \geq a_1)$$

At a subsequent stage k,

$$\alpha_k = P_{\theta=0}(b_j \leq z_j < a_j, j = 1, 2, \ldots, k-1, z_k \geq a_k)$$

Similarly, the Type II error probability

$$\beta = \sum_{k=1}^{K} \beta_k$$

where β_k is the β spending at stage k. That is, at stage 1,

$$\beta_1 = P_{\theta=\theta_1}(z_1 < b_1)$$

At a subsequent stage k,

$$\beta_k = P_{\theta=\theta_1}(b_j \leq z_j < a_j, j = 1, 2, \ldots, k-1, z_k < b_k)$$

With an upper alternative hypothesis $H_1 : \theta = \theta_1 > 0$, the power $1 - \beta$ is the probability of rejecting the null hypothesis for the upper alternative.

$$1 - \beta = 1 - \sum_{k=1}^{K} \beta_k = \sum_{k=1}^{K} P_{\theta=\theta_1}(b_j \le z_j < a_j, j = 1, 2, \ldots, k-1, z_k \ge a_k)$$

For a design with early stopping to reject H_0 only, the interim upper β critical values are set to $-\infty$, $b_k = -\infty, k = 1, 2, \ldots, K-1$, and $\beta = \beta_K$. For a design with early stopping to accept H_0 only, the interim upper α critical values are set to ∞, $a_k = \infty, k = 1, 2, \ldots, K-1$, and $\alpha = \alpha_K$.

Similarly, the Type I and Type II error probabilities for a K-stage design with a lower alternative hypothesis $H_0 : \theta = -\theta_1$ can also be derived.

Two-Sided Tests

For a K-stage group sequential design with two-sided alternative hypotheses $H_{1u} : \theta = \theta_{1u}$ and $H_{1l} : \theta = \theta_{1l}$, and early stopping to reject or accept the null hypothesis $H_0 : \theta = 0$, the boundaries contain the upper α critical values a_k, upper β critical values b_k, lower β critical values $_b_k$, and lower α critical values $_a_k$, $k = 1, 2, \ldots, K$. At each interim stage, $_a_k < _b_k \le b_k < a_k$, the null hypothesis H_0 is rejected if the observed statistic $z_k \ge a_k$ or $z_k \le _a_k$, H_0 is accepted if $_b_k < z_k < b_k$, or the process is continued to the next stage if $b_k \le z_k < a_k$ or $_a_k < z_k \le _b_k$. At the final stage $b_K = a_K$ and $_b_K = _a_K$, the hypothesis is either rejected or accepted.

The overall upper Type I error probability α_u is given by

$$\alpha_u = \sum_{k=1}^{K} \alpha_{uk}$$

where α_{uk} is the α spending at stage k for the upper alternative. That is, at stage 1,

$$\alpha_{u1} = P_{\theta=0}(z_1 \ge a_1)$$

At a subsequent stage k,

$$\alpha_{uk} = P_{\theta=0}(_a_j < z_j \le _b_j \text{ or } b_j \le z_j < a_j, j = 1, 2, \ldots, k-1, z_k \ge a_k)$$

Similarly, the overall lower Type I error probability α_l can also be derived, and the overall Type I error probability $\alpha = \alpha_l + \alpha_u$.

The overall upper Type II error probability β_u is given by

$$\beta_u = \sum_{k=1}^{K} \beta_{uk}$$

where β_{uk} is the upper β spending at stage k. That is, at stage 1,

$$\beta_{u1} = P_{\theta=\theta_{1u}}(z_1 < _a_1 \text{ or } _b_1 < z_1 < b_1)$$

At a subsequent stage k,

$$\beta_{uk} = P_{\theta=\theta_{1u}}(_a_j < z_j \le _b_j \text{ or } b_j \le z_j < a_j,\ j = 1, 2, \ldots, k-1,\ z_k < _a_k \text{ or } _b_k < z_k < b_k)$$

With an upper alternative hypothesis $H_1 : \theta = \theta_{1u} > 0$, the power $1 - \beta_u$ is the probability of rejecting the null hypothesis for the upper alternative:

$$1 - \beta_u = 1 - \sum_{k=1}^{K} \beta_{uk}$$

which is

$$P_{\theta=\theta_{1u}}(_a_j < z_j \le _b_j \text{ or } b_j \le z_j < a_j,\ j = 1, 2, \ldots, k-1,\ z_k \ge a_k)$$

The overall lower Type II error probability β_l and power $1 - \beta_l$ can be similarly derived.

For a design with early stopping only to reject H_0, both the interim lower and upper β critical values are set to missing, $k = 1, 2, \ldots, K-1$, and $\beta_{lK} = \beta_l$, $\beta_{uK} = \beta_u$. For a design with early stopping only to accept H_0, the interim upper α critical values are set to ∞, $a_{uk} = \infty$, and the interim lower α critical values are set to $-\infty$, $a_{lk} = -\infty$, $k = 1, 2, \ldots, K-1$, and $\alpha_{uK} = \alpha_u$, $\alpha_{lK} = \alpha_l$.

Unified Family Methods

Unified family methods (Kittelson and Emerson 1999) derive boundary values with a specified boundary shape. For example, Pocock's method (Pocock 1977) derives equal boundary values for all stages in the standardized Z scale. In addition to Pocock's method, the unified family methods include the O'Brien-Fleming, power family, and unified family triangular methods.

The boundary values at each stage depend on the information fractions

$$\Pi_k = \frac{I_k}{I_X}$$

where I_k is the information available at stage k and I_X is the maximum information, the information available at the end of the trial if the trial does not stop early.

Boundary Values in Standardized *Z* Scale

With the unified family method, the boundary values for the upper α boundary $Z_{\alpha u}$, upper β boundary $Z_{\beta u}$, lower β boundary $Z_{\beta l}$, and lower α boundary $Z_{\alpha l}$, using the standardized normal scale, are given by the following:

- $Z_{\alpha u}(\Pi_k) = f_{\alpha u}(\Pi_k)\, C_{\alpha u}$
- $Z_{\beta u}(\Pi_k) = \theta_{1u}\, I_k^{\frac{1}{2}} - f_{\beta u}(\Pi_k)\, C_{\beta u}$

- $Z_{\beta l}(\Pi_k) = \theta_{1l}\, I_k^{\frac{1}{2}} + f_{\beta l}(\Pi_k)\, C_{\beta l}$
- $Z_{\alpha l}(\Pi_k) = -f_{\alpha l}(\Pi_k)\, C_{\alpha l}$

where $\theta_{1l}(< 0)$ and $\theta_{1u}(> 0)$ are the lower and upper alternative references, $f_{\alpha l}(\Pi_k)$, $f_{\beta l}(\Pi_k)$, $f_{\beta u}(\Pi_k)$, and $f_{\alpha u}(\Pi_k)$ are the specified shape functions, and $C_{\alpha l}$, $C_{\beta l}$, $C_{\beta u}$, and $C_{\alpha u}$ are the critical values derived to achieve the specified α and β levels.

If a derived lower β boundary value $Z_{\beta l}(\Pi_k)$ is greater than its corresponding upper β boundary value $Z_{\beta u}(\Pi_k)$, then both values are set to missing.

Note that the drift parameters $d_l = \theta_{1l}\sqrt{I_X}$ and $d_u = \theta_{1u}\sqrt{I_X}$ are derived in the SEQDESIGN procedure. The boundary values in standardized Z scale can be derived without specifying the maximum information and alternative reference.

Shape Parameters

The shape function in the SEQDESIGN procedure is given by

$$f(\Pi_k) = f(\Pi_k; \tau, \rho) = \tau\, \Pi_k^{\frac{1}{2}} + \Pi_k^{-\rho} = \Pi_k^{\frac{1}{2}}\, (\tau + \Pi_k^{-(\rho+\frac{1}{2})})$$

where the parameters $\rho \geq 0$ and $0 \leq \tau \leq 2\rho$. can be specified for each boundary separately.

The parameters τ and ρ determine the shape of the boundaries. Special cases of the unified family methods also include power family methods and triangular methods. Table 77.6 summarizes the corresponding parameter values in the unified family for these methods.

Table 77.6 Parameters in the Unified Family for Various Methods

Method	Option	Unified Family	
		Rho	Tau
Pocock	POC	0	0
O'Brien-Fleming	OBF	0.5	0
Power family	POW (RHO=ρ)	ρ	0
Triangular	TRI (TAU=τ)	0.5	τ

Note that the power parameter $\rho = 1/2 - \Delta = \rho^* - 1/2$, where Δ is the power parameter used in Jennison and Turnbull (2000) and Wang and Tsiatis (1987) and ρ^* is the power parameter used in Kittelson and Emerson (1999).

Also note that instead of the three parameters used in the unified family methods by Kittelson and Emerson (1999), only two parameters are used in the SEQDESIGN procedure. The other parameter is fixed at zero.

Boundary Values in MLE Scale

If the maximum information is available, the boundary values derived from a unified family method can also be displayed in the MLE scale:

- $\theta_{\alpha u}(\Pi_k) = I_k^{-\frac{1}{2}} f_{\alpha u}(\Pi_k) C_{\alpha u}$
- $\theta_{\beta u}(\Pi_k) = \theta_{1u} - I_k^{-\frac{1}{2}} f_{\beta u}(\Pi_k) C_{\beta u}$
- $\theta_{\beta l}(\Pi_k) = \theta_{1l} + I_k^{-\frac{1}{2}} f_{\beta l}(\Pi_k) C_{\beta l}$
- $\theta_{\alpha l}(\Pi_k) = -I_k^{-\frac{1}{2}} f_{\alpha l}(\Pi_k) C_{\alpha l}$

These MLE scale boundary values are computed by multiplying $I_k^{-\frac{1}{2}}$ by the standardized Z scale boundary values at stage k.

Boundary Values in Score Scale

If the maximum information is available, the boundary values derived from a unified family method can also be displayed in the score scale:

- $S_{\alpha u}(\Pi_k) = I_k^{\frac{1}{2}} f_{\alpha u}(\Pi_k) C_{\alpha u}$
- $S_{\beta u}(\Pi_k) = \theta_{1u} I_k - I_k^{\frac{1}{2}} f_{\beta u}(\Pi_k) C_{\beta u}$
- $S_{\beta l}(\Pi_k) = \theta_{1l} I_k + I_k^{\frac{1}{2}} f_{\beta l}(\Pi_k) C_{\beta l}$
- $S_{\alpha l}(\Pi_k) = -I_k^{\frac{1}{2}} f_{\alpha l}(\Pi_k) C_{\alpha l}$

These MLE scale boundary values are computed by multiplying $I_k^{\frac{1}{2}}$ by the standardized Z scale boundary values at stage k.

Boundary Values in *p*-Value Scale

For a design with a lower alternative or a two-sided alternative, the p-value scale boundary values are the cumulative normal distribution function values of the standardized Z boundary values:

- $P_{\alpha u}(\Pi_k) = \Phi(Z_{\alpha u}(\Pi_k))$
- $P_{\beta u}(\Pi_k) = \Phi(Z_{\beta u}(\Pi_k))$
- $P_{\beta l}(\Pi_k) = \Phi(Z_{\beta l}(\Pi_k))$
- $P_{\alpha l}(\Pi_k) = \Phi(Z_{\alpha l}(\Pi_k))$

These nominal p-values are the one-sided fixed-sample p-values under the null hypothesis with a lower alternative.

For a one-sided design with an upper alternative, the p-value scale boundary values are the one-sided fixed-sample p-values under the null hypothesis with an upper alternative:

- $P_{\alpha u}(\Pi_k) = 1 - \Phi(Z_{\alpha u}(\Pi_k))$
- $P_{\beta u}(\Pi_k) = 1 - \Phi(Z_{\beta u}(\Pi_k))$

Pocock's Method

The shape function for Pocock's method (Pocock 1977) is given by

$$f(\Pi_k) = 1$$

The resulting boundary values for a two-sided design with an early stopping to reject the null hypothesis $H_0 : \theta = 0$ are as follows:

- $Z_{\alpha u}(\Pi_k) = C_{\alpha u}$
- $Z_{\alpha l}(\Pi_k) = -C_{\alpha l}$

That is, the rejection boundary values are constant over all stages of different information levels in the standardized Z scale.

Note that compared with other designs, Pocock's design tends to stop the trials early with a larger p-value. For a new treatment, Pocock's design to stop a trial early with a large p-value might not be persuasive enough to make a new treatment widely accepted (Pocock and White 1999). A Pocock design is illustrated in Example 77.3.

O'Brien-Fleming Method

The shape function for the O'Brien-Fleming method (O'Brien and Fleming 1979) is given by

$$f(\Pi_k) = \Pi_k^{-\frac{1}{2}}$$

The resulting boundary values for a two-sided design with early stopping to reject the null hypothesis $H_0 : \theta = 0$ are as follows:

- $Z_{\alpha u}(\Pi_k) = \Pi_k^{-\frac{1}{2}} C_{\alpha u}$
- $Z_{\alpha l}(\Pi_k) = -\Pi_k^{-\frac{1}{2}} C_{\alpha l}$

That is, the rejection boundaries are inversely proportional to the square root of the information levels in the standardized Z scale.

In the score scale, these boundaries can be displayed as follows:

- $S_{\alpha u}(\Pi_k) = C_{\alpha u}\, I_X^{\frac{1}{2}}$
- $S_{\alpha l}(\Pi_k) = -C_{\alpha l}\, I_X^{\frac{1}{2}}$

which are constants over all stages in the score scale. An O'Brien-Fleming design is illustrated in Example 77.2.

Power Family Method

The shape function for a power family method (Wang and Tsiatis 1987; Emerson and Fleming 1989; Pampallona and Tsiatis 1994) is given by

$$f(\Pi_k) = \Pi_k^{-\rho}$$

The resulting boundary values for a two-sided design with early stopping to reject the null hypothesis $H_0 : \theta = 0$ are as follows:

- $Z_{\alpha u}(\Pi_k) = \Pi_k^{-\rho}\, C_{\alpha u}$
- $Z_{\alpha l}(\Pi_k) = -\Pi_k^{-\rho}\, C_{\alpha l}$

The rejection boundaries depend on the power parameter ρ. The power family includes the Pocock and O'Brien-Fleming methods, and the power parameter is used to allow continuous movement between these two methods. A power family design is illustrated in Example 77.5.

Triangular Method

The shape function for a triangular method (Kittelson and Emerson 1999) in the unified family is given by

$$f(\Pi_k) = \Pi_k^{-\frac{1}{2}} + \tau\, \Pi_k^{\frac{1}{2}}$$

The resulting boundary values for a two-sided design with early stopping to reject the null hypothesis $H_0 : \theta = 0$ are as follows:

- $Z_{\alpha u}(\Pi_k) = (\Pi_k^{-\frac{1}{2}} + \tau\, \Pi_k^{\frac{1}{2}})\, C_{\alpha u} = C_{\alpha u}\, \Pi_k^{-\frac{1}{2}}\, (1 + \tau\, \Pi_k)$
- $Z_{\alpha l}(\Pi_k) = -(\Pi_k^{-\frac{1}{2}} + \tau\, \Pi_k^{\frac{1}{2}})\, C_{\alpha l} = -C_{\alpha l}\, \Pi_k^{-\frac{1}{2}}\, (1 + \tau\, \Pi_k)$

In the score scale, these boundaries are as follows:

- $S_{\alpha u}(\Pi_k) = C_{\alpha u}\, I_X^{\frac{1}{2}}\,(1 + \tau\,\Pi_k) = C_{\alpha u}\, I_X^{\frac{1}{2}} + C_{\alpha u}\tau I_X^{-\frac{1}{2}}\, I_k$
- $S_{\alpha l}(\Pi_k) = -C_{\alpha l}\, I_X^{\frac{1}{2}}\,(1 + \tau\,\Pi_k) = -C_{\alpha l}\, I_X^{\frac{1}{2}} - C_{\alpha l}\tau I_X^{-\frac{1}{2}}\, I_k$

Thus, in the score scale, the boundary function is a linear function of the information I_k. With these straight-line boundaries, a triangular method for a one-sided trial with early stopping to reject or accept the null hypothesis produces a triangular continuation region. Similarly, for a two-sided design, the continuation region is a union of two separate triangular regions. A triangular method is illustrated in Example 77.6.

Haybittle-Peto Method

The Haybittle-Peto method (Haybittle 1971; Peto et al. 1976) uses a value of 3 for the critical values in interim stages, so that the critical value at the final stage is close to the original design without interim monitoring.

In the SEQDESIGN procedure, the Haybittle-Peto method has been generalized to allow for different boundary values at different stages. That is, with the standardized normal scale, the boundary values are given by the following:

- $Z_{\alpha u}(\Pi_k) = z_{\alpha uk}$
- $Z_{\beta u}(\Pi_k) = \theta_{1u}\, I_k^{\frac{1}{2}} - z_{\beta uk}$
- $Z_{\beta l}(\Pi_k) = \theta_{1l}\, I_k^{\frac{1}{2}} + z_{\beta lk}$
- $Z_{\alpha l}(\Pi_k) = -z_{\alpha lk}$

where θ_{1l} and θ_{1u} are the lower and upper alternative references and the boundary values $z_{\alpha uk}$, $z_{\beta uk}$, $z_{\beta lk}$, and $z_{\alpha lk}$ are specified either explicitly with the HP(Z= *numbers*) option or implicitly with the HP(PVALUE= *numbers*) option. The HP(PVALUE= *numbers*) option specifies the nominal p-values p_k for the corresponding boundary values z_k:

$$z_k = \Phi^{-1}(1 - p_k)$$

The Haybittle-Peto method is illustrated in Example 77.5.

Whitehead Methods

The Whitehead methods (Whitehead and Stratton 1983; Whitehead 1997, 2001) derive boundary values by adjusting the boundary values generated from continuous monitoring. With continuous monitoring, the boundary values are on a straight line in the score scale for each boundary. For a group sequential design, the boundary values at an interim stage k depend on the information fractions

$$\Pi_k = \frac{I_k}{I_X}$$

where I_k is the information available at stage k and I_X is the maximum information, the information available at the end of the trial if the trial does not stop early.

One-Sided Symmetric Designs

A one-sided symmetric design is a one-sided design with identical Type I and Type II error probabilities. For a one-sided symmetric design with an upper alternative, $\alpha_u = \beta_u$, the boundary values in the score scale from continuous monitoring are as follows:

- $S_{\alpha u}(\Pi_k) = C_u\theta_u^{-1} + \tau_u\theta_u I_k$
- $S_{\beta u}(\Pi_k) = \theta_u\, I_k - (C_u\theta_u^{-1} - \tau_u\theta_u I_k)$

where θ_u is the upper alternative reference, τ_u is a specified constant for the slope, $0 \le \tau_u < \frac{1}{2}$, and C_u is a constant, fixed for STOP=BOTH and derived for STOP=ACCEPT and STOP=REJECT.

The upper β boundary value can also be expressed as

- $S_{\beta u}(\Pi_k) = -C_u\theta_u^{-1} + (1-\tau_u)\theta_u I_k$

Thus, these straight-line boundaries form a triangle in the score statistic scale.

To adjust for the nature of discrete monitoring, the group sequential boundary values are given by the following:

- $S_{\alpha u}(\Pi_k) = C_u\theta_u^{-1} + \tau_u\theta_u I_k - g_k$
- $S_{\beta u}(\Pi_k) = -C_u\theta_u^{-1} + (1-\tau_u)\theta_u I_k + g_k$

where $g_1 = 0.583\sqrt{I_1}$ and $g_k = 0.583\sqrt{I_k - I_{(k-1)}}$, $k > 1$ are the adjustments.

Note that with the adjustment g_k, the resulting boundaries form a Christmas tree shape within the original triangle and are referred to as the Christmas tree boundaries (Whitehead 1997, p. 73).

One-Sided Asymmetric Designs

For a one-sided asymmetric design with an upper alternative, $\alpha_u \neq \beta_u$, the boundary values computed using the score scale, are given by the following:

- $S_{\alpha u}(\Pi_k) = C_u \tilde{\theta}_u^{-1} + \tau_u \tilde{\theta}_u I_k - g_k$
- $S_{\beta u}(\Pi_k) = -C_u \tilde{\theta}_u^{-1} + (1-\tau_u) \tilde{\theta}_u I_k + g_k$

where $\tilde{\theta_u}$ is the modified alternative reference

$$\tilde{\theta_u} = \frac{2\Phi^{-1}(1-\alpha_u)}{\Phi^{-1}(1-\alpha_u) + \Phi^{-1}(1-\beta_u)}\,\theta_u$$

The modified alternative reference $\tilde{\theta}_u = \theta_u$ if $\alpha_u = \beta_u$.

For a design with early stopping to reject or accept the null hypothesis, $S_{\alpha u}(1) = S_{\beta u}(1)$, the boundary values at the final stage are equal. The modified drift parameter $\tilde{d_u}$ is given by

$$\tilde{d_u} = \tilde{\theta}_u \sqrt{I_X} = \frac{1}{1-2\tau_u}\left(\sqrt{{h_K}^2 + 2C_u(1-2\tau_u)} - h_K\right)$$

where $h_K = g_K\, {I_X}^{-\frac{1}{2}} = 0.583\sqrt{1-\Pi_{(K-1)}}$.

A one-sided Whitehead design with early stopping to reject or accept the null hypothesis is illustrated in Example 77.7.

Two-Sided Designs

The boundary values for a two-sided design are generated by combining boundary values from two one-sided designs. With the STOP=BOTH option, this produces a double triangular design (Whitehead 1997, p. 98).

The boundary values for a two-sided design, using the score scale, are then given by the following:

- $S_{\alpha u}(\Pi_k) = C_u \tilde{\theta}_u^{-1} + \tau_u \tilde{\theta}_u I_k - g_k$
- $S_{\beta u}(\Pi_k) = -C_u \tilde{\theta}_u^{-1} + (1-\tau_u) \tilde{\theta}_u I_k + g_k$
- $S_{\beta l}(\Pi_k) = -C_l \tilde{\theta}_l^{-1} + (1-\tau_l) \tilde{\theta}_l I_k - g_k$
- $S_{\alpha l}(\Pi_k) = C_l \tilde{\theta}_l^{-1} + \tau_l \tilde{\theta}_l I_k + g_k$

where the modified alternative references are

$$\tilde{\theta_u} = \frac{2\Phi^{-1}(1-\alpha_u)}{\Phi^{-1}(1-\alpha_u) + \Phi^{-1}(1-\beta_u)}\,\theta_u$$

$$\tilde{\theta}_l = \frac{2\Phi^{-1}(1-\alpha_l)}{\Phi^{-1}(1-\alpha_l)+\Phi^{-1}(1-\beta_l)}\,\theta_l$$

The modified alternative reference $\tilde{\theta}_u = \theta_u$ if $\alpha_u = \beta_u$ and $\tilde{\theta}_l = \theta_l$ if $\alpha_l = \beta_l$.

For a design with early stopping to reject or accept the null hypothesis, the two upper boundary values at the final stage are identical and the two lower boundary values at the final stage are identical. That is, $S_{\alpha l}(1) = S_{\beta l}(1)$ and $S_{\alpha u}(1) = S_{\beta u}(1)$. These modified drift parameters are then given by

$$\tilde{d}_l = \tilde{\theta}_l\sqrt{I_X} = \frac{1}{1-2\tau_l}\left(\sqrt{{h_K}^2 + 2C_l(1-2\tau_l)} - h_K\right)$$

$$\tilde{d}_u = \tilde{\theta}_u\sqrt{I_X} = \frac{1}{1-2\tau_u}\left(\sqrt{{h_K}^2 + 2C_u(1-2\tau_u)} - h_K\right)$$

where $h_K = g_K I_X^{-\frac{1}{2}} = 0.583\sqrt{1-\Pi_{(K-1)}}$.

For a design with early stopping to reject the null hypothesis, or a design with early stopping to accept the null hypothesis, you can specify the slope parameters τ_u and τ_l in the TAU= option, and then the intercept parameters C_u and C_l, and the resulting boundary values are derived. If both the maximum information and alternative references are specified, the procedure derives C_u and C_l by maintaining either the overall α levels (BOUNDARYKEY=ALPHA) or the overall β levels (BOUNDARYKEY=BETA). If the maximum information and alternative reference are not both specified, the procedure derives the boundary values C_u and C_l by maintaining both the overall α and overall β levels.

For a design with early stopping to reject or accept the null hypothesis (STOP=BOTH), Whitehead's triangular test uses $\tau_u = \tau_l = 0.25$ and compute $C_u = -2\log(2\alpha_u)$ and $C_l = -2\log(2\alpha_l)$ for the boundary values. If the maximum information and alternative reference are both specified, the BOUNDARYKEY=ALPHA option uses the specified α values to compute the β values and boundary values. The final-stage boundary values are modified to maintain the overall α levels if they exist. Similarly, the BOUNDARYKEY=BETA option uses the specified β values to compute the α values and boundary values. The final-stage boundary values are modified to maintain the overall β levels if they exist.

If the maximum information and alternative reference are not both specified, the specified α and β values are used to derive boundary values. The BOUNDARYKEY=NONE option uses these boundary values without adjustment. The BOUNDARYKEY=ALPHA option modifies the final-stage boundary values to maintain the overall α levels if they exist. Similarly, the BOUNDARYKEY=BETA option modifies the final-stage boundary values to maintain the overall β levels if they exist.

Two-sided Whitehead designs with early stopping to reject the null hypothesis are illustrated in Example 77.9.

Applicable Boundary Keys

Table 77.7 lists applicable boundary keys for a design that uses Whitehead methods.

Table 77.7 Applicable Boundary Keys for Whitehead Methods

	Specified Parameters		Boundary Keys			
Early Stopping	**(Alt Ref – Max Info)**	**Tau**	**Alpha**	**Beta**	**None**	**Both**
Reject H_0	X	X	X	X		
Accept H_0	X	X	X	X		
Reject/Accept H_0	X	0.25	X	X		
Reject H_0		X				X
Accept H_0		X				X
Reject/Accept H_0		0.25	X	X	X	

Note that the symbol "X" under "(Alt Ref – Max Info)" indicates that both alternative reference and maximum information are specified.

For a design with early stopping to reject the null hypothesis, or a design with early stopping to accept the null hypothesis, you can specify the slope parameter τ_u in the TAU= option, and then the intercept parameter C_u and the resulting boundary values are derived. If both the maximum information and alternative reference are specified, the procedure derives C_u by maintaining either the overall α levels (BOUNDARYKEY=ALPHA) or the overall β levels (BOUNDARYKEY=BETA). If the maximum information and alternative reference are not both specified, the procedure derives the boundary values and C_u by maintaining both the overall α and overall β levels.

For a design with early stopping to reject or accept the null hypothesis (STOP=BOTH), Whitehead's triangular test uses $\tau_u = 0.25$ and solves $C_u = 2\log(\frac{1}{2\alpha_u})$ for the boundary values. If the maximum information and alternative reference are both specified, the BOUNDARYKEY=ALPHA option uses the specified α value to compute the β value and boundary values. The final-stage boundary value is modified to maintain the overall α level if it exists. Similarly, the BOUNDARYKEY=BETA option uses the specified β value to compute the α value and boundary values. The final-stage boundary value is modified to maintain the overall β level if it exists.

If the maximum information and alternative reference are not both specified, the specified α and β values are used to derive boundary values. The BOUNDARYKEY=NONE option uses these boundary values without adjustment. The BOUNDARYKEY=ALPHA option modifies the final-stage boundary value to maintain the overall α level if it exists. Similarly, the BOUNDARYKEY=BETA option modifies the final-stage boundary value to maintain the overall β level if it exists.

Error Spending Methods

For each sequential design, the α and β errors spent at each stage can be computed from the boundary values. For example, for a K-stage design with an upper alternative hypothesis $H_1 : \theta = \theta_1$ and early stopping to reject the null hypothesis $H_0 : \theta = 0$, the boundary values in a standardized Z

scale are the upper α critical values $a_k, k = 1, 2, \ldots, K$. At each interim stage, the null hypothesis H_0 is rejected if the observed standardized Z statistic $z_k \geq a_k$. Otherwise, the process continues to the next stage. At the final stage, the hypothesis is rejected if $z_K \geq a_K$. Otherwise, the null hypothesis is accepted.

The boundary values a_k are derived such that the overall Type I error probability

$$\alpha = \sum_{k=1}^{K} \alpha_k$$

where α_k is the α spending at stage k. That is, at stage 1,

$$\alpha_1 = P_{\theta=0}\,(\,z_1 \geq a_1\,)$$

At a subsequent stage k,

$$\alpha_k = P_{\theta=0}\,(\,z_j < a_j, j = 1, 2, \ldots, k-1,\ z_k \geq a_k\,)$$

Since each design can be uniquely identified by the α and β errors spent at each stage, a design can then be derived by specifying the α and β errors to be used at each stage. The error spending method (Lan and DeMets 1983) distributes the error to be used at each stage and then derives the boundary values. Numerous forms of the error spending function are available. Kim and DeMets (1987) examine the functions $f(t) = t$, $f(t) = t^{\frac{3}{2}}$, and $f(t) = t^2$, where t is the information fraction. Jennison and Turnbull (2000, p. 148) generalize these functions to the power functions $f(t; \rho) = t^\rho, \rho > 0$.

The ERRFUNCPOC option uses the cumulative error spending function (Lan and DeMets 1983)

$$E(t) = \begin{cases} 1 & \text{if } t \geq 1 \\ \log(\,1 + (e-1)t) & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

With a specified error of α or β, the cumulative error spending at stage k is $\alpha\, E(\Pi_k)$ or $\beta\, E(\Pi_k)$, where $\Pi_k = I_k / I_X$ is the information fraction at stage k. The method produces boundaries similar to those produced with Pocock's method.

The ERRFUNCOBF option uses the cumulative error spending function (Lan and DeMets 1983)

$$E(t; a) = \begin{cases} 1 & \text{if } t \geq 1 \\ \frac{1}{a}\, 2\,(1 - \Phi(\frac{z_{(1-a/2)}}{\sqrt{t}})) & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

where a is either α for the α spending function or β for the β spending function. That is, with a specified error of α or β, the cumulative error spending at stage k is $\alpha\, E(\Pi_k; \alpha)$ or $\beta\, E(\Pi_k; \beta)$. The method produces boundaries similar to those produced with the O'Brien-Fleming method.

The ERRFUNCGAMMA option uses the gamma cumulative error spending function (Hwang, Shih, and DeCani 1990)

$$E(t;\gamma) = \begin{cases} 1 & \text{if } t \geq 1 \\ \frac{1-e^{-\gamma t}}{1-e^{-\gamma}} & \text{if } 0 < t < 1, \gamma \neq 0 \\ t & \text{if } 0 < t < 1, \gamma = 0 \\ 0 & \text{otherwise} \end{cases}$$

where γ is the parameter γ specified in the GAMMA= option. That is, with a specified error of α or β, the cumulative error spending at stage k is $\alpha\, E(\Pi_k;\gamma)$ or $\beta\, E(\Pi_k;\gamma)$.

The ERRFUNCPOW option uses the cumulative error spending function (Jennison and Turnbull 2000, p. 148)

$$E(t;\rho) = \begin{cases} 1 & \text{if } t \geq 1 \\ t^{\rho} & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

where ρ is the power parameter specified in the RHO= option. That is, with a specified error of α or β, the cumulative error spending at stage k is $\alpha\, E(\Pi_k;\rho)$ or $\beta\, E(\Pi_k;\rho)$.

Error spending methods derive boundary values at each stage sequentially and require much more computation than other types of methods for group sequential trials with a large number of stages, especially for a two-sided asymmetric design with early stopping to accept H_0, or to reject or accept H_0.

Note that for a two-sided design with the STOP=BOTH or STOP=ACCEPT option, at each interim stage, the SEQDESIGN procedure first produces the lower and upper β boundary values based on the one-sided β spending. If the lower β boundary value is greater than or equal to its corresponding upper β boundary value, there is no early stopping to accept the null hypothesis at this stage, and the corresponding β spending is distributed proportionally to the remaining stages.

For the error spending functions not available in the SEQDESIGN procedure, you can first compute the corresponding error spending at each stage explicitly, then use the SEQDESIGN procedure with the ERRSPEND= option to specify these errors directly.

For example, if the information levels are equally spaced in a five-stage design, the option ERRFUNCPOW (RHO=2) produces relative cumulative errors of $(1/5)^2$, $(2/5)^2$, $(3/5)^2$, $(4/5)^2$, and 1. This is equivalent to using the option ERRSPEND (1 4 9 16 25).

A one-sided error spending design is illustrated in Example 77.8 and a two-sided asymmetric error spending design is illustrated in Example 77.11.

Boundary Adjustments for Overlapping Lower and Upper β Boundaries

For the fixed boundary shape methods and Whitehead methods, the boundary values for all stages are derived simultaneously for each boundary. For a two-sided design with STOP=ACCEPT or

STOP=BOTH, simultaneous derivation might result in overlapping of the lower and upper β boundaries. That is, at an interim stage k, the lower β boundary value might be greater than its corresponding upper β boundary value. In this case, these two β boundary values are set to missing and the design does not stop at stage k to accept the null hypothesis (Jennison and Turnbull 2000, p. 113).

For the error spending methods, the boundary values are derived sequentially for the stages. For a two-sided design with STOP=ACCEPT or STOP=BOTH, a small β spending at an interim stage might result in overlapping of the lower and upper β boundaries for the two corresponding one-sided tests. Specifically, this form of overlapping occurs at an interim stage k if the upper β boundary value derived from the one-sided test for the upper alternative is less than the lower β boundary value derived from the one-sided test for the lower alternative (Kittelson and Emerson 1999, pp. 881–882; Rudser and Emerson 2007, p. 6). You can use the BETAOVERLAP= option to specify how this type of overlapping is to be handled.

If BETAOVERLAP=ADJUST (which is the default) is specified, the procedure derives the boundary values for the two-sided design and then checks for overlapping of the two one-sided β boundaries at interim stages. If overlapping occurs at a particular stage, the β boundary values for the two-sided design are set to missing (so the trial does not stop to accept the null hypothesis at this stage), and the β spending values at subsequent stages are adjusted proportionally as follows.

If the β boundary values are set to missing at stage k in a K-stage trial, the adjusted β spending value at stage k, e'_k, is updated for these missing β boundary values, and then the β spending values at subsequent stages are adjusted proportionally by

$$e'_j = e'_k + \frac{e_j - e_k}{e_K - e_k}\,(e_K - e'_k)$$

for $j = k+1, \ldots, K$, where e_j and e'_j are the cumulative β spending values st stage j before and after the adjustment, respectively.

After all these adjusted β spending values are computed, the boundary values are then further modified for these adjusted β spending values.

If you specify BETAOVERLAP=NOADJUST, no adjustment is made when overlapping of one-sided β boundaries occurs. The BETAOVERLAP= option is illustrated in Example 77.10.

Specified and Derived Parameters

In the SEQDESIGN procedure, the type of alternative hypothesis (ALT= option) and the condition for early stopping (STOP= option) must be specified for each sequential design. The drift parameters are derived for each design specified. Other parameters, such as Type I error probability α, Type II error probability β, the alternative reference θ_1, and maximum information are either specified or derived in the SEQDESIGN procedure.

Table 77.8 summarizes the available combinations for the specified and derived parameters in the SEQDESIGN procedure.

Table 77.8 Specified and Derived Parameters in the SEQDESIGN Procedure

Specified Parameters				Derived Parameters				
Alt Ref	**Max Info**	**Alpha**	**Beta**	**Alt Ref**	**Max Info**	**Alpha**	**Beta**	**Drift**
Z	X	X					X	X
Z	X		X			X		X
Z	X					X	X	X
Z		X	X		X			X
	X	X	X	X				X
		X	X					X

The symbol "X" indicates that the parameter is either specified or derived in the design and the symbol "Z" indicates that the alternative reference is either specified explicitly with the ALTREF= option or derived from the SAMPLESIZE statement. The drift parameter is always derived in the SEQDESIGN procedure.

For example, if the ALTREF= option is specified without the MAXINFO= option being specified, then the maximum information is derived in the SEQDESIGN procedure with the specified α and β, as illustrated in Example 77.5.

The drift parameter is the standardized reference difference at the final stage. For a design, the drift parameter is

$$d_l = \theta_{1l}\sqrt{I_X}$$

if it has a lower alternative, and

$$d_u = \theta_{1u}\sqrt{I_X}$$

if it has an upper alternative, where I_X is the maximum information and θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively.

If the alternative reference and the maximum information are not both specified, then the specified α and β are used to derive the drift parameter. Then if either the alternative reference or the maximum information is specified, the other is derived from the drift parameter.

If both the alternative reference and the maximum information are specified, then either the α error or the β error is derived in the procedure. However, for a Haybittle-Peto method with the BOUNDARYKEY=NONE option, both α and β errors are derived from the completely specified boundary values.

For a nonsymmetric two-sided design with different lower and upper specifications (such as different lower and upper α errors, β errors, or alternative references in absolute values), the derived lower and upper boundaries are not symmetric. If the alternative references θ_{1l} and θ_{1u} are not both specified, then the SEQDESIGN procedure assumes symmetric alternative references, $\theta_1 = \theta_{1u} = -\theta_{1l}$, for the computation of the boundary values.

Applicable Boundary Keys

In the SEQDESIGN procedure, the BOUNDARYKEY= option in the DESIGN statement specifies the types of errors to be maintained for the design. Table 77.9 lists applicable boundary keys for designs that use unified family and Haybittle-Peto methods, designs that use error spending methods, and designs that use the Haybittle-Peto method only.

Table 77.9 Applicable Boundary Keys for Designs without Whitehead Methods

Method	Specified Parameters (Alt Ref – Max Info)	Boundary Keys Alpha	Beta	None	Both
Unified	X	X	X		
Unified/Haybittle-Peto	X	X	X		
Error spending	X	X	X		
Haybittle-Peto	X	X	X	X	
Unified/Haybittle-Peto					X
Error spending					X
Haybittle-Peto					X

Note that the symbol "X" under "(Alt Ref – Max Info)" indicates that both the alternative reference and maximum information are specified, and the method "Unified/Haybittle-Peto" indicates that both the unified method and the Haybittle-Peto method are used in the same design.

If the ALTREF= and MAXINFO= options are both specified, then Type I and Type II error probability levels cannot be met simultaneously if both error probabilities are specified. The BOUNDARYKEY=ALPHA option maintains the Type I error probability level α and derives Type II error probability β. The BOUNDARYKEY=BETA option maintains the Type II error probability level β and derives Type I error probability α.

If the Haybittle-Peto method is used for all boundaries, the BOUNDARYKEY=NONE option uses the specified α boundary value (STOP=REJECT or STOP=BOTH) and the specified β boundary value (STOP=ACCEPT) at the final stage for the design.

If the ALTREF= and MAXINFO= options are not both specified, the BOUNDARYKEY=BOTH option derives boundary values that maintain both Type I and Type II error probability levels.

Table 77.10 lists applicable boundary keys for a design that uses Whitehead methods.

Table 77.10 Applicable Boundary Keys for Whitehead Methods

Early Stopping	Specified Parameters (Alt Ref – Max Info)	Tau	Boundary Keys Alpha	Beta	None	Both
Reject H_0	X	X	X	X		
Accept H_0	X	X	X	X		
Reject/Accept H_0	X	0.25	X	X		
Reject H_0		X				X
Accept H_0		X				X
Reject/Accept H_0		0.25	X	X	X	

Note that the symbol "X" under "(Alt Ref – Max Info)" indicates that both alternative reference and maximum information are specified.

If the ALTREF= and MAXINFO= options are both specified, then Type I and Type II error probability levels cannot be achieved simultaneously if both are specified. the BOUNDARYKEY=ALPHA option maintains the Type I error probability level α and derives Type II error probability β. The BOUNDARYKEY=BETA option maintains the Type II error probability level β and derives the Type I error probability α.

If the ALTREF= and MAXINFO= options are not both specified, then for a design with the STOP=REJECT or STOP=ACCEPT option, the BOUNDARYKEY=BOTH option derives boundary values that maintain both Type I and Type II error probability levels. If the STOP=BOTH option is specified, Whitehead's triangular method produces boundaries with approximate Type I and Type II error probabilities. The BOUNDARYKEY=NONE option specifies no adjustment to these boundaries. The BOUNDARYKEY=ALPHA and BOUNDARYKEY=BETA options maintain the Type I error probability level α and Type II error probability level β, respectively, by adjusting boundary values at the final stage.

Sample Size Computation

The SEQDESIGN procedure assumes that the data are from a multivariate normal distribution and the sequence of the standardized test statistics $\{Z_1, Z_2, \ldots, Z_K\}$ has the following canonical joint distribution:

- $(Z_1, Z_2, \ldots, Z_K)$ is multivariate normal
- $Z_k \sim N\left(\theta\sqrt{I_k}, 1\right)$
- $\mathrm{Cov}(Z_{k_1}, Z_{k_2}) = \sqrt{I_{k_1}/I_{k_2}} \quad , \quad 1 \le k_1 \le k_2 \le K$

where K is the total number of stages and I_k is the information available at stage k.

If the test statistic is computed from the data that are not from a normal distribution, such as a binomial distribution, then it is assumed that the test statistic is computed from a large sample such that the statistic has an approximately normal distribution.

In a typical clinical trial, the sample size required depends on the Type I error probability level α, alternative reference θ_1, power $1-\beta$, and variance of the response variable. Given a one-sided null hypothesis $H_0 : \theta = 0$ with an upper alternative hypothesis $H_1 : \theta = \theta_1$, the information required for a fixed-sample test is given by

$$I_0 = \frac{(\Phi^{-1}(1-\alpha) + \Phi^{-1}(1-\beta))^2}{\theta_1^2}$$

The parameter θ and the subsequent alternative reference θ_1 depend on the test specified in the clinical trial. For example, suppose you are comparing two binomial populations $p_a = p_b$; then $\theta = p_a - p_b$ is the difference between two proportions if the proportion difference statistic is used,

and $\theta = \log\left(\frac{p_a(1-p_b)}{p_b(1-p_a)}\right)$, the log odds ratio for the two proportions if the log odds ratio statistic is used.

If the maximum likelihood estimate $\hat{\theta}$ from the likelihood function can be derived, then the asymptotic variance for $\hat{\theta}$ is $\text{Var}(\hat{\theta}) = 1/I$, where I is Fisher information for θ. The resulting statistic $\hat{\theta}$ corresponds to the MLE statistic scale as specified in the BOUNDARYSCALE=MLE option in the PROC SEQDESIGN statement, $\hat{\theta}\sqrt{I}$ corresponds to the standardized Z scale (BOUNDARYSCALE=STDZ), and $\hat{\theta}\, I$ corresponds to the score statistic scale (BOUNDARYSCALE=SCORE).

Alternatively, if the score statistic S is derived in a statistical procedure, it can be used as the test statistic and its asymptotic variance is given by Fisher information, I. In this case, $S/\sqrt{I}$ corresponds to the standardized Z scale and S/I corresponds to the MLE statistic scale.

For a group sequential trial, the maximum information I_X is derived in the SEQDESIGN procedure with the specified α, β, and θ_1. With the maximum information

$$I_X = \frac{1}{\text{Var}(\hat{\theta})}$$

the sample size required for a specified test statistic in the trial can be evaluated or estimated from the known or estimated variance of the response variable. Note that different designs might produce different maximum information levels for the same hypothesis, and this in turn might require a different number of observations for the trial.

If each observation in the data set provides one unit of information in a hypothesis testing, such as a one-sample test for the mean, the required sample size for the sequential design can be derived from the maximum information. However, for a survival analysis, an individual in the survival time data might provide only partial information because of censoring. In this case, the required number of events can be derived from the maximum information. With addition accrual information, the sample size can also be computed.

The SEQDESIGN procedure provides sample size computation for some one-sample and two-sample tests in the SAMPLESIZE statement. It also provides sample size computation for tests of a parameter in regression models such as normal regression, logistic regression, and proportional hazards regression. In addition, the procedure can also compute the required sample size or number of events from the corresponding number in the fixed-sample design.

Table 77.11 lists the options available in the SAMPLESIZE statement.

Table 77.11 SAMPLESIZE Statement Options

Option	Description
Fixed-Sample Models	
INPUTNOBS	specifies sample size for fixed-sample design
INPUTNEVENTS	specifies number of events for fixed-sample design
One-Sample Models	
ONESAMPLEMEAN	specifies one-sample Z test for mean
ONESAMPLEFREQ	specifies one-sample test for binomial proportion

Table 77.11 *continued*

Option	Description
Two-Sample Models	
TWOSAMPLEMEAN	specifies two-sample Z test for mean difference
TWOSAMPLEFREQ	specifies two-sample test for binomial proportions
TWOSAMPLESURVIVAL	specifies log-rank test for two survival distributions
Regression Models	
REG	specifies test for a regression parameter
LOGISTIC	specifies test for a logistic regression parameter
PHREG	specifies test for a proportional hazards regression parameter

The MODEL=INPUTNOBS and MODEL=INPUTNEVENTS options are described next, and the remaining options are described in the next three sections.

Input Sample Size for Fixed-Sample Design

The MODEL=INPUTNOBS option derives the sample size required for a group sequential trial from the sample size n_0 for the corresponding fixed-sample design. With the N= n_0 option specifying the sample size n_0 for a fixed-sample design, the sample size required for a group sequential trial is then computed as

$$N_X = \frac{I_X}{I_0}\, n_0$$

where I_X is the maximum information for the group sequential design and I_0 is the information for the corresponding fixed-sample design. The information ratio between I_X and I_0 is derived in the SEQDESIGN procedure.

The SAMPLE=ONE option specifies a one-sample test, and the SAMPLE=TWO option specifies a two-sample test. For a two-sample test, the WEIGHT= option specifies the sample size allocation weights for the two groups.

Input Number of Events for Fixed-Sample Design

The MODEL=INPUTNOBS option derives the number of events required for a group sequential trial from the number of events d_0 for the corresponding fixed-sample design. With the D= d_0 option specifies the number of events d_0 for a fixed-sample survival analysis, the number of events required for a group sequential trial is then computed as

$$d_X = \frac{I_X}{I_0}\, d_0$$

where I_X is the maximum information for the group sequential design and I_0 is the information for the corresponding fixed-sample design. The information ratio between I_X and I_0 is derived in the SEQDESIGN procedure.

The SAMPLE=ONE option specifies a one-sample test, and the SAMPLE=TWO option specifies a two-sample test. For a two-sample test, the WEIGHT= option specifies the sample size allocation weights for the two groups.

With the computed number of events d_X for a group sequential survival design, the required total sample size and sample size at each stage can be derived with specifications of hazard rates, accrual rate, and accrual time.

For a study group, if the hazard rate h is constant, corresponding to an exponential survival distribution, and the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a, Kim and Tsiatis (1990, pp. 83–84) show that the expected number of events by time t is given by

$$D_h(t) = \begin{cases} r_a \left(t - \frac{1-e^{-ht}}{h} \right) & \text{if } t \le T_a \\ r_a \left(T_a - \frac{e^{-ht}}{h}(e^{hT_a} - 1) \right) & \text{if } t > T_a \end{cases}$$

For a one-sample design, such as a proportional hazards regression, the expected number of events by time t is $E(t) = D_h(t)$, where h is the hazard rate for the group. For a two-sample design, such as a log-rank test for two survival distributions, the expected number of events by time t is

$$E(t) = \frac{R}{R+1} D_{h_a}(t) + \frac{1}{R+1} D_{h_b}(t)$$

where h_a and h_b are hazard rates in groups A and B, respectively, and R is the ratio of the sample size allocation weights w_a/w_b.

If the accrual rate r_a is specified without the accrual time T_a, follow-up time T_f, and total study time $T = T_a + T_f$, the SEQDESIGN procedure computes the minimum and maximum accrual times from the following equation, as described in Kim and Tsiatis (1990, p. 85):

$$\frac{d_X}{r_a} \le T_a \le E^{-1}(d_X)$$

If the accrual rate r_a is specified with one of the three time parameters—the accrual time, follow-up time, and total study time—then the other two time parameters are computed in the SEQDESIGN procedure. Similarly, if the accrual rate r_a is not specified, but two of the three time parameters are specified, then the accrual rate is derived in the SEQDESIGN procedure.

With the accrual rate r_a and the accrual time T_a, the total sample size is

$$N_X = r_a \; T_a$$

At each stage k, the number of events is given by

$$d_k = \frac{I_k}{I_X} \; d_X$$

The corresponding time T_k can be derived from the equation for the expected number of events, $E(t) = d_k$, and the resulting sample size is computed as

$$N_k = r_a \; T_k$$

The following three sections describe examples of test statistics with their resulting information levels, which can then be used to derive the required sample size. The maximum likelihood estimators are used for all tests except to compare two survival distributions with a log-rank test, where a score statistic is used.

Applicable One-Sample Tests and Sample Size Computation

The SEQDESIGN procedure provides sample size computation for two one-sample tests: normal mean and binomial proportion. The required sample size depends on the variance of the response variable—that is, the sample proportion for a binomial proportion test.

In a typical clinical trial, a hypothesis is designed to reject, not accept, the null hypothesis to show the evidence for the alternative hypothesis. Thus, in most cases, the proportion under the alternative hypothesis is used to derive the required sample size. For a test of the binomial proportion, the REF=NULLPROP and REF=PROP options use proportions under the null and alternative hypotheses, respectively.

Test for a Normal Mean

The MODEL=ONESAMPLEMEAN option in the SAMPLESIZE statement derives the sample size required to test a normal mean by using the sample mean statistic for the null hypothesis $\mu = \mu_0$. At stage k, the sample mean is computed as

$$\overline{y}_k = \frac{1}{N_k} \sum_{j=1}^{N_k} y_{kj}$$

where y_{kj} is the value of the jth observation available in the kth stage and N_k is the cumulative sample size at stage k.

An equivalent hypothesis is $H_0 : \theta = 0$, where $\theta = \mu - \mu_0$.

The MLE statistic for θ,

$$\hat{\theta}_k = \overline{y}_k - \mu_0 \sim N\left(\theta,\ {I_k}^{-1}\right)$$

where the information

$$I_k = \frac{1}{\mathrm{Var}(\hat{\theta})} = \frac{1}{\mathrm{Var}(\overline{y}_k)} = \frac{N_k}{\sigma^2}$$

is the inverse of the variance.

That is, the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} = (\overline{y}_k - \mu_0)\sqrt{I_k} \sim N\left(\theta\sqrt{I_k},\ 1\right)$$

Thus, to test the hypothesis $H_0 : \theta = 0$ against a two-sided alternative $H_1 : \theta = \theta_1$, H_0 is rejected at stage k if the statistic Z_k is less than or equal to the lower α boundary value or if Z_k is greater than or equal to the upper α boundary value at stage k.

If the variance σ^2 is unknown, the sample variance can be used if it is assumed that the sample variance is computed from a large sample such that the test statistic has an approximately normal distribution.

The maximum information is needed to derive the required sample size. If the maximum information is not specified or derived with the ALTREF= option in the procedure, the MEAN=θ_1 option in the SAMPLESIZE statement is used to specify the alternative reference and thus to derive the maximum information.

In the SEQDESIGN procedure, the computed total sample size

$$N_K = \sigma^2 \; I_X$$

where I_X is the maximum information and σ is the specified standard deviation. With an available maximum information, you can specify the MODEL=ONESAMPLEMEAN(STDDEV= σ) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A procedure such as PROC MEANS can be used to derive a one-sample Z test for a normal mean.

Test for a Binomial Proportion

The MODEL=ONESAMPLEFREQ option in the SAMPLESIZE statement derives the sample size required to test a binomial proportion by using the null hypothesis $p = p_0$, where p is the proportion of a binomial population. At stage k, the MLE for p is computed as

$$\hat{p}_k = \frac{1}{N_k} \sum_{j=1}^{N_k} y_{kj}$$

where y_{kj} is the value of the jth observation available in the kth stage and N_k is the cumulative sample size at stage k.

An equivalent hypothesis is $H_0 : \theta = 0$, where $\theta = p - p_0$. If p_0 is not close to 0 or 1, then for a large sample, $\hat{\theta}_k = \hat{p}_k - p_0$ has an approximately normal distribution

$$\hat{\theta}_k \sim N\left(\theta, \; I_k^{-1}\right)$$

where the information $I_k = (p\,(1-p) \,/\, N_k)^{-1}$ is the inverse of the variance Var($\hat{\theta}$).

Then the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} \sim N\left(\theta \sqrt{I_k}, \; 1\right)$$

In practice, the estimated sample proportion $\hat{p}$ at stage k can be used to derive the information I_k and test statistic Z_k. Thus, to test the hypothesis H_0 against an upper alternative $H_1 : \theta = \theta_1 > 0$, H_0 is rejected at stage k if the statistic Z_k is greater than or equal to the upper α boundary at stage k.

The maximum information I_X is needed to derive the required sample size. If the maximum information is not specified or derived with the ALTREF= option in the procedure, the PROP= option in the SAMPLESIZE statement is used to specify the alternative reference and to derive the maximum information for the sample size calculation.

It is assumed that the sample size is sufficiently large such that the test statistic has an approximately normal distribution. With the hypotheses $H_0 : p = p_0$ and $H_1 : p = p_1$, the SEQDESIGN procedure derives the total sample size

$$N_X = p^* (1 - p^*) I_X$$

where $p^* = p_0$ if REF=NULLPROP is specified. Otherwise, $p^* = p_1$.

If the PROP= option in the SAMPLESIZE statement is not specified, then the alternative reference θ_1 derived in the SEQDESIGN procedure is used to compute $p_1 = p_0 + \theta_1$.

The ALTREF= option in the PROC statement can be used to specify θ_1. Otherwise, the PROP= option in the SAMPLESIZE statement must be specified.

For example, with $H_0 : p = 0.5$, $H_1 : p = 0.6$ and the default REF=PROP,

$$N_K = p^*(1 - p^*) I_X = (0.6 \times 0.4) I_X = 0.24 I_X$$

You can specify the MODEL=ONESAMPLEFREQ option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A procedure such as PROC GENMOD with the default DIST=NORMAL option in the MODEL statement can be used to derive the Z test for a binomial proportion.

Applicable Two-Sample Tests and Sample Size Computation

The SEQDESIGN procedure provides sample size computation for two-sample tests: the test for the difference between two normal means, tests for binomial proportions, and the log-rank test for two survival distributions. These tests for binomial proportions include the test for the difference between two binomial proportions, the log odds ratio test for binomial proportions, and the log relative risk test for binomial proportions,

For a test of difference between two sample means, the required sample size depends on the assumed sample variances. Similarly, for a test of two-sample proportions, the required sample size depends on the assumed sample proportions. For a log-rank test of two survival distributions, the required sample size depends on the assumed sample hazard rates, accrual rate, and accrual time.

If the REF=NULLPROP or REF=NULLHAZARD option is specified, the proportions or hazard rates under the null hypothesis are used to derive the required sample size or number of events. Otherwise, the default REF=PROP option in the TWOSAMPLEFREQ option or the REF=HAZARD option in the TWOSAMPLESURVIVAL option uses proportions or hazard rates under the alternative hypothesis to derive the required sample size or number of events.

Test for the Difference between Two Normal Means

The MODEL=TWOSAMPLEMEAN option in the SAMPLESIZE statement derives the sample size required to test the difference between the means of two normal populations μ_a and μ_b by using the null hypothesis $H_0 : \theta = 0$, where $\theta = \mu_a - \mu_b$.

At stage k, the MLE for θ is computed as

$$\hat{\theta}_k = \overline{y}_{ak} - \overline{y}_{bk} = \frac{1}{N_{ak}} \sum_{j=1}^{N_{ak}} y_{akj} - \frac{1}{N_{bk}} \sum_{j=1}^{N_{bk}} y_{bkj}$$

where y_{akj} and y_{bkj} are the values of the jth observation available in the kth stage groups A and B, respectively, and N_{ak} and N_{bk} are the cumulative sample sizes at stage k for these two groups.

The statistic $\hat{\theta}_k$ has a normal distribution

$$\hat{\theta}_k \sim N\left(\theta,\ {I_k}^{-1}\right)$$

where the information I_k is the inverse of the variance $\text{Var}(\hat{\theta}_k) = \sigma_a^2/N_{ak} + \sigma_b^2/N_{bk}$.

Then the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} \sim N\left(\theta \sqrt{I_k},\ 1\right)$$

Thus, to test the hypothesis $H_0 : \theta = 0$ against an upper alternative $H_1 : \theta = \theta_1, \theta_1 > 0$, H_0 is rejected at stage k if the statistic $Z_k \geq a_k$, the upper α boundary for the standardized Z statistic at stage k.

If the variances σ_a^2 and σ_b^2 are unknown, the sample variances can be used to derive the information I_k if it is assumed that each sample variance is computed from a large sample such that the test statistic has an approximately normal distribution.

The maximum information is needed to derive the required sample size. If the maximum information is not specified or derived in the procedure, the alternative reference θ_1^* specified in the MEANDIFF option is used to derive the maximum information.

Note that in order to derive the sample sizes N_{ak} and N_{bk} uniquely from the information, $N_{ak} = R\, N_{bk}$ is assumed for $k = 1, 2, \ldots, K$, where $R = w_a/w_b$ is the constant allocation ratio computed from the WEIGHT=w_a w_b option in the SAMPLESIZE statement.

In PROC SEQDESIGN, the computed total sample sizes for the two groups are

$$N_{aK} = (\sigma_a^2 + R\,\sigma_b^2)\, I_X = R\,(\frac{\sigma_a^2}{R} + \sigma_b^2)\, I_X$$

$$N_{bK} = (\frac{\sigma_a^2}{R} + \sigma_b^2)\, I_X$$

where I_X is the maximum information derived in the SEQDESIGN procedure, R is the constant allocation ratio, and σ_a and σ_b are the specified standard deviations.

For $R = 1$, the two sample sizes are equal, then

$$N_{aK} = N_{bK} = \frac{N_K}{2} = (\sigma_a^2 + \sigma_b^2)\, I_X$$

If the variances from the two groups are equal, $\sigma_a^2 = \sigma_b^2 = \sigma^2$, then the total sample sizes for the two groups are

$$N_{aK} = (1 + R)\,\sigma^2\, I_X$$

$$N_{bK} = (1 + \frac{1}{R})\,\sigma^2\, I_X$$

and the total sample size is

$$N_X = N_{aK} + N_{bK} = \frac{(R+1)^2}{R}\,\sigma^2\, I_X$$

Furthermore, for $R = 1$, the two sample sizes are equal, then

$$N_{aK} = N_{bK} = \frac{N_X}{2} = 2\,\sigma^2\, I_X$$

With an available maximum information, you can specify the MODEL=TWOSAMPLEMEAN(WEIGHT= R STDDEV= σ_a σ_b) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A procedure such as PROC GLM can be used to derive the two-sample Z test for the mean difference.

Test for the Difference between Two Binomial Proportions

The MODEL=TWOSAMPLEFREQ(TEST=PROP) option in the SAMPLESIZE statement derives the sample size required to test the difference between two binomial populations with $H_0 : \theta = 0$, where $\theta = p_a - p_b$. At stage k, the MLE for θ is

$$\hat{\theta}_k = \hat{p}_{ak} - \hat{p}_{bk} = \frac{1}{N_{ak}} \sum_{j=1}^{N_{ak}} y_{akj} - \frac{1}{N_{bk}} \sum_{j=1}^{N_{bk}} y_{bkj}$$

where y_{akj} and y_{bkj} are the values of the jth observation available in the kth stage for groups A and B, respectively, and N_{ak} and N_{bk} are the cumulative sample sizes at stage k for these two groups.

For sufficiently large sample sizes N_{ak} and N_{bk}, the statistic $\hat{\theta}_k$ has an approximate normal distribution

$$\hat{\theta}_k \sim N\left(\theta,\, {I_k}^{-1}\right)$$

where the information is the inverse of the variance

$$\mathrm{Var}(\hat{\theta}_k) = \frac{p_a\,(1-p_a)}{N_{ak}} + \frac{p_b\,(1-p_b)}{N_{bk}}$$

Thus, the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} \sim N\left(\theta\sqrt{I_k},\, 1\right)$$

In practice, $p_a = \hat{p}_a$ and $p_b = \hat{p}_b$, the estimated sample proportions for groups A and B, respectively, at stage k, can be used to derive the information I_k and the test statistic Z_k. Thus, to test the hypothesis H_0 against an upper alternative $H_1 : \theta > 0$, H_0 is rejected at stage k if the statistic $Z_k \geq a_k$, the upper α boundary for the standardized Z statistic at stage k.

The maximum information I_X is needed to derive the required sample size. If the maximum information is not specified or derived with the ALTREF= option in the procedure, the PROP= option in the SAMPLESIZE statement is used to provide proportions under the alternative hypothesis for the alternative reference and then to derive the maximum information.

The proportions in the two groups are needed to derive the sample size. Also, in order to derive the sample sizes N_{ak} and N_{bk} uniquely from the information, $N_{ak} = R\, N_{bk}$ is assumed for $k = 1, 2, \ldots, K$, where $R = w_a/w_b$ is the constant allocation ratio computed from the WEIGHT=w_a w_b option in the SAMPLESIZE statement. Then

$$I_X = \left(\frac{p_a\,(1-p_a)}{N_{aK}} + \frac{p_b\,(1-p_b)}{N_{bK}} \right)^{-1} = \frac{N_{aK}}{p_a(1-p_a) + R\,p_b(1-p_b)}$$

In PROC SEQDESIGN, the total sample sizes in the two groups are computed as

$$N_{aK} = \left(p_a^*\,(1-p_a^*) + R\,p_b^*\,(1-p_b^*) \right)\, I_X$$

$$N_{bK} = \frac{1}{R}\, N_{aK}$$

where $R = w_a/w_b$ is the constant allocation ratio, and p_a^* and p_b^* are proportions specified with the REF= option:

- REF=NULLPROP uses proportions under H_0: $p_a^* = p_{0a}$, $p_b^* = p_{0b}$
- REF=AVGNULLPROP uses the average proportion under H_0: $p_a^* = p_b^* = (Rp_{0a} + p_{0b})/(R+1)$
- REF=PROP uses proportions under H_1: $p_a^* = p_{1a}$, $p_b^* = p_{1b}$
- REF=AVGPROP uses the average proportion under $H_1 : p_a^* = p_b^* = (Rp_{1a} + p_{1b})/(R+1)$

The total sample size is given by

$$N_X = N_{aK} + N_{bK} = (R+1)\left(\frac{1}{R}\, p_a^*\,(1-p_a^*) + p_b^*\,(1-p_b^*) \right)\, I_X$$

For $R = 1$, the two sample sizes are equal,

$$N_{aK} = N_{bK} = \frac{N_X}{2} = \left(p_a^*\,(1-p_a^*) + p_b^*\,(1-p_b^*) \right)\, I_X$$

You can specify the MODEL=TWOSAMPLEFREQ(TEST=PROP WEIGHT=R) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A procedure such as PROC GENMOD with the default DIST=NORMAL option in the MODEL statement can be used to derive the two-sample Z test for proportion difference.

Test for Two Binomial Proportions with a Log Odds Ratio Statistic

The MODEL=TWOSAMPLEFREQ(TEST=LOGOR) option in the SAMPLESIZE statement derives the sample size required to test two binomial proportions by using a log odds ratio statistic. The odds ratio is the ratio of the odds in one group to the odds in the other group, and the log odds ratio is the logarithm of the odds ratio

$$\theta = \log\left(\frac{p_a/(1-p_a)}{p_b/(1-p_b)}\right) = \log\left(\frac{p_a(1-p_b)}{p_b(1-p_a)}\right)$$

The hypothesis of no difference between two proportions, $p_a = p_b$, can be tested through the null hypothesis $H_0 : \theta = 0$, where θ is the log odds ratio. For example, with $H_0 : p_a = p_b = 0.6$ and $H_1 : p_a = 0.8$, $p_b = 0.6$, it corresponds to the equivalent hypothesis $H_0 : \theta = 0$ and $H_1 : \theta = \log\left(\frac{0.8(1-0.6)}{0.6(1-0.8)}\right) = \log(8/3) = 0.98083$.

The maximum likelihood estimate of θ is given by

$$\hat{\theta} = \log\left(\frac{\hat{p}_a(1-\hat{p}_b)}{\hat{p}_b(1-\hat{p}_a)}\right)$$

with an asymptotic variance

$$\mathrm{Var}(\hat{\theta}) = I^{-1} = \frac{1}{N_a\, p_a(1-p_a)} + \frac{1}{N_b\, p_b(1-p_b)}$$

where I is the information (Diggle et al. 2002, pp. 341–342). That is, the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} \sim N\left(\theta\sqrt{I_k},\, 1\right)$$

In practice, $p_a = \hat{p}_a$ and $p_b = \hat{p}_b$, the estimated sample proportions for groups A and B, respectively, at stage k, can be used to derive the information I_k and the test statistic $Z_k = \hat{\theta}_k\sqrt{I_k}$ if the two sample sizes N_a and N_b are sufficiently large such that the test statistic has an approximately normal distribution.

The maximum information I_X is needed to derive the required sample size. If the maximum information is not specified or derived with the ALTREF= option in the procedure, the PROP= option in the SAMPLESIZE statement is used to provide proportions under the alternative hypothesis for the alternative reference and then to derive the maximum information.

In order to derive the sample sizes N_{ak} and N_{bk} uniquely from the information, $N_{ak} = R\, N_{bk}$ is assumed for $k = 1, 2, \ldots, K$, where $R = w_a/w_b$ is the constant allocation ratio computed from the WEIGHT=w_a w_b option in the SAMPLESIZE statement. Then with

$$I_X = N_{bK}\left(\frac{1}{R\, p_a(1-p_a)} + \frac{1}{p_b(1-p_b)}\right)^{-1}$$

the sample size can be computed.

In PROC SEQDESIGN, the total sample sizes in the two groups are computed as

$$N_{bK} = I_X \left(\frac{1}{R\, p_a^*(1-p_a^*)} + \frac{1}{p_b^*(1-p_b^*)} \right)$$

$$N_{aK} = R\, N_{bK}$$

where $R = w_a/w_b$ is the constant allocation ratio, and p_a^* and p_b^* are proportions specified with the REF= option:

- REF=NULLPROP uses proportions under H_0: $p_a^* = p_{0a}$, $p_b^* = p_{0b}$
- REF=AVGNULLPROP uses the average proportion under H_0: $p_a^* = p_b^* = (Rp_{0a} + p_{0b})/(R+1)$
- REF=PROP uses proportions under H_1: $p_a^* = p_{1a}$, $p_b^* = p_{1b}$
- REF=AVGPROP uses the average proportion under H_1 : $p_a^* = p_b^* = (Rp_{1a} + p_{1b})/(R+1)$

You can specify the MODEL=TWOSAMPLEFREQ(TEST=LOGOR WEIGHT=R) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A procedure such as PROC LOGISTIC can be used to derive the log odds ratio statistic.

Test for Two Binomial Proportions with a Log Relative Risk Statistic

The MODEL=TWOSAMPLEFREQ(TEST=LOGRR) option in the SAMPLESIZE statement derives the sample size required to test two binomial proportions by using a log relative risk statistic. The relative risk is the ratio of the proportion in one group to the proportion in the other group. The log relative risk statistic is the logarithm of the relative risk

$$\theta = \log\left(\frac{p_a}{p_b}\right)$$

The hypothesis of no difference between two proportions, $p_a = p_b$, can be tested through the null hypothesis $H_0 : \theta = 0$. For example, with $H_0 : p_a = p_b = 0.6$ and $H_1 : p_a = 0.8$, $p_b = 0.6$, it corresponds to the equivalent hypothesis $H_0 : \theta = 0$ and $H_1 : \theta = \log\left(\frac{0.8}{0.6}\right) = \log(4/3) = 0.28768$.

The maximum likelihood estimate of θ is given by

$$\hat{\theta} = \log\left(\frac{\hat{p}_a}{\hat{p}_b}\right)$$

with an asymptotic variance

$$I^{-1} = \frac{1-p_a}{N_a\, p_a} + \frac{1-p_b}{N_b\, p_b}$$

where I is the information (Chow and Liu 1998, p. 329).

In practice, $p_a = \hat{p}_a$ and $p_b = \hat{p}_b$, the estimated sample proportions for groups A and B, respectively, at stage k, are used to derive the information I_k and the test statistic $Z_k = \hat{\theta}_k \sqrt{I_k}$.

The maximum information I_X and proportions p_a and p_b are needed to derive the required sample size. If the maximum information is not specified or derived with the ALTREF= option in the procedure, the PROP= option in the SAMPLESIZE statement is used to provide proportions under the alternative hypothesis for the alternative reference and then to derive the maximum information.

Note that in order to derive the sample sizes N_{ak} and N_{bk} uniquely from the information, $N_{ak} = R\, N_{bk}$ is assumed for $k = 1, 2, \ldots, K$, where $R = w_a/w_b$ is the constant allocation ratio computed from the WEIGHT=w_a w_b option in the SAMPLESIZE statement. Then the sample size can be computed from

$$I_X = N_{bK} \left(\frac{1 - p_a}{R\, p_a} + \frac{1 - p_b}{p_b} \right)^{-1}$$

In PROC SEQDESIGN, the computed sample sizes in the two groups are

$$N_{bK} = I_X \left(\frac{1 - p_a^*}{R\, p_a^*} + \frac{1 - p_b^*}{p_b^*} \right)$$

$$N_{aK} = R\, N_{bK}$$

where $R = w_a/w_b$ is the constant allocation ratio, and p_a^* and p_b^* are proportions specified with the REF= option:

- REF=NULLPROP uses proportions under H_0: $p_a^* = p_{0a}$, $p_b^* = p_{0b}$
- REF=AVGNULLPROP uses the average proportion under H_0: $p_a^* = p_b^* = (Rp_{0a} + p_{0b})/(R+1)$
- REF=PROP uses proportions under H_1: $p_a^* = p_{1a}$, $p_b^* = p_{1b}$
- REF=AVGPROP uses the average proportion under H_1 : $p_a^* = p_b^* = (Rp_{1a} + p_{1b})/(R+1)$

You can specify the MODEL=TWOSAMPLEFREQ(TEST=LOGRR WEIGHT=R) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A procedure such as PROC LOGISTIC can be used to derive the log relative risk statistic.

Test for Two Survival Distributions with a Log-Rank Test

The MODEL=TWOSAMPLESURV option in the SAMPLESIZE statement derives the number of events required for a log-rank test of two survival distributions. The analysis of survival data involves the survival times for both censored and uncensored data. A noncensored survival time is the time from treatment to an event such as remission or relapse for an individual. A censored survival time is the time from treatment to the time of analysis for an individual surviving at that time, and the status is unknown beyond that time.

Let T be the random variable of the survival time. Then the survival function

$$S(t) = \Pr(T > t)$$

is the probability that an individual from the population has a survival time that exceeds t. And the hazard function is given by

$$h(t) = \frac{f(t)}{S(t)}$$

where $f(t)$ is the density function of T.

The hazard functions can be used to test the equality of two survival distributions $S_a(t) = S_b(t)$ with the null hypothesis $H_0 : h_a(t) = h_b(t), t > 0$, where $S_a(t)$ and $S_b(t)$ are survival functions for groups A and B, respectively, and $h_a(t)$ and $h_b(t)$ are the corresponding hazard functions.

If the two hazards are proportional, $h_a(t) = \lambda\, h_b(t)$, where λ is a constant, then an equivalent null hypothesis is

$$H_0 : \lambda = \frac{h_a(t)}{h_b(t)} = 1$$

Alternatively, another equivalent null hypothesis is given by

$$H_0 : \theta = -\log(\lambda) = 0$$

Suppose that the hazard rate h is a constant. Then with a specified median survival time T_m, the hazard rate can be derived from the equation

$$e^{-h\,T_m} = \frac{1}{2}$$

Denote the distinct event times at stage k as $\tau_{kj}, j = 1, 2, \ldots, t_k$, where t_k is the total number of distinct event times. Then the score statistic is the log-rank statistic (Jennison and Turnbull 2000, pp. 259–261; Whitehead 1997, pp. 36–39)

$$S_k = \sum_{j=1}^{t_k} (d_{akj} - e_{akj})$$

where d_{akj} is the number of events from group A and e_{akj} is the number of expected events from A. The number of expected events from A is computed as

$$e_{akj} = d_{kj} \frac{r_{akj}}{r_{kj}}$$

where d_{kj} is the number of events from both groups, r_{akj} is the number of individuals from the treatment group who survived up to time τ_{kj}, and r_{kj} is the number of individuals from both groups who survived up to time τ_{kj}.

If the number of events d_{kj} is small relative to r_{kj}, the number of individuals survived up to time τ_{kj}, then with a sufficiently large sample size, S_k has an approximately normal distribution

$$S_k \sim N(\theta\, I_k,\ I_k)$$

where the variance of S_k is the estimated information

$$I_k = \sum_{j=1}^{t_k} \frac{r_{akj}\, r_{bkj}\, d_{kj}}{r_{kj}^2}$$

In order to derive the number of events from the information I_k, $N_{ak} = R\, N_{bk}$ is assumed for $k = 1, 2, \ldots, K$, where $R = w_a/w_b$ is the constant allocation ratio computed from the WEIGHT=w_a w_b option in the SAMPLESIZE statement.

The maximum information I_X is needed to derive the required sample size. If the maximum information is specified or derived with the ALTREF= option in the procedure, the HAZARD=, MEDSURVTIME=, and HAZARDRATIO= options are not applicable. Otherwise, the HAZARD=, MEDSURVTIME=, or HAZARDRATIO= option is used to compute the alternative reference and then to derive the maximum information for the sample size calculation.

With $N_{aK} = R\, N_{bK}$, if the number of events is few relative to the number of individuals who survived, then $r_{aKj} \approx R\, r_{bKj}$, and

$$I_X \approx \sum_{j=1}^{t_K} \frac{R}{(R+1)^2} d_{Kj} = \frac{R}{(R+1)^2}\, D_X$$

where D_X is the total number of events.

Thus, the required total number of events

$$D_X = \frac{(R+1)^2}{R}\, I_X$$

For a study group, if the hazard rate is constant, corresponding to an exponential survival distribution, and the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a, then the required total sample size and sample size at each stage can be derived. See the section "Input Number of Events for Fixed-Sample Design" on page 5856 for a detailed description of the sample size computation that uses hazard rates, accrual rate, and accrual time.

You can specify the MODEL=TWOSAMPLESURVIVAL option in the SAMPLESIZE statement to compute the required total number of events and individual number of events at each stage. With the specifications of hazard rates, accrual rate, and accrual time, the required total sample size and individual sample size at each stage can also be derived. If the REF=NULLHAZARD option is specified, the hazard rates under the null hypothesis, h_{0a} and h_{0b}, are used in the sample size computation. Otherwise, the hazard rates under the alternative hypothesis, h_{1a} and h_{1b}, are used. A procedure such as PROC LIFETEST can be used to derive the log-rank statistic.

Applicable Regression Parameter Tests and Sample Size Computation

The SEQDESIGN procedure provides sample size computation for tests of a regression parameter in three regression models: normal regression, logistic regression, and proportional hazards regression.

To test a parameter β_1 in a regression model, the variance of the parameter estimate $\hat{\beta}_1$ is needed for the sample size computation. In a simple regression model with one covariate X1, the variance of $\hat{\beta}_1$ is inversely related to the variance of X1, σ_x^2. That is,

$$\text{Var}(\hat{\beta}_1) \propto \frac{1}{N\,\sigma_x^2}$$

for the normal regression and logistic regression models, where N is the sample size, and

$$\text{Var}(\hat{\beta}_1) \propto \frac{1}{D\,\sigma_x^2}$$

for the proportional hazards regression model, where D is the number of events.

For a regression model with more than one covariate, the variance of $\hat{\beta}_1$ for the normal regression and logistic regression models is inversely related to the variance of X1 after adjusting for other covariates. That is,

$$\text{Var}(\hat{\beta}_1) \propto \frac{1}{N\,(1-r_x^2)\,\sigma_x^2}$$

where $\hat{\beta}_1$ is the estimate of the parameter β_1 in the model and r_x^2 is the R square from the regression of X1 on other covariates—that is, the proportion of the variance σ_x^2 explained by these covariates.

Similarly, for a proportional hazards regression model,

$$\text{Var}(\hat{\beta}_1) \propto \frac{1}{D\,(1-r_x^2)\,\sigma_x^2}$$

Thus, with the derived maximum information, the required sample size or number of events can also be computed for the testing of a parameter in a regression model with covariates.

Test for a Parameter in the Regression Model

The MODEL=REG option in the SAMPLESIZE statement derives the sample size required for a Z test of a normal regression. For a normal linear regression model, the response variable is normally distributed with the mean equal to a linear function of the explanatory variables and the constant variance σ^2.

The normal linear model is

$$\mathbf{y} \sim N\left(\mathbf{X}\boldsymbol{\beta},\, \sigma_y^2\,\mathbf{I}_{(N)}\right)$$

where $\mathbf{Y}_{(N\times 1)}$ is the vector of the N observed responses, $\mathbf{X}_{(N\times p)}$ is the design matrix for these N observations, $\boldsymbol{\beta}_{(p\times 1)}$ is the parameter vector, and $\mathbf{I}_{(N)}$ is the $(N \times N)$ identity matrix.

The least squares estimate is

$$\hat{\boldsymbol{\beta}} = \left(\mathbf{X}'\mathbf{X}\right)^{-1}\mathbf{X}'\mathbf{Y}$$

and is normally distributed with mean $\boldsymbol{\beta}$ and variance

$$\text{Var}(\hat{\boldsymbol{\beta}}) = \sigma_y^2(\mathbf{X}'\mathbf{X})^{-1}$$

For a model with only one covariate X1,

$$\hat{\beta}_1 \sim N\left(\beta_1,\ \text{Var}(\hat{\beta}_1)\right)$$

where the variance

$$\text{Var}(\hat{\beta}_1) = I_{\beta_1}^{-1} = \sigma_y^2\ \frac{1}{N\,\sigma_x^2}$$

Thus, with the derived maximum information $I_X = I_{\beta_1}$, the required sample size is given by

$$N = I_X\ \frac{\sigma_y^2}{\sigma_x^2}$$

For a normal linear model with more than one covariate, the variance of a single parameter β_1 is

$$\text{Var}(\hat{\beta}_1) = \sigma_y^2\ (\mathbf{X}'\mathbf{X})^{-1}_{(11)} = \sigma_y^2\ \frac{1}{N\,\sigma_x^2\,(1-r_x^2)}$$

where $(\mathbf{X}'\mathbf{X})^{-1}_{(11)}$ is the diagonal element of the $(\mathbf{X}'\mathbf{X})^{-1}$ matrix corresponding to the parameter β_1, σ_x^2 is the variance of the variable X1, and r_x^2 is the proportion of variance of X1 explained by other covariates. The value $\sigma_x^2\,(1-r_x^2)$ represents the variance of X1 after adjusting for all other covariates.

Thus, with the derived maximum information I_X, the required sample size is

$$N = I_X\ \frac{\sigma_y^2}{(1-r_x^2)\,\sigma_x^2}$$

In the SEQDESIGN procedure, you can specify the MODEL=REG(VARIANCE=σ_y^2 XVARIANCE=σ_x^2 XRSQUARE=r_x^2) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A SAS procedure such as PROC REG can be used to compute the parameter estimate and its standard error at each stage.

Test for a Parameter in the Logistic Regression Model

The MODEL=LOGISTIC option in the SAMPLESIZE statement derives the sample size required for a Z test of a logistic regression parameter. The linear logistic model has the form

$$\text{logit}(p) = \log\left(\frac{p}{1-p}\right) = \mathbf{x}\boldsymbol{\beta}$$

where p is the response probability to be modeled and $\boldsymbol{\beta}$ is a vector of parameters.

Following the derivation in the section "Test for a Parameter in the Regression Model" on page 5869, the required sample size for testing a parameter in $\boldsymbol{\beta}$ is given by

$$N = I_X\ \frac{\sigma_y^2}{(1-r_x^2)\,\sigma_x^2}$$

With the variance of the logit response, $\sigma_y^2 = 1/(p(1-p))$,

$$N = I_X \frac{1}{p(1-p)} \frac{1}{(1-r_x^2)\,\sigma_x^2}$$

where σ_x^2 is the variance of X and r_x^2 is the proportion of variance explained by other covariates.

In the SEQDESIGN procedure, you can specify the MODEL=LOGISTIC(PROP=p XVARIANCE=σ_x^2 XRSQUARE=r_x^2) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage.

A SAS procedure such as PROC LOGISTIC can be used to compute the parameter estimate and its standard error at each stage.

Test for a Parameter in the Proportional Hazards Regression Model

The MODEL=PHREG option in the SAMPLESIZE statement derives the number of events required for a Z test of a proportional hazards regression parameter. For analyses of survival data, Cox's semiparametric model is often used to examine the effect of explanatory variables on hazard rates. The survival time of each observation in the population is assumed to follow its own hazard function, $h_i(t)$, expressed as

$$h_i(t) = h(t; \mathbf{X}_i) = h_0(t)\exp(\mathbf{X}_i'\boldsymbol{\beta})$$

where $h_0(t)$ is an arbitrary and unspecified baseline hazard function, $\mathbf{x}_i$ is the vector of explanatory variables for the ith individual, and $\boldsymbol{\beta}$ is the vector of regression parameters associated with the explanatory variables.

Hsieh and Lavori (2000, p. 553) show that the required number of events for testing a parameter in $\boldsymbol{\beta}$, β_1, associated with the variable X1 is given by

$$D_X = I_X \frac{1}{(1-r_x^2)\,\sigma_x^2}$$

where σ_x^2 is the variance of X1 and r_x^2 is the proportion of variance of X1 explained by other covariates.

In the SEQDESIGN procedure, you can specify the MODEL=PHREG(XVARIANCE=σ_x^2 XRSQUARE=r_x^2) option in the SAMPLESIZE statement to compute the required number of events and individual number of events at each stage.

A SAS procedure such as PROC PHREG can be used to compute the parameter estimate and its standard error at each stage.

Note that for a two-sample test, X1 is an indicator variable and is the only covariate in the model. Thus, if the two sample sizes are equal, then the variance $\sigma_x^2 = 1/4$ and the required number of events for testing the parameter β_1 is given by

$$D_X = I_X \frac{1}{\sigma_x^2} = 4\,I_X$$

See the section "Input Number of Events for Fixed-Sample Design" on page 5856 for a detailed description of the sample size computation that uses hazard rates, accrual rate, and accrual time.

Aspects of Group Sequential Designs

This section summarizes various aspects of group sequential designs that are encountered in applications of the SEQDESIGN procedure. Features are illustrated through two-sided designs with $\alpha = 0.05$ and $\beta = 0.10$. The null hypothesis $H_0 : \theta = 0$ and an alternative reference $\theta_1 = \pm 0.25$ are used for the designs with early stopping only to reject the null hypothesis.

Canonical Joint Distribution

The SEQDESIGN procedure assumes that with a total number of stages K, the sequence of the standardized test statistics $\{Z_1, Z_2, \ldots, Z_K\}$ has the canonical joint distribution with information levels $\{I_1, I_2, \ldots, I_K\}$ for the parameter θ (Jennison and Turnbull 2000, p. 49):

- $(Z_1, Z_2, \ldots, Z_K)$ is multivariate normal
- $Z_k \sim N\left(\theta\sqrt{I_k},\ 1\right),\ k = 1, 2, \ldots, K$
- $\mathrm{Cov}(Z_{k_1}, Z_{k_2}) = \sqrt{(I_{k_1}/I_{k_2})},\quad 1 \le k_1 \le k_2 \le K$

Normality Assumption

The SEQDESIGN procedure derives the boundary values by assuming that the sequence of the standardized test statistics $\{Z_1, Z_2, \ldots, Z_K\}$ has the canonical joint distribution with information levels $\{I_1, I_2, \ldots, I_K\}$ for the parameter θ. If the test statistic Z_k does not have a normal distribution, it is assumed that the test statistic is computed from a large sample, so that the resulting statistic has an approximately normal distribution.

Number of Stages

For group sequential trials with fixed significance level α, power $1 - \beta$, and alternative reference, if the number of stages is increased, the required maximum information is also increased, but the average sample number under the alternative hypothesis is likely to decrease.

For example, with O'Brien-Fleming designs specified in the section, the maximum information increases from 168.12 for a fixed-sample design to 169.32 for a two-stage design, 172.57 for a five-stage design, and then 174.42 for a ten-stage design. In the mean time, the average sample number (as a percentage of fixed-sample) under the alternative hypothesis decreases from 100 for a fixed-sample design to 85.11 for a two-stage design, 75.03 for a five-stage design, and then 71.80 for a ten-stage design. The reduction in average sample number decreases as the number of stages increases. Thus there seems to be little to gain from choosing a design with more than five stages (Pocock 1982, p. 155).

Alternative Reference

The alternative reference θ_1 is the hypothetical reference under the alternative hypothesis at which the power is computed. It is a treatment value that the investigators would hope to detect with high probability (Jennison and Turnbull 2000, p. 21).

For a group sequential design with specified parameters such as α and β errors, the drift parameter $\theta_1\sqrt{I_X}$ is always derived in the SEQDESIGN procedure. Thus, with a smaller alternative reference θ_1, a larger maximum information level I_X is needed. That is, in order to detect a smaller difference with the same high power, a larger sample size is required.

Maximum Information

In a clinical trial, the amount of information about an unknown parameter available from the data can be measured by the Fisher information, the variance of the score statistic. The maximum information is the information level needed at the final stage of the group sequential trial if the trial does not stop at an interim stage. For a group sequential design, the maximum information can be derived with the specified alternative reference.

The maximum information is proportional to the sample size or number of events required for the design. Thus, it can also be used to compare different designs. Generally, a design with a larger probability to stop the trial early tends to have a larger maximum information. For example, with four-stage designs specified in the section, the Pocock method has a maximum information of 198.91 and the O'Brien-Fleming method has a maximum information of 171.85, indicating a much larger information level required for the Pocock method.

Drift Parameter

The drift parameter $\theta_1\sqrt{I_X}$ is derived for each design in the SEQDESIGN procedure, where θ_1 is the alternative reference. It is proportional to the square root of maximum information required for the design and can be used to compare maximum information for different designs with the same alternative reference. For example, with the four-stage designs specified in the section, the Pocock method has a drift parameter 3.526 and the O'Brien-Fleming method has a drift parameter 3.277, indicating that a larger maximum information level is required for the Pocock method than for the O'Brien-Fleming method.

Average Sample Number

The average sample number is the expected sample size (for nonsurvival data) or expected number of events (for survival data) of the design under a specific hypothetical reference. The percent average sample numbers with respect to the corresponding fixed-sample design are displayed in the SEQDESIGN procedure.

The design that requires a larger maximum information level tends to have a smaller average sample number under the alternative hypothesis. For example, with the four-stage designs specified in the section, the Pocock design has a maximum information of 198.91 and an average sample number

(in percentage of fixed-sample design) of 69.748 under the alternative hypothesis, and the O'Brien-Fleming design has a maximum information of 171.85 and an average sample number of 76.740.

Sample Size

The maximum information for the sequential design expressed as a percentage of its corresponding fixed-sample information is derived in the SEQDESIGN procedure. The sample size or number of events needed for a group sequential trial is computed by multiplying the sample size or number of events for the corresponding fixed-sample design by the derived percentage.

If the sample size or number of events for the fixed-sample design is available, you can use the MODEL=INPUTNOBS or MODEL=INPUTNEVENTS option in the SAMPLESIZE statement to derive the sample size or number of events needed at each stage. Otherwise, with the specified or derived maximum information, you can use the MODEL= option in the SAMPLESIZE statement to specify a hypothesis test and then to derive the sample size or number of events needed at each stage. See the section "Sample Size Computation" on page 5854 for the sample size computation for commonly used tests.

Summary of Methods in Group Sequential Designs

There are three different types of methods available in the SEQDESIGN procedure: fixed boundary shape methods for specified boundary shape, Whitehead methods for boundaries from continuous monitoring, and error spending methods for specified error spending at each stage.

The fixed boundary shape methods include unified family methods and Haybittle-Peto methods. The unified family methods include Pocock, O'Brien-Fleming, power family, and triangular methods.

Pocock Method

Pocock derives the constant boundary on the standardized Z scale to demonstrate the sequential design while maintaining the overall α and β levels (Pocock 1977). The resulting boundary tends to stop the trials early with a larger p-value. This boundary is commonly called a Pocock boundary, but Pocock himself does not advocate these boundary values for stopping a trial early to reject the null hypothesis, because large p-values might not be persuasive enough (Pocock and White 1999). Also, the nominal p-value at the final stage is much smaller than the overall p-value of the design. That is, the trial might stop at the final stage with a small nominal p-value, but the test is not rejected, which might not be easy to justify.

O'Brien-Fleming Method

O'Brien-Fleming boundary values are inversely proportional to the square root of information levels on the standardized Z scale (O'Brien and Fleming 1979). The O'Brien-Fleming boundary is

conservative in the early stages and tends to stop the trials early only with a small p-value. But the nominal value at the final stage is close to the overall p-value of the design.

Power Family Method

The power family method (Wang and Tsiatis 1987; Emerson and Fleming 1989; Pampallona and Tsiatis 1994) generalizes the Pocock and O'Brien-Fleming methods with a power parameter to allow continuous movement between the Pocock and O'Brien-Fleming methods. The power parameter is $\rho = 0$ for the Pocock method and $\rho = 0.5$ for the O'Brien-Fleming method.

Triangular Method

The unified family triangular method (Kittelson and Emerson 1999) contains straight-line boundaries on the score scale. For a one-sided trial with early stopping either to reject and to accept the null hypothesis, the method produces a triangular continuation region. The boundary shape is specified with the slope parameter τ.

Unified Family Method

The unified family method (Kittelson and Emerson 1999) extends power family methods to incorporate the triangular method, which contains straight-line boundaries on the score scale.

Haybittle-Peto Method

The Haybittle-Peto method (Haybittle 1971; Peto et al. 1976) uses a Z value of 3 for the critical values in interim stages and derives the critical value at the final stage. With this method, the final-stage critical value is close to the original design without interim monitoring. The SEQDESIGN procedure extends this method further to allow for different Z or nominal p-values for the boundaries.

Whitehead Method

Whitehead methods (Whitehead and Stratton 1983; Whitehead 1997, 2001) derive the boundary values by adapting the continuous monitoring tests to the discrete monitoring of group sequential tests. With early stopping to reject or accept the null hypothesis in a one-sided test, the derived continuation region has a triangular shape on the score-scaled boundaries. Only elementary calculations are needed to derive the boundary values in Whitehead's triangular methods. The resulting Type I error probability and power are extremely close but differ slightly from the specified values due to the approximations used in deriving the tests (Jennison and Turnbull 2000, p. 106). The SEQDESIGN procedure provides the BOUNDARYKEY= option to adjust the boundary value at the final stage for the exact Type I or Type II error probability levels.

Error Spending Method

The error spending method uses the specified α and β errors to be used at each stage of the design to derive the boundary values.

Error Spending Function Method

The error spending function method uses the error spending function to compute the α and β errors to be used at each stage of the design and then to derive the boundary values for these errors. The following four error spending functions are available in the SEQDESIGN procedure:

- The Pocock-type error spending function (Lan and DeMets 1983) produces boundaries similar to those produced with Pocock's method.
- The O'Brien-Fleming-type error spending function (Lan and DeMets 1983) produces boundaries similar to those produced with the O'Brien-Fleming method.
- The gamma error spending function (Hwang, Shih, and DeCani 1990) specifies a gamma cumulative error spending function indexed by the gamma parameter γ. The boundaries created with $\gamma = 1$ are similar to the boundaries from the Pocock method, and the boundaries created with $\gamma = -4$ or $\gamma = -5$ are similar to the boundaries from the O'Brien-Fleming method.
- The power error spending function (Jennison and Turnbull 2000, p. 148) specifies a power cumulative error spending function indexed by the power parameter ρ. The boundaries created with $\rho = 1$ are similar to the boundaries from the Pocock method, and the boundaries created with $\rho = 3$ are similar to the boundaries from the O'Brien-Fleming method.

Table Output

For each design, the SEQDESIGN procedure displays the "Design Information," "Method Information," and "Boundary Information" tables by default.

Boundary Information

The "Boundary Information" table displays the following information at each stage:

- proportion of information
- actual information level, if the maximum information is either specified or derived
- alternative references with the specified statistic scale. If a p-value scale is specified, the standardized Z scale is used.
- boundary values with the specified statistic scale to reject or accept the null hypothesis

Note that implicitly, the boundary information table also contains variables for the boundary scale, stopping criterion, and type of alternative hypothesis. That is, if an ODS statement is used to save the table, the data set also contains the variables _Scale_ for the boundary scale, _Stop_ for the stopping criterion, and _ALT_ for the type of alternative hypothesis.

Design Information

The "Design Information" table displays the design specifications and derived statistics. The derived Max Information (Percent Fixed-Sample) is the maximum information for the sequential design in percentage of the corresponding fixed-sample information.

The Null Ref ASN (Percent Fixed-Sample) is the average sample number (expected sample size for nonsurvival data or expected number of events for survival data) required under the null hypothesis for the group sequential design in percentage of the corresponding fixed-sample design. Similarly, the Alt Ref ASN (Percent Fixed-Sample) is the average sample number required under the alternative reference for the group sequential design in percentage of the corresponding fixed-sample design.

If both the maximum information (MAXINFO= option) and the alternative reference θ_1 (ALTREF= option) are specified, then either the ALPHA= option is used to derive the Type II error probability β (BOUNDARYKEY=ALPHA) or the BETA= option is used to derive the Type I error probability α (BOUNDARYKEY=BETA).

Error Spending Information

The "Error Spending Information" table displays the following information at each stage:

- proportion of information
- actual information level, if the maximum information is either specified or derived
- cumulative error spending for each boundary

Method Information

The "Method Information" table displays detailed method information for the design. For each boundary, it displays the following:

- the group sequential method used
- the α or β errors
- the specified parameter ρ, if an error spending function is used
- the specified parameters ρ and τ with the derived critical value C, if a unified family method is used

- the alternative reference θ_1, if either the ALTREF= or the MAXINFO= option is specified
- the derived drift parameter, $\theta_1\sqrt{I_X}$, where I_X is the maximum information and θ_1 is the alternative reference

Note that the alternative references are displayed with the MLE scale in the "Method Information" table. In contrast, the alternative references in the "Boundary Information" table are displayed with the specified statistic scale (if the p-value scale is not specified) or the standardized Z scale (if the p-value scale is specified).

Powers and Expected Sample Sizes

The "Powers and Expected Sample Sizes" table displays the following information under each of the specified hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option.

- coefficient c_i for the hypothetical references. The value $c_i = 0$ corresponds to the null hypothesis and $c_i = 1$ corresponds to the alternative hypothesis
- power
- expected sample size, as percentage of fixed-sample size

For a one-sided design, the power and expected sample sizes under the hypothetical references $\theta = c_i\theta_1$ are displayed.

For a two-sided symmetric design, the power and expected sample sizes under each of the hypothetical references $\theta = c_i\theta_{1u}$ are displayed, where θ_{1u} is the upper alternative reference.

For a two-sided asymmetric design, the power and expected sample sizes under each of the hypothetical references $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively.

For a two-sided design, the power is the probability of correctly rejecting the null hypothesis for the correct alternative. Thus, under the null hypothesis, the displayed power corresponds to a one-sided Type I error probability level—that is, the lower α level or the upper α level.

The expected sample size as a percentage of the corresponding fixed-sample design is

$$100 \times \frac{\sum_{k=1}^{K} p_k\, I_k}{I_0}$$

where p_k is the stopping probability at stage k, $\sum_{k=1}^{K} p_k\, I_k$ is the expected information level, and I_0 is the information level for the fixed-sample design.

Sample Size Summary

When you use the SAMPLESIZE statement with the SEQDESIGN procedure, the "Sample Size Summary" table displays parameters for the sample size computation. It also displays the expected sample sizes or numbers of events for the model under both the null and alternative hypotheses.

The expected sample size is the average sample size

$$\frac{\sum_{k=1}^{K} p_k I_k}{I_0} N_0$$

where p_k is the stopping probability at stage k, $\sum_{k=1}^{K} p_k I_k$ is the expected information level, I_0 is the information level for the fixed-sample design, and N_0 is the sample size for the fixed-sample design.

The expected number of events is the average number of events

$$\frac{\sum_{k=1}^{K} p_k I_k}{I_0} D_0$$

where D_0 is the fixed-sample number of events for the model.

Sample Size Information

The "Sample Sizes (N)" table displays the required sample sizes and information levels at each stage, in both fractional and integer numbers. The derived fractional sample sizes are under the heading "Fractional N." These sample sizes are rounded up to integers under the heading "Ceiling N." The matched integer sample sizes are also displayed for two-sample tests.

The "Required Number of Events (D)" table displays the required number of events required and information level at each stage.

The "Number of Events (D) and Sample Sizes (N)" table displays the number of events and sample size required at each stage with the study time. The derived times under the heading "Fractional Time" are not integers. These times are rounded up to integers under the heading "Ceiling Time."

Stopping Probabilities

The "Expected Cumulative Stopping Probabilities" table displays the following information under each of the specified hypothetical references $\theta = c_i \theta_1$, where c_i are values specified in the CREF= option, and θ_1 is the alternative reference:

- coefficient c_i for the hypothetical references. The value $c_i = 0$ corresponds to the null hypothesis, and $c_i = 1$ corresponds to the alternative hypothesis
- expected stopping stage
- source of the stopping probability: reject H_0 (with STOP=REJECT or STOP=BOTH), accept H_0 (with STOP=ACCEPT or STOP=BOTH), or either reject or accept H_0 (with STOP=BOTH)
- expected cumulative stopping probabilities at each stage

For a one-sided design, the expected cumulative stopping probabilities under the hypothetical references $\theta = c_i \theta_1$ are displayed.

For a two-sided design, the expected cumulative stopping probabilities under each of the hypothetical references $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively.

Note that for a symmetric two-sided design, only the expected cumulative stopping probabilities under the hypothetical references $\theta = c_i\theta_{1u}$ are derived.

The expected stopping stage is given by $k_0 + d$, where the integer k_0 and the fraction d $(0 \leq d < 1)$ are derived from the expected information level equation

$$\sum_{k=1}^{K} p_k\, I_k = I_{k_0} + d\,(I_{(k_0+1)} - I_{k_0})$$

where p_k is the stopping probability at stage k.

For equally spaced information levels, the expected stopping stage is reduced to the weighted average

$$\sum_{k=1}^{K} p_k\, k$$

ODS Table Names

PROC SEQDESIGN assigns a name to each table it creates. You must use these names to reference tables when using the Output Delivery System (ODS). These names are listed in Table 77.12. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 77.12 ODS Tables Produced by PROC SEQDESIGN

ODS Table Name	Description	Statement	Option
Boundary	Boundary values		
Design	Design information		
ErrSpend	Error spending		ERRSPEND
Method	Method information		
PowerSampleSize	Power and expected sample size		PSS
SampleSize	Derived sample sizes	SAMPLESIZE	
SampleSizeSummary	Sample size summary	SAMPLESIZE	
StopProb	Stopping probabilities		STOPPROB

Graphics Output

This section describes the use of ODS for creating graphics with the SEQDESIGN procedure. To request these graphs, you must specify the ODS GRAPHICS ON statement in addition to the associated graphics options in the PROC SEQDESIGN statement. Except for the PLOTS=BOUNDARY

option, where a detailed boundary plot is generated for each design separately, each option produces a plot for all designs together. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

Sequential ASN Plot

The PLOTS=ASN option displays the average sample numbers (expected sample sizes for nonsurvival data or expected numbers of events for survival data) under various hypothetical references. The average sample numbers are connected for each design, and these connected curves for all designs are displayed in the "Sequential ASN Plot" graph.

For a one-sided design, average sample numbers under the hypothetical references $\theta = c_i\theta_1$ are displayed, where c_i are the values specified in the CREF= option and θ_1 is the alternative reference. The horizontal axis displays the c_i values of these hypothetical references.

For a two-sided design, average sample numbers under each of the hypothetical references $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The horizontal axis displays $-c_i$ values for lower hypothetical references $\theta = c_i\theta_{1l}$ and c_i values for upper hypothetical references $\theta = c_i\theta_{1u}$.

Note that for a symmetric two-sided design, only average sample numbers under the hypothetical references $\theta = c_i\theta_{1u}$ are derived.

Sequential Boundary Plot

The PLOTS=BOUNDARY option displays boundary values and the acceptance and rejection regions at each stage for each design separately in the "Detailed Boundary Information" graph. The BOUNDARYSCALE= option is used to specify the scale of the boundaries on the vertical axis. The keywords MLE, SCORE, STDZ, and PVALUE in the BOUNDARYSCALE= option correspond to the boundary with the MLE scale, score statistic scale, standardized normal Z scale, and p-value scale, respectively.

The stage numbers are displayed on the horizontal axis. In addition, the HSCALE= option in the PLOTS=BOUNDARY option can be used to specify the scale on the horizontal axis. The keywords INFO and SAMPLESIZE in the HSCALE= option correspond to the information levels and sample sizes, respectively.

Combined Sequential Boundary Plot

The PLOTS=COMBINEDBOUNDARY option displays boundary values. The boundary values are connected for each boundary in each design, and these connected curves for all designs are displayed in the "Sequential Boundary Information" graph. The BOUNDARYSCALE= option is used to specify the scale of the boundaries on the vertical axis. The keywords MLE, SCORE, STDZ, and PVALUE in the BOUNDARYSCALE= option correspond to the boundary with the MLE scale, score statistic scale, standardized normal Z scale, and p-value scale, respectively.

The HSCALE= option in the PLOTS=COMBINEDBOUNDARY option can be used to specify the scale on the horizontal axis. The keywords INFO, SAMPLESIZE, and STAGE in the HSCALE= option correspond to the information levels, sample sizes, and stage numbers, respectively.

Sequential Error Spending Plot

The PLOTS=ERRSPEND option displays the cumulative error spending at each stage on each boundary in the "Sequential Error Spending Plot" graph. A legend table uses the design labels to identify the curves for the corresponding design in the plot. Another legend table uses symbols to identify boundaries in the plot.

Sequential Power Plot

The PLOTS=POWER option displays the powers under various hypothetical references. The powers are connected for each design, and these connected curves for all designs are displayed in the "Sequential Power Plot" graph.

For a one-sided design, powers under hypothetical references $\theta = c_i\theta_1$ are displayed, where c_i are the values specified in the CREF= option and θ_1 is the alternative reference. The horizontal axis displays the c_i values of these hypothetical references.

For a two-sided design, powers under hypothetical references $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The horizontal axis displays $-c_i$ values for lower hypothetical references $\theta = c_i\theta_{1l}$ and c_i values for upper hypothetical references $\theta = c_i\theta_{1u}$.

Note that for a symmetric two-sided design, only powers under hypothetical references $\theta = c_i\theta_{1u}$ are derived.

ODS Graphics

PROC SEQDESIGN assigns a name to each graph it creates. You can use these names to reference the graphs when using ODS. The names are listed in Table 77.13.

To request these graphs, you must specify the ODS GRAPHICS ON statement in addition to the options indicated in Table 77.13. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

Table 77.13 ODS Graphics Produced by PROC SEQDESIGN

ODS Graph Name	Plot Description	Option
ASNPlot	Average sample numbers	PLOTS=ASN
BoundaryPlot	Detailed boundary values	PLOTS=BOUNDARY
CombinedBoundaryPlot	Boundary values	PLOTS=COMBINEDBOUNDARY
ErrSpendPlot	Error spending	PLOTS=ERRSPEND
PowerPlot	Power curves	PLOTS=POWER

Examples: SEQDESIGN Procedure

The following examples demonstrate the usage of group sequential methods. Example 77.1 uses the NSTAGES=1 option to derive boundaries of critical values for a fixed-sample design. The remaining examples use different methods to create boundaries for various group sequential designs.

Example 77.1: Creating Fixed-Sample Designs

This example demonstrates a one-sided fixed-sample design and a two-sided fixed-sample design. The following statements request a fixed-sample design with an upper alternative:

```
ods graphics on;
proc seqdesign pss
               ;
   OneSidedFixedSample: design nstages=1
                               alt=upper
                               alpha=0.025 beta=0.10
                               ;
   samplesize model=onesamplemean(mean=0.25);
run;
ods graphics off;
```

In the DESIGN statement, the label `OneSidedFixedSample` identifies the design in the output tables. The NSTAGES=1 option specifies that the design has only one stage; this corresponds to a fixed-sample design. In the SEQDESIGN procedure, the null hypothesis for the design is $H_0 : \theta = 0$ and the ALT=UPPER option specifies an upper alternative hypothesis $H_1 : \theta = \theta_1 > 0$. The MEAN=0.25 option in the SAMPLESIZE statement specifies the upper alternative reference $\theta_1 = 0.25$.

The options ALPHA=0.025 and BETA=0.10 specify the Type I error probability level $\alpha = 0.025$ and the Type II error probability level $\beta = 0.10$. That is, the design has a power $1 - \beta = 0.90$ at $\theta_1 = 0.25$.

The "Design Information" table in Output 77.1.1 displays design specifications and the derived statistics such as power. As expected, the derived statistics such as maximum information and average sample number (in percentage of its corresponding fixed-sample information) are 100 for the fixed-sample design (NSTAGES=1). Also, for a fixed-sample design, the STOP= and METHOD= options in the DESIGN statement are not applicable.

Output 77.1.1 One-Sided Fixed-Sample Design Information

The SEQDESIGN Procedure
Design: OneSidedFixedSample

Design Information

Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Alternative Reference	0.25
Number of Stages	1
Alpha	0.025
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	100
Max Information	168.1188
Null Ref ASN (Percent of Fixed Sample)	100
Alt Ref ASN (Percent of Fixed Sample)	100

The "Method Information" table in Output 77.1.2 displays the α and β error levels. It also displays the derived drift parameter, which is the standardized reference improvement, $\theta_1\sqrt{I_0}$, where θ_1 is the alternative reference and I_0 is the maximum information for the design. If either θ_1 or I_0 is specified, the other statistic is derived in the SEQDESIGN procedure. For a fixed-sample design,

$$\theta_1\sqrt{I_0} = \Phi^{-1}(1-\alpha) + \Phi^{-1}(1-\beta) = \Phi^{-1}(0.975) + \Phi^{-1}(0.90) = 3.2415$$

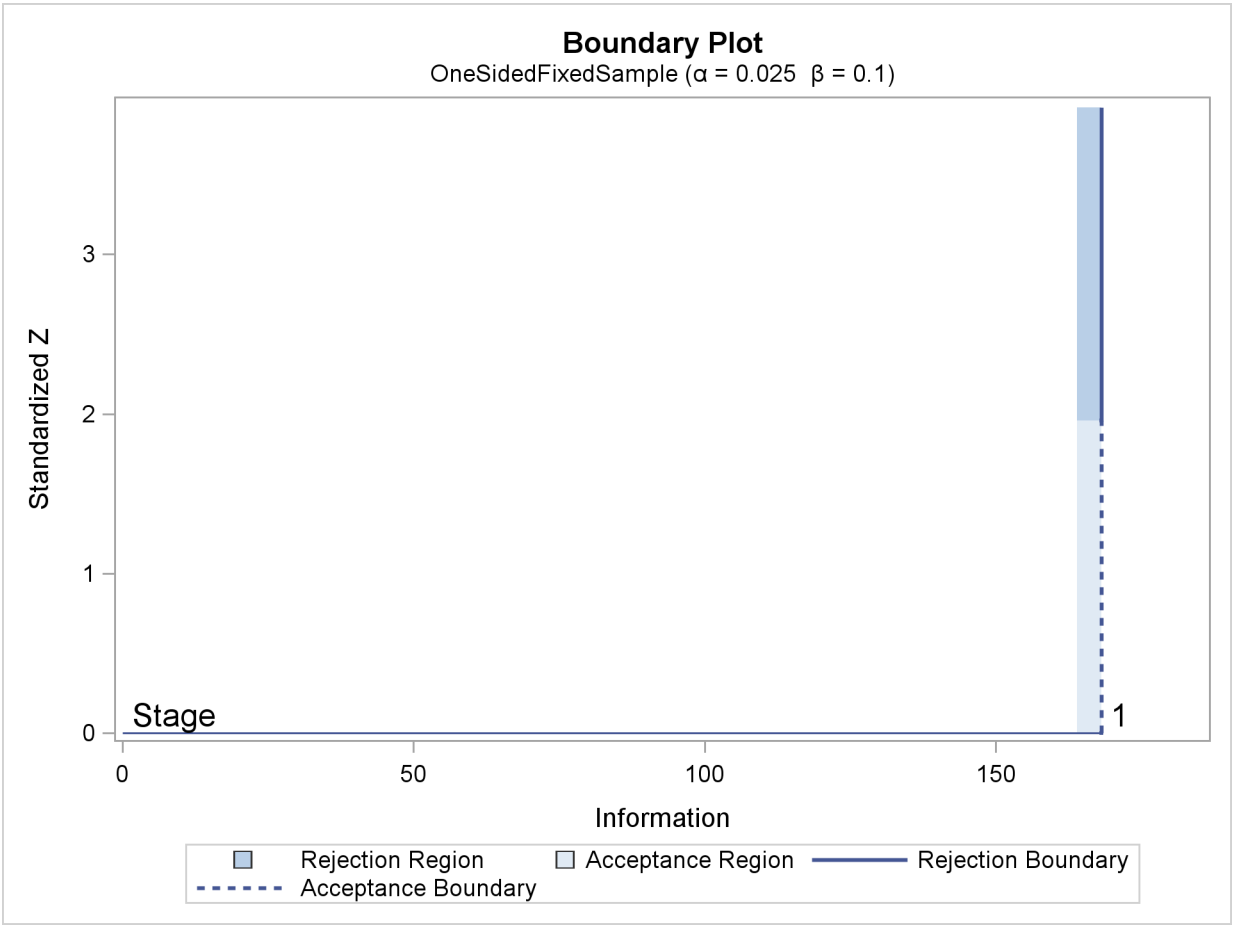
Output 77.1.2 Method Information

Method Information

Boundary	Alpha	Beta	Alternative Reference	Drift
Upper Alpha	0.02500	0.10000	0.25	3.241516

The "Boundary Information" table in Output 77.1.3 displays information level, alternative reference, and boundary value at each stage. The information proportion indicates the proportion of maximum information available at the stage. With only one stage for a fixed-sample design, the proportion is 1. With the SAMPLESIZE statement, the required sample size N is also displayed under the heading "Information Level."

Output 77.1.3 Boundary Information



Boundary Information (Standardized Z Scale)
Null Reference = 0

	--------Information Level-------			-Alternative- --Reference--	-Boundary Values- ------Upper------
Stage	Proportion	Actual	N	Upper	Alpha
1	1.0000	168.1188	168.1188	3.24152	1.95996

With the default BOUNDARYSCALE=STDZ option, output alternative references and boundaries are displayed with the standardized normal Z scale. The alternative reference on the standardized Z scale at stage 1 is given by $\theta_1\sqrt{I_1}$, where I_1 is the information level at stage 1. With a boundary value 1.96, the hypothesis of $\theta = 0$ is rejected if the standardized normal statistic $Z \geq 1.96$.

If the ODS GRAPHICS ON statement is specified, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 77.1.4. The boundary values in the "Boundary Information" table in Figure 77.1.3 are displayed in the plot.

Output 77.1.4 Boundary Plot

The "Sample Size Summary" table in Output 77.1.5 displays parameters for the sample size computation of the test for a normal mean.

Output 77.1.5 Sample Size Summary

Sample Size Summary

Test	One-Sample Mean
Mean	0.25
Standard Deviation	1
Max Sample Size	168.1188
Expected Sample Size (Null Ref)	168.1188
Expected Sample Size (Alt Ref)	168.1188

The "Sample Sizes (N)" table in Output 77.1.6 displays the derived sample sizes, in both fractional and integer numbers. With the resulting integer sample sizes, the corresponding information level is slightly larger than the level from the design. This can increase the power slightly if the integer sample size is used in the trial.

Output 77.1.6 Derived Sample Sizes

Sample Sizes (N)
One-Sample Z Test for Mean

	Fractional N		Ceiling N	
Stage	N	Information	N	Information
1	168.12	168.1	169	169.0

The following statements request a two-sided fixed-sample design with a specified alternative reference:

```
ods graphics on;
proc seqdesign altref=1.2
               pss
               ;
   TwoSidedFixedSample: design nstages=1
                               alt=twosided
                               alpha=0.05 beta=0.10
                               ;
   samplesize model=twosamplemean(stddev=2 weight=2);
run;
ods graphics off;
```

In the SEQDESIGN procedure, the null hypothesis for the design is $H_0 : \theta = 0$. The ALT=TWOSIDED option specifies a two-sided alternative hypothesis $H_1 : \theta = \theta_1 \neq 0$. The ALTREF=1.2 option in the PROC SEQDESIGN statement specifies the alternative reference $\theta_1 = \pm 1.2$.

The ALPHA=0.05 option specifies the two-sided Type I error probability level $\alpha = 0.05$. That is, the lower and upper Type I error probabilities $\alpha_l = \alpha_u = 0.025$. The BETA=0.10 option specifies the Type II error probability level $\beta = 0.10$, and the design has a power $1 - \beta = 0.90$ at the alternative reference $\theta_1 = \pm 1.2$.

The "Design Information" table in Output 77.1.7 displays design specifications and the derived power. With a specified alternative reference, the maximum information is derived.

Output 77.1.7 Two-Sided Fixed-Sample Design Information

The SEQDESIGN Procedure
Design: TwoSidedFixedSample

Design Information

Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Alternative Reference	1.2
Number of Stages	1
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	100
Max Information	7.296822
Null Ref ASN (Percent of Fixed Sample)	100
Alt Ref ASN (Percent of Fixed Sample)	100

The "Method Information" table in Output 77.1.8 displays the α and β errors, alternative references, and drift parameter. For a fixed-sample design, the derived drift parameter

$$\theta_1 \sqrt{I_0} = \Phi^{-1}(1 - \frac{\alpha}{2}) + \Phi^{-1}(1 - \beta) = \Phi^{-1}(0.975) + \Phi^{-1}(0.90) = 3.2415$$

Output 77.1.8 Method Information

Method Information

Boundary	Alpha	Beta	Alternative Reference	Drift
Upper Alpha	0.02500	0.10000	1.2	3.241516
Lower Alpha	0.02500	0.10000	-1.2	-3.24152

With a specified alternative reference $\theta_1 = 1.2$, the maximum information

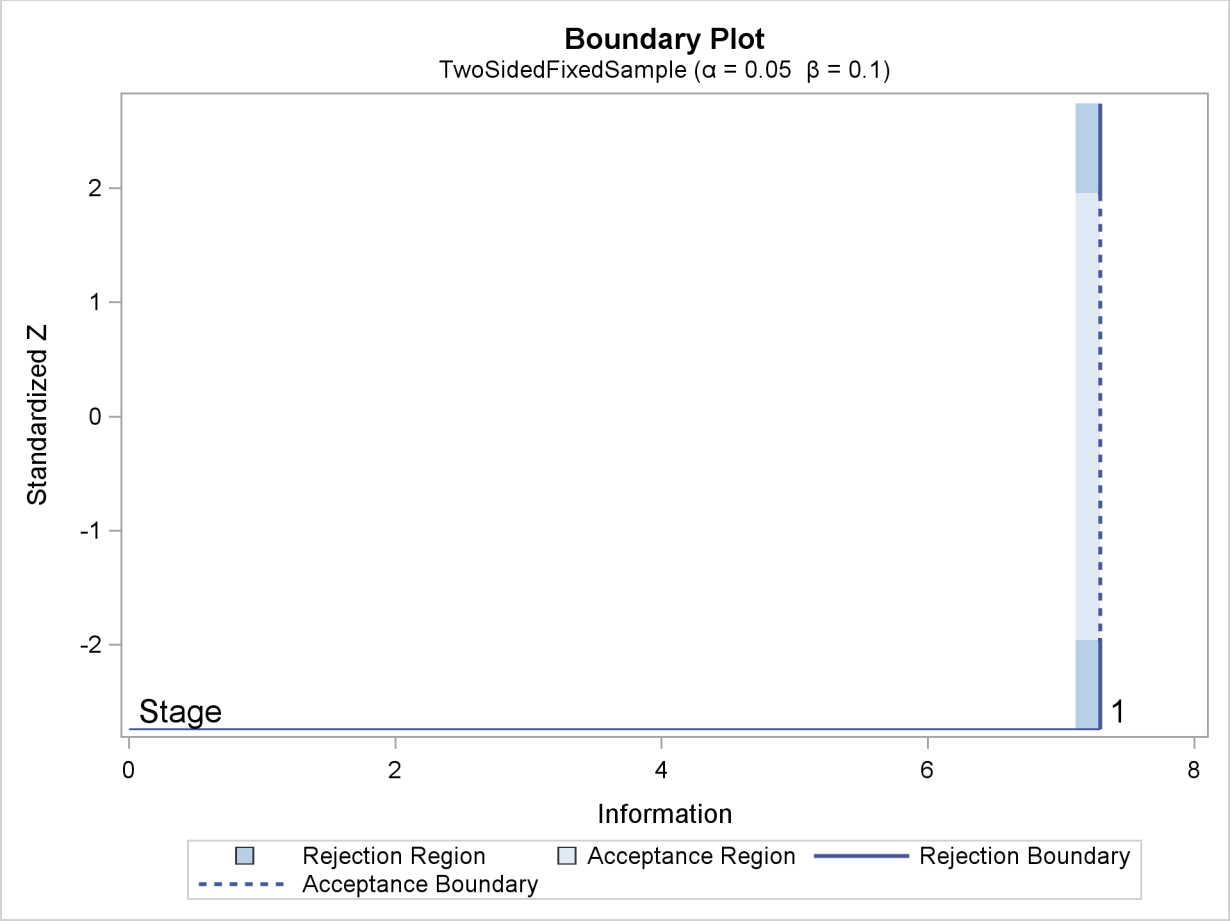
$$I_0 = \left(\frac{3.2415}{1.2}\right)^2 = 7.2968$$

The default "Boundary Information" table in Output 77.1.9 displays information level, alternative reference, and boundary values. With the default BOUNDARYSCALE=STDZ option, alternative reference and boundary values are displayed with the standardized normal Z scale. Thus, the standardized alternative references $\pm\theta_1\sqrt{I_0}$ are displayed.

Output 77.1.9 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0

	Information Level			Alternative Reference	
Stage	Proportion	Actual	N	Lower	Upper
1	1.0000	7.296822	131.3428	-3.24152	3.24152



Boundary Information (Standardized Z Scale)
Null Reference = 0

	Boundary Values	
	Lower	Upper
Stage	Alpha	Alpha
1	-1.95996	1.95996

With boundary values of -1.96 and 1.96, the hypothesis of $\theta = 0$ is rejected if the standardized normal statistic $Z \geq 1.96$ or $Z \leq -1.96$.

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 77.1.10 . The boundary values in the "Boundary Information" table in Figure 77.1.9 are displayed in the plot.

Output 77.1.10 Boundary Plot

The "Sample Size Summary" table in Output 77.1.11 displays parameters for the sample size computation of the test for a normal mean.

Output 77.1.11 Sample Size Summary

Sample Size Summary

Test	Two-Sample Means
Mean Difference	1.2
Standard Deviation	2
Max Sample Size	131.3428
Expected Sample Size (Null Ref)	131.3428
Expected Sample Size (Alt Ref)	131.3428
Weight (Group A)	2
Weight (Group B)	1

The "Sample Sizes (N)" table in Output 77.1.12 displays the derived sample sizes, in both fractional and integer numbers. With the WEIGHT=2 option, the allocation ratio is 2 for the first group and 1 for the second group. With the resulting integer sample sizes, the corresponding information level is slightly larger than the level from the design. This can increase the power slightly if the integer sample size is used in the trial.

Output 77.1.12 Derived Sample Sizes

Sample Sizes (N)
Two-Sample Z Test for Mean Difference

	Fractional N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	131.34	87.56	43.78	7.2968

Sample Sizes (N)
Two-Sample Z Test for Mean Difference

	Ceiling N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	132	88	44	7.3333

Example 77.2: Creating a One-Sided O'Brien-Fleming Design

This example demonstrates a group sequential design for a clinical study. A clinic is conducting a study on the effect of vitamin C supplements in treating flu symptoms. The study groups consist of patients in the clinic with their first sign of flu symptoms within the last 24 hours. These individuals are randomly assigned to either the control group, which receives the placebo pills, or the treatment group, which receives large doses of vitamin C supplements. At the end of a five-day period, the flu symptoms of each individual are recorded.

Suppose that from past experience, 60% of individuals experiencing flu symptoms have the symptoms disappeared within five days. The clinic wants to detect a 75% symptoms disappearance with a high probability in the trial. A test that compares the proportions directly is to specify a null hypothesis $H_0 : \theta = p_a - p_b = 0$ with a Type I error probability level $\alpha = 0.025$, where p_a and p_b are the proportions of symptoms' disappearance in the treatment group and control group, respectively. A one-sided alternative $H_1 : \theta > 0$ is also specified with a power of $1 - \beta = 0.90$ at $H_1 : \theta = 0.15$.

For a one-sided fixed-sample design, the critical value for the standardized Z test statistic is given by $C_\alpha = \Phi^{-1}(1-\alpha) = 1.96$. That is, at the end of study, if the test statistic $z \geq C_\alpha$, then the null hypothesis is rejected and the efficacy of vitamin C supplements is declared. Otherwise, the null hypothesis is not rejected and the effect of vitamin C supplements is not significant.

To achieve a $1 - \beta = 0.90$ power at $H_1 : \theta = 0.15$ for a fixed-sample design, the information required is given by

$$I_0 = \frac{(\Phi^{-1}(1-\alpha) + \Phi^{-1}(1-\beta))^2}{0.15^2} = \frac{(1.96 + 1.28155)^2}{0.0225} = 466.99$$

With an equal sample size on the treatment and control groups, $N_a = N_b$, the sample size required for each group under H_1 is computed from the information I_0:

$$N_a = N_b = \left(p_{1a}\left(1 - p_{1a}\right) + p_{1b}\left(1 - p_{1b}\right)\right) I_0$$

where $p_{1a} = 0.75$ and $p_{1b} = 0.60$ are proportions in the treatment and control groups under H_1. That is,

$$N_a = N_b = (0.75 \times 0.25 + 0.6 \times 0.4) \times 466.99 = 199.64$$

Thus, 200 individuals are required for each group in the fixed-sample study. See the section "Test for the Difference between Two Binomial Proportions" on page 5862 for a detailed derivation of these required sample sizes.

Instead of a fixed-sample design for the trial, a group sequential design is used to stop the trial early for ethical concerns of possible harm or an unexpected strong efficacy outcome of the new drug. It can also save time and resources in the process. The following statements invoke the SEQDESIGN procedure and request a four-stage group sequential design that uses an O'Brien-Fleming method for normally distributed statistics. The design uses a one-sided alternative hypothesis H_1 with early stopping to reject or accept H_0.

```
ods graphics on;
proc seqdesign altref=0.15
               ;
   OneSidedOBrienFleming: design nstages=4
                          method=obf
                          alt=upper   stop=both
                          alpha=0.025 beta=0.10
                          ;
   samplesize model=twosamplefreq(nullprop=0.6 test=prop);
ods output Boundary=Bnd_Prop;
run;
ods graphics off;
```

In a sequential design, a hypothesis can be rejected, accepted, or continued to the next time point at each interim stage. The STOP=BOTH option specifies early stopping to reject or accept the null hypothesis. The "Design Information," "Method Information," and "Boundary Information" tables are displayed by default.

The "Design Information" table in Output 77.2.1 displays design specifications and derived statistics such as power and maximum information. With a specified alternative reference, ALTREF=0.15, the maximum information I_X is derived.

Output 77.2.1 Design Information

The SEQDESIGN Procedure
Design: OneSidedOBrienFleming

Design Information

Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	0.15
Number of Stages	4
Alpha	0.025
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	107.6741
Max Information	502.8343
Null Ref ASN (Percent of Fixed Sample)	61.12891
Alt Ref ASN (Percent of Fixed Sample)	75.89782

The Max Information (Percent Fixed-Sample) is the ratio in percentage between the maximum information for the group sequential design and the information required for a corresponding fixed-sample design:

$$100 \times \frac{I_X}{I_0} = 100 \times \frac{502.83}{466.99} = 107.67$$

That is, if the group sequential trial does not stop at any interim stages, the information needed is 7.67% more than is needed for the corresponding fixed-sample design. For a two-sample test for binomial proportions, the information is proportional to the sample size. Thus, 7.67% more observations are needed for the group sequential trial.

The Null Ref ASN (Percent Fixed-Sample) is the ratio in percentage between the expected sample size required under the null hypothesis for the group sequential design and the sample size required for the corresponding fixed-sample design. With a ratio of 61.1%, the expected sample size for the group sequential trial under the null hypothesis is 61.1% of the sample size in the corresponding fixed-sample design.

Similarly, the Alt Ref ASN (Percent Fixed-Sample) is the ratio in percentage between the expected sample size required under the alternative hypothesis for the group sequential design and the sample size required for the corresponding fixed-sample design. With a ratio of 75.9%, the expected sample size for the group sequential trial under the alternative hypothesis is 75.9% of the sample size in the corresponding fixed-sample design.

For a one-sided design with an upper alternative and early stopping to reject or accept the null hypothesis, upper α and β boundaries are created. The "Method Information" table in Output 77.2.2 displays the Type I error probability α, the Type II error probability β, and the derived drift parameter. The drift parameter is the standardized reference improvement between the alternative and null hypotheses at the final stage. It is also the standardized alternative reference at the final stage if the null reference is zero.

Output 77.2.2 Method Information

Method Information

Boundary	Method	Alpha	Beta	Unified Family: Rho	Unified Family: Tau	Unified Family: C
Upper Alpha	O'Brien-Fleming	0.02500	.	0.5	0	1.9784
Upper Beta	O'Brien-Fleming	.	0.10000	0.5	0	1.3852

Method Information

Boundary	Alternative Reference	Drift
Upper Alpha	0.15	3.363595
Upper Beta	0.15	3.363595

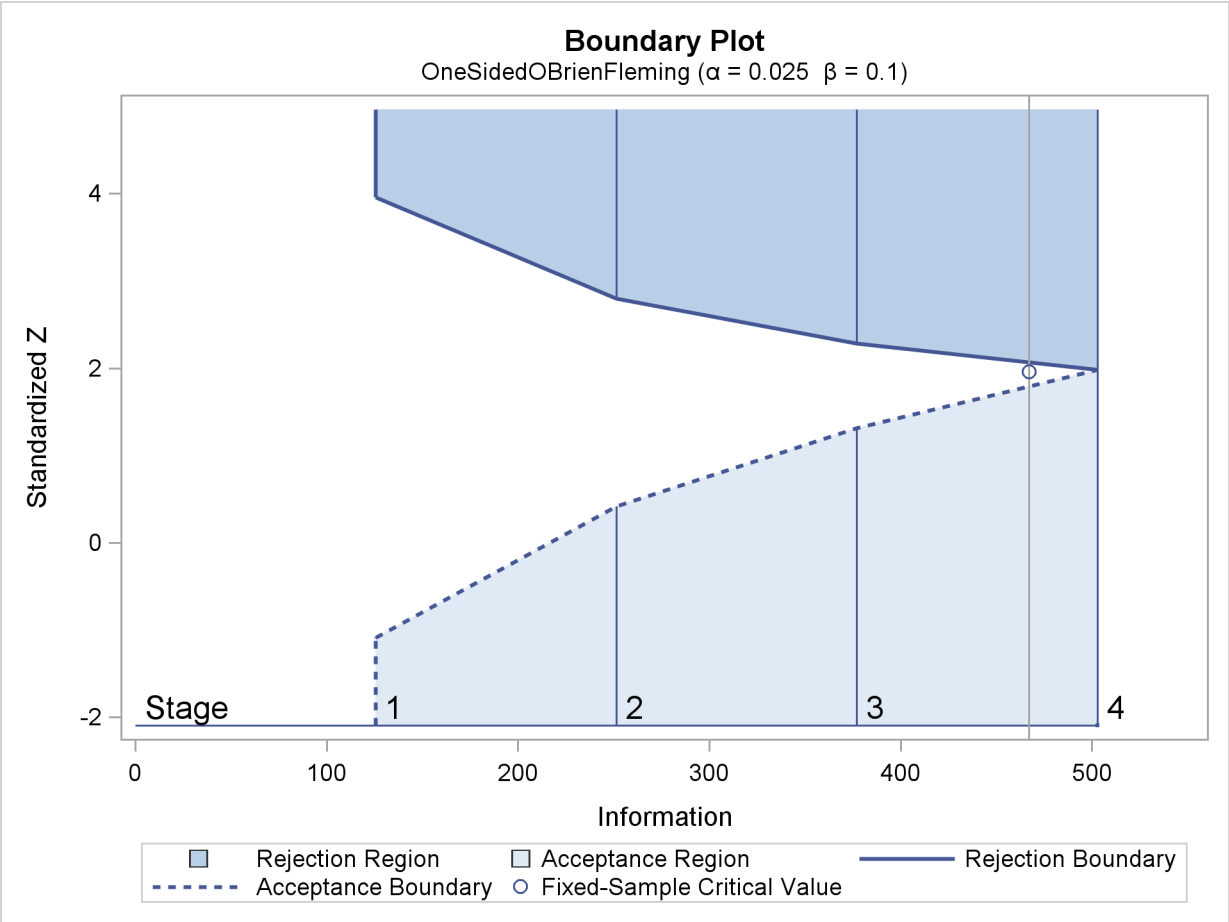
With the METHOD=OBF option, the O'Brien-Fleming method is used for each boundary. The O'Brien-Fleming method is one of the unified family methods, and the "Method Information" table displays the corresponding parameter ρ in the unified family method. The table also displays the critical values $C_\alpha = 1.9784$ for the α boundary and $C_\beta = 1.3852$ for the β boundary. These critical values are used to create the boundary values. With the default BOUNDARYSCALE=STDZ option, the boundaries are displayed with the standardized Z statistic scale.

The "Boundary Information" table in Output 77.2.3 displays information level, alternative reference, and boundary values at each stage. The default BOUNDARYSCALE=STDZ option specifies that the standardized Z scale be used to display the alternative references and boundary values. The resulting standardized alternative reference at stage k is given by $\theta_1 \sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information level at stage k, $k = 1, 2, 3, 4$.

Output 77.2.3 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0

Stage	Information Level: Proportion	Information Level: Actual	Information Level: N	Alternative Reference: Upper	Boundary Values: Upper: Beta	Boundary Values: Upper: Alpha
1	0.2500	125.7086	107.4808	1.68180	-1.08860	3.95679
2	0.5000	251.4171	214.9617	2.37842	0.41946	2.79788
3	0.7500	377.1257	322.4425	2.91296	1.31347	2.28446
4	1.0000	502.8343	429.9233	3.36360	1.97840	1.97840



By default, equally spaced information levels are used. An information proportion is the proportion of maximum information available at each stage. With the derived maximum information, the actual information level at each stage is also displayed. With the SAMPLESIZE statement, the required sample size N is also displayed under the heading "Information Level."

At each interim stage, if the standardized Z test statistic is larger than or equal to the corresponding upper α boundary, then the hypothesis $H_0 : \theta = 0$ is rejected. If the test statistic is less than the corresponding upper β boundary, then the trial is stopped and the hypothesis H_0 is accepted. Otherwise, the process continues to the next stage. At the final stage, stage 4, the trial stops and the hypothesis H_0 is rejected if the standardized Z statistic $Z_4 \geq 1.9784$. Otherwise, the trial is accepted.

The ODS OUTPUT statement with the BOUNDARY=BND_PROP option creates an output data set that contains the resulting boundary information. After the actual data from the clinical trial are collected and analyzed at each stage with a procedure such as PROC GENMOD, the SEQTEST procedure is used to test the resulting statistics at stage 1 with the boundary information stored in the BOUND_PROP data set.

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 77.2.4.

Output 77.2.4 Boundary Plot

The horizontal axis indicates the information levels for the design. The stages are indicated by vertical lines with accompanying stage numbers. If at any stage a test statistic is in a rejection region, the trial stops and the hypothesis is rejected. If a test statistic is in an acceptance region, then the trial also stops and the hypothesis is accepted. If the statistic is not in a rejection region

or an acceptance region, the trial continues to the next stage. The boundary plot also displays the information level and critical value for the corresponding fixed-sample design.

The SEQDESIGN procedure derives the drift parameter $\theta_1\sqrt{I_X}$, where θ_1 is the alternative reference and I_X is the maximum information. If either θ_1 or I_X is specified, the other can be derived. With the SAMPLESIZE statement, the maximum information is used to compute the required sample size for the study.

The "Sample Size Summary" table in Output 77.2.5 displays parameters for the sample size computation. With the MODEL=TWOSAMPLEFREQ(NULLPROP=0.6 TEST=PROP) option in the SAMPLESIZE statement, the total sample size in each group for testing the difference between two proportions is computed. With the default REF=PROP option, the required sample sizes are computed under the alternative hypothesis. That is,

$$N_a = N_b = \left(p_{1a}\left(1 - p_{1a}\right) + p_{1b}\left(1 - p_{1b}\right)\right) I_X$$

where $p_{1b} = 0.60$ and $p_{1a} = p_{1b} + \theta_1 = 0.75$ are the proportions in the control and treatment groups, respectively, under the alternative hypothesis H_1. See the section "Test for the Difference between Two Binomial Proportions" on page 5862 for a detailed description of these parameters.

Output 77.2.5 Sample Size Summary

Sample Size Summary

Test	Two-Sample Proportions
Null Proportion	0.6
Proportion (Group A)	0.75
Test Statistic	Z for Proportion
Reference Proportions	Alt Ref
Max Sample Size	429.9233
Expected Sample Size (Null Ref)	244.0768
Expected Sample Size (Alt Ref)	303.0464

The "Sample Sizes (N)" table in Output 77.2.6 displays the required sample sizes at each stage, in both fractional and integer numbers. The derived fractional sample sizes are under the heading "Fractional N." These sample sizes are rounded up to integers under the heading "Ceiling N." In practice, integer sample sizes are used, and the resulting information levels increase slightly. Thus, 54, 108, 162, and 215 individuals are needed in each group for the four stages, respectively.

Output 77.2.6 Derived Sample Sizes

Sample Sizes (N)
Two-Sample Z Test for Proportion Difference

	Fractional N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	107.48	53.74	53.74	125.7
2	214.96	107.48	107.48	251.4
3	322.44	161.22	161.22	377.1
4	429.92	214.96	214.96	502.8

Sample Sizes (N)
Two-Sample Z Test for Proportion Difference

	Ceiling N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	108	54	54	126.3
2	216	108	108	252.6
3	324	162	162	378.9
4	430	215	215	502.9

Example 77.3: Creating Two-Sided Pocock and O'Brien-Fleming Designs

This example requests two 4-stage group sequential designs for normally distributed statistics with equally spaced information levels at all stages. One design uses Pocock's method and the other uses the O'Brien-Fleming method. With the default BOUNDARYSCALE=STDZ option, the output boundaries are displayed with the standardized normal Z scale.

In the following statements, the default ALT=TWOSIDED option specifies a null hypothesis with a two-sided alternative, and the default STOP=REJECT option indicates an early stop to reject the null hypothesis H_0:

```
proc seqdesign altref=0.4
               pss
               stopprob
               errspend
               ;
   TwoSidedPocock:         design nstages=4 method=poc;
   TwoSidedOBrienFleming: design nstages=4 method=obf;
   samplesize model=twosamplemean(stddev=0.8 weight=2);
run;
```

The "Design Information" table in Output 77.3.1 displays design specifications and derived statistics for the Pocock's design. With the specified ALTREF= option, the maximum information $I_X = 77.6984$ is also derived.

Output 77.3.1 Pocock Design Information

The SEQDESIGN Procedure
Design: TwoSidedPocock

Design Information

Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	Pocock
Boundary Key	Both
Alternative Reference	0.4
Number of Stages	4
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	118.3143
Max Information	77.69844
Null Ref ASN (Percent of Fixed Sample)	115.6074
Alt Ref ASN (Percent of Fixed Sample)	69.74805

With the corresponding fixed-sample information

$$I_0 = \frac{(\Phi^{-1}(1-\alpha/2) + \Phi^{-1}(1-\beta))^2}{0.4^2} = \frac{(1.96 + 1.28155)^2}{0.16} = 65.6728$$

the fixed-sample information ratio is $77.6984/65.6728 = 1.1831$.

For a two-sided design with early stopping to reject the null hypothesis, lower and upper α boundaries are created. The "Method Information" table in Output 77.3.2 displays the α and β errors, alternative references, and derived drift parameters, which are the standardized alternative references at the final stage.

Output 77.3.2 Method Information

Method Information

Boundary	Method	Alpha	Beta	-------Unified Family------ Rho	Tau	C
Upper Alpha	Pocock	0.02500	0.10000	0	0	2.36129
Lower Alpha	Pocock	0.02500	0.10000	0	0	2.36129

Method Information

Boundary	Alternative Reference	Drift
Upper Alpha	0.4	3.525869
Lower Alpha	-0.4	-3.52587

With the METHOD=POC option, the Pocock method is used for each boundary. The Pocock method is one of the unified family methods, and the table also displays its corresponding parameters $\rho = 0$ as a unified family method and the derived parameters $C = 2.3613$ for the boundary values.

With the PSS option, the "Power and Expected Sample Sizes" table in Output 77.3.3 displays powers and expected sample sizes under various hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option. By default, $c_i = 0, 0.5, 1.0, 1.5$.

Output 77.3.3 Power and Expected Sample Size Information

Powers and Expected Sample Sizes
Reference = CRef * (Alt Reference)

CRef	Power	-Sample Size- Percent Fixed-Sample
0.0000	0.02500	115.6074
0.5000	0.34252	104.0615
1.0000	0.90000	69.7480
1.5000	0.99869	43.6600

Note that at $c_i = 0$, the null reference $\theta = 0$, and the power 0.025 corresponds to the one-sided Type I error probability 0.025. At $c_i = 1$, $\theta = \theta_1$, the power 0.9 is the power of the design. The expected sample sizes are displayed in a percentage scale to its corresponding fixed-sample size design. With the specified SAMPLESIZE statement, the expected sample sizes for the specified model in the SAMPLESIZE statement are also displayed.

With the STOPPROB option, the "Expected Cumulative Stopping Probabilities" table in Output 77.3.4 displays the expected cumulative stopping stage and cumulative stopping probability to reject the null hypothesis H_0 at each stage under various hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option. By default, $c_i = 0, 0.5, 1.0, 1.5$.

Output 77.3.4 Stopping Probabilities

Expected Cumulative Stopping Probabilities
Reference = CRef * (Alt Reference)

CRef	Expected Stopping Stage	Source	--------Stopping Probabilities-------- Stage_1	Stage_2	Stage_3	Stage_4
0.0000	3.908	Reject Null	0.01821	0.03155	0.04176	0.05000
0.5000	3.518	Reject Null	0.07005	0.15939	0.25242	0.34327
1.0000	2.358	Reject Null	0.27482	0.58074	0.78638	0.90002
1.5000	1.476	Reject Null	0.61145	0.92348	0.98900	0.99869

Note that at $c_i = 0$, the cumulative stopping probability to reject H_0 at the final stage is the overall Type I error probability 0.05. At $c_i = 1$, the alternative hypothesis $H_1 : \theta = \theta_1$, the cumulative

stopping probability to reject H_0 includes both the probability in the lower rejection region and the probability in the upper rejection region. This stopping probability to reject H_0 at the final stage, 0.90002, is slightly greater than the power $1 - \beta = 0.90$, which corresponds to the cumulative stopping probability in the upper rejection region only. See the section "Type I and Type II Errors" on page 5836 for a detailed description of the Type II error probability β.

The "Boundary Information" table in Output 77.3.5 displays the information level, alternative references, and boundary values at each stage. The default BOUNDARYSCALE=STDZ option specifies that the standardized Z scale be used to display the alternative references and boundary values. The resulting standardized alternative reference at stage k is given by $\theta_1 \sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information level at stage k, $k = 1, 2, 3, 4$.

Output 77.3.5 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0

	Information Level			Alternative Reference	
Stage	Proportion	Actual	N	Lower	Upper
1	0.2500	19.42461	55.94288	-1.76293	1.76293
2	0.5000	38.84922	111.8858	-2.49317	2.49317
3	0.7500	58.27383	167.8286	-3.05349	3.05349
4	1.0000	77.69844	223.7715	-3.52587	3.52587

Boundary Information (Standardized Z Scale)
Null Reference = 0

	Boundary Values	
	Lower	Upper
Stage	Alpha	Alpha
1	-2.36129	2.36129
2	-2.36129	2.36129
3	-2.36129	2.36129
4	-2.36129	2.36129

By default, equally spaced information levels are used, and the procedure displays the output boundaries in terms of standardized statistics (BOUNDARYSCALE=STDZ). With the SAMPLESIZE statement, the required sample size N is also displayed under the heading "Information Level." With the Pocock method, the standardized Z boundary values are identical at all stages for each α boundary.

At each interim stage, the hypothesis of $H_0 : \theta = 0$ is rejected if the standardized normal test statistic $z \leq -2.36129$, the lower α boundary, or $z \geq 2.36129$, the upper α boundary. Otherwise, the trial continues to the next stage. At the final stage, stage 4, the trial stops and the hypothesis is rejected if the test statistic $|z_4| \geq 2.36129$. Otherwise, the hypothesis is accepted.

The "Error Spending Information" in Output 77.3.6 displays cumulative error spending at each stage for each boundary. It shows that more α errors are used in early stages than in later stages.

Output 77.3.6 Error Spending Information

Error Spending Information

Stage	-Information Level- Proportion	--------Cumulative Error Spending------- -------Lower------ Alpha	Beta	-------Upper------ Beta	Alpha
1	0.2500	0.00911	0.00002	0.00002	0.00911
2	0.5000	0.01577	0.00002	0.00002	0.01577
3	0.7500	0.02088	0.00002	0.00002	0.02088
4	1.0000	0.02500	0.10000	0.10000	0.02500

The "Sample Size Summary" table in Output 77.3.7 displays the specified parameters for the sample size computation of the two-sample test for mean difference.

Output 77.3.7 Sample Size Summary

Sample Size Summary

Test	Two-Sample Means
Mean Difference	0.4
Standard Deviation	0.8
Max Sample Size	223.7715
Expected Sample Size (Null Ref)	218.652
Expected Sample Size (Alt Ref)	131.9167
Weight (Group A)	2
Weight (Group B)	1

The "Sample Sizes (N)" table in Output 77.3.8 displays the derived sample sizes at each stage, in both fractional and integer numbers. With the WEIGHT=2 option, the allocation ratio is 2 for the first group and 1 for the second group. See the section "Test for the Difference between Two Normal Means" on page 5860 for the derivation of these sample sizes. With the fixed-sample information ratio 1.1831, the derived sample sizes in fractional numbers are derived by multiplying 1.1831 by the corresponding sample sizes in the fixed-sample design.

Output 77.3.8 Sample Sizes

Sample Sizes (N)
Two-Sample Z Test for Mean Difference

	Fractional N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	55.94	37.30	18.65	19.4246
2	111.89	74.59	37.30	38.8492
3	167.83	111.89	55.94	58.2738
4	223.77	149.18	74.59	77.6984

Sample Sizes (N)
Two-Sample Z Test for Mean Difference

	Ceiling N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	57	38	19	19.7917
2	113	75	38	39.4082
3	168	112	56	58.3333
4	225	150	75	78.1250

These fractional sample sizes are rounded up to integers under the heading "Ceiling N." When the resulting integer sample sizes are used, the corresponding information levels are slightly larger than the levels from the design. This can increase the power slightly if a trial uses these integer sample sizes.

Note that compared with other designs, a Pocock design can stop the trial early with a larger p-value. However, this might not be persuasive enough to make a new treatment widely accepted (Pocock and White, 1999).

The "Design Information" table in Output 77.3.9 displays design specifications and the derived statistics for the O'Brien-Fleming design. With the specified ALTREF= option, the maximum information $I_X = 67.1268$ is derived.

Output 77.3.9 O'Brien-Fleming Design Information

The SEQDESIGN Procedure
Design: TwoSidedOBrienFleming

Design Information

Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	0.4
Number of Stages	4
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	102.2163
Max Information	67.12682
Null Ref ASN (Percent of Fixed Sample)	101.5728
Alt Ref ASN (Percent of Fixed Sample)	76.7397

With the corresponding fixed-sample information

$$I_0 = \frac{(\Phi^{-1}(1-\alpha/2) + \Phi^{-1}(1-\beta))^2}{0.4^2} = \frac{(1.96 + 1.28155)^2}{0.16} = 65.6728$$

the fixed-sample information ratio is $67.1268/65.6728 = 1.022$. That is, the maximum information for the O'Brien-Fleming design is only 2.2% more than for the corresponding fixed-sample design.

The "Method Information" table in Output 77.3.10 displays the Type I α level and Type II β level. It also displays the derived drift parameter $\theta_1\sqrt{I_X}$, which is the standardized alternative reference at the final stage.

Output 77.3.10 Method Information

Method Information

				Unified Family		
Boundary	Method	Alpha	Beta	Rho	Tau	C
Upper Alpha	O'Brien-Fleming	0.02500	0.10000	0.5	0	2.02429
Lower Alpha	O'Brien-Fleming	0.02500	0.10000	0.5	0	2.02429

Method Information

Boundary	Alternative Reference	Drift
Upper Alpha	0.4	3.277238
Lower Alpha	-0.4	-3.27724

With the METHOD=OBF option, the O'Brien-Fleming method is used for each boundary. The O'Brien-Fleming method is one of the unified family methods, and the table also displays its corresponding parameters $\rho = 0.5$ as a unified family method and the derived parameter $C = 2.0243$ for the boundary values.

With the PSS option, the "Power and Expected Sample Sizes" table in Output 77.3.11 displays powers and expected sample sizes under various hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option.

Output 77.3.11 Power and Expected Sample Size Information

Powers and Expected Sample Sizes
Reference = CRef * (Alt Reference)

CRef	Power	-Sample Size- Percent Fixed-Sample
0.0000	0.02500	101.5728
0.5000	0.36495	96.3684
1.0000	0.90000	76.7397
1.5000	0.99821	57.2590

Compared with the corresponding Pocock design, the O'Brien-Fleming design has a smaller maximum sample size, and smaller expected sample sizes under hypothetical references $\theta = 0$ and $\theta = 0.5\,\theta_1$, but larger expected sample sizes under hypothetical references $\theta = \theta_1$ and $\theta = 1.5\,\theta_1$.

With the STOPPROB option, the "Expected Cumulative Stopping Probabilities" table in Output 77.3.12 displays the expected stopping stage and cumulative stopping probability to reject the null hypothesis at each stage under various hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option.

Output 77.3.12 Stopping Probabilities

Expected Cumulative Stopping Probabilities
Reference = CRef * (Alt Reference)

CRef	Expected Stopping Stage	Source	--------Stopping Probabilities------- Stage_1	Stage_2	Stage_3	Stage_4
0.0000	3.975	Reject Null	0.00005	0.00422	0.02091	0.05000
0.5000	3.771	Reject Null	0.00062	0.04430	0.18392	0.36515
1.0000	3.003	Reject Null	0.00798	0.29296	0.69603	0.90000
1.5000	2.241	Reject Null	0.05584	0.73031	0.97315	0.99821

Compared with the corresponding Pocock design, the O'Brien-Fleming design has smaller stopping probabilities in early stages under each hypothetical reference.

The "Boundary Information" table in Output 77.3.13 displays the boundary values for the design that uses the O'Brien-Fleming method. Compared with the Pocock method, the standardized statistics α boundary values derived from the O'Brien-Fleming method in absolute values are larger in

early stages and smaller in later stages. This makes the O'Brien-Fleming design less likely to reject the null hypothesis in early stages than the Pocock design. With the derived parameter $C = 2.0243$ for the α boundary, the α boundaries at stage j are computed as $C\sqrt{4/j}$, $j = 1, \ldots, 4$.

Output 77.3.13 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0

	Information Level			Alternative Reference	
Stage	Proportion	Actual	N	Lower	Upper
1	0.2500	16.7817	48.33131	-1.63862	1.63862
2	0.5000	33.56341	96.66262	-2.31736	2.31736
3	0.7500	50.34511	144.9939	-2.83817	2.83817
4	1.0000	67.12682	193.3252	-3.27724	3.27724

Boundary Information (Standardized Z Scale)
Null Reference = 0

	Boundary Values	
	Lower	Upper
Stage	Alpha	Alpha
1	-4.04859	4.04859
2	-2.86278	2.86278
3	-2.33745	2.33745
4	-2.02429	2.02429

The "Error Spending Information" in Output 77.3.14 displays cumulative error spending at each stage for each boundary. With smaller α spending in early stages for the O'Brien-Fleming method, it also indicates that the O'Brien-Fleming design is less likely to reject the null hypothesis in early stages than the Pocock design.

Output 77.3.14 Error Spending Information

Error Spending Information

	Information Level	Cumulative Error Spending			
		Lower		Upper	
Stage	Proportion	Alpha	Beta	Beta	Alpha
1	0.2500	0.00003	0.00000	0.00000	0.00003
2	0.5000	0.00211	0.00000	0.00000	0.00211
3	0.7500	0.01046	0.00000	0.00000	0.01046
4	1.0000	0.02500	0.10000	0.10000	0.02500

The "Sample Size Summary" table in Output 77.3.15 displays the specified parameters for the sample size computation of the two-sample test for mean difference.

Output 77.3.15 Sample Size Summary

Sample Size Summary

Test	Two-Sample Means
Mean Difference	0.4
Standard Deviation	0.8
Max Sample Size	193.3252
Expected Sample Size (Null Ref)	192.1081
Expected Sample Size (Alt Ref)	145.1404
Weight (Group A)	2
Weight (Group B)	1

The "Sample Sizes (N)" table in Output 77.3.16 displays the derived sample sizes at each stage, in both fractional and integer numbers. With the fixed-sample information ratio 1.0222, the required sample sizes in fractional numbers are derived by multiplying 1.0222 by the corresponding sample sizes in the fixed-sample design.

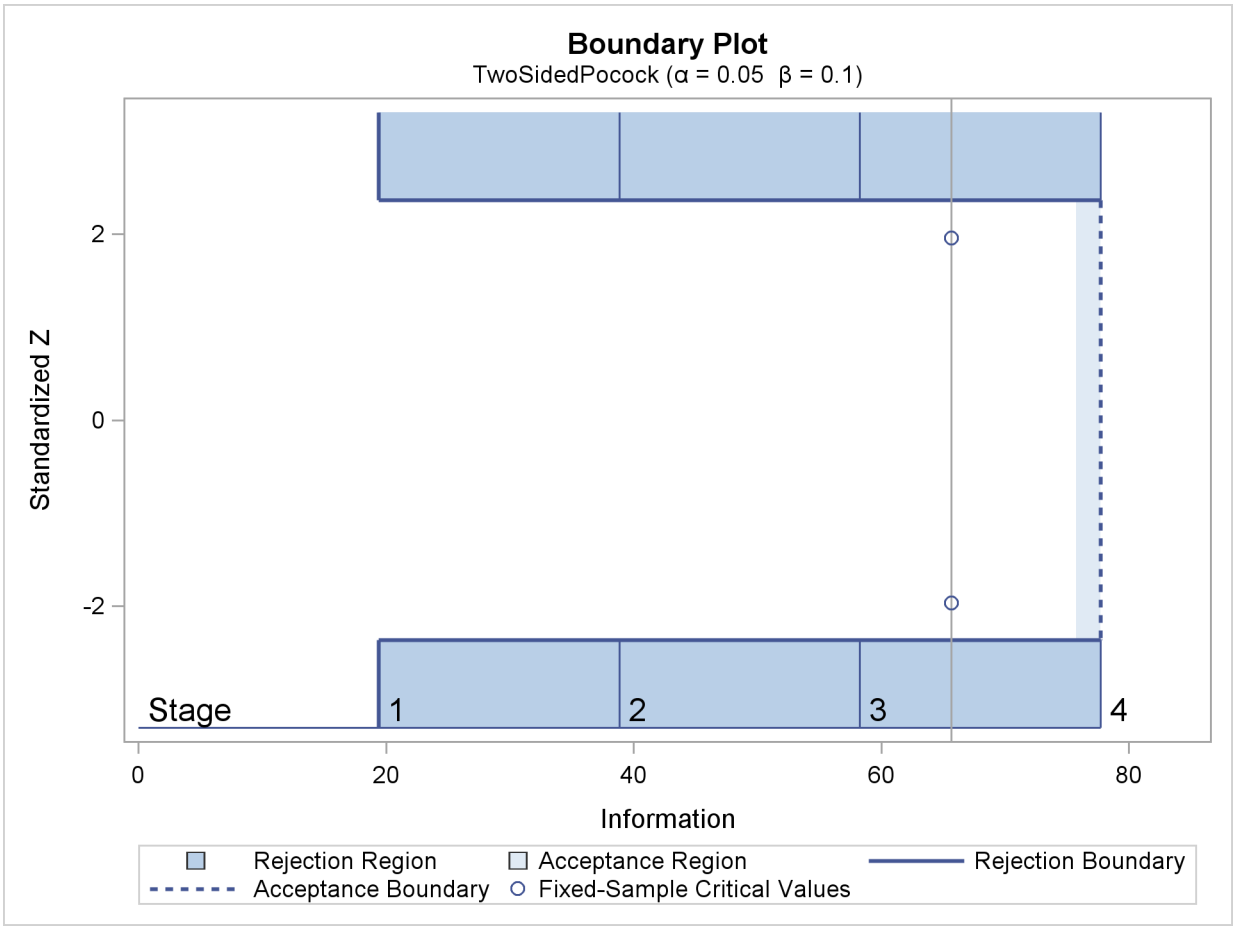
Output 77.3.16 Derived Sample Sizes

Sample Sizes (N)
Two-Sample Z Test for Mean Difference

	Fractional N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	48.33	32.22	16.11	16.7817
2	96.66	64.44	32.22	33.5634
3	144.99	96.66	48.33	50.3451
4	193.33	128.88	64.44	67.1268

Sample Sizes (N)
Two-Sample Z Test for Mean Difference

	Ceiling N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	50	33	17	17.5313
2	98	65	33	34.1996
3	146	97	49	50.8669
4	194	129	65	67.5338

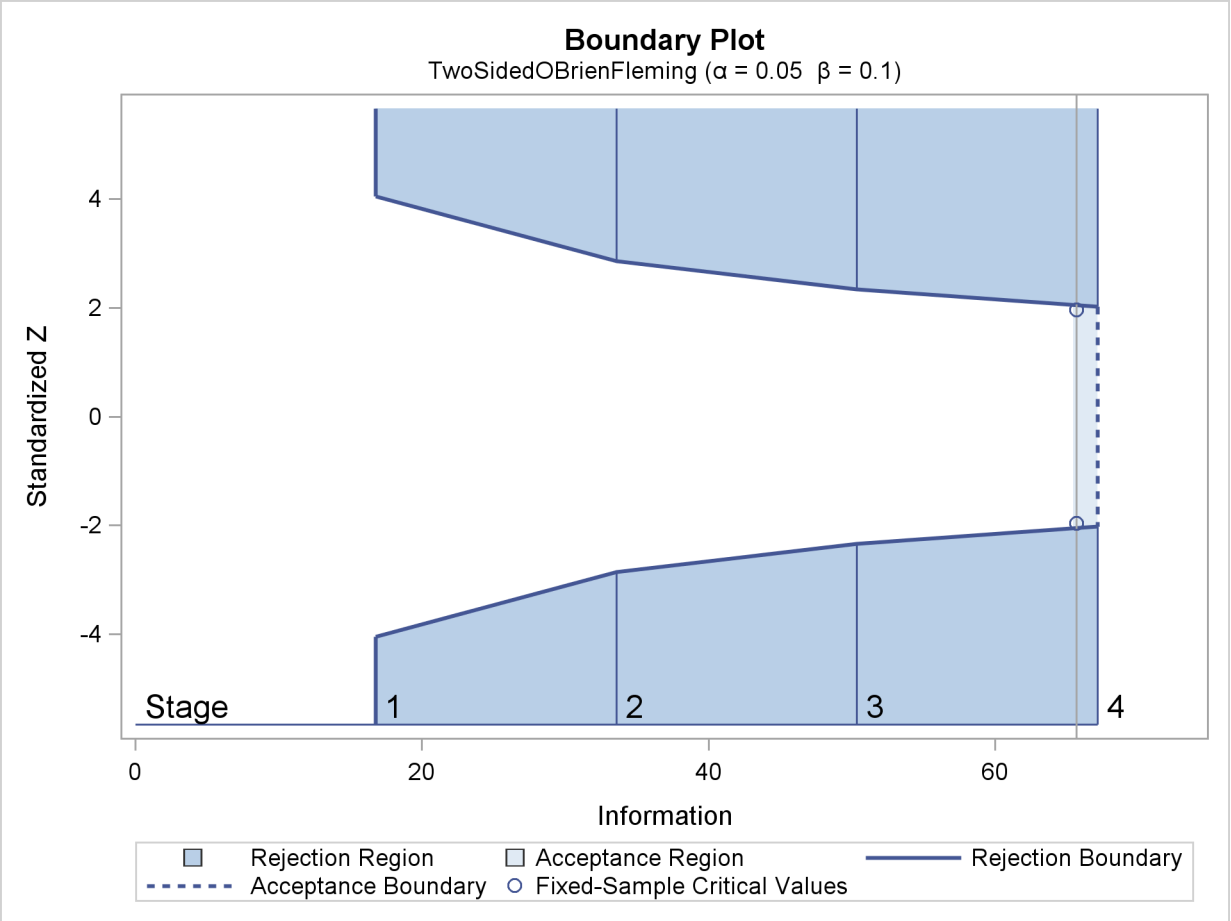


Example 77.4: Generating Graphics Display for Sequential Designs

This example creates the same group sequential design as in Example 77.3 and creates graphics by using ODS Graphics. The following statements request all available graphs in the SEQDESIGN procedure:

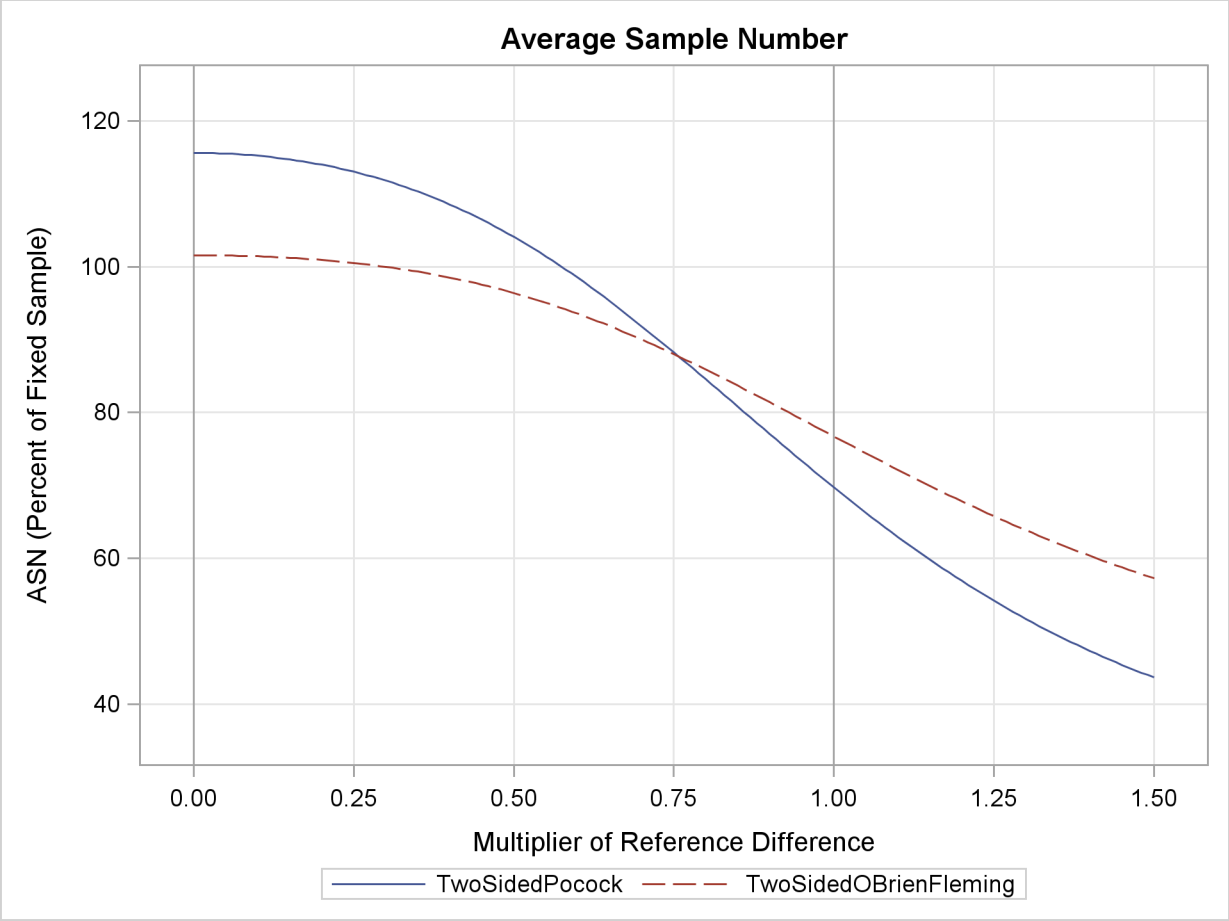
```
ods graphics on;
proc seqdesign altref=0.4
               plots=all
               ;
   TwoSidedPocock:         design nstages=4 method=poc;
   TwoSidedOBrienFleming: design nstages=4 method=obf;
run;
ods graphics off;
```

With the PLOTS=ALL option, a detailed boundary plot with the rejection region and acceptance region is displayed for the Pocock design, as shown in Output 77.4.1. With the default STOP=REJECT option, the rejection boundaries are also generated at interim stages.



Output 77.4.1 Pocock Boundary Plot

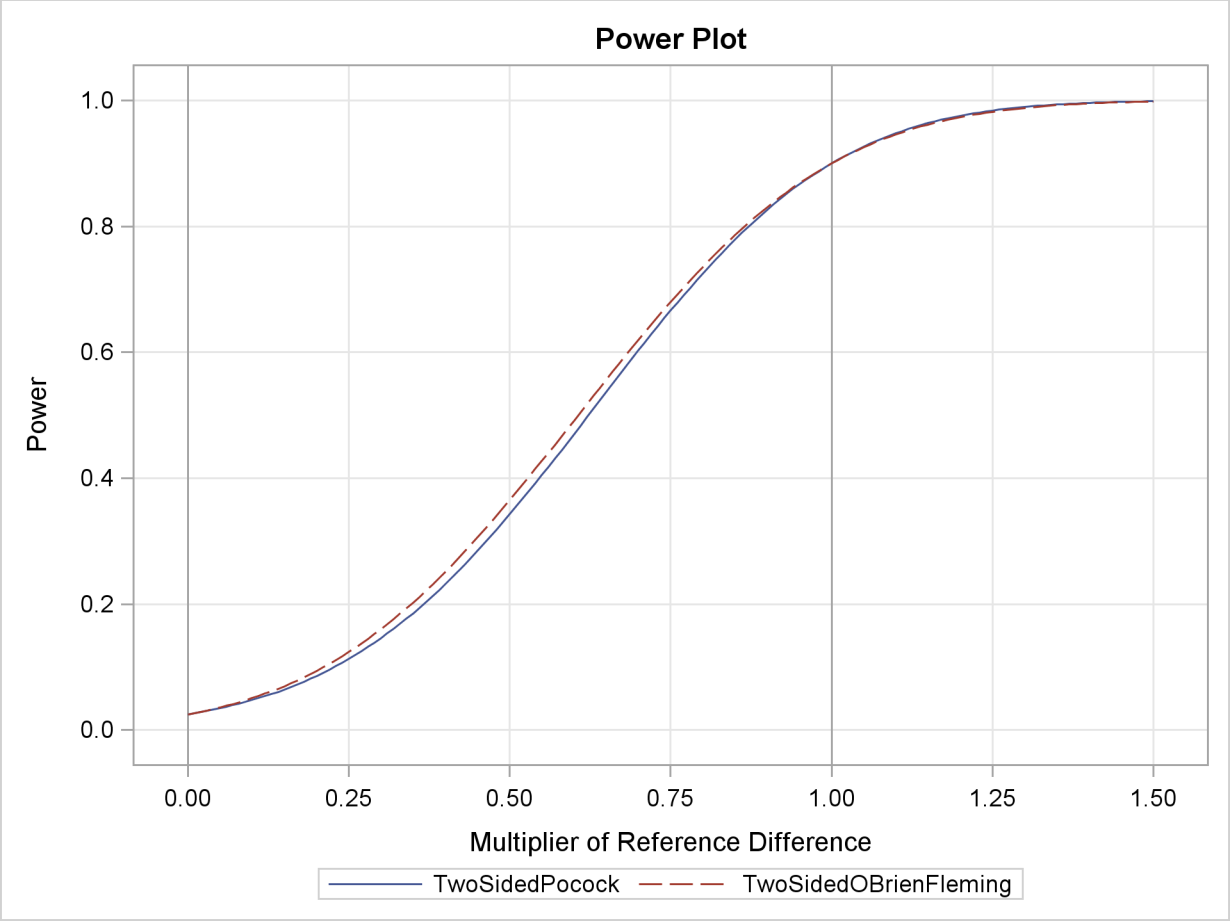
The plot shows identical boundary values in each boundary in the standardized Z scale for the Pocock design. The information level and critical value for the corresponding fixed-sample design are also displayed.



With the PLOTS=ALL option, a detailed boundary plot with the rejection region and acceptance region is also displayed for the O'Brien-Fleming design, as shown in Output 77.4.2. The plot shows that the rejection boundary values are decreasing as the trial advances in the standardized Z scale.

Output 77.4.2 O'Brien-Fleming Boundary Plot

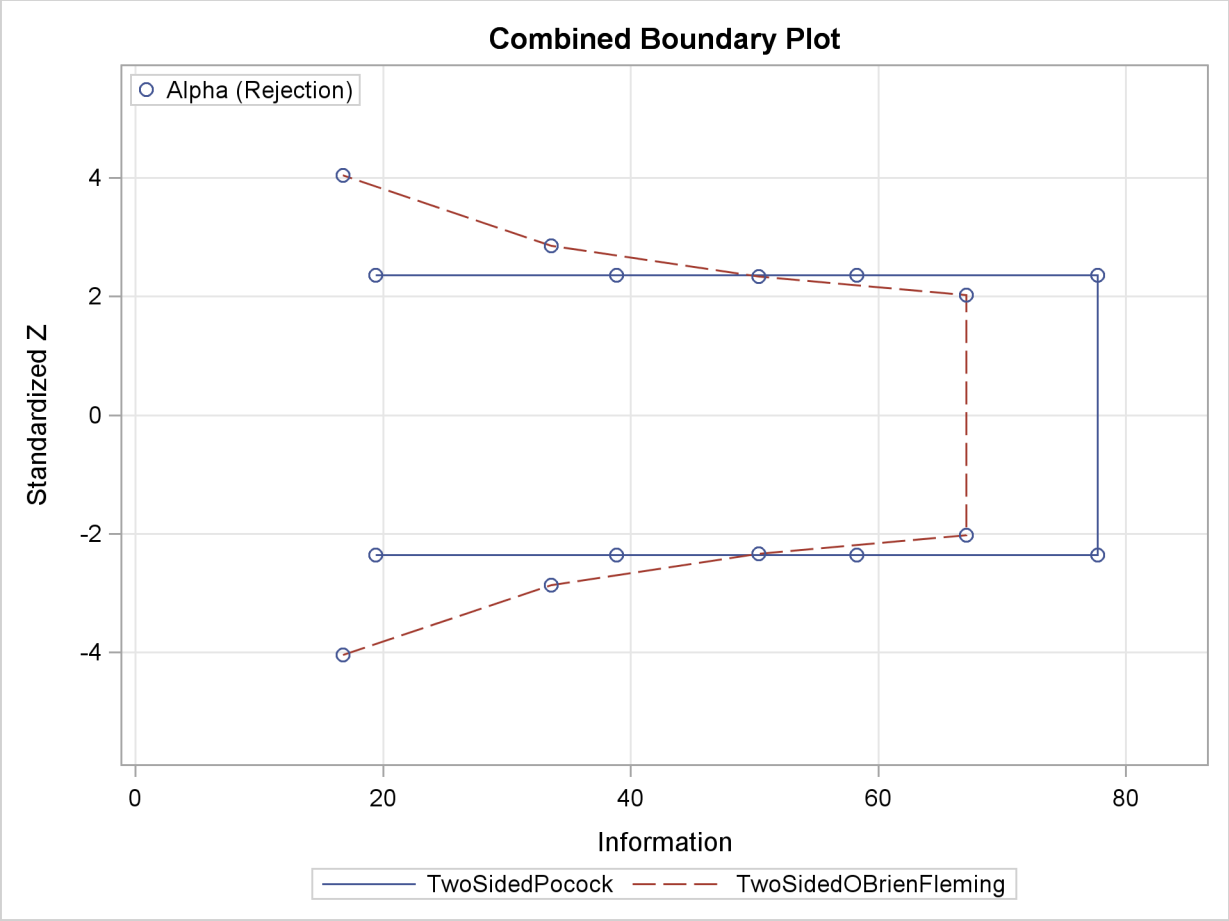
With the PLOTS=ALL option, the procedure displays a plot of average sample numbers (expected sample sizes for nonsurvival data or expected numbers of events for survival data) under various hypothetical references for all designs simultaneously, as shown in Output 77.4.3. By default, the option CREF= $0, 0.01, 0.02, \ldots, 1.50$ and expected sample sizes under the hypothetical references $\theta = c_i\,\theta_1$ are displayed, where c_i are values specified in the CREF= option. These CREF= values are displayed on the horizontal axis.



Output 77.4.3 ASN Plot

The plot shows that the Pocock design has a larger expected sample size than the O'Brien-Fleming design under the null hypothesis ($c_i = 0$) and has a smaller expected sample size under the alternative hypothesis ($c_i = 1$).

With the PLOTS=ALL option, the procedure displays a plot of the power curves under various hypothetical references for all designs simultaneously, as shown in Output 77.4.4. By default, the option CREF= $0, 0.01, 0.02, \ldots, 1.50$ and powers under hypothetical references $\theta = c_i\,\theta_1$ are displayed, where c_i are values specified in the CREF= option. These CREF= values are displayed on the horizontal axis.



Output 77.4.4 Power Plot

Under the null hypothesis, $c_i = 0$, the power is 0.025, the upper Type I error probability. Under the alternative hypothesis, $c_i = 1$, the power is 0.9, one minus the Type II error probability. The plot shows only minor difference between the two designs.

With the PLOTS=ALL option, the procedure displays a plot of sequential boundaries for all designs simultaneously, as shown in Output 77.4.5. By default, the information levels are used on the horizontal axis.

Output 77.4.5 Combined Boundary Plot

The plot shows that the α boundary values (in absolute value) created from the O'Brien-Fleming method are greater in early stages and smaller in later stages than the boundary values from the Pocock method. The plot also shows that the information level in the Pocock design is larger than the corresponding level in the O'Brien-Fleming design at each stage.

With the PLOTS=ALL option, the procedure displays a plot of cumulative error spends for all boundaries in the designs simultaneously, as shown in Output 77.4.6. With a symmetric two-sided design, cumulative error spending is displayed only for the upper α boundary. The plot shows that for the upper α boundary, the O'Brien-Fleming method spends fewer errors in early stages and more errors in later stages than the corresponding Pocock method.

Output 77.4.6 Error Spending Plot

Example 77.5: Creating Designs Using Haybittle-Peto Methods

This example requests two 3-stage group sequential designs for normally distributed statistics. Each design uses a Haybittle-Peto method with a two-sided alternative and early stopping to reject the hypothesis. One design uses the specified interim boundary Z values and derives the final-stage boundary value for the specified α and β errors. The other design uses the specified boundary Z values and derives the overall α and β errors.

The following statements specify the interim boundary Z values and derive the final-stage boundary value for the specified $\alpha = 0.05$ and $\beta = 0.10$:

```
ods graphics on;
proc seqdesign altref=0.25
               errspend
               stopprob
               plots=errspend
               ;
   OneSidedPeto: design nstages=3
                 method=peto( z=3)
```

```
                    alt=upper   stop=reject
                    alpha=0.05  beta=0.10;
run;
ods graphics off;
```

The "Design Information" table in Output 77.5.1 displays design specifications and maximum information in percentage of its corresponding fixed-sample design.

Output 77.5.1 Haybittle-Peto Design Information

The SEQDESIGN Procedure
Design: OneSidedPeto

Design Information

Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Reject Null
Method	Haybittle-Peto
Boundary Key	Both
Alternative Reference	0.25
Number of Stages	3
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	100.2466
Max Information	137.3592
Null Ref ASN (Percent of Fixed Sample)	100.1192
Alt Ref ASN (Percent of Fixed Sample)	87.35

The "Method Information" table in Output 77.5.2 displays the α and β errors and the derived drift parameter, which is the standardized alternative reference at the final stage.

Output 77.5.2 Method Information

Method Information

Boundary	Method	Alpha	Beta	Alternative Reference	Drift
Upper Alpha	Haybittle-Peto	0.05000	0.10000	0.25	2.930009

With the STOPPROB option, the "Expected Cumulative Stopping Probabilities" table in Output 77.5.3 displays the expected stopping stage and cumulative stopping probability to reject the null hypothesis at each stage under various hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ are the default values in the CREF= option.

Output 77.5.3 Stopping Probabilities

Expected Cumulative Stopping Probabilities
Reference = CRef * (Alt Reference)

CRef	Expected Stopping Stage	Source	----Stopping Probabilities--- Stage_1	Stage_2	Stage_3
0.0000	2.996	Reject Null	0.00135	0.00246	0.05000
0.5000	2.941	Reject Null	0.01561	0.04372	0.42762
1.0000	2.614	Reject Null	0.09538	0.29057	0.90000
1.5000	1.944	Reject Null	0.32185	0.73442	0.99698

The "Boundary Information" table in Output 77.5.4 displays information level, alternative references, and boundary values. The default BOUNDARYSCALE=STDZ option specifies that the standardized Z scale be used to display the alternative references and boundary values. The resulting standardized alternative reference at stage k is given by $\theta_1\sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information level at stage k, $k = 1, 2, 3$.

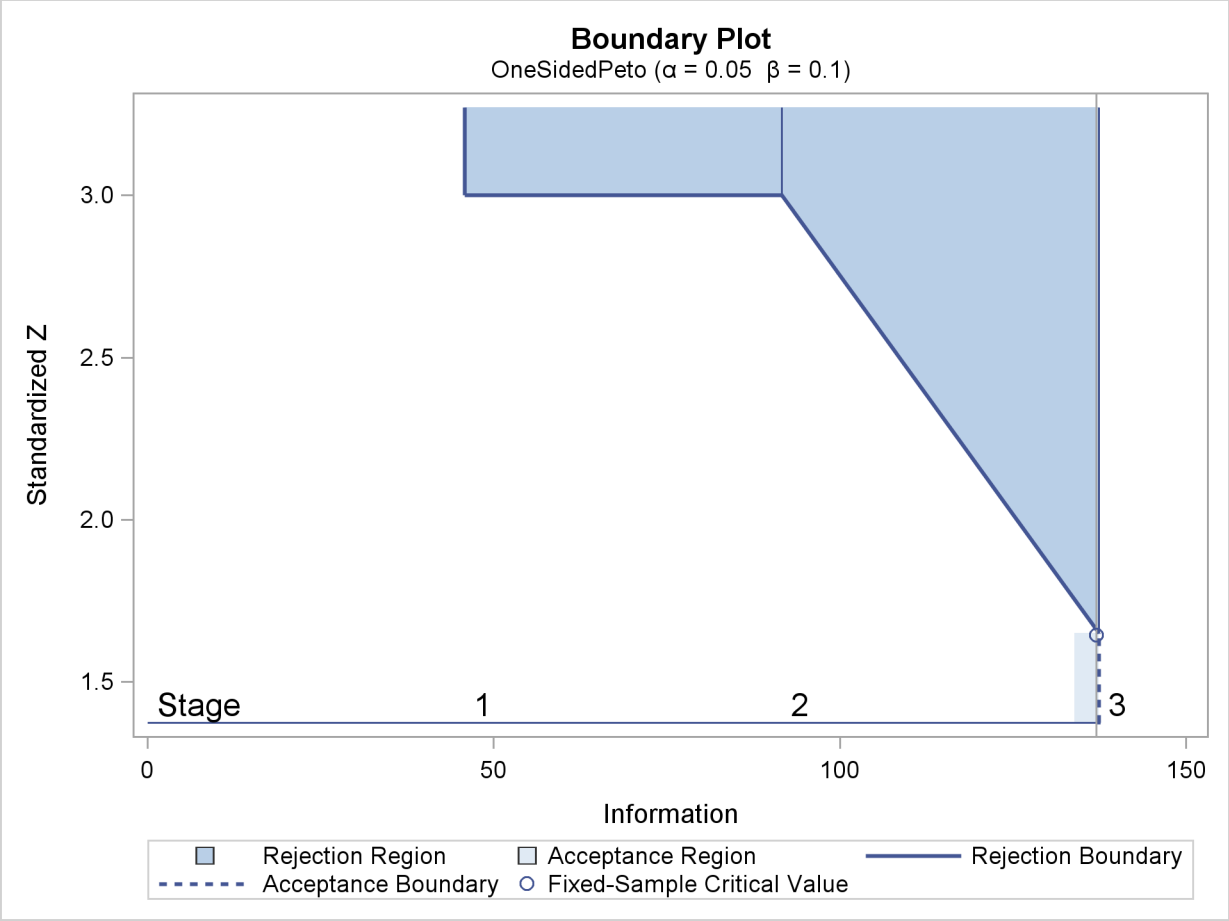
Output 77.5.4 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0

Stage	---Information Level-- Proportion	Actual	-Alternative- --Reference-- Upper	-Boundary Values- ------Upper------ Alpha
1	0.3333	45.7864	1.69164	3.00000
2	0.6667	91.57281	2.39234	3.00000
3	1.0000	137.3592	2.93001	1.65042

At each interim stage, if the standardized statistic $z \geq 3$, the trial is stopped and the null hypothesis is rejected. If the statistic $z < 3$, the trial continues to the next stage. At the final stage, the null hypothesis is rejected if the statistic $z_3 > 1.65$. Otherwise, the hypothesis is accepted. Note that the boundary values at the final stage, 1.65, are close to the critical values 1.645 in the corresponding fixed-sample design.

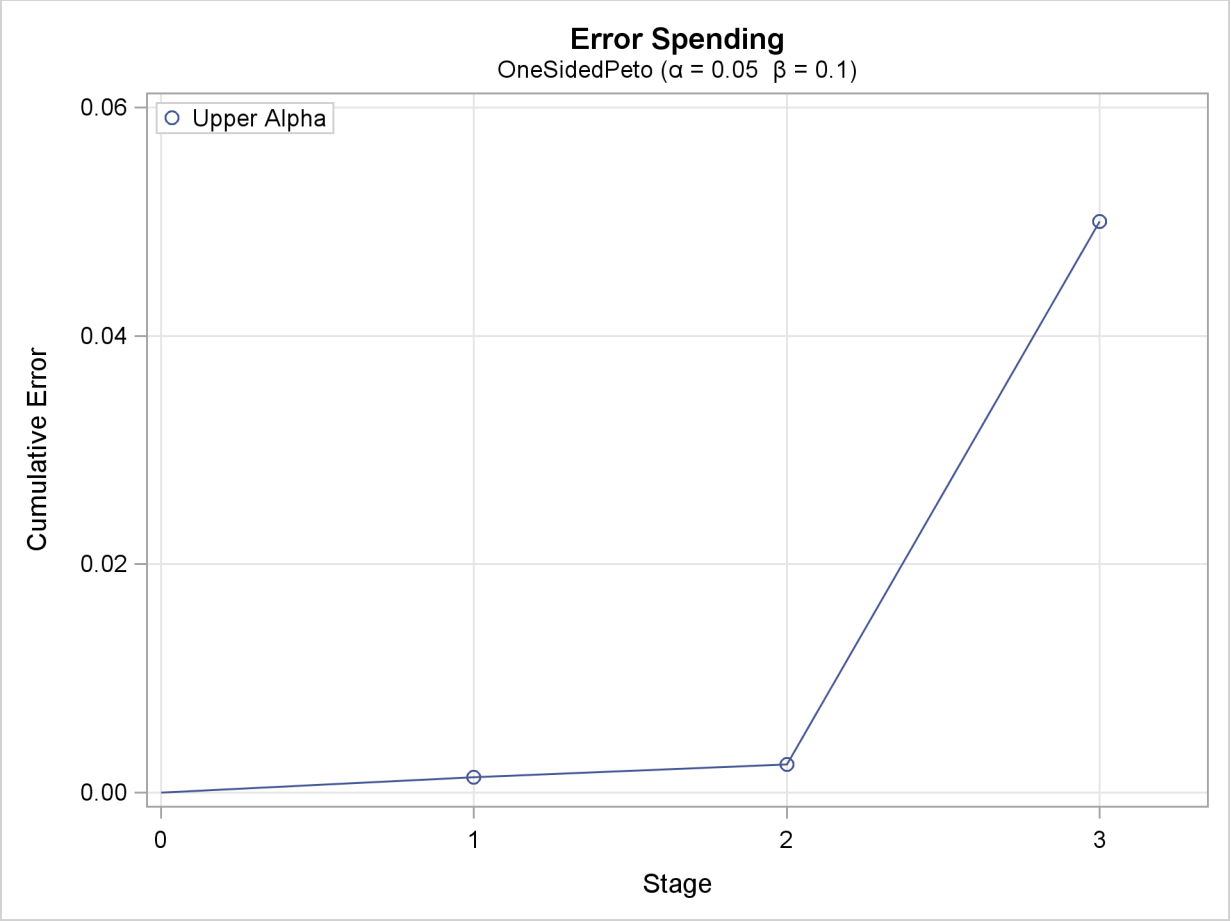
The "Error Spending Information" in Output 77.5.5 displays cumulative error spending at each stage for each boundary. The stage 1 α spending 0.00135 corresponds to the one-sided p-value for a standardized Z statistic, $Z > 3$.



Output 77.5.5 Error Spending Information

Error Spending Information

Stage	-Information Level- Proportion	-Cumulative Error Spending- -----Upper----- Beta	Alpha
1	0.3333	0.00000	0.00135
2	0.6667	0.00000	0.00246
3	1.0000	0.10000	0.05000



With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 77.5.6. With the STOP=REJECT option, the interim rejection boundaries are displayed.

Output 77.5.6 Boundary Plot

With the PLOTS=ERRSPEND option, the procedure displays a plot of error spending for each boundary, as shown in Output 77.5.7. The error spending values in the "Error Spending Information" in Output 77.5.4 are displayed in the plot. As expected, the error spending at each of the first two stages is small, with the standardized Z boundary value 3.

Output 77.5.7 Error Spending Plot

The following statements specify the boundary Z values and derive the α and β errors from these completely specified boundary values:

```
ods graphics on;
proc seqdesign altref=0.25
               maxinfo=200
               errspend
               stopprob
               plots=errspend
               ;
   OneSidedPeto: design nstages=3
                 method=peto(z=3 2.5 2)
                 alt=upper  stop=reject
                 boundarykey=none
                 ;
run;
ods graphics off;
```

The "Design Information" table in Output 77.5.8 displays design specifications and derived α and β error levels.

Output 77.5.8 Design Information

The SEQDESIGN Procedure
Design: OneSidedPeto

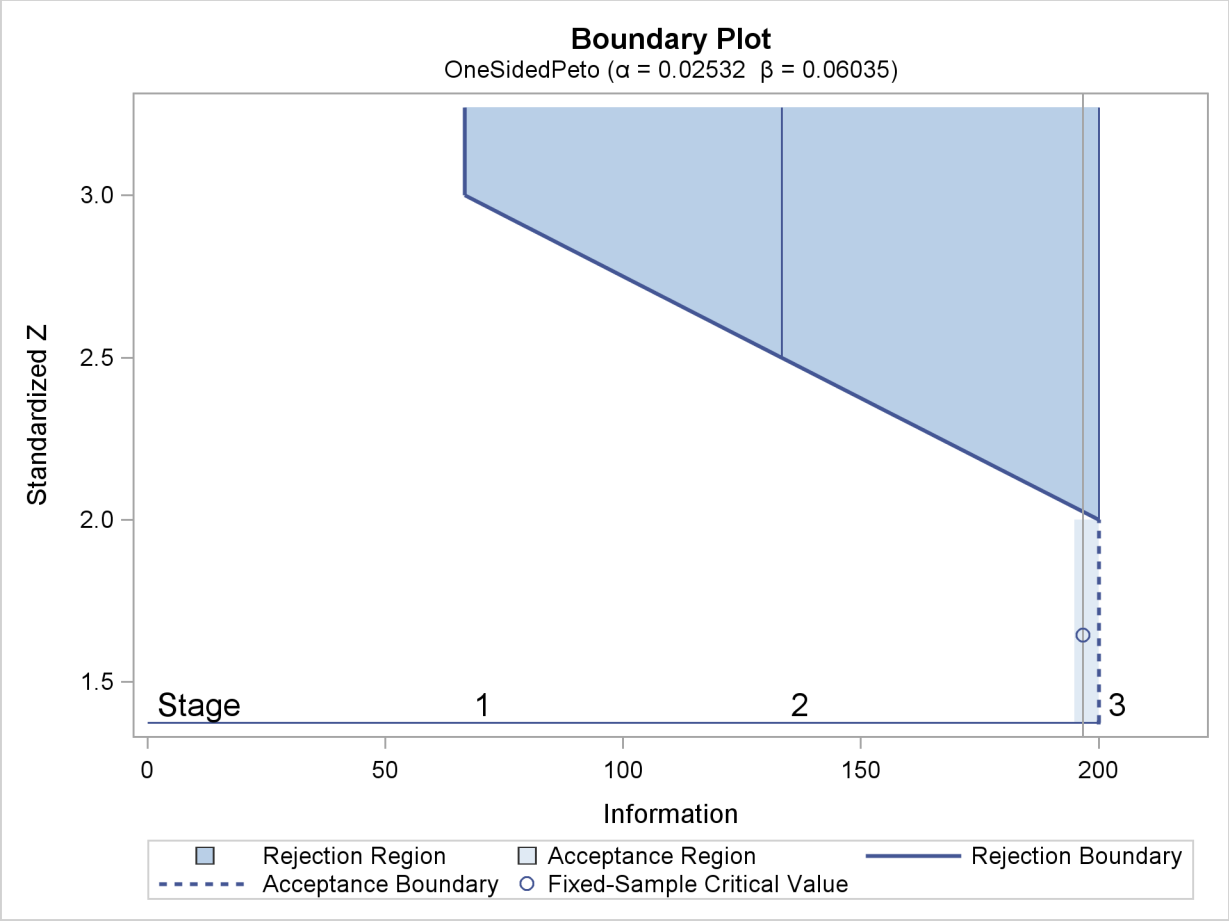
The "Boundary Information" table in Output 77.5.11 displays information level, alternative references, and boundary values.

Output 77.5.11 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0

Stage	Information Level Proportion	Information Level Actual	Alternative Reference Upper	Boundary Values Upper Alpha
1	0.3333	66.66667	2.04124	3.00000
2	0.6667	133.3333	2.88675	2.50000
3	1.0000	200	3.53553	2.00000

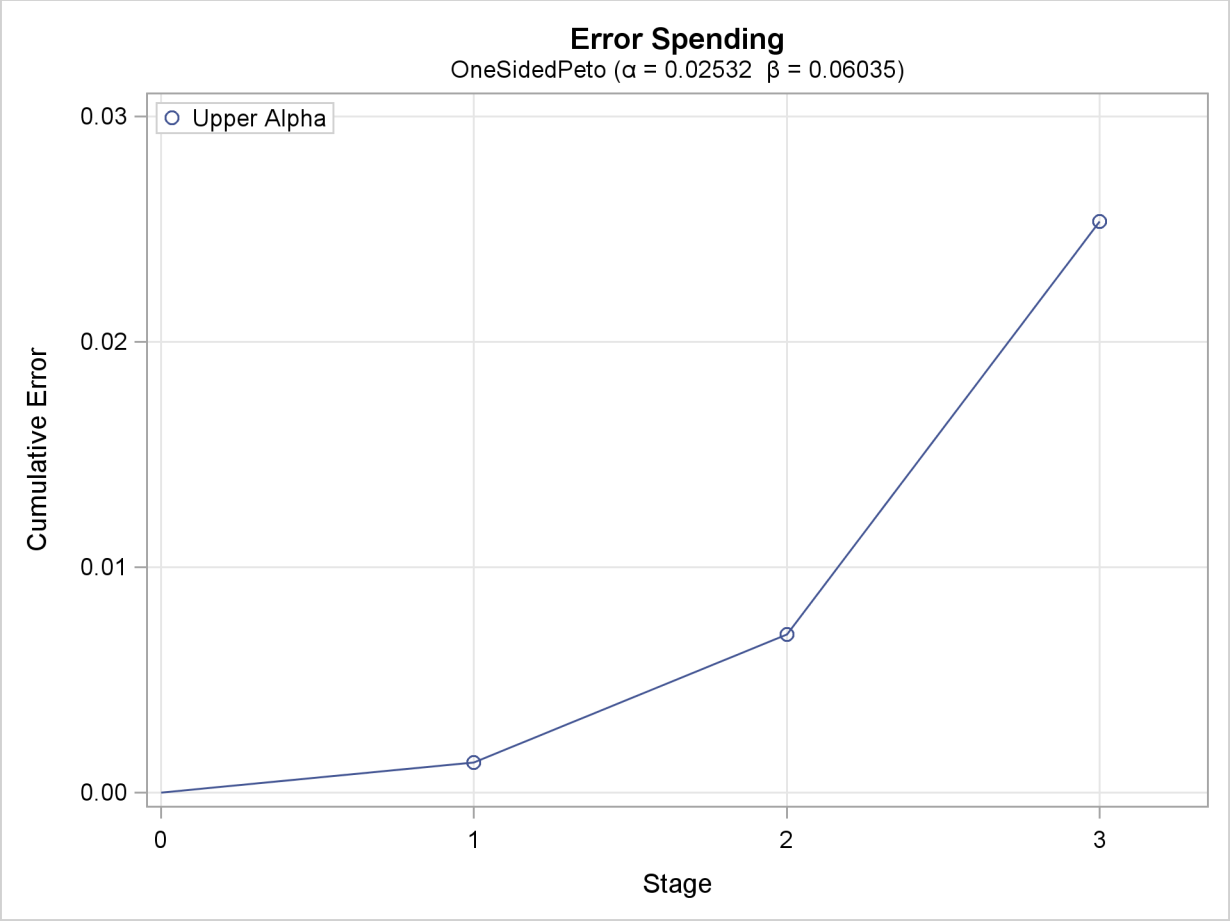
The "Error Spending Information" in Output 77.5.12 displays cumulative error spending at each stage for each boundary. The first-stage α spending 0.00135 corresponds to the one-sided p-value for a standardized Z statistic, $Z > 3$.



Output 77.5.12 Error Spending Information

Error Spending Information

Stage	Information Level Proportion	Cumulative Error Spending Upper Beta	Cumulative Error Spending Upper Alpha
1	0.3333	0.00000	0.00135
2	0.6667	0.00000	0.00702
3	1.0000	0.06035	0.02532



With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 77.5.13. With the STOP=REJECT option, the interim rejection boundaries are displayed.

Output 77.5.13 Boundary Plot

With the PLOTS=ERRSPEND option, the procedure displays a plot of error spending for each boundary, as shown in Output 77.5.14. The error spending values in the "Error Spending Information" table in Output 77.5.10 are displayed in the plot.

Output 77.5.14 Error Spending Plot

Example 77.6: Creating Designs with Various Stopping Criteria

This example requests three 5-stage group sequential designs for normally distributed statistics. Each design uses a triangular method with the specified one-sided upper alternative reference $\theta_1 = 0.2$. The resulting boundary values are displayed with the score scale. Note that these unified family triangular designs are different from Whitehead's triangular designs.

The following statements request three designs with different stopping criterion:

```
ods graphics on;
proc seqdesign altref=0.2
               bscale=score
               errspend
               plots=(combinedboundary errspend(hscale=info))
               ;
   StopToRejectAccept: design nstages=5 method=tri alt=upper stop=both;
   StopToReject:       design nstages=5 method=tri alt=upper stop=reject;
   StopToAccept:       design nstages=5 method=tri alt=upper stop=accept;
run;
ods graphics off;
```

The first design has early stopping to reject or accept the null hypothesis H_0.

The "Design Information" table in Output 77.6.1 displays design specifications and derived statistics. With the specified alternative reference, the maximum information is derived.

Output 77.6.1 Triangular Design Information

The SEQDESIGN Procedure
Design: StopToRejectAccept

Design Information

Statistic Distribution	Normal
Boundary Scale	Score
Alternative Hypothesis	Upper

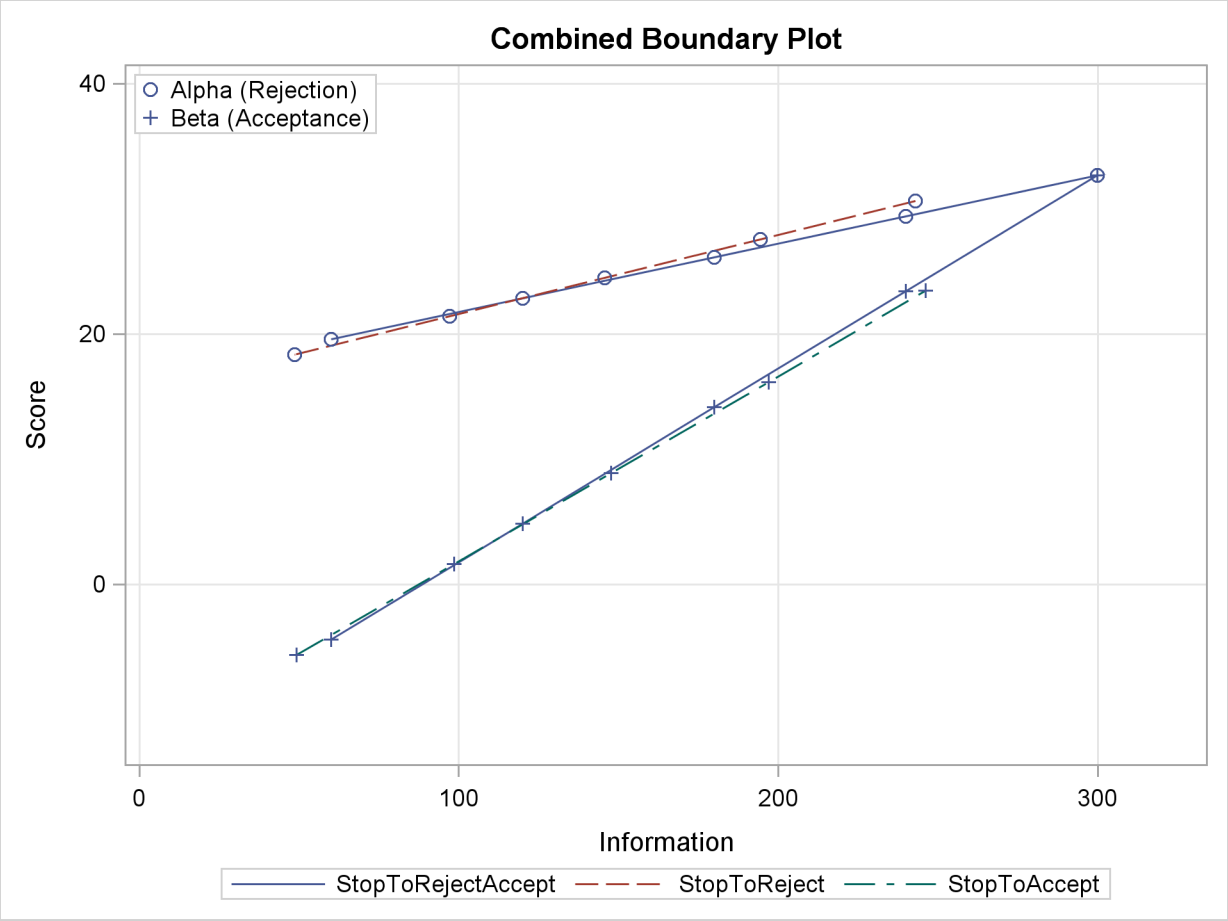
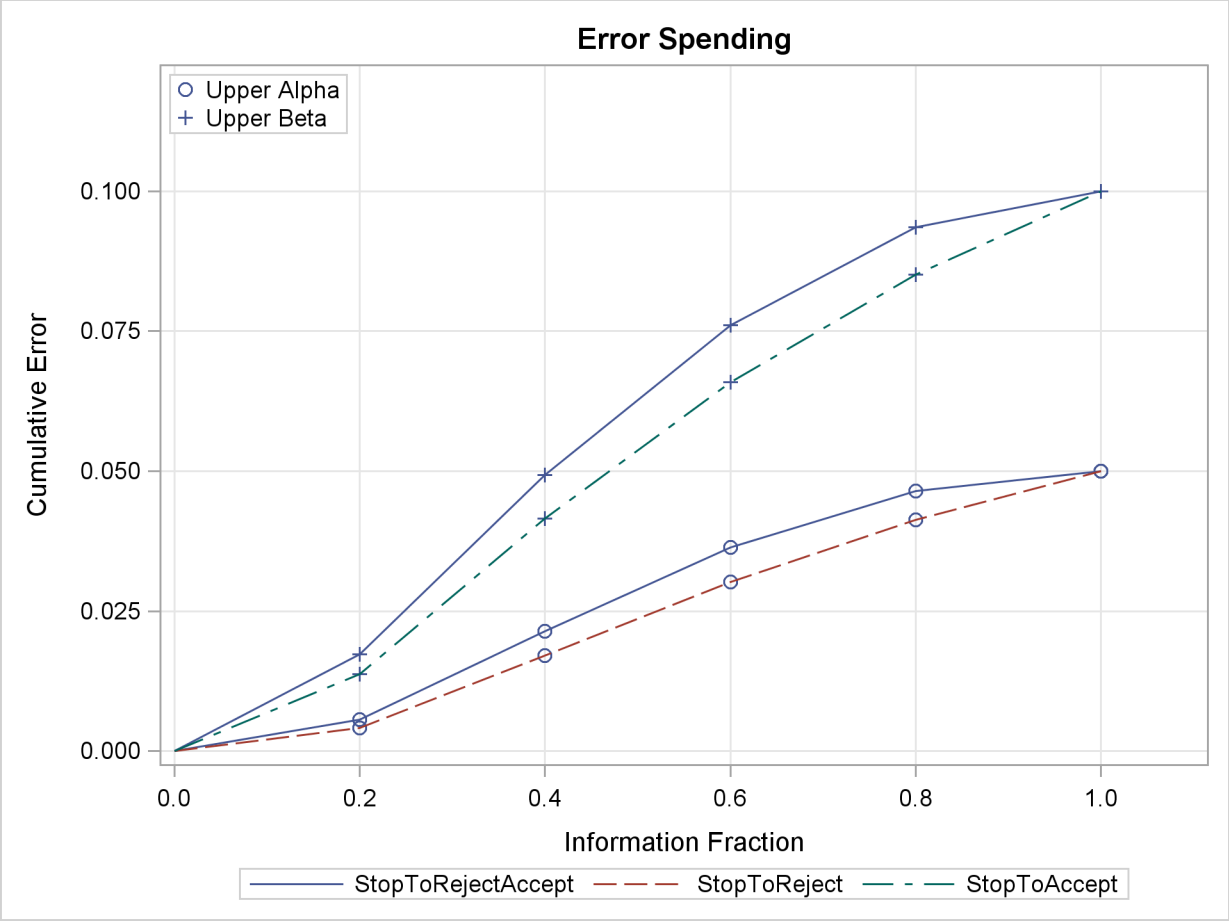
4	0.8000	0.08513	0.00000
5	1.0000	0.10000	0.05000



With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 77.6.15. For a triangular design, these rejection boundaries form a straight line with the score scale.

Output 77.6.15 Boundary Plot with Score Scale



With the PLOTS=COMBINEDBOUNDARY option, a plot of the resulting sequential boundaries for all designs is displayed, as shown in Output 77.6.16. The plot shows that the design with early stopping to reject and to accept H_0 has larger maximum information than the other two designs.

Output 77.6.16 Combined Boundary Plot with Score Scale

With the PLOTS=ERRSPEND(HSCALE=INFO) option, the error spending plot is displayed with the information level on the horizontal axis, as shown in Output 77.6.17. The design with early stopping to reject or accept the null hypothesis H_0 has larger α spending and larger β spending in early stages than the other two designs.

Output 77.6.17 Error Spending Plot

Example 77.7: Creating Whitehead's Triangular Designs

This example requests three 4-stage Whitehead's triangular designs for normally distributed statistics. Each design has a one-sided alternative hypothesis with early stopping to reject or accept the null hypothesis H_0. Note that Whitehead's triangular designs are different from unified family triangular designs.

Suppose that a clinic is conducting a study of the effect of a new cancer treatment. The study consists of exposing mice to a carcinogen and randomly assigning them to either the control group or the treatment group. The event of interest is death from cancer induced by the carcinogen, and the response is the time from randomization to death.

Following the derivations in the section "Test for Two Survival Distributions with a Log-Rank Test" on page 5866, the hypothesis $H_0 : \theta = -\log(\lambda) = 0$ with an alternative hypothesis $H_1 : \theta = \theta_1 > 0$ is used, where λ is the hazard ratio between the treatment group and the control group.

Also suppose that from past experience, the median survival time for the control group is $t_0 = 20$ days, and the study wants to detect a $t_1 = 40$ days' median survival time with a 80% power in the trial. Assuming exponential survival functions for the two groups, the hazard rates can be computed

from

$$S_j(t_j) = e^{-h_j t_j} = \frac{1}{2}$$

where $j = 0, 1$.

Thus, with $h_0 = 0.0346574$ and $h_1 = 0.0173287$, the hazard ratio $\lambda_1 = h_1/h_0 = 1/2$, and the alternative reference is

$$\theta_1 = -\log(\lambda_1) = -\log(\frac{1}{2}) = 0.693147$$

The following statements invoke the SEQDESIGN procedure and specify three Whitehead's triangular designs:

```
ods graphics on;
proc seqdesign altref=0.693147
               bscale=score
               plots=combinedboundary
               ;
   BoundaryKeyNone:  design nstages=4
                            method=whitehead
                            boundarykey=none
                            alt=upper   stop=both
                            alpha=0.05  beta=0.20
                            ;
   BoundaryKeyAlpha: design nstages=4
                            method=whitehead
                            boundarykey=alpha
                            alt=upper   stop=both
                            alpha=0.05  beta=0.20
                            ;
   BoundaryKeyBeta:  design nstages=4
                            method=whitehead
                            boundarykey=beta
                            alt=upper   stop=both
                            alpha=0.05  beta=0.20
                            ;
run;
ods graphics off;
```

Whitehead methods with early stopping to reject or accept the null hypothesis create boundaries that approximately satisfy the Type I and Type II error probability specification. The BOUNDARYKEY=NONE option specifies no adjustment to the boundary value at the final stage to maintain either a Type I or a Type II error probability level.

The "Design Information" table in Output 77.7.1 displays design specifications and maximum information. Note that with the BOUNDARYKEY=NONE option, the derived errors $\alpha = 0.05071$ and $\beta = 0.19771$ are not the same as the specified errors $\alpha = 0.05$ and $\beta = 0.20$.

Output 77.7.1 Whitehead Design Information

The SEQDESIGN Procedure
Design: BoundaryKeyNone

Design Information

Statistic Distribution	Normal
Boundary Scale	Score
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Method	Whitehead
Boundary Key	None

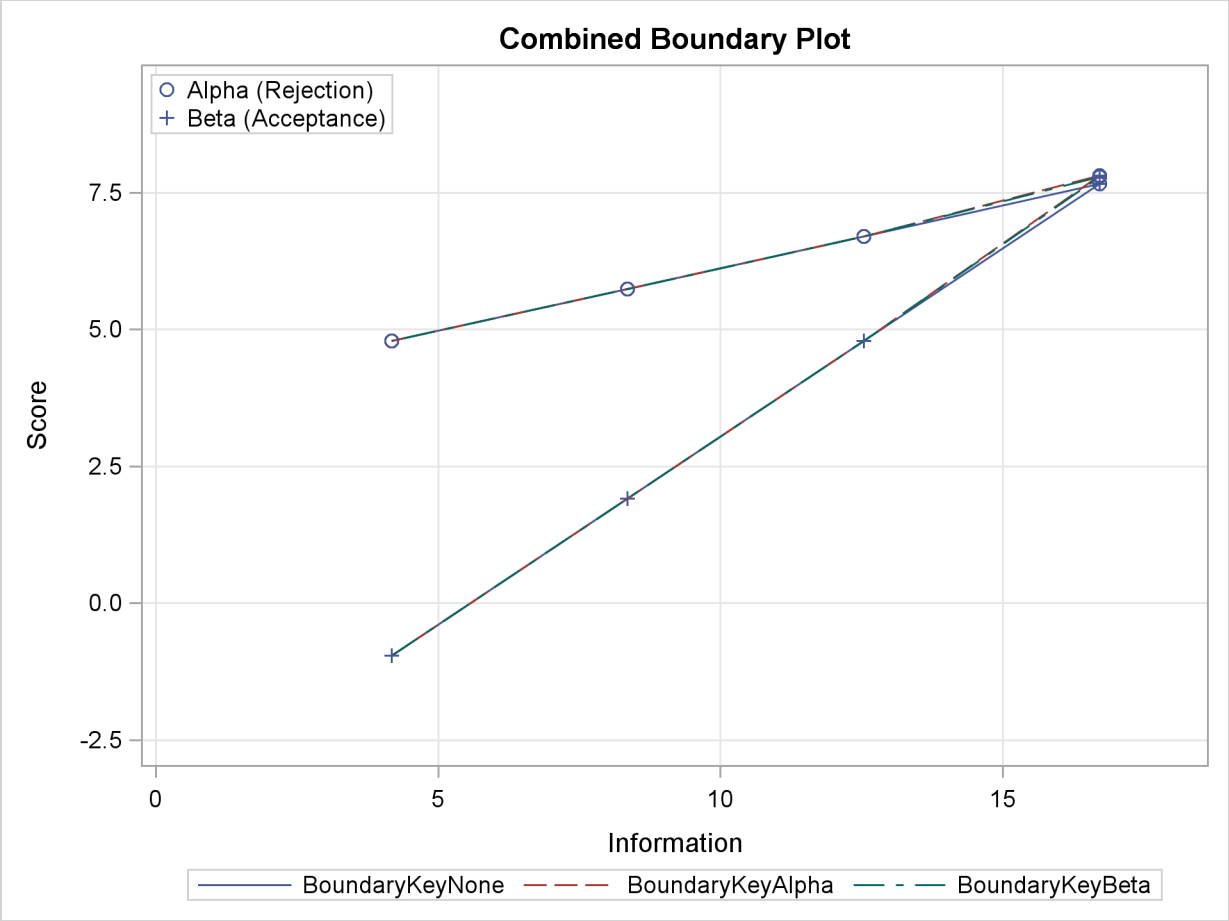
4	1.0000	16.70639	11.57998	7.78899	7.78899



With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 77.7.12.

Output 77.7.12 Boundary Plot

With the PLOTS=COMBINEDBOUNDARY option, a combined plot of group sequential boundaries for all designs is displayed, as shown in Output 77.7.13. It shows that three designs are similar, with a slightly smaller boundary value at the final stage for the design with the BOUNDARYKEY=NONE option.

Output 77.7.13 Combined Boundary Plot

The following statements invoke the SEQDESIGN procedure and specify the SAMPLESIZE statement to derive required sample sizes for a log-rank test comparing two survival distributions for the treatment effect (Jennison and Turnbull 2000 pp. 77–79; Whitehead 1997, pp. 36–39):

```
proc seqdesign altref=0.693147
               bscale=score
               ;
  BoundaryKeyAlpha: design nstages=4
                           method=whitehead
                           boundarykey=alpha
                           alt=upper   stop=both
                           alpha=0.05  beta=0.20
                           ;
  samplesize model=twosamplesurvival
                  ( nullhazard=0.03466 accrate=10);
run;
```

The design is identical to the previous design with the BOUNDARYKEY=ALPHA option except with the addition of the sample size computation.

The "Sample Size Summary" table in Output 77.7.14 displays parameters for the sample size computation. Since the ACCTIME= option is not specified for the accrual time, the minimum and maximum accrual times are derived for the specified accrual rate.

Output 77.7.14 Sample Size Summary

The SEQDESIGN Procedure
Design: BoundaryKeyAlpha

Sample Size Summary

Test	Two-Sample Survival
Null Hazard Rate	0.03466
Hazard Rate (Group A)	0.01733
Hazard Rate (Group B)	0.03466
Hazard Ratio	0.5
log(Hazard Ratio)	-0.69315
Reference Hazards	Alt Ref
Accrual Rate	10
Min Accrual Time	6.682556
Min Sample Size	66.82556
Max Accrual Time	25.40111
Max Sample Size	254.0111
Max Number of Events	66.82556

If the ACCTIME=20 option is specified in the SAMPLESIZE statement, the "Sample Size Summary" table in Output 77.7.15 also displays the follow-up time and maximum sample size with the specified accrual time.

Output 77.7.15 Sample Size Summary

The SEQDESIGN Procedure
Design: WhiteheadKeyAlpha

Sample Size Summary

Test	Two-Sample Survival
Null Hazard Rate	0.03466
Hazard Rate (Group A)	0.01733
Hazard Rate (Group B)	0.03466
Hazard Ratio	0.5
log(Hazard Ratio)	-0.69315

Example 77.8: Creating a One-Sided Error Spending Design

This example requests a five-stage, one-sided group sequential design for normally distributed statistics. The design uses an O'Brien-Fleming-type error spending function for the α boundary and a Pocock-type error spending function for the β boundary. The following statements request a one-sided design by using different α and β spending functions:

```
ods graphics on;
proc seqdesign altref=0.2  errspend
               pss(cref=0 0.5 1)
               stopprob(cref=0 0.5 1)
```

```
                plots=(asn power errspend)
                ;
   OneSidedErrorSpending: design nstages=5
                          method(alpha)=errfuncobf
                          method(beta)=errfuncpoc
                          alt=upper  stop=both
                          alpha=0.025
                          ;
run;
ods graphics off;
```

The "Design Information" table in Output 77.8.1 displays design specifications and the derived statistics. With the specified alternative reference, the maximum information is derived.

Output 77.8.1 Error Spending Method Design Information

The SEQDESIGN Procedure
Design: OneSidedErrorSpending

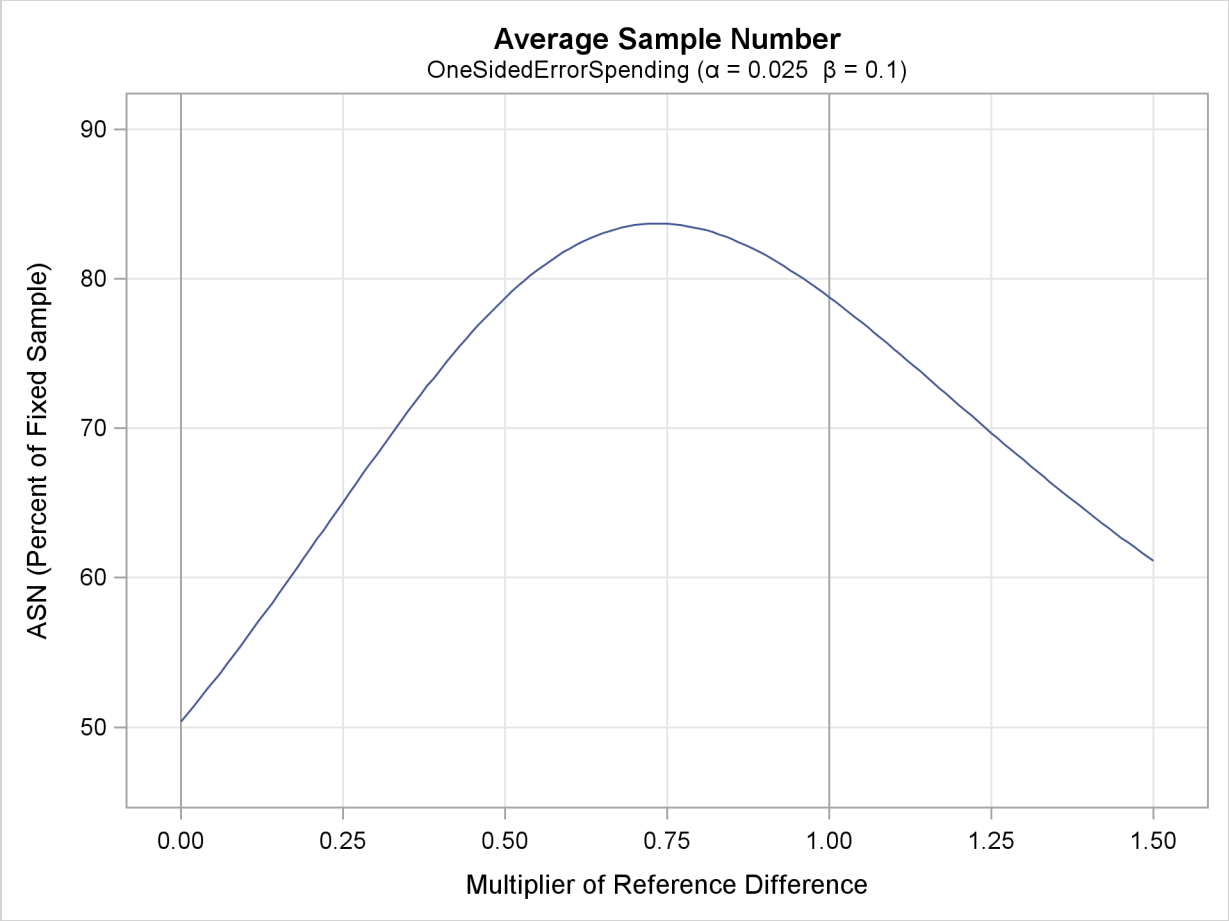
With the PSS option, the "Power and Expected Sample Sizes" table in Output 77.8.4 displays powers and expected sample sizes under various hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ are the default values in the CREF= option.

Output 77.8.4 Power and Expected Sample Size Information

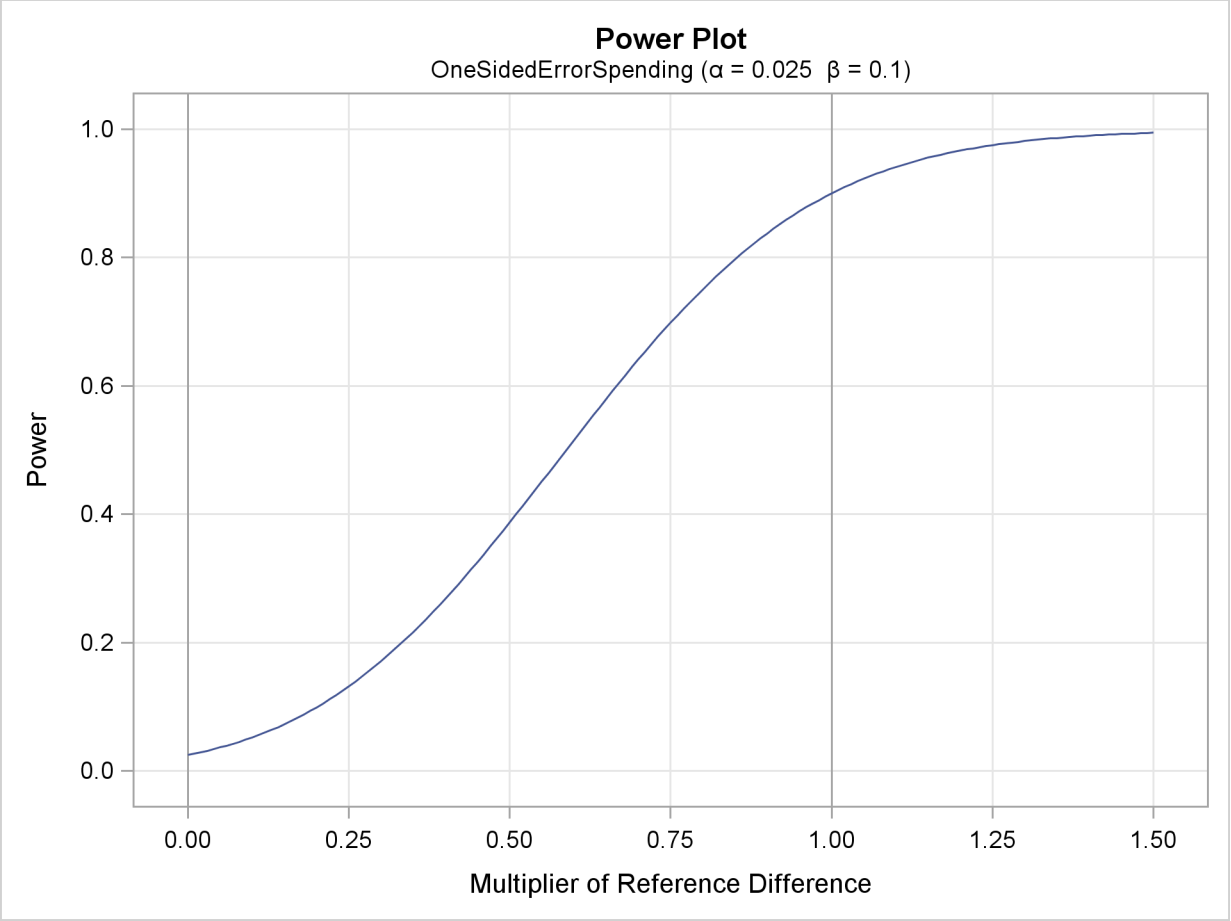


Powers and Expected Sample Sizes
Reference = CRef * (Alt Reference)

CRef	Power	-Sample Size- Percent Fixed-Sample
0.0000	0.02500	50.3541
0.5000	0.38724	78.7219
1.0000	0.90000	78.7722

With the PLOTS=ASN option, the procedure displays a plot of expected sample sizes under various hypothetical references, as shown in Output 77.8.5. By default, expected sample sizes under the

hypotheses $\theta = c_i\,\theta_1$, $c_i = 0, 0.01, 0.02, \ldots, 1.50$, are displayed, where θ_1 is the alternative reference.



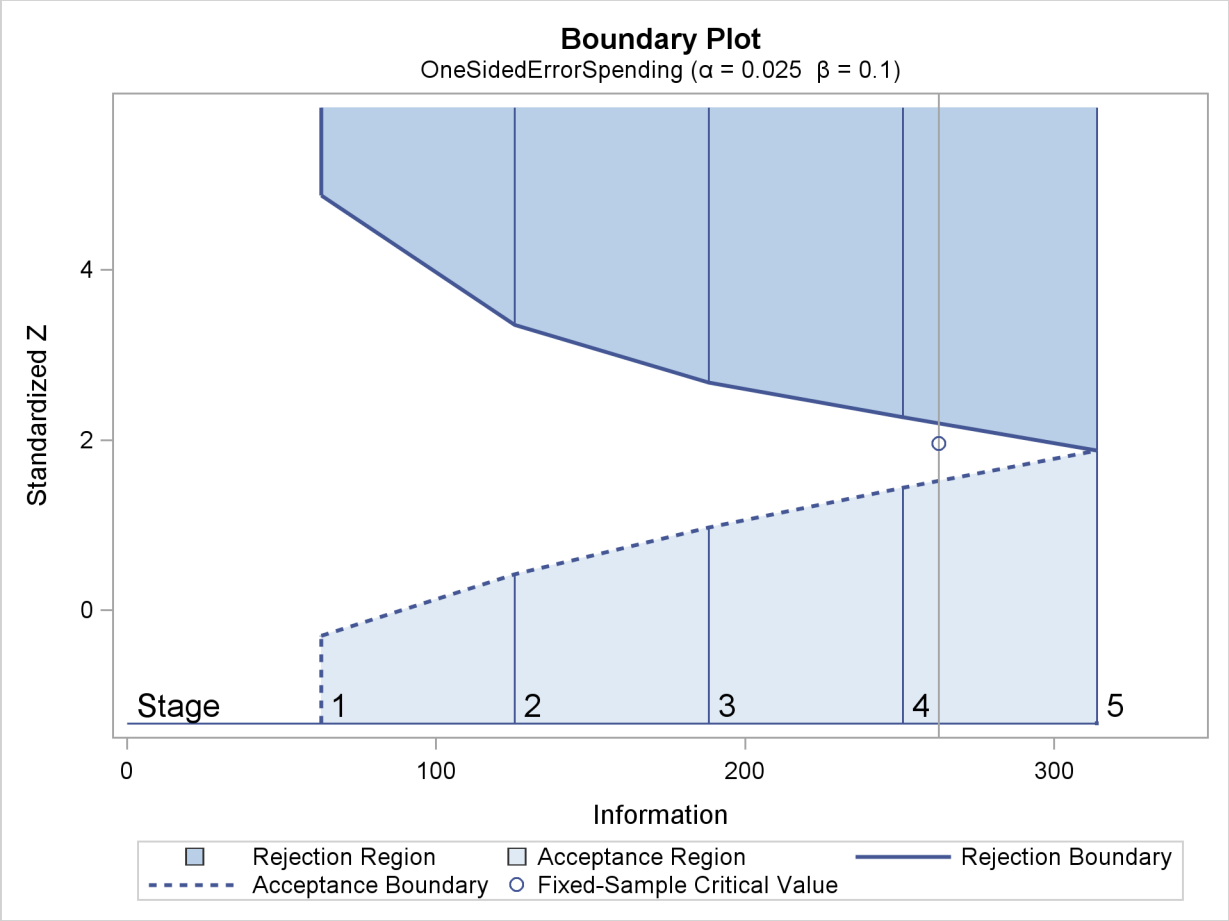
Output 77.8.5 ASN Plot

With the PLOTS=POWER option, the procedure displays a plot of the power curves under various hypothetical references for all designs simultaneously, as shown in Output 77.8.6. By default, the option CREF= $0, 0.01, 0.02, \ldots, 1.50$ and powers under hypothetical references $\theta = c_i\,\theta_1$ are displayed, where c_i are values specified in the CREF= option. These CREF= values are displayed on the horizontal axis.

Under the null hypothesis, $c_i = 0$, the power is 0.025, the upper Type I error probability. Under the alternative hypothesis, $c_i = 1$, the power is 0.9, one minus the Type II error probability. The plot shows only minor difference between the two designs.

Output 77.8.6 Power Plot

The "Boundary Information" table in Output 77.8.7 displays information level, alternative reference, and boundary values. By default, the alternative reference and boundary values are displayed with the default standardized Z scale. That is, the resulting standardized alternative reference at stage k is given by $\theta_1\sqrt{I_k}$, where θ_1 is the specified alternative reference and I_k is the information level at stage k, $k = 1, 2, \ldots, 5$.



Output 77.8.7 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0

	---Information Level--		-Alternative- --Reference--	-----Boundary Values---- ----------Upper---------	
Stage	Proportion	Actual	Upper	Beta	Alpha
1	0.2000	62.74393	1.58422	-0.30338	4.87688

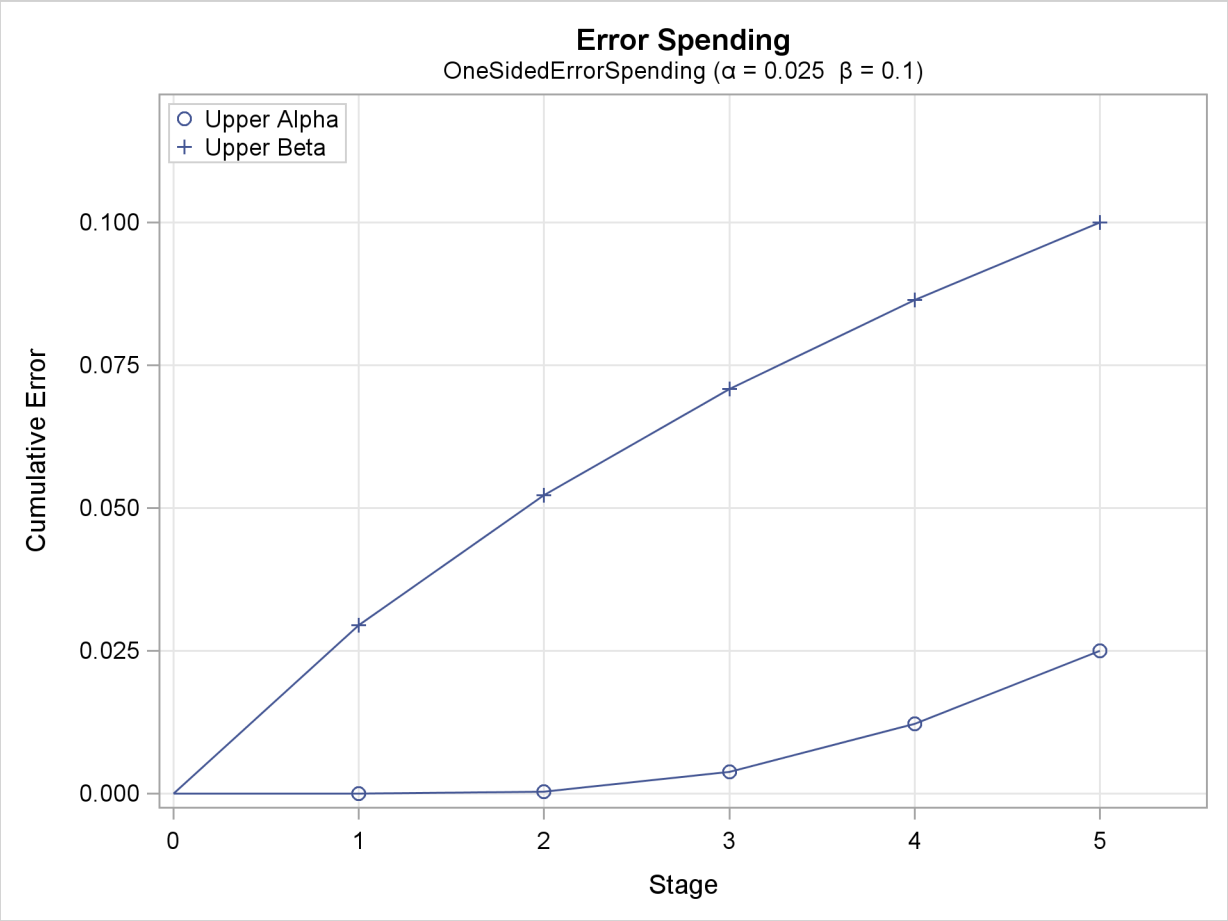
3	0.6000	188.2318	2.74395	0.97165	2.67766
4	0.8000	250.9757	3.16844	1.43627	2.26535
5	1.0000	313.7196	3.54243	1.87522	1.87522

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 77.8.8. This plot displays the boundary values in the "Boundary Information" table in Output 77.8.7.

Output 77.8.8 Boundary Plot

The "Error Spending Information" table in Output 77.8.9 displays cumulative error spending at each stage for each boundary.



Output 77.8.9 Error Spending Information

Error Spending Information

Stage	-Information Level- Proportion	-Cumulative Error Spending- ----------Upper---------- Beta	Alpha
1	0.2000	0.02954	0.00000
2	0.4000	0.05231	0.00039
3	0.6000	0.07085	0.00381
4	0.8000	0.08648	0.01221
5	1.0000	0.10000	0.02500

With the PLOTS=ERRSPEND option, the procedure displays a plot of error spending for each boundary, as shown in Output 77.8.10. This plot displays the cumulative error spending at each stage in the "Error Spending Information" table in Output 77.8.9. The O'Brien-Fleming-type α spending function is conservative in early stages because it uses much less at early stages than in the later stages. In contrast, the Pocock-type β spending function uses more at early stages than in the later stages.

Output 77.8.10 Error Spending Plot

Example 77.9: Creating Designs with Various Number of Stages

This example requests three group sequential designs for normally distributed statistics. Each design uses the power family error spending function with the default power parameter $\rho = 2$. The specified error spending method is between the approximated Pocock method ($\rho = 1$) and the approximated O'Brien-Fleming method ($\rho = 3$) (Jennison and Turnbull 1999, p. 148). The three designs are identical except for the specified number of stages. The following statements request the group sequential design with the default standardized Z scale for the boundary values:

```
ods graphics on;
proc seqdesign plots=( asn
                       power
                       combinedboundary
                       errspend(hscale=info)
                       )
                ;
   TwoStageDesign:  design nstages=2
                    method=errfuncpow
                    alt=upper  stop=reject
                    ;
   FiveStageDesign: design nstages=5
                    method=errfuncpow
                    alt=upper  stop=reject
                    ;
   TenStageDesign:  design nstages=10
                    method=errfuncpow
                    alt=upper  stop=reject
                    ;
run;
ods graphics off;
```

The "Design Information" table in Output 77.9.1 displays design information for the two-stage design.

Output 77.9.1 Design Information

The SEQDESIGN Procedure
Design: TwoStageDesign

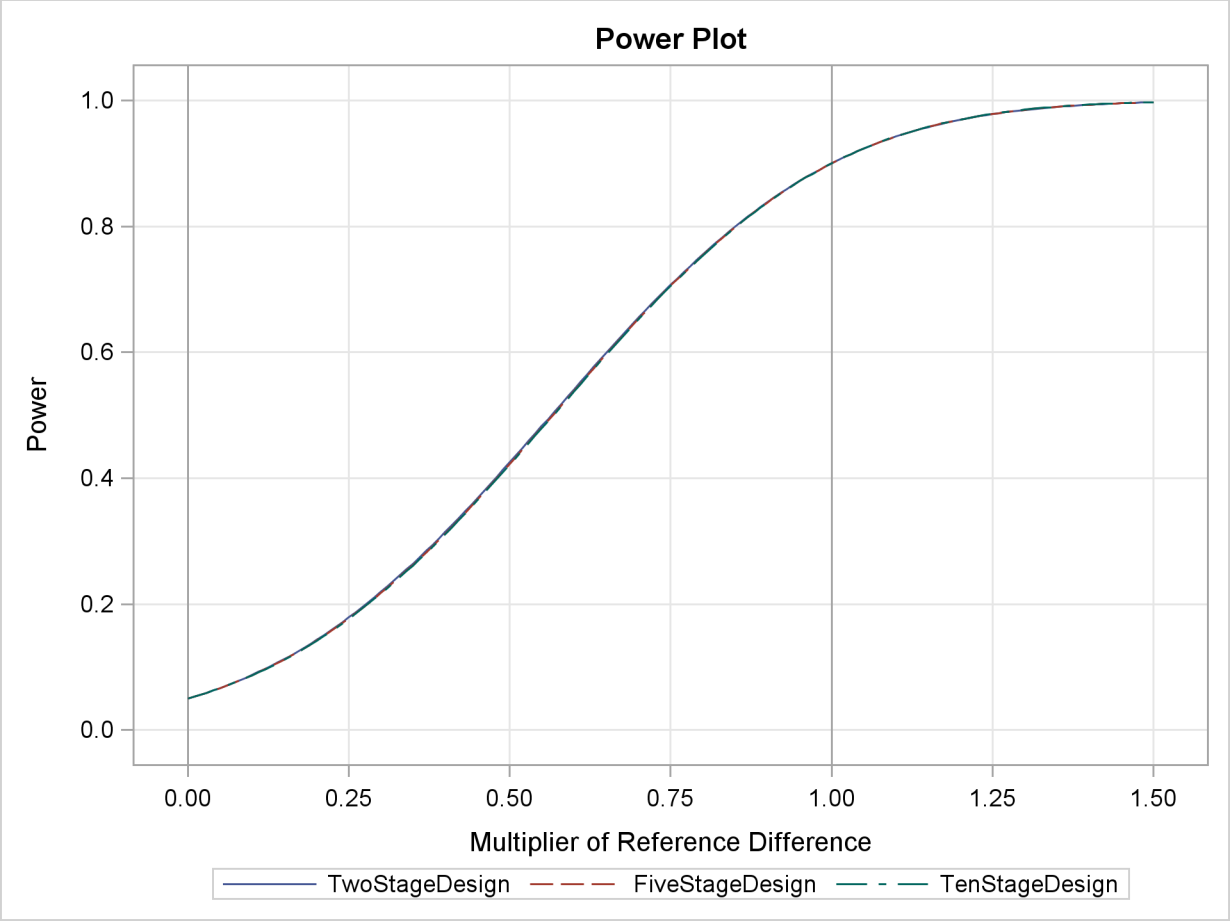
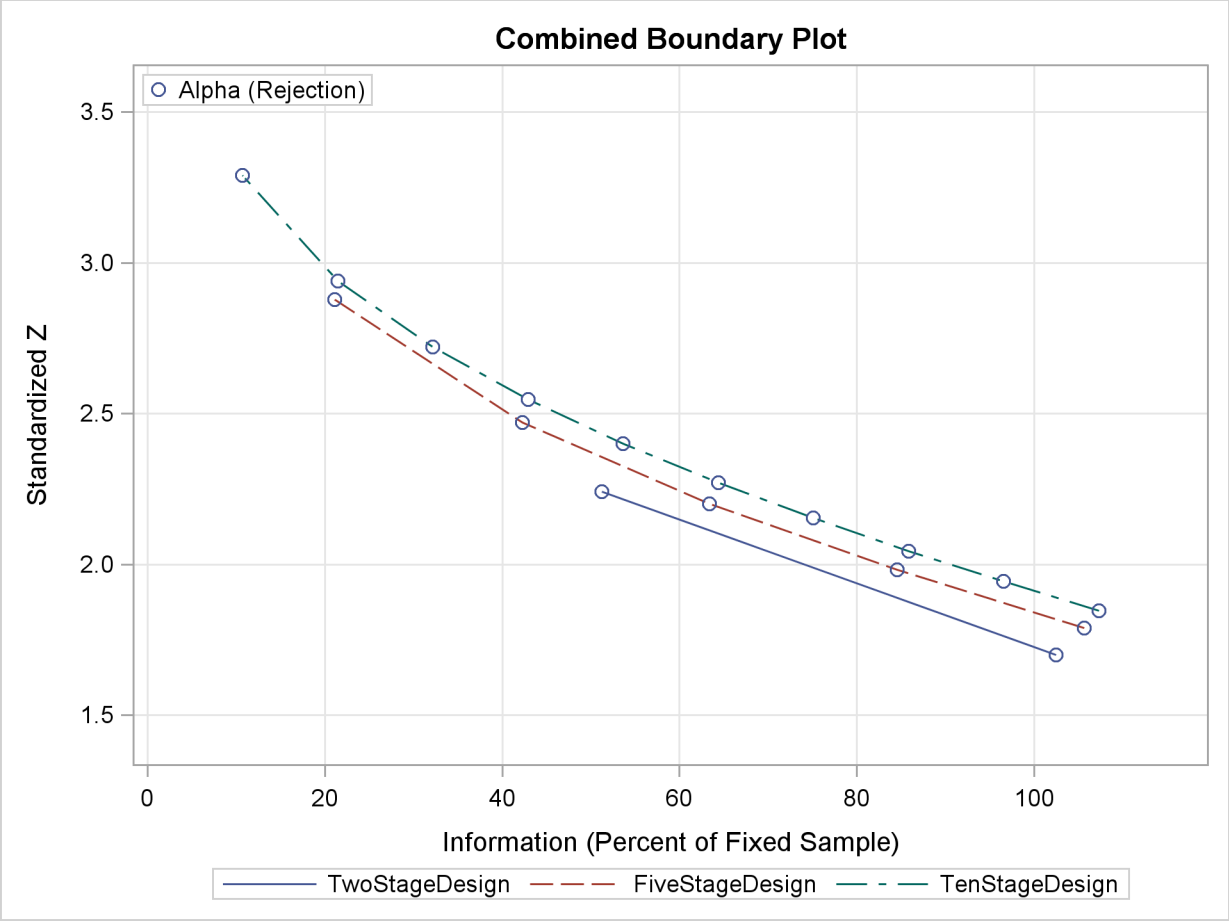
With the PLOTS=ASN option, the procedure displays a plot of average sample numbers under various hypothetical references for all designs simultaneously, as shown in Output 77.9.7. By default, the option CREF= $0, 0.01, 0.02, \ldots, 1.50$ and expected sample sizes under the hypothetical references $\theta = c_i\,\theta_1$ are displayed, where c_i are values specified in the CREF= option. These CREF= values are displayed on the horizontal axis.



Output 77.9.7 ASN Plot

The plot shows that as the number of stages increases, the average sample number as a percentage of the fixed-sample design increases under the null hypothesis ($c_i = 0$) but decreases under the alternative hypothesis ($c_i = 1$).

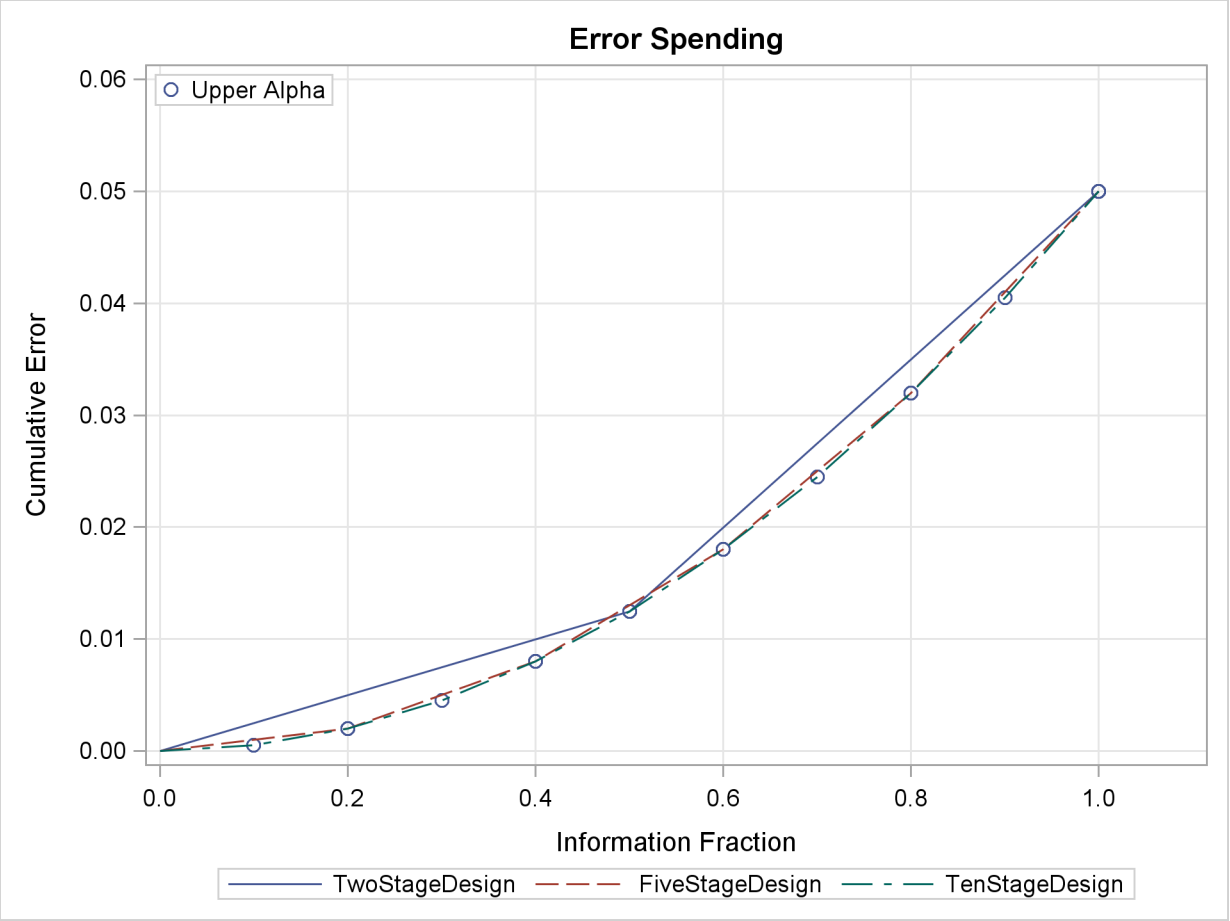
With the PLOTS=POWER option, the procedure displays a plot of the power curves under various hypothetical references for all designs simultaneously, as shown in Output 77.9.8. By default, the option CREF= $0, 0.01, 0.02, \ldots, 1.50$ and powers under hypothetical references $\theta = c_i\,\theta_1$ are displayed, where c_i are values specified in the CREF= option. These CREF= values are displayed on the horizontal axis.



Output 77.9.8 Power Plot

Under the null hypothesis, $c_i = 0$, the power is 0.05, the upper Type I error probability. Under the alternative hypothesis, $c_i = 1$, the power is 0.9, one minus the Type II error probability. The plot shows only minor difference among the three designs.

With the PLOTS=COMBINEDBOUNDARY option, the procedure displays a plot of sequential boundaries for all designs simultaneously, as shown in Output 77.9.9. By default, the information levels are used on the horizontal axis. Since the maximum information is not available for the design, the percent information ratios with respect to the corresponding fixed-sample design are displayed in the plot.



Output 77.9.9 Combined Boundary Plot

The plot shows that as the number of stages increases, the maximum information increases and the α boundary values also increase.

With the PLOTS=ERRSPEND(HSCALE=INFO) option, the procedure displays a plot of cumulative error spends for all boundaries in the designs simultaneously, as shown in Output 77.9.10.

Output 77.9.10 Error Spending Plot

The plot shows similar error spending for these three designs since all three designs are generated from the same power family error spending function.

Example 77.10: Creating Two-Sided Error Spending Designs with and without Overlapping Lower and Upper β Boundaries

This example requests two three-stage group sequential designs for normally distributed statistics. Each design uses a power family error spending function with a specified two-sided alternative hypothesis $H_1 : \theta_1 = \pm 0.2$ and early stopping only to accept the null hypothesis H_0.

The first design uses the BETAOVERLAP=NOADJUST option to derive acceptance boundary values without adjusting for the possible overlapping of the lower and upper β boundaries computed from the two corresponding one-sided tests. The second design uses the BETAOVERLAP=ADJUST option to test the overlapping of the β boundaries at each interim stage based on the two corresponding one-sided tests and then to set the β boundary values at the stage to missing if overlapping occurs at that stage.

The following statements request a two-sided design with the BETAOVERLAP=NOADJUST option:

```
ods graphics on;
proc seqdesign altref=0.2 errspend;
   design nstages=3
          method=errfuncpow
          alt=twosided  stop=accept
          betaoverlap=noadjust
          beta=0.09
          ;
run;
ods graphics off;
```

The "Design Information" table in Output 77.10.1 displays design specifications and the derived statistics for the first design. With the specified alternative reference $\theta_1 = 0.2$, the maximum information is derived.

Output 77.10.1 Design Information

The SEQDESIGN Procedure
Design: Design_1

Alt Ref ASN (Percent of Fixed Sample)	102.1476

The "Boundary Information" table in Output 77.10.2 displays the information level, alternative reference, and boundary values. With a specified alternative reference θ_1, the maximum information is derived from the procedure, and the actual information level at each stage is displayed in the table. With the default BOUNDARYSCALE=STDZ option, the alternative reference in the standardized Z scale at stage k is given by $\theta_1\sqrt{I_k}$, where θ_1 is the specified alternative reference and I_k is the information level at stage k, $k = 1, 2, 3$.

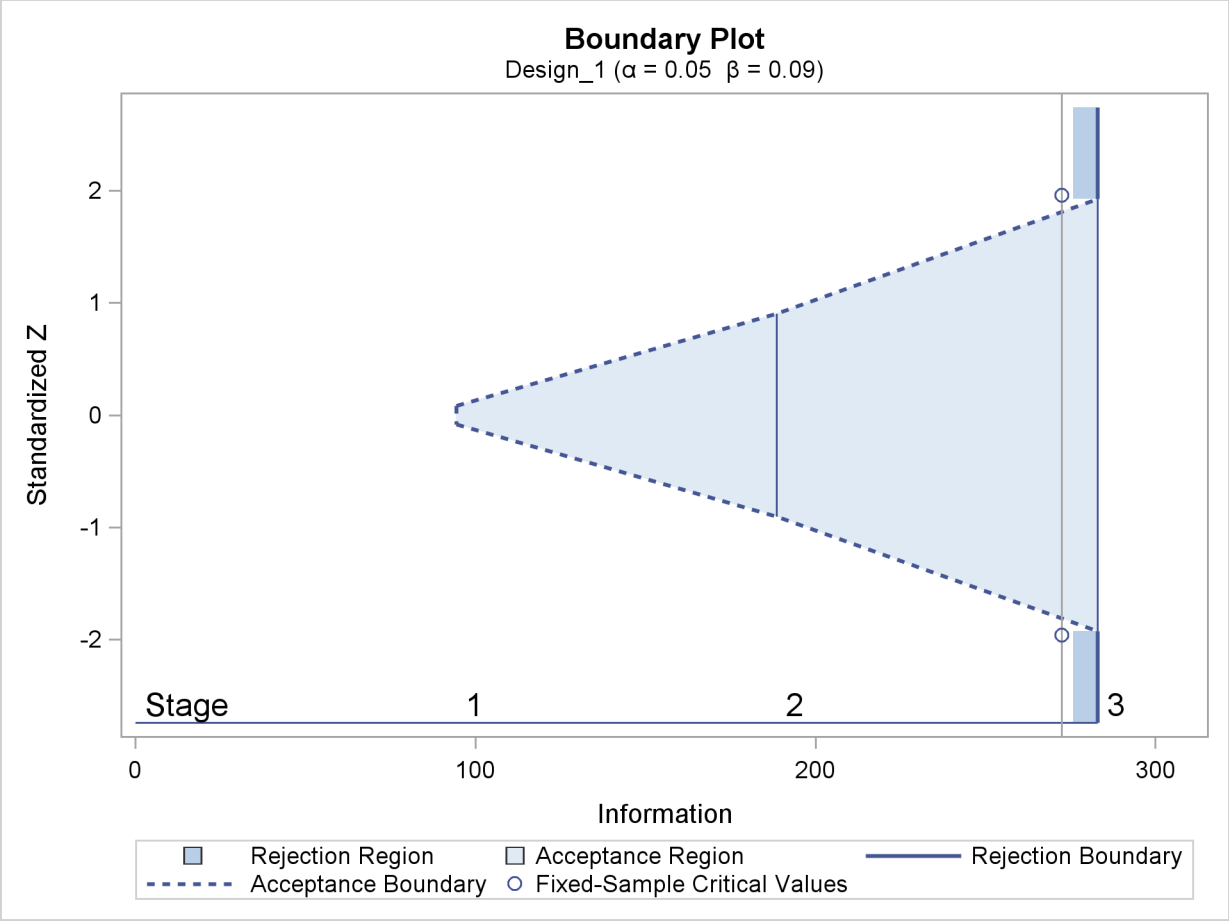
Output 77.10.2 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0

Stage	Information Level- Proportion	Information Level- Actual	Alternative Reference Lower	Alternative Reference Upper	Boundary Values Lower Beta	Boundary Values Upper Beta
1	0.3333	94.31094	-1.94228	1.94228	-0.08239	0.08239
2	0.6667	188.6219	-2.74679	2.74679	-0.90351	0.90351
3	1.0000	282.9328	-3.36412	3.36412	-1.92519	1.92519

The "Error Spending Information" table in Output 77.10.3 displays the cumulative error spending at each stage for each boundary.

Output 77.10.3 Error Spending Information



Error Spending Information

Stage	Information Level- Proportion	Cumulative Error Spending Lower Alpha	Cumulative Error Spending Lower Beta	Cumulative Error Spending Upper Beta	Cumulative Error Spending Upper Alpha
1	0.3333	0.00000	0.01000	0.01000	0.00000
2	0.6667	0.00000	0.04000	0.04000	0.00000
3	1.0000	0.02500	0.09000	0.09000	0.02500

With the STOP=ACCEPT option, the design does not stop at interim stages to reject H_0, and the α spending at each interim stage is zero. For the power family error spending function with the default parameter $\rho = 2$, the beta spending at stage 1 is $(1/3)^\rho \beta = (1/3)^2 0.09 = 0.01$, and the cumulative beta spending at stage 2 is $(2/3)^\rho \beta = (2/3)^2 0.09 = 0.04$.

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the acceptance and rejection regions is displayed by default, as shown in Output 77.10.4.

Output 77.10.4 Boundary Plot

The following statements request a two-sided design with the BETAOVERLAP=ADJUST option, which is the default:

```
ods graphics on;
proc seqdesign altref=0.2 errspend;
   design nstages=3
          method=errfuncpow
          alt=twosided
          stop=accept
          betaoverlap=adjust
          beta=0.09
          ;
run;
ods graphics off;
```

With the BETAOVERLAP=ADJUST option, the procedure first derives the usual β boundary values for the two-sided design and then checks for overlapping of the β boundaries for the two corresponding one-sided tests at each stage. If this type of overlapping occurs at a particular stage, the β boundary values for that stage are set to missing, the β spending values at that stage are reset to zero, and the β spending values at subsequent stages are adjusted proportionally.

The boundary values without adjusting for the possible overlapping of the two one-sided β boundaries are identical to the boundary values derived in the first design (with the BETAOVERLAP=NOADJUST option, as shown in Output 77.10.2). At stage 1, the upper β boundary value for the corresponding one-sided test is

$$\theta_1\sqrt{I_1} - \Phi^{-1}(1-\beta_1) = 0.2\sqrt{94.31094} - \Phi^{-1}(0.99) = 1.94228 - 2.32635 = -0.38407$$

where $\theta_1 = 0.2$ is the upper alternative reference, $I_1 = 94.31094$ is the information level at stage 1, and $\beta_1 = 0.01$ is the β spending at stage 1 (as shown in Output 77.10.3).

Similarly, the lower β boundary value for the corresponding one-sided test is computed as 0.38407. Since the upper β boundary value is less than the lower β boundary at stage 1, overlapping occurs, and so the β boundary values for the two-sided design are set to missing at stage 1.

With the β boundary values set to missing at stage 1 and the β spending $\beta'_1 = 0$ the β spending values at subsequent interim stages are adjusted proportionally. In this example, the adjusted β spending at stage 2 is computed as

$$\beta'_2 = \beta'_1 + \frac{\beta_2 - \beta_1}{\beta_3 - \beta_1}(\beta_3 - \beta'_1) = 0 + \frac{0.04 - 0.01}{0.09 - 0.01}\,0.09 = 0.03375$$

where β_k is the cumulative β spending at stage k before the adjustment, $k = 1, 2, 3$.

The "Design Information" table in Output 77.10.5 displays design specifications and derived statistics for the design.

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the acceptance and rejection regions is displayed by default, as shown in Output 77.10.8.

Output 77.10.8 Boundary Plot

Example 77.11: Creating a Two-Sided Asymmetric Error Spending Design with Early Stopping to Reject H_0

This example requests a three-stage two-sided asymmetric group sequential design for normally distributed statistics.

The O'Brien-Fleming boundary can be approximated using a power family error spending function with parameter $\rho = 3$, and the Pocock boundary can be approximated using a power family error spending function with parameter $\rho = 1$ (Jennison and Turnbull 2000, p. 148). The following statements use the power family error spending function to creates a two-sided asymmetric design with early stopping to reject the null hypothesis H_0:

```
ods graphics on;
proc seqdesign altref=1.0
               pss(cref=0 0.5 1)
               stopprob(cref=0 0.5 1)
               errspend
               plots=(asn power errspend)
               ;
```

```
   TwoSidedErrorSpending: design nstages=3
                          method(upperalpha)=errfuncpow(rho=3)
                          method(loweralpha)=errfuncpow(rho=1)
                          info=cum(2 3 4)
                          alt=twosided
                          stop=reject
                          alpha=0.075(upper=0.025)
                          ;
run;
ods graphics off;
```

The design uses power family error spending functions with $\rho = 1$ for the lower α boundary and $\rho = 3$ for the upper α boundary. Thus, the design is conservative in the early stages and tends to stop the trials early only with a small p-value for the upper α boundary. The upper α level 0.025 is specified explicitly, and the lower α level is computed as $0.075 - 0.025 = 0.05$.

The "Design Information" table in Output 77.11.1 displays design specifications and the derived maximum information. Note that in order to attain the same information level for the asymmetric lower and upper boundaries, the derived power at the lower alternative 0.92963 is larger than the default 0.90.

Output 77.11.1 Design Information

The SEQDESIGN Procedure
Design: TwoSidedErrorSpending

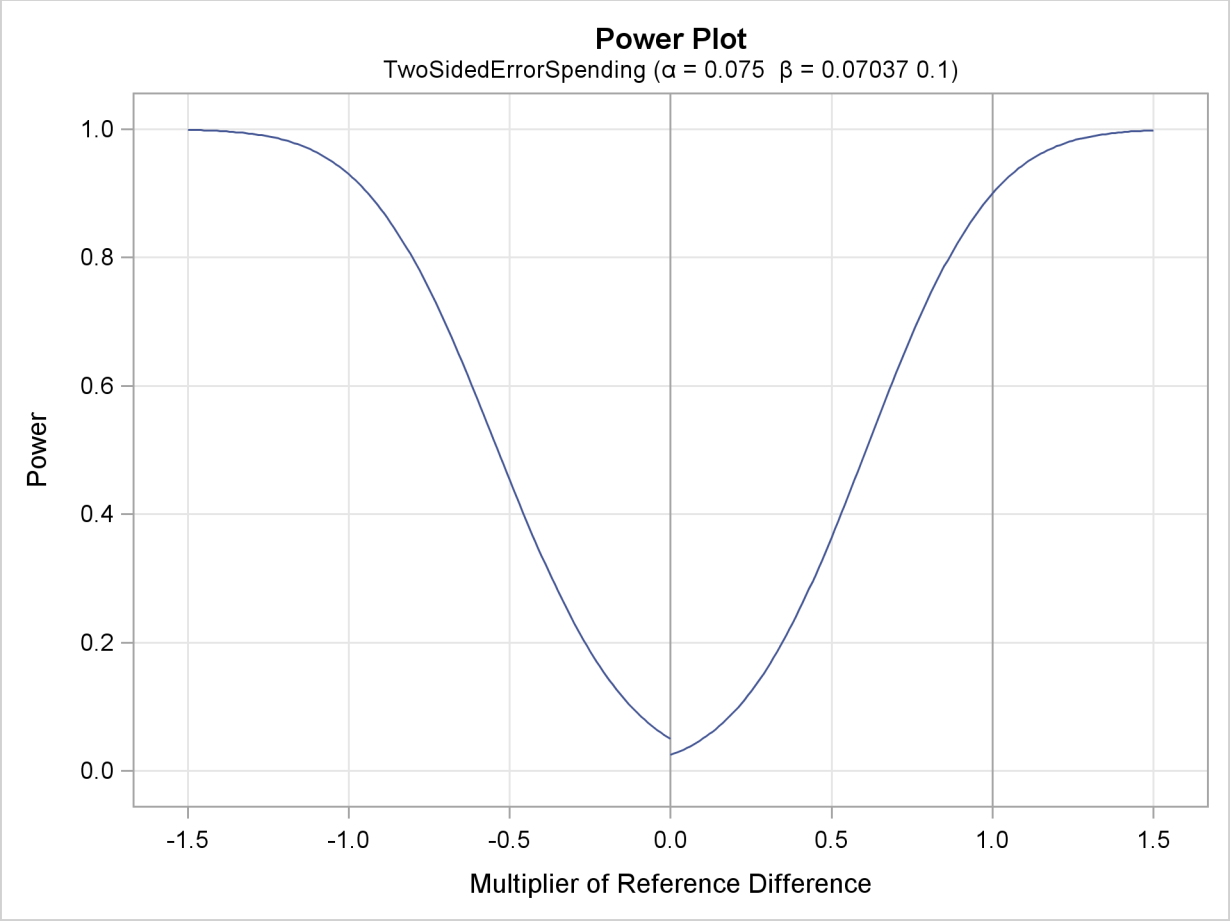
1.0000	Upper Alt	0.33927	0.69357	0.90001

"Rej Null (Lower Alt)" and "Rej Null (Upper Alt)" under the heading "Source" indicate the probabilities of rejecting the null hypothesis for the lower alternative and for the upper alternative, respectively. "Reject Null" indicates the probability of rejecting the null hypothesis for either the lower or upper alternative.

Note that with the STOP=REJECT option, the cumulative stopping probability of accepting the null hypothesis H_0 at each interim stage is zero and is not displayed.

With the PSS(CREF=0 0.5 1.0) option, the "Power and Expected Sample Sizes" table in Output 77.11.4 displays powers and expected sample sizes under hypothetical references $\theta = 0$ (null hypothesis H_0), $\theta = 0.5\,\theta_1$, and $\theta = \theta_1$ (alternative hypothesis H_1), where θ_1 is the alternative reference. The expected sample sizes are displayed in a percentage scale relative to the corresponding fixed-sample size design.

Output 77.11.4 Power and Expected Sample Size Information

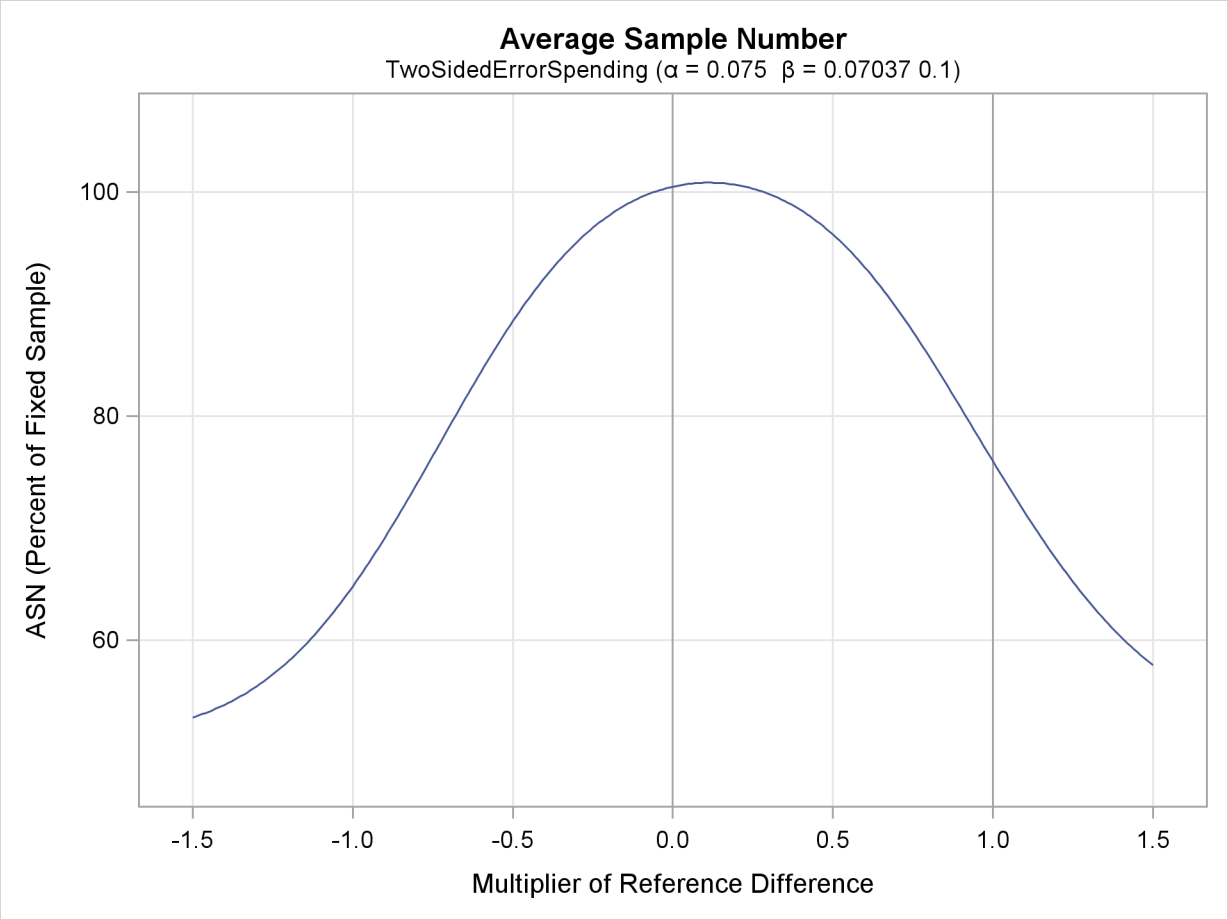


Powers and Expected Sample Sizes
Reference = CRef * (Alt Reference)

CRef	Ref	Power	-Sample Size- Percent Fixed-Sample
0.0000	Lower Alt	0.05000	100.4877
0.5000	Lower Alt	0.45370	88.5090
1.0000	Lower Alt	0.92963	64.8288
0.0000	Upper Alt	0.02500	100.4877
0.5000	Upper Alt	0.36458	96.2309
1.0000	Upper Alt	0.90000	75.9878

Note that at $c_i = 0$, the null reference $\theta = 0$, the power with the lower alternative is the lower α error 0.05, and the power with the upper alternative is the upper α error 0.025. At $c_i = 1$, the alternative reference $\theta = \theta_1$, the power with the upper alternative is the specified power 0.90, and the power with the lower alternative 0.92963 is greater than the specified power 0.90 because the same information level is used for these two asymmetric boundaries.

With the PLOTS=POWER option, the procedure displays a plot of the power curves under various hypothetical references, as shown in Output 77.11.5. By default, powers under the lower hypotheses $\theta = c_i\,\theta_{1l}$ and under the upper hypotheses $\theta = c_i\,\theta_{1u}$ are displayed for a two-sided asymmetric design, where $c_i = 0, 0.01, 0.02, \ldots, 1.50$ and $\theta_{1l} = -1$ and $\theta_{1u} = 1$ are the lower and upper alternative references, respectively.



Output 77.11.5 Power Plot

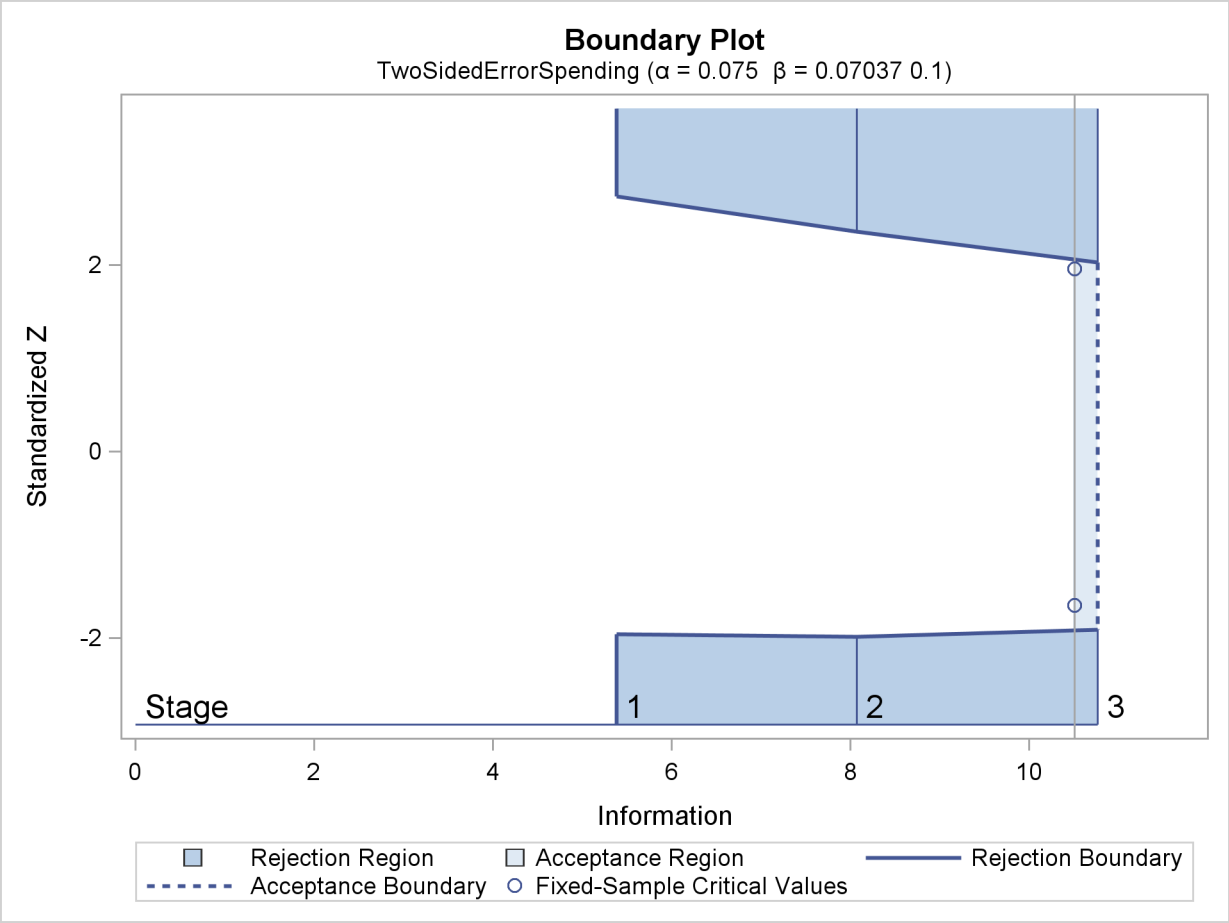
The horizontal axis displays the multiplier of the reference difference. A positive multiplier corresponds to c_i for the upper alternative hypothesis, and a negative multiplier corresponds to $-c_i$ for the lower alternative hypothesis. For lower reference hypotheses, the power is the lower α error 0.05 under the null hypothesis ($c_i = 0$) and is 0.92963 under the alternative hypothesis ($c_i = 1$). For upper reference hypotheses, the power is the upper α error 0.025 under the null hypothesis ($c_i = 0$) and is 0.90 under the alternative hypothesis ($c_i = 1$).

With the PLOTS=ASN option, the procedure displays a plot of expected sample sizes under various hypothetical references, as shown in Output 77.11.6. By default, expected sample sizes under the lower hypotheses $\theta = c_i\,\theta_{1l}$ and under the upper hypotheses $\theta = c_i\,\theta_{1u}$, $c_i = 0, 0.01, 0.02, \ldots, 1.50$, are displayed for a two-sided asymmetric design, where $\theta_{1l} = -1$ and $\theta_{1u} = 1$ are the lower and upper alternative references, respectively.

Output 77.11.6 ASN Plot

The horizontal axis displays the multiplier of the reference difference. A positive multiplier corresponds to c_i for the upper alternative hypothesis and a negative multiplier corresponds to $-c_i$ for the lower alternative hypothesis.

The "Boundary Information" table in Output 77.11.7 displays the information levels, alternative references, and boundary values. The default BOUNDARYSCALE=STDZ option specifies that the standardized Z scale be used to display the alternative references and boundary values. The resulting standardized alternative references at stage k are given by $\pm\theta_1\sqrt{I_k}$, where θ_1 is the specified alternative reference and I_k is the information level at stage k, $k = 1, 2, 3$.



Output 77.11.7 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0

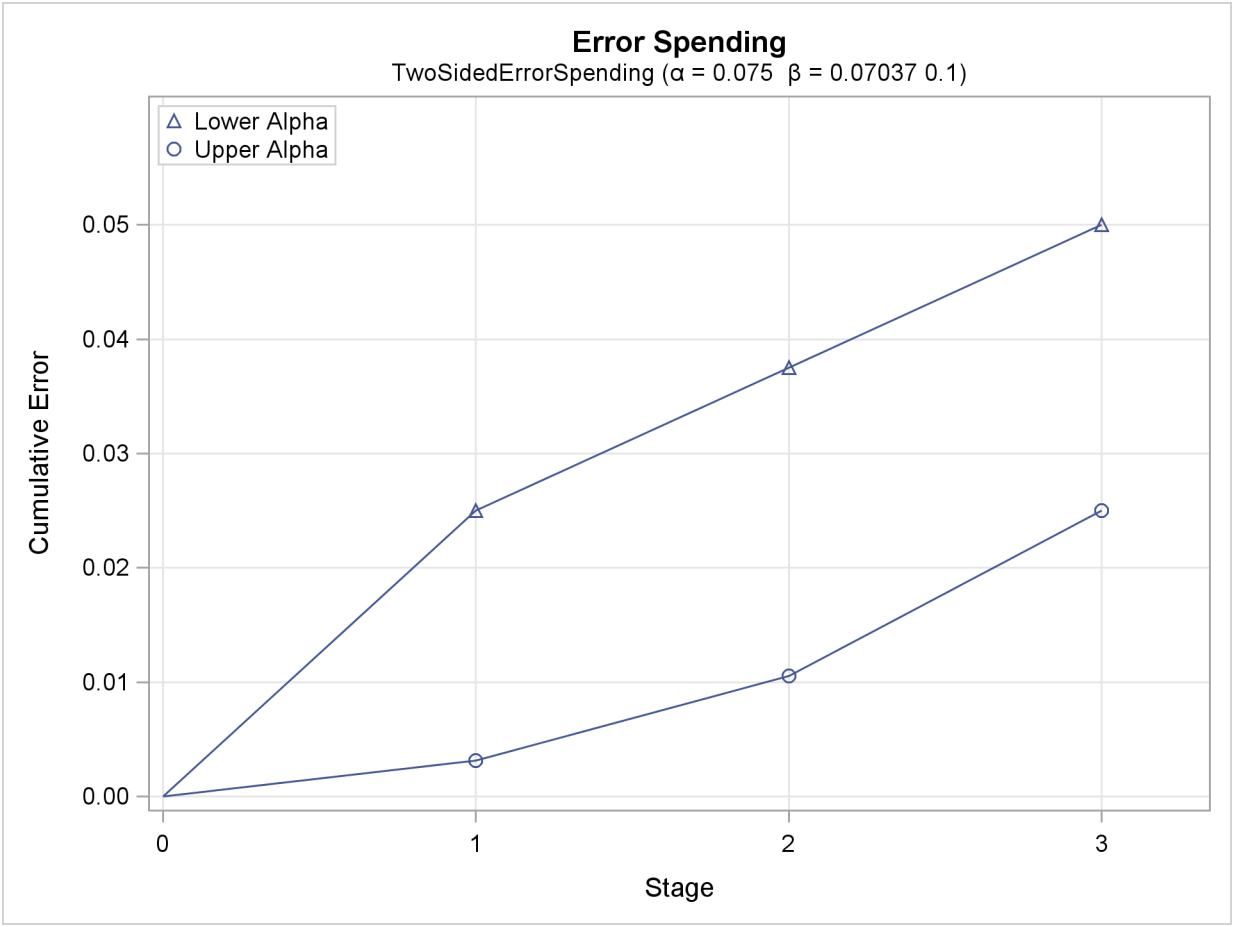
Stage	--Information Level- Proportion	Actual	------Alternative----- -------Reference------ Lower	Upper	----Boundary Values--- ---Lower-- Alpha	---Upper-- Alpha
1	0.5000	5.381827	-2.31988	2.31988	-1.95996	2.73437
2	0.7500	8.07274	-2.84126	2.84126	-1.98394	2.35681
3	1.0000	10.76365	-3.28080	3.28080	-1.90855	2.02853

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 77.11.8.

Output 77.11.8 Boundary Plot

The "Error Spending Information" table in Output 77.11.9 displays the cumulative error spending at each stage for each boundary.

Output 77.11.9 Error Spending Information



Error Spending Information

Stage	-Information Level- Proportion	--------Cumulative Error Spending------- -------Lower------ Alpha	Beta	-------Upper------ Beta	Alpha
1	0.5000	0.02500	0.00000	0.00001	0.00313
2	0.7500	0.03750	0.00000	0.00001	0.01055
3	1.0000	0.05000	0.07037	0.10000	0.02500

With the STOP=REJECT option, there is no early stopping to accept H_0, and the corresponding β spending at an interim stage is computed from the rejection region. For example, the upper β spending at stage 1 (0.00001) is the probability of rejecting H_0 for the lower alternative under the upper alternative reference.

With the PLOTS=ERRSPEND option, the procedure displays a plot of the cumulative error spending on each boundary at each stage, as shown in Output 77.11.10.

Output 77.11.10 Error Spending Plot

Example 77.12: Creating a Two-Sided Asymmetric Error Spending Design with Early Stopping to Reject or Accept H_0

This example requests a four-stage two-sided asymmetric group sequential design for normally distributed statistics. The O'Brien-Fleming boundary can be approximated by a gamma family error spending function with parameter $\gamma = -4$ or -5, and the Pocock boundary can be approximated with parameter $\gamma = 1$ (Hwang, Shih, and DeCani 1990, p. 1440). The following statements use the gamma error spending function with early stopping to reject or accept the null hypothesis H_0:

```
ods graphics on;
proc seqdesign altref=2
               pss(cref=0 0.5 1)
               stopprob(cref=0 1)
               errspend
               plots=(asn power errspend)
               ;
TwoSidedAsymmetric: design nstages=4
                    method=errfuncgamma(gamma=1)
                    method(beta)=errfuncgamma(gamma=-2)
                    method(upperalpha)=errfuncgamma(gamma=-5)
                    alt=twosided
                    stop=both
                    beta=0.1
                    ;
run;
ods graphics off;
```

The design uses gamma family error spending functions with $\gamma = -5$ for the upper α boundary, $\gamma = 1$ for the lower α boundary, and $\gamma = -2$ for the lower and upper β boundaries.

The "Design Information" table in Output 77.12.1 displays design specifications and the derived maximum information. Note that in order to attain the same information level for the asymmetric lower and upper boundaries, the derived power at the upper alternative 0.93655 is larger than the specified $1 - \beta = 0.90$.

Output 77.12.1 Design Information

The SEQDESIGN Procedure
Design: TwoSidedAsymmetric

Design Information

Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Accept/Reject Null
Method	Error Spending
Boundary Key	Both
Alternative Reference	2
Number of Stages	4
Alpha	0.05
Beta (Lower)	0.1
Beta (Upper)	0.06345
Power (Lower)	0.9
Power (Upper)	0.93655
Max Information (Percent of Fixed Sample)	104.0688
Max Information	3.162386
Null Ref ASN (Percent of Fixed Sample)	74.16654
Lower Alt Ref ASN (Percent of Fixed Sample)	59.10271
Upper Alt Ref ASN (Percent of Fixed Sample)	73.78797

The "Method Information" table in Output 77.11.2 displays the specified α and β error levels and the derived drift parameter. With the same information level used for the asymmetric lower and upper boundaries, only one of the β levels is maintained and the other is derived to have the level less than or equal to the specified level.

Output 77.12.2 Method Information

Method Information

Boundary	Method	Alpha	Beta	----Error Spending---- Function
Upper Alpha	Error Spending	0.02500	.	Gamma (Gamma=-5)
Upper Beta	Error Spending	.	0.06345	Gamma (Gamma=-2)
Lower Beta	Error Spending	.	0.10000	Gamma (Gamma=-2)
Lower Alpha	Error Spending	0.02500	.	Gamma (Gamma=1)

Method Information

Boundary	Alternative Reference	Drift
Upper Alpha	2	3.55662
Upper Beta	2	3.55662
Lower Beta	-2	-3.55662
Lower Alpha	-2	-3.55662

With the STOPPROB(CREF=0 1) option, the "Expected Cumulative Stopping Probabilities" table in Output 77.12.3 displays the expected stopping stage and cumulative stopping probabilities at each stage under the null reference $\theta = 0$ and under the alternative reference $\theta = \theta_1$.

Output 77.12.3 Stopping Probabilities

Expected Cumulative Stopping Probabilities
Reference = CRef * (Alt Reference)

CRef	Ref	Expected Stopping Stage	Source
0.0000	Lower Alt	2.851	Rej Null (Lower Alt)
0.0000	Lower Alt	2.851	Rej Null (Upper Alt)
0.0000	Lower Alt	2.851	Reject Null

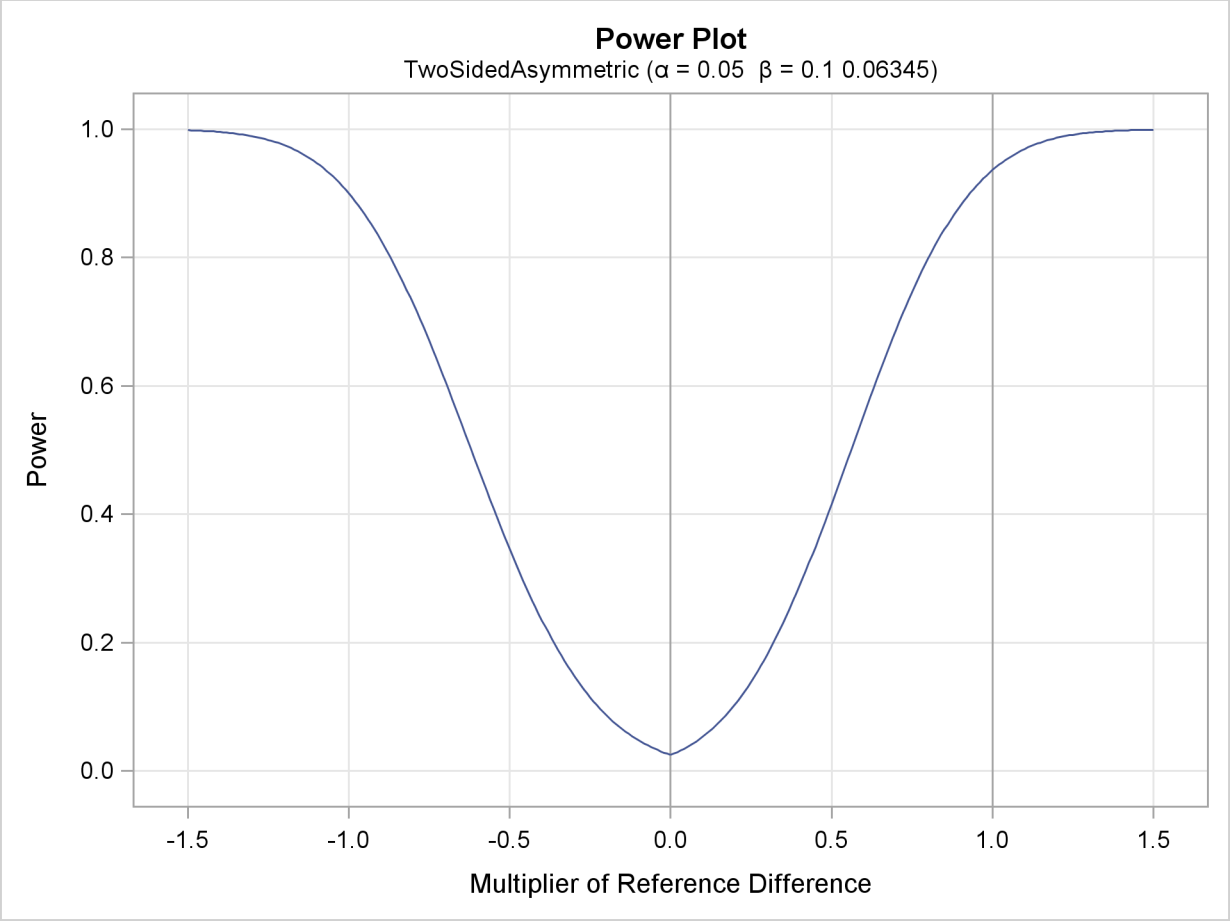
1.0000	Upper Alt	0.05947	0.33804	0.72325	0.93657
1.0000	Upper Alt	0.00000	0.01182	0.03131	0.06343
1.0000	Upper Alt	0.05947	0.34986	0.75456	1.00000

"Rej Null (Lower Alt)" and "Rej Null (Upper Alt)" under the heading "Source" indicate the probabilities of rejecting the null hypothesis for the lower alternative and for the upper alternative, respectively. "Reject Null" indicates the probability of rejecting the null hypothesis for either the lower or upper alternative, "Accept Null" indicates the probability of accepting the null hypothesis, and "Total" indicates the total probability of stopping the trial.

With the PSS(CREF=0 0.5 1.0) option, the "Power and Expected Sample Sizes" table in Output 77.12.4 displays powers and expected sample sizes under hypothetical references $\theta = 0$ (null hypothesis H_0), $\theta = 0.5\,\theta_1$, and $\theta = \theta_1$ (alternative hypothesis H_1), where θ_1 is the alternative reference. The expected sample sizes are displayed in a scale that indicates a percentage of its corresponding fixed-sample size design.

Output 77.12.4 Power and Expected Sample Size Information

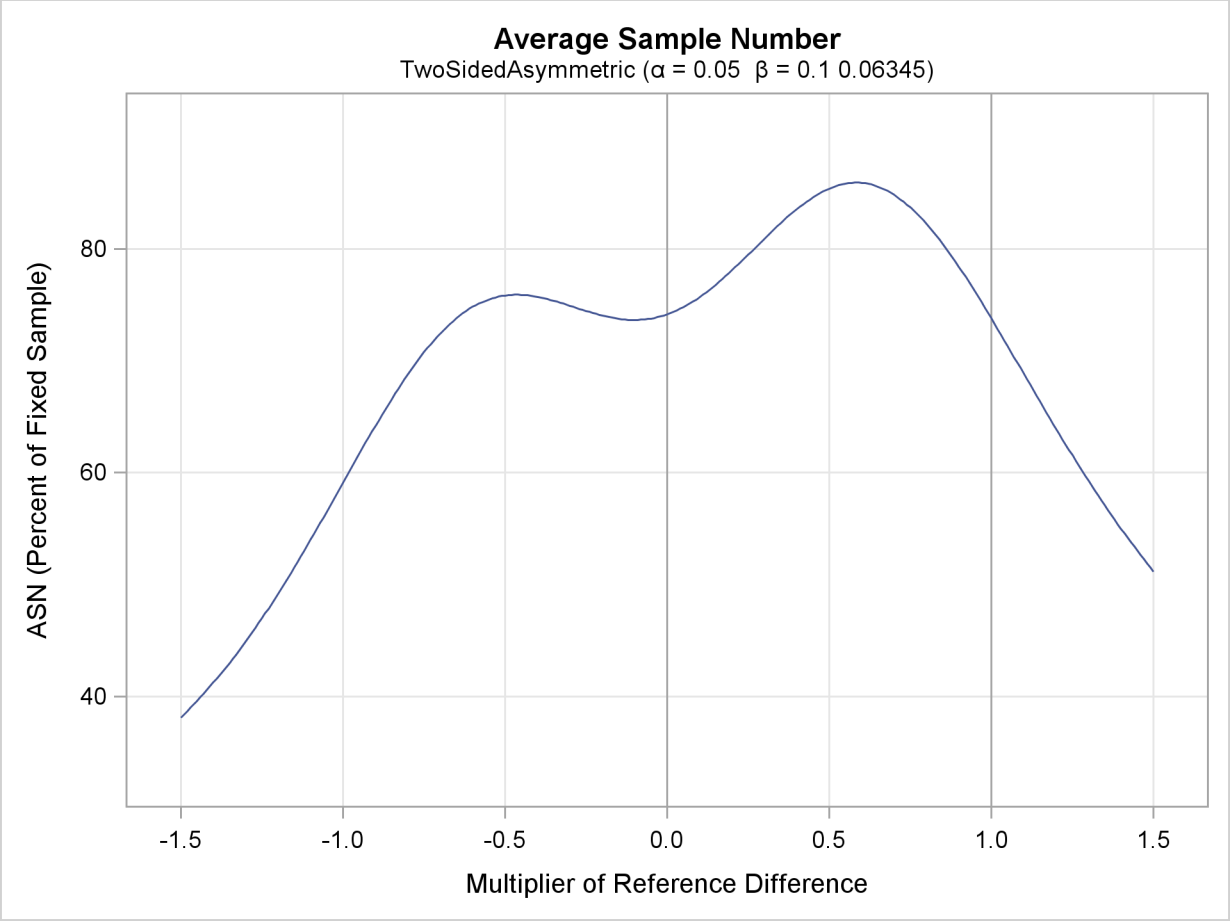


Powers and Expected Sample Sizes
Reference = CRef * (Alt Reference)

CRef	Ref	Power	-Sample Size- Percent Fixed-Sample
0.0000	Lower Alt	0.02500	74.1665
0.5000	Lower Alt	0.34601	75.8425
1.0000	Lower Alt	0.90000	59.1027
0.0000	Upper Alt	0.02500	74.1665
0.5000	Upper Alt	0.41647	85.3976
1.0000	Upper Alt	0.93655	73.7880

Note that at $c_i = 0$, the null reference $\theta = 0$, the power with the lower alternative is the lower α error 0.025, and the power with the upper alternative is the upper α error 0.025. At $c_i = 1$, the alternative reference $\theta = \theta_1$, the power with the lower alternative is the specified power 0.90, and the power with the upper alternative 0.93655 is greater than the specified power 0.90 because the same information level is used for these two asymmetric boundaries.

With the PLOTS=POWER option, the procedure displays a plot of the power curves under various hypothetical references, as shown in Output 77.12.5. By default, powers under the lower hypotheses $\theta = c_i\,\theta_{1l}$ and under the upper hypotheses $\theta = c_i\,\theta_{1u}$, are displayed for a two-sided asymmetric design, where $c_i = 0, 0.01, 0.02, \ldots, 1.50$ and $\theta_{1l} = -1$ and $\theta_{1u} = 1$ are the lower and upper alternative references, respectively.



Output 77.12.5 Power Plot

The horizontal axis displays the multiplier of the reference difference. A positive multiplier corresponds to c_i for the upper alternative hypothesis, and a negative multiplier corresponds to $-c_i$ for the lower alternative hypothesis. For lower reference hypotheses, the power is the lower α error 0.025 under the null hypothesis ($c_i = 0$) and is 0.90 under the alternative hypothesis ($c_i = 1$). For upper reference hypotheses, the power is the upper α error 0.025 under the null hypothesis ($c_i = 0$) and is 0.93655 under the alternative hypothesis ($c_i = 1$).

With the PLOTS=ASN option, the procedure displays a plot of expected sample sizes under various hypothetical references, as shown in Output 77.12.6. By default, expected sample sizes under the lower hypotheses $\theta = c_i\,\theta_{1l}$ and under the upper hypotheses $\theta = c_i\,\theta_{1u}$ are displayed for a two-sided asymmetric design, where $c_i = 0, 0.01, 0.02, \ldots, 1.50$ and $\theta_{1l} = -1$ and $\theta_{1u} = 1$ are the lower and upper alternative references, respectively.

Output 77.12.6 ASN Plot

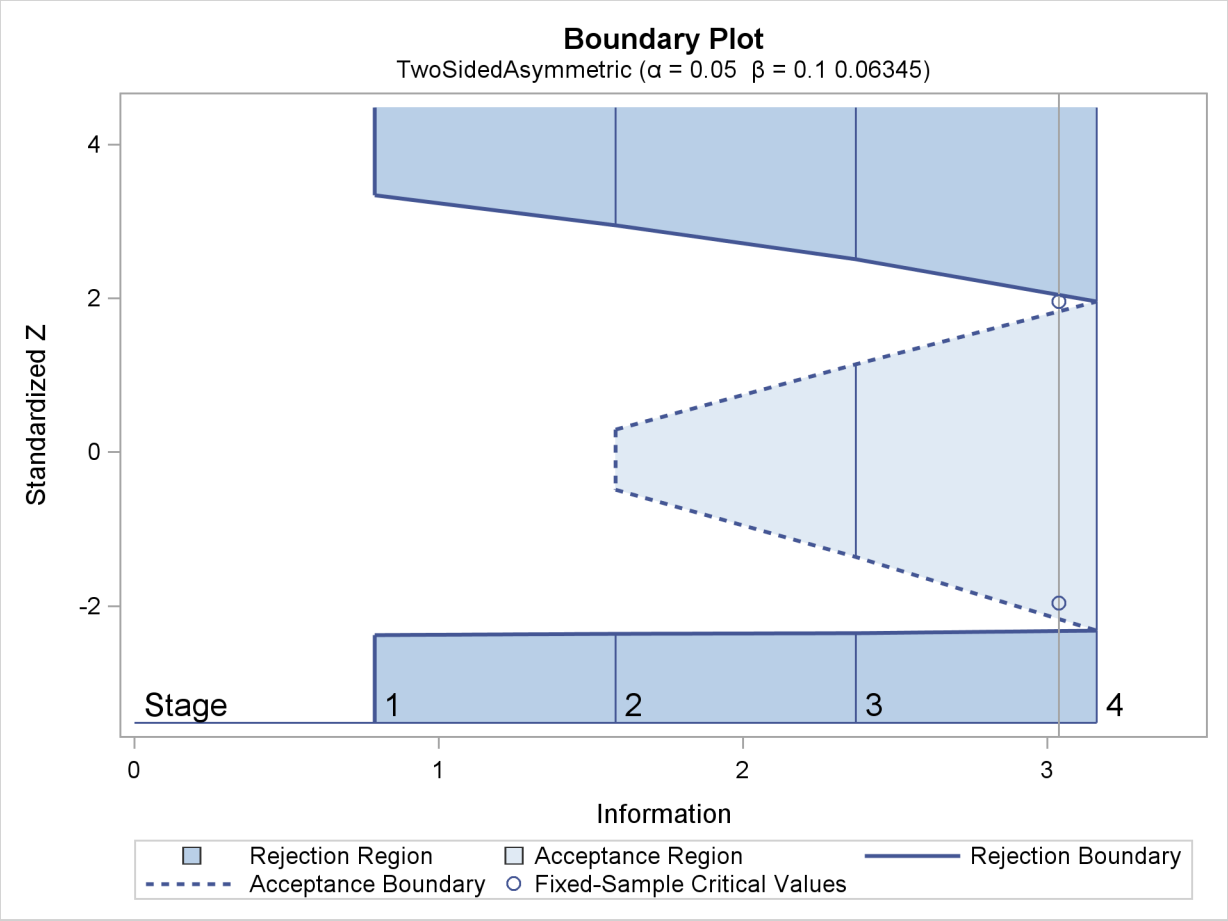
The horizontal axis displays the multiplier of the reference difference. A positive multiplier corresponds to c_i for the upper alternative hypothesis, and a negative multiplier corresponds to $-c_i$ for the lower alternative hypothesis.

By default, or when you specify BETAOVERLAP=ADJUST, the SEQDESIGN procedure first derives boundary values without adjusting for the possible overlapping of the two one-sided β boundaries based on two corresponding one-sided tests. Then the procedure checks for overlapping of the β boundaries at the interim stages. Since the two β boundaries overlap at stage 1, the β boundary values for stage 1 are set to missing, the β spending values at stage 1 are set to zero, and the β spending values at subsequent stages are adjusted proportionally.

The "Boundary Information" table in Output 77.12.7 displays the information levels, alternative references, and boundary values. The default BOUNDARYSCALE=STDZ option specifies that the standardized Z scale be used to display the alternative references and boundary values. The resulting standardized alternative references at stage k is given by $\pm\theta_1\sqrt{I_k}$, where θ_1 is the specified alternative reference and I_k is the information level at stage k, $k = 1, 2, 3, 4$.

Output 77.12.7 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0



Stage	---Information Level-- Proportion	Actual	-------Alternative------ --------Reference------- Lower	Upper
1	0.2500	0.790597	-1.77831	1.77831
2	0.5000	1.581193	-2.51491	2.51491
3	0.7500	2.37179	-3.08012	3.08012
4	1.0000	3.162386	-3.55662	3.55662

Boundary Information (Standardized Z Scale)
Null Reference = 0

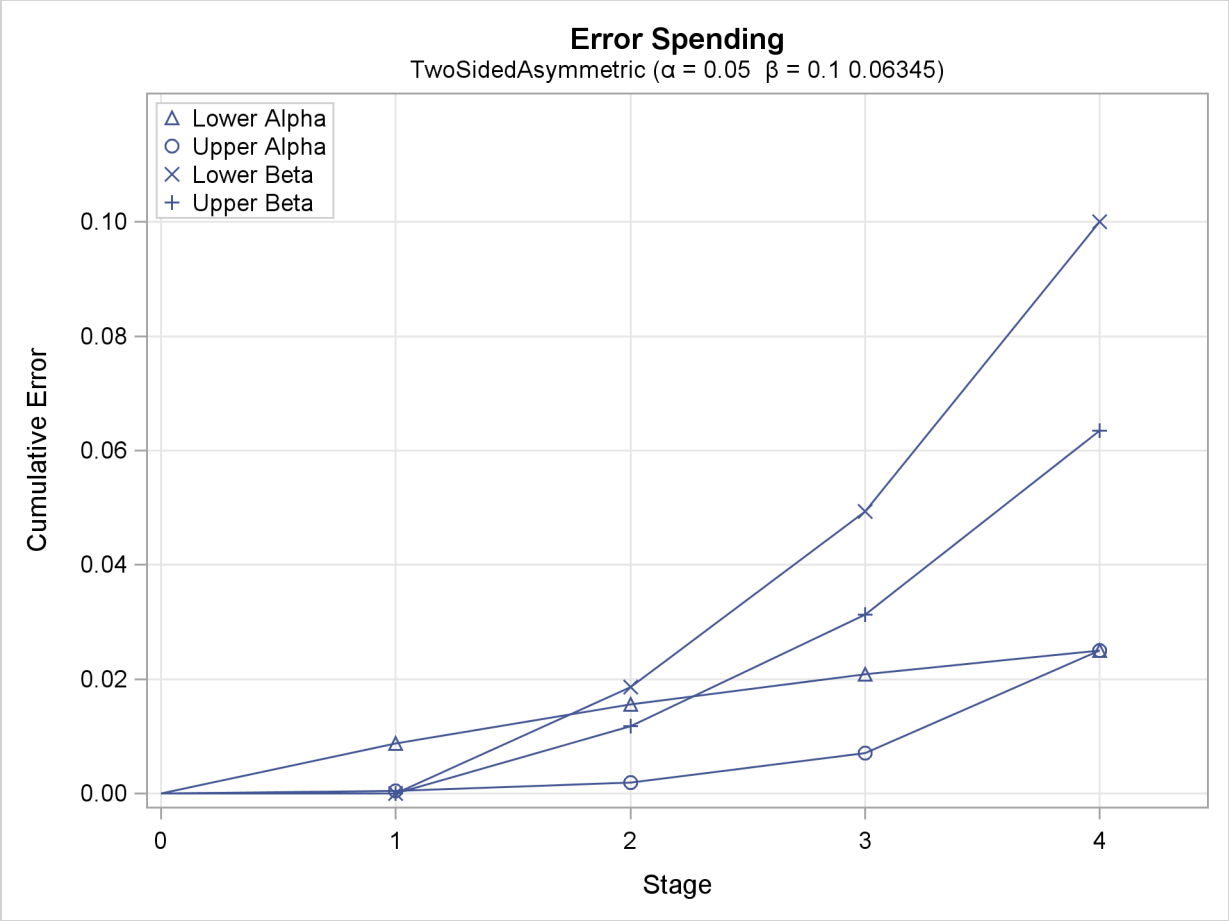
	----------Boundary Values---------- ----------Lower----------		----------Upper----------	
Stage	Alpha	Beta	Beta	Alpha
1	-2.37610	.	.	3.33772
2	-2.35714	-0.48408	0.29400	2.94871
3	-2.34861	-1.36183	1.13898	2.50473
4	-2.32105	-2.32105	1.95675	1.95675

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 77.12.8.

Output 77.12.8 Boundary Plot

The "Error Spending Information" in Output 77.12.9 displays the cumulative error spending at each stage for each boundary.

Output 77.12.9 Error Spending Information



Error Spending Information

		Cumulative Error Spending			
	Information Level	Lower		Upper	
Stage	Proportion	Alpha	Beta	Beta	Alpha
1	0.2500	0.00875	0.00000	0.00002	0.00042
2	0.5000	0.01556	0.01863	0.01184	0.00190
3	0.7500	0.02087	0.04935	0.03132	0.00704
4	1.0000	0.02500	0.10000	0.06345	0.02500

With the β boundary values missing at stage 1, there is no early stopping to accept H_0 at stage 1, and the corresponding β spending at stage 1 is computed from the rejection region. For example, the upper β spending at stage 1 (0.00002) is the probability of rejecting H_0 for the lower alternative under the upper alternative reference.

With the PLOTS=ERRSPEND option, the procedure displays a plot of the cumulative error spending on each boundary at each stage, as shown in Output 77.12.10.

Output 77.12.10 Error Spending Plot

Acknowledgments

In addition to being shaped by the research literature listed in the section "References" on page 5979, the development of the SEQDESIGN and SEQTEST procedures has benefited significantly from the advice and expertise of the following researchers:

- Lu Cui, Eisai Medical Research
- Alex Dmitrienko, Eli Lilly
- Scott Emerson, University of Washington
- Gordon Lan, Johnson & Johnson
- Steve Snapinn, Amgen
- John Whitehead, University of Reading

The time and effort that these researchers have contributed is gratefully acknowledged.

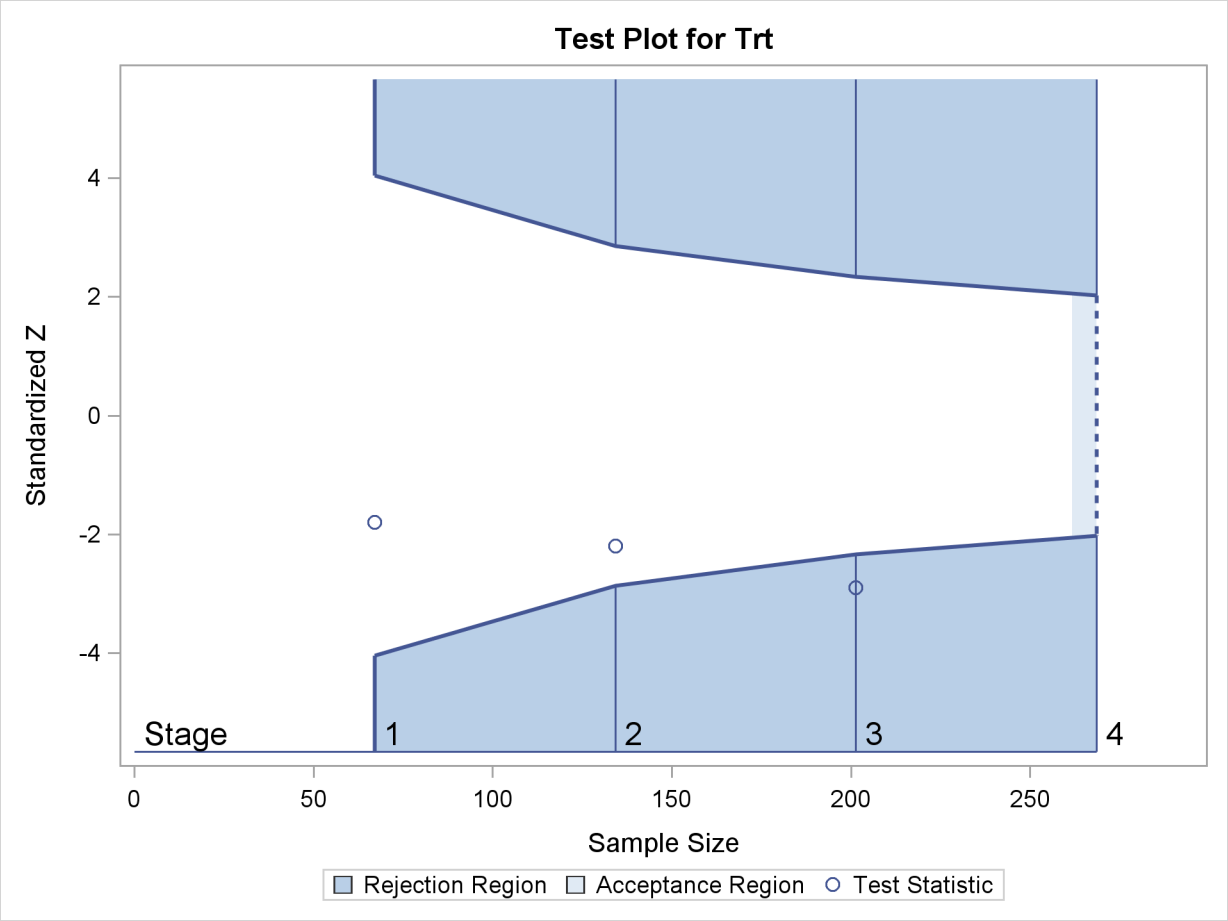
Overview: SEQTEST Procedure

The purpose of the SEQTEST procedure is to perform interim analyses for clinical trials. Clinical trials are experiments on human beings to demonstrate the efficacy and safety of new drugs or treatments. A simple example is a trial to test the effectiveness of a new drug in humans by comparing the outcomes in a group of patients who receive the new drug with the outcomes in a comparable group of patients who receive a placebo.

A clinical trial is conducted according to a plan called a *protocol*. A protocol details the objectives of the trial, the data collection process, and the analyses of the data. The protocol contains information such as a null hypothesis and an alternative hypothesis, a test statistic, the probability α of a Type I error (incorrectly rejecting the null hypothesis), the probability β of a Type II error (incorrectly accepting the null hypothesis), the sample size needed to attain a specified power (probability of correctly rejecting the null hypothesis) of $1 - \beta$ at an alternative reference, and critical values that are associated with the test statistic for hypothesis testing.

In a fixed-sample trial, data about all individuals are first collected and then examined at the end of the study. Most major trials have data safety monitoring boards or data monitoring committees that periodically monitor safety and efficacy data during the trial and recommend that a trial be stopped for safety concerns such as an unacceptable toxicity level. In certain rare situations, the board or committee might even recommend that a trial be stopped for efficacy. In contrast to a fixed-sample trial, a group sequential trial provides for interim analyses before the formal completion of the trial while maintaining the specified overall Type I and Type II error probability levels.

A group sequential trial is most useful in situations where it is important to monitor the trial to prevent unnecessary exposure of patients to an unsafe new drug, or alternatively to a placebo treatment if the new drug shows significant improvement. If a group sequential trial stops early, then it usually requires fewer participants than a corresponding fixed-sample trial.



Thus, in most cases, if a group sequential trial stops early for safety of the new treatment, fewer patients will be exposed to the new treatment than in the fixed-sample trial. Also, if a trial stops early for efficacy of the new treatment, the new treatment will be available sooner than it would be in a fixed-sample trial. Furthermore, if a trial stops early, this can also save time and resources.

A group sequential design provides detailed specifications for a group sequential trial. In addition to the usual specification for a fixed-sample design, it provides the total number of stages (the number of interim stages plus a final stage) and a stopping criterion to reject, to accept, or to either reject or accept the null hypothesis at each interim stage. It also provides critical values and the sample size at each stage for the trial.

At each interim stage, the data collected at the current stage in addition to the data collected at previous stages are analyzed, and statistics such as a maximum likelihood test statistic and its associated standard error are computed. The test statistic is then compared with its corresponding critical values at the stage, and the trial is stopped or continued. If a trial continues to the final stage, the null hypothesis is either rejected or accepted. The critical values for each stage are chosen in such a way to maintain the overall α level, the overall β level, or both the overall α and β levels.

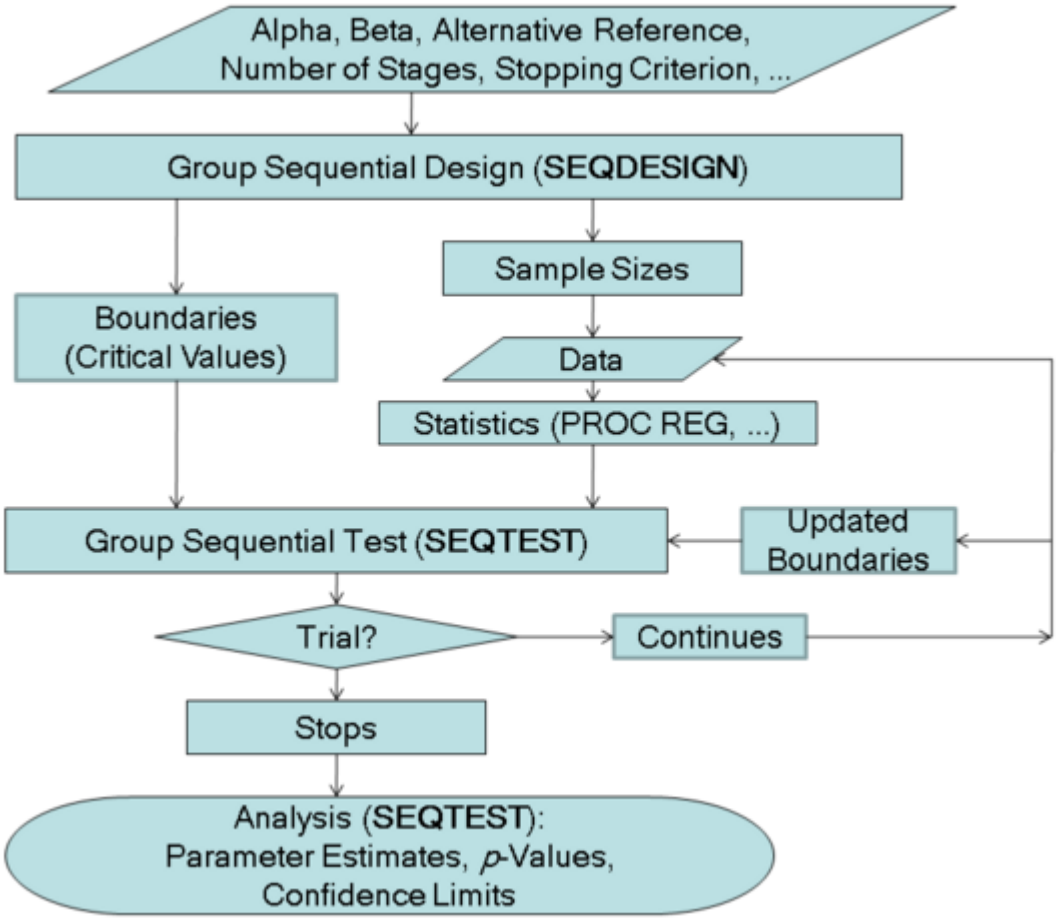
Figure 78.1 shows a two-sided symmetric group sequential trial that stops early to reject the null hypothesis that the parameter Trt is zero.

Figure 78.1 Sequential Plot for Two-Sided Test

The trial has four stages, which are indicated by vertical lines with accompanying stage numbers. With early stopping to reject the null hypothesis, the lower rejection boundary is constructed by connecting the lower critical values (boundary values) for the stages. Similarly, the upper rejection boundary is constructed by connecting the upper critical values for the stages. The horizontal axis indicates the sample size for the group sequential trial, and the vertical axis indicates the boundary values and test statistics on the standardized Z scale.

At each interim stage, if the standardized Z test statistic falls into a rejection region (the darker shaded areas in Figure 78.1), the trial stops and the null hypothesis is rejected. Otherwise, the trial continues to the next stage. At the final stage (stage 4), the trial is rejected if Z falls into a rejection region. Otherwise, the trial is accepted. In Figure 78.1, the test statistic does not fall into the rejection regions for stages 1 and 2, and so the trial continues to stage 3. At stage 3, the test statistic falls into the rejection region, and the null hypothesis is rejected.

A group sequential trial usually involves six steps:



1. You specify the statistical details of the design, including the null and alternative hypotheses, a test statistic for the hypothesis test, the Type I and II error probabilities, a stopping criterion, the total number of stages, and the relative information level at each stage.
2. You compute the boundary values for the trial based on the specifications in Step 1. You also compute the sample size required at each stage for the specified hypothesis test.
3. At each stage, you collect additional data with the required sample sizes. The data available at each stage include the data collected at previous stages in addition to the data collected at the current stage.
4. At each stage, you analyze the available data with a procedure such as the REG procedure, and you compute the test statistic.
5. At each stage, you compare the test statistic with the corresponding boundary values. You stop the trial to reject or accept the hypothesis, or you continue the trial to the next stage. If you continue the trial to the final stage, you either accept or reject the hypothesis.
6. After the trial stops, you compute parameter estimates, confidence limits for the parameter, and a p-value for the hypothesis test.

You use the companion SEQDESIGN procedure at Step 2 to compute the boundary values and required sample sizes for the trial. You use the SEQTEST procedure at Step 5 to compare the test statistic with its boundary values. At stage 1, the boundary values are derived by using the boundary information tables created by the SEQDESIGN procedure. These boundary information tables are structured for input to the SEQTEST procedure. At each subsequent stage, the boundary values are derived by using the test information tables created by the SEQTEST procedure at the previous stage. These test information tables are also structured for input to the SEQTEST procedure. You also use the SEQTEST procedure at Step 6 to compute parameter estimates, confidence limits, and p-values after the trial stops.

Note that for some clinical trials, the information levels are derived from statistics based on individuals specified in the design plan and might not reach the target maximum information level. For example, if an estimate of the variance is used to compute the required sample size for a group sequential trial, the computed variance at each stage might not be the same as the estimated variance. Thus, instead of specifying the number of individuals in the protocol, the information level can be specified. You can then adjust the sample sizes with the updated variance estimate at interim stages to achieve the target maximum information level for the trial (Jennison and Turnbull 2000, p. 295).

The flowchart in Figure 78.2 summarizes the steps in a typical group sequential trial and the relevant SAS procedures.

Figure 78.2 Group Sequential Trial

Features of the SEQTEST Procedure

At each stage, the data are analyzed with a statistical procedure such as the REG procedure, and a test statistic and its associated information level are computed. The information level is the amount of information available about the unknown parameter. For a maximum likelihood statistic, the information level is the inverse of its variance.

At each stage, you use the SEQTEST procedure to compare the test statistic with its boundary values. At stage 1, the boundary values are derived by using the boundary information tables created by the SEQDESIGN procedure. At each subsequent stage, the boundary values are derived by using the test information tables created by the SEQTEST procedure at the previous stage.

If the observed information level does not match the corresponding information level in the BOUNDARY= data set, the SEQTEST procedure modifies the boundary values to adjust for new information levels at the current and subsequent stages. See the section "Boundary Adjustments for Information Levels" on page 6017 for a detailed description of these boundary adjustments.

Either you can specify the test statistic and its information level in the DATA= input data set, or you can specify the test statistic and its associated standard error in the PARMS= input data set. With

the PARMS= input data set, the information level for the test statistic is computed from its standard error. See the section "Input Data Sets" on page 6012 for a detailed description of these input data sets.

At the end of a trial, the parameter estimate is computed. The median unbiased estimate, confidence limits, and p-value depend on the specified sample space ordering. A sample space ordering specifies the ordering for test statistics that result in the stopping of a trial. That is, for all the statistics in the rejection region and in acceptance region, the SEQTEST procedure provides three different sample space orderings: the stagewise ordering uses counterclockwise ordering around the continuation region, the LR ordering uses the distance between the observed Z statistic z and its hypothetical value, and the MLE ordering uses the observed maximum likelihood estimate. See the section "Available Sample Space Orderings in a Sequential Test" on page 6025 for a detailed description of these orderings.

Output from the SEQTEST Procedure

In addition to the adjusted boundary values and test results for the group sequential trial, the SEQTEST procedure also computes the following quantities:

- average sample numbers (as percentages of the corresponding fixed-sample sizes for nonsurvival data or fixed-sample numbers of events for survival data) under various hypothetical references, including the null and alternative references
- stopping probabilities at each stage under various hypothetical references to indicate how likely it is that the trial will stop at that stage
- conditional power given the most recently observed statistic under specified hypothetical references
- predictive power given the most recently observed statistic
- repeated confidence intervals for the parameter from the observed statistic at each stage
- parameter estimate, p-value for hypothesis testing, and median and confidence limits for the parameter at the conclusion of a sequential trial

Getting Started: SEQTEST Procedure

The following example illustrates a clinical study that uses a two-sided O'Brien-Fleming design (O'Brien and Fleming 1979) to stop the trial early for ethical concerns about possible harm or for unexpectedly strong efficacy of the new drug.

Suppose that a pharmaceutical company is conducting a clinical trial to test the efficacy of a new cholesterol-lowering drug. The primary focus is low-density lipoprotein (LDL), the so-called bad cholesterol, which is a risk factor for coronary heart disease. LDL is measured in mg/dL, milligrams per deciliter of blood.

The trial consists of two groups of equally allocated patients with elevated LDL level: an experimental group given the new drug and a placebo control group. Suppose the changes in LDL level after the treatment for patients in the experimental and control groups are normally distributed with means μ_e and μ_c, respectively, and have a common variance σ^2. Then the null hypothesis of no effect for the new drug is $H_0 : \theta = \mu_e - \mu_c = 0$. Also suppose that the alternative reference $\theta = -10$ is the clinically meaningful difference that the trial should detect with a high probability (power), and that a good estimate of the standard deviation for the changes in LDL level is $\hat{\sigma} = 20$.

The following statements invoke the SEQDESIGN procedure and request a four-stage O'Brien-Fleming design for standardized normal test statistics:

```
ods graphics on;
proc seqdesign altref=-10.0;
  TwoSidedOBrienFleming: design nstages=4
                         method=obf
                         ;
  samplesize model=twosamplemean(stddev=20);
  ods output Boundary=Bnd_LDL;
run;
ods graphics off;
```

The ALTREF= option specifies the alternative reference, and the actual maximum information is derived in the SEQDESIGN procedure.

In the DESIGN statement, the label `TwoSidedOBrienFleming` identifies the design in the output tables. The default ALT=TWOSIDED option specifies a two-sided alternative hypothesis. The default STOP=REJECT option specifies early stopping in the interim stages only for the purpose of rejecting the null hypothesis. That is, at each interim stage, the trial will either be stopped to reject the null hypothesis or continue to the next stage.

The NSTAGES=4 option in the DESIGN statement specifies the total number of stages in the group sequential trial, including three interim stages and a final stage. In the SEQDESIGN procedure, the null hypothesis for the design is $H_0 : \theta = 0$. The default ALPHA=0.05 option specifies a Type I error probability $\alpha = 0.05$, and the default BETA=0.10 option specifies a Type II error probability $\beta = 0.10$, which corresponds to a power of $1-\beta = 0.90$ at the alternative reference $H_1 : \theta = -10$.

For a two-sided design with early stopping to reject the null hypothesis, there are two boundaries for the design: an upper α (rejection) boundary that consists of upper rejection critical values and a lower α boundary that consists of lower rejection critical values. Each boundary is a set of critical values, one from each stage. With the METHOD=OBF option in the DESIGN statement, the O'Brien-Fleming method is used for the two boundaries for the design; see Figure 78.5.

The SAMPLESIZE statement with the MODEL=TWOSAMPLEMEAN option uses the derived maximum information to compute required sample sizes for a two-sample test for mean difference.

The ODS OUTPUT statement with the BOUNDARY=BND_LDL option creates an output data set named BND_LDL which contains the resulting boundary information. At each stage of the trial, data are collected and analyzed with a statistical procedure, and a test statistic and its corresponding information level are computed.

In this example, you can use the REG procedure to compute the maximum likelihood estimate $\hat{\theta}$ for the drug effect and the corresponding standard error for $\hat{\theta}$. At stage 1, you can use the SEQTEST procedure to compare the test statistic with adjusted boundaries that are derived from the boundary information stored in the BOUND_LDL data set. At each subsequent stage, you can use the SEQTEST procedure to compare the test statistic with adjusted boundaries that are derived from the boundary information stored in the test information table that was created by the SEQTEST procedure at the previous stage. The test information tables are structured for input to the SEQTEST procedure.

At each interim stage, the trial will either be stopped to reject the null hypothesis or continue to the next stage. At the final stage, the null hypothesis is either rejected or accepted.

By default, the SEQDESIGN procedure derives boundary values with equally spaced information levels for all stages—that is, the same information increment between successive stages.

The "Design Information" table in Figure 78.3 displays design specifications and three derived statistics: the maximum information, the average sample number under the null hypothesis (Null Ref ASN), and the average sample number under the alternative hypothesis (Alt Ref ASN). Each statistic is expressed as a percentage of the identical statistic for the corresponding fixed-sample information. The average sample number is the expected sample size (for nonsurvival data) or expected number of events (for survival data). When you specify an alternative reference (in this case, ALTREF=−10), the actual maximum information 0.1074 is also computed. Note that for a symmetric two-sided design, the ALTREF=−10 option implies a lower alternative reference of −10 and an upper alternative reference of 10.

Figure 78.3 O'Brien-Fleming Design Information

The SEQDESIGN Procedure
Design: TwoSidedOBrienFleming

Design Information

Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	-10
Number of Stages	4
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	102.2163
Max Information	0.107403
Null Ref ASN (Percent of Fixed Sample)	101.5728
Alt Ref ASN (Percent of Fixed Sample)	76.7397

The "Boundary Information" table in Figure 78.4 displays the information level, the lower and upper alternative references, and the lower and upper boundary values at each stage. By default, the SEQDESIGN procedure uses equally spaced information levels for all stages.

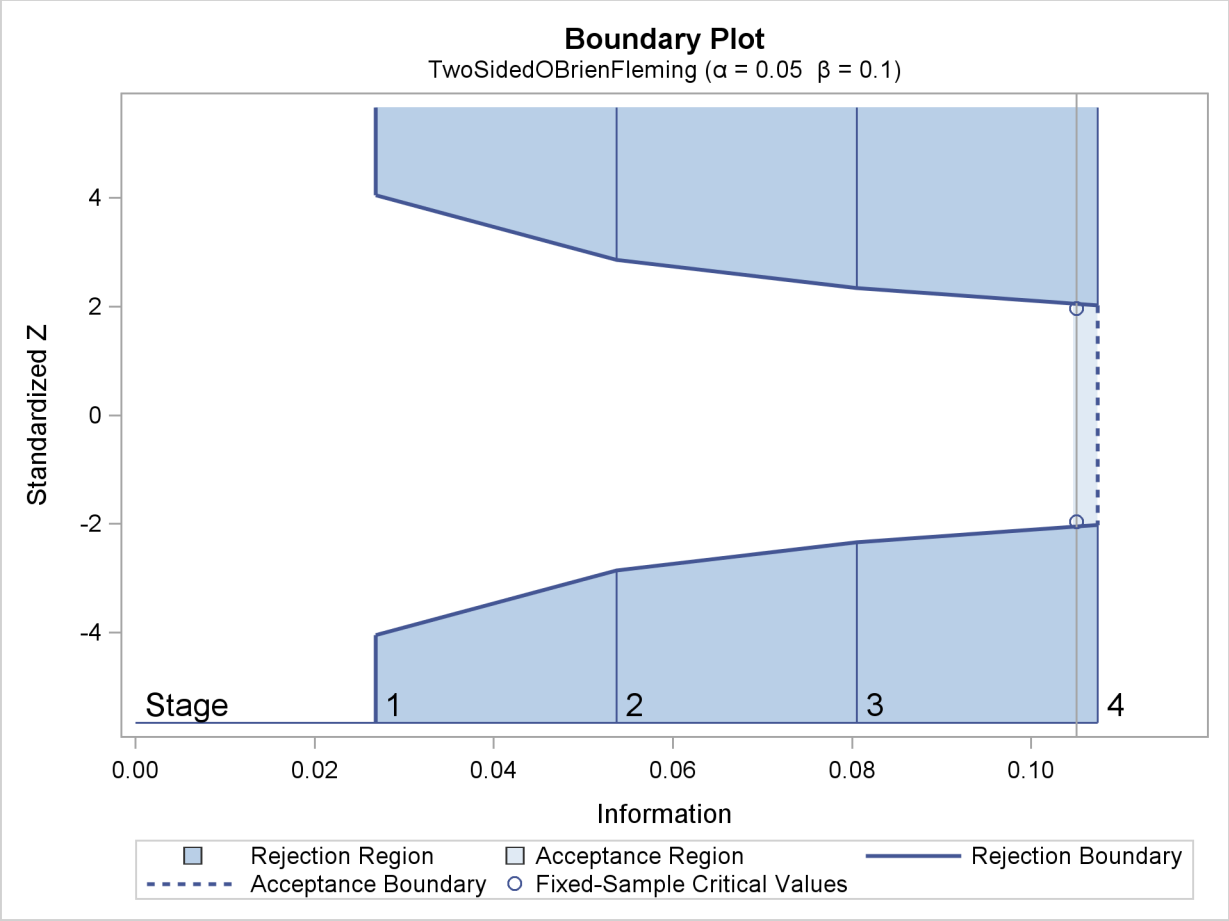
Figure 78.4 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0

Stage	Information Level Proportion	Information Level Actual	Information Level N	Alternative Reference Lower	Alternative Reference Upper
1	0.2500	0.026851	42.96116	-1.63862	1.63862
2	0.5000	0.053701	85.92233	-2.31736	2.31736
3	0.7500	0.080552	128.8835	-2.83817	2.83817
4	1.0000	0.107403	171.8447	-3.27724	3.27724

Boundary Information (Standardized Z Scale)
Null Reference = 0

Stage	Boundary Values Lower Alpha	Boundary Values Upper Alpha
1	-4.04859	4.04859
2	-2.86278	2.86278
3	-2.33745	2.33745
4	-2.02429	2.02429



The information proportion is the proportion of maximum information available at each stage. With the BOUNDARYSCALE=STDZ option, the alternative references and boundary values are displayed with the standardized Z statistic scale. The alternative reference in the standardized Z scale at stage k is given by $\theta_1\sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information available at stage k, $k = 1, 2, 3, 4$.

In this example, a standardized Z statistic is computed by standardizing the parameter estimate of the effect in LDL level. A lower Z test statistic indicates a beneficial effect. Consequently, at each interim stage, if the standardized Z test statistic is less than or equal to the corresponding lower α boundary value, the hypothesis $H_0 : \theta = 0$ is rejected for efficacy. If the test statistic is greater than or equal to the corresponding upper α boundary value, the hypothesis H_0 is rejected for harmful effect. Otherwise, the process continues to the next stage. At the final stage (stage 4), the hypothesis H_0 is rejected for efficacy if the Z statistic is less than or equal to the corresponding lower α boundary value -2.0243, and the hypothesis H_0 is rejected for harmful effect if the Z statistic is greater than or equal to the corresponding upper α boundary value 2.0243. Otherwise, the hypothesis of no significant difference is accepted.

Note that in a typical trial, the actual information levels do not match the information levels specified in the design. Consequently, the SEQTEST procedure modifies the boundary values stored in the BND_LDL data set to adjust for these new information levels.

If the ODS GRAPHICS ON statement is specified, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Figure 78.5.

Figure 78.5 O'Brien-Fleming Boundary Plot

This boundary plot displays the boundary values in the "Boundary Information" table in Figure 78.4. The stages are indicated by vertical lines with accompanying stage numbers. The horizontal axis indicates the information levels for the stages. If a test statistic at an interim stage is in the rejection region (shaded area), the trial stops and the null hypothesis is rejected. If the statistic is not in any rejection region, the trial continues to the next stage. The plot also displays critical values for the corresponding fixed-sample design. The symbol "○" identifies the fixed-sample critical values of -1.96 and 1.96.

When you specify the SAMPLESIZE statement, the maximum information (either explicitly specified or derived in the SEQDESIGN procedure) is used to compute the required sample sizes for the study. The MODEL=TWOSAMPLEMEAN(STDDEV=20) option specifies the test for the difference between two normal means. See the section "Test for the Difference between Two Normal Means" in the chapter "The SEQDESIGN Procedure" for a detailed description of how these required sample sizes are calculated.

The "Sample Size Summary" table in Figure 78.6 displays the parameters for the sample size computation and the resulting maximum and expected sample sizes.

Figure 78.6 Required Sample Size Summary

Sample Size Summary

Test	Two-Sample Means
Mean Difference	-10
Standard Deviation	20
Max Sample Size	171.8447
Expected Sample Size (Null Ref)	170.7627
Expected Sample Size (Alt Ref)	129.0137

With the derived maximum information 0.1074 and the specified MODEL=TWOSAMPLEMEAN (STDDEV=20) option in the SAMPLESIZE statement, the total sample size in each group is

$$N_a = N_b = 2\sigma^2 I_X = 2 \times 20^2 \times 0.1074 = 85.92$$

The "Sample Sizes (N)" table in Figure 78.7 displays the required sample sizes at each stage for the trial, in both fractional and integer numbers. The derived fractional sample sizes are displayed under the heading "Fractional N." These sample sizes are rounded up to integers under the heading "Ceiling N." With the default WEIGHT=1 option in the SAMPLESIZE statement, the sample sizes for the two groups are equal for the two-sample test.

Figure 78.7 Required Sample Sizes

Sample Sizes (N)
Two-Sample Z Test for Mean Difference

	Fractional N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	42.96	21.48	21.48	0.0269
2	85.92	42.96	42.96	0.0537
3	128.88	64.44	64.44	0.0806
4	171.84	85.92	85.92	0.1074

Sample Sizes (N)
Two-Sample Z Test for Mean Difference

	Ceiling N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	44	22	22	0.0275
2	86	43	43	0.0538
3	130	65	65	0.0812
4	172	86	86	0.1075

In practice, integer sample sizes are used in the trial, and the resulting information levels increase slightly. Thus, each of the two groups needs 22, 43, 65, and 86 patients for the four stages, respectively.

Suppose that 22 patients are available in each group at stage 1 and that their measurements for LDL are saved in the data set LDL_1. Figure 78.8 lists the first 10 observations in the data set LDL_1.

Figure 78.8 Clinical Trial Data

First 10 Obs in the Trial Data

Obs	Trt	Ldl
1	0	33.33
2	1	-14.89
3	0	15.30
4	1	4.71
5	0	26.89
6	1	-48.74
7	0	-39.35
8	1	-8.13
9	0	-8.22
10	1	12.35

The variable Trt is an indicator variable with value 1 for patients in the treatment group and value 0 for patients in the placebo control group. The variable Ldl is the LDL level of these patients.

The following statements use the REG procedure to estimate the mean treatment difference and its associated standard error at stage 1:

```
proc reg data=LDL_1;
   model Ldl=Trt;
ods output ParameterEstimates=Parms_LDL1;
run;
```

The following statements create the data set for the mean treatment difference and its associated standard error as a PARMS= data set, which will subsequently serve as an input data set for PROC SEQTEST. Note that all of the variables are required for a PARMS= data set, as described in the section "PARMS < (TESTVAR= *variable*) > = SAS Data Set" on page 6014.

```
data Parms_LDL1;
   set Parms_LDL1;
   if Variable='Trt';
   _Scale_='MLE';
   _Stage_= 1;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_LDL1;
   title 'Statistics Computed at Stage 1';
run;
```

Figure 78.9 displays the statistics computed at stage 1.

Figure 78.9 Statistics Computed at Stage 1

Statistics Computed at Stage 1

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Trt	-2.52591	5.68572	MLE	1

Since the sample sizes derived are based on the estimated variance at the designing phase, the information level that corresponds to the test statistic at stage 1 is estimated by

$$I_1 = \frac{1}{s_1^2} = \frac{1}{5.686^2} = 0.0309$$

where s_1 is the standard error of the treatment estimate.

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_LDL
             Parms(Testvar=Trt)=Parms_LDL1
             ;
ods output Test=Test_LDL1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_LDL1 option specifies the input data set PARMS_LDL1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=TRT option identifies the test variable TRT in the data set.

The ODS OUTPUT statement with the TEST=TEST_LDL1 option creates an output data set named TEST_LDL1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage. See the section "Boundary Adjustments for Information Levels" on page 6017 for details.

The "Design Information" table in Figure 78.10 displays design specifications. By default, the boundary values are modified for the updated information levels to maintain the Type I α level. The maximum information remains the same as in the original design, but the derived Type II error probability β and power $1 - \beta$ are slightly different with new information levels. With the updated power $1 - \beta$, the corresponding fixed-sample design is also updated.

Figure 78.10 Design Information

The SEQTEST Procedure

Design Information

BOUNDARY Data Set	WORK.BND_LDL
Data Set	WORK.PARMS_LDL1
Statistic Distribution	Normal

Beta	0.10074
Power	0.89926
Max Information (Percent of Fixed Sample)	102.4815
Max Information	0.10740291
Null Ref ASN (Percent of Fixed Sample)	101.7765
Alt Ref ASN (Percent of Fixed Sample)	75.4928

The "Test Information" table in Figure 78.11 displays the boundary values for the test statistic with the default standardized Z scale. Since only the information level at stage 1 is available from the PARMS= data set, information levels at future interim stages are derived proportionally from the corresponding information levels in the original design.

Figure 78.11 Sequential Tests

Test Information (Standardized Z Scale)
Null Reference = 0

	Information Level		Alternative Reference		Boundary Values	
Stage	Proportion	Actual	Lower	Upper	Lower Alpha	Upper Alpha
1	0.2880	0.030934	-1.75879	1.75879	-3.39532	3.39532
2	0.5253	0.056423	-2.37536	2.37536	-2.77374	2.77374

Test Information (Standardized Z Scale)
Null Reference = 0

	Test Trt	
Stage	Estimate	Action
1	-0.44426	Continue
2	.	
3	.	
4	.	

At stage 1, the standardized Z statistic -0.44426 is between the lower and upper α boundary values, and so the trial continues to the next stage. With the observed information level at stage 1, $I_1 = 0.0309$ (which is not substantially different from the target information level at stage 1), the trial continues to the next stage without adjustment of the sample size according to the study plan.

Note that if an observed information level is different from its target level at an interim stage, the sample sizes at future stages might be adjusted to achieve the target maximum information level according to the study plan. For example, a study plan might modify the final sample size to achieve the target maximum information level if the observed information level is different from its target level by a specified amount at the interim stage. If the variance estimate is used to compute the required sample size for the group sequential trial, the study plan might use the current variance estimate to update the required sample size for the trial (Jennison and Turnbull 2000, p. 295).

If the ODS GRAPHICS ON statement is specified, a detailed test plot with the rejection and acceptance regions is displayed by default, as shown in Figure 78.12. This plot displays the boundary values in the "Test Information" table in Figure 78.11. The stages are indicated by vertical lines with accompanying stage numbers. The horizontal axis indicates the information levels for the stages. As expected, the test statistic is in the continuation region between the lower and upper α boundaries.

Figure 78.12 Sequential Test Plot

The following statements use the REG procedure with the data available at the first two stages to estimate the mean treatment difference and its associated standard error at stage 2:

```
proc reg data=LDL_2;
   model Ldl=Trt;
ods output ParameterEstimates=Parms_LDL2;
run;
```

The following statements create and display (in Figure 78.13) the data set for the mean treatment difference and its associated standard error:

```
data Parms_LDL2;
   set Parms_LDL2;
   if Variable='Trt';
   _Scale_='MLE';
   _Stage_= 2;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_LDL2;
   title 'Statistics Computed at Stage 2';
run;
```

Figure 78.13 Statistics Computed at Stage 2

Statistics Computed at Stage 2

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Trt	-8.37628	4.24405	MLE	2

Using the standard error for the treatment estimate available at stage 2, the information level that corresponds to the test statistic at stage 2 is estimated by

$$I_2 = \frac{1}{s_2^2} = \frac{1}{4.244^2} = 0.0555$$

where s_2 is the standard error of the treatment estimate at stage 2.

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
proc seqtest Boundary=Test_LDL1
             Parms(Testvar=Trt)=Parms_LDL2
             ;
ods output Test=Test_LDL2;
run;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_LDL2 option creates an output data set named TEST_LDL2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Test Information" table in Figure 78.14 displays the boundary values for the test statistic with the default standardized Z scale.

Figure 78.14 Sequential Tests

The SEQTEST Procedure

Test Information (Standardized Z Scale)
Null Reference = 0

Stage	--Information Level- Proportion	Actual	------Alternative----- -------Reference------ Lower	Upper	----Boundary Values--- ---Lower-- Alpha	---Upper-- Alpha
1	0.2880	0.030934	-1.75879	1.75879	-3.39532	3.39532
2	0.5169	0.055519	-2.35624	2.35624	-2.78456	2.78456
3	0.7585	0.081461	-2.85413	2.85413	-2.32908	2.32908

Test Information (Standardized Z Scale)
Null Reference = 0

Stage	----------Test---------- ----------Trt---------- Estimate	Action
1	-0.44426	Continue
2	-1.97365	Continue
3	.	
4	.	

At stage 2, the standardized test statistic, $z = -8.37628/4.24405 = -1.97365$, is between its corresponding lower and upper α boundary values. Therefore, the trial continues to the next stage.

The following statements use the REG procedure with the data available at the first three stages to estimate the mean treatment difference and its associated standard error at stage 3:

```
proc reg data=LDL_3;
   model Ldl=Trt;
ods output ParameterEstimates=Parms_LDL3;
run;
```

The following statements create and display (in Figure 78.15) the data set for the mean treatment difference and its associated standard error:

```
data Parms_LDL3;
   set Parms_LDL3;
   if Variable='Trt';
   _Scale_='MLE';
   _Stage_= 3;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_LDL3;
   title 'Statistics Computed at Stage 3';
run;
```

Figure 78.15 Statistics Computed at Stage 3

Statistics Computed at Stage 3

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Trt	-9.21369	3.42149	MLE	3

The following statements invoke the SEQTEST procedure to test for early stopping at stage 3:

```
ods graphics on;
proc seqtest Boundary=Test_LDL2
             Parms(Testvar=Trt)=Parms_LDL3
             ;
ods output Test=Test_LDL3;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 3, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_LDL3 option creates an output data set named TEST_LDL3 which contains the updated boundary information for the test at stage 3. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

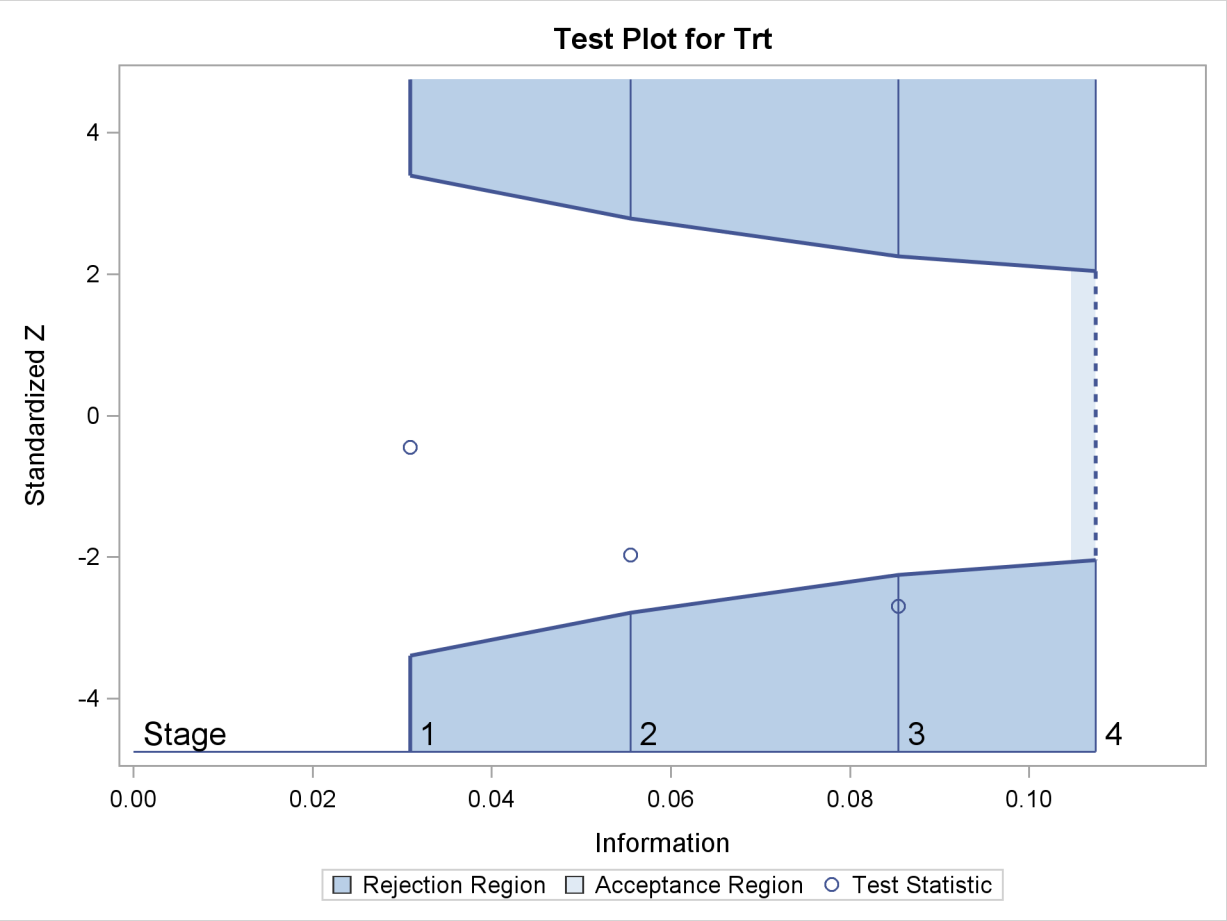
The "Test Information" table in Figure 78.16 displays the boundary values for the test statistic with the default standardized Z scale.

Figure 78.16 Sequential Tests

The SEQTEST Procedure

Test Information (Standardized Z Scale)
Null Reference = 0

Stage	--Information Level- Proportion	Actual	------Alternative----- -------Reference------ Lower	Upper	----Boundary Values--- ---Lower-- Alpha	---Upper-- Alpha
1	0.2880	0.030934	-1.75879	1.75879	-3.39532	3.39532
2	0.5169	0.055519	-2.35624	2.35624	-2.78456	2.78456
3	0.7953	0.085422	-2.92271	2.92271	-2.25480	2.25480
4	1.0000	0.107403	-3.27724	3.27724	-2.04573	2.04573



Test Information (Standardized Z Scale)
Null Reference = 0

Stage	----------Test---------- ----------Trt---------- Estimate	Action
1	-0.44426	Continue
2	-1.97365	Continue
3	-2.69289	Reject Null
4	.	

The sequential test stops at stage 3 to reject the null hypothesis for the lower alternative because the test statistic -2.69289 is less than the corresponding upper α boundary -2.25480. That is, the test demonstrates significant beneficial effect for the new drug.

The "Test Plot" displays boundary values for the design and the test statistic at the first three stages, as shown in Figure 78.17. It shows that the test statistic is in the "Rejection Region" below the lower α boundary at stage 3.

Figure 78.17 Sequential Test Plot

When a trial stops, the "Parameter Estimates" table in Figure 78.18 displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and p-value under the null hypothesis $H_0 : \theta = 0$. As expected, the p-value 0.0108 is significant at the two-sided α level, $\alpha = 0.05$, and the confidence interval does not contain the value zero. The p-value, unbiased median estimate, and confidence limits depend on the ordering of the sample space (k, z), where k is the stage number and z is the standardized Z statistic. See the section "Analysis after a Sequential Test" on page 6024 for a detailed description of these statistics.

Syntax: SEQTEST Procedure

The following PROC SEQTEST statement is required for the SEQTEST procedure:

PROC SEQTEST < *options* > ;

PROC SEQTEST Statement

Table 78.1 summarizes the options in the PROC SEQTEST statement.

Table 78.1 Summary of PROC SEQTEST Options

Option	Description
Input Data Sets	
BOUNDARY=	specifies data set for boundary information
DATA=	specifies data set for parameter estimates and information levels
PARMS=	specifies data set for parameter estimates and standard errors
Boundaries	
BETAOVERLAP=	checks for overlapping of the lower and upper β boundaries at the current and subsequent interim stages in a two-sided design
BOUNDARYADJ=	specifies boundary adjustment for information levels
BOUNDARYKEY=	specifies boundary key to maintain Type I and II error probability levels
BOUNDARYSCALE=	specifies boundary scale
ERRSPENDMIN=	specifies minimum error spending for the boundaries
NSTAGES=	specifies number of stages

Table 78.1 *continued*

Option	Description
Test Statistics	
DATA(TESTVAR=)	specifies test variable in DATA= data set
PARMS(TESTVAR=)	specifies test variable in PARMS= data set
***p*-Values and Confidence Intervals**	
CIALPHA=	specifies significance levels for the confidence interval
CITYPE=	specifies types of confidence interval
ORDER=	specifies the ordering of the sample space used to derive the p-values and confidence limits
Table Output	
CONDPOWER	displays conditional powers
ERRSPEND	displays cumulative error spending at each stage
PREDPOWER	displays predictive powers
PSS	displays powers and expected sample sizes
RCI	displays repeated confidence intervals
STOPPROB	displays expected cumulative stopping probabilities
Graphics Output	
PLOTS=ASN	displays expected sample numbers plot
PLOTS=CONDPOWER	displays conditional powers plot
PLOTS=ERRSPEND	displays error spending plot
PLOTS=POWER	displays powers plot
PLOTS=RCI	displays repeated confidence intervals plot
PLOTS=TEST	displays boundary plot with test statistics

The BOUNDARY= option provides the information for the design and is required in the PROC SEQTEST statement. By default, the SEQTEST procedure displays tables of design information and test information. If the ODS GRAPHICS ON statement is specified, the procedure also displays a sequential test plot.

The following options can be used in the PROC SEQTEST statement. They are listed in alphabetical order.

BETAOVERLAP=ADJUST | NOADJUST

OVERLAP=ADJUST | NOADJUST

specifies whether to check for overlapping of the lower and upper β boundaries for the two corresponding one-sided tests at the current and subsequent interim stages. This option applies to two-sided designs with early stopping to accept H_0, or to either accept or reject H_0. This type of overlapping might result from a small β spending at an interim stage. When you specify BETAOVERLAP=ADJUST, the procedure checks for this type of overlapping at the current and subsequent interim stages. If such overlapping is found, the β boundaries for the two-sided design at that stage are set to missing, and the β spending values at subsequent stages are adjusted, as described in the section "Boundary Adjustments for Overlapping Lower and Upper β Boundaries" on page 6020.

You can specify BETAOVERLAP=NOADJUST to request that no adjustment be made. The default is BETAOVERLAP=ADJUST.

BOUNDARY=*SAS-data-set*

names the required SAS data set that contains the design boundary information. At stage 1, the data set is usually created from the "Boundary Information" table created by the SEQDESIGN procedure. At each subsequent stage, the data set is usually created from the "Test Information" table created by the SEQTEST procedure at the previous stage. The data set includes the variables _Scale_ for the boundary scale, _Stop_ for the stopping criterion, and _ALT_ for the type of alternative hypothesis. It also includes _Stage_ for the stage number, Info_Prop for the information proportion, and a set of the boundary variables from Bound_LA, Bound_LB, Bound_UB, and Bound_UA for boundary values at each stage.

The data set might also include _Info_ for the actual information level, NObs for the number of observation, and Events for the number of events required at each stage.

BOUNDARYADJ=*method*

BOUNDARYADJ(*boundary***)=***method*

ERRSPENDADJ=*method*

ERRSPENDADJ(*boundary***)=***method*

specifies methods for boundary adjustments if the observed information level at a stage does not match the information level in the design specified with the BOUNDARY= data set. The default is BOUNDARYADJ=ERRLINE.

The following options specify available methods for the boundary adjustment:

NONE

specifies that the cumulative error spending at each interim stage not be changed, even if the corresponding information level has been changed.

ERRLINE

specifies the linear interpolation method for the adjustment.

ERRFUNCGAMMA < (GAMMA= γ **) >**

specifies the gamma function method for the adjustment. The GAMMA= suboption specifies the γ parameter in the function, where $\gamma \leq 3$. The default is GAMMA=-2.

ERRFUNCOBF

specifies the approximate O'Brien-Fleming cumulative error spending function for the adjustment.

ERRFUNCPOC

specifies the approximate Pocock cumulative error spending function for the adjustment.

ERRFUNCPOW < (RHO= ρ **) >**

specifies the power function method for the adjustment. The RHO= suboption specifies the power parameter ρ in the function, where $\rho \geq 0.25$. The default is RHO=2.

See the section "Boundary Adjustments for Information Levels" on page 6017 for a detailed description of the available boundary adjustment methods in the SEQTEST procedure.

If a boundary adjustment method is used for all boundaries in the design, you can use the BOUNDARYADJ=*method* option to specify the method. Otherwise, you can use the following BOUNDARYADJ(*boundary*)=*method* options to specify different methods for the boundaries.

BOUNDARYADJ(ALPHA)=*method*

BOUNDARYADJ(REJECT)=*method*

specifies the adjustment method for the α (rejection) boundary of a one-sided design or the lower and upper α boundaries of a two-sided design.

BOUNDARYADJ(LOWERALPHA)=*method*

BOUNDARYADJ(LOWERREJECT)=*method*

specifies the adjustment method for the lower α boundary of a two-sided design.

BOUNDARYADJ(UPPERALPHA)=*method*

BOUNDARYADJ(UPPERREJECT)=*method*

specifies the adjustment method for the upper α boundary of a two-sided design.

BOUNDARYADJ(BETA)=*method*

BOUNDARYADJ(ACCEPT)=*method*

specifies the adjustment method for the β (acceptance) boundary of a one-sided design or the lower and upper β boundaries of a two-sided design.

BOUNDARYADJ(LOWERBETA)=*method*

BOUNDARYADJ(LOWERACCEPT)=*method*

specifies the adjustment method for the lower β boundary of a two-sided design.

BOUNDARYADJ(UPPERBETA)=*method*

BOUNDARYADJ(UPPERACCEPT)=*method*

specifies the adjustment method for the upper β boundary of a two-sided design.

BOUNDARYKEY=ALPHA | BETA | BOTH

specifies the boundary key to be maintained in the boundary adjustments. The BOUNDARYKEY=ALPHA option maintains the Type I α level and derives the Type II error probability, and the BOUNDARYKEY=BETA option maintains the Type II β level and derives the Type I error probability. The BOUNDARYKEY=BOTH option maintains both α and β levels simultaneously by deriving a new maximum information. The default is BOUNDARYKEY=ALPHA.

BOUNDARYSCALE=MLE | SCORE | STDZ | PVALUE

BSCALE=MLE | SCORE | STDZ | PVALUE

specifies the boundary scale to be displayed in the output boundary table and plot. The BOUNDARYSCALE=MLE, BOUNDARYSCALE=SCORE, BOUNDARYSCALE=STDZ, and BOUNDARYSCALE=PVALUE options correspond to the boundary with the maximum likelihood estimator scale, score statistic scale, standardized normal Z scale, and p-value scale, respectively. The default is BOUNDARYSCALE=STDZ.

With the BOUNDARYSCALE=MLE or BOUNDARYSCALE=SCORE option, either the MAXINFO= option must be specified or the _Info_ variable must be in the BOUNDARY= data set to provide the necessary information level at each stage to derive the boundary values. Usually, these values are obtained from analysis output in SAS procedures.

Note that for a two-sided design, the p-value scale displays the one-sided fixed-sample p-value under the null hypothesis with a lower alternative hypothesis.

CIALPHA=α **< (< LOWER=**α_l **> < UPPER=**α_u **>) >**

specifies the significance levels for the confidence interval, where $0 < \alpha < 1$, $0 < \alpha_l < 0.5$, and $0 < \alpha_u < 0.5$. The default is CIALPHA= 0.05.

For a lower confidence interval (CITYPE=LOWER), the CIALPHA=α option produces a $(1 - \alpha)$ lower confidence interval. For an upper confidence interval (CITYPE=UPPER), the CIALPHA=α option produces a $(1 - \alpha)$ upper confidence interval. The LOWER= and UPPER= suboptions are applicable only for a two-sided confidence interval (CITYPE=TWOSIDED). The LOWER= suboption specifies the lower significance level α_l and the upper significance level $\alpha_u = 1 - \alpha_l$. The UPPER= suboption specifies the upper significance level α_u and the lower significance level $\alpha_l = 1 - \alpha_u$. If both LOWER= and UPPER= suboptions are not specified, $\alpha_l = \alpha_u = \alpha/2$. The significance levels α_l and α_u are then used for the $(1 - \alpha_l)$ lower confidence limit and $(1 - \alpha_u)$ upper confidence limit, respectively.

CITYPE=LOWER | UPPER | TWOSIDED

specifies the type of confidence interval. The CITYPE=LOWER, CITYPE=UPPER, and CITYPE=TWOSIDED options correspond to the lower confidence interval, upper confidence interval, and two-sided confidence interval, respectively. The default is CITYPE=LOWER for the design with an upper alternative, CITYPE=UPPER for the design with a lower alternative, and CITYPE=TWOSIDED for the design with a two-sided alternative.

DATA < (TESTVAR=*variable***) >=***SAS-data-set*

names the SAS data set that contains the test statistic and its associated information level for the stage. The data set includes the stage variable _Stage_ and a variable to identify or derive the information level: _Info_ for the information level, NObs for the number of observation, or Events for the number of events. If the information level that corresponds to the test statistic is not available, the information level derived in the BOUNDARY= data set is used.

If the TESTVAR= option is specified, the data set also includes the test variable specified in the TESTVAR= option and the scale variable _Scale_ for the test statistic. Usually, these test variable values are obtained from analysis output in SAS procedures.

ERRSPENDMIN=*numbers*

ERRSPENDMIN(*boundary***)=***numbers*

specifies the minimum error spending values at the current observed and future interim stages for the boundaries specified in the BOUNDARYKEY= option. The default is ERRSPENDMIN=0.

If a set of numbers is used for each boundary in the design, you can use the ERRSPENDMIN=*numbers* option. Otherwise, you can use the following ERRSPENDMIN(*boundary*)=*numbers* options to specify different sets of minimum error spending values

for the boundaries. For a boundary, the error spending value at stage 1 is identical to its nominal p-value.

ERRSPENDMIN(ALPHA)=*numbers*

ERRSPENDMIN(REJECT)=*numbers*

specifies the minimum error spending values for the α boundary of a one-sided design or the lower and upper α boundaries of a two-sided design.

ERRSPENDMIN(LOWERALPHA)=*numbers*

ERRSPENDMIN(LOWERREJECT)=*numbers*

specifies the minimum error spending values for the lower α boundary of a two-sided design.

ERRSPENDMIN(UPPERALPHA)=*numbers*

ERRSPENDMIN(UPPERREJECT)=*numbers*

specifies the minimum error spending values for the upper α boundary of a two-sided design.

ERRSPENDMIN(BETA)=*numbers*

ERRSPENDMIN(ACCEPT)=*numbers*

specifies the minimum error spending values for the β boundary of a one-sided design or the lower and upper β boundaries of a two-sided design.

ERRSPENDMIN(LOWERBETA)=*numbers*

ERRSPENDMIN(LOWERACCEPT)=*numbers*

specifies the minimum error spending values for the lower β boundary of a two-sided design.

ERRSPENDMIN(UPPERBETA)=*numbers*

ERRSPENDMIN(UPPERACCEPT)=*numbers*

specifies the minimum error spending values for the upper β boundary of a two-sided design.

NSTAGES=*number*

specifies the number of stages for the clinical trial. The default is the number derived from the BOUNDARY= data set.

The specified NSTAGES= number might or might not be the same as the number derived in the BOUNDARY= data set. You can use the NSTAGES= option to set the next stage as the final stage to compute the conditional power, as described in the section "Conditional Power Approach" on page 6021.

ORDER=LR | MLE | STAGEWISE

specifies the ordering of the sample space (k, z), where k is the stage number and z is the observed standardized Z statistic. The ordering is used to derive the p-values for the observed (k, z) statistic and to create unbiased median estimate and confidence limits from the statistic. The ORDER=LR option specifies the LR ordering that compares the distances between observed standardized Z statistics and their corresponding hypothetical values, the ORDER=MLE option specifies the MLE ordering that compares values in the MLE scale,

and the ORDER=STAGEWISE specifies the stagewise ordering that uses counterclockwise ordering around the continuation region. The default is ORDER=STAGEWISE. See the section "Available Sample Space Orderings in a Sequential Test" on page 6025 for a detailed description of these sample space orderings.

PARMS < (TESTVAR=*variable***) > =***SAS-data-set*

names the SAS data set that contains the parameter estimate and its associated standard error for the stage. The data set includes the stage variable _Stage_, the test statistic Estimate, the standard error of the estimate StdErr, and the test statistic scale variable _Scale_. The standard error is are used to derive the information level. If the standard error is not available, the information level derived in the BOUNDARY= data set is used.

The data set also includes the variable Parameter, Effect, Variable, or Parm that contains the test variable specified in the TESTVAR= option. Usually, these test variable values are obtained from analysis output in SAS procedures.

Table Output Options

The following options can be used in the PROC SEQTEST statement to display additional table output. They are listed in alphabetical order.

CONDPOWER < (CREF=*numbers* **) >**

displays conditional powers given the most recently observed statistic under specified hypothetical references, where the numbers $c_i \geq 0$. In the SEQTEST procedure, the conditional power is the probability that the test statistic at the final stage would exceed the rejection critical value given the observed statistic.

If interim stages exist between the current stage and the final stage, the conditional power is not the conditional probability to reject the null hypothesis H_0. In this case, you can set the next stage as the final stage, and the conditional power is the conditional probability to reject H_0.

For a one-sided test, the powers are derived under the hypothetical references $\theta = \hat{\theta}$ and $\theta = c_i\theta_1$, where $\hat{\theta}$ is the observed statistic, θ_1 is the alternative reference, and c_i are the values specified in the CREF= option. For a two-sided test, the powers are derived under hypothetical references $\theta = \hat{\theta}$, $\theta = c_i\theta_{1l}$, and $\theta = c_i\theta_{1u}$, where θ_{1l} is the lower alternative reference and θ_{1u} is the upper alternative reference. The default is CREF= 0 0.5 1.0 1.5.

ERRSPEND

displays the error spending at each stage for each sequential boundary.

PREDPOWER

displays predictive powers given the most recently observed statistic. The predictive power is the posterior probability that the test statistic at the final stage would exceed the rejection critical value given the observed statistic and a prior distribution of the hypothetical reference. A noninformative prior is used in the procedure.

PSS < (CREF=*numbers* **) >**

displays powers and expected sample sizes under various hypothetical references, where the numbers $c_i \geq 0$.

For a one-sided design with the null reference $\theta_0 = 0$, the power and expected sample sizes under hypotheses $\theta = c_i\ \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, the power and expected sample sizes under hypotheses $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The default is CREF= 0 0.5 1.0 1.5.

Note that for a symmetric two-sided design, only the power and expected sample sizes under hypotheses $\theta = c_i\ \theta_{1u}$ are derived.

RCI

displays repeated confidence intervals for the parameter from the observed statistic at each stage. Repeated confidence intervals include both rejection and acceptance confidence intervals.

With the STOP=REJECT or STOP=BOTH option, rejection confidence limits can be derived, and the null hypothesis $H_0 : \theta = 0$ is rejected if the lower rejection confidence limit is greater than 0 or the upper rejection confidence limit is less than 0.

With the STOP=ACCEPT or STOP=BOTH option, acceptance confidence limits can be derived, and the null hypothesis is accepted with alternative hypotheses $H_{1l} : \theta = \theta_{1l}$ and $H_{1u} : \theta = \theta_{1u}$ if the upper acceptance confidence limit is less than θ_{1u} and the lower acceptance confidence limit is greater than θ_{1l}.

STOPPROB < (CREF=*numbers* **) >**

displays expected cumulative stopping probabilities under various hypothetical references, where the numbers $c_i \geq 0$.

For a one-sided design, expected cumulative stopping probabilities at each stage under hypotheses $\theta = c_i\ \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, expected cumulative stopping probabilities at each stage under hypotheses $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only expected cumulative stopping probabilities under hypotheses $\theta = c_i\ \theta_{1u}$ are derived. The default is CREF= 0 0.5 1.0 1.5.

Graphics Output Options

This section describes the options for using ODS Graphics with the SEQTEST procedure to create plots. To request these plots, you must specify the ODS GRAPHICS ON statement in addition to the following options in the PROC SEQTEST statement. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

The following options can be used in the PROC SEQTEST statement to display plots with ODS Graphics. They are listed in alphabetical order.

PLOTS < (ONLY) > < = *plot-request* >

PLOTS < (ONLY) > < = (*plot-request* < . . . *plot-request* >) >

specifies options that control the details of the plots. The default is PLOTS=TEST. The global plot option ONLY suppresses the default plots and displays only plots specifically requested.

The plot request options include the following.

ALL

produces all appropriate plots.

ASN < (CREF=*numbers*) >

displays a plot of the average sample numbers (expected sample sizes for nonsurvival data or expected number of events for survival data) under various hypothetical references, where the numbers $c_i \geq 0$.

For a one-sided design, expected sample numbers under hypotheses $\theta = c_i\ \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, expected sample numbers under hypotheses $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only the average sample numbers under hypotheses $\theta = c_i\ \theta_{1u}$ are derived. The default is CREF= 0 to 1.5 by 0.01.

CONDPOWER < (CREF=*numbers*) >

displays a plot of conditional powers given the most recently observed statistic under specified hypothetical references, where the numbers $c_i \geq 0$. In the SEQTEST procedure, the conditional power is the probability that the test statistic at the final stage would exceed the rejection critical value given the observed statistic.

For a one-sided test, the powers are derived under hypothetical references $\theta = \hat{\theta}$ and $\theta = c_i \theta_1$, where $\hat{\theta}$ is the observed statistic, θ_1 is the alternative reference, and c_i are the values specified in the CREF= option. For a two-sided test, the powers are derived under hypothetical references $\theta = \hat{\theta}$, $\theta = c_i \theta_{1l}$, and $\theta = c_i \theta_{1u}$, where θ_{1l} is the lower alternative reference and θ_{1u} is the upper alternative reference. The default is CREF= 0 to 1.5 by 0.01.

ERRSPEND < (HSCALE=INFO | STAGE) >

displays a plot of the error spending for all sequential boundaries in the designs simultaneously. You can display the information level (HSCALE=INFO) or the stage number (HSCALE=STAGE) on the horizontal axis. With HSCALE=INFO, the information fractions are used in the plot. The default is HSCALE=STAGE.

NONE

suppresses all plots.

POWER < (CREF=*numbers*) >

displays a plot of the power curves under various hypothetical references, where the numbers $c_i \geq 0$.

For a one-sided design, powers under hypotheses $\theta = c_i\,\theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, powers under hypotheses $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only powers under hypotheses $\theta = c_i\,\theta_{1u}$ are derived. The default is CREF= 0 to 1.5 by 0.01.

RCI

displays a plot of repeated confidence intervals. Repeated confidence intervals include both rejection and acceptance confidence intervals.

With the STOP=REJECT or STOP=BOTH option, rejection confidence limits can be derived and the null hypothesis $H_0 : \theta = 0$ is rejected if the lower rejection confidence limit is greater than 0 or the upper rejection confidence limit is less than 0.

With the STOP=ACCEPT or STOP=BOTH option, acceptance confidence limits can be derived and the null hypothesis is accepted with alternative hypotheses $H_{1l} : \theta = \theta_{1l}$ and $H_{1u} : \theta = \theta_{1u}$ if the upper acceptance confidence limit is less than θ_{1u} and the lower acceptance confidence limit is greater than θ_{1l}.

TEST < (HSCALE=INFO | SAMPLESIZE) >

displays a plot of the sequential boundaries and test variables. Either the information level (HSCALE=INFO) or the sample size (HSCALE=SAMPLESIZE) is displayed on the horizontal axis. The HSCALE=SAMPLESIZE option is applicable only if the sample size information is available in both the input BOUNDARY= data set and input DATA= data set. The stage number for each stage is displayed inside the plot. The default is HSCALE=INFO.

Details: SEQTEST Procedure

Input Data Sets

The BOUNDARY= data set option is required, and if neither the DATA= nor the PARMS= data set option is specified, the procedure derives statistics such as Type I and Type II error probabilities from the BOUNDARY= data set. The resulting boundaries are displayed with the scale specified in the BOUNDARYSCALE= option.

BOUNDARY= SAS Data Set

The BOUNDARY= data set provides the boundary information for the sequential test. At stage 1, the data set is usually created with an ODS OUTPUT statement from the "Boundary Information" table created by the SEQDESIGN procedure. At each subsequent stage, the data set is usually created with an ODS OUTPUT statement from the "Test Information" table that was created by the

SEQTEST procedure at the previous stage. See the section "Getting Started: SEQTEST Procedure" on page 5988 for an illustration of the BOUNDARY= data set option.

The BOUNDARY= data set contains the following variables:

- _Scale_, the boundary scale, with the value MLE for the maximum likelihood estimate, STDZ for the standardized Z, SCORE for the score statistic, or PVALUE for the nominal p-value. Note that for a two-sided design, the nominal p-value is the one-sided fixed-sample p-value under the null hypothesis with a lower alternative hypothesis.
- _Stop_, the stopping criterion, with the value REJECT for rejecting the null hypothesis H_0, ACCEPT for accepting H_0, or BOTH for both rejecting and accepting H_0
- _ALT_, the type of alternative hypothesis, with the value UPPER for an upper alternative, LOWER for a lower alternative, or TWOSIDED for a two-sided alternative
- _Stage_, the stage number
- the boundary variables, a subset of Bound_LA for lower α boundary, Bound_LB for lower β boundary, Bound_UB for upper β boundary, and Bound_UA for upper α boundary
- AltRef_L, the lower alternative reference, if ALT=LOWER or ALT=TWOSIDED
- AltRef_U, the upper alternative reference, if ALT=UPPER or ALT=TWOSIDED
- _InfoProp_, the information proportion at each stage

Optionally, the BOUNDARY= data set also contains the following variables:

- _Info_, the information level at each stage
- NObs, the required number of observations for nonsurvival data at each stage
- Events, the required number of events for survival data at each stage
- Parameter, the variable specified in the DATA(TESTVAR=) or PARMS(TESTVAR=) option
- Estimate, the parameter estimate

If the BOUNDARY= data set contains the variable Parameter for the test variable that is specified in the TESTVAR= option, and the variable Estimate for the test statistics, then these test statistics are also displayed in the output test information table and output test plot.

DATA < (TESTVAR= *variable*) > = SAS Data Set

The DATA= data set provides the test variable information for the current stage of the trial. Such data sets are usually created with an ODS OUTPUT statement by using a procedure such as PROC MEANS. See "Example 78.4: Testing a Binomial Proportion" on page 6079 for an illustration of the DATA= data set option.

The DATA= data set includes the following variables:

- _Stage_, the stage number
- _Scale_, the scale for the test statistic, with the value MLE for the maximum likelihood estimate, STDZ for the standardized Z, SCORE for the score statistic, or PVALUE for the nominal p-value
- _Info_, the information level
- NObs, the number of observations for nonsurvival data at each stage
- Events, the number of events for survival data at each stage
- test variable, specified in the TESTVAR= option, contains the test variable value in the scale specified in the _Scale_ variable

With the specified DATA= data set, the procedure derives boundary values from the information levels in the _Info_ variable. If the data set does not include the _Info_ variable, then the information levels are derived from the NObs or Events variable in the DATA= data set if the variable is also in the input BOUNDARY= data set. That is, the information level at stage k is computed as $I_k^* = I_k \times (n_k^*/n_k)$, where I_k and n_k are the information level and sample size at stage k in the BOUNDARY= data set and n_k^* is the sample size at stage k in the DATA= data set. Otherwise, the information levels from the BOUNDARY= data set are used.

If the TESTVAR= option is specified, the DATA= data set must also include the test variable for the test statistic and _Scale_ variable for the corresponding scale. Note that for a two-sided design, the nominal p-value is the one-sided fixed-sample p-value under the null hypothesis with a lower alternative hypothesis.

PARMS < (TESTVAR= *variable*) > = SAS Data Set

The PARMS= data set provides a parameter estimate and associated standard error for the current stage of the trial. Such data sets are usually created with an ODS OUTPUT statement by using procedures such as the GENMOD, GLM, LOGISTIC, and REG procedures. See the section "Getting Started: SEQTEST Procedure" on page 5988 for an illustration of the PARMS= data set option.

The PARMS= data set includes the following variables:

- _Stage_, the stage number
- _Scale_, the scale for the test statistic, with the value MLE for the maximum likelihood estimate, STDZ for the standardized Z, SCORE for the score statistic, or PVALUE for the nominal p-value
- Parameter, Effect, Variable, or Parm, which contains the variable specified in the TESTVAR= option
- Estimate, the parameter estimate
- StdErr, standard error of the parameter estimate

With the specified PARMS= data set, the information level is derived from the StdErr variable. For a score statistic, the information level I_k is the variance of the statistic, $\hat{s}_k^2$, where $\hat{s}_k$ is the standard error in the StdErr variable. Otherwise, the information level is the inverse of the variance of the statistic, $\hat{s}_k^{-2}$. If the data set does not include the StdErr variable, the information levels derived from the BOUNDARY= data set are used.

If the TESTVAR= option is specified, the PARMS= data set also includes the variable Parameter, Effect, Variable, or Parm for the test variable, Estimate for the test statistic, and _Scale_ variable for the corresponding scale. Note that for a two-sided design, the nominal p-value is the one-sided fixed-sample p-value under the null hypothesis with a lower alternative hypothesis.

Boundary Variables

The boundaries created in group sequential trials depend on the type of the alternative hypothesis and the early stopping criterion. Table 78.2 shows the boundaries created with various design specifications.

Table 78.2 Boundary Variables

Specifications		Boundary Variables			
Alternative		**Lower**		**Upper**	
Hypothesis	**Early Stopping**	**Alpha**	**Beta**	**Beta**	**Alpha**
Lower	Accept H_0		X		
	Reject H_0	X			
	Accept/Reject H_0	X	X		
Upper	Accept H_0			X	
	Reject H_0				X
	Accept/Reject H_0			X	X
Two-sided	Accept H_0		X	X	
	Reject H_0	X			X
	Accept/Reject H_0	X	X	X	X

Up to four different boundaries can be generated in a group sequential design:

- the upper α boundary, used to reject the null hypothesis in favor of an upper alternative hypothesis
- the upper β boundary, used to accept the null hypothesis with an upper alternative hypothesis
- the lower β boundary, used to accept the null hypothesis with a lower alternative hypothesis
- the lower α boundary, used to reject the null hypothesis in favor of a lower alternative hypothesis

For a two-sided design, the null hypothesis is accepted only if both the null hypothesis is accepted with an upper alternative hypothesis and the null hypothesis is accepted with a lower alternative hypothesis.

For a one-sided design with a lower alternative, only the lower boundaries are created. Similarly, for a one-sided design with an upper alternative, only the upper boundaries are created. For example, Figure 78.19 shows the boundary plot for a one-sided test with an upper alternative.

Figure 78.19 Boundary Plot for One-Sided Test

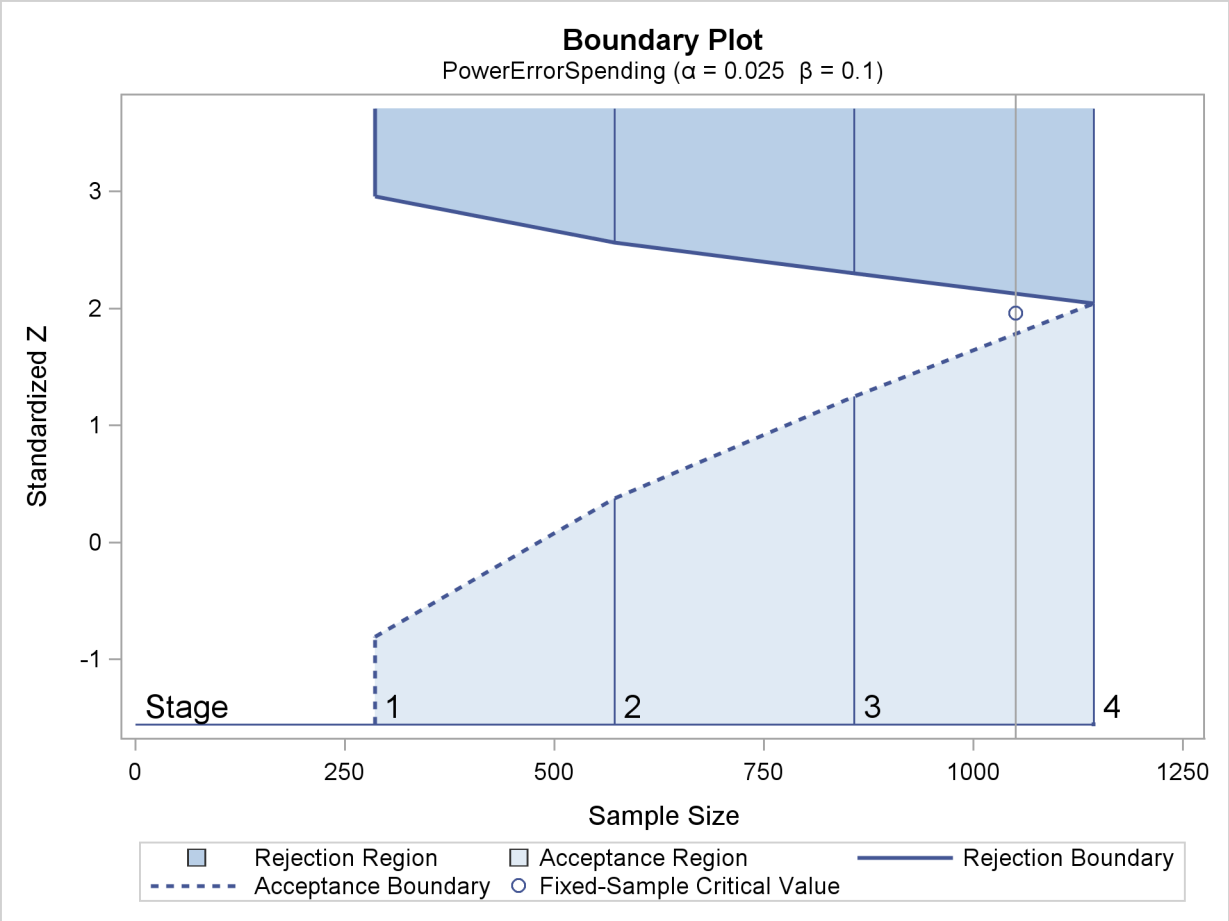

Figure 78.19 corresponds to a one-sided sequential design with early stopping to reject or accept the null hypothesis. For a sequential test with early stopping only to reject the null hypothesis, there are no acceptance boundary values at interim stages. The acceptance boundary value and its associated acceptance region are displayed only at the final stage. Similarly, for a sequential test with early stopping only to accept the null hypothesis, there are no rejection boundary values at interim stages. The rejection boundary value and its associated rejection region are displayed only at the final stage.

For a two-sided design, both the lower and upper boundaries are created. For a design with early stopping to reject the null hypothesis, α boundaries are created. Similarly, for a design with early stopping to accept the null hypothesis, β boundaries are created. For a design with early stopping to accept or reject the null hypothesis, both the α and β boundaries are created.

For example, Figure 78.20 shows the boundary plot for a two-sided test.

Figure 78.20 Boundary Plot for Two-Sided Test

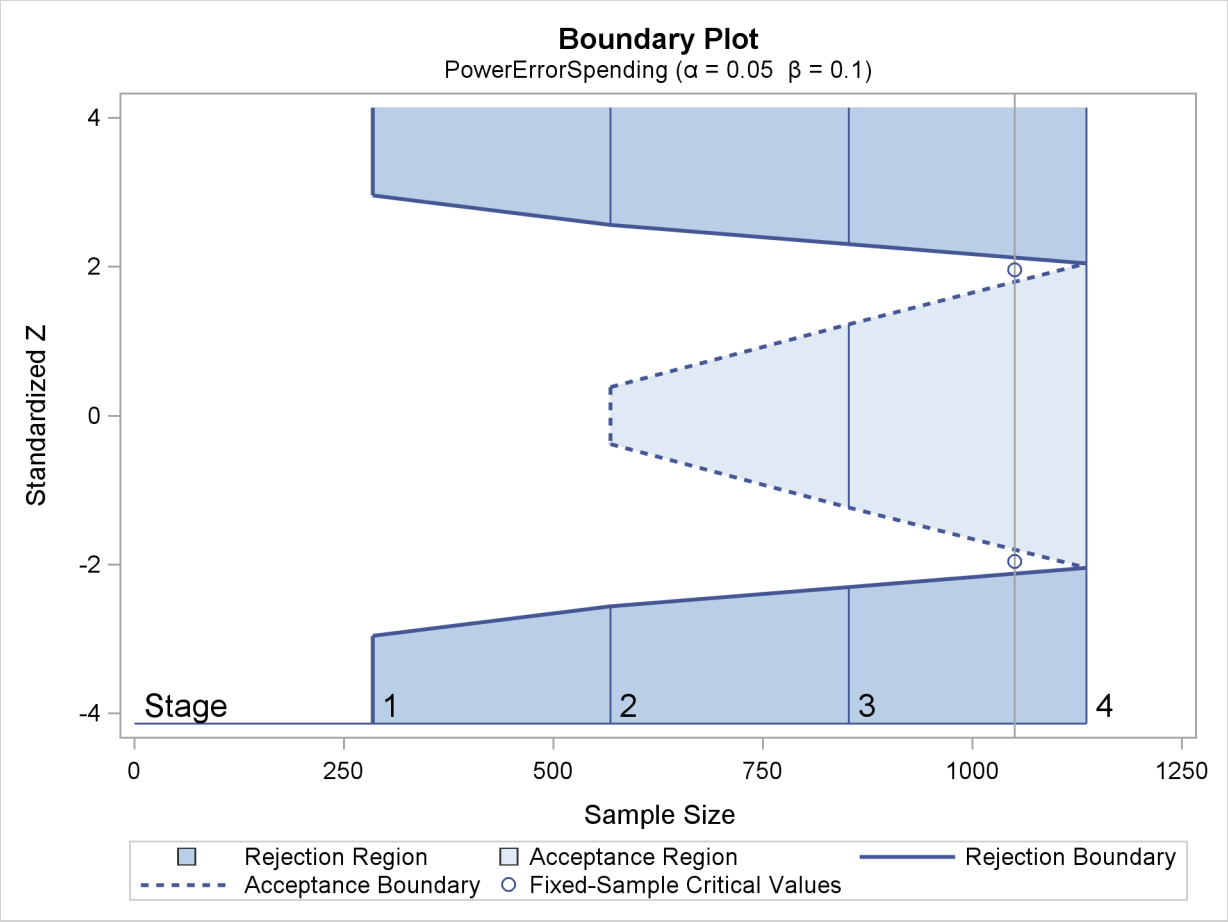

Figure 78.20 corresponds to a two-sided sequential design with early stopping to reject or accept the null hypothesis. For a sequential test with early stopping only to reject the null hypothesis, there are no acceptance boundary values at interim stages. The acceptance boundary value and its associated acceptance region are displayed only at the final stage. Similarly, for a sequential test with early stopping only to accept the null hypothesis, there are no rejection boundary values at interim stages. The rejection boundary value and its associated rejection region are displayed only at the final stage.

Boundary Adjustments for Information Levels

In a group sequential clinical trial, the information level for the observed test statistic generally does not match the corresponding information level in the BOUNDARY= data set. In this situation, the SEQTEST procedure first modifies the information levels at future interim stages to accommodate the information level for the test statistic and computes the error spending values at the current and future stages. The SEQTEST procedure then derives boundary values at the current and future stages for the trial with these new error spending values.

Denote the information level at stage k for the K-stage design stored in the BOUNDARY= data set by I_k, $k = 1, 2, \ldots, K$. Also denote the information level that corresponds to the test statistic at an interim stage k_0 by I'_{k_0}, $1 \le k_0 \le K-1$. Then for the updated design, the information level at stage k, $k = k_0 + 1, \ldots, K-1$, is computed as

$$I'_k = I'_{k_0} + (I_K - I'_{k_0}) \frac{I_k - I_{k_0}}{I_K - I_{k_0}}$$

Note that if $I'_{k_0} \ge I_K$, the information level at stage k_0 reaches the maximum information level in the design, the trial stops at stage k_0, and no future information levels are derived.

The BOUNDARYADJ= option provides various methods to compute error spending values for these new information levels at the current and future interim stages.

The BOUNDARYADJ=NONE option keeps the error spending the same at each stage. The BOUNDARYADJ=ERRLINE option uses a linear interpolation on the cumulative error spending in the design stored in the BOUNDARY= data set to derive the error spending for each unmatched information level (Kittelson and Emerson 1999, p. 882). That is, the cumulative error spending for an information level I is computed as

$$e(I) = \begin{cases} e_1 \left(\frac{I}{I_1}\right) & \text{if } I < I_1 \\ e_j + (\alpha_{j+1} - \alpha_j) \left(\frac{I - I_j}{I_{j+1} - I_j}\right) & \text{if } I_j \le I < I_{j+1} \\ e_K & \text{if } I \ge I_K \end{cases}$$

where $e_1, e_2, \ldots, e_K$ are the cumulative errors at the K stages of the design that is stored in the BOUNDARY= data set.

The BOUNDARYADJ=ERRFUNCPOC option uses Pocock-type cumulative error spending function (Lan and DeMets 1983):

$$E(t) = \begin{cases} 1 & \text{if } t \ge 1 \\ \log(1 + (e-1)t) & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

With an error level of α or β, the cumulative error spending for an information level I is $e(I) = \alpha\, E(I/I_K)$ or $e(I) = \beta\, E(I/I_K)$.

The BOUNDARYADJ=ERRFUNCOBF option uses O'Brien-Fleming-type cumulative error spending function (Lan and DeMets 1983):

$$E(t; a) = \begin{cases} 1 & \text{if } t \ge 1 \\ \frac{1}{a}\, 2\,(1 - \Phi(\frac{z_{(1-a/2)}}{\sqrt{t}})) & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

where a is either α for the α spending function or β for the β spending function, and Φ is the cumulative distribution function of the standardized Z statistic. That is, with an error level of α or β, the cumulative error spending for an information level I is $e(I) = \alpha\, E(I/I_K; \alpha)$ or $e(I) = \beta\, E(I/I_K; \beta)$.

The BOUNDARYADJ=ERRFUNCGAMMA option uses gamma cumulative error spending function (Hwang, Shih, and DeCani 1990):

$$E(t;\gamma) = \begin{cases} 1 & \text{if } t \geq 1 \\ \frac{1-e^{-\gamma t}}{1-e^{-\gamma}} & \text{if } 0 < t < 1, \gamma \neq 0 \\ t & \text{if } 0 < t < 1, \gamma = 0 \\ 0 & \text{otherwise} \end{cases}$$

where γ is the parameter γ specified in the GAMMA= option. That is, with an error level of α or β, the cumulative error spending for an information level I is $e(I) = \alpha\, E(I/I_K;\gamma)$ or $e(I) = \beta\, E(I/I_K;\gamma)$.

The BOUNDARYADJ=ERRFUNCPOW option uses power cumulative error spending function (Jennison and Turnbull 2000, p. 148):

$$E(t;\rho) = \begin{cases} 1 & \text{if } t \geq 1 \\ t^{\rho} & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

where ρ is the power parameter specified in the RHO= suboption. With an error level of α or β, the cumulative error spending for an information level I is $e(I) = \alpha\, E(I/I_K;\rho)$ or $e(I) = \beta\, E(I/I_K;\rho)$.

If the BOUNDARYKEY=BOTH option is specified, the maximum information (information level at the final stage) required for the trial might not be the same as the maximum information level stored in the BOUNDARY= data set. In this case, the information levels at future stages are adjusted proportionally, and the same error spending values that were computed based on the maximum information level stored in the BOUNDARY= data set are used to derive boundary values for the trial.

If an error spending function is used to create boundaries for the original design in the SEQDESIGN procedure, then in order to better maintain the design features throughout the group sequential trial, the same error spending function to create boundaries for the original design in the SEQDESIGN procedure should be used to modify boundaries in the SEQTEST procedure at each subsequent stage.

Boundary Adjustments for Minimum Error Spending

In a group sequential clinical trial, boundary values created from a design such as an O'Brien-Fleming design might be too conservative in early stages. Thus the trial is unlikely to stop in early stages. Lan and Demets (1983, p. 662) suggest truncating boundary values to a number such as 3.5 for the trial to have a reasonable probability of stopping at early stages. Instead of truncating boundary values by a specified number, the ERRSPENDMIN= option provides individual minimum error spending at each interim stage to stop the trial early.

For a K-stage trial, denote the derived cumulative error spending at stage k after adjusting for information levels by $e_k, k = 1, 2, \ldots, K$. Also denote the specified minimum error spending at interim stage k by $\epsilon_k, k = 1, 2, \ldots, K-1$. Then the cumulative error spending at stage 1 is $e'_1 = \max(e_1,\ \epsilon_1)$. If $e_1 < e'_1$, the error spending values at subsequent interim stages are adjusted

proportionally by

$$e'_j = e'_1 + \frac{e_j - e_1}{e_K - e_1}\,(e_K - e'_1)$$

for $j = 2, \ldots, K-1$.

The process is repeated at each subsequent interim stage. That is, at stage $k, k = 2, \ldots, K-1$, denote the updated cumulative β spending at stage j by e_j, $j = k, k+1, \ldots, K$. Then the cumulative error spending at stage k is $e'_k = \max(e_k,\ e'_{k-1} + \epsilon_k)$. If $e_k < e'_k$, the error spending values at subsequent interim stages are adjusted proportionally by

$$e'_j = e'_k + \frac{e_j - e_k}{e_K - e_k}\,(e_K - e'_k)$$

for $j = k+1, \ldots, K-1$.

Note that the ERRSPENDMIN= option is applicable only to the boundaries specified in the BOUNDARYKEY= option. That is, the ERRSPENDMIN= option is applicable to the α boundaries with BOUNDARYKEY=ALPHA or BOUNDARYKEY=BOTH, and it is applicable to the β boundaries with BOUNDARYKEY=BETA or BOUNDARYKEY=BOTH.

Boundary Adjustments for Overlapping Lower and Upper β Boundaries

In the SEQTEST procedure, the α and β spending values at the stages are used to derive the boundary values for the trial. For a two-sided design with early stopping to accept H_0, or to either reject or accept H_0, a zero β spending at an interim stage sets the β boundary values to missing. A small β spending at the current or subsequent interim stage might result in overlapping of the lower and upper β boundaries for the two corresponding one-sided tests. Specifically, this form of overlapping occurs at an interim stage k if the upper β boundary value that is derived from the one-sided test for the upper alternative is less than the lower β boundary value that is derived from the one-sided test for the lower alternative (Kittelson and Emerson 1999, pp. 881–882; Rudser and Emerson 2007, p. 6). You can use the BETAOVERLAP= option to specify how this type of overlapping is to be handled.

If BETAOVERLAP=ADJUST (which is the default) is specified, the procedure derives the boundary values for the two-sided design and then checks for overlapping of the two one-sided β boundaries at the current and subsequent interim stages. If overlapping occurs at a particular stage, the β boundary values for the two-sided design are set to missing (so the trial does not stop to accept the null hypothesis at this stage), and the β spending values at subsequent stages are adjusted proportionally as follows.

If the β boundary values are set to missing at stage k in a K-stage trial, the adjusted β spending value at stage k, e'_k, is updated for these missing β boundary values, and then the β spending values at subsequent stages are adjusted proportionally by

$$e'_j = e'_k + \frac{e_j - e_k}{e_K - e_k}\,(e_K - e'_k)$$

for $j = k+1, \ldots, K$, where e_j and e'_j are cumulative β spending values at stage j before and after the adjustment, respectively.

After all these adjusted β spending values are computed, the boundary values are then further modified for these adjusted β spending values.

If you specify BETAOVERLAP=NOADJUST, no adjustment is made when overlapping of one-sided β boundaries occurs.

Stochastic Curtailment

Lan, Simon, and Halperin (1982) introduce stochastic curtailment to stop a trial if, given current data, it is likely to predict the outcome of the trial with high probability. That is, a trial can be stopped to reject the null hypothesis H_0 if the conditional probability of rejecting H_0 under H_0, given current data in the analyses at the end of the trial, is greater than γ, where the constant γ should be between 0.5 and 1, and values of 0.8 or 0.9 are recommended (Jennison and Turnbull 2000, p. 206). Similarly, a trial can be stopped to accept the null hypothesis H_0 if the conditional probability of rejecting H_0 under the alternative hypothesis H_1, given current data in the analyses at the end of the trial, is less than γ.

The following two approaches for stochastic curtailment are available in the SEQTEST procedures: conditional power approach and predictive power approach. For each approach, the derived group sequential test is used as the reference test for rejection.

Conditional Power Approach

In the SEQTEST procedure, the conditional power at an interim stage k is the probability that the test statistic at the final stage (stage K) would exceed the rejection critical value (Cui, Hung, and Wang 1999, p. 854; Emerson, Kittelson, and Gillen 2005, p. 13). If there exist interim stages between the kth stage and the final stage, $k < K-1$, the conditional power is not the conditional probability to reject the null hypothesis H_0. In this case, you can set the next stage as the final stage, and the conditional power is the conditional probability to reject H_0.

The conditional distribution of Z_K given the observed statistic z_k at the kth stage and the hypothetical reference θ is

$$Z_K \,|\, (z_k, \theta) \sim N\left(z_k \ \Pi_k^{\frac{1}{2}} + \theta \ I_X^{\frac{1}{2}} (1 - \Pi_k) \,,\ 1 - \Pi_k \right)$$

where $\Pi_k = I_k / I_X$ is the fraction of information at the kth stage.

The power for the upper alternative, prob($Z_K > a_K \,|\, z_k, \theta$), is then given by

$$p_{ku}(\theta) = \Phi\left((1 - \Pi_k)^{-\frac{1}{2}} \left(z_k \ \Pi_k^{\frac{1}{2}} - a_K \right) \ + \ \theta \ I_X^{\frac{1}{2}} (1 - \Pi_k)^{\frac{1}{2}} \right)$$

where Φ is the cumulative distribution function of the standardized Z statistic and a_K is the upper critical value at the final stage.

Similarly, the power for the lower alternative, prob($Z_K < a_K \,|\, z_k, \theta$), is

$$p_{kl}(\theta) = 1 - \Phi\left((1 - \Pi_k)^{-\frac{1}{2}} \left(z_k \ \Pi_k^{\frac{1}{2}} - a_K \right) \ + \ \theta \ I_X^{\frac{1}{2}} (1 - \Pi_k)^{\frac{1}{2}} \right)$$

where a_K is the lower critical value at the final stage.

A special case of the conditional power is the futility index (Ware, Muller, and Braunwald, 1985). It is one minus the conditional power under $H_1 : \theta = \theta_1$:

$$1 - p_{ku}(\theta_1) \text{ or } 1 - p_{kl}(\theta_1)$$

That is, it is the probability of accepting the null hypothesis under the alternative hypothesis given current data. A high futility index indicates a small probability of success (rejecting H_0) given the current data.

If $\theta = \hat{\theta}_k = z_k I_k^{-\frac{1}{2}}$, the maximum likelihood estimate at stage k, the powers for the upper and lower alternatives can be simplified:

$$p_{ku}(\theta) = \Phi\left((1-\Pi_k)^{-\frac{1}{2}}\ (z_k\ \Pi_k^{-\frac{1}{2}} - a_K)\right)$$

$$p_{kl}(\theta) = 1 - \Phi\left((1-\Pi_k)^{-\frac{1}{2}}\ (z_k\ \Pi_k^{-\frac{1}{2}} - a_K)\right)$$

Predictive Power Approach

The conditional power depends on the specified reference θ, which might be supported by the current data (Jennison and Turnbull 2000, p. 210). An alternative is to use the predictive power (Herson 1979), which is a weighted average of the conditional power over values of θ. Without prior knowledge about θ, then with $\hat{\theta} = z_k/\sqrt{I_k}$, the maximum likelihood estimate at stage k, the posterior distribution for θ (Jennison and Turnbull 2000, p. 211) is

$$\theta \mid Z_K \sim N\left(\frac{z_k}{\sqrt{I_k}},\ \frac{1}{I_k}\right)$$

Thus, the predictive power at stage k for the upper and lower alternatives can be derived as

$$p_{ku} = 1 - \Phi\left((1-\Pi_k)^{-\frac{1}{2}}\ (a_K\ \Pi_k^{\frac{1}{2}} - z_k)\right)$$

$$p_{kl} = \Phi\left((1-\Pi_k)^{-\frac{1}{2}}\ (a_K\ \Pi_k^{\frac{1}{2}} - z_k)\right)$$

where a_K and a_K are the upper and lower critical values at the final stage.

Repeated Confidence Intervals

In a group sequential test, repeated confidence intervals for a parameter θ are defined as a sequence of intervals $(\hat{\theta}_{kl}, \hat{\theta}_{ku})$, $k = 1, 2, \ldots, K$, for which a simultaneous coverage probability is maintained (Jennison and Turnbull 2000, p. 189). That is, a $(1-\alpha)$ sequence of repeated confidence intervals has

$$\text{Prob}(\hat{\theta}_{kl} \le \theta \le \hat{\theta}_{ku}) = 1 - \alpha$$

These confidence limits $\hat{\theta}_{kl}$ and $\hat{\theta}_{ku}$ can be created from observed statistic and boundary values at each stage.

Two-Sided Repeated Confidence Intervals

Two sequences of repeated confidence intervals can be derived for a two-sided test. One is a $(1-\alpha_l-\alpha_u)$ rejection repeated confidence intervals $(\hat{\theta}_{kl}(\alpha), \hat{\theta}_{ku}(\alpha)), k = 1, 2, \ldots, K$, and the other is a $(1-\beta_l-\beta_u)$ acceptance repeated confidence intervals $(\hat{\theta}_{kl}(\beta), \hat{\theta}_{ku}(\beta)), k = 1, 2, \ldots, K$, where α_l and α_u are the lower and upper Type I error probabilities for the test and β_l and β_u are the lower and upper Type II error probabilities for the test (Jennison and Turnbull 2000, p. 196).

The rejection lower and upper repeated confidence limits at stage k are

$$\hat{\theta}_{kl}(\alpha) = \hat{\theta}_k - \frac{a_k}{\sqrt{I_k}} \qquad \hat{\theta}_{ku}(\alpha) = \hat{\theta}_k - \frac{a_k}{\sqrt{I_k}}$$

The hypothesis is rejected for upper alternative if the lower limit $\hat{\theta}_{kl}(\alpha) > \theta_{0u}$ and is rejected for lower alternative if the upper limit $\hat{\theta}_{ku}(\alpha) < \theta_{0l}$. That is, the hypothesis is rejected if both θ_{0l} and θ_{0u} are not in a rejection repeated confidence interval $(\hat{\theta}_{kl}(\alpha), \hat{\theta}_{ku}(\alpha))$.

The acceptance lower and upper repeated confidence limits at stage k are

$$\hat{\theta}_{kl}(\beta) = \hat{\theta}_k + \left(\theta_{1l} - \frac{b_k}{\sqrt{I_k}}\right) \qquad \hat{\theta}_{ku}(\beta) = \hat{\theta}_k + \left(\theta_{1u} - \frac{b_k}{\sqrt{I_k}}\right)$$

The hypothesis is accepted if the lower limit $\hat{\theta}_{kl}(\beta) > \theta_{1l}$ and the upper limit $\hat{\theta}_{ku}(\beta) < \theta_{1u}$. That is, a repeated confidence interval is contained in the interval $(\theta_{1l}, \theta_{1u})$.

One-Sided Repeated Confidence Intervals

Like the two-sided repeated confidence intervals, two sequences of repeated confidence intervals can be derived for a one-sided test. Suppose the one-sided test has an upper alternative θ_{1u}. Then one sequence of repeated confidence intervals is a $(1-\alpha_u)$ rejection repeated confidence intervals $(\hat{\theta}_{kl}(\alpha), \infty), k = 1, 2, \ldots, K$, and the other is a $(1-\beta_u)$ acceptance repeated confidence intervals $(-\infty, \hat{\theta}_{ku}(\beta)), k = 1, 2, \ldots, K$, where α_u and β_u are the upper Type I and Type II error probabilities for the test. Thus, a sequence of repeated confidence intervals with confidence level greater than or equal to $(1-\alpha_u-\beta_u)$ is given by $(\hat{\theta}_{kl}(\alpha), \hat{\theta}_{ku}(\beta))$.

The rejection lower repeated confidence limit and the acceptance upper repeated confidence limit at stage k are

$$\hat{\theta}_{kl}(\alpha) = \hat{\theta}_k - \left(\frac{a_k}{\sqrt{I_k}} - \theta_{0u}\right) \qquad \hat{\theta}_{ku}(\beta) = \hat{\theta}_k + \left(\theta_{1u} - \frac{b_k}{\sqrt{I_k}}\right)$$

The hypothesis is rejected if the lower limit $\hat{\theta}_{kl}(\alpha) > \theta_{0u}$. and it is accepted if the upper limit $\hat{\theta}_{ku}(\beta) < \theta_{1u}$.

Analysis after a Sequential Test

At the end of a trial, the hypothesis is either rejected or accepted. But the p-value, median, and confidence limits depend on the ordering the sample space (k, z), where k is the stage number and z is the standardized Z statistic.

Following the notations used in Jennison and Turnbull (2000, pp. 179–180), $(k', z') \succ (k, z)$ if (k', z') has a higher order or more extreme than (k, z). Then for a given ordering, the p-value, median, and confidence limits associated with the observed statistics (k, z) can be derived.

p-value

With the observed pair of statistics (k_0, z_0) when the trial is stopped, a one-sided upper p-value is computed as

$$\text{Prob}\{\, (k, z) \succeq (k_0, z_0) \,\}$$

A one-sided lower p-value is computed as

$$\text{Prob}\{\, (k, z) \preceq (k_0, z_0) \,\}$$

A two-sided p-value is twice the smaller of the lower and upper p-values.

Median Unbiased Estimate

With the observed pair (k_0, z_0), a median unbiased estimate θ_m is computed from

$$\text{Prob}\{\, (k, z) \succeq (k_0, z_0) \mid \theta_m \,\} = 0.50$$

Confidence Limits

With the observed pair (k_0, z_0), a lower $(1 - \alpha_l)$ confidence limit for θ, θ_l, is computed from

$$\text{Prob}\{\, (k, z) \succeq (k_0, z_0) \mid \theta_l \,\} = \alpha_l$$

Similarly, an upper $(1 - \alpha_u)$ confidence limit for θ, θ_u, is computed from

$$\text{Prob}\{\, (k, z) \preceq (k_0, z_0) \mid \theta_u \,\} = \alpha_u$$

Available Sample Space Orderings in a Sequential Test

At the end of a trial, the hypothesis is either rejected or accepted. Denote the stage number and the statistic at the end of a trial by a pair of statistics (k, z), where k is the stage number and z is the standardized Z statistic. Then an ordering on the sample space (k, z) is needed to derive the p-value, median, and confidence limits associated with the observed statistics (k^*, z^*).

The SEQTEST procedure provides the stagewise, LR, and MLE orderings. Refer to Jennison and Turnbull (2000 pp. 179–187) for a detailed description and comparison of these orderings.

Stagewise Ordering

If the continuation regions of a design are intervals, the stagewise ordering (Fairbanks and Madsen 1982; Tsiatis, Rosner, and Mehta 1984; Jennison and Turnbull 2000, pp. 179–180) uses counterclockwise ordering around the continuation region to compute the p-value, unbiased median estimate, and confidence limits. This ordering depends on the stopping region, stopping stage, and standardized statistic at the stopping stage. But it does not depend on information levels beyond the observed stage. For a one-sided design with an upper alternative, $(k', z') \succ (k, z)$ if one of the following criteria holds:

- $k' = k$ and $z' > z$
- $k' < k$ and $z' \geq a_{k'}$, the upper α boundary at stage k'
- $k' > k$ and $z < b_k$, the upper β boundary at stage k

Similar criteria can be derived for a one-sided design with a lower alternative.

For a two-sided design with early stopping to reject the null hypothesis, $(k', z') \succ (k, z)$ if one of the following criteria holds:

- $k' = k$ and $z' > z$
- $k' < k$ and $z' \geq a_{k'}$, the upper α boundary at stage k'
- $k' > k$ and $z \leq _a_k$, the lower α boundary at stage k

Note that the stagewise ordering is not applicable for two-sided designs with early stopping to accept H_0 or to either accept or reject H_0, which might have two disjoint continuous intervals at each interim stage.

For a two-sided design with early stopping either to reject or to accept the null hypothesis, $(k', z') \succ (k, z)$ if one of the following criteria holds:

- $z' \geq a_{k'}$ and $z < b_k$
- $z' > _b_{k'}$ and $z \leq _a_k$

That is, each value in the continuation region is less extreme than each value in the upper rejection region and more extreme than each value in the lower rejection region. Then, combining with the ordering defined for a two-sided design with early stopping to reject the null hypothesis, the p-value, median, and confidence limits can be derived for the observed statistics in the lower or upper rejection region.

Thus, if the stagewise ordering is specified in the SEQTEST procedure for a two-sided design with early stopping to either reject or accept the null hypothesis, the stagewise ordering is used to derive these statistics only if the observed statistics is in the lower or upper rejection region. Otherwise, the LR ordering is used.

LR Ordering

The LR ordering (Chang 1989) depends on the observed standardized Z statistic z, information levels, and a specified hypothetical reference. For the LR ordering under a given hypothesis $H : \theta = \theta_g$, $(k', z') \succ (k, z)$ if

$$(z' - \theta_g \sqrt{I_{k'}}) > (z - \theta_g \sqrt{I_k})$$

Under the null hypothesis $H_0 : \theta = 0$, it reduces to

$$z' > z$$

and can be used to derive statistics under H_0, such as p-values.

The LR ordering is applicable to all designs if all information levels are available. But depending on the boundary shape, some observed statistics (k, z) in the rejection region might be less extreme than the statistics in the acceptance region. That is, the p-value for observed statistics in the rejection region might be greater than the significance level.

MLE Ordering

The MLE ordering (Emerson and Fleming 1990) depends only on the observed maximum likelihood estimate. $(k', z') \succ (k, z)$ if

$$\frac{z'}{\sqrt{I_{k'}}} > \frac{z}{\sqrt{I_k}}$$

The MLE ordering is applicable to all designs if all information levels are available.

Applicable Tests and Sample Size Computation

The SEQDESIGN procedure assumes that the data are from a multivariate normal distribution and the sequence of the standardized test statistics $\{Z_1, Z_2, \ldots, Z_K\}$ have the following canonical joint distribution:

- $Z_k \sim N\left(\theta\sqrt{I_k}, 1\right)$
- $\text{Cov}(Z_{k_1}, Z_{k_2}) = \sqrt{I_{k_1}/I_{k_2}} \quad , \quad 1 \le k_1 \le k_2 \le K$

where K is the total number of stages and I_k is the information available at stage k.

If the data are not from a normal distribution such as binomial distribution, then it is assumed that the test statistic is computed from a large sample such that the statistic has an approximately normal distribution.

In a clinical trial, the sample size required depends on the Type I error probability α, reference improvement θ_1, power $1-\beta$, and variance of the response variable. Given a null hypothesis $H_0 : \theta = 0$ with an upper alternative hypothesis $H_1 : \theta = \theta_1$, the information required for a fixed-sample test is given by

$$I_0 = \frac{(\Phi^{-1}(1-\alpha) + \Phi^{-1}(1-\beta))^2}{\theta_1^2}$$

where the parameter θ depends on the test specified in the clinical trial. For example, if you are comparing two binomial populations $H_0 : \theta = 0$, then $\theta = p_t - p_c$ is the difference between two proportions if the proportion difference statistic is used, and $\theta = \log\left(\frac{p_t(1-p_c)}{p_c(1-p_t)}\right)$, the log odds ratio for the two proportions if the log odds ratio statistic is used.

If the maximum likelihood estimate $\hat{\theta}$ from the likelihood function can be derived, then the asymptotic variance for $\hat{\theta}$ is $\text{Var}(\hat{\theta}) = 1/I$, where I is Fisher's information for θ.

The resulting statistic $\hat{\theta}$ corresponds to the MLE scale as specified in the BOUNDARYSCALE=MLE option in the PROC SEQDESIGN statement, $\hat{\theta}\sqrt{I}$ corresponds to the standardized Z scale (BOUNDARYSCALE=STDZ), and $\hat{\theta}I$ corresponds to the score scale (BOUNDARYSCALE=SCORE).

Alternatively, if the score statistic is derived, it can also be used as the test statistic and its asymptotic variance is given by Fisher's information.

For a group sequential trial, the maximum information I_X is derived in the SEQDESIGN procedure by using the specified α, β, and θ_1. With the maximum information

$$I_X = \frac{1}{\text{Var}(\hat{\theta})}$$

the sample size required for a specified test statistic in the trial can be evaluated or estimated from the known or estimated variance of the response variable. Note that different designs might produce different maximum information levels for the same hypothesis, and this in turn might require a different number of observations for the trial.

With a specified test statistic, the resulting information levels can be computed and then used to derive the required sample size. These tests include commonly used tests for normal means, binomial proportions, and survival distributions. See the section "Applicable Tests and Sample Size Computation" in "The SEQDESIGN Procedure" for a description of these tests.

Table Output

The SEQTEST procedure displays the "Design Information" and "Test Information" tables by default.

Conditional Power

The "Conditional Power Information" table displays the following information under a hypothetical reference:

- stopping stage
- MLE, observed maximum likelihood estimate
- conditional power under the hypothetical reference

For a one-sided test, the power are derived under hypothetical references $\theta = \hat{\theta}$ and $\theta = c_i\theta_1$, where $\hat{\theta}$ is the observed statistic, θ_1 is the alternative reference, and c_i are the values specified in the CREF= option. For a two-sided test, the power are derived under the hypothetical references $\theta = \hat{\theta}$, $\theta = c_i\theta_{1l}$, and $\theta = c_i\theta_{1u}$, where θ_{1l} is the lower alternative reference and θ_{1u} is the upper alternative reference. The default is CREF= 0 0.5 1.0 1.5.

Design Information

The "Design Information" table displays the design specifications and derived statistics. The derived Max Information (Percent Fixed-Sample) is the maximum information for the sequential design in percentage of the corresponding fixed-sample information.

The Null Ref ASN (Percent Fixed-Sample) is the average sample size required under the null hypothesis for the group sequential design in percentage of the corresponding fixed-sample design. Similarly, the Alt Ref ASN (Percent Fixed-Sample) is the average sample size required under the alternative reference for the group sequential design in percentage of the corresponding fixed-sample design.

Error Spending Information

The "Error Spending Information" table displays the following information at each stage:

- proportion of information
- actual information level, if the maximum information is either specified or derived
- cumulative error spending for each boundary

Parameter Estimates

The "Parameter Estimates" table displays the following information at the conclusion of a sequential trial:

- stopping stage
- parameter estimate
- median and confidence limits based on the specified ordering
- p-value for the hypothesis H_0 based on the specified ordering

Powers and Expected Sample Sizes

The "Powers and Expected Sample Sizes" table displays the following information under each of the specified hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option.

- coefficient c_i for the hypothetical references. The value $c_i = 0$ corresponds to the null hypothesis and $c_i = 1$ corresponds to the alternative hypothesis
- power
- expected sample size, as percentage of fixed-sample size

For a one-sided design, the power and expected sample sizes under the hypothetical references $\theta = c_i\theta_1$ are displayed.

For a two-sided symmetric design, the power and expected sample sizes under each of the hypothetical references $\theta = c_i\theta_{1u}$ are displayed, where θ_{1u} is the upper alternative reference.

For a two-sided asymmetric design, the power and expected sample sizes under each of the hypothetical references $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively.

For a two-sided design, the power is the probability of correctly rejecting the null hypothesis for the correct alternative. Thus, under the null hypothesis, the displayed power corresponds to a one-sided Type I error probability level—that is, the lower α level or the upper α level.

The expected sample size as a percentage of the corresponding fixed-sample design is

$$100 \times \frac{\sum_{k=1}^{K} p_k\, I_k}{I_0}$$

where p_k is the stopping probability at stage k, $\sum_{k=1}^{K} p_k\, I_k$ is the expected information level, and I_0 is the information level for the fixed-sample design.

Predictive Power

The "Predictive Power Information" table displays the following information:

- stopping stage
- MLE, observed maximum likelihood estimate
- predictive power

Repeated Confidence Intervals

The "Repeated Confidence Intervals" table displays the following information for the observed statistic at each stage:

- information level
- parameter estimate
- rejection confidence limits. The null hypothesis is rejected for the upper alternative if the lower rejection confidence limit is greater than the null parameter value. Similarly, the null hypothesis is rejected for the lower alternative if the upper rejection confidence limit is less than the null parameter value.
- acceptance confidence limits. The upper alternative hypothesis is rejected if the upper acceptance confidence limit is less than the upper alternative value. Similarly, the lower alternative hypothesis is rejected if the lower acceptance confidence limit is greater than the upper alternative value. For a two-sided design, if both upper and lower alternative hypothesis are rejected, the null hypothesis is accepted.

Stopping Probabilities

The "Expected Cumulative Stopping Probabilities" table displays the following information under each of the specified hypothetical references $\theta = c_i\theta_1$, where c_i are values specified in the CREF= option, and θ_1 is the alternative reference:

- coefficient c_i for the hypothetical references. The value $c_i = 0$ corresponds to the null hypothesis, and $c_i = 1$ corresponds to the alternative hypothesis
- expected stopping stage
- source of the stopping probability: reject H_0 (with STOP=REJECT or STOP=BOTH), accept H_0 (with STOP=ACCEPT or STOP=BOTH), or either reject or accept H_0 (with STOP=BOTH)
- expected cumulative stopping probabilities at each stage

For a one-sided design, the expected cumulative stopping probabilities under the hypothetical references $\theta = c_i\theta_1$ are displayed.

For a two-sided design, the expected cumulative stopping probabilities under each of the hypothetical references $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively.

Note that for a symmetric two-sided design, only the expected cumulative stopping probabilities under the hypothetical references $\theta = c_i\theta_{1u}$ are derived.

The expected stopping stage is given by $k_0 + d$ and is derived from the expected information level

$$\sum_{k=1}^{K} p_k\, I_k = I_{k_0} + d\,(I_{(k_0+1)} - I_{k_0})$$

where p_k is the stopping probability at stage k and $0 \leq d < 1$.

For equally spaced information levels, the expected stopping stage is reduced to the weighted average

$$\sum_{k=1}^{K} p_k\, k$$

Test Information

The "Test Information" table displays the following information at each stage:

- proportion of information
- actual information level, if the maximum information is available from the input BOUNDARY= data set
- alternative references with the specified statistic scale. If a p-value scale is specified, the standardized Z scale is used.
- boundary values with the specified statistic scale to reject or accept the null hypothesis

Note that implicitly, the test information table also contains variables for the boundary scale, stopping criterion, and type of alternative hypothesis. That is, if an ODS statement is used to save the table, the data set also contains the variables _Scale_ for the boundary scale, _Stop_ for the stopping criterion, and _ALT_ for the type of alternative hypothesis.

If the test variable is specified, the table also displays the following:

- test statistic
- resulting action of test statistic: continue to the next stage, accept the null hypothesis H_0, or reject H_0

ODS Table Names

PROC SEQTEST assigns a name to each table it creates. You must use these names to reference tables when using the Output Delivery System (ODS). These names are listed in Table 78.3. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 78.3 ODS Tables Produced by PROC SEQTEST

ODS Table Name	Description	Option
CondPower	Conditional power	CONDPOWER
Design	Design information	
ErrSpend	Error spending	ERRSPEND
ParameterEstimates	Parameter estimates	DATA(TESTVAR=) or PARMS(TESTVAR=)
PowerSampleSize	Power and expected sample sizes	PSS
PredPower	Predictive power	PREDPOWER
RepeatedCI	Repeated confidence intervals	RCI
StopProb	Stopping probabilities	STOPPROB
Test	Test statistics and boundary values	

Graphics Output

This section describes the use of ODS for creating graphics with the SEQTEST procedure. To request these graphs, you must specify the ODS GRAPHICS ON statement in addition to the associated graphics options in the PROC SEQTEST statement. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

Sequential ASN Plot

The PLOTS=ASN option displays the average sample numbers (expected sample sizes for nonsurvival data or expected numbers of events for survival data) under various hypothetical references. The average sample numbers are connected for each design, and these connected curves for all designs are displayed in the "Sequential ASN Plot" graph.

For a one-sided design, average sample numbers under the hypothetical references $\theta = c_i\theta_1$ are displayed, where c_i are the values specified in the CREF= option and θ_1 is the alternative reference. The horizontal axis displays the c_i values of these hypothetical references.

For a two-sided design, average sample numbers under each of the hypothetical references $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The horizontal axis displays $-c_i$ values for lower hypothetical references $\theta = c_i\theta_{1l}$ and c_i values for upper hypothetical references $\theta = c_i\theta_{1u}$. Note that for a symmetric two-sided design, only average sample numbers under the hypothetical references $\theta = c_i\theta_{1u}$ are derived.

If the trial stops after the sequential test, the hypothetical reference corresponding to the test statistic is also indicated in the plot.

Conditional Power Plot

The PLOTS=CONDPOWER option displays the conditional powers given the observed statistic under various hypothetical references. These powers are connected and are displayed in the "Conditional Power Plot" graph.

For a one-sided test, the power are derived under the hypothetical references $\theta = \hat{\theta}$ and $\theta = c_i\theta_1$, where $\hat{\theta}$ is the observed statistic, θ_1 is the alternative reference, and c_i are the values specified in the CREF= option. The horizontal axis displays these c_i values for hypothetical references.

For a two-sided test, the power are derived under hypothetical references $\theta = \hat{\theta}$, $\theta = c_i\theta_{1l}$, and $\theta = c_i\theta_{1u}$, where θ_{1l} is the lower alternative reference and θ_{1u} is the upper alternative reference. The horizontal axis displays $-c_i$ values for hypothetical references $\theta = c_i\theta_{1l}$ and c_i values for hypothetical references $\theta = c_i\theta_{1u}$.

If the trial stops after the sequential test, the hypothetical reference corresponding to the test statistic is also indicated in the plot.

Sequential Error Spending Plot

The PLOTS=ERRSPEND option displays the cumulative error spending at each stage on each boundary in the "Sequential Error Spending Plot" graph. A legend table uses the design labels to identify the curves for the corresponding design in the plot.

Sequential Power Plot

The PLOTS=POWER option displays the powers under various hypothetical references. The powers are connected for each design, and these connected curves for all designs are displayed in the "Sequential Power Plot" graph.

For a one-sided design, powers under hypothetical references $\theta = c_i\theta_1$ are displayed, where c_i are the values specified in the CREF= option and θ_1 is the alternative reference. The horizontal axis displays the c_i values of these hypothetical references.

For a two-sided design, powers under hypothetical references $\theta = c_i\theta_{1l}$ and $\theta = c_i\theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The horizontal axis displays $-c_i$ values for lower hypothetical references $\theta = c_i\theta_{1l}$ and c_i values for upper hypothetical references $\theta = c_i\theta_{1u}$. Note that for a symmetric two-sided design, only powers under hypothetical references $\theta = c_i\theta_{1u}$ are derived.

If the trial stops after the sequential test, the hypothetical reference corresponding to the test statistic is also indicated in the plot.

Repeated Confidence Intervals Plot

The PLOTS=RCI option displays repeated confidence intervals at each stage given the observed statistic at that stage. These repeated confidence intervals are displayed in the "Repeated Confidence Intervals Plot" graph.

Sequential Test Plot

The PLOTS=TEST option displays boundary values and test statistics in the "Test Plot" graph. The boundary values are connected for each boundary, and both the stage number and the information level at each stage are displayed. The legend table identifies the acceptance and rejection regions in the plot.

ODS Graphics

PROC SEQTEST assigns a name to each graph it creates. You can use these names to reference the graphs when using ODS. The names are listed in Table 78.4.

To request these graphs, you must specify the ODS GRAPHICS ON statement in addition to the options indicated in Table 78.4. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

Table 78.4 ODS Graphics Produced by PROC SEQTEST

ODS Graph Name	Plot Description	Option
AsnPlot	Average sample numbers	PLOTS=ASN
CondPowerPlot	Conditional power curves	PLOTS=CONDPOWER
ErrSpendPlot	Error spending	PLOTS=ERRSPEND
PowerPlot	Power curves	PLOTS=POWER
RepeatedCIPlot	Repeated confidence intervals	PLOTS=RCI
TestPlot	Boundary values and test statistics	PLOTS=TEST

Examples: SEQTEST Procedure

The following examples perform group sequential tests with various designs and test statistics.

Four statistic scales are available for the input boundary values, the input test statistic, and the displayed test information in the SEQTEST procedure. These are the maximum likelihood estimator scale, score statistic scale, standardized normal Z scale, and p-value scale. There is a unique one-to-one transformation between any two of the scales, and you can use different scales for the input boundary values and input test statistic. These boundary values and test statistic are displayed with

the scale specified in the BOUNDARYSCALE= option in the SEQTEST procedure.

Example 78.1: Testing the Difference between Two Proportions

This example demonstrates group sequential tests that use an O'Brien-Fleming group sequential design. A clinic is studying the effect of vitamin C supplements in treating flu symptoms. The study consists of patients in the clinic who have exhibited the first sign of flu symptoms within the last 24 hours. These patients are randomly assigned to either the control group (which receives placebo pills) or the treatment group (which receives large doses of vitamin C supplements). At the end of a five-day period, the flu symptoms of each patient are recorded.

Suppose that you know from past experience that flu symptoms disappear in five days for 60% of patients who experience flu symptoms. The clinic would like to detect a 75% symptom disappearance with a high probability. A test that compares the proportions directly specifies the null hypothesis $H_0 : \theta = p_t - p_c = 0$ with a one-sided alternative $H_1 : \theta > 0$ and a power of 0.90 at $H_1 : \theta = 0.15$, where p_t and p_c are the proportions of symptom disappearance in the treatment group and control group, respectively.

The following statements invoke the SEQDESIGN procedure and request a four-stage group sequential design by using an O'Brien-Fleming method for normally distributed data. The design uses a one-sided alternative hypothesis with early stopping either to accept or reject the null hypothesis H_0. The BOUNDARYSCALE=MLE option uses the MLE scale to display statistics in the boundary table and boundary plots.

```
ods graphics on;
proc seqdesign altref=0.15
               boundaryscale=mle
               ;
   OBrienFleming: design method=obf
                         nstages=4
                         alt=upper
                         stop=both
                         alpha=0.025
                         ;
   samplesize model=twosamplefreq(nullprop=0.6 test=prop);
ods output Boundary=Bnd_Count;
run;
ods graphics off;
```

The ODS OUTPUT statement with the BOUNDARY=BND_COUNT option creates an output data set named BND_COUNT which contains the resulting boundary information for the subsequent sequential tests.

The "Design Information" table in Output 78.1.1 displays design specifications. With the specified alternative hypothesis $H_1 : \theta = 0.15$, the maximum information is derived to achieve a power of 0.90 at H_1. The derived fixed-sample information ratio 1.0767 is the maximum information needed for a group sequential design relative to its corresponding fixed-sample design.

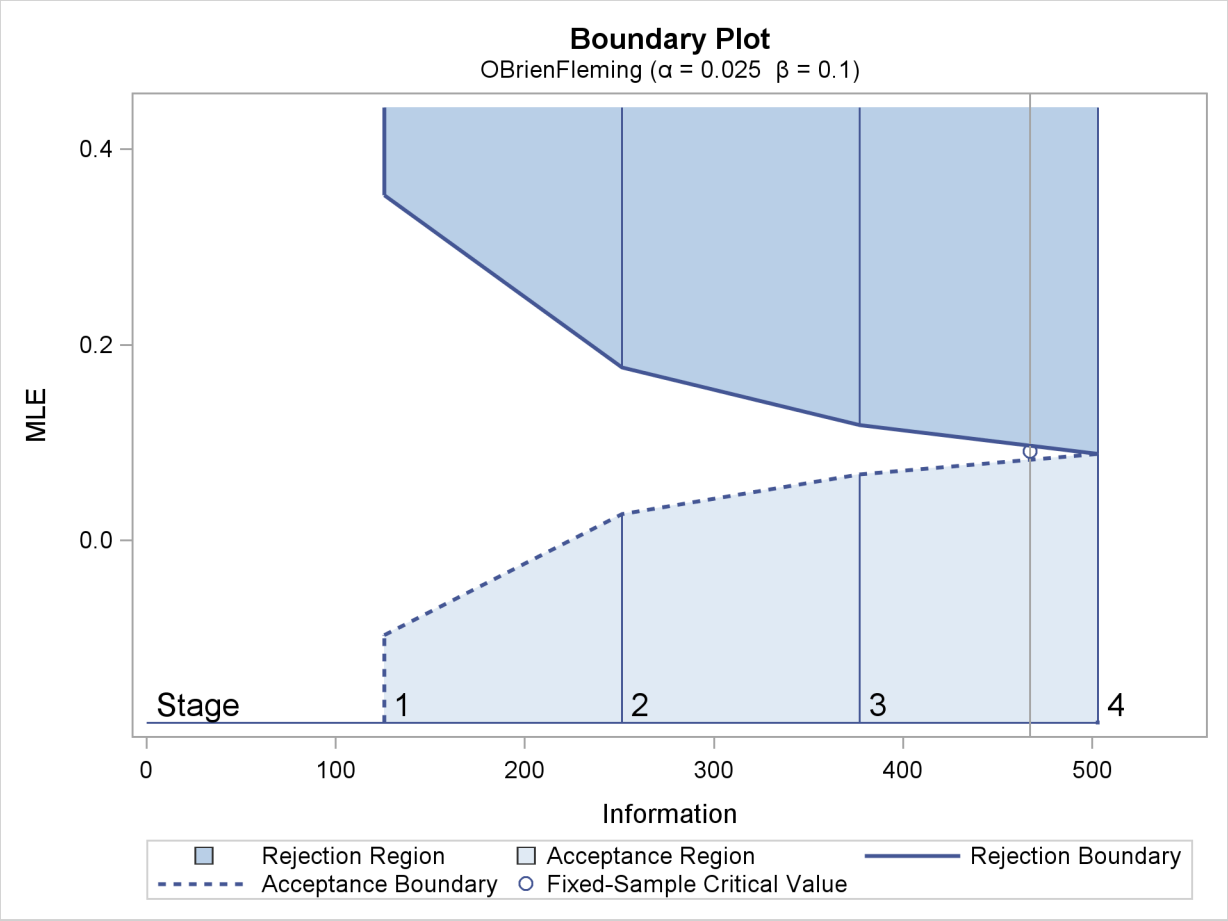
Output 78.1.1 O'Brien-Fleming Design Information

The SEQDESIGN Procedure
Design: OBrienFleming

Design Information

Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	0.15
Number of Stages	4
Alpha	0.025
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	107.6741
Max Information	502.8343
Null Ref ASN (Percent of Fixed Sample)	61.12891
Alt Ref ASN (Percent of Fixed Sample)	75.89782

The "Boundary Information" table in Output 78.1.2 displays the information level, alternative reference, and boundary values at each stage. With the BOUNDARYSCALE=MLE option, the SEQDESIGN procedure displays the output boundaries with the maximum likelihood estimator scale.



Output 78.1.2 O'Brien-Fleming Boundary Information

Boundary Information (MLE Scale)
Null Reference = 0

	Information Level			Alternative Reference	Boundary Values	
					Upper	
Stage	Proportion	Actual	N	Upper	Beta	Alpha
1	0.2500	125.7086	107.4808	0.15000	-0.09709	0.35291
2	0.5000	251.4171	214.9617	0.15000	0.02645	0.17645
3	0.7500	377.1257	322.4425	0.15000	0.06764	0.11764
4	1.0000	502.8343	429.9233	0.15000	0.08823	0.08823

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 78.1.3. The horizontal axis indicates the information levels for the design. The stages are indicated by vertical lines with accompanying stage numbers. If the test statistic at a stage is in a rejection region, the trial stops and the hypothesis is rejected. If the test statistic is in an acceptance region, then the trial also stops and the hypothesis is accepted. If the statistic is not in a rejection or an acceptance region, the trial continues to the next stage.

Output 78.1.3 O'Brien-Fleming Boundary Plot

The boundary plot also displays the information level and critical value for the corresponding fixed-sample design. The solid and dashed lines at the fixed-sample information level correspond to the rejection and acceptance lines, respectively.

With the SAMPLESIZE statement, the maximum information is used to derive the required sample size for the study. The "Sample Size Summary" table in Output 78.1.4 displays parameters for the sample size computation.

Output 78.1.4 Required Sample Size Summary

Sample Size Summary

Test	Two-Sample Proportions
Null Proportion	0.6
Proportion (Group A)	0.75
Test Statistic	Z for Proportion
Reference Proportions	Alt Ref
Max Sample Size	429.9233
Expected Sample Size (Null Ref)	244.0768
Expected Sample Size (Alt Ref)	303.0464

With the derived maximum information and the specified MODEL= option in the SAMPLESIZE statement, the total sample size in each group for testing the difference between two proportions under the alternative hypothesis is

$$N_1 = N_2 = \left(p_{1c}\left(1 - p_{1c}\right) + p_{1t}\left(1 - p_{1t}\right)\right) I_X$$

where $p_{1c} = 0.6$ and $p_{1t} = p_{1c} + \theta_1 = 0.75$. By default (or equivalently, if you specify REF=PROP), the required sample sizes are computed under the alternative hypothesis. See the section "Test for the Difference between Two Binomial Proportions" in the chapter "The SEQDESIGN Procedure" for a description of these parameters.

The "Sample Sizes (N)" table in Output 78.1.5 displays the required sample sizes at each stage, in both fractional and integer numbers. The derived sample sizes under the heading Fractional N which correspond to the design are not integers. These sample sizes are rounded up to integers under the heading Ceiling N. In practice, integer sample sizes are used, and the information levels increase slightly. Thus, 54, 108, 162, and 215 patients are needed in each group for the four stages, respectively.

Output 78.1.5 Required Sample Sizes

Sample Sizes (N)
Two-Sample Z Test for Proportion Difference

	Fractional N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	107.48	53.74	53.74	125.7
2	214.96	107.48	107.48	251.4
3	322.44	161.22	161.22	377.1
4	429.92	214.96	214.96	502.8

Sample Sizes (N)
Two-Sample Z Test for Proportion Difference

	Ceiling N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	108	54	54	126.3
2	216	108	108	252.6
3	324	162	162	378.9
4	430	215	215	502.9

Suppose the trial follows the study plan, and 54 patients are available in each group at stage 1. The data set count_1 contains these 108 patients. Output 78.1.6 lists the first 10 observations of the data set.

Output 78.1.6 Clinical Trial Data

First 10 Obs in the Trial Data

Obs	Trt	Resp
1	0	0
2	1	1
3	0	1
4	1	0
5	0	0
6	1	0
7	0	0
8	1	1
9	0	1
10	1	0

The Trt variable is a grouping variable with value 0 for a patient in the placebo control group and value 1 for a patient in the treatment group who is given vitamin C supplements. The Resp variable is an indicator variable with value 1 for a patient without flu symptoms after five days and value 0 for a patient with flu symptoms after five days.

The following statements use the GENMOD procedure to estimate the treatment effect at stage 1:

```
proc genmod data=count_1;
   model Resp= Trt;
ods output ParameterEstimates=Parms_Count1;
run;
```

Output 78.1.7 displays the treatment effect at stage 1.

Output 78.1.7 Stage 1 Treatment Difference

The GENMOD Procedure

Analysis Of Maximum Likelihood Parameter Estimates

Parameter	DF	Estimate	Standard Error	Wald 95% Confidence Limits		Wald Chi-Square	Pr > ChiSq
Intercept	1	0.6296	0.0627	0.5066	0.7526	100.68	<.0001
Trt	1	0.1111	0.0887	-0.0628	0.2850	1.57	0.2105
Scale	1	0.4611	0.0314	0.4035	0.5269		

NOTE: The scale parameter was estimated by maximum likelihood.

The test statistic is $\hat{\theta}_1 = \hat{p}_t - \hat{p}_c = 0.1111$, and its associated standard error is

$$\sqrt{\mathrm{Var}(\hat{\theta}_1)} = \sqrt{\frac{\hat{p}_c(1-\hat{p}_c)}{54} + \frac{\hat{p}_t(1-\hat{p}_t)}{54}} = 0.0887$$

The following statements create and display (in Output 78.1.8) the data set that contains the parameter estimate at stage 1, $\hat{\theta}_1 = 0.1111$, and its associated standard error $\sqrt{\text{Var}(\hat{\theta}_1)} = 0.0887$ which are used in the SEQTEST procedure:

```
data Parms_Count1;
   set Parms_Count1;
   if Parameter='Trt';
   _Scale_='MLE';
   _Stage_= 1;
   keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;

proc print data=Parms_Count1;
   title 'Statistics Computed at Stage 1';
run;
```

Output 78.1.8 Statistics Computed at Stage 1

Statistics Computed at Stage 1

Obs	Parameter	Estimate	StdErr	_Scale_	_Stage_
1	Trt	0.1111	0.0887	MLE	1

The initial required sample sizes are derived with the proportions $p_c = 0.6$ and $p_t = 0.75$. If the observed proportions are different from these assumed values, or if the number of available patients is different from the original plan in one of the stages, then the information level that corresponds to the test statistic is estimated from

$$I_k = \frac{1}{\text{Var}(\hat{\theta}_k)}$$

The following statements invoke the SEQTEST procedure and test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Count
             Parms(Testvar=Trt)=Parms_Count1
             errspendmin=0.001
             boundaryscale=mle
             errspend
             plots=errspend
             ;
ods output Test=Test_Count1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_COUNT1 option specifies the input data set PARMS_COUNT1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=TRT option identifies the test variable TRT in the data set.

The O'Brien-Fleming design is conservative in early stages and might not be desirable in a clinical trial. The ERRSPENDMIN=0.001 option specifies the minimum error spending at each stage to be 0.001, and it might increase the corresponding nominal p-value in early stages for the trial. The BOUNDARYSCALE=MLE option uses the MLE scale to display test statistics in the boundary table and boundary plots.

The ODS OUTPUT statement with the TEST=TEST_COUNT1 option creates an output data set named TEST_COUNT1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Design Information" table in Output 78.1.9 displays design specifications. The derived statistics, such as the overall α and β levels, are derived from the specified maximum information and boundary values in the BOUNDARY= data set. Note that with a minor change in the information level at stage 1, the power also changes slightly from the original design.

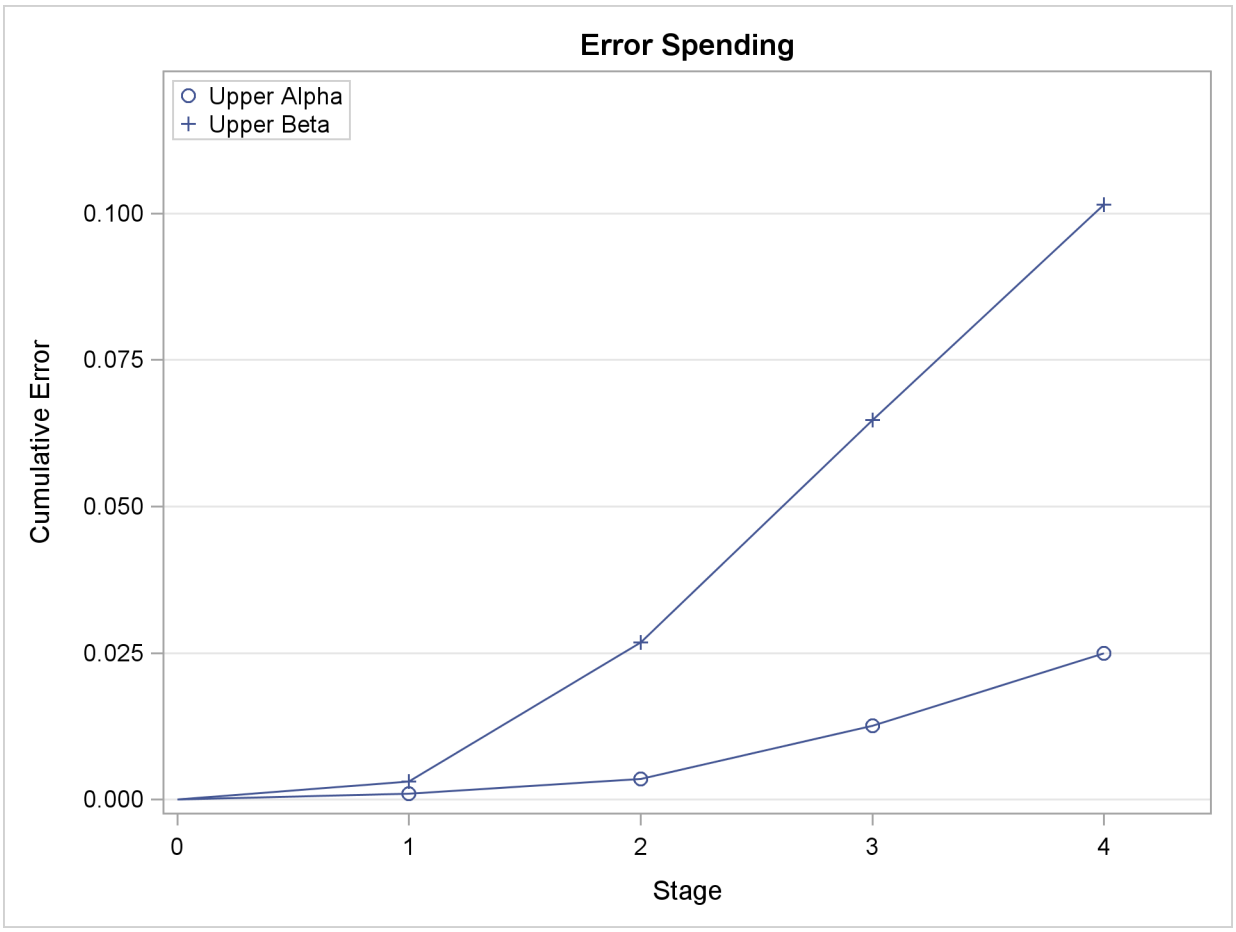
Output 78.1.9 Design Information

The SEQTEST Procedure

Design Information

BOUNDARY Data Set	WORK.BND_COUNT
Data Set	WORK.PARMS_COUNT1
Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Number of Stages	4
Alpha	0.025
Beta	0.10154
Power	0.89846
Max Information (Percent of Fixed Sample)	108.2541
Max Information	502.834283
Null Ref ASN (Percent of Fixed Sample)	61.13266
Alt Ref ASN (Percent of Fixed Sample)	73.9393

With the ERRSPEND option, the "Error Spending Information" table in Output 78.1.10 displays cumulative error spending at each stage for each boundary. With the default BOUNDARYKEY=ALPHA and the specified ERRSPENDMIN=0.001 options, the α spending at each stage is at least 0.001.



Output 78.1.10 Error Spending Information

Error Spending Information

Stage	---Information Level-- Proportion	Actual	-Cumulative Error Spending- ----------Upper---------- Beta	Alpha
1	0.2525	126.9871	0.00308	0.00100
2	0.5017	252.2695	0.02680	0.00349
3	0.7508	377.5519	0.06472	0.01258
4	1.0000	502.8343	0.10154	0.02500

With the PLOTS=ERRSPEND option, the procedure displays a plot of error spending for each boundary, as shown in Output 78.1.11. The error spending values in the "Error Spending Information" table in Output 78.1.10 are displayed in the plot.

Output 78.1.11 Error Spending Plot

The "Test Information" table in Output 78.1.12 displays the boundary values for the design, test statistic, and resulting action at each stage. With the BOUNDARYSCALE=MLE option, the maximum likelihood estimator scale is used for the test statistic and boundary values. The table shows

that the test statistic 0.1111 is between the upper α and β boundaries, so the trial continues to the next stage.

Output 78.1.12 Sequential Test

Test Information (MLE Scale)
Null Reference = 0

Stage	Information Level Proportion	Information Level Actual	Alternative Reference Upper	Boundary Values Upper Beta	Boundary Values Upper Alpha
1	0.2525	126.9871	0.15000	-0.09304	0.27423
2	0.5017	252.2695	0.15000	0.02724	0.17450

2	.	
3	.	
4	.	

The information level at stage 1 is derived from the standard error,

$$I_1 = \frac{1}{\mathrm{Var}(\hat{\theta}_1)} = \frac{1}{(\mathrm{s.e.}(\hat{\theta}_1))^2}$$

With the default PLOTS=TEST option, the "Test Plot" graph displays boundary values of the design and the test statistic at stage 1, as shown in Output 78.1.13. It also shows that the observed statistic is in the continuation region.

Output 78.1.13 Sequential Test Plot

The observed information level at stage 1, $I_1 = 126.987$, is slightly larger than the target information level at the design. If an observed information level in the study is substantially different from its target level in the design, then the sample sizes should be adjusted in the subsequent stages to achieve the target information levels.

Suppose the trial continues to the next stage, and 108 patients are available in each group at stage 2. The data set COUNT_2 contains these 216 patients.

The following statements use the GENMOD procedure to estimate the treatment effect at stage 2:

```
proc genmod data=Count_2;
   model Resp= Trt;
ods output ParameterEstimates=Parms_Count2;
run;
```

The following statements create the parameter estimate at stage 2, $\hat{\theta}_2 = \hat{p}_2 - \hat{p}_1 = 0.1759$, and its associated standard error $\sqrt{\mathrm{Var}(\hat{\theta}_2)} = 0.0623$ into a test data set:

```
data Parms_Count2;
   set Parms_Count2;
   if Parameter='Trt';
```

```
   _Scale_='MLE';
   _Stage_= 2;
   keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;

proc print data=Parms_Count2;
   title 'Statistics Computed at Stage 2';
run;
```

Output 78.1.14 displays the test statistics at stage 2.

Output 78.1.14 Statistics Computed at Stage 2

Statistics Computed at Stage 2

Obs	Parameter	Estimate	StdErr	_Scale_	_Stage_
1	Trt	0.1759	0.0623	MLE	2

The following statements invoke the SEQTEST procedure and test for early stopping at stage 2:

```
ods graphics on;
proc seqtest Boundary=Test_Count1
             Parms(Testvar=Trt)=Parms_Count2
             boundaryscale=mle
             ;
ods output Test=Test_Count2;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

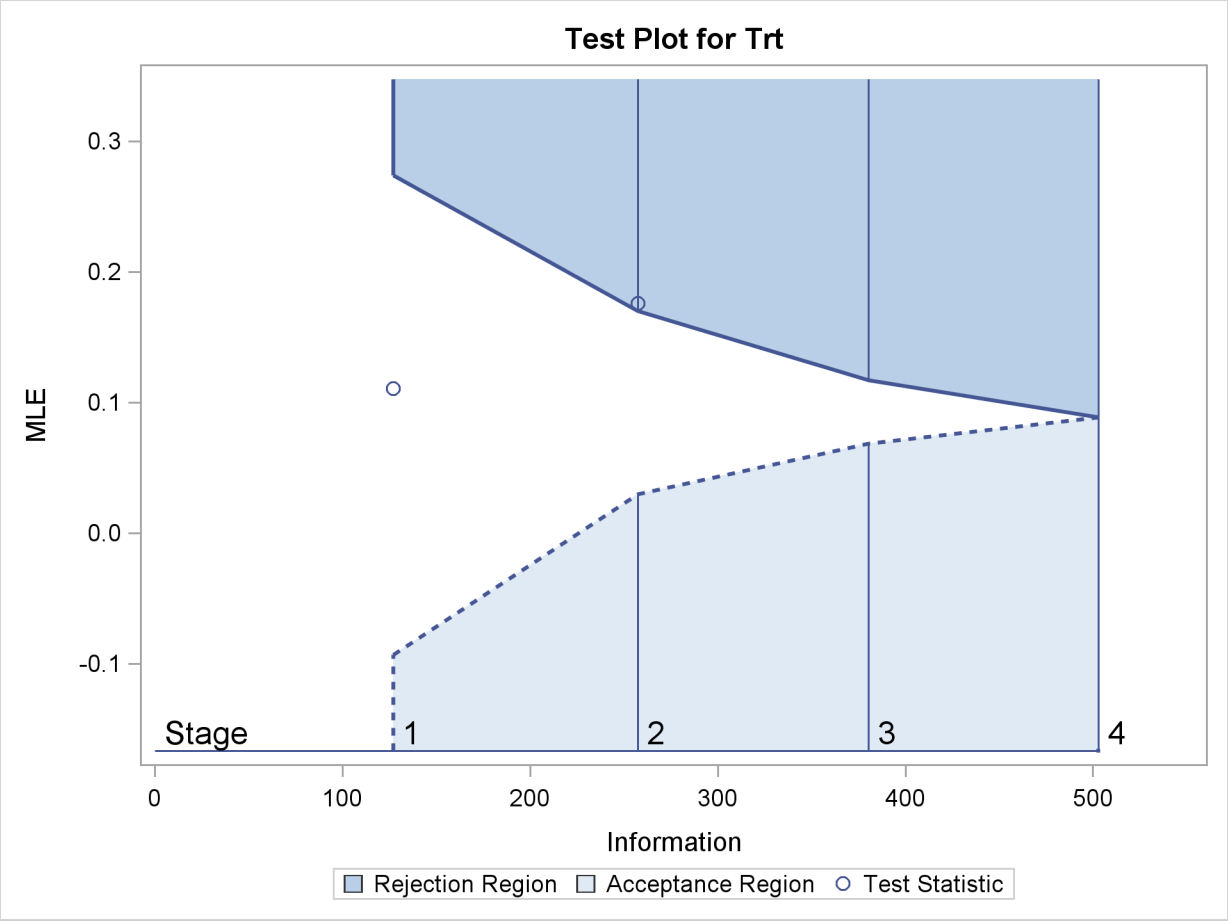
The ODS OUTPUT statement with the TEST=TEST_COUNT2 option creates an output data set named TEST_COUNT2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Test Information" table in Output 78.1.15 displays the boundary values, test statistic, and resulting action at each stage. The table shows that the test statistic 0.17593 is larger than the corresponding upper alpha boundary value, so the trial stops to reject the hypothesis.

Output 78.1.15 Sequential Test

The SEQTEST Procedure

Test Information (MLE Scale)
Null Reference = 0



Stage	Information Level-- Proportion	Actual	-Alternative- --Reference-- Upper	Boundary Values---- ----------Upper--------- Beta	Alpha
1	0.2525	126.9871	0.15000	-0.09304	0.27423
2	0.5122	257.5571	0.15000	0.03024	0.17001
3	0.7561	380.1957	0.15000	0.06863	0.11722
4	1.0000	502.8343	0.15000	0.08882	0.08882

Test Information (MLE Scale)

1	0.11111	Continue
2	0.17593	Reject Null
3	.	
4	.	

With the specified ODS GRAPHICS ON statement, the "Test Plot" is displayed by default, as shown in Output 78.1.16. The plot displays boundary values of the design and the test statistics at the first two stages. As expected, the test statistic at stage 2 is in the "Upper Rejection Region" above the upper alpha boundary.

Output 78.1.16 Sequential Test Plot

After a trial is stopped, the "Parameter Estimates" table in Output 78.1.17 displays the stopping stage and the maximum likelihood estimate of the parameter. It also displays the p-value, median estimate, and confidence limits for the parameter that correspond to the observed statistic by using the specified sample space ordering.

Output 78.1.17 Parameter Estimates

Parameter Estimates
Stagewise Ordering

Parameter	Stopping Stage	MLE	p-Value for H0:Parm=0	Median Estimate	Lower 95% CL
Trt	2	0.175926	0.0031	0.174462	0.07059

The MLE statistic at the stopping stage is the maximum likelihood estimate of the parameter and is biased. The computation of p-value, unbiased median estimate, and confidence limits depends on the ordering of the sample space (k, z), where k is the stage number and z is the observed standardized Z statistic. With the default ORDER=STAGEWISE option, the stagewise ordering

that uses counterclockwise ordering around the continuation region is used to compute the p-value, unbiased median estimate, and confidence limits. As expected, the p-value is less than 0.025, and the confidence interval does not contain the null reference zero. With the stagewise ordering, the p-value is computed as

$$P_{\theta=0}\left(Z_1 > a_1\right) + P_{\theta=0}\left(Z_2 > z_2 \mid _a_1 < Z_1 < a_1\right)$$

where z_2 is the observed standardized Z statistic at stage 2, Z_1 is the standardized normal variate at stage 1, Z_2 is the standardized normal variate at stage 2, and $_a_1$ and a_1 are the stage 1 lower and upper rejection boundary values, respectively.

See the section "Available Sample Space Orderings in a Sequential Test" on page 6025 for a detailed description of the stagewise ordering.

Example 78.2: Testing an Effect in a Regression Model

This example demonstrates a two-sided group sequential test that uses an error spending design with early stopping to reject the null hypothesis. A study is conducted to examine the effects of Age (years), Weight (kg), RunTime (time in minutes to run 1.5 miles), RunPulse (heart rate while running), and MaxPulse (maximum heart rate recorded while running) on Oxygen (oxygen intake rate, ml per kg body weight per minute). The primary interest is whether oxygen intake rate is associated with weight.

The hypothesis is tested using the following linear model:

$$\text{Oxygen} = \text{Age} + \text{Weight} + \text{RunTime} + \text{RunPulse} + \text{MaxPulse}$$

The null hypothesis is $H_0 : \beta_w = 0$, where β_w is the regression parameter for the variable Weight. Suppose that $\beta_w = 0.10$ is the reference improvement that should be detected at a 0.90 level. Then the maximum information I_X can be derived in the SEQDESIGN procedure.

Following the derivations in the section "Test for a Parameter in the Regression Model" in the chapter "The SEQDESIGN Procedure," the required sample size can be derived from

$$N = I_X \frac{\sigma_y^2}{\left(1 - r_x^2\right)\sigma_x^2}$$

where σ_y^2 is the variance of the response variable in the regression model, r_x^2 is the proportion of variance of Weight explained by other covariates, and σ_x^2 is the variance of Weight.

Further suppose that from past experience, $\sigma_y^2 = 5$, $r_x^2 = 0.10$, and $\sigma_x^2 = 64$. Then the required sample size can be derived using the SAMPLESIZE statement in the SEQDESIGN procedure.

The following statements invoke the SEQDESIGN procedure and request a three-stage group sequential design for normally distributed data to test the null hypothesis of a regression parameter $H_0 : \beta_w = 0$ against the alternative $H_1 : \beta_w \neq 0$:

```
ods graphics on;
proc seqdesign altref=0.10;
   OBFErrorFunction: design method=errfuncobf
                           nstages=3
                           info=cum(2 3 4)
                           ;
   samplesize model=reg(variance=5 xvariance=64 xrsquare=0.10);
ods output Boundary=Bnd_Fit;
run;
ods graphics off;
```

By default, the procedure uses a Type I error probability 0.05 and a Type II error probability 0.10. The ALTREF=0.10 option specifies a power of $1 - \beta = 0.90$ at the alternative hypothesis $H_1 : \beta_w = \pm 0.10$. The INFO=CUM(2 3 4) option specifies that the study perform the first interim analysis with information proportion $2/4 = 0.5$—that is, after half of the total observations are collected.

The ODS OUTPUT statement with the BOUNDARY=BND_FIT option creates an output data set named BND_FIT which contains the resulting boundary information for the subsequent sequential tests.

The "Design Information" table in Output 78.2.1 displays design specifications and derived statistics. Since the alternative reference is specified, the maximum information is derived.

Output 78.2.1 Error Spending Design Information

The SEQDESIGN Procedure
Design: OBFErrorFunction

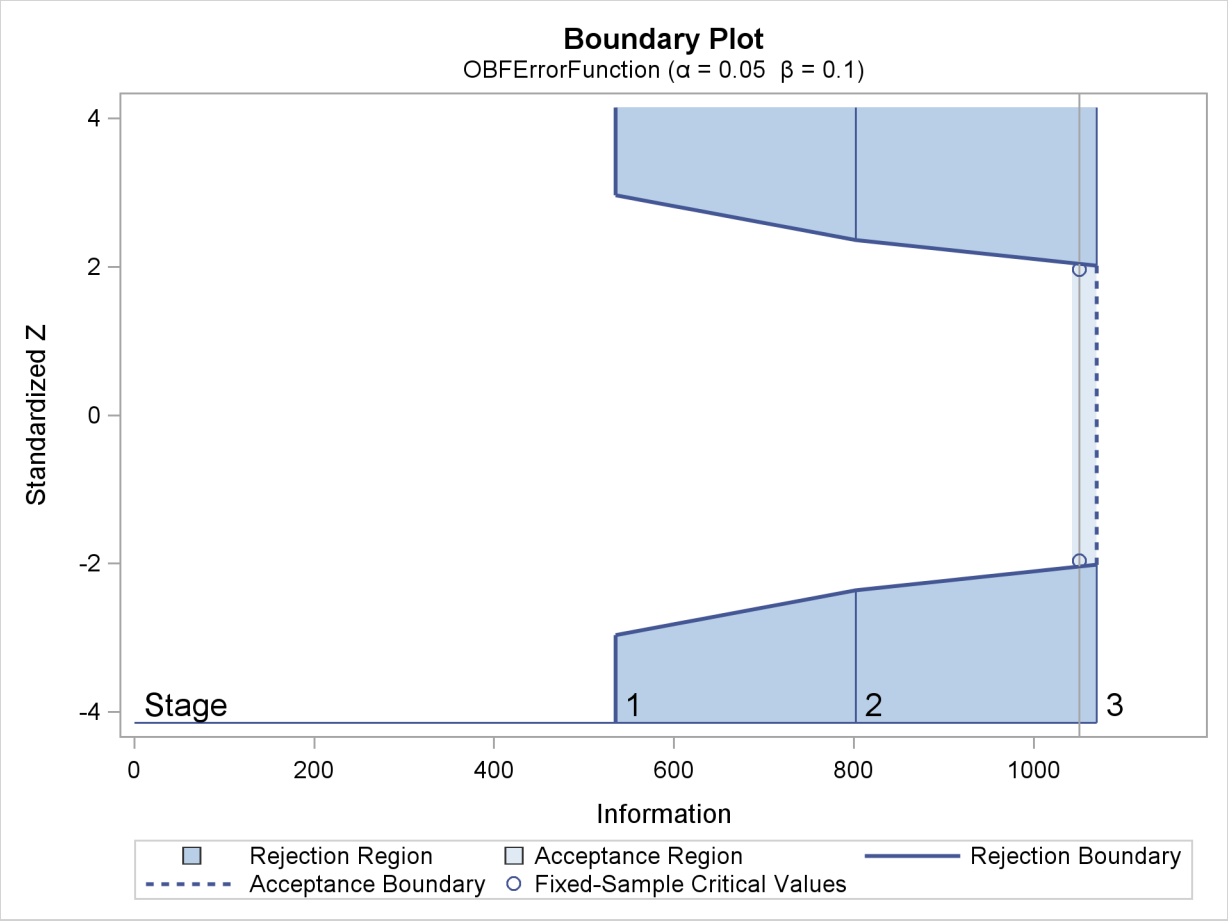
Design Information

Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	Error Spending
Boundary Key	Both
Alternative Reference	0.1
Number of Stages	3
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	101.8276
Max Information	1069.948
Null Ref ASN (Percent of Fixed Sample)	101.2587
Alt Ref ASN (Percent of Fixed Sample)	77.81586

The "Boundary Information" table in Output 78.2.2 displays information level, alternative reference, and boundary values at each stage.

Output 78.2.2 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0



Stage	Information Level Proportion	Information Level Actual	Information Level N	Alternative Reference Lower	Alternative Reference Upper
1	0.5000	534.9738	46.43869	−2.31295	2.31295
2	0.7500	802.4606	69.65804	−2.83277	2.83277
3	1.0000	1069.948	92.87739	−3.27101	3.27101

Boundary Information (Standardized Z Scale)
Null Reference = 0

Stage	Boundary Values Lower Alpha	Boundary Values Upper Alpha
1	−2.96259	2.96259
2	−2.35902	2.35902
3	−2.01409	2.01409

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 78.2.3. The boundary plot also displays the information level and critical value for the corresponding fixed-sample design. This design has characteristics of an O'Brien-Fleming design; the probability for early stopping is low, and the maximum information and critical values at the final stage are similar to those of the corresponding fixed-sample design.

Output 78.2.3 Boundary Plot

With the MODEL=REG option in the SAMPLESIZE statement, the "Sample Size Summary" table in Output 78.2.4 displays the parameters for the sample size computation.

Output 78.2.4 Required Sample Size Summary

Sample Size Summary

Test	Reg Parameter
Parameter	0.1
Variance	5
X Variance	64
R Square (X)	0.1
Max Sample Size	92.87739
Expected Sample Size (Null Ref)	92.35845
Expected Sample Size (Alt Ref)	70.97617

The "Sample Sizes" table in Output 78.2.5 displays the required sample sizes for the group sequential clinical trial.

Output 78.2.5 Required Sample Sizes

Sample Sizes (N)
Z Test for Regression Parameter

Stage	------Fractional N----- N	Information	-------Ceiling N------- N	Information
1	46.44	535.0	47	541.4
2	69.66	802.5	70	806.4
3	92.88	1069.9	93	1071.4

Thus, 47, 70, and 93 individuals are needed in stages 1, 2, and 3, respectively. Since the sample sizes are derived from estimated values of σ_y^2, r_x^2, and σ_x^2, the actual information levels might not achieve the target information levels. Thus, instead of specifying sample sizes in the protocol, you can specify the maximum information levels. Then if an actual information level is much less than the target level, you can increase the sample sizes for the remaining stages to achieve the desired information levels and power.

Suppose that 47 individuals are available at stage 1. Output 78.2.6 lists the first 10 observations of the trial data.

Output 78.2.6 Clinical Trial Data

First 10 Obs in the Trial Data

Obs	Oxygen	Age	Weight	RunTime	Run Pulse	Max Pulse
1	54.5521	44	87.7676	11.6949	178.435	181.607
2	52.2821	40	75.4853	9.8872	184.433	183.667
3	62.1871	44	89.0638	8.7950	155.540	167.108
4	65.3269	42	67.7310	8.4577	162.926	173.877

10	68.3357	38	80.2490	8.5066	171.824	184.011

The following statements use the REG procedure to estimate the slope β_w and its associated standard error at stage 1:

```
proc reg data=Fit_1;
   model Oxygen=Age Weight RunTime RunPulse MaxPulse;
   ods output ParameterEstimates=Parms_Fit1;
run;
```

The following statements create and display (in Output 78.2.7) the input data set that contains slope β_w and its associated standard error for the SEQTEST procedure:

```
data Parms_Fit1;
   set Parms_Fit1;
   if Variable='Weight';
   _Scale_='MLE';
   _Stage_= 1;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_Fit1;
   title 'Statistics Computed at Stage 1';
run;
```

Output 78.2.7 Statistics Computed at Stage 1

Statistics Computed at Stage 1

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Weight	0.03772	0.04345	MLE	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Fit
             Parms(Testvar=Weight)=Parms_Fit1
             boundaryadj=errfuncobf
             order=lr
             stopprob
             ;
ods output Test=Test_Fit1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1 (this data set was generated in the SEQDESIGN procedure). Recall that these boundary values were derived for the information levels specified with the INFO=CUM(2 3 4) option in the SEQDESIGN procedure. The PARMS=PARMS_FIT1 option specifies the input data set PARMS_FIT1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=WEIGHT option identifies the test variable WEIGHT in the data set.

The ORDER=LR option uses the LR ordering to derive the p-value, the unbiased median estimate, and the confidence limits for the regression slope estimate. The boundaries are adjusted using an O'Brien-Fleming-type cumulative error spending function, as specified with the BOUNDARYADJ= option.

The ODS OUTPUT statement with the TEST=TEST_FIT1 option creates an output data set named TEST_FIT1 which contains the updated boundary information for the test at stage 1. The adjustment is needed because the observed information level is different from the information level in the BOUNDARY= data set. The data set TEST_FIT1 also provides the boundary information that is needed for the group sequential test at the next stage.

The "Design Information" table in Output 78.2.8 displays the design specifications. By default, the boundary values are modified for the new information levels to maintain the Type I α level. The maximum information remains the same as in the BOUNDARY= data set, but the derived Type II error probability β and power $1-\beta$ are different because of the new information level.

Output 78.2.8 Design Information

The SEQTEST Procedure

Design Information

BOUNDARY Data Set	WORK.BND_FIT
Data Set	WORK.PARMS_FIT1
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Number of Stages	3
Alpha	0.05

Test Information (Standardized Z Scale)
Null Reference = 0

Stage	----------Test---------- ----------Weight--------- Estimate	Action
1	0.86798	Continue
2	.	
3	.	

The information levels at stages 2 and 3 are derived proportionally from the corresponding information levels in the BOUNDARY= data set. See the section "Boundary Adjustments for Information Levels" on page 6017 for details about how these information levels are computed.

At stage 1, the standardized Z statistic 0.86798 is between the lower α boundary -2.97951 and the upper α boundary 2.97951, so the trial continues to the next stage.

With the specified ODS GRAPHICS ON statement, a boundary plot with test statistics is displayed by default, as shown in Output 78.2.11. As expected, the test statistic is in the continuation region between the lower and upper α boundaries.

Output 78.2.11 Sequential Test Plot

The following statements use the REG procedure to estimate the slope β_w and its associated standard error at stage 2:

```
proc reg data=Fit_2;
   model Oxygen=Age Weight RunTime RunPulse MaxPulse;
   ods output ParameterEstimates=Parms_Fit2;
run;
```

Note that the data set Fit_2 contains both the data from stage 1 and the data from stage 2.

The following statements create and display (in Output 78.2.12) the input data set that contains slope β_w and its associated standard error at stage 2 for the SEQTEST procedure:

```
data Parms_Fit2;
   set Parms_Fit2;
   if Variable='Weight';
   _Scale_='MLE';
   _Stage_= 2;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;
```

```
proc print data=Parms_Fit2;
   title 'Statistics Computed at Stage 2';
run;
```

Output 78.2.12 Statistics Computed at Stage 2

Statistics Computed at Stage 2

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Weight	0.02932	0.03520	MLE	2

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
proc seqtest Boundary=Test_Fit1
             Parms(Testvar=Weight)=Parms_Fit2
             boundaryadj=errfuncobf
             order=lr
             ;
ods output Test=Test_Fit2;
run;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_FIT2 option creates an output data set named TEST_FIT2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

Since the data set PARMS_FIT2 does not contain the test information at stage 1, the information level at stage 1 in the TEST_FIT1 data set is used to generate boundary values for the test at stage 2.

Following the process at stage 1, the slope estimate is also between its corresponding lower and upper α boundary values, so the trial continues to the next stage.

The following statements use the REG procedure to estimate the slope β_w and its associated standard error at the final stage:

```
proc reg data=Fit_3;
   model Oxygen=Age Weight RunTime RunPulse MaxPulse;
   ods output ParameterEstimates=Parms_Fit3;
run;
```

The following statements create the input data set that contains slope β_w and its associated standard error at stage 3 for the SEQTEST procedure:

```
data Parms_Fit3;
   set Parms_Fit3;
   if Variable='Weight';
   _Scale_='MLE';
   _Stage_= 3;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;
```

The following statements print (in Output 78.2.13) the test statistics at stage 3:

```
proc print data=Parms_Fit3;
   title 'Statistics Computed at Stage 3';
run;
```

Output 78.2.13 Statistics Computed at Stage 3

Statistics Computed at Stage 3

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Weight	0.02189	0.03028	MLE	3

The following statements invoke the SEQTEST procedure to test the hypothesis:

```
ods graphics on;
proc seqtest Boundary=Test_Fit2
             Parms(testvar=Weight)=Parms_Fit3
             boundaryadj=errfuncobf
             order=lr
             pss
             plots=(asn power)
             ;
ods output Test=Test_Fit3;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 3, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 3, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_FIT3 option creates an output data set named TEST_FIT3 which contains the updated boundary information for the test at stage 3.

The "Design Information" table in Output 78.2.14 displays design specifications. By default, the boundary values are modified for the new information levels to maintain the Type I α level.

Output 78.2.14 Design Information

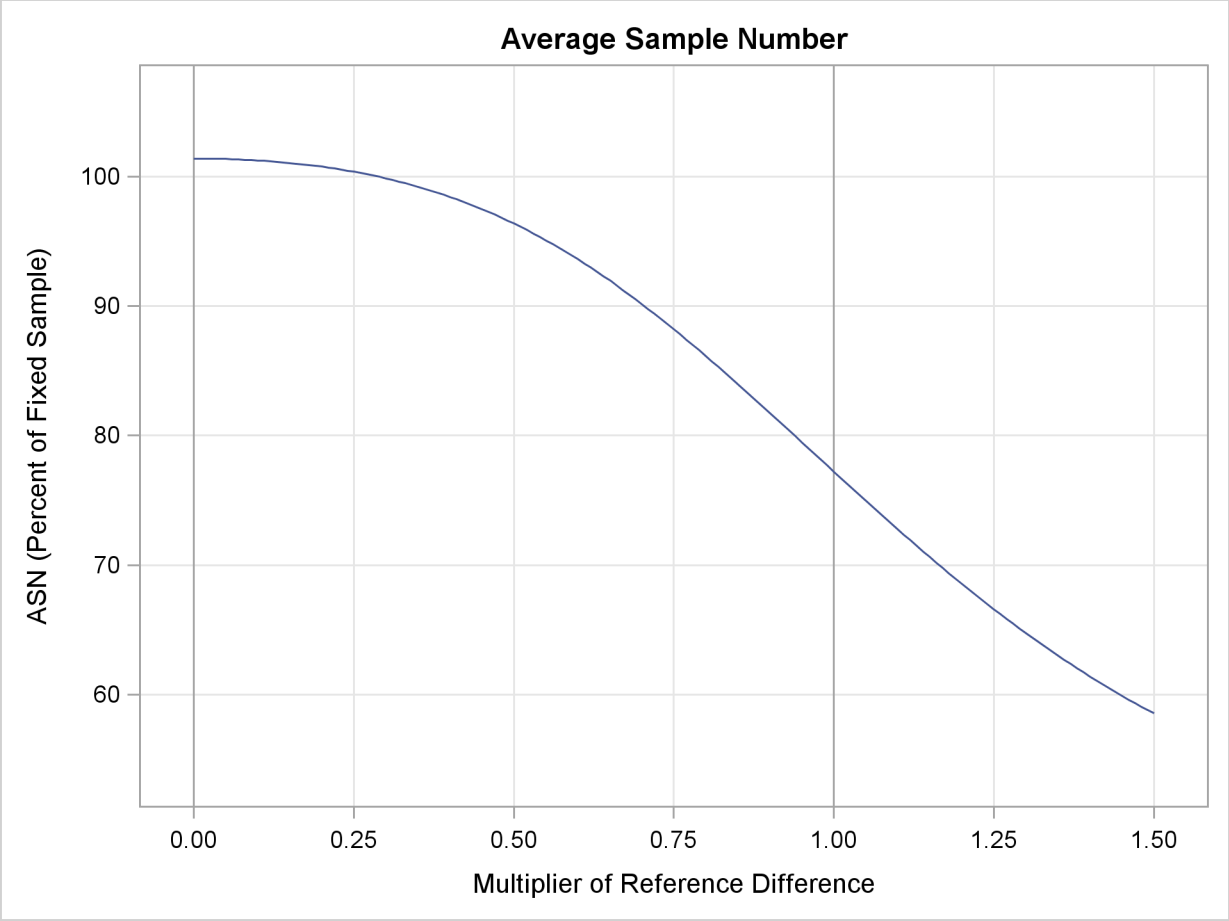
The SEQTEST Procedure

Design Information

BOUNDARY Data Set	WORK.TEST_FIT2
Data Set	WORK.PARMS_FIT3
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Number of Stages	3
Alpha	0.05
Beta	0.09514
Power	0.90486
Max Information (Percent of Fixed Sample)	102.0102
Max Information	1090.63724
Null Ref ASN (Percent of Fixed Sample)	101.4122
Alt Ref ASN (Percent of Fixed Sample)	77.22139

The maximum information is derived from the standard error associated with the slope estimate at the final stage and is larger than the target level. The derived Type II error probability β and power $1-\beta$ are different because of the new information levels.

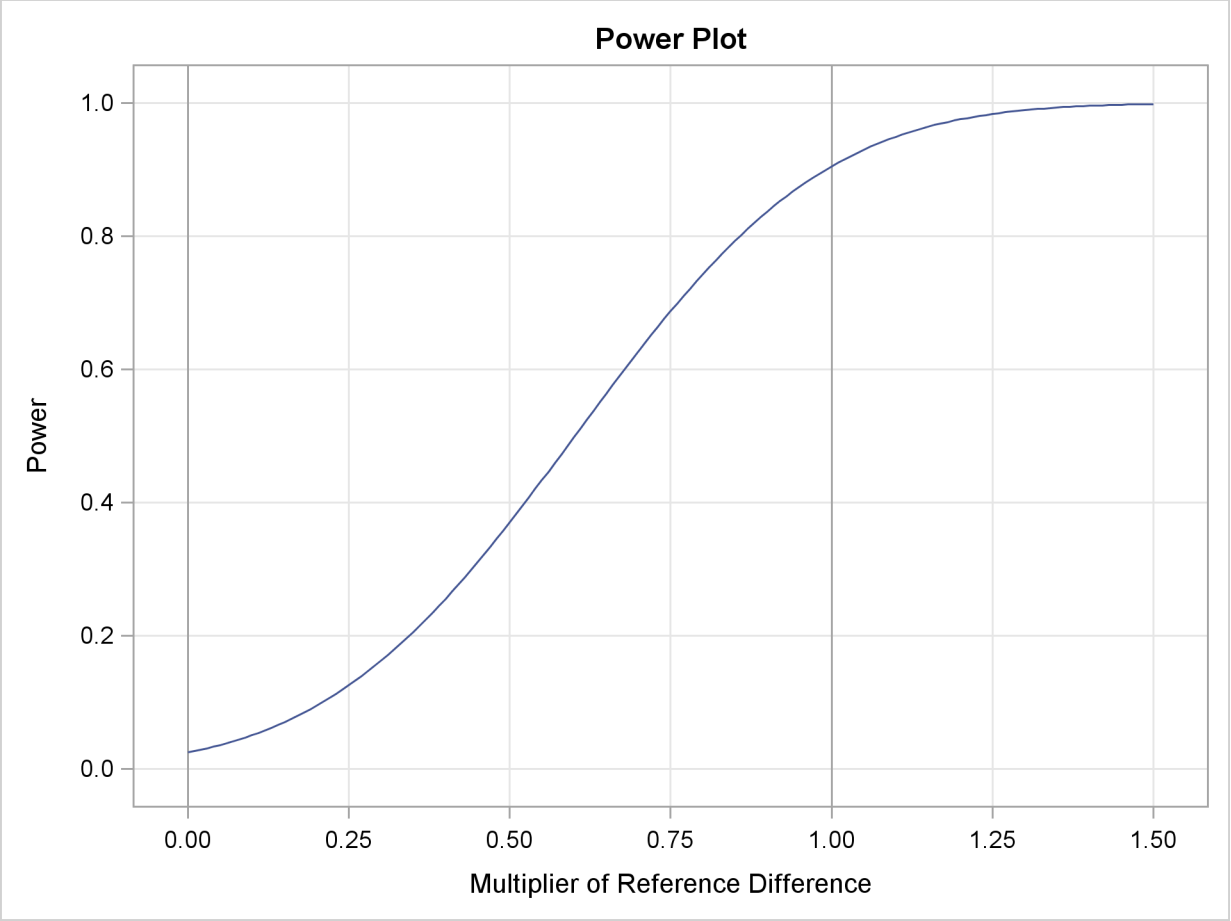
With the PSS option, the "Power and Expected Sample Sizes" table in Output 78.2.15 displays powers and expected mean sample sizes under various hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ by default. You can specify the c_i values with the CREF= option.



Output 78.2.15 Power and Expected Sample Size Information

Powers and Expected Sample Sizes
Reference = CRef * (Alt Reference)

CRef	Power	-Sample Size- Percent Fixed-Sample
0.0000	0.02500	101.4122
0.5000	0.37046	96.3754
1.0000	0.90486	77.2214
1.5000	0.99844	58.5301



With the PLOTS=ASN option, the procedure displays a plot of expected sample sizes under various hypothetical references, as shown in Output 78.2.16. By default, expected sample sizes under the hypotheses $\theta = c_i\,\theta_1$, $c_i = 0, 0.01, 0.02, \ldots, 1.50$, are displayed, where θ_1 is the alternative reference.

Output 78.2.16 ASN Plot

With the PLOTS=POWER option, the procedure displays a plot of powers under various hypothetical references, as shown in Output 78.2.17. By default, powers under hypothetical references $\theta = c_i\,\theta_1$ are displayed, where $c_i = 0, 0.01, 0.02, \ldots, 1.50$ by default. You can specify c_i values with the CREF= option. The c_i values are displayed on the horizontal axis.

Output 78.2.17 Power Plot

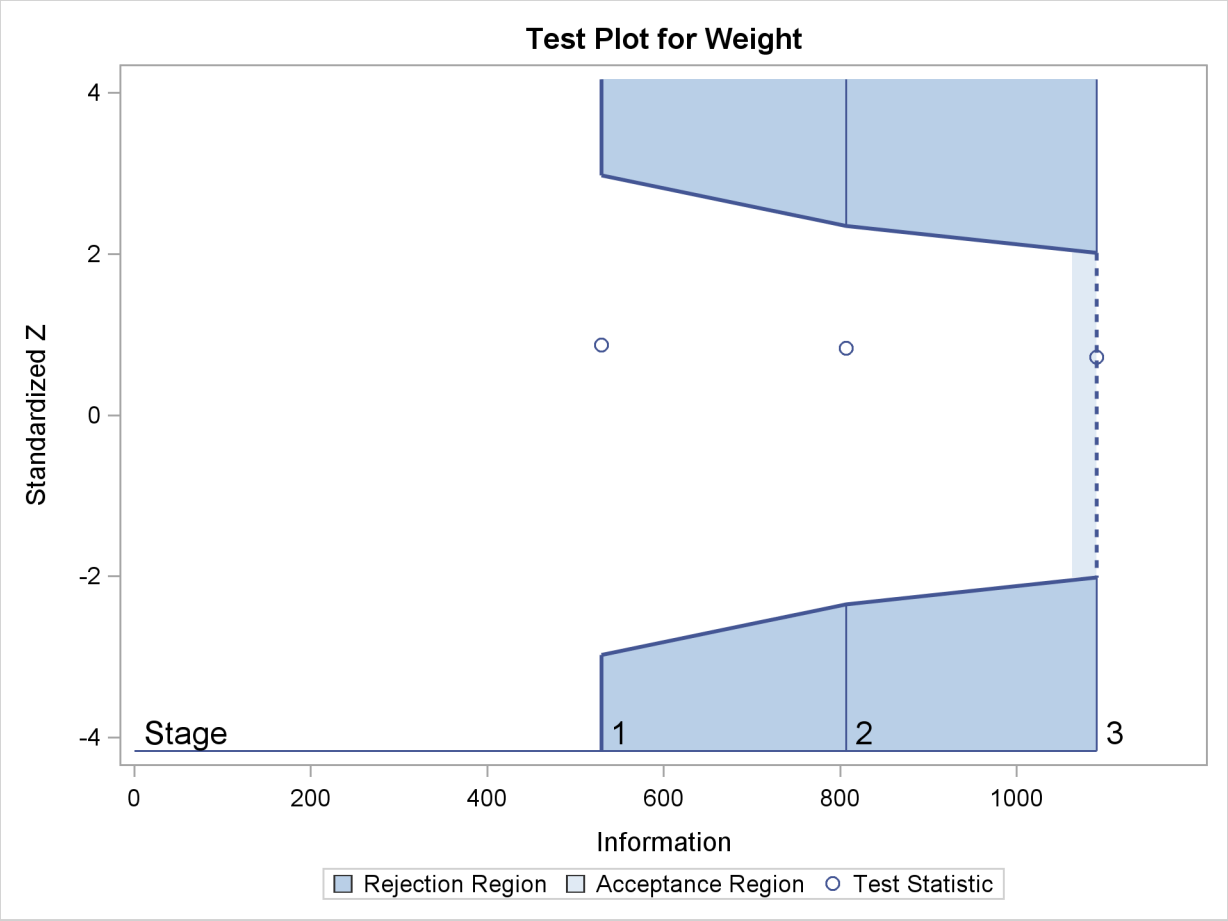
Under the null hypothesis, $c_i = 0$, the power is 0.025, which is the upper Type I error probability. Under the alternative hypothesis, $c_i = 1$, the power is 0.90486, which is one minus the Type II error probability.

The "Test Information" table in Output 78.2.18 displays the boundary values for the test statistic with the default standardized Z scale. The information level at the current stage is derived from the standard error for the current stage in the PARMS= data set. At stage 3, the standardized slope estimate 0.72284 is still between the lower and upper α boundary values. Since it is the final stage, the trial stops to accept the null hypothesis that the variable Weight has no effect on the oxygen intake rate after adjusting for other covariates.

Output 78.2.18 Sequential Tests

Test Information (Standardized Z Scale)
Null Reference = 0

Stage	--Information Level- Proportion	Actual	------Alternative----- -------Reference------ Lower	Upper	----Boundary Values--- ---Lower-- Alpha	---Upper-- Alpha
1	0.4856	529.6232	-2.30135	2.30135	-2.97951	2.97951
2	0.7401	807.1954	-2.84112	2.84112	-2.34945	2.34945
3	1.0000	1090.637	-3.30248	3.30248	-2.01885	2.01885



Test Information (Standardized Z Scale)
Null Reference = 0

Stage	----------Test---------- ----------Weight--------- Estimate	Action
1	0.86798	Continue
2	0.83305	Continue
3	0.72284	Accept Null

Since the data set FIT_3 contains the test information only at stage 3, the information levels at previous stages in the TEST_FIT2 data set are used to generate boundary values for the test.

With the specified ODS GRAPHICS ON statement, a boundary plot with test statistics is displayed by default, as shown in Output 78.2.19. As expected, the test statistic is in the acceptance region between the lower and upper α boundaries at the final stage.

Output 78.2.19 Sequential Test Plot

After a trial is stopped, the "Parameter Estimates" table in Output 78.2.20 displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and the p-value under the null hypothesis $H_0 : \beta_w = 0$.

Output 78.2.20 Parameter Estimates

Parameter Estimates
LR Ordering

Parameter	Stopping Stage	MLE	p-Value for H0:Parm=0	Median Estimate
Weight	3	0.021888	0.4699	0.021884

Parameter Estimates
LR Ordering

Parameter	95% Confidence Limits	
Weight	-0.03747	0.08123

As expected, the p-value 0.4699 is not significant at the $\alpha = 0.05$ level, and the confidence interval does contain the value zero. The p-value, unbiased median estimate, and confidence limits depend on the ordering of the sample space (k, z), where k is the stage number and z is the standardized Z statistic. With the specified LR ordering, the p-values are computed with the ordering $(k', z') \succ (k, z)$ if $z' > z$. See the section "Available Sample Space Orderings in a Sequential Test" on page 6025 for a detailed description of the LR ordering.

Example 78.3: Testing an Effect with Early Stopping to Accept H_0

This example demonstrates a two-sided group sequential test that uses an error spending design with early stopping to accept the null hypothesis H_0. The example is similar to Example 78.2 but with early stopping to accept H_0.

A study is conducted to examine the effects of Age (years), Weight (kg), RunTime (time in minutes to run 1.5 miles), RunPulse (heart rate while running), and MaxPulse (maximum heart rate recorded while running) on Oxygen (oxygen intake rate, ml per kg body weight per minute). The primary interest is whether oxygen intake rate is associated with weight.

The hypothesis is tested using the following linear model:

$$\text{Oxygen} = \text{Age} + \text{Weight} + \text{RunTime} + \text{RunPulse} + \text{MaxPulse}$$

The null hypothesis is $H_0 : \beta_w = 0$, where β_w is the regression parameter for the variable Weight. Suppose that $\beta_w = 0.10$ is the reference improvement that should be detected at a 0.90 level. Then the maximum information I_X can be derived in the SEQDESIGN procedure.

Following the derivations in the section "Test for a Parameter in the Regression Model" in the chapter "The SEQDESIGN Procedure," the required sample size can be derived from

$$N = I_X \frac{\sigma_y^2}{(1 - r_x^2)\,\sigma_x^2}$$

where σ_y^2 is the variance of the response variable in the regression model, r_x^2 is the proportion of variance of Weight explained by other covariates, and σ_x^2 is the variance of Weight.

Further suppose that from past experience, $\sigma_y^2 = 5$, $r_x^2 = 0.10$, and $\sigma_x^2 = 64$. Then the required sample size can be derived using the SAMPLESIZE statement in the SEQDESIGN procedure.

The following statements invoke the SEQDESIGN procedure and request a three-stage group sequential design for normally distributed data to test the null hypothesis of a regression parameter $H_0 : \beta_w = 0$ against the alternative $H_1 : \beta_w \neq 0$:

```
ods graphics on;
proc seqdesign altref=0.10;
   OBFErrorFunction: design method=errfuncgamma
                            stop=accept
                            nstages=3
                            info=cum(2 3 4)
                            ;
```

```
   samplesize model=reg( variance=5 xvariance=64 xrsquare=0.10);
ods output Boundary=Bnd_Fit;
run;
ods graphics off;
```

By default, the procedure uses a Type I error probability 0.05 and a Type II error probability 0.10. The ALTREF=0.10 option specifies a power of $1 - \beta = 0.90$ at the alternative hypothesis $H_1 : \beta_w = \pm 0.10$. The INFO=CUM(2 3 4) option specifies that the study perform the first interim analysis with information proportion $2/4 = 0.5$—that is, after half of the total observations are collected.

The ODS OUTPUT statement with the BOUNDARY=BND_FIT option creates an output data set named BND_FIT which contains the resulting boundary information for the subsequent sequential tests.

The "Design Information" table in Output 78.3.1 displays design specifications and derived statistics. Since the alternative reference is specified, the maximum information is derived.

Output 78.3.1 Error Spending Design Information

The SEQDESIGN Procedure
Design: OBFErrorFunction

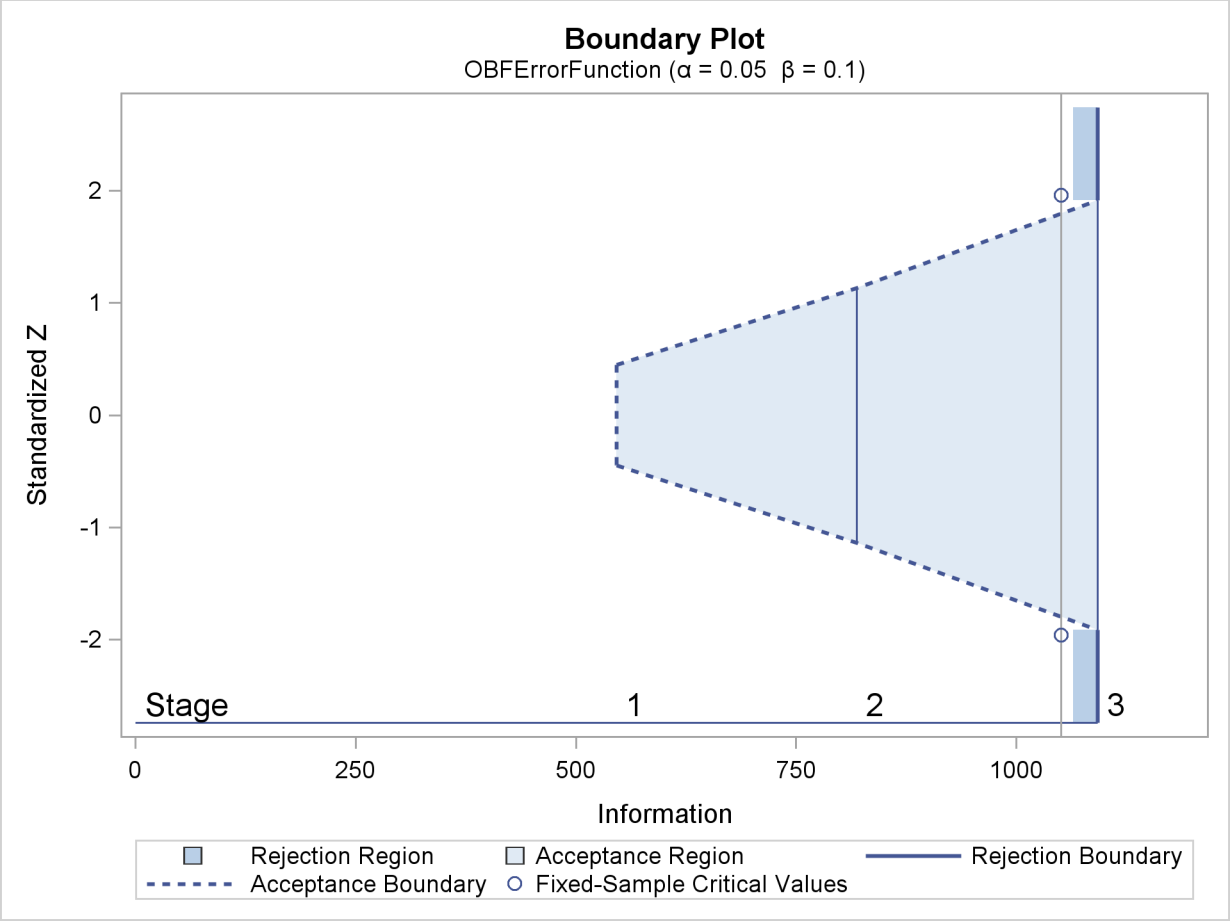
Design Information

Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Accept Null
Method	Error Spending
Boundary Key	Both
Alternative Reference	0.1
Number of Stages	3
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	103.9245
Max Information	1091.972
Null Ref ASN (Percent of Fixed Sample)	75.00521
Alt Ref ASN (Percent of Fixed Sample)	101.8099

The "Boundary Information" table in Output 78.3.2 displays information level, alternative reference, and boundary values at each stage.

Output 78.3.2 Boundary Information

Boundary Information (Standardized Z Scale)
Null Reference = 0



Stage	Information Level Proportion	Information Level Actual	Information Level N	Alternative Reference Lower	Alternative Reference Upper
1	0.5000	545.9862	47.39463	−2.33663	2.33663
2	0.7500	818.9792	71.09195	−2.86178	2.86178
3	1.0000	1091.972	94.78926	−3.30450	3.30450

Boundary Information (Standardized Z Scale)
Null Reference = 0

Stage	Boundary Values Lower Beta	Boundary Values Upper Beta
1	−0.44937	0.44937
2	−1.13583	1.13583
3	−1.91428	1.91428

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 78.3.3. The boundary plot also displays the information level and critical value for the corresponding fixed-sample design.

Output 78.3.3 Boundary Plot

With the MODEL=REG option in the SAMPLESIZE statement, the "Sample Size Summary" table in Output 78.3.4 displays the parameters for the sample size computation.

Output 78.3.4 Required Sample Size Summary

Sample Size Summary

Test	Reg Parameter
Parameter	0.1
Variance	5
X Variance	64
R Square (X)	0.1
Max Sample Size	94.78926
Expected Sample Size (Null Ref)	68.41207
Expected Sample Size (Alt Ref)	92.86057

The "Sample Sizes" table in Output 78.3.5 displays the required sample sizes for the group sequential clinical trial.

Output 78.3.5 Required Sample Sizes

Sample Sizes (N)
Z Test for Regression Parameter

Stage	Fractional N		Ceiling N	
	N	Information	N	Information
1	47.39	546.0	48	553.0
2	71.09	819.0	72	829.4
3	94.79	1092.0	95	1094.4

Thus, 48, 72, and 95 individuals are needed in stages 1, 2, and 3, respectively. Since the sample sizes are derived from estimated values of σ_y^2, r_x^2, and σ_x^2, the actual information levels might not achieve the target information levels. Thus, instead of specifying sample sizes in the protocol, you can specify the maximum information levels. Then if an actual information level is much less than the target level, you can increase the sample sizes for the remaining stages to achieve the desired information levels and power.

Suppose that 48 individuals are available at stage 1. Output 78.3.6 lists the first 10 observations of the trial data.

Output 78.3.6 Clinical Trial Data

First 10 Obs in the Trial Data

Obs	Oxygen	Age	Weight	RunTime	Run Pulse	Max Pulse
1	54.5521	44	87.7676	11.6949	178.435	181.607
2	52.2821	40	75.4853	9.8872	184.433	183.667
3	62.1871	44	89.0638	8.7950	155.540	167.108
4	65.3269	42	67.7310	8.4577	162.926	173.877
5	59.9809	37	93.1902	9.3228	179.033	180.144
6	52.5588	47	75.9044	12.0385	177.753	175.033
7	51.7838	40	73.5422	11.6607	175.838	178.140
8	57.0024	43	81.2861	11.2219	160.963	171.770
9	48.0775	44	85.2290	13.1789	173.722	176.548
10	68.3357	38	80.2490	8.5066	171.824	184.011

The following statements use the REG procedure to estimate the slope β_w and its associated standard error at stage 1:

```
proc reg data=Fit_1;
   model Oxygen=Age Weight RunTime RunPulse MaxPulse;
   ods output ParameterEstimates=Parms_Fit1;
run;
```

The following statements create and display (in Output 78.3.7) the input data set that contains slope β_w and its associated standard error for the SEQTEST procedure:

```
data Parms_Fit1;
   set Parms_Fit1;
   if Variable='Weight';
   _Scale_='MLE';
   _Stage_= 1;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_Fit1;
   title 'Statistics Computed at Stage 1';
run;
```

Output 78.3.7 Statistics Computed at Stage 1

Statistics Computed at Stage 1

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Weight	0.04660	0.04308	MLE	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Fit
             Parms(testvar=Weight)=Parms_Fit1
             boundaryadj=errfuncgamma
             stopprob
             order=lr
             ;
ods output Test=Test_Fit1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_FIT1 option specifies the input data set PARMS_FIT1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=WEIGHT option identifies the test variable WEIGHT in the data set.

The ORDER=LR option uses the LR ordering to derive the p-value, the unbiased median estimate, and the confidence limits for the regression slope estimate. The boundaries are adjusted using gamma cumulative error spending function, as specified with the BOUNDARYADJ= option.

The ODS OUTPUT statement with the TEST=TEST_FIT1 option creates an output data set named TEST_FIT1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Design Information" table in Output 78.3.8 displays the design specifications. By default, the boundary values are modified for the new information levels to maintain the Type I α level. The maximum information remains the same as in the BOUNDARY= data set, but the derived Type II error probability β and power $1-\beta$ are different because of the new information level.

Output 78.3.8 Design Information

The SEQTEST Procedure

Design Information

BOUNDARY Data Set	WORK.BND_FIT
Data Set	WORK.PARMS_FIT1
Statistic Distribution	Normal

Alt Ref ASN (Percent of Fixed Sample)	101.8186

With the STOPPROB option, the "Expected Cumulative Stopping Probabilities" table in Output 78.3.9 displays the expected stopping stage and the cumulative stopping probability of accepting the null hypothesis at each stage under various hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ by default. You can specify other values for c_i with the CREF= option.

Output 78.3.9 Stopping Probabilities

Expected Cumulative Stopping Probabilities
Reference = CRef * (Alt Reference)

CRef	Expected Stopping Stage	Source	----Stopping Probabilities--- Stage_1	Stage_2	Stage_3
0.0000	1.905	Accept Null	0.33294	0.76168	0.95000
0.5000	2.417	Accept Null	0.17674	0.40627	0.62824
1.0000	2.920	Accept Null	0.02635	0.05405	0.10003
1.5000	2.997	Accept Null	0.00109	0.00165	0.00242

The "Test Information" table in Output 78.3.10 displays the boundary values for the test statistic with the default standardized Z scale. The information level at stage 1 is derived from the standard error s_1 in the PARMS= data set,

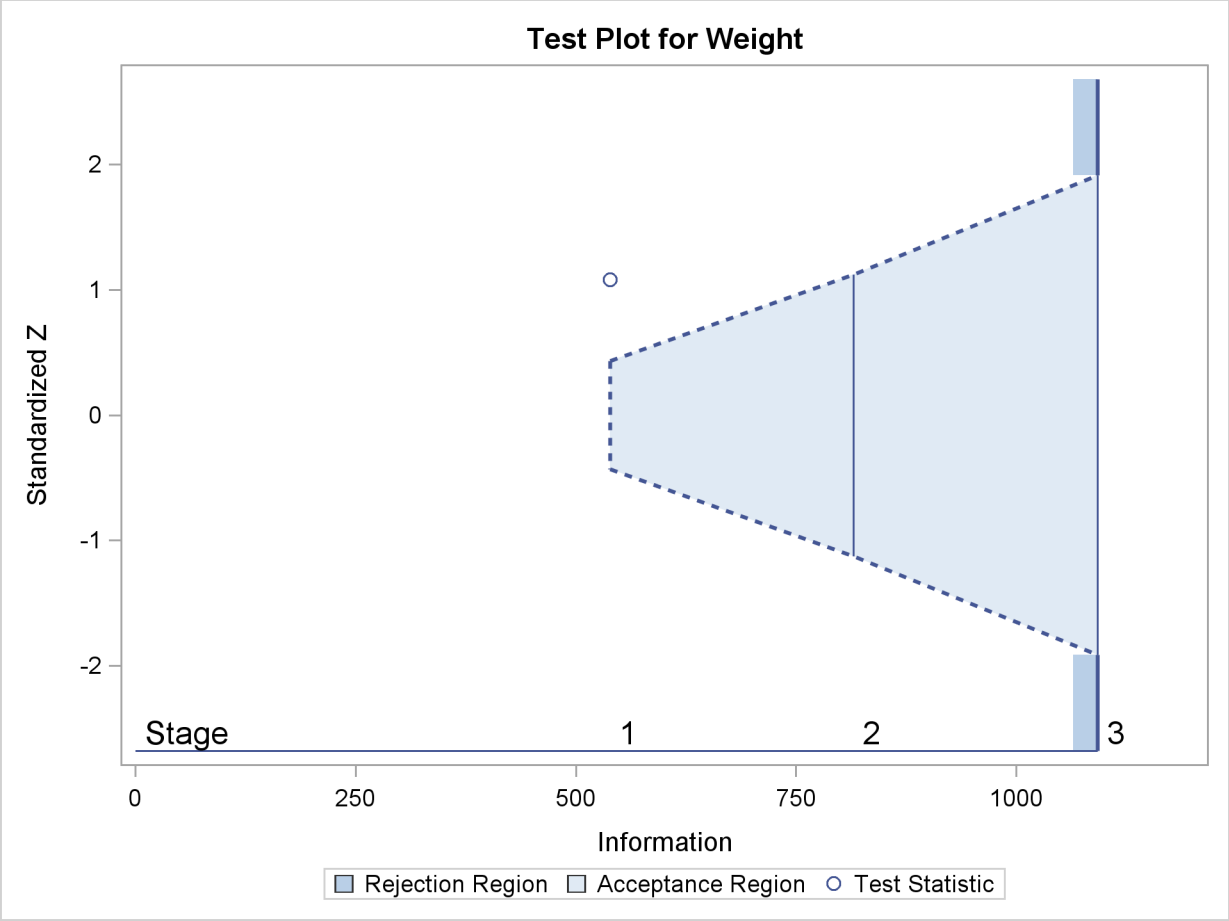
$$I_1 = \frac{1}{s_1^2} = \frac{1}{0.04308^2} = 538.8$$

Output 78.3.10 Sequential Tests

Test Information (Standardized Z Scale)
Null Reference = 0

Stage	Information Level Proportion	Information Level Actual	Alternative Reference Lower	Alternative Reference Upper
1	0.4934	538.7887	-2.32118	2.32118
2	0.7467	815.3805	-2.85549	2.85549
3	1.0000	1091.972	-3.30450	3.30450

Test Information (Standardized Z Scale)
Null Reference = 0



Stage	Boundary Values Lower Beta	Boundary Values Upper Beta	Test Weight Estimate	Test Weight Action
1	-0.43019	0.43019	1.08174	Continue
2	-1.12435	1.12435	.	
3	-1.91475	1.91475	.	

The information levels at stages 2 and 3 are derived proportionally from the corresponding information levels in the BOUNDARY= data set. See the section "Boundary Adjustments for Information Levels" on page 6017 for details about how these information levels are computed.

At stage 1, the standardized Z statistic 1.08174 is greater than the upper β boundary 0.43019, so the trial continues to the next stage.

With the specified ODS GRAPHICS ON statement, a boundary plot with test statistics is displayed by default, as shown in Output 78.3.11. As expected, the test statistic is in the continuation region.

Output 78.3.11 Sequential Test Plot

The following statements use the REG procedure to estimate the slope β_w and its associated standard error at stage 2:

```
proc reg data=Fit_2;
   model Oxygen=Age Weight RunTime RunPulse MaxPulse;
   ods output ParameterEstimates=Parms_Fit2;
run;
```

Note that the data set Fit_2 contains both the data from stage 1 and the data from stage 2,

The following statements create and display (in Output 78.3.12) the input data set that contains slope β_w and its associated standard error at stage 2 for the SEQTEST procedure:

```
data Parms_Fit2;
   set Parms_Fit2;
   if Variable='Weight';
   _Scale_='MLE';
   _Stage_= 2;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_Fit2;
```

```
   title 'Statistics Computed at Stage 2';
run;
```

Output 78.3.12 Statistics Computed at Stage 2

Statistics Computed at Stage 2

1	Weight	0.02925	0.03490	MLE	2

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
ods graphics on;
proc seqtest Boundary=Test_Fit1
             Parms(testvar=Weight)=Parms_Fit2
             boundaryadj=errfuncgamma
             order=lr
             pss
             plots=(asn power)
             ;
ods output Test=Test_Fit2;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

Since the data set PARMS_FIT2 does not contain the test information at stage 1, the information level at stage 1 in the TEST_FIT1 data set is used to generate boundary values for the test.

The ORDER=LR option uses the LR ordering to derive the p-value, unbiased median estimate, and confidence limits for the regression slope estimate.

The ODS OUTPUT statement with the TEST=TEST_FIT2 option creates an output data set named TEST_FIT2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Design Information" table in Output 78.3.13 displays design specifications. By default, the boundary values are modified for the new information levels to maintain the Type I α level.

Output 78.3.13 Design Information

The SEQTEST Procedure

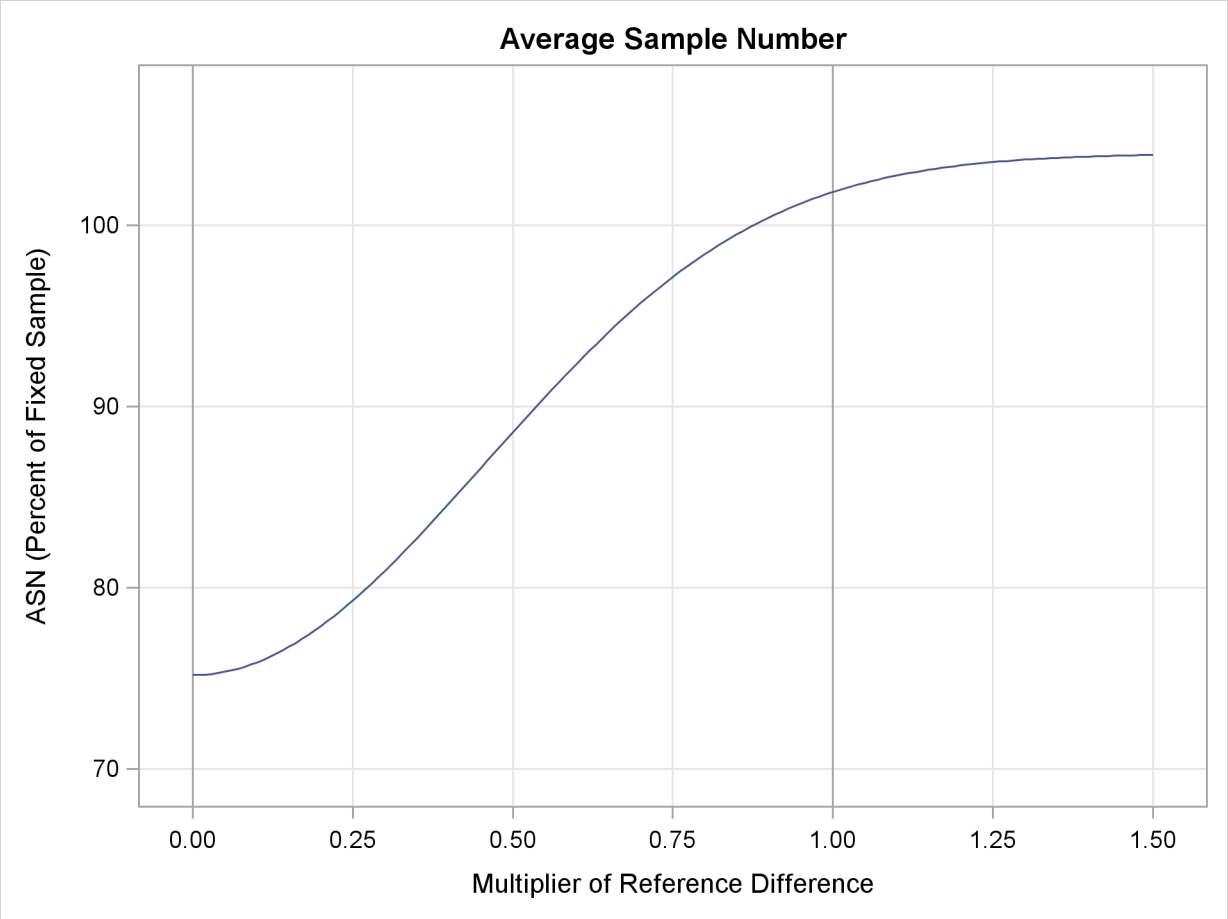
Alt Ref ASN (Percent of Fixed Sample)	101.8341

The derived Type II error probability β and power $1-\beta$ are different because of the new information levels.

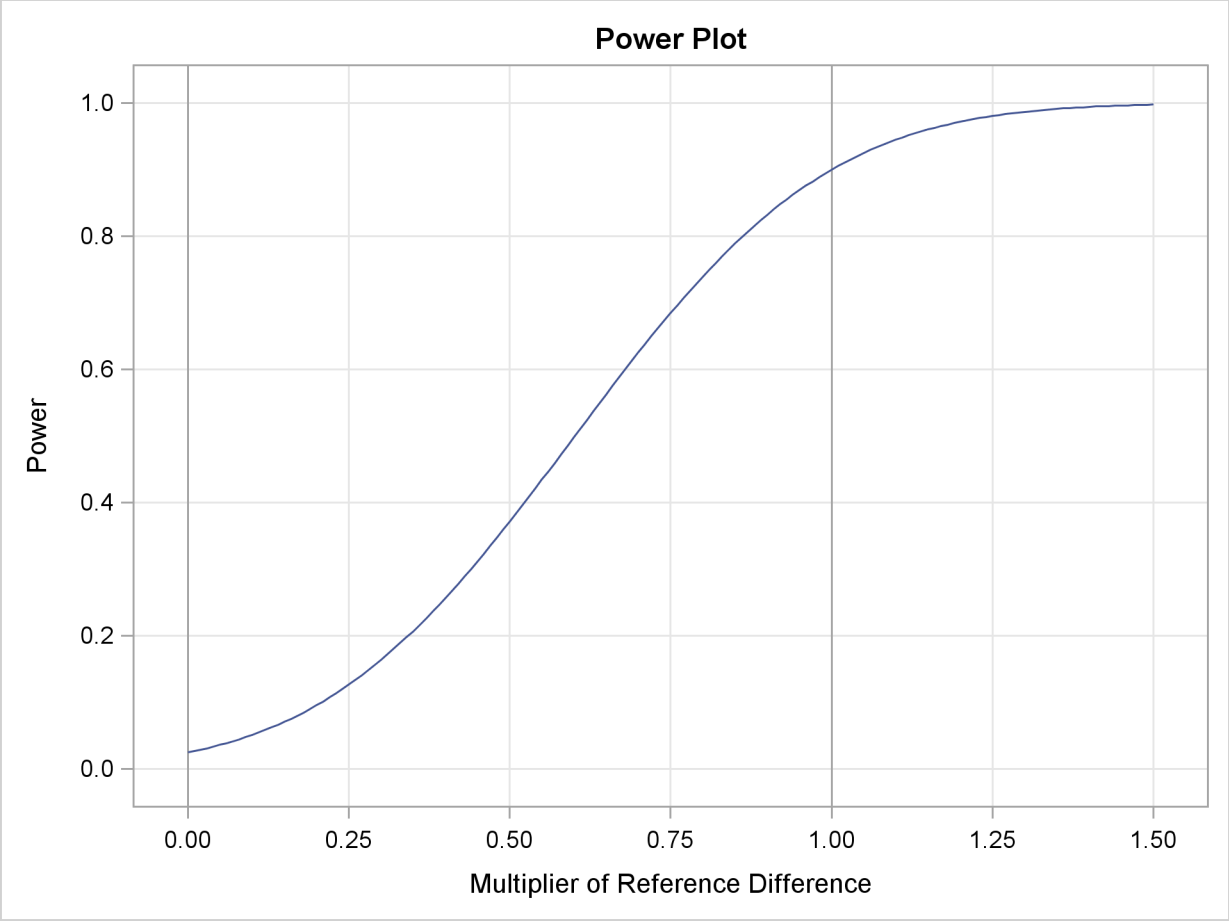
With the PSS option, the "Power and Expected Sample Sizes" table in Output 78.3.14 displays powers and expected mean sample sizes under various hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ are the default values in the CREF= option.



Output 78.3.14 Power and Expected Sample Size Information

Powers and Expected Sample Sizes
Reference = CRef * (Alt Reference)

CRef	Power	-Sample Size- Percent Fixed-Sample
0.0000	0.02500	75.1848
0.5000	0.37154	88.5985
1.0000	0.89991	101.8341
1.5000	0.99758	103.8830



With the PLOTS=ASN option, the procedure displays a plot of expected sample sizes under various hypothetical references, as shown in Output 78.3.15. By default, expected sample sizes under the hypotheses $\theta = c_i\,\theta_1$, $c_i = 0, 0.01, 0.02, \ldots, 1.50$, are displayed, where θ_1 is the alternative reference.

Output 78.3.15 ASN Plot

With the PLOTS=POWER option, the procedure displays a plot of the power curves under various hypothetical references for all designs simultaneously, as shown in Output 78.3.16. By default, powers under hypothetical references $\theta = c_i\,\theta_1$ are displayed, where $c_i = 0, 0.01, 0.02, \ldots, 1.50$ by default. You can specify c_i values with the CREF= option. The c_i values are displayed on the horizontal axis.

Output 78.3.16 Power Plot

Under the null hypothesis, $c_i = 0$, the power is 0.025, which is the upper Type I error probability. Under the alternative hypothesis, $c_i = 1$, the power is 0.89991, which is one minus the Type II error probability, as displayed in the "Design Information" table in Output 78.3.13.

The "Test Information" table in Output 78.3.17 displays the boundary values for the test statistic with the default standardized Z scale. At stage 2, the standardized slope estimate 0.83805 is between the lower and upper β boundary values. The trial stops to accept the null hypothesis that the variable Weight has no effect on the oxygen intake rate after adjusting for other covariates.

Output 78.3.17 Sequential Tests

Test Information (Standardized Z Scale)
Null Reference = 0

Stage	Information Level-- Proportion	Actual	Alternative-- Reference Lower	Upper
1	0.4934	538.7887	-2.32118	2.32118
2	0.7517	820.8509	-2.86505	2.86505

2	-1.14237	1.14237	0.83805	Accept Null
3	-1.91409	1.91409	.	

Since the data set PARMS_FIT2 contains the test information only at stage 2, the information level at stage 1 in the TEST_FIT1 data set is used to generate boundary values for the test.

With the specified ODS GRAPHICS ON statement, a boundary plot with test statistics is displayed by default, as shown in Output 78.3.18. As expected, the test statistic is in the acceptance region between the lower and upper α boundaries at the final stage.

Output 78.3.18 Sequential Test Plot

After a trial is stopped, the "Parameter Estimates" table in Output 78.3.19 displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and the p-value under the null hypothesis $H_0 : \beta_w = 0$. As expected, the p-value 0.3056 is not significant at the $\alpha = 0.05$ level, and the confidence interval does contain the value zero. The p-value, unbiased median estimate, and confidence limits depend on the ordering of the sample space (k, z), where k is the stage number and z is the standardized Z statistic. With the specified LR ordering, the p-values are computed with the ordering $(k', z') \succ (k, z)$ if $z' > z$. See the section "Available Sample Space Orderings in a Sequential Test" on page 6025 for a detailed description of the LR ordering.

Output 78.3.19 Parameter Estimates

Parameter Estimates

Weight	-0.03368	0.10532

Example 78.4: Testing a Binomial Proportion

This example tests a binomial proportion by using a four-stage group sequential design. Suppose a supermarket is developing a new store-brand coffee. From past studies, the positive response for the current store-brand coffee from customers is around 60%. The store is interested in whether the new brand has a better positive response than the current brand.

A power family method is used for the group sequential trial with the null hypothesis $H_0 : p = p_0 = 0.60$ and a one-sided upper alternative with a power of 0.80 at $H_1 : p = 0.70$. To accommodate the zero null reference that is assumed in the SEQDESIGN procedure, an equivalent hypothesis $H_0 : \theta = 0$ with $H_1 : \theta = 0.10$ is used, where $\theta = p - p_0$. The following statements request a power family method with early stopping to reject the null hypothesis:

```
ods graphics on;
proc seqdesign altref=0.10
               boundaryscale=mle
               ;
   PowerFamily: design method=pow
                       nstages=4
                       alt=upper
                       beta=0.20
                       ;
   samplesize model=onesamplefreq( nullprop=0.6);
ods output Boundary=Bnd_Prop;
run;
ods graphics off;
```

The NULLPROP= option in the SAMPLESIZE statement specifies $p_0 = 0.60$ for the sample size computation. The ODS OUTPUT statement with the BOUNDARY=BND_PROP option creates an output data set named BND_PROP which contains the resulting boundary information for the subsequent sequential tests.

With the BOUNDARYSCALE=MLE option, the procedure displays the output boundaries in terms of the maximum likelihood estimates. The "Design Information" table in Output 78.4.1 displays design specifications and derived statistics. With the specified alternative reference $\theta_1 = p_1 - p_0 = 0.7 - 0.6 = 0.1$, the maximum information 670.38 is also derived.

Output 78.4.1 Design Information

The SEQDESIGN Procedure
Design: PowerFamily

Design Information

3	105.58	502.8	106	504.8
4	140.78	670.4	141	671.4

Thus, 36 customers are needed at stage 1, and 35 new customers are needed at each of the remaining stages. Suppose that 36 customers are available at stage 1. Output 78.4.6 lists the 10 observations in the data set count_1.

Output 78.4.6 Clinical Trial Data

First 10 Obs in the Trial Data

Obs	Resp
1	1
2	1
3	0
4	0
5	1
6	1
7	0
8	1
9	1
10	1

The Resp variable is an indicator variable with a value of 1 for a customer with a positive response and a value of 0 for a customer without a positive response.

The following statements use the MEANS procedure to compute the mean response at stage 1:

```
proc means data=Prop_1;
   var Resp;
   ods output Summary=Data_Prop1;
run;
```

The following statements create and display (in Output 78.4.7) the data set for the centered mean positive response, $\hat{p} - p_0$:

```
data Data_Prop1;
   set Data_Prop1;
   _Scale_='MLE';
   _Stage_= 1;
   NObs= Resp_N;
```

```
   PDiff= Resp_Mean - 0.6;
   keep _Scale_ _Stage_ NObs PDiff;
run;
proc print data=Data_Prop1;
   title 'Statistics Computed at Stage 1';
run;
```

Output 78.4.7 Statistics Computed at Stage 1

Statistics Computed at Stage 1

Obs	_Scale_	_Stage_	NObs	PDiff
1	MLE	1	36	-0.016667

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Prop
             Data(Testvar=PDiff)=Data_Prop1
             boundaryscale=mle
             ;
ods output Test=Test_Prop1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The DATA=DATA_PROP1 option specifies the input data set DATA_PROP1 that contains the test statistic and its associated sample size at stage 1, and the TESTVAR=PDIFF option identifies the test variable PDIFF in the data set.

The ODS OUTPUT statement with the TEST=TEST_PROP1 option creates an output data set named TEST_PROP1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Design Information" table in Output 78.4.8 displays design specifications. By default, when the boundary values are modified for the new information levels, the Type I error probability α is maintained. The power has been modified for the new information levels.

Output 78.4.8 Design Information

The information level at stage 1 is computed as $I_1^* = I_1 \times (n_1^*/n_1)$, where I_1 and n_1 are the information level and sample size at stage 1 in the BOUNDARY= data set, and $n_1^* = 36$ is the available sample size at stage 1. Since only the information level at stage 1 is derived from the DATA= data

set, the information levels at stages 2 and 3 are derived proportionally from the corresponding information levels in the original design. At stage 1, the statistic $\hat{\theta} = \hat{p} - p_0 = 0.58333 - 0.6 = -0.01667$ is less than the upper α boundary value 0.19638, so the trial continues to the next stage.

With the specified ODS GRAPHICS ON statement, a boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 78.4.10. As expected, the test statistic is in the continuation region.

Output 78.4.10 Sequential Test Plot

The following statements use the MEANS procedure to compute the mean response at stage 2:

```
proc means data=Prop_2;
   var Resp;
   ods output Summary=Data_Prop2;
run;
```

The following statements create and display (in Output 78.4.11) the data set for the centered mean positive response ($\hat{p} - p_0$) at stage 2:

```
data Data_Prop2;
   set Data_Prop2;
   _Scale_='MLE';
```

```
   _Stage_= 2;
   NObs= Resp_N;
   PDiff= Resp_Mean - 0.6;
   keep _Scale_ _Stage_ NObs PDiff;
run;

proc print data=Data_Prop2;
   title 'Statistics Computed at Stage 2';
run;
```

Output 78.4.11 Statistics Computed at Stage 2

Statistics Computed at Stage 2

Obs	_Scale_	_Stage_	NObs	PDiff
1	MLE	2	71	-0.064789

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
ods graphics on;
proc seqtest Boundary=Test_Prop1
             Data(Testvar=PDiff)=Data_Prop2
             boundaryscale=mle
             condpower(cref=1)
             predpower
             plots=condpower
             ;
ods output test=Test_Prop2;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The DATA= option specifies the input data set that contains the test statistic and its associated sample size at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_PROP2 option creates an output data set named TEST_PROP2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The CONDPOWER(CREF=1) option requests the conditional power with the observed statistic under the alternative hypothesis, in addition to the conditional power under the hypothetical reference $\theta = \hat{\theta}$, the MLE estimate. The PREDPOWER option requests the noninformative predictive power with the observed statistic.

The "Test Information" table in Output 78.4.12 displays the boundary values for the test statistic with the specified MLE scale. The test statistic $\hat{\theta} = -0.06479$ is less than the corresponding upper α boundary 0.11834, so the sequential test does not stop at stage 2 to reject the null hypothesis.

Output 78.4.12 Sequential Tests

The SEQTEST Procedure

Test Information (MLE Scale)
Null Reference = 0

	Information Level			Alternative Reference	Boundary Values Upper	
Stage	Proportion	Actual	N	Upper	Upper	Alpha
1	0.2557	171.4286	36	0.10000		0.19638

4	.	

With the specified ODS GRAPHICS ON statement, the "Test Plot" displays boundary values of the design and the test statistic by default, as shown in Output 78.4.13. It also shows that the test statistic is in the "Continuation Region" below the upper α boundary value at stage 2.

Output 78.4.13 Sequential Test Plot

The predictive power is the probability to reject the null hypothesis under the posterior distribution with a noninformative prior given the observed statistic $\hat{\theta} = -0.06479$. The "Predictive Power Information" table in Output 78.4.14 indicates that the predictive power at $\hat{\theta} = -0.06479$ is 0.0002.

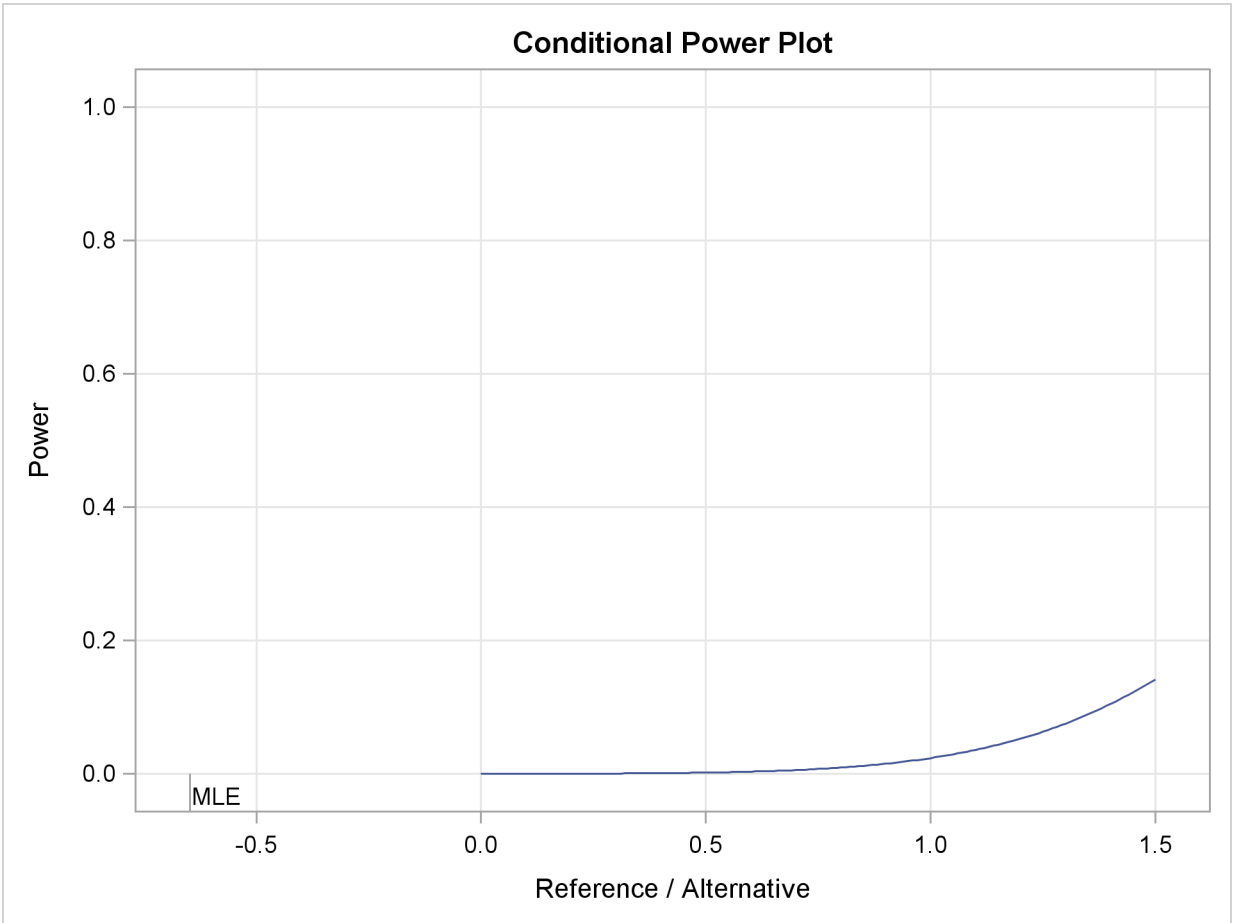
Output 78.4.14 Predictive Power

Predictive Power Information

Stopping Stage	MLE	Predictive Power
2	-0.06479	0.00020

The "Conditional Power Information" table in Output 78.4.15 displays conditional powers given the observed statistic under hypothetical references $\theta = \hat{\theta}$, the maximum likelihood estimate, and $\theta = \theta_1$. The constant c under CRef for the MLE is derived from $\hat{\theta} = c\theta_1$; that is, $c = \hat{\theta}/\theta_1 = -0.06479/0.1 = -0.6479$.

Output 78.4.15 Conditional Power



Conditional Power Information
Reference = CRef * (Alt Reference)

Stopping Stage	MLE	Reference Ref	Reference CRef	Conditional Power
2	−0.06479	MLE	−0.6479	0.00000
2	−0.06479	Alternative	1.0000	0.02367

The conditional power is the probability of rejecting the null hypothesis under these hypothetical references given the observed statistic $\hat{\theta} = -0.06479$. The table in Output 78.4.15 shows a weak conditional power of 0.02367 under the alternative hypothesis.

The "Conditional Power Plot" displays conditional powers given the observed statistic under various hypothetical references, as shown in Output 78.4.16. These references include $\theta = \hat{\theta}$, the maximum likelihood estimate, and $\theta = c_i\theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.01, \ldots, 1.50$ are constants that are specified in the CREF= option. Output 78.4.16 shows that the conditional power increases as c_i increases.

Output 78.4.16 Conditional Power Plot

With a predictive power 0.0002 and a conditional power of 0.02367 under H_1, the supermarket decides to stop the trial and accept the null hypothesis. That is, the positive response for the new store-brand coffee is not better than that for the current store-brand coffee.

Output 78.4.17 Predictive Power

Predictive Power Information

Stopping Stage	MLE	Predictive Power
2	-0.06479	0.00020

In the SEQTEST procedure, the conditional probability at an interim stage k is the probability that the test statistic at the final stage (stage 4) would exceed the rejection critical value. Since an interim stage exists between the current stage (stage 2) and the final stage, the conditional power is not the conditional probability to reject the null hypothesis H_0.

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2. The NSTAGES=3 option sets the next stage as the final stage (stage 3). The CONDPOWER(CREF=1) option requests the conditional power with the observed statistic under the alternative hypothesis, in addition to the conditional power under the hypothetical reference $\theta = \hat{\theta}$, the MLE estimate.

```
proc seqtest Boundary=Test_Prop1
             Data(Testvar=PDiff)=Data_Prop2
             nstages=3
             boundaryscale=mle
             condpower(cref=1)
             ;
run;
```

The "Test Information" table in Output 78.4.18 displays the boundary values for the test statistic with the specified MLE scale, assuming that the next stage is the final stage.

Output 78.4.18 Sequential Tests

The SEQTEST Procedure

Test Information (MLE Scale)
Null Reference = 0

Stage	Information Level Proportion	Information Level Actual	Information Level N	Alternative Reference Upper	Boundary Values Upper Alpha
1	0.2557	171.4286	36	0.10000	0.19638
2	0.5043	338.0952	71	0.10000	0.11834
3	1.0000	670.3782	140.7794	0.10000	0.06730

Test Information (MLE Scale)
Null Reference = 0

Stage	Test PDiff Estimate	Test PDiff Action
1	-0.01667	Continue
2	-0.06479	Continue
3	.	

The "Conditional Power Information" table in Output 78.4.19 displays conditional powers given the observed statistic, assuming that the next stage is the final stage.

Output 78.4.19 Conditional Power

Conditional Power Information
Reference = CRef * (Alt Reference)

Stopping Stage	MLE	Reference Ref	Reference CRef	Conditional Power
2	-0.06479	MLE	-0.6479	0.00000
2	-0.06479	Alternative	1.0000	0.03188

The conditional power is the probability of rejecting the null hypothesis under these hypothetical references given the observed statistic $\hat{\theta} = -0.06479$. The table in Output 78.4.19 also shows a weak conditional power of 0.03188 under the alternative hypothesis.

Example 78.5: Comparing Two Proportions with a Log Odds Ratio Test

This example compares two binomial proportions by using a log odds ratio statistic in a five-stage group sequential test. A clinic is studying the effect of vitamin C supplements in treating flu symptoms. The study consists of patients in the clinic who exhibit the first sign of flu symptoms within the last 24 hours. These patients are randomly assigned to either the control group (which receives placebo pills) or the treatment group (which receives large doses of vitamin C supplements). At the end of a five-day period, the flu symptoms of each patient are recorded.

Suppose that you know from past experience that flu symptoms disappear in five days for 60% of patients who experience flu symptoms. The clinic would like to detect a 70% symptom disappearance with a high probability. A test that compares the proportions directly specifies the null hypothesis $H_0 : \theta = p_t - p_c = 0$ with a one-sided alternative $H_1 : \theta > 0$ and a power of 0.90 at $H_1 : \theta = 0.10$, where p_t and p_c are the proportions of symptom disappearance in the treatment group and control group, respectively. An alternative trial tests an equivalent hypothesis by using the log odds ratio statistics:

$$\theta = \log\left(\frac{(\frac{p_t}{1-p_t})}{(\frac{p_c}{1-p_c})}\right)$$

Then the null hypothesis is $H_0 : \theta = \theta_0 = 0$ and the alternative hypothesis is

$$H_1 : \theta = \theta_1 = \log\left(\frac{(\frac{0.70}{0.30})}{(\frac{0.6}{0.4})}\right) = 0.441833$$

The following statements invoke the SEQDESIGN procedure and request a five-stage group sequential design by using an error spending function method for normally distributed statistics. The design uses a two-sided alternative hypothesis with early stopping to reject the null hypothesis H_0.

```
ods graphics on;
proc seqdesign altref=0.441833
               boundaryscale=mle
               ;
   OneSidedErrorSpending: design method=errfuncpow
                                 nstages=5
                                 alt=upper
                                 stop=accept
                                 alpha=0.025;
   samplesize model=twosamplefreq( nullprop=0.6 test=logor);
ods output Boundary=Bnd_CSup;
run;
ods graphics off;
```

The ODS OUTPUT statement with the BOUNDARY=BND_CSUP option creates an output data set named BND_CSUP which contains the resulting boundary information for the subsequent sequential tests.

The "Design Information" table in Output 78.5.1 displays design specifications and derived statistics. With the specified alternative reference, the maximum information 56.30934 is derived.

Output 78.5.1 Design Information

The SEQDESIGN Procedure
Design: OneSidedErrorSpending

Design Information

Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Upper
Early Stop	Accept Null

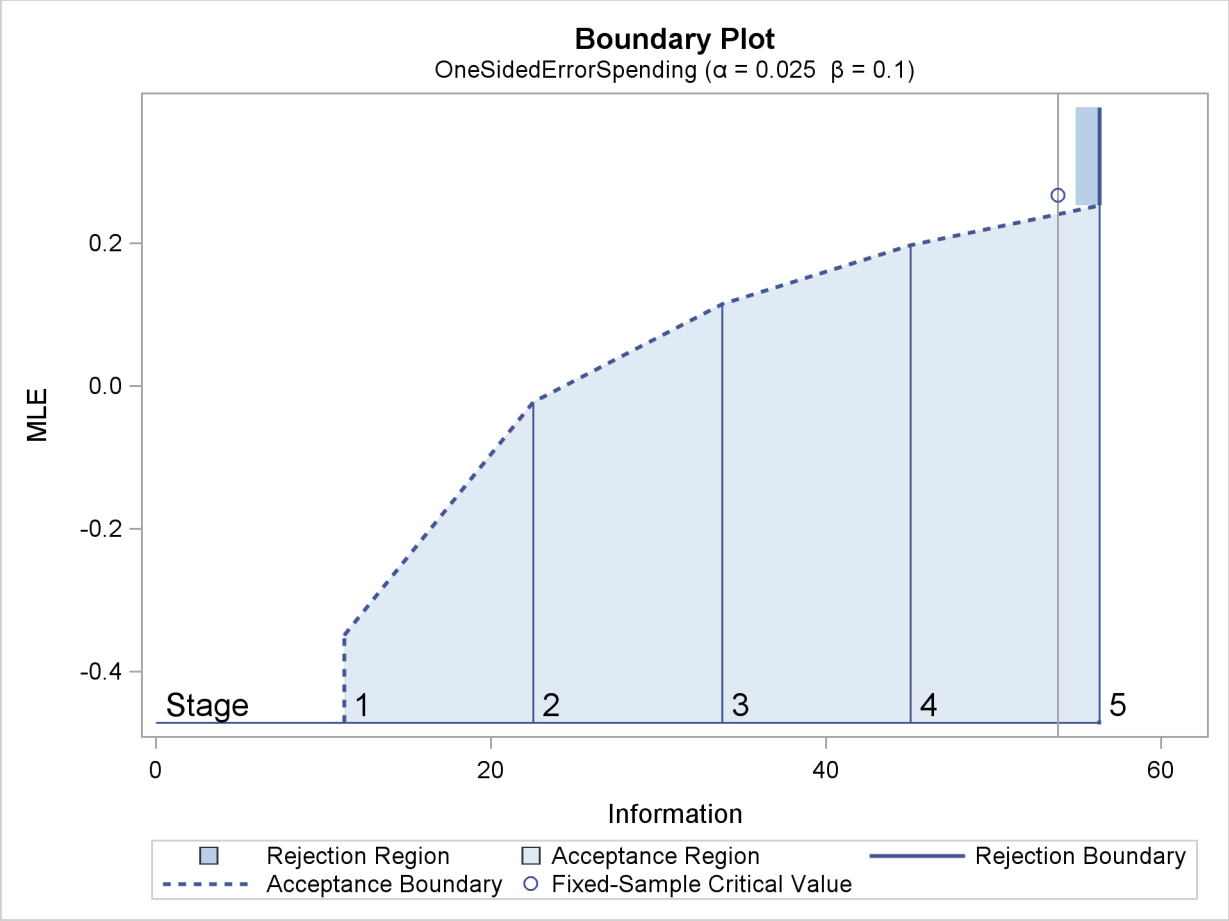
Max Information	56.30934
Null Ref ASN (Percent of Fixed Sample)	57.21399
Alt Ref ASN (Percent of Fixed Sample)	102.1058

The "Boundary Information" table in Output 78.5.2 displays information level, alternative reference, and boundary values at each stage. With the specified BOUNDARYSCALE=MLE option, the procedure displays the output boundaries in terms of the MLE scale.



Output 78.5.2 Boundary Information

Boundary Information (MLE Scale)
Null Reference = 0

	Information Level			Alternative Reference	Boundary Values
Stage	Proportion	Actual	N	Upper	Upper Beta
1	0.2000	11.26187	201.1048	0.44183	−0.34844
2	0.4000	22.52374	402.2096	0.44183	−0.02262
3	0.6000	33.7856	603.3144	0.44183	0.11527
4	0.8000	45.04747	804.4192	0.44183	0.19708
5	1.0000	56.30934	1005.524	0.44183	0.25345

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 78.5.3.

Output 78.5.3 Boundary Plot

With the SAMPLESIZE statement, the "Sample Size Summary" table in Output 78.5.4 displays the parameters for the sample size computation.

Output 78.5.4 Sample Size Summary

Sample Size Summary

Test	Two-Sample Proportions
Null Proportion	0.6
Proportion (Group A)	0.7
Test Statistic	Log Odds Ratio
Reference Proportions	Alt Ref
Max Sample Size	1005.524
Expected Sample Size (Null Ref)	549.9132
Expected Sample Size (Alt Ref)	981.3914

The "Sample Sizes" table in Output 78.5.5 displays the required sample sizes for the group sequential clinical trial.

Output 78.5.5 Required Sample Sizes

Sample Sizes (N)
Two-Sample Log Odds Ratio Test for Proportion Difference

	Fractional N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	201.10	100.55	100.55	11.2619
2	402.21	201.10	201.10	22.5237
3	603.31	301.66	301.66	33.7856
4	804.42	402.21	402.21	45.0475
5	1005.52	502.76	502.76	56.3093

Sample Sizes (N)
Two-Sample Log Odds Ratio Test for Proportion Difference

	Ceiling N			
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	202	101	101	11.3120
2	404	202	202	22.6240
3	604	302	302	33.8240
4	806	403	403	45.1360
5	1006	503	503	56.3360

Thus, 101 new patients are needed in each group at stages 1, 2, and 4, and 100 new patients are needed in each group at stages 3 and 5. Suppose that 101 patients are available in each group at stage 1. Output 78.5.6 lists the 10 observations in the data set count_1.

Output 78.5.6 Clinical Trial Data

First 10 Obs in the Trial Data

Obs	TrtGrp	Resp
1	Control	1
2	C_Sup	0
3	Control	0
4	C_Sup	1
5	Control	1
6	C_Sup	1
7	Control	1
8	C_Sup	0
9	Control	0
10	C_Sup	1

The TrtGrp variable is a grouping variable with the value Control for a patient in the placebo control group and the value C_Sup for a patient in the treatment group who receives vitamin C supplements. The Resp variable is an indicator variable with the value 1 for a patient without flu symptoms after five days and the value 0 for a patient with flu symptoms after five days.

The following statements use the LOGISTIC procedure to compute the log odds ratio statistic and its associated standard error at stage 1:

```
proc logistic data=CSup_1 descending;
   class TrtGrp / param=ref;
   model Resp= TrtGrp;
   ods output ParameterEstimates=Parms_CSup1;
run;
```

The DESCENDING option is used to reverse the order for the response levels, so the LOGISTIC procedure is modeling the probability that Resp = 1.

The following statements create and display (in Output 78.5.7) the data set for the log odds ratio statistic and its associated standard error:

```
data Parms_CSup1;
   set Parms_CSup1;
   if Variable='TrtGrp' and ClassVal0='C_Sup';
   _Scale_='MLE';
   _Stage_= 1;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_CSup1;
   title 'Statistics Computed at Stage 1';
run;
```

Output 78.5.7 Statistics Computed at Stage 1

Statistics Computed at Stage 1

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	TrtGrp	0.3247	0.2856	MLE	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_CSup
             Parms(Testvar=TrtGrp)=Parms_CSup1
             boundaryadj=errfuncpow
             boundarykey=both
             boundaryscale=mle
             ;
ods output test=Test_CSup1; run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_CSUP1 option specifies the input data set PARMS_CSUP1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=TRTGRP option identifies the test variable TRTGRP in the data set.

The ODS OUTPUT statement with the TEST=TEST_CSUP1 option creates an output data set named TEST_CSUP1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Design Information" table in Output 78.5.8 displays design specifications. With the specified BOUNDARYKEY=BOTH option, the information levels and boundary values at future stages are modified to maintain both the α and β levels.

Output 78.5.8 Design Information

The SEQTEST Procedure

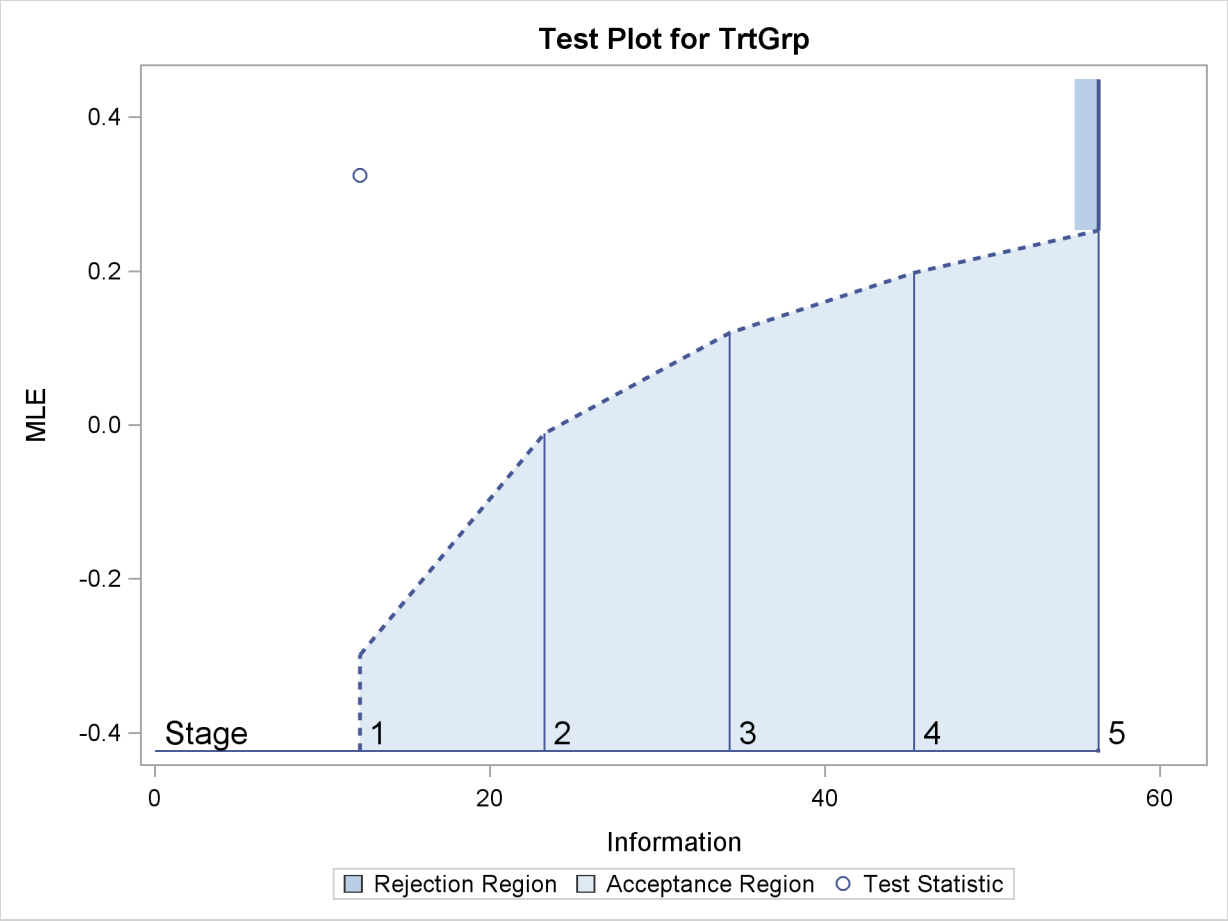
Design Information

BOUNDARY Data Set	WORK.BND_CSUP
Data Set	WORK.PARMS_CSUP1
Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Upper
Early Stop	Accept Null
Number of Stages	5
Alpha	0.025
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	104.6673
Max Information	56.3361718
Null Ref ASN (Percent of Fixed Sample)	57.02894
Alt Ref ASN (Percent of Fixed Sample)	102.1369

The "Test Information" table in Output 78.5.9 displays the boundary values for the test statistic with the specified MLE scale. Since the information level at stage 1 is derived from the PARMS= data set and other information levels are not specified, equal increments are used at remaining stages. At stage 1, the MLE statistic 0.32474 is greater than the corresponding upper β boundary value -0.29906, so the sequential test continues to the next stage.

Output 78.5.9 Sequential Tests

Test Information (MLE Scale)
Null Reference = 0



Stage	---Information Level-- Proportion	Actual	-Alternative- --Reference-- Upper
1	0.2176	12.26014	0.44183
2	0.4132	23.27914	0.44183
3	0.6088	34.29815	0.44183
4	0.8044	45.31716	0.44183
5	1.0000	56.33617	0.44183

Test Information (MLE Scale)
Null Reference = 0

Stage	-Boundary Values- ------Upper------ Beta	----------Test---------- ----------TrtGrp---------- Estimate	Action
1	-0.29906	0.32474	Continue
2	-0.01067	.	
3	0.11942	.	
4	0.19829	.	
5	0.25325	.	

With the specified ODS GRAPHICS ON statement, a boundary plot with the boundary values and test statistics is displayed, as shown in Output 78.5.10. As expected, the test statistic is in the continuation region.

Output 78.5.10 Sequential Test Plot

The following statements use the LOGISTIC procedure to compute the log odds ratio statistic and its associated standard error at stage 2:

```
proc logistic data=CSup_2 descending;
   class TrtGrp / param=ref;
   model Resp= TrtGrp;
   ods output ParameterEstimates=Parms_CSup2;
run;
```

The following statements create and display (in Output 78.5.11) the data set for the mean positive response and its associated standard error at stage 2:

```
data Parms_CSup2;
   set Parms_CSup2;
   if Variable='TrtGrp' and ClassVal0='C_Sup';
   _Scale_='MLE';
   _Stage_= 2;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;
proc print data=Parms_CSup2;
   title 'Statistics Computed at Stage 2';
run;
```

Output 78.5.11 Statistics Computed at Stage 2

Statistics Computed at Stage 2

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	TrtGrp	0.2356	0.2073	MLE	2

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
proc seqtest Boundary=Test_CSup1
             Parms( testvar=TrtGrp)=Parms_CSup2
             boundaryadj=errfuncpow
             boundarykey=both
             boundaryscale=mle
             ;
ods output Test=Test_CSup2;
run;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=CSUP_LDL2 option creates an output data set named CSUP_LDL2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Test Information" table in Output 78.5.12 displays the boundary values for the test statistic with the specified MLE scale. The test statistic 0.2356 is greater than the corresponding upper β boundary value -0.01068, so the sequential test continues to the next stage.

Output 78.5.12 Sequential Tests

The SEQTEST Procedure

Test Information (MLE Scale)
Null Reference = 0

Stage	Information Level Proportion	Information Level Actual	Alternative Reference Upper
1	0.2176	12.26014	0.44183
2	0.4132	23.27916	0.44183
3	0.6088	34.29799	0.44183
4	0.8044	45.31681	0.44183
5	1.0000	56.33563	0.44183

Test Information (MLE Scale)
Null Reference = 0

Stage	Boundary Values Upper Beta	Test TrtGrp Estimate	Test TrtGrp Action
1	−0.29906	0.32474	Continue
2	−0.01068	0.23560	Continue
3	0.11942	.	
4	0.19829	.	
5	0.25325	.	

Similar results are found at stages 3 and stage 4, so the trial continues to the final stage. The following statements use the LOGISTIC procedure to compute the log odds ratio statistic and its associated standard error at stage 5:

```
proc logistic data=CSup_5 descending;
   class TrtGrp / param=ref;
   model Resp= TrtGrp;
   ods output ParameterEstimates=Parms_CSup5;
run;
```

The following statements create and display (in Output 78.5.13) the data set for the log odds ratio statistic and its associated standard error at stage 5:

```
data Parms_CSup5;
   set Parms_CSup5;
   if Variable='TrtGrp' and ClassVal0='C_Sup';
   _Scale_='MLE';
   _Stage_= 5;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_CSup5;
   title 'Statistics Computed at Stage 5';
run;
```

Output 78.5.13 Statistics Computed at Stage 5

Statistics Computed at Stage 5

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	TrtGrp	0.2043	0.1334	MLE	5

The following statements invoke the SEQTEST procedure to test for the hypothesis at stage 5:

```
ods graphics on;
proc seqtest Boundary=Test_CSup4
             Parms( testvar=TrtGrp)=Parms_CSup5
             boundaryadj=errfuncpow
             boundaryscale=mle
             cialpha=.025
             rci
             plots=rci
             ;
run;
ods graphics off;
```

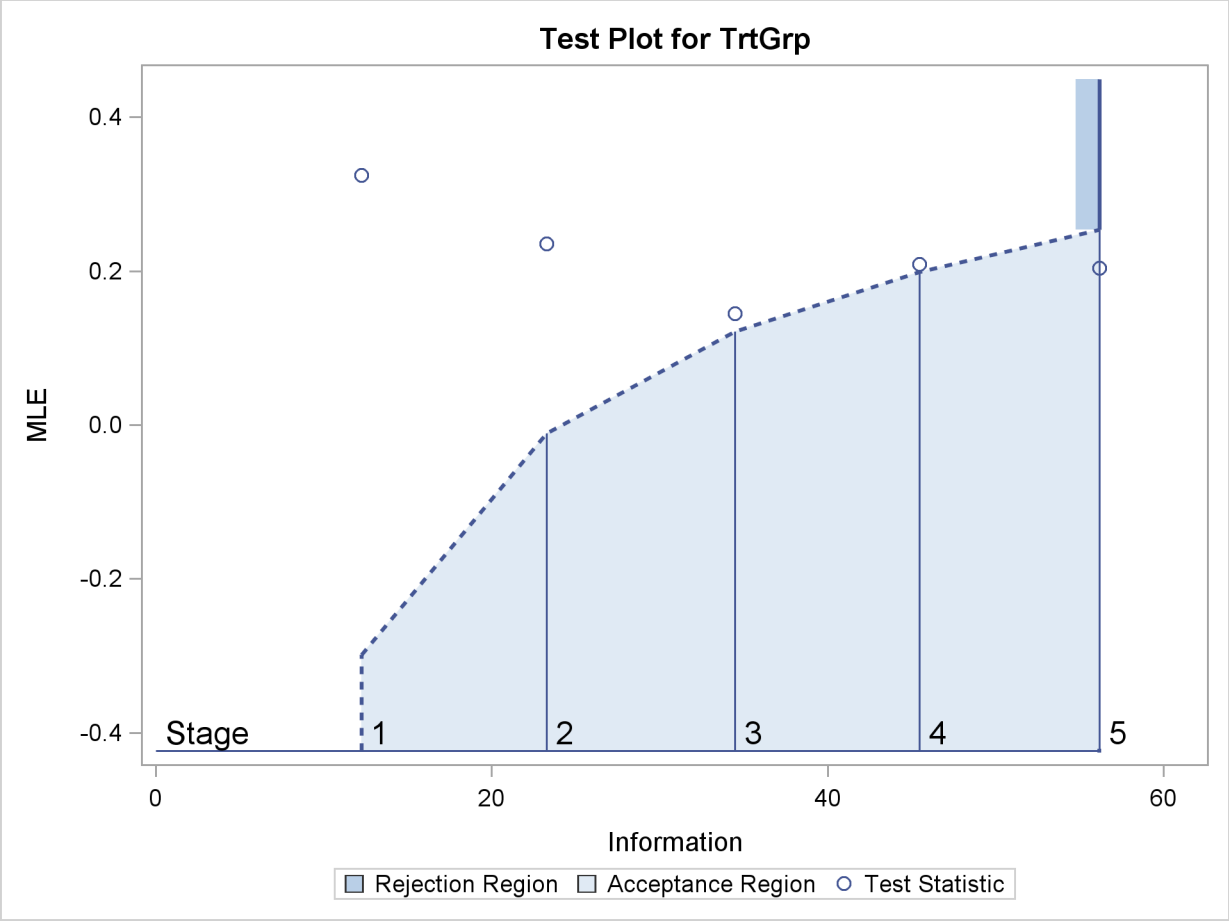
The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 5, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 5, and the TESTVAR= option identifies the test variable in the data set. With the default BOUNDARYKEY=ALPHA option, the boundary value at stage 5 is derived to maintain the α level.

The "Test Information" table in Output 78.5.14 displays the boundary values for the test statistic with the specified MLE scale. The test statistic 0.2043 is less than the corresponding upper β boundary 0.25375, so the sequential test stops to accept the null hypothesis. That is, there is no reduction in duration of symptoms for the group receiving vitamin C supplements.

Output 78.5.14 Sequential Tests

The SEQTEST Procedure

Test Information (MLE Scale)
Null Reference = 0



Stage	Information Level Proportion	Information Level Actual	Alternative Reference Upper
1	0.2183	12.26014	0.44183
2	0.4145	23.27916	0.44183
3	0.6141	34.48793	0.44183
4	0.8092	45.44685	0.44183
5	1.0000	56.16068	0.44183

Test Information (MLE Scale)
Null Reference = 0

Stage	Boundary Values Upper Beta	Test TrtGrp Estimate	Action
1	−0.29906	0.32474	Continue
2	−0.01068	0.23560	Continue
3	0.12134	0.14482	Continue
4	0.19899	0.20855	Continue
5	0.25375	0.20430	Accept Null

The "Test Plot" displays boundary values of the design and the test statistics, as shown in Output 78.5.15. It also shows that the test statistic is in the "Acceptance Region" at the final stage.

Output 78.5.15 Sequential Test Plot

After a trial is stopped, the "Parameter Estimates" table in Output 78.5.16 displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and the p-value under the null hypothesis $H_0 : \theta = 0$. As expected, the p-value 0.0456 is not significant at $\alpha = 0.025$ level and the lower 97.5% confidence limit is less than the value $\theta_0 = 0$. The p-value, unbiased median estimate, and confidence limits depend on the ordering of the sample space (k, z), where k is the stage number and z is the standardized Z statistic.

Output 78.5.16 Parameter Estimates

Parameter Estimates
Stagewise Ordering

Parameter	Stopping Stage	MLE	p-Value for H0:Parm=0	Median Estimate	Lower 97.5% CL
TrtGrp	5	0.204303	0.0456	0.234494	-0.03712

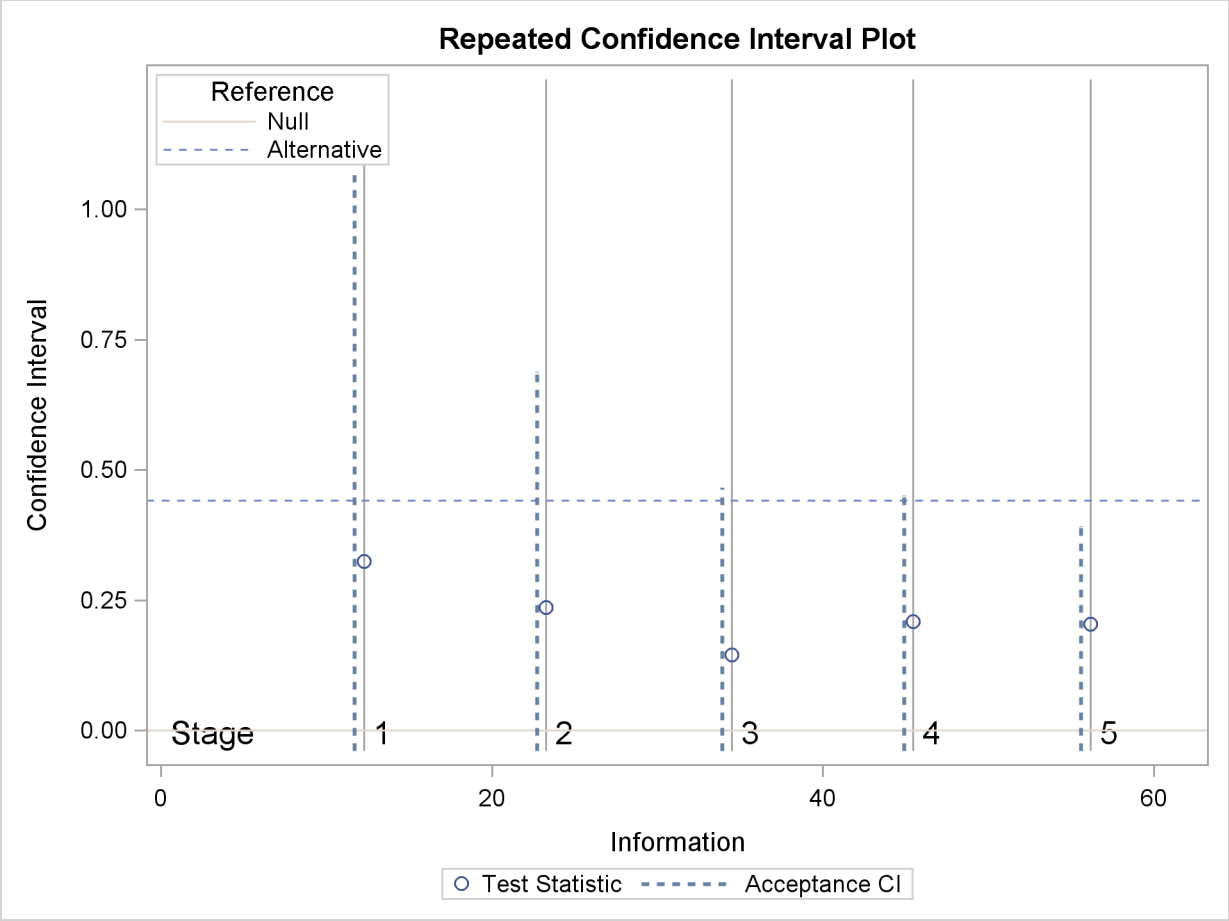
Since the test is accepted at stage 5, the p-value computed by using the default stagewise ordering

can be expressed as

$$\alpha_u = P_{\theta=0}\left(z_5 < Z_5 \mid b_k < Z_k, k < 5\right)$$

where $z_5 = 1.53105$ is the test statistic at stage 5, Z_k is a standardized normal variate at stage k, and b_k is the upper β boundary value in the standardized Z scale at stage $k, k = 1, 2, \ldots, 5$.

With the RCI option, the "Repeated Confidence Intervals" table in Output 78.5.17 displays repeated confidence intervals for the parameter. For a one-sided test with an upper alternative hypothesis, since the upper acceptance repeated confidence limit 0.3924 at the final stage is less than the alternative reference 0.441833, the null hypothesis is accepted.



Output 78.5.17 Repeated Confidence Intervals

Repeated Confidence Intervals

Stage	Information Level	Parameter Estimate	-Acceptance Boundary- Upper 89.94% CL
1	12.2601	0.32474	1.0656
2	23.2792	0.23560	0.6881
3	34.4879	0.14482	0.4653
4	45.4468	0.20855	0.4514
5	56.1607	0.20430	0.3924

With the PLOTS=RCI option, the "Repeated Confidence Intervals Plot" displays repeated confidence intervals for the parameter, as shown in Output 78.5.18. It shows that the upper acceptance repeated confidence limit at the final stage is less than the alternative reference 0.441833. This implies that the study accepts the null hypothesis at the final stage.

Output 78.5.18 Repeated Confidence Intervals Plot

Example 78.6: Comparing Two Survival Distributions with a Log-Rank Test

This example requests a log-rank test that compares two survival distributions for the treatment effect (Jennison and Turnbull 2000, pp. 77–79; Whitehead 1997, pp. 36–39).

A clinic is studying the effect of a new cancer treatment. The study consists of mice exposed to a carcinogen and randomized to either the control group or the treatment group. The event of interest is the death from cancer induced by the carcinogen, and the response is the time from randomization to death.

Following the derivations in the section "Test for Two Survival Distributions with a Log-Rank Test" in the chapter "The SEQDESIGN Procedure," the hypothesis $H_0 : \theta = -\log(\lambda) = 0$ with an alternative hypothesis $H_1 : \theta = \theta_1 > 0$ can be used, where λ is the hazard ratio between the treatment group and control group.

Suppose that from past experience, the median survival time for the control group is $t_0 = 20$ weeks, and the study would like to detect a $t_1 = 40$ weeks median survival time with a 80% power in the trial. Assuming exponential survival functions for the two groups, the hazard rates can be computed

from

$$S_j(t_j) = e^{-h_j t_j} = \frac{1}{2}$$

where $j = 0, 1$.

Thus, with $h_0 = 0.03466$ and $h_1 = 0.01733$, the hazard ratio $\lambda_1 = h_1/h_0 = 1/2$ and the alternative hypothesis is

$$\theta_1 = -\log(\lambda_1) = -\log(\frac{1}{2}) = 0.69315$$

The following statements invoke the SEQDESIGN procedure and request a four-stage group sequential design for normally distributed data. The design uses a one-sided alternative hypothesis with early stopping to reject and to accept the null hypothesis H_0. Whitehead's triangular method is used to derive the boundaries.

```
ods graphics on;
proc seqdesign altref=0.69315
               boundaryscale=score
               ;
   OneSidedWhitehead: design method=whitehead
                             nstages=4
                             boundarykey=alpha
                             alt=upper  stop=both
                             beta=0.20;
   samplesize model=twosamplesurvival
                    ( nullhazard=0.03466
                      accrate=10);
run;
ods graphics off;
```

A Whitehead method creates boundaries that approximately satisfy the Type I and Type II error probability level specification. The BOUNDARYKEY=ALPHA option is used to adjust the boundary value at the last stage and to meet the specified Type I probability level.

The specified ACCRATE=10 option indicates that 10 mice will be accrued each week and the resulting minimum and maximum accrual times are displayed. With the BOUNDARYSCALE=SCORE option, the procedure displays the output boundaries with the score statistics.

The "Design Information" table in Output 78.6.1 displays design specifications and derived statistics.

Output 78.6.1 Design Information

The SEQDESIGN Procedure
Design: OneSidedWhitehead

Design Information

Statistic Distribution	Normal
Boundary Scale	Score
Alternative Hypothesis	Upper

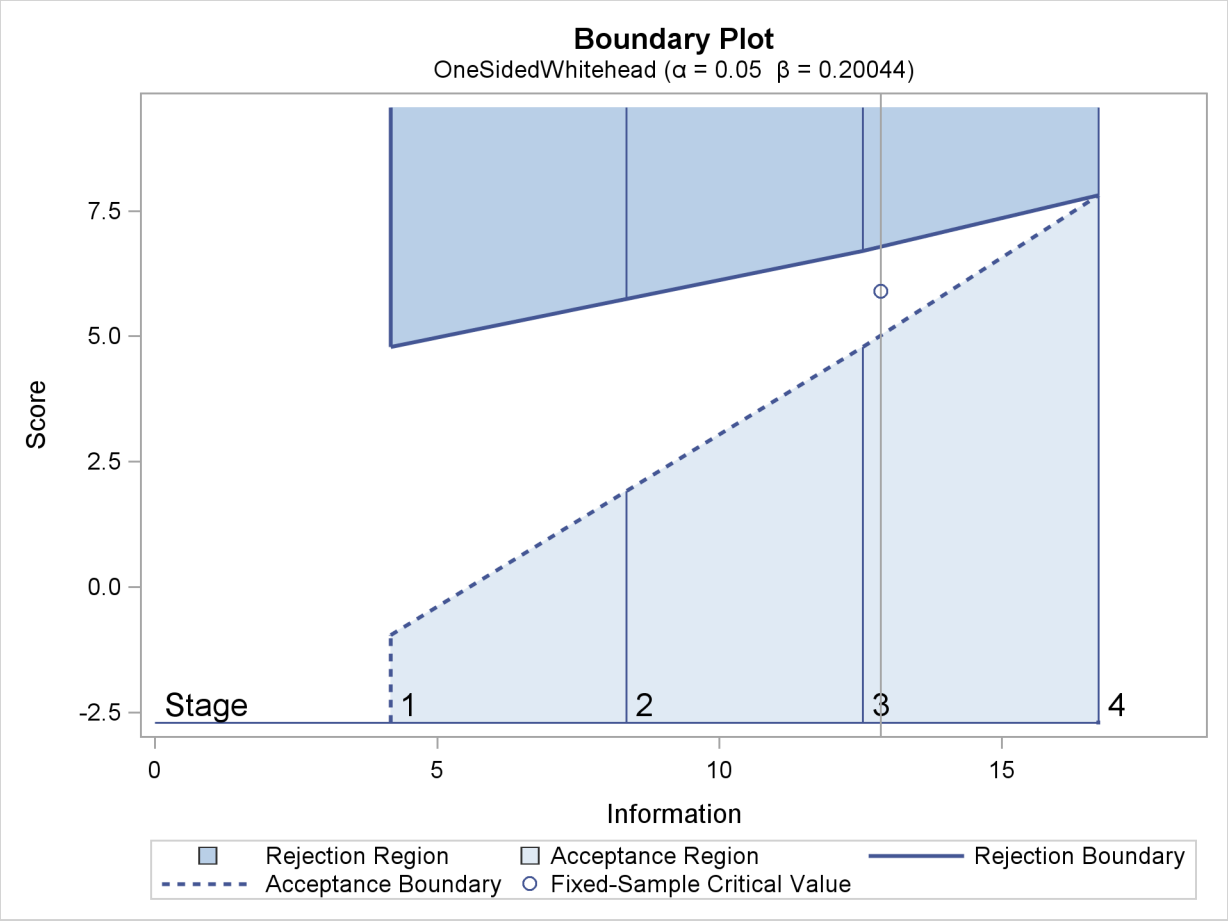
Power	0.79956
Max Information (Percent of Fixed Sample)	129.9894
Max Information	16.70624
Null Ref ASN (Percent of Fixed Sample)	62.6302
Alt Ref ASN (Percent of Fixed Sample)	74.00064

The "Boundary Information" table in Output 78.6.2 displays the information level, alternative reference, and boundary values at each stage.



Output 78.6.2 Boundary Information

Boundary Information (Score Scale)
Null Reference = 0

	Information Level			Alternative Reference	Boundary Values	
					Upper	
Stage	Proportion	Actual	Events	Upper	Beta	Alpha
1	0.2500	4.176561	16.70624	2.89498	-0.95755	4.78773
2	0.5000	8.353122	33.41249	5.78997	1.91509	5.74527
3	0.7500	12.52968	50.11873	8.68495	4.78773	6.70282
4	1.0000	16.70624	66.82498	11.57993	7.81296	7.81296

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed by default, as shown in Output 78.6.3.

Output 78.6.3 Boundary Plot

With the MODEL=TWOSAMPLESURVIVAL option in the SAMPLESIZE statement, the "Sample Size Summary" table in Output 78.6.4 displays the parameters for the sample size computation.

Output 78.6.4 Required Sample Size Summary

Sample Size Summary

Test	Two-Sample Survival
Null Hazard Rate	0.03466
Hazard Rate (Group A)	0.01733
Hazard Rate (Group B)	0.03466
Hazard Ratio	0.499999
log(Hazard Ratio)	-0.69315
Reference Hazards	Alt Ref
Accrual Rate	10
Min Accrual Time	6.682498
Min Sample Size	66.82498
Max Accrual Time	25.401
Max Sample Size	254.01
Max Number of Events	66.82498

With a minimum accrual time of 6.6825 weeks and a maximum accrual time of 25.401 weeks, an accrual time of 20 weeks is used in the study.

The "Numbers of Events" table in Output 78.6.5 displays the required number of events for the group sequential clinical trial.

Output 78.6.5 Required Numbers of Events

Numbers of Events (D)
Two-Sample Log-Rank Test

Stage	D	Information
1	16.71	4.1766
2	33.41	8.3531
3	50.12	12.5297
4	66.82	16.7062

The following statements invoke the SEQDESIGN procedure and provide more detailed sample size information:

```
proc seqdesign altref=0.69315
               boundaryscale=score
               ;
   OneSidedWhitehead: design method=whitehead
                             nstages=4
                             boundarykey=alpha
                             alt=upper
                             stop=both
                             beta=0.20;
   samplesize model=twosamplesurvival
                    ( nullhazard=0.03466
                      accrate=10 acctime=20);
ods output Boundary=Bnd_Surv;
run;
```

The ODS OUTPUT statement with the BOUNDARY=BND_SURV option creates an output data set named BND_SURV which contains the resulting boundary information for the subsequent sequential tests.

With an accrual time of 20 weeks, the "Sample Size Summary" table in Output 78.6.6 displays the follow-up time for the trial.

Output 78.6.6 Required Sample Size Summary

The SEQDESIGN Procedure
Design: OneSidedWhitehead

3	100.00	12.7667
4	100.00	17.1377

Thus the study will perform three interim analyses after 12, 18, and 22 weeks and a final analysis after 27 weeks if the study does not stop at any of the interim analyses.

Note that the SEQDESIGN procedure does not compute numbers of events or sample sizes for all statistical models. If the number of events or sample size for a fixed-sample design is available, then the MODEL=INPUTNEVENTS or MODEL=INPUTNOBS option can be used to input fixed-sample information. For example, with a required fixed-sample number of events 51.4073, the following SAMPLESIZE statement can be used to produce the same sample size results:

```
samplesize model=inputnevents
                ( d=51.47 sample=two
                  hazard=0.03466 0.01733
                  accrate=10 acctime=20);
```

Suppose that 120 mice are available after week 12 for the first interim analysis. Output 78.6.8 lists the 10 observations in the data set weeks_1.

Output 78.6.8 Clinical Trial Data

First 10 Obs in the Trial Data

Obs	Trt Gp	Event	Weeks
1	0	0	11
2	1	0	11
3	0	0	11
4	1	0	11
5	0	1	6
6	1	0	11
7	0	0	11
8	1	0	11
9	0	1	9
10	1	0	11

The TrtGp variable is a grouping variable with the value 0 for a mouse in the placebo control group and the value 1 for a mouse in the treatment group. The Weeks variable is the survival time variable measured in weeks and the Event variable is the censoring variable with the value 0 indicating censoring. That is, the values of Weeks are considered censored if the corresponding values of Event are 0; otherwise, they are considered as event times.

The following statements use the LIFETEST procedure to estimate the log-rank statistic at stage 1:

```
proc lifetest data=Surv_1;
   time Weeks*Event(0);
   test TrtGp;
ods output logunichisq=Parms_Surv1;
run;
```

The following statements create and display (in Output 78.6.9) the data set for the log-rank statistic and its associated standard error:

```
data Parms_Surv1;
   set Parms_Surv1(rename=(Statistic=Estimate));
   if Variable='TrtGp';
   _Scale_='Score';
   _Stage_= 1;
   keep Variable _Scale_ _Stage_ StdErr Estimate;
run;

proc print data=Parms_Surv1;
   title 'Statistics Computed at Stage 1';
run;
```

Output 78.6.9 Statistics Computed at Stage 1

Statistics Computed at Stage 1

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	TrtGp	3.2004	1.9979	Score	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Surv
             Parms(Testvar=TrtGp)=Parms_Surv1
             boundaryscale=score
             ;
ods output Test=Test_Surv1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_SURV1 option specifies the input data set PARMS_SURV1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=TRTGP option identifies the test variable TRTGP in the data set.

The ODS OUTPUT statement with the TEST=TEST_SURV1 option creates an output data set named TEST_SURV1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Design Information" table in Output 78.6.10 displays design specifications. By default, when the boundary values are modified for the new information levels, the Type I α level is maintained. The maximum information and the power have been modified for the new information levels.

Output 78.6.10 Design Information

The SEQTEST Procedure

Design Information

BOUNDARY Data Set	WORK.BND_SURV
Data Set	WORK.PARMS_SURV1
Statistic Distribution	Normal
Boundary Scale	Score
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Number of Stages	4
Alpha	0.05
Beta	0.20007
Power	0.79993
Max Information (Percent of Fixed Sample)	129.854
Max Information	16.7062448
Null Ref ASN (Percent of Fixed Sample)	62.56841
Alt Ref ASN (Percent of Fixed Sample)	74.05609

The "Test Information" table in Output 78.6.11 displays the boundary values for the test statistic with the SCORE statistic scale. Since only the information level at stage 1 is specified in the DATA= data set, the information levels at subsequent stages are derived proportionally from the corresponding information levels in the original design. At stage 1, the score statistic 3.2004 is between the upper β boundary value -1.0407 and the upper α boundary value 4.7142, so the trial continues to the next stage.

Output 78.6.11 Sequential Tests

Test Information (Score Scale)
Null Reference = 0

	---Information Level--		-Alternative- --Reference--	-----Boundary Values---- ----------Upper---------	
Stage	Proportion	Actual	Upper	Beta	Alpha

Null Reference = 0

	----------Test---------- ----------TrtGp----------	
Stage	Estimate	Action
1	3.20040	Continue
2	.	
3	.	
4	.	

Note that the observed information level 3.9917 corresponds to a proportion of 0.2389 in information level. If the observed information level is much smaller than the target proportion of 0.25, then you need to increase the accrual rate, accrual time, or follow-up time to achieve the target maximum information level for the trial. Scharfstein and Tsiatis (1998) use the simulation and bootstrap methods to modify the trial at interim stages to achieve the target maximum information level. These modifications should be specified in the study protocol or study plan before the study starts.

With the specified ODS GRAPHICS ON statement, a boundary plot with test statistics is displayed, as shown in Output 78.6.12. As expected, the test statistic is in the continuation region between the upper β and α boundary values.

Output 78.6.12 Sequential Test Plot

Note that the input DATA= option can also be used for the test statistics. For example, the following statements create and display (in Output 78.6.13) the data set for the log-rank statistic and its associated standard error after the LIFETEST procedure. Since the log-rank statistic is a score statistic, the corresponding information level is the variance of the statistic.

```
proc lifetest data=Surv_1;
   time Weeks*Event(0);
   test TrtGp;
ods output logunichisq=Parms_Surv1a;
run;

data Parms_Surv1a;
   set Parms_Surv1a(rename=(Statistic=TrtGp));
   keep _Scale_ _Stage_ _Info_ TrtGp;
   _Scale_='Score';
   _Stage_= 1;
   _Info_= StdErr * StdErr;
   if Variable='TrtGp';
run;
```

```
proc print data=Parms_Surv1a;
   title 'Statistics Computed at Stage 1';
run;
```

Output 78.6.13 Statistics Computed at Stage 1

Statistics Computed at Stage 1

Obs	TrtGp	_Scale_	_Stage_	_Info_
1	3.2004	Score	1	3.99170

The following statements can be used to invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Surv
             Data(Testvar=TrtGp)=Parms_Surv1a
             boundaryscale=score
             ;
ods output Test=Test_Surv1;
run;
ods graphics off;
```

The following statements use the LIFETEST procedure to compute the log-rank statistic and its associated standard error at stage 2:

```
proc lifetest data=Surv_2;
   time Weeks*Event(0);
   test TrtGp;
ods output logunichisq=Parms_Surv2;
run;
```

The following statements create and display (in Output 78.6.14) the data set for the log-rank statistic and its associated standard error for each of the first two stages:

```
data Parms_Surv2;
   set Parms_Surv2 (rename=(Statistic=Estimate));
   if Variable='TrtGp';
   _Scale_='Score';
   _Stage_= 2;
   keep Variable _Scale_ _Stage_ StdErr Estimate;
run;

proc print data=Parms_Surv2;
   title 'Statistics Computed at Stage 2';
run;
```

Output 78.6.14 Statistics Computed at Stage 2

Statistics Computed at Stage 2

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	TrtGp	7.3136	2.9489	Score	2

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
ods graphics on;
proc seqtest Boundary=Test_Surv1
             Parms(Testvar=TrtGp)=Parms_Surv2
             boundaryscale=score
             citype=lower
             ;
ods output Test=Test_Surv2;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_SURV2 option creates an output data set named TEST_SURV2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage if the trial does not stop at the current stage.

The "Test Information" table in Output 78.6.15 displays the boundary values for the test statistic. The test statistic 7.31365 is larger than the corresponding upper α boundary 5.79886, so the study stops and rejects the null hypothesis. That is, there is evidence of reduction in hazard rate for the new treatment.

Output 78.6.15 Sequential Tests

The SEQTEST Procedure

Test Information (Score Scale)
Null Reference = 0

	---Information Level--		-Alternative- --Reference--	-----Boundary Values---- ----------Upper---------	
Stage	Proportion	Actual	Upper	Beta	Alpha
1	0.2389	3.991698	2.76685	-1.04069	4.71422
2	0.5205	8.696125	6.02772	2.15758	5.79895
3	0.7603	12.70118	8.80383	4.85836	6.77006
4	1.0000	16.70624	11.57993	7.79713	7.79713

Test Information (Score Scale)
Null Reference = 0

	----------Test---------- ----------TrtGp----------	
Stage	Estimate	Action
1	3.20040	Continue

3	.	
4	.	

With the specified ODS GRAPHICS ON statement, the "Test Plot" displays boundary values of the design and the test statistic at the first two stages, as shown in Output 78.6.16. It also shows that the test statistic is in the "Rejection Region" above the upper α boundary value at stage 2.

Output 78.6.16 Sequential Test Plot

After the stopping of a trial, the "Parameter Estimates" table in Output 78.6.17 displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and p-value under the null hypothesis $H_0 : \theta = 0$.

Output 78.6.17 Parameter Estimates

Parameter Estimates
Stagewise Ordering

Parameter	Stopping Stage	MLE	p-Value for H0:Parm=0	Median Estimate	Lower 95% CL
TrtGp	2	0.841024	0.0139	0.810328	0.21615

As expected, the p-value 0.0139 is significant at the $\alpha = 0.05$ level and the lower 95% confidence limit is larger than $\theta_0 = 0$. The p-value, unbiased median estimate, and lower confidence limit depend on the ordering of the sample space (k, z), where k is the stage number and z is the standardized Z statistic. With the specified stagewise ordering, the p-value is $p_1 + p_2$, where p_1 is the

α spending at stage 1,

$$p_1 = P_{\theta=0}(Z_1\sqrt{I_1} \geq 4.71422) = 0.00915$$

$$p_2 = P_{\theta=0}(Z_2\sqrt{I_2} \geq 7.31365 \mid -1.04069 < Z_1\sqrt{I_1} < 4.71422)$$

where Z_k is a standardized normal variate and I_k is the information level at stage k for $k = 1, 2$.

Example 78.7: Testing an Effect in a Proportional Hazards Regression Model

This example compares two survival distributions for the treatment effect. The example uses a power family method to generate two-sided asymmetric boundaries and then uses a proportional hazards regression model to test the hypothesis with a covariate.

A clinic is conducting a clinical study for the effect of a new cancer treatment. The study consists of mice exposed to a carcinogen and randomized to either the control group or the treatment group. The event of interest is the death from cancer induced by the carcinogen, and the response is the time from randomization to death.

Consider the proportional hazards regression model

$$h(t;\ \text{TrtGp},\ \text{Wgt}) = h_0(t)\ \exp(\beta_g\ \text{TrtGp}\ +\ \beta_w \text{Wgt})$$

where $h_0(t)$ is an arbitrary and unspecified baseline hazard function, TrtGp is the grouping variable for the two groups, Wgt is the initial weight of the mice, and β_g and β_w are the regression parameters associated with the variables TrtGp and Wgt, respectively. The grouping variable has the value 0 for each mouse in the control group and the value 1 for each mouse in the treatment group.

The hypothesis $H_0 : \beta_g = 0$ with an alternative hypothesis $H_1 : \beta_g \neq 0$ is used for the study.

Suppose that from past experience, the median survival time for the control group is $t_0 = 20$ weeks. The study would like to detect a $t_1 = 40$ weeks median survival time with a 80% power in the trial. Assuming exponential survival functions for the two groups, the hazard rates can be computed from

$$S_j(t_j) = e^{-h_j t_j} = \frac{1}{2}$$

where $j = 0, 1$.

Thus, with the hazard rates $h_0 = 0.03466$ and $h_1 = 0.01733$, the hazard ratio $\exp(\beta_g) = h_1/h_0 = 1/2$ and the alternative hypothesis

$$\beta_{g1} = \log(\frac{1}{2}) = -0.69315$$

Following the derivations in the section "Test for a Parameter in the Proportional Hazards Regression Model" in the chapter "The SEQDESIGN Procedure," the required number of events for testing a parameter in $\boldsymbol{\beta}$ is given by

$$D_X = I_X\ \frac{1}{(1 - r_x^2)\ \sigma_x^2}$$

where σ_x^2 is the variance of TrtGp and r_x^2 is the proportion of variance of TrtGp explained by the variable Wgt.

If the two groups have the same number of mice in the study, then the MLE of the variance is $\hat{\sigma}_x^2 = 0.25$. Further, if $r_x^2 = 0.10$, then you can specify the MODEL=PHREG(XVARIANCE=0.25 XRSQUARE=0.10) option in the SAMPLESIZE statement in the SEQDESIGN procedure to compute the required number of events and the individual number of events at each stage.

The following statements invoke the SEQDESIGN procedure and request a four-stage group sequential design for normally distributed data. The design uses a two-sided alternative hypothesis with early stopping to reject the null hypothesis H_0. A power family method is used to derive the boundaries.

```
ods graphics on;
proc seqdesign altref=0.69315;
   TwoSidedPowerFamily: design method=pow
                               nstages=4
                               alpha=0.075(lower=0.025)
                               beta=0.20;
   samplesize model=phreg( xvariance=0.25 xrsquare=0.10
                           hazard=0.02451 accrate=10);
run;
ods graphics off;
```

The ALPHA=0.075(LOWER=0.025) option specifies a lower α level 0.025 for the lower rejection boundary and an upper α level $0.05 = 0.075 - 0.025$ for the upper rejection boundary. The geometric average hazard $\sqrt{h_0 \times h_1} = \sqrt{0.03466 \times 0.01733} = 0.02451$ is used in the HAZARD= option in the SAMPLESIZE statement to compute the required sample size. The specified ACCRATE=10 option indicates that 10 mice will be accrued each week and the resulting minimum and maximum accrual times will be displayed.

The "Design Information" table in Output 78.7.1 displays the design specifications and the derived statistics.

Output 78.7.1 Design Information

The SEQDESIGN Procedure
Design: TwoSidedPowerFamily

4	−2.11334	1.83246

With the specified ODS GRAPHICS ON statement, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in Output 78.7.3.

Output 78.7.3 Boundary Plot

With the MODEL=PHREG option in the SAMPLESIZE statement, the "Sample Size Summary" table in Output 78.7.4 displays the parameters used in the sample size computation for the proportional hazards regression model.

Output 78.7.4 Required Sample Size Summary

Sample Size Summary

Test	PH Reg Parameter
Parameter	0.69315
X Variance	0.25
R Square (X)	0.1
Hazard Rate	0.02451
Accrual Rate	10
Min Accrual Time	7.73017
Min Sample Size	77.3017
Max Accrual Time	27.97872
Max Sample Size	279.7872
Max Number of Events	77.3017

With a minimum accrual time of 7.73 weeks and maximum accrual time of 27.98 weeks, an accrual time of 20 weeks is used in the study. The "Numbers of Events" table in Output 78.7.5 displays the required numbers of events for the group sequential clinical trial.

Output 78.7.5 Required Sample Sizes

Numbers of Events (D)
Z Test for PH Regression Parameter

Stage	D	Information
1	19.33	4.3482
2	38.65	8.6964
3	57.98	13.0447
4	77.30	17.3929

The following statements invoke the SEQDESIGN procedure and provide more detailed sample size information with a 20-week accrual time:

```
proc seqdesign altref=0.69315;
   TwoSidedPowerFamily: design method=pow
                               nstages=4
                               alpha=0.075(lower=0.025)
                               beta=0.20;
   samplesize model=phreg( xvariance=0.25 xrsquare=0.10
                           hazard=0.02451
                           accrate=10 acctime=20);
ods output Boundary=Bnd_Time;
run;
```

The ODS OUTPUT statement with the BOUNDARY=BND_TIME option creates an output data set named BND_TIME which contains the resulting boundary information for the subsequent sequential tests.

With an accrual time of 20 weeks, the "Sample Size Summary" table in Output 78.7.6 displays the follow-up time for the trial.

Output 78.7.6 Sample Size Summary

The SEQDESIGN Procedure
Design: TwoSidedPowerFamily

6	1	0	23.2240	12
7	0	1	22.6845	6
8	1	0	27.9292	12
9	0	0	22.5514	12
10	1	1	27.3793	11

The TrtGp variable is a grouping variable with the value 0 for a mouse in the placebo control group and the value 1 for a mouse in the treatment group.

The Weeks variable is the survival time variable measured in weeks and the Event variable is the censoring variable with the value 0 indicating censoring. That is, the values of Weeks are considered censored if the corresponding values of Event are 0; otherwise, they are considered as event times.

The following statements use the PHREG procedure to estimate the treatment effect after adjusting for the Wgt variable at stage 1:

```
proc phreg data=Time_1;
   model Weeks*Event(0)= TrtGp Wgt;
ods output parameterestimates=Parms_Time1;
run;
```

The following statements create and display (in Output 78.7.9) the data set for the treatment effect MLE statistic and its associated standard error. Note that for a MLE statistic, the inverse of the variance of the statistic is the information.

```
data Parms_Time1;
   set Parms_Time1;
   if Parameter='TrtGp';
   _Scale_='MLE';
   _Stage_= 1;
   keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;

proc print data=Parms_Time1;
   title 'Statistics Computed at Stage 1';
run;
```

Output 78.7.9 Statistics Computed at Stage 1

Statistics Computed at Stage 1

Obs	Parameter	Estimate	StdErr	_Scale_	_Stage_
1	TrtGp	0.00836	0.46588	MLE	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Time
             Parms(Testvar=TrtGp)=Parms_Time1
             order=lr
             ;
ods output Test=Test_Time1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_TIME1 option specifies the input data set PARMS_TIME1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=TRTGP option identifies the test variable TRTGP in the data set.

The ORDER=LR option uses the LR ordering to derive the p-value, the unbiased median estimate, and the confidence limits for the regression slope estimate.

The ODS OUTPUT statement with the TEST=TEST_TIME1 option creates an output data set named TEST_TIME1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Design Information" table in Output 78.7.10 displays design specifications. By default, when the boundary values are modified for the new information levels, the Type I α level is maintained. The maximum information and the power have been modified for the new information levels.

Output 78.7.10 Design Information

1	0.01795	Continue
2	.	
3	.	
4	.	

Since only the information level at stage 1 is derived in the PARMS= data set, the information levels at subsequent stages are derived proportionally from the corresponding information levels in the original design. At stage 1, the standardized Z statistic 0.01795 is between the lower and upper α boundary values of -2.92457 and 2.54086, so the trial continues to the next stage.

Note that the observed information level 4.6073 corresponds to a proportion of 0.2649 in the information level. If the observed information level is much smaller than the target proportion of 0.25, then you need to increase the accrual rate, accrual time, or follow-up time to achieve target information levels for subsequent stages. These modifications should be specified in the study plan before the study begins.

With the specified ODS GRAPHICS ON statement, a boundary plot with test statistics is displayed by default, as shown in Output 78.7.12. As expected, the test statistic is in the continuation region between the lower and upper α boundary values.

Output 78.7.12 Sequential Test Plot

The following statements use the PHREG procedure to compute the MLE statistic and its associated standard error at stage 2:

```
proc phreg data=Time_2;
   model Weeks*Event(0)= TrtGp Wgt;
```

```
ods output parameterestimates= Parms_Time2;
run;
```

The following statements create the data set for the MLE statistic and its associated standard error at stage 2:

```
data Parms_Time2;
   set Parms_Time2;
   if Parameter='TrtGp';
   _Scale_='MLE';
   _Stage_= 2;
   keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;
```

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
proc seqtest Boundary=Test_Time1
             Parms(Testvar=TrtGp)=Parms_Time2
             order=lr
             ;
ods output Test=Test_Time2;
run;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_TIME2 option creates an output data set named TEST_TIME2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Test Information" table in Output 78.7.13 displays the boundary values for the test statistic with the MLE statistic scale. At stage 2, the standardized Z statistic -0.43552 is between the lower α and upper boundary values, -2.47689 and 2.14819, respectively, so the trial continues to the next stage.

Output 78.7.13 Sequential Tests

The SEQTEST Procedure

Test Information (Standardized Z Scale)
Null Reference = 0

Since the data set PARMS_Time2 contains the test information only at stage 2, the information level at stage 1 in the TEST_Time1 data set is used to generate boundary values for the test.

Similarly, the test statistic at stage 3 is also between its corresponding lower and upper α boundary values. The trial continues to the next stage.

The following statements use the PHREG procedure to compute the MLE statistic and its associated standard error at the final stage:

```
proc phreg data=Time_4;
   model Weeks*Event(0)= TrtGp Wgt;
ods output parameterestimates= Parms_Time4;
run;
```

The following statements create and display (in Output 78.7.14) the data set for the MLE statistic and its associated standard error at each stage of the study:

```
data Parms_Time4;
   set Parms_Time4;
   if Parameter='TrtGp';
   _Scale_='MLE';
   _Stage_= 4;
   keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;

proc print data=Parms_Time4;
   title 'Statistics Computed at Stage 4';
run;
```

Output 78.7.14 Statistics Computed at Stage 4

Statistics Computed at Stage 4

Obs	Parameter	Estimate	StdErr	_Scale_	_Stage_
1	TrtGp	-0.04451	0.23971	MLE	4

The following statements invoke the SEQTEST procedure to test the hypothesis at stage 4:

```
ods graphics on;
proc seqtest Boundary=Test_Time3
             Parms(Testvar=TrtGp)=Parms_Time4
             order=lr
             ;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 4, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 4, and the TESTVAR= option identifies the test variable in the data set.

The "Test Information" table in Output 78.7.15 displays the boundary values for the test statistic. The standardized test statistic -0.1857 is between the lower and upper α boundary values of -2.10447 and 1.82112, respectively, so the study stops and accepts the null hypothesis. That is, there is no evidence of reduction in hazard rate for the new treatment.

Output 78.7.15 Sequential Tests

The SEQTEST Procedure

Test Information (Standardized Z Scale)
Null Reference = 0

The "Test Plot" displays boundary values of the design and the test statistic at the first two stages, as shown in Output 78.7.16. It also shows that the test statistic is in the "Acceptance Region" between the lower and upper α boundary values at stage 4.

Output 78.7.16 Sequential Test Plot

After the stopping of a trial, the "Parameter Estimates" table in Output 78.7.17 displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and p-value under the null hypothesis $H_0 : \theta = 0$.

Output 78.7.17 Parameter Estimates

Parameter Estimates
LR Ordering

Parameter	Stopping Stage	MLE	p-Value for H0:Parm=0	Median Estimate
TrtGp	4	-0.044514	0.8525	-0.044577

Parameter Estimates
LR Ordering

Parameter	95% Confidence Limits	
TrtGp	-0.51461	0.42538

As expected, the two-sided p-value 0.8525 is not significant at the lower $\alpha = 0.025$ level and the upper $\alpha = 0.05$ level, and the two-sided 95% confidence interval contains the null value zero. The p-value, unbiased median estimate, and lower confidence limit depend on the ordering of the sample space (k, z), where k is the stage number and z is the standardized Z statistic. With the specified LR ordering, the two-sided p-value is derived from the one-sided p-value

$$p_u = \sum_{k=1}^{4} P_{\theta=0}\left(Z_k \geq z_4 \mid _a_{k'} < Z_{k'} < a_{k'}, k' < k\right)$$

where $z_4 = -0.1857$ is the observed test statistic at stage 4, Z_k is a standardized normal variate at stage k, and $_a_{k'}$ and $a_{k'}$ are the stage k lower and upper rejection boundary values, respectively.

Thus,

$$p_u = \alpha_u + P_{\theta=0}\left(z_4 \leq Z_4 < a_4 \mid _a_{k'} < Z_{k'} < a_{k'}, k' < 4\right)$$

where $\alpha_u = 0.05$ is the upper α level and $a_4 = 1.82112$.

Since $P_{\theta=0}\left(z_4 \leq Z_4 \leq a_4 \mid _a_{k'} < Z_{k'} < a_{k'}, k' < 4\right) = 0.52374$, $p_u = 0.05 + 0.52374 = 0.57374$, which is greater than 0.50. Thus, the two-sided p-value is given by $2 \times (1.0 - p_u) = 0.8525$.

Example 78.8: Testing an Effect in a Logistic Regression Model

This example requests a two-sided test for the dose effect in a dose-response model (Whitehead 1997, pp. 262–263). Consider the logistic regression model

$$\text{logit}(p) = \log\left(\frac{p}{1-p}\right) = \beta_0 + \beta_1 \,\text{LDose}$$

where $p = \text{Prob}(\text{Resp} = 1 \,|\, \text{LDose})$ is the response probability to be modeled for the binary response Resp and LDose = log(Dose +1) is the covariate. The dose levels are 0 for the control group, and they are 1, 3, and 6 for the three treatment groups.

Following the derivations in the section "Test for a Parameter in the Logistic Regression Model" in the chapter "The SEQDESIGN Procedure," the required sample size can be derived from

$$N = I_X \, \frac{\sigma_y^2}{(1 - r_x^2)\,\sigma_x^2}$$

where σ_y^2 is the variance of the response variable in the logistic regression model, r_x^2 is the proportion of variance of LDose explained by other covariates, and σ_x^2 is the variance of LDose.

Since LDose is the only covariate in the model, $r_x^2 = 0$. For a logistic model, the variance σ^2 can be estimated by

$$\sigma_y^2 = \frac{1}{\hat{p}(1-\hat{p})}$$

where $\hat{p}$ is the estimated probability of the response variable Resp. Thus, the sample size can be computed as

$$N = I_X \frac{1}{p(1-p)} \frac{1}{\sigma_x^2}$$

The null hypothesis $H_0 : \beta_1 = 0$ corresponds to no treatment effect. Suppose that the alternative hypothesis $H_1 : \beta_1 = 0.5$ is the reference improvement that should be detected at a 0.90 level.

Note that $\beta_1 = 0.5$ corresponds to an odds ratio of 2 between the treatment group with dose level 3 and the control group. The log odds ratio between the two groups is

$$\log\left(\frac{p_t(1-p_c)}{(1-p_t)p_0}\right) = \log\left(\frac{p_t}{1-p_t}\right) - \log\left(\frac{p_c}{1-p_c}\right)$$

which corresponds to

$$(\beta_0 + \beta_1 \log(3+1)) - (\beta_0 + \beta_1 \log(1)) = \beta_1 \log(4) = \log(2)$$

If the same number of patients are assigned in each of the four groups, then the MLE of the variance of LDose is $\hat{\sigma}_x^2 = 0.5345$. Further, if the response rate is 0.40, then the required sample size can be derived using the SAMPLESIZE statement in the SEQDESIGN procedure.

The following statements invoke the SEQDESIGN procedure and request a three-stage group sequential design for normally distributed data. The design has a null hypothesis of no treatment effect $H_0 : \beta_1 = 0$ with early stopping to reject the null hypothesis with a two-sided alternative hypothesis $H_1 : \beta_1 = \pm 0.5$.

```
ods graphics on;
proc seqdesign altref=0.5;
   TwoSidedErrorSpending: design method=errfuncpow
                                method(loweralpha)=errfuncpow(rho=1)
                                method(upperalpha)=errfuncpow(rho=3)
                                nstages=3
                                stop=both;
   samplesize model=logistic( prop=0.4 xvariance=0.5345);
ods output Boundary=Bnd_Dose;
run;
ods graphics off;
```

The ODS OUTPUT statement with the BOUNDARY=BND_DOSE option creates an output data set named BND_DOSE which contains the resulting boundary information for the subsequent sequential tests.

The "Design Information" table in Output 78.8.1 displays design specifications and derived statistics. Since the alternative reference is specified, the maximum information 47.22445 is derived.

Output 78.8.1 Error Spending Design Information

The SEQDESIGN Procedure
Design: TwoSidedErrorSpending

9	0	0	0.00000
10	0	1	0.69315

The following statements use the LOGISTIC procedure to estimate the slope β_1 and its associated standard error at stage 1:

```
proc logistic data=Dose_1;
   model Resp(event='1')= LDose;
   ods output ParameterEstimates=Parms_Dose1;
run;
```

The following statements create and display (in Output 78.8.7) the input data set that contains slope β_1 and its associated standard error for the SEQTEST procedure:

```
data Parms_Dose1;
   set Parms_Dose1;
   if Variable='LDose';
   _Scale_='MLE';
   _Stage_= 1;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_Dose1;
   title 'Statistics Computed at Stage 1';
run;
```

Output 78.8.7 Statistics Computed at Stage 1

Statistics Computed at Stage 1

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	LDose	0.5741	0.2544	MLE	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Dose
             Parms(testvar=LDose)=Parms_Dose1
             order=mle
             boundaryscale=mle
             ;
ods output Test=Test_Dose1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_DOSE1 option specifies the input data set PARMS_DOSE1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=LDOSE option identifies the test variable LDOSE in the data set.

The ORDER=MLE option uses the MLE ordering to derive the p-value, the unbiased median estimate, and the confidence limits for the regression slope estimate.

The ODS OUTPUT statement with the TEST=TEST_DOSE1 option creates an output data set named TEST_DOSE1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Design Information" table in Output 78.8.8 displays design specifications. By default, the boundary values are modified for the new information levels to maintain the Type I α level. The maximum information remains the same as the design stored in the BOUNDARY= data set, but the derived Type II error probability β and power $1 - \beta$ are different because of the new information levels.

Output 78.8.8 Design Information

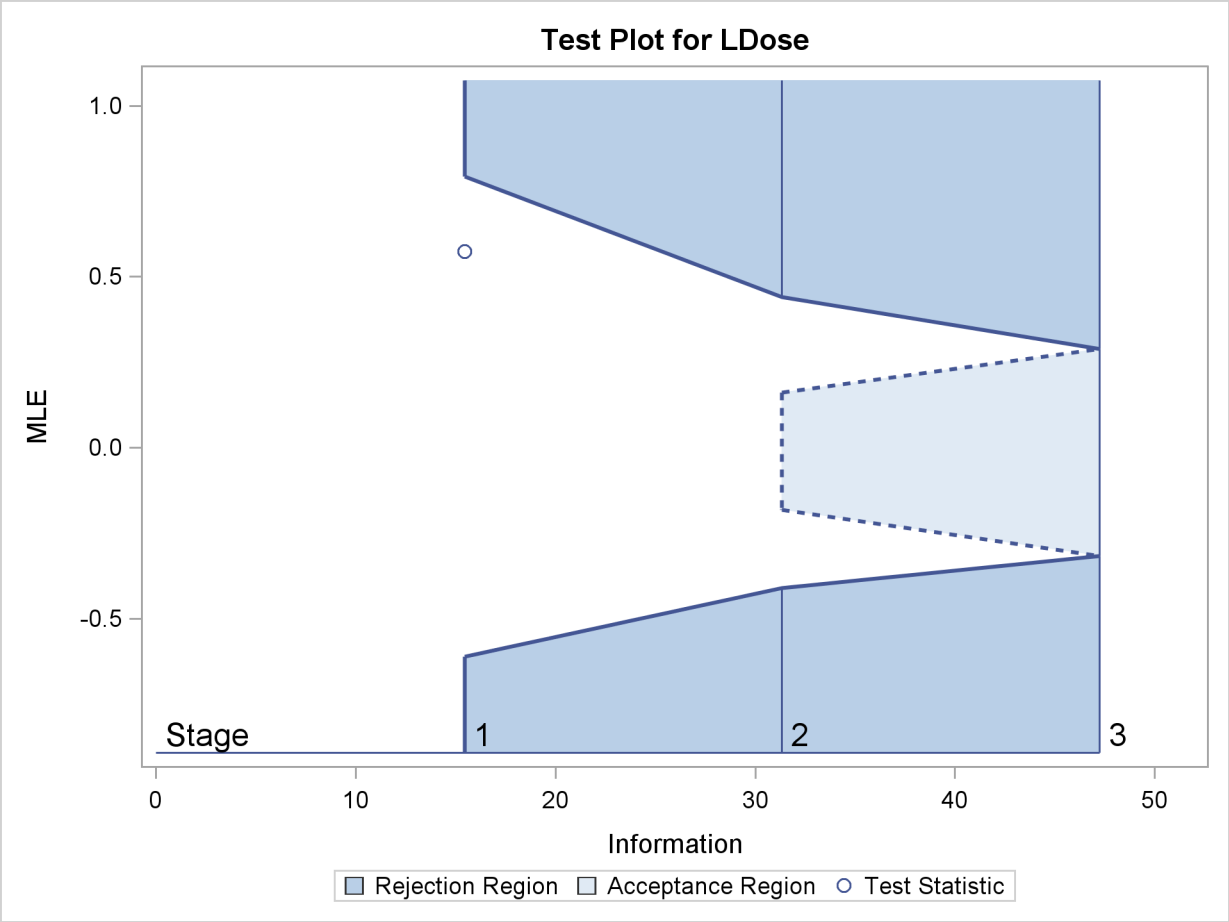
Stage	Alpha	Beta	Beta	Alpha	Estimate	Action
1	-0.61078	.	.	0.79337	0.57409	Continue
2	-0.40974	-0.18169	0.16222	0.44033	.	
3	-0.31633	-0.31633	0.28860	0.28860	.	



The information level at stage 1 is derived from the standard error s_1 in the PARMS= data set,

$$I_1 = \frac{1}{s_1^2} = \frac{1}{0.2544^2} = 15.45$$

The remaining interim information levels are derived proportionally from the corresponding information levels in the original design. At stage 1, the β boundary values are missing and there is no early stopping to accept H_0. The MLE statistic 0.57409 is between the lower and upper α boundaries, so the trial continues to the next stage.

With the specified ODS GRAPHICS ON statement, a boundary plot with the boundary values and test statistics is displayed, as shown in Output 78.8.10. As expected, the test statistic is in the continuation region below the upper alpha boundary.

Output 78.8.10 Sequential Test Plot

The following statements use the LOGISTIC procedure to estimate the slope β_1 and its associated standard error at stage 2:

```
proc logistic data=dose_2;
   model Resp(event='1')=LDose;
   ods output ParameterEstimates=Parms_Dose2;
run;
```

The following statements create and display (in Output 78.8.11) the input data set that contains slope β_1 and its associated standard error at stage 2 for the SEQTEST procedure:

```
data Parms_Dose2;
   set Parms_Dose2;
   if Variable='LDose';
   _Scale_='MLE';
   _Stage_= 2;
   keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_Dose2;
   title 'Statistics Computed at Stage 2';
run;
```

Output 78.8.11 Statistics Computed at Stage 2

Statistics Computed at Stage 2

Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	LDose	0.5213	0.1788	MLE	2

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
ods graphics on;
proc seqtest Boundary=Test_Dose1
             Parms(Testvar=LDose)=Parms_Dose2
             order=mle
             boundaryscale=mle
             rci
             plots=rci
             ;
ods output Test=Test_Dose2;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ORDER=MLE option uses the MLE ordering to derive the p-value, unbiased median estimate, and confidence limits for the regression slope estimate.

The ODS OUTPUT statement with the TEST=TEST_DOSE2 option creates an output data set named TEST_DOSE2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Design Information" table in Output 78.8.12 displays design specifications. By default, the boundary values are modified for the new information levels to maintain the Type I α level.

Output 78.8.12 Design Information

The SEQTEST Procedure

Design Information

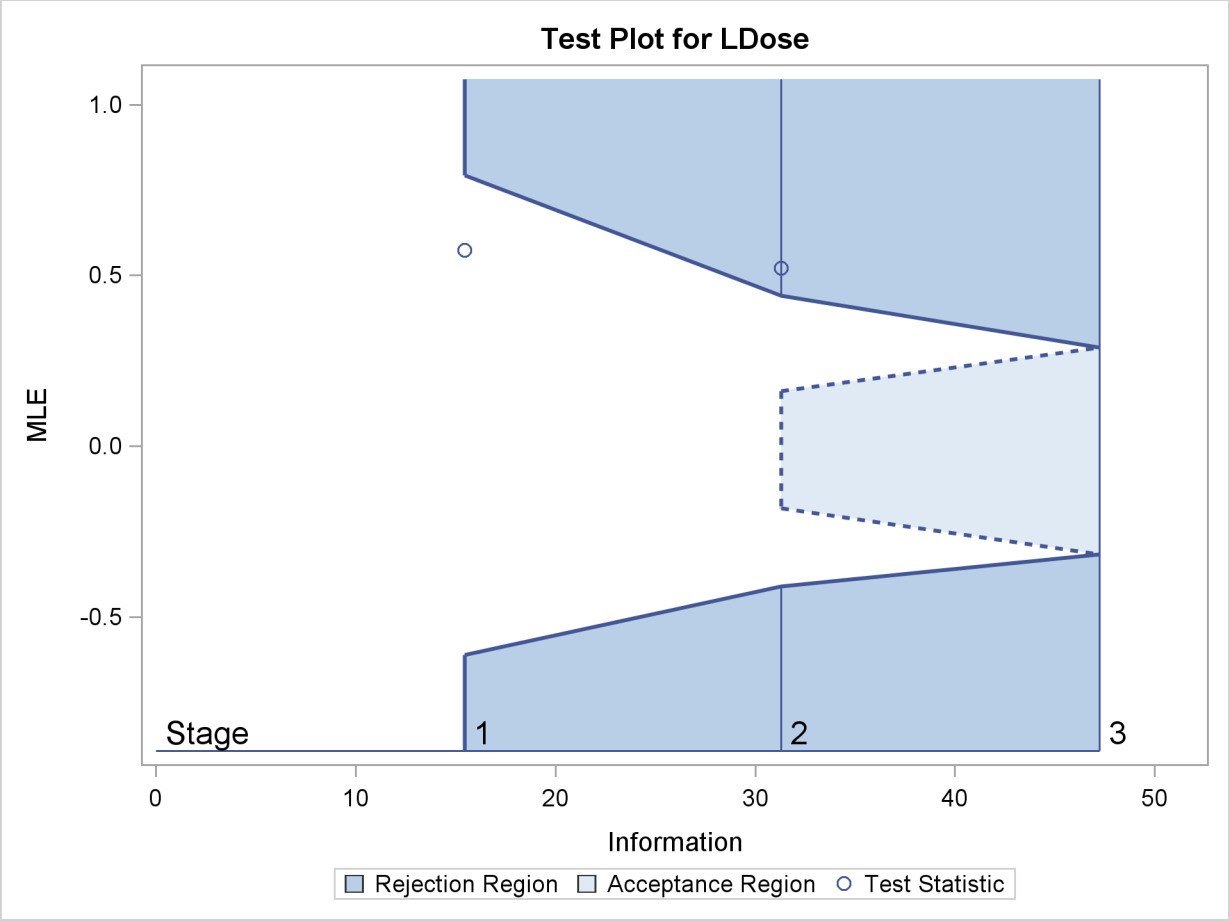
BOUNDARY Data Set	WORK.TEST_DOSE1
Data Set	WORK.PARMS_DOSE2
Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Two-Sided
Early Stop	Accept/Reject Null
Number of Stages	3
Alpha	0.05
Beta (Lower)	0.0999
Beta (Upper)	0.07871
Power (Lower)	0.9001
Power (Upper)	0.92129
Max Information (Percent of Fixed Sample)	103.7227
Max Information	47.2244524
Null Ref ASN (Percent of Fixed Sample)	79.44086
Lower Alt Ref ASN (Percent of Fixed Sample)	66.04641
Upper Alt Ref ASN (Percent of Fixed Sample)	76.22739

The information is derived from the standard error associated with the slope estimate at the final stage and is larger than the target level. The derived Type II error probability β and power $1-\beta$ are different because of the new information levels.

The "Test Information" table in Output 78.8.13 displays the boundary values for the test statistic with the specified MLE scale. The information levels are derived from the standard errors in the PARMS= data set. At stage 2, the slope estimate 0.52128 is larger than 0.44091, the upper α boundary value, the trial stops to reject the null hypothesis of no treatment effect.

Output 78.8.13 Sequential Tests

Test Information (MLE Scale)
Null Reference = 0



Stage	Information Level-- Proportion	Actual	Alternative------ Reference------- Lower	Upper
1	0.3272	15.45062	-0.50000	0.50000
2	0.6624	31.28346	-0.50000	0.50000
3	1.0000	47.22445	-0.50000	0.50000

Test Information (MLE Scale)
Null Reference = 0

	Boundary Values				Test	
	Lower		Upper		LDose	
Stage	Alpha	Beta	Beta	Alpha	Estimate	Action
1	-0.61078	.	.	0.79337	0.57409	Continue
2	-0.41028	-0.18112	0.16166	0.44091	0.52128	Reject Null
3	-0.31628	-0.31628	0.28861	0.28861	.	

With the specified ODS GRAPHICS ON statement, a boundary plot with the boundary values and test statistics is displayed, as shown in Output 78.8.14. As expected, the test statistic is above the upper α boundary in the upper rejection region at stage 2.

Output 78.8.14 Sequential Test Plot

After a trial is stopped, the "Parameter Estimates" table in Output 78.8.15 displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and the p-value under the null hypothesis $H_0 : \beta_1 = 0$.

Output 78.8.15 Parameter Estimates

Parameter Estimates
MLE Ordering

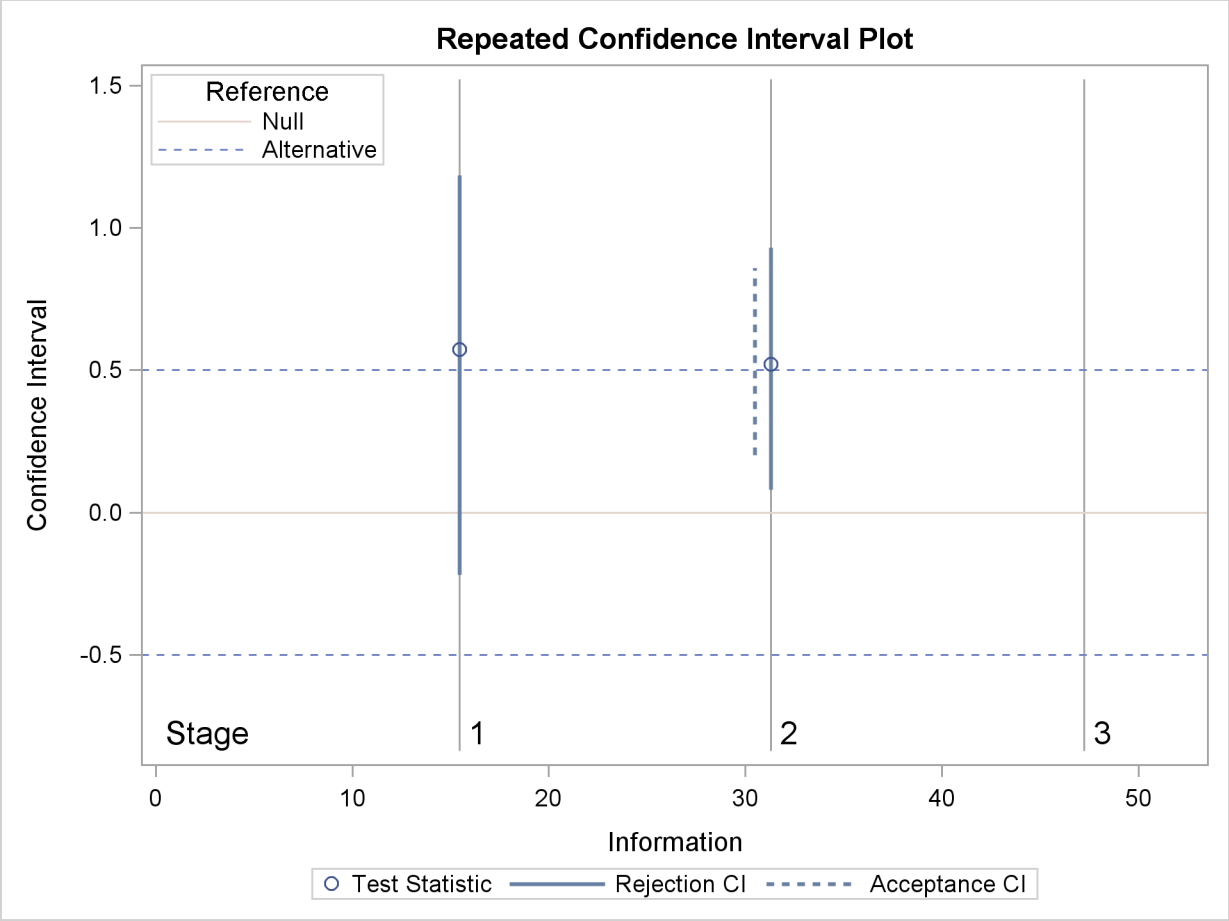
Parameter	Stopping Stage	MLE	p-Value for H0:Parm=0	Median Estimate
LDose	2	0.521275	0.0050	0.502647

Parameter Estimates
MLE Ordering

Parameter	95% Confidence Limits	
LDose	0.15745	0.85154

With the ORDER=MLE option, the MLE ordering is used to compute the p-value, unbiased median estimate, and confidence limits. As expected, the p-value 0.005 is significant at the $\alpha = 0.05$ level and the confidence interval does not contain the null reference zero.

With the RCI option, the "Repeated Confidence Intervals" table in Output 78.8.16 displays repeated confidence intervals for the parameter. For a two-sided test, since the rejection lower repeated confidence limit 0.0804 is greater than the null reference zero, the trial is stopped to reject the hypothesis.



Output 78.8.16 Repeated Confidence Intervals

Repeated Confidence Intervals

Stage	Information Level	Parameter Estimate	-Rejection Boundary- Lower 97.5% Repeated CL	Upper 97.5% Repeated CL	-Acceptance Boundary- Lower 90.01% Repeated CL	Upper 92.13% Repeated CL
1	15.4506	0.57409	-0.2193	1.1849	.	.
2	31.2835	0.52128	0.0804	0.9316	0.2024	0.8596

With the PLOTS=RCI option, the "Repeated Confidence Intervals Plot" displays repeated confidence intervals for the parameter, as shown in Output 78.8.17. It shows that the null reference zero is inside the rejection repeated confidence interval at stage 1 but outside the rejection repeated confidence interval at stage 2. This implies that the study stops at stage 2 to reject the hypothesis.

Output 78.8.17 Repeated Confidence Intervals Plot

Note that the hypothesis is accepted if at any stage, the acceptance repeated confidence interval falls within the interval $(-0.5, 0.5)$ of the alternative references.

Acknowledgments

In addition to being shaped by the research literature listed in the section "References" on page 6151, the development of the SEQDESIGN and SEQTEST procedures has benefited significantly from the advice and expertise of the following researchers:

- Lu Cui, Eisai Medical Research
- Alex Dmitrienko, Eli Lilly
- Scott Emerson, University of Washington
- Gordon Lan, Johnson & Johnson
- Steve Snapinn, Amgen
- John Whitehead, University of Reading

We gratefully acknowledge the time and effort that these researchers have contributed.

Overview: SIM2D Procedure

The SIM2D procedure produces a spatial simulation for a Gaussian random field with a specified mean and covariance structure in two dimensions by using an LU decomposition technique.

The simulation can be conditional or unconditional. If it is conditional, a set of coordinates and associated field values are read from a SAS data set. The resulting simulation honors these data values.

You can specify the mean structure as a quadratic function in the coordinates. You can specify the covariance by naming the form and supplying the associated parameters.

PROC SIM2D can handle anisotropic and nested semivariogram models. Three covariance models are supported: Gaussian, exponential, and spherical. A single nugget effect is also supported.

You can specify the locations of simulation points in a GRID statement, or they can be read from a SAS data set. The grid specification is most suitable for a regular grid; the data set specification can handle any irregular pattern of points.

The SIM2D procedure writes the simulated values for each grid point to an output data set. The SIM2D procedure now uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." For more information about the graphics available in PROC SIM2D, see the section "ODS Graphics" on page 6181.

Introduction to Spatial Simulation

The purpose of spatial simulation is to produce a set of partial realizations of a spatial random field (SRF) $Z(\boldsymbol{s}), \boldsymbol{s} \in D \subset \mathcal{R}^2$ in a way that preserves a specified mean $\mu(\boldsymbol{s}) = E[Z(\boldsymbol{s})]$ and covariance structure $C_z(\boldsymbol{s}_1 - \boldsymbol{s}_2) = \text{Cov}(Z(\boldsymbol{s}_1), Z(\boldsymbol{s}_2))$. The realizations are partial in the sense that they occur only at a finite set of locations $(\boldsymbol{s}_1, \boldsymbol{s}_2, \cdots, \boldsymbol{s}_n)$. These locations are typically on a regular grid, but they can be arbitrary locations in the plane.

PROC SIM2D produces simulations for continuous processes in two dimensions by using the lower-upper (LU) decomposition method. In these simulations the possible values of the measured quantity $Z(\boldsymbol{s}_0)$ at location $\boldsymbol{s}_0 = (x_0, y_0)$ can vary continuously over a certain range. An additional assumption, needed for computational purposes, is that the spatial random field $Z(\boldsymbol{s})$ is Gaussian. The section "Details: SIM2D Procedure" on page 6176 provides more information about different types of spatial simulation and associated computational methods.

Spatial simulation is different from spatial prediction, where the emphasis is on predicting a point value at a given grid location. In this sense, spatial prediction is local. In contrast, spatial simulation is global; the emphasis is on the entire realization $(Z(\boldsymbol{s}_1), Z(\boldsymbol{s}_2), \cdots, Z(\boldsymbol{s}_n))$.

Given the correct mean $\mu(\boldsymbol{s})$ and covariance structure $C_z(\boldsymbol{s}_1 - \boldsymbol{s}_2)$, SRF quantities that are difficult or impossible to calculate in a spatial prediction context can easily be approximated by functions of multiple simulations.

Getting Started: SIM2D Procedure

Spatial simulation, just like spatial prediction, requires a model of spatial dependence, usually in terms of the covariance $C_z(\boldsymbol{h})$. For a given set of spatial data $Z(\boldsymbol{s}_i), i = 1, \cdots, n$, the covariance structure (both the form and parameter values) can be found by the VARIOGRAM procedure. This example uses the coal seam thickness data that are also used in the section "Getting Started: VARIOGRAM Procedure" on page 7519.

In this example, the data consist of coal seam thickness measurements (in feet) taken over an area of 100×100 (10^6 ft^2). The coordinates are offsets from a point in the southwest corner of the measurement area, with the north and east distances in units of thousands of feet.

Preliminary Spatial Data Analysis

The semivariogram analysis of the thick data set in "Example 95.1: Theoretical Semivariogram Model Fitting" on page 7570 of the VARIOGRAM procedure considered the spatial random field (SRF) $Z(\boldsymbol{s})$ of the thickness values to be free of surface trends. The expected value $E[Z(\boldsymbol{s})]$ is then a constant $\mu(\boldsymbol{s}) = \mu$, which suggests that you can work with the original thickness data rather than residuals from a trend surface fit. In fact, a reasonable approximation of the spatial process generating the coal seam data is given by

$$Z(\boldsymbol{s}) = \mu + \varepsilon(\boldsymbol{s})$$

where $\varepsilon(\boldsymbol{s})$ is a Gaussian SRF with Gaussian covariance structure

$$C_z(\boldsymbol{h}) = c_0 \exp\left(-\frac{h^2}{a_0^2}\right)$$

Note that the term "Gaussian" is used in two ways in this description. For a set of locations $\boldsymbol{s}_1, \boldsymbol{s}_2, \cdots, \boldsymbol{s}_n$, the random vector

$$\boldsymbol{Z}(\boldsymbol{s}) = \begin{bmatrix} Z(\boldsymbol{s}_1) \\ Z(\boldsymbol{s}_2) \\ \vdots \\ Z(\boldsymbol{s}_n) \end{bmatrix}$$

has a multivariate Gaussian or normal distribution $N_n(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. The (i, j)th element of $\boldsymbol{\Sigma}$ is computed by $C_z(\boldsymbol{s}_i - \boldsymbol{s}_j)$, which happens to be a Gaussian functional form.

Any functional form for $C_z(\boldsymbol{h})$ that yields a valid covariance matrix $\boldsymbol{\Sigma}$ can be used. Both the functional form of $C_z(\boldsymbol{h})$ and the parameter values

$$\mu = 40.1173$$

$$c_0 = 7.2881$$

$$a_0 = 30.6239$$

are estimated by using PROC VARIOGRAM and PROC NLIN in "Example 95.1: Theoretical Semivariogram Model Fitting" on page 7570 in the VARIOGRAM procedure. Specifically, the expected value μ is reported in the VARIOGRAM procedure OUTV output data set, and the parameters c_0 and a_0 are estimates derived from a weighted least squares fit.

The choice of a Gaussian functional form for $C_z(\boldsymbol{h})$ is simply based on the data, and it is not at all crucial to the simulation. However, it *is* crucial to the simulation method used in PROC SIM2D that $Z(\boldsymbol{s})$ be a Gaussian SRF. For details, see the section "Computational and Theoretical Details of Spatial Simulation" on page 6176.

Investigating Variability by Simulation

The variability of $Z(\boldsymbol{s})$, as modeled by

$$Z(\boldsymbol{s}) = \mu + \varepsilon(\boldsymbol{s})$$

with the Gaussian covariance structure $C_z(\boldsymbol{h})$ found previously, is not obvious from the covariance model form and parameters. The variation around the mean of the surface is relatively small, making it difficult visually to pick up differences in surface plots of simulated realizations.

Instead, you can compute the mean for each location on a grid from a series of realizations in a simulation. Then, the standard deviation of all the simulated values at each grid location will provide you with a measure of the variability of $Z(\boldsymbol{s})$ for the given covariance structure. You can also investigate variations at selected grid points in more detail, as shown in the "Example 79.2: Variability at Selected Locations" on page 6187.

In the present example you will see how to use ODS Graphics with PROC SIM2D to investigate the mean and standard deviation of simulated values. In particular, you produce 5,000 realizations of a simulation with PROC SIM2D, where you specify the Gaussian model with the parameters found previously. You want the simulated data to pass through the simulated values, so first you define the data with the following DATA step:

```
data thick;
   input East North Thick @@;
   label Thick='Coal Seam Thickness';
   datalines;
    0.7  59.6  34.1   2.1  82.7  42.2   4.7  75.1  39.5

   ;
```

Since this is a conditional simulation, you can specify the OBSERV option in the PLOT option in PROC SIM2D to see the locations and values of the measured points in the area where you want to perform spatial simulations.

Furthermore, the MEANS suboption in the PLOT option specifies that you want to create a plot that shows the means of the simulated values across the region. The MEANS suboption with no other arguments produces a plot that shows the contours of the simulated means in the foreground and the gradient of the simulated standard deviations in the background.

You obtain these PROC SIM2D results at the nodes of an output grid that you specify according to your application needs. In the present analysis, a convenient area that encompasses all the Thick data points is a square with a side length of 100,000 feet. You define a regular grid for your simulation in this area. Assume a distance of 2,500 feet between grid nodes in both directions for a smooth contour plot. Based on this choice, your square grid has 41 nodes on each side. This means that PROC SIM2D computes the simulated values at a total of 1,681 grid points. You use the GRID statement of the PROC SIM2D to specify this grid.

The SIMULATE statement specifies the parameters of your simulation across the output grid. In particular, the VAR= option specifies the conditional simulation variable. The number of realizations in the simulation is specified with the NUMREAL option. The SEED= option specifies the seed for the simulation random number generator.

The spatial correlation model for the simulation is also specified in the SIMULATE statement. You specify the model type by using the FORM= option. The options SCALE= and RANGE= specify the covariance structure sill c_0 and range a_0 parameters, respectively, as discussed in the previous section.

Although it is not included in the original spatial structure, note that a minimal nugget effect is specified with the NUGGET= option to avoid singularity issues. Singularity can appear in the present example as a result of the combined use of the Gaussian covariance model and relatively short distances between nodes, data, or nodes and data in the simulation area.

These steps are implemented using the following DATA step and statements:

```
ods graphics on;

proc sim2d data=thick outsim=sim plot=(observ means);
   coordinates xc=East yc=North;
   simulate var=Thick numreal=5000 seed=79931
      scale=7.2881 range=30.6239 nugget=1e-8 form=gauss;
   mean 40.1173;
   grid x=0 to 100 by 2.5 y=0 to 100 by 2.5;
run;
```

The table in Figure 79.1 shows the number of observations read and used in the conditional simulation. This table can provide you with useful information in case you have missing values in the input data.

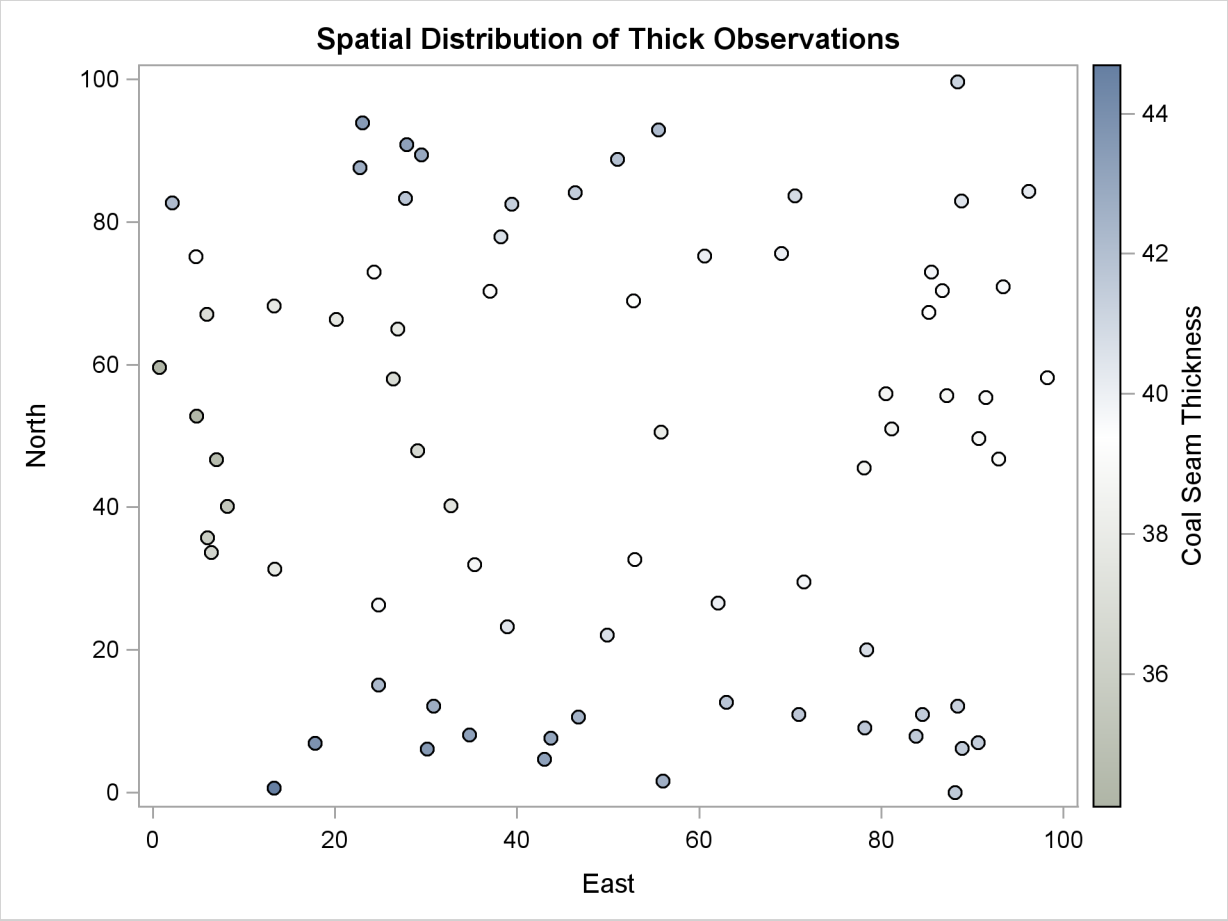

Figure 79.1 Number of Observations for the thick Data Set

```
                    The SIM2D Procedure
          Simulation: Sim1, Dependent Variable: Thick

            Number of Observations Read          75
            Number of Observations Used          75
```

The sample locations are then plotted in Figure 79.2. The figure clearly shows some small-scale variation that is typical of spatial data.

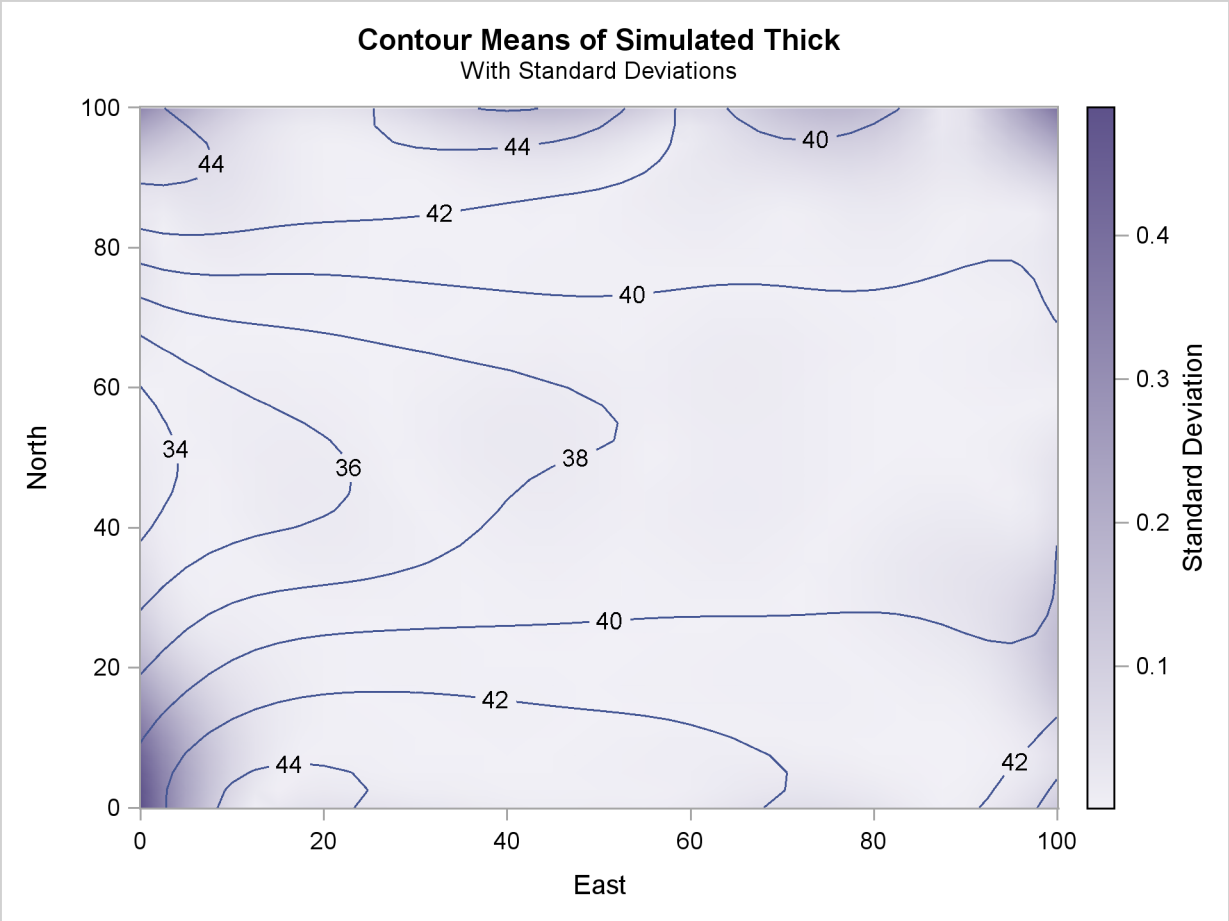
Figure 79.2 Scatter Plot of the Observations Spatial Distribution

PROC SIM2D also produces the table shown in Figure 79.3, which contains information about the type of simulation you run and the number of realizations requested.

Figure 79.3 Simulation Analysis Information

Simulation Information

Type	**Conditional**
Number of Realizations	**5000**



The table in Figure 79.4 displays the spatial correlation model information that will be used by PROC SIM2D for the current simulation. If applicable, the table provides the effective range, as well. This is the distance r_ϵ at which the covariance is 5% of its value at zero. Here you specified the Gaussian model, for which the effective range r_ϵ is $\sqrt{3}a_0$.

Figure 79.4 Simulation Covariance Model Information

Covariance Model Information	
Type	Gaussian
Sill	7.2881
Range	30.6239
Effective Range	53.042151
Nugget Effect	1E-8

Eventually, the SIM2D procedure produces the requested means plot shown in Figure 79.5. The contours of the mean of the simulated values show the average of the simulated realizations at each grid node, which is based on the given spatial structure characteristics. In this case, these means are also conditioned by the Thick observations across the region.

Figure 79.5 Contour Plot of Conditionally Simulated Coal Seam Thickness

Note also that the gradient showing the standard deviation of the simulated values at each grid node is generally small throughout the region. A few exceptions are evident close to the region borders. In these areas the simulated realizations depend on a limited amount of neighboring data. The simulation at these locations relies mainly on the underlying spatial structure.

In addition to the simulation analysis, you can use the PROC SIM2D output to obtain statistical information about the simulated values at selected locations. Let us assume that you would like some basic statistics for the extreme southwest point at (East=0, North=0) and the point (East=75, North=75) toward the northeast corner of the region. You use the following DATA step to select the realizations for these points from the OUTSIM= output data set:

```
data selected;
   set sim(where=((gxc=0 and gyc=0) or (gxc=75 and gyc=75)));
   label gxc = "X-coord";
   label gyc = "Y-coord";
run;
```

Then, you use PROC SORT to sort the selected data set entries and PROC MEANS to produce the simulation statistics for the selected points. The following statements yield the mean, standard deviation, and maximum values of the 5,000 realizations of the Thick values at each one of the selected locations:

```
proc sort data=selected;
   by gxc gyc;
run;

proc means data=selected Mean Std Max;
   class gxc gyc;
   ways 2;
   where (   ((gxc =  0) & (gyc =  0))
           | ((gxc = 75) & (gyc = 75)));
   var SValue;
run;

ods graphics off;
```

The requested statistics for the grid points (East=0, North=0) and (East=75,North=75) are shown in Figure 79.6.

Figure 79.6 Simulation Statistics at Grid Points (East=0, North=0) and (East=75, North=75)

```
                          The MEANS Procedure

          Analysis Variable : SVALUE Simulated Value at Grid Point

     X-coord        Y-coord    N Obs           Mean         Std Dev         Maximum
-------------------------------------------------------------------------------------
           0              0     5000     40.6064093       0.4900041      42.4131782

          75             75     5000     40.1099449       0.0020988      40.1187941
-------------------------------------------------------------------------------------
```

"Example 79.2: Variability at Selected Locations" on page 6187 shows you how to perform a simulation at a set of selected locations rather than a domain-wide grid, and how to obtain more detailed statistics from the simulation.

Syntax: SIM2D Procedure

The following statements are available in PROC SIM2D:

PROC SIM2D *options* ;
  BY *variables* ;
  COORDINATES *coordinate-variables* ;
  GRID *grid-options* ;
  SIMULATE *simulate-options* ;
  MEAN *mean-options* ;

The SIMULATE and MEAN statements are hierarchical; you can specify any number of SIMULATE statements, but you must specify at least one. If you specify a MEAN statement, it refers to the preceding SIMULATE statement. If you do not specify a MEAN statement, a zero-mean model is simulated.

You must specify a single COORDINATES statement to identify the x and y coordinate variables in the input data set when you perform a conditional simulation. You must also specify a single GRID statement to specify the grid information.

The following table outlines the options available in PROC SIM2D classified by function.

Table 79.1 Options Available in the SIM2D Procedure

Task	Statement	Option
Data Set Options		
Specify input data set	PROC SIM2D	DATA=
Specify grid data set	GRID	GDATA=
Write simulated values	PROC SIM2D	OUTSIM=
Specify plot display and options	PROC SIM2D	PLOTS=
Specify quadratic form data set	MEAN	QDATA=
Specify plot display and options	PROC SIM2D	PLOTS=
Declaring the Role of Variables		
Specify variables to define analysis subgroups	BY	
Specify the conditioning variable	SIMULATE	VAR=
Specify the x and y coordinate variables in the DATA= data set	COORDINATES	XC= YC=
Specify the x and y coordinate variables in the GDATA= data set	GRID	XC= YC=
Specify the constant coefficient variable in the QDATA= data set	MEAN	CONST=
Specify the linear x coefficient variable in the QDATA= data set	MEAN	CX=
Specify the linear y coefficient variable in the QDATA= data set	MEAN	CY=

Table 79.1 *continued*

Task	Statement	Option
Specify the quadratic x coefficient variable in the QDATA= data set	MEAN	CXX=
Specify the quadratic y coefficient variable in the QDATA= data set	MEAN	CYY=
Specify the quadratic xy coefficient variable in the QDATA= data set	MEAN	CXY=
Controlling the Simulation		
Specify the number of realizations	SIMULATE	NUMREAL=
Specify the seed value for the random generator	SIMULATE	SEED=
Controlling the Mean Quadratic Surface		
Specify the CONST term	MEAN	CONST=
Specify the linear x term	MEAN	CX=
Specify the linear y term	MEAN	CY=
Specify the quadratic x term	MEAN	CXX=
Specify the quadratic y term	MEAN	CYY=
Specify the quadratic cross term	MEAN	CXY=
Controlling the Semivariogram Model		
Specify a nugget effect	SIMULATE	NUGGET=
Specify a functional form	SIMULATE	FORM=
Specify nested functional forms	SIMULATE	FORM=($f_1, \cdots, f_k$)
Specify a range parameter	SIMULATE	RANGE=
Specify nested range parameters	SIMULATE	RANGE=($r_1, \cdots, r_k$)
Specify a scale parameter	SIMULATE	SCALE=
Specify nested scale parameters	SIMULATE	SCALE=($s_1, \cdots, s_k$)
Specify an angle for an anisotropic model	SIMULATE	ANGLE=
Specify nested angles	SIMULATE	ANGLE=($a_1, \cdots, a_k$)
Specify a minor-major axis ratio for an anisotropic model	SIMULATE	RATIO=
Specify nested minor-major axis ratios	SIMULATE	RATIO=($ra_1, \cdots, ra_k$)

PROC SIM2D Statement

PROC SIM2D *options* **;**

You can specify the following options with the PROC SIM2D statement.

DATA=*SAS-data-set*
specifies a SAS data set that contains the x and y coordinate variables and the VAR= variables that are used in the SIMULATE statements. This data set is required if you specify the BY

statement or if any of the SIMULATE statements are conditional—that is, if you specify the VAR= option in any of those. Otherwise, you do not need the DATA= option and this option is ignored if you specify it.

NARROW

restricts the variables included in the OUTSIM= data set. When you specify the NARROW option, only four variables are included. This option is useful when a large number of simulations are produced. Including only four variables reduces the memory required for the OUTSIM= data set. For details on the variables that are excluded with the NARROW option, see the section "Output Data Set" on page 6180.

NOPRINT

suppresses the normal display of results. The NOPRINT option is useful when you want only to create one or more output data sets with the procedure. Note that this option temporarily disables the Output Delivery System (ODS); see the section "ODS Graphics" on page 6181 for more information.

OUTSIM=*SAS-data-set*

specifies a SAS data set to store the simulation values, iteration number, simulate statement label, variable name, and grid location. For details, see the section "Output Data Set" on page 6180.

PLOTS <(*global-plot-option***)> <= *plot-request* <(***options***)>>**

PLOTS <(*global-plot-option***)> <= (***plot-request* <(***options***)>** **<... *plot-request* <(***options***)>>)>**

controls the plots produced through ODS Graphics. When you specify only one plot request, you can omit the parentheses around the plot request. Here are some examples:

```
plots=none
plots=observ
plots=(observ(outl) means)
plots=(means(fill=mean line=sd obs=grad) means(fill=sd))
```

You must enable ODS Graphics before requesting plots, for example, like this:

```
ods graphics on;

proc sim2d data=thick outsim=sim;
   coordinates xc=East yc=North;
   simulate var=Thick numreal=5000 seed=79931
      scale=7.2881 range=30.6239 form=gauss;
   mean 40.1173;
   grid x=0 to 100 by 2.5 y=0 to 100 by 2.5;
run;

ods graphics off;
```

For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." PROC SIM2D does not have default plots. This means that unless you have enabled ODS Graphics, specified the PLOTS= option, or specified PLOTS=ALL, then PROC SIM2D will produce no plots.

The following *global-plot-option* is available:

ONLY
produces only plots specifically requested.

The following individual *plot-requests* and plot *options* are available:

ALL
produces all appropriate plots. You can specify other options with ALL. For example, to request all appropriate plots and an additional plot of the simulation means, specify PLOTS=(ALL MEANS).

EQUATE
specifies that all appropriate plots be produced in a way that the axes coordinates have equal size units.

NONE
supresses all plots.

OBSERVATIONS < (*observations-plot-options*) >

OBSERV < (*observations-plot-options*) >

OBS < (*observations-plot-options*) >
produces the observed data plot. Only one observations plot will be created if you specify the OBSERVATIONS option more than once within a PLOTS option.

The OBSERVATIONS option has the following suboptions:

GRADIENT
specifies that observations be displayed as circles colored by the observed measurement.

OUTLINE
specifies that observations be displayed as circles with a border but with a completely transparent fill.

OUTLINEGRADIENT
is the same as OBSERVATIONS(GRADIENT) except that a border is shown around each observation.

SHOWMISSING
specifies that observations with missing values be displayed in addition to the observations with nonmissing values. By default, missing values locations are not shown on the plot. If you specify multiple instances of the OBSERVATIONS option, and you specify the SHOWMISSING suboption in any of those, then the resulting observations plot will display the observations with missing values.

For the GRADIENT, OUTLINE, and OUTLINEGRADIENT suboptions: The OUTLINEGRADIENT is the default suboption if you do not specify any of those three. If you specify multiple instances of the OBSERVATIONS option or multiple suboptions for OBSERVATIONS, then the resulting observations plot will honor the last specified GRADIENT, OUTLINE, or OUTLINEGRADIENT suboption.

MEANS < (*means-plot-options*) >

MEA < (*means-plot-options*) >

specifies that a plot of the means and standard deviations of the simulation realizations at each grid point be produced. You can specify the MEANS option multiple times in the same PLOTS option to request instances of plots with the following *means-plot-options*:

FILL=NONE | MEAN | SD

produces a surface plot for either the values of the means or the standard deviations. FILL=SD is the default; however, if you do not specify the FILL suboption the behavior depends on the LINE suboption as follows: If you specify LINE=NONE or do not specify the LINE suboption at all, then the FILL suboption will be set to its default value. If LINE=PRED or LINE=SE, then the FILL suboption will be set to the same value as the LINE suboption.

LINE=NONE | MEAN | SD

produces a contour line plot for either the values of the means or the standard deviations. LINE=MEAN is the default; however, if you do not specify the LINE suboption the behavior depends on the FILL suboption as follows: If you specify FILL=NONE or do not specify the FILL suboption at all, then the LINE suboption will be set to its default value. If FILL=PRED or FILL=SE, then the LINE suboption will be set to the same value as the FILL suboption.

OBS=*obs-options*

produces an overlaid scatter plot of the observations in addition to the specified contour plots. The following *obs-options* are available:

GRAD

specifies that observations be displayed as circles colored by the observed measurement. The same color gradient is used to display the means surface and the observations. The conditional simulation honors the observed values, so the means surface at the observation locations has the same color as the corresponding observations.

LINEGRAD

is the same as OBS=GRAD except that a border is shown around each observation.

NONE

specifies that no observations be displayed.

OUTL

specifies that observations be displayed as circles with a border but with a completely transparent fill.

OBS=NONE is the default.

If you specify multiple instances of the FILL, LINE, or OBS suboptions in the same MEANS option, then the resulting means plot will honor the last value specified for any of the suboptions.

Any combination where you specify FILL=NONE and LINE=NONE is not available.

The MEANS option requires that simulations be requested at more than one location on a rectangular grid. The plot is not available when you use the GRIDDATA= data set option in the GRID statement, because the GRIDDATA= option allows you to specify any coordinates for the simulation locations.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC SIM2D to obtain separate analyses on observations in groups defined by the BY variables. Hence, in PROC SIM2D it makes sense to use the BY statement when you request conditional simulations where observations are involved. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The *variables* are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement options NOTSORTED or DESCENDING in the BY statement for the SIM2D procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

The use of the BY statement assumes that you have specified an input data set with the DATA= option in the PROC SIM2D statement. Note that in PROC SIM2D if you do not specify the VAR= option in the SIMULATE statement, then this is a request for unconditional simulation even if you have specified the DATA= option in the PROC SIM2D statement. Therefore, it is possible to specify the BY statement and request mixed types of simulations by specifying multiple SIMULATE statements in the same PROC SIM2D step.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

COORDINATES Statement

COORDINATES *coordinate-variables* **;**

The following two options give the name of the variables in the DATA= data set containing the values of the x and y coordinates of the conditioning data.

Only one COORDINATES statement is allowed, and it is applied to all SIMULATE statements that have the VAR= specification. In other words, it is assumed that all the VAR= variables in all SIMULATE statements have the same x and y coordinates.

You can abbreviate the COORDINATES statement as COORD.

XCOORD=*(variable-name)*

XC=*(variable-name)*

gives the name of the variable containing the x coordinate of the data in the DATA= data set.

YCOORD=*(variable-name)*

YC=*(variable-name)*

gives the name of the variable containing the y coordinate of the data locations in the DATA= data set.

GRID Statement

GRID *grid-options* **;**

The following options can be used to specify the grid of spatial locations at which to perform the simulations. A single GRID statement is required and is applied to all SIMULATE statements.

There are two basic methods for specifying the grid. You can specify the x and y coordinates explicitly, or they can be read from a SAS data set.

The options for the explicit specification of grid locations are as follows.

X=*number*

X=$x_1, \ldots, x_m$

X=x_1 *to* x_m

X=x_1 *to* x_m *by* δx

specifies the x coordinate of the grid locations.

Y=*number*

Y=$y_1, \ldots, y_m$

Y=y_1 *to* y_m

Y=y_1 *to* y_m *by* δy

specifies the y coordinate of the grid locations.

For example, the following two GRID statements are equivalent:

```
grid x=1,2,3,4,5  y=0,2,4,6,8,10;

grid x=1 to 5 y=0 to 10 by 2;
```

To specify grid locations from a SAS data set, you must provide the name of the data set and the variables containing the values of the x and y coordinates.

GRIDDATA=*SAS-data-set*

GDATA=*SAS-data-set*

specifies a SAS data set containing the x and y grid coordinates.

XCOORD=*(variable-name)*

XC=*(variable-name)*

gives the name of the variable containing the x coordinate of the grid locations in the GRIDDATA= data set.

YCOORD=*(variable-name)*

YC=*(variable-name)*

gives the name of the variable containing the y coordinate of the grid locations in the GRIDDATA= data set.

SIMULATE Statement

SIMULATE *simulate-options* **;**

The SIMULATE statement specifies details on the simulation and the covariance model used in the simulation. You can specify the following options with a SIMULATE statement, which can be abbreviated by SIM.

NUMREAL=*number*

NUMR=*number*

NR=*number*

specifies the number of realizations to produce for the spatial process specified by the covariance model. Note that the number of observations in the OUTSIM= data set contributed by a given SIMULATE statement is the product of the NUMREAL= value with the number of grid points. This can cause the OUTSIM= data set to become large even for moderate values of the NUMREAL= option.

VAR=*(variable-name)*

specifies the single numeric variable used as the conditioning variable in the simulation. In other words, the simulation is conditional on the values of the VAR= variable found in the DATA= data set. If you omit the VAR= option or if all observations of the VAR= variable are missing values, then the simulation is *unconditional*. Since multiple SIMULATE statements are allowed, you can perform both unconditional and conditional simulations with a single PROC SIM2D statement.

Covariance Model Specification

There are two ways to specify a semivariogram or covariance model. In the first method, you can specify the required parameters SCALE, RANGE, and FORM, and possibly the optional parameters NUGGET, ANGLE, and RATIO, explicitly in the SIMULATE statement.

In the second method, you can specify an MDATA= data set. This data set contains variables corresponding to the required SCALE, RANGE, and FORM parameters, and, optionally, variables for the NUGGET, ANGLE, and RATIO parameters.

The two methods are exclusive; either you specify all parameters explicitly, or they are all are read from the MDATA= data set.

ANGLE=*angle*

ANGLE=*(angle*$_1$*,...,angle*$_k$*)*

specifies the angle of the major axis for anisotropic models, measured in degrees clockwise from the N–S axis. In the case of a nested semivariogram model, you can specify an angle for each nesting. The default is ANGLE=0.

FORM=*form_spec*

FORM=*(form_spec*$_1$*, form_spec*$_2$*,...,form_spec*$_k$*)*

specifies the functional form or forms of the semivariogram model, where *form_spec* can take only the values SPHERICAL, EXPONENTIAL, and GAUSSIAN. The two ways of specifying the FORM= parameter allow specification of both nested and non-nested models.

The following abbreviations are permitted. For the spherical model, you can specify the *form_spec* as FORM=SPHERICAL, FORM=SPH, or FORM=S. For the exponential model, you can specify the *form_spec* as FORM=EXPONENTIAL, FORM=EXP, or FORM=E. For the Gaussian model, you can specify the *form_spec* as FORM=GAUSSIAN, FORM=GAUSS, or FORM=G.

MDATA=*SAS-data-set*

specifies the input data set that contains parameter values for the covariance or semivariogram model. The MDATA= data set must contain variables named SCALE, RANGE, and FORM, and it can optionally contain the variables NUGGET, ANGLE, and RATIO.

The FORM variables must be character, and they can assume the same values allowed in the explicit FORM= syntax described previously. The RANGE and SCALE variables must be numeric. The optional variables ANGLE, RATIO, and NUGGET must also be numeric if present.

The number of observations present in the MDATA= data set corresponds to the level of nesting of the covariance or semivariogram model. For example, to specify a non-nested model that uses a spherical covariance, an MDATA= data set might contain the following statements:

```
data md1;
   input scale range form $;
   datalines;
   25 10 SPH
run;
```

The PROC SIM2D statement to use the MDATA= specification is of the form shown in the following:

```
proc sim2d data=...;
   sim var=.... mdata=md1;
run;
```

This is equivalent to the following explicit specification of the covariance model parameters:

```
proc sim2d data=...;
   sim var=.... scale=25 range=10 form=sph;
run;
```

The following MDATA= data set is an example of an anisotropic nested model:

```
data md2;
   input scale range form $ nugget angle ratio;
   datalines;
   20 8 S  5 35 .7
   12 3 G  5 0  .8
   4  1 G  5 45 .5
   ;

proc sim2d data=...;
   sim var=.... mdata=md2;
run;
```

This is equivalent to the following explicit specification of the covariance model parameters:

```
proc sim2d data=...;
   sim var=.... scale=(20,12,4) range=(8,3,1) form=(S,G,G)
                angle=(35,0,45) ratio=(.7,.8,.5) nugget=5;
run;
```

This example is somewhat artificial in that it is usually hard to detect different anisotropy directions and ratios for different nestings by using an experimental semivariogram. Note that the NUGGET value is the same for all nestings. This is always the case; the nugget effect is a single additive term for all models. For further details, refer to the section "The Nugget Effect" on page 2954 in the KRIGE2D procedure.

The SIMULATE statement can be given a label. This is useful for identification in the OUTSIM= data set when multiple SIMULATE statements are specified. For example:

```
proc sim2d data=...;
   gauss1: sim var=.... form=gauss;
   mean ....;
   gauss2: sim var=.... form gauss;
   mean ....;
   exp1: sim var=.... form=exp;
   mean ....;
   exp2: sim var=.... form=exp;
   mean ....;
run;
```

In the OUTSIM= data set, the values "GAUSS1," "GAUSS2," "EXP1," and "EXP2" for the LABEL variable help to identify the realizations corresponding to the four SIMULATE statements. If you do not provide a label for a SIMULATE statement, a default label of SIM*n* is given, where *n* is the number of unlabeled SIMULATE statements seen so far.

NUGGET=*number*

specifies the nugget effect for the model. This effect is due to a discontinuity in the semivariogram as determined by plotting the sample semivariogram (refer to the section "The Nugget Effect" on page 2954 in the KRIGE2D procedure for details). For models without any nugget effect, the NUGGET= option is left out. The default is NUGGET=0.

RANGE=*range*

RANGE=*(range*$_1$*,. . . ,range*$_k$*)*

specifies the range parameter in the semivariogram models. In the case of a nested semivariogram model, you must specify a range for each nesting.

The range parameter is the divisor in the exponent in all supported models. It has the units of distance or distance squared for these models, and it is related to the correlation scale for the underlying spatial process.

Refer to the section "Theoretical Semivariogram Models" on page 2947 in the KRIGE2D procedure for details on how the RANGE= values are determined.

RATIO=*ratio*

RATIO=*(ratio*$_1$*,. . . ,ratio*$_k$*)*

specifies the ratio of the length of the minor axis to the length of the major axis for anisotropic models. The value of the RATIO= option must be between 0 and 1. In the case of a nested semivariogram model, you can specify a ratio for each nesting. The default is RATIO=1.

SCALE=*scale*

SCALE=*(scale*$_1$*,. . . ,scale*$_k$*)*

specifies the scale (or *sill*) parameter in semivariogram models. In the case of a nested semivariogram model, you must specify a scale for each nesting. The scale parameter is the multiplicative factor in all supported models; it has the same units as the variance of the VAR= variable.

Refer to the section "Theoretical Semivariogram Models" on page 2947 in the KRIGE2D procedure for details on how the SCALE= values are determined.

SEED=*seed value*

specifies the seed to use for the random number generator. The SEED= value has to be an integer.

SINGULAR=*number*

gives the singularity criteria for solving the set of linear equations involved in the computation of the mean and covariance of the conditional distribution associated with a given SIMULATE statement. The larger the value of the SINGULAR= option, the easier it is for the covariance matrix system to be declared singular. The default is SINGULAR=1E–8.

For more details on the use of the SINGULAR= option, see the section "Computational and Theoretical Details of Spatial Simulation" on page 6176.

MEAN Statement

MEAN *spec*$_1$,...,*spec*$_6$ **;**

MEAN QDATA= *SAS-data-set CONST=var*$_1$ *CX=var*$_2$ *CY=var*$_3$
CXX=var$_4$ *CYY=var*$_5$ *CXY=var*$_6$ **;**

MEAN QDATA= *SAS-data-set* **;**

A mean function $\mu(s)$ that is a quadratic in the coordinates can be written

$$\mu(s) = \mu(x, y) = \beta_0 + \beta_1 x + \beta_2 y + \beta_3 x^2 + \beta_4 y^2 + \beta_5 xy$$

The MEAN statement is used to specify the quadratic surface to use as the mean function for the simulated SRF. There are three ways to specify the MEAN statement. The MEAN statement allows the specification of the coefficients $\beta_0, \cdots, \beta_5$ either explicitly or through a QDATA= data set.

An example of an explicit specification is the following:

```
mean 1.4 + 2.5*x + 3.6*y + 0.47*x*x + 0.58*y*y + 0.69*x*y;
```

In this example, all terms have a nonzero coefficient. Any term with a zero coefficient is simply left out of the specification. For example,

```
mean 1.4;
```

is a valid quadratic form with all terms having zero coefficients except the constant term.

An equivalent way of specifying the mean function is through the QDATA= data set. For example, the MEAN statement

```
mean 1.4 + 2.5*x + 3.6*y + 0.47*x*x + 0.58*y*y + 0.69*x*y;
```

can be alternatively specified by the following DATA step and MEAN statement:

```
data q1;
   input c1 c2 c3 c4 c5 c6;
   datalines;
   1.4 2.5 3.6 0.47 0.58 0.69
run;

proc sim2d data=....;
   simulate ...;
   mean qdata=q1 const=c1 cx=c2 cy=c3 cxx=c4
            cyy=c5 cxy=c6;
run;
```

The QDATA= data set specifies the data set containing the coefficients. The parameters CONST=, CX=, CY=, CXX=, CYY=, and CYX= specify the variables in the QDATA= data set that correspond to the constant, linear x, linear y, and so on. For any coefficient not specified in this list, the

QDATA= data set is checked for the presence of variables with default names of CONST, CX, CY, CXX, CYY, and CXY. If these variables are present, their values are taken as the corresponding coefficients. Hence, you can rewrite the previous example as follows:

```
data q1;
   input const cx cy cxx cyy cxy;
   datalines;
   1.4 2.5 3.6 0.47 0.58 0.69
   ;

proc sim2d data=....;
   simulate ...;
   mean qdata=q1;
run;
```

If a given coefficient does not appear in the list or in the data set with the default name, a value of zero is assumed.

Details: SIM2D Procedure

Computational and Theoretical Details of Spatial Simulation

Introduction

There are a number of approaches to simulating spatial random fields or, more generally, simulating sets of dependent random variables. This includes sequential indicator methods, turning bands, and the Karhunen-Loeve Expansion. Refer to Christakos (1992, Chapter 8) and Deutsch and Journel (1992, Chapter V) for details.

A particularly simple method available for Gaussian spatial random fields is the LU decomposition method. This method is computationally efficient. For a given covariance matrix, the $LU = \mathbf{L}\mathbf{L}^T$ decomposition is computed once, and the simulation proceeds by repeatedly generating a vector of independent $N(0, 1)$ random variables and multiplying by the $\mathbf{L}$ matrix.

One problem with this technique is memory requirements; memory is required to hold the full data and grid covariance matrix in core. While this is especially limiting in the three-dimensional case, you can use PROC SIM2D, which handles only two-dimensional data, for moderately sized simulation problems.

Theoretical Development

It is a simple matter to produce an $N(0, 1)$ random number, and by stacking k $N(0, 1)$ random numbers in a column vector, you can obtain a vector with independent standard normal components

$\mathbf{W} \sim N_k(\mathbf{0}, \mathbf{I})$. The meaning of the terms *independence* and *randomness* in the context of a deterministic algorithm required for the generation of these numbers is subtle; refer to Knuth (1981, Chapter 3) for details.

Rather than $\mathbf{W} \sim N_k(\mathbf{0}, \mathbf{I})$, what is required is the generation of a vector $\mathbf{Z} \sim N_k(\mathbf{0}, \mathbf{C})$—that is,

$$\mathbf{Z} = \begin{bmatrix} Z_1 \\ Z_2 \\ \vdots \\ Z_k \end{bmatrix}$$

with covariance matrix

$$\mathbf{C} = \begin{pmatrix} C_{11} & C_{12} & \cdots & C_{1k} \\ C_{21} & C_{22} & \cdots & C_{2k} \\ & \ddots & & \\ C_{k1} & C_{k2} & \cdots & C_{kk} \end{pmatrix}$$

If the covariance matrix is symmetric and positive definite, it has a Cholesky root $\mathbf{L}$ such that $\mathbf{C}$ can be factored as

$$\mathbf{C} = \mathbf{L}\mathbf{L}^T$$

where $\mathbf{L}$ is lower triangular. Refer to Ralston and Rabinowitz (1978, Chapter 9, Section 3-3) for details. This vector $\mathbf{Z}$ can be generated by the transformation $\mathbf{Z} = \mathbf{L}\mathbf{W}$. Note that this is where the assumption of a Gaussian SRF is crucial. When $\mathbf{W} \sim N_k(\mathbf{0}, \mathbf{I})$, then $\mathbf{Z} = \mathbf{L}\mathbf{W}$ is also Gaussian. The mean of $\mathbf{Z}$ is

$$E(\mathbf{Z}) = \mathbf{L}(E(\mathbf{W})) = \mathbf{0}$$

and the variance is

$$\text{Var}(\mathbf{Z}) = \text{Var}(\mathbf{L}\mathbf{W}) = E(\mathbf{L}\mathbf{W}\mathbf{W}^T\mathbf{L}^T) = \mathbf{L}E(\mathbf{W}\mathbf{W}^T)\mathbf{L}^T = \mathbf{L}\mathbf{L}^T = \mathbf{C}$$

Consider now an SRF $Z(\boldsymbol{s}), \boldsymbol{s} \in D \subset \mathcal{R}^2$, with spatial covariance function $C(\boldsymbol{h})$. Fix locations $\boldsymbol{s}_1, \boldsymbol{s}_2, \cdots, \boldsymbol{s}_k$, and let $\mathbf{Z}$ denote the random vector

$$\mathbf{Z} = \begin{bmatrix} Z(\boldsymbol{s}_1) \\ Z(\boldsymbol{s}_2) \\ \vdots \\ Z(\boldsymbol{s}_k) \end{bmatrix}$$

with corresponding covariance matrix

$$\mathbf{C}_z = \begin{pmatrix} C(\mathbf{0}) & C(\boldsymbol{s}_1 - \boldsymbol{s}_2) & \cdots & C(\boldsymbol{s}_1 - \boldsymbol{s}_k) \\ C(\boldsymbol{s}_2 - \boldsymbol{s}_1) & C(\mathbf{0}) & \cdots & C(\boldsymbol{s}_2 - \boldsymbol{s}_k) \\ & \ddots & & \\ C(\boldsymbol{s}_k - \boldsymbol{s}_1) & C(\boldsymbol{s}_k - \boldsymbol{s}_2) & \cdots & C(\mathbf{0}) \end{pmatrix}$$

Since this covariance matrix is symmetric and positive definite, it has a Cholesky root, and the $Z(\boldsymbol{s}_i), i = 1, \cdots, k$, can be simulated as described previously. This is how the SIM2D procedure implements unconditional simulation in the zero-mean case. More generally,

$$Z(\boldsymbol{s}) = \mu(\boldsymbol{s}) + \varepsilon(\boldsymbol{s})$$

with $\mu(\boldsymbol{s})$ being a quadratic form in the coordinates $\boldsymbol{s} = (x, y)$, and the $\varepsilon(\boldsymbol{s})$ being an SRF having the same covariance matrix $\mathbf{C}_z$ as previously. In this case, the $\mu(\boldsymbol{s}_i), i = 1, \cdots, k$, is computed once and added to the simulated vector $\varepsilon(\boldsymbol{s}_i), i = 1, \cdots, k$, for each realization.

For a conditional simulation, this distribution of

$$\mathbf{Z} = \begin{bmatrix} Z(\boldsymbol{s}_1) \\ Z(\boldsymbol{s}_2) \\ \vdots \\ Z(\boldsymbol{s}_k) \end{bmatrix}$$

must be conditioned on the observed data. The relevant general result concerning conditional distributions of multivariate normal random variables is the following. Let $\mathbf{X} \sim N_m(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, where

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \end{bmatrix}$$

$$\boldsymbol{\mu} = \begin{bmatrix} \boldsymbol{\mu}_1 \\ \boldsymbol{\mu}_2 \end{bmatrix}$$

$$\boldsymbol{\Sigma} = \begin{pmatrix} \boldsymbol{\Sigma}_{11} & \boldsymbol{\Sigma}_{12} \\ \boldsymbol{\Sigma}_{21} & \boldsymbol{\Sigma}_{22} \end{pmatrix}$$

The subvector $\mathbf{X}_1$ is $k \times 1$, $\mathbf{X}_2$ is $n \times 1$, $\boldsymbol{\Sigma}_{11}$ is $k \times k$, $\boldsymbol{\Sigma}_{22}$ is $n \times n$, and $\boldsymbol{\Sigma}_{12} = \boldsymbol{\Sigma}_{21}^T$ is $k \times n$, with $k + n = m$. The full vector $\mathbf{X}$ is partitioned into two subvectors, $\mathbf{X}_1$ and $\mathbf{X}_2$, and $\boldsymbol{\Sigma}$ is similarly partitioned into covariances and cross covariances.

With this notation, the distribution of $\mathbf{X}_1$ conditioned on $\mathbf{X}_2 = \boldsymbol{x}_2$ is $N_k(\tilde{\boldsymbol{\mu}}, \tilde{\boldsymbol{\Sigma}})$, with

$$\tilde{\boldsymbol{\mu}} = \boldsymbol{\mu}_1 + \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}(\boldsymbol{x}_2 - \boldsymbol{\mu}_2)$$

and

$$\tilde{\boldsymbol{\Sigma}} = \boldsymbol{\Sigma}_{11} - \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}\boldsymbol{\Sigma}_{21}$$

Refer to Searle (1971, pp. 46–47) for details. The correspondence with the conditional spatial simulation problem is as follows. Let the coordinates of the observed data points be denoted $\tilde{\boldsymbol{s}}_1, \tilde{\boldsymbol{s}}_2, \cdots, \tilde{\boldsymbol{s}}_n$, with values $\tilde{z}_1, \tilde{z}_2, \cdots, \tilde{z}_n$. Let $\tilde{\mathbf{Z}}$ denote the random vector

$$\tilde{\mathbf{Z}} = \begin{bmatrix} Z(\tilde{\boldsymbol{s}}_1) \\ Z(\tilde{\boldsymbol{s}}_2) \\ \vdots \\ Z(\tilde{\boldsymbol{s}}_n) \end{bmatrix}$$

The random vector $\tilde{\mathbf{Z}}$ corresponds to $\mathbf{X}_2$, while $\mathbf{Z}$ corresponds to $\mathbf{X}_1$. Then $\left(\mathbf{Z} \mid \tilde{\mathbf{Z}} = \tilde{\mathbf{z}}\right) \sim N_k(\tilde{\boldsymbol{\mu}}, \tilde{\mathbf{C}})$ as in the previous distribution. The matrix

$$\tilde{\mathbf{C}} = \mathbf{C}_{11} - \mathbf{C}_{12}\mathbf{C}_{22}^{-1}\mathbf{C}_{21}$$

is again positive definite, so a Cholesky factorization can be performed.

The dimension n for $\tilde{\mathbf{Z}}$ is simply the number of nonmissing observations for the VAR= variable; the values $\tilde{z}_1, \tilde{z}_2, \cdots, \tilde{z}_n$ are the values of this variable. The coordinates $\tilde{\boldsymbol{s}}_1, \tilde{\boldsymbol{s}}_2, \cdots, \tilde{\boldsymbol{s}}_n$ are also found in the DATA= data set, with the variables corresponding to the x and y coordinates identified in the COORDINATES statement. Note that all VAR= variables use the same set of conditioning coordinates; this fixes the matrix $\mathbf{C}_{22}$ for all simulations.

The dimension k for $\mathbf{Z}$ is the number of grid points specified in the GRID statement. Since there is a single GRID statement, this fixes the matrix $\mathbf{C}_{11}$ for all simulations. Similarly, $\mathbf{C}_{12}$ is fixed.

The Cholesky factorization $\tilde{\mathbf{C}} = \mathbf{L}\mathbf{L}^T$ is computed once, as is the mean correction

$$\tilde{\boldsymbol{\mu}} = \boldsymbol{\mu}_1 + \mathbf{C}_{12}\mathbf{C}_{22}^{-1}(\boldsymbol{x}_2 - \boldsymbol{\mu}_2)$$

Note that the means $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ are computed using the grid coordinates $\boldsymbol{s}_1, \boldsymbol{s}_2, \cdots, \boldsymbol{s}_k$, the data coordinates $\tilde{\boldsymbol{s}}_1, \tilde{\boldsymbol{s}}_2, \cdots, \tilde{\boldsymbol{s}}_n$, and the quadratic form specification from the MEAN statement. The simulation is now performed exactly as in the unconditional case. A $k \times 1$ vector of independent standard $N(0, 1)$ random variables is generated and multiplied by $\mathbf{L}$, and $\tilde{\boldsymbol{\mu}}$ is added to the transformed vector. This is repeated N times, where N is the value specified for the NR= option.

Computational Details

In the computation of $\tilde{\boldsymbol{\mu}}$ and $\boldsymbol{\Sigma}$ described in the previous section, the inverse $\boldsymbol{\Sigma}_{22}^{-1}$ is never actually computed; an equation of the form

$$\boldsymbol{\Sigma}_{22}\mathbf{A} = \mathbf{B}$$

is solved for $\mathbf{A}$ by using a modified Gaussian elimination algorithm that takes advantage of the fact that $\boldsymbol{\Sigma}_{22}$ is symmetric with constant diagonal $C_z(0)$ that is larger than all off-diagonal elements. The SINGULAR= option pertains to this algorithm. The value specified for the SINGULAR= option is scaled by $C_z(0)$ before comparison with the pivot element.

Memory Usage

For conditional simulations, the largest matrix held in core at any one time depends on the number of grid points and data points. Using the previous notation, the data-data covariance matrix $\mathbf{C}_{22}$ is $n \times n$, where n is the number of nonmissing observations for the VAR= variable in the DATA= data set. The grid-data cross covariance $\mathbf{C}_{12}$ is $n \times k$, where k is the number of grid points. The grid-grid covariance $\mathbf{C}_{11}$ is $k \times k$. The maximum memory required at any one time for storing these matrices is

$$\max\left(k(k+1), n(n+1) + 2(n \times k)\right) \times \text{sizeof(double)}$$

There are additional memory requirements that add to the total memory usage, but usually these matrix calculations dominate, especially when the number of grid points is large.

Output Data Set

The SIM2D procedure produces a single output data set: the OUTSIM=*SAS-data-set*. The OUTSIM= data set contains all the needed information to uniquely identify the simulated values.

The OUTSIM= data set contains the following variables:

- LABEL, which is the label for the current SIMULATE statement
- VARNAME, which is the name of the conditioning variable for the current SIMULATE statement
- _ITER_, which is the iteration number within the current SIMULATE statement
- GXC, which is the x coordinate for the current grid point
- GYC, which is the y coordinate for the current grid point
- SVALUE, which is the value of the simulated variable

If you specify the NARROW option in the PROC SIM2D statement, the LABEL and VARNAME variables are not included in the OUTSIM= data set. This option is useful in the case where the number of data points, grid points, and realizations are such that they generate a very large OUTSIM= data set. The size of the OUTSIM= data set is reduced when these variables are not included.

In the case of an unconditional simulation, the VARNAME variable is not included. In the case of mixed conditional and unconditional simulations (that is, when multiple SIMULATE statements are specified, and one or more contain a VAR= specification and one or more do *not* contain a VAR= specification), the VARNAME variable is included but is given a missing value for those observations corresponding to an unconditional simulation.

Displayed Output

In addition to the output data set, the SIM2D procedure produces output objects as well. The SIM2D procedure output objects are the following:

- a default "Number of Observations" table that displays the number of observations read from the input data set and the number of observations used in the analysis
- a map showing the spatial distribution of the observations of the current VAR variable in the SIMULATE statement, in the case of conditional simulations. The observations are displayed by default with circled markers whose color indicates the VAR value at the corresponding location.
- a default table for each SIMULATE statement that summarizes the simulation specifications
- a default table for each SIMULATE statement that shows the covariance model parameters for the corresponding simulation
- plots of the mean and standard deviation of the simulation realizations at each point of the specified output grid. You can produce more than one of these plots for every SIMULATE statement with styles that you can specify by using the available suboptions of the PLOTS=MEANS option.

ODS Table Names

Each table created by PROC SIM2D has a name associated with it, and you must use this name to reference the table when using ODS Graphics. These names are listed in Table 79.2.

Table 79.2 ODS Tables Produced by PROC SIM2D

ODS Table Name	Description	Statement	Option
ModelInfo	Parameters of the covariance model used in current simulation	PROC	default output
NObs	Number of observations read and used	PROC	default output
SimuInfo	General information about the simulation	PROC	default output

ODS Graphics

This section describes the use of the Output Delivery System (ODS) for creating graphics with the SIM2D procedure.

To request these graphs, you must specify the ODS GRAPHICS statement. For additional control of the graphics that are displayed, see the PLOTS= option in the section "PROC SIM2D Statement" on page 6165. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

ODS Graph Names

PROC SIM2D assigns a name to each graph it creates by using ODS Graphics. You can use these names to reference the graphs when using ODS Graphics. The names are listed in Table 79.3.

Table 79.3 ODS Graphics Produced by PROC SIM2D

ODS Graph Name	Plot Description	Statement	Option
MeansPlot	Contour plot of the simulated means, surface of the standard deviation, and outlines of the observation locations	PROC	PLOTS=MEANS
ObservationsPlot	Scatter plot of observed data and colored markers indicating observed values	PROC	PLOTS=OBSERV

To request this graph, you must specify the ODS GRAPHICS statement in addition to the statements indicated in Table 79.3. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

Examples: SIM2D Procedure

Example 79.1: Simulation

Continuing with the coal seam thickness example from the section "Getting Started: SIM2D Procedure" on page 6157, this example asks a more complicated question. This question is economic in nature, and the (approximate) answer requires the use of simulation.

Simulating a Subregion for Economic Feasibility

The coal seam must be of a minimum thickness, called a *cutoff value*, for a mining operation to be profitable. Suppose that, for a subregion of the measured area, the cost of mining is higher than in the remaining areas due to the geology of the overburden. This higher cost results in a higher thickness cutoff value for the subregion. Suppose also that it is determined from a detailed cost analysis that at least 60% of the subregion must exceed a seam thickness of 39.7 feet for profitability.

How can you use the SRF model (μ and $C_z(\boldsymbol{s})$) and the measured seam thickness values $Z(\boldsymbol{s}_i), i = 1, \cdots, 75$, to determine, in some approximate way, if at least 60% of the subregion exceeds this minimum?

Spatial prediction does not appear to be helpful in answering this question. While it is easy to determine whether a predicted value at a location in the subregion is above the 39.7-feet cutoff value, it is not clear how to incorporate the standard error associated with the predicted value. The standard error is what characterizes the stochastic nature of the prediction (and the underlying SRF). It is clear that it must be included in any realistic approach to the problem.

A conditional simulation, on the other hand, seems to be a natural way of obtaining an approximate answer. By simulating the SRF on a sufficiently fine grid in the subregion, you can determine the proportion of grid points in which the mean value over realizations exceeds the 39.7-feet cutoff and compare it with the 60% value needed for profitability.

It is desirable in any simulation study that the quantity being estimated (in this case, the proportion exceeding the 39.7-feet cutoff) not depend on the number of simulations performed. For example, suppose that the maximum seam thickness is simulated. It is likely that the maximum value increases as the number of simulations performed increases. Hence, a simulation is not useful for such an estimate. A simulation is useful for determining the *distribution* of the maximum, but there are general theoretical results for such distributions, making such a simulation unnecessary. Refer to Leadbetter, Lindgren, and Rootzen (1983) for details.

In the case of simulating the proportion exceeding the 39.7-feet cutoff, it is expected that this quantity will settle down to a fixed value as the number of realizations increases. At a fixed grid point, the quantity being compared with the cutoff value is the mean over all simulated realizations; this mean value settles down to a fixed number as the number of realizations increases. In the same manner, the proportion of the grid where the mean values exceed the cutoff also becomes constant. This can be tested using PROC SIM2D.

A crucial, nonprovable assumption in applying SRF theory to the coal seam thickness data is that the values $Z(\boldsymbol{s}_i), i = 1, \cdots, 75$, represent a *single* realization from the set of all possible realizations consistent with the SRF model (μ and $C_z(\boldsymbol{h})$). A conditional simulation repeatedly produces other possible simulated realizations consistent with the model and data. However, the only concern of the mining company is this single unique realization. It is not concerned about similar coal fields to be mined sometime in the future; it might never see another coal field remotely similar to this one, or it might not be in business in the future.

Hence the proportion found by generating repeated simulated realizations must somehow relate back to the unique realization that is the coal field (seam thickness). This is done by interpreting the proportion found from a simulation to the spatial mean proportion for the unique realization. The term "spatial mean" is simply an appropriate integral over the fixed (but unknown) spatial function $z(\boldsymbol{s})$. (The SRF is denoted $Z(\boldsymbol{s})$; a particular realization, a deterministic function of the spatial coordinates, is denoted $z(\boldsymbol{s})$.)

This interpretation requires an ergodic assumption, which is also needed in the original estimation of $C_z(\boldsymbol{s})$. Refer to Cressie (1993, pp. 53–58) for a discussion of ergodicity and Gaussian SRFs.

Implementation Using PROC SIM2D

The subregion to be considered is the southeast corner of the field, which is a square region with a length of 40 distance units (in thousands of feet). First, you input the thickness data as the following DATA step shows:

```
data thick;
   input East North Thick @@;
   label Thick='Coal Seam Thickness';
   datalines;
 0.7  59.6  34.1   2.1  82.7  42.2   4.7  75.1  39.5
 4.8  52.8  34.3   5.9  67.1  37.0   6.0  35.7  35.9
 6.4  33.7  36.4   7.0  46.7  34.6   8.2  40.1  35.4

;
```

PROC SIM2D is run on the entire data set for conditioning, while the simulation grid covers only this subregion. It is convenient to be able to vary the seed, the grid increment, and the number of simulations performed. The following macro implements the computation of the percent area exceeding the cutoff value by using the seed, the grid increment, and the number of simulated realizations as macro arguments.

Within the macro, the data set produced by PROC SIM2D is transposed with PROC TRANSPOSE so that each grid location is a separate variable. The MEANS procedure is then used to average the simulated value at each grid point over all realizations. It is this average that is compared to the cutoff value. The last DATA step does the comparison, uses an appropriate loop to determine the percent of the grid locations that exceed this cutoff value, and writes the results to the listing file in the form of a report. This sequence is implemented with the following statements:

```
/* Construct macro for conditional simulation ------------------*/

%let cc0=7.2881;
%let aa0=30.6239;
%let ngt=1e-8;
%let form=gauss;
%let cut=39.7;

%macro area_sim(seed=,nr=,ginc=);

   %let ngrid=%eval(40/&ginc+1);
   %let tgrid=%eval(&ngrid*&ngrid);

   proc sim2d data=thick outsim=sim1;
      coordinates xc=east yc=north;
      simulate var=thick numreal=&nr seed=&seed
               scale=&cc0 range=&aa0 nugget=&ngt form=&form;
      mean 40.1173;
      grid x=60 to 100 by &ginc
           y= 0 to  40 by &ginc;
   run;

   proc transpose data=sim1 out=sim2 prefix=sims;
      by _iter_;
      var svalue;
   run;

   proc means data=sim2 noprint n mean;
      var sims1-sims&tgrid;
      output out=msim n=numsim mean=ms1-ms&tgrid;
   run;

   data _null_;
      file print;
      array simss ms1-ms&tgrid;
      set msim;

      cflag=0;
      do ss=1 to &tgrid;
         tempv=simss[ss];
         if simss[ss] > &cut then do;
            cflag + 1;
         end;
      end;

      area_per=100*(cflag/&tgrid);
      put // +5 'Conditional Simulation of Coal Seam'
                ' Thickness for Subregion';
      put / +5 'Subregion is South-East Corner 40 by 40 distance units';
      put / +5 "Seed:&seed" +2 "Grid Increment:&ginc";
      put / +5 "Total Number of Grid Points:&tgrid" +2
               "Number of Simulations:&nr";
```

```
      put / +5 "Percent of Subregion Exceeding Cutoff of %left(&cut) ft.:"
                +2 area_per 5.2;
   run;
%mend area_sim;
```

In the following statement, you invoke the macro three times. Each time, the macro is invoked with a different seed and combination of the grid increment and number of simulations. The macro is first invoked with a relatively coarse grid (grid increment of 10 distance units) and a small number of realizations (5). The output of this conditional simulation is shown in Output 79.1.1.

```
/* Execute macro for coarse grid ------------------------------*/
%area_sim(seed=12345,nr=5,ginc=10);
```

Output 79.1.1 Conditional Simulation of Coal Seam Thickness on a Coarse Grid

```
Conditional Simulation of Coal Seam Thickness for Subregion

Subregion is South-East Corner 40 by 40 distance units

Seed:12345  Grid Increment:10

Total Number of Grid Points:25  Number of Simulations:5

Percent of Subregion Exceeding Cutoff of 39.7 ft.:  76.00
```

The next invocation, in the following statement, uses a finer grid and 50 realizations. The output of the second conditional simulation is shown in Output 79.1.2.

```
/* Execute macro for fine grid and fewer simulations -----------*/
%area_sim(seed=54321,nr=50,ginc=1);
```

Output 79.1.2 Conditional Simulation of Coal Seam Thickness on a Fine Grid

```
Conditional Simulation of Coal Seam Thickness for Subregion

Subregion is South-East Corner 40 by 40 distance units

Seed:54321  Grid Increment:1

Total Number of Grid Points:1681  Number of Simulations:50

Percent of Subregion Exceeding Cutoff of 39.7 ft.:  76.74
```

The final invocation, in the following statement, uses the same grid increment and 500 realizations. The output of this conditional simulation is shown in Output 79.1.3.

```
/* Execute macro for fine grid and more simulations ------------*/
%area_sim(seed=655311,nr=500,ginc=1);
```

Output 79.1.3 Conditional Simulation of Coal Seam Thickness on a Fine Grid

```
Conditional Simulation of Coal Seam Thickness for Subregion

Subregion is South-East Corner 40 by 40 distance units

Seed:655311  Grid Increment:1

Total Number of Grid Points:1681  Number of Simulations:500

Percent of Subregion Exceeding Cutoff of 39.7 ft.:  76.68
```

The results from the preceding simulations indicate that 76% to 77% of the subregion exceeds the cutoff value.

Note also that the number of grid points in the simulation increases with the square of the decrease in the grid increment, leading to long CPU processing times. Increasing the number of realizations results in a linear increase in processing times. Hence, using as coarse a grid as possible allows for more realizations and experimentation with different seeds.

Example 79.2: Variability at Selected Locations

This example exhibits a more detailed investigation of the variation of simulated Thick values. You use the same thick data set from the section "Getting Started: SIM2D Procedure" on page 6157, and you are interested in the simulated values statistics at two selected grid points.

Specifically, you perform a simulation asking for 5,000 realizations (iterations) at two points of the region defined in the section "Preliminary Spatial Data Analysis" on page 6157. These are the extreme southwest point and a point toward the northeast corner of the region. Since you do not want to perform the simulation across the whole region, you need to produce a GDATA= data set to specify the coordinates of the selected points. These steps are implemented using the following DATA step and statements:

```
data thick;
   input East North Thick @@;
   label Thick='Coal Seam Thickness';
   datalines;
    0.7  59.6  34.1   2.1  82.7  42.2   4.7  75.1  39.5

   78.1  45.5  38.7  78.2   9.1  41.7  78.4  20.0  40.8
   80.5  55.9  38.7  81.1  51.0  38.6  83.8   7.9  41.6
   84.5  11.0  41.5  85.2  67.3  39.4  85.5  73.0  39.8
   86.7  70.4  39.6  87.2  55.7  38.8  88.1   0.0  41.6
   88.4  12.1  41.3  88.4  99.6  41.2  88.8  82.9  40.5
   88.9   6.2  41.5  90.6   7.0  41.5  90.7  49.6  38.9
   91.5  55.4  39.0  92.9  46.8  39.1  93.4  70.9  39.7
   55.8  50.5  38.1  96.2  84.3  40.3  98.2  58.2  39.5
   ;

data grid;
   input xc yc;
   datalines;
   0   0
   75  75
run;
```

Then, you run PROC SIM2D with the same parameters and characteristics as those in the section "Preliminary Spatial Data Analysis" on page 6157. This time, however, you ask for simulated values only at the two locations you specified in the previous DATA step. The following statements execute the requested simulation:

```
proc sim2d data=thick outsim=sim1;
   coordinates xc=East yc=North;
   simulate var=Thick numreal=5000 seed=79931
            scale=7.2881 range=30.6239 form=gauss;
   mean 40.1173;
   grid gdata=grid xc=xc yc=yc;
run;
```

Once the simulation is performed, summary statistics are computed for each of the specified grid points. In particular, you use PROC UNIVARIATE and a BY statement to request at these locations the quantiles and the extreme observations, as the following statements show:

```
proc sort data=sim1;
   by gxc gyc;
run;

proc univariate data=sim1;
   var svalue;
   by gxc gyc;
   ods select Quantiles ExtremeObs;
   title 'Simulation Statistics at Selected Grid Points';
run;
```

The summary statistics for the first grid point (East=0, North=0) are presented in Output 79.2.1.

Output 79.2.1 Simulation Statistics at Grid Point (East=0, North=0)

Overview: SIMNORMAL Procedure

The SIMNORMAL procedure can perform conditional and unconditional simulation for a set of correlated normal or Gaussian random variables.

The means, variances, and covariances (or correlations) are read from an input TYPE=CORR or TYPE=COV data set. This data set is typically produced by the CORR procedure. Conditional simulations are performed by appending a special observation, identified by the value of 'COND' for the _TYPE_ variable, which contains the conditioning value.

The output data set from PROC SIMNORMAL contains simulated values for each of the analysis variables. Optionally, the output data set also contains the seed stream and the values of the conditioning variables. PROC SIMNORMAL produces no printed output.

Getting Started: SIMNORMAL Procedure

The following example illustrates the use of PROC SIMNORMAL to generate variable values conditioned on a set of related or correlated variables.

Suppose you are given a sample of size 50 from ten normally distributed, correlated random variables, $IN_{1,i}, \cdots, IN_{5,i}, OUT_{1,i}, \cdots, OUT_{5,i}, i = 1, \cdots, 50$. The first five variables represent input variables for a chemical manufacturing process, and the last five are output variables.

First, the data are input and the correlation structure is determined by using PROC CORR, as in the following statements. The results are shown in Figure 80.1.

```
data a ;
   input in1-in5 out1-out5 ;
   datalines ;
 9.3500    10.0964     7.3177    10.3617    10.3444    9.4612

After the mean and correlation structure are determined, any subset of these variables can be simulated. Suppose you are interested in a particular function of the output variables for two sets of values of the input variables for the process. In particular, you are interested in the mean and variability of the following function over 500 runs of the process conditioned on each set of input values:

$$f(out_1, \cdots, out_5) = \frac{out_1 - out_3}{out_1 + out_2 + out_3 + out_4 + out_5}$$

Although the distribution of these quantities could be determined theoretically, it is simpler to perform a conditional simulation by using PROC SIMNORMAL.

To do this, you first append a _TYPE_='COND' observation to the covariance data set produced by PROC CORR for each group of input values:

```
data cond1 ;
      _TYPE_='COND' ;
      in1 = 8    ;
      in2 = 10.5 ;
      in3 = 12   ;
      in4 = 13.5 ;
      in5 = 14.4 ;
      output ;
run ;

data cond2 ;
      _TYPE_='COND' ;
      in1 = 15.4 ;
      in2 = 13.7 ;
      in3 = 11 ;
      in4 = 7.9 ;
      in5 = 5.5 ;
      output ;
run ;
```

Next, each of these conditioning observations is appended to a copy of the OUTP=OUTCOV data from the CORR procedure, as in the following statements. A new variable, INPUT, is added to distinguish the sets of input values. This variable is used as a BY variable in subseqent steps.

```
data outcov1 ;
   input=1 ;
   set outcov cond1 ;
run ;

data outcov2 ;
   input=2 ;
   set outcov cond2 ;
run ;
```

Finally, these two data sets are concatenated:

```
data outcov ;
  set outcov1 outcov2 ;
run ;
proc print data=outcov ;
where (_type_ ne 'COV') ;
run ;
```

Figure 80.2 shows the added observations.

You now run PROC SIMNORMAL, specifying the input data set and the VAR and COND variables. Note that you must specify a TYPE=COV or TYPE=CORR for the input data set. PROC CORR automatically assigns a TYPE=COV or TYPE=CORR attribute for the OUTP= data set. However, since the intermediate DATA steps that appended the _TYPE_='COND' observations turned off this attribute, an explicit TYPE=CORR in the DATA= option in the PROC SIMNORMAL statement is needed.

The specification of PROC SIMNORMAL now follows from the problem description. The condition variables are IN1–IN5, the analysis variables are OUT1–OUT5, and 500 realizations are required. A seed value can be chosen arbitrarily, or the system clock can be used. Note that in the following statements, the simulation is done for each of the values of the BY variable INPUT:

```
proc simnormal data=outcov(type=cov)
      out = osim
      numreal = 500
      seed = 33179
      ;
   by input ;
   var out1-out5 ;
   cond in1-in5 ;
   run;

data b;
   set osim ;
   denom = sum(of out1-out5) ;
   if abs(denom) < 1e-8 then ff = . ;
   else ff = (out1-out3)/denom ;
run ;
```

The DATA step that follows the simulation computes the function $f(out_1, \cdots, out_5)$; in the following statements the UNIVARIATE procedure computes the simple statistics for this function for each set of conditioning input values. This is shown in Figure 80.3, and Figure 80.4 shows the distribution of the function values for each set of input values by using the SGPANEL procedure.

```
proc univariate data=b ;
   by input ;
   var ff ;
run ;
title ;
proc sgpanel data=b ;
   panelby input ;
   REFLINE 0 / axis= x ;
   density ff ;
run ;
```

Figure 80.4 Frequency Plot for ff for Each Set of Input Values

Syntax: SIMNORMAL Procedure

PROC SIMNORMAL *DATA=SAS-data-set* ;
<options>
VAR *variables* ;
BY *variables* ;
CONDITION *variables* ;

Both the PROC SIMNORMAL and VAR statements are required. The following statements can be used with the SIMNORMAL procedure:

PROC SIMNORMAL Statement

Table 80.1 summarizes the options in the PROC SIMNORMAL statement.

Table 80.1 Summary of PROC SIMNORMAL Statement Options

Option	Description
Specify Input and Output Data Sets	
DATA=	specifies input data set (TYPE=CORR, COV, and so on)
OUT=	creates output data set that contains simulated values
Seed Values	
SEED=	specifies seed value (integer)
SEEDBY	requests reinitialization of seed for each BY group
Control Contents of OUT= Data Set	
OUTSEED	requests seed values written to OUT= data set
OUTCOND	requests conditioning variable values written to OUT=data set
Control Number of Simulated Values	
NUMREAL=	specifies the number of realizations for each BY group written to the OUT= data set
Singularity Criteria	
SINGULAR1=	sets the singularity criterion for Cholesky decomposition
SINGULAR2=	sets the singularity criterion for covariance matrix sweeping

The following options can be used with the PROC SIMNORMAL statement.

DATA=*SAS-data-set*

specifies the input data set that must be a specially structured TYPE=CORR, COV, UCORR, UCOV, or SSCP SAS data set. If the DATA= option is omitted, the most recently created SAS data set is used.

SEED=*seed-value*

specifies the seed to use for the random number generator. If the SEED= value is omitted, the system clock is used. If the system clock is used, a note is written to the log; the note gives the seed value based on the system clock. In addition, the random seed stream is copied to the OUT= data set if the OUTSEED option is specified.

SEEDBY

specifies that the seed stream be reinitialized for each BY group. By default, a single random stream is used over all BY groups. If you specify SEEDBY, the random stream starts again at the initial seed value. This initial value is from the SEED= value that you specify. If you do not specify a SEED=value, the system clock generates this initial seed.

For example, suppose you had a TYPE=CORR data set with BY groups, and the mean, variances, and covariance or correlation values were identical for each BY group. Then if you specified SEEDBY, the simulated values in each BY group in the OUT= data set would be identical.

OUT=*SAS-data-set*

specifies a SAS data set in which to store the simulated values for the VAR variables. If you omit the OUT=option, the output data set is created and given a default name by using the DATA*n* convention.

See the section "OUT= Output Data Set" on page 6205 for details.

NUMREAL=*n*

specifies the number of realizations to generate. A value of NUMREAL=500 generates 500 observations in the OUT=dataset, or 500 observations within each BY group if a BY statement is given.

NUMREAL can be abbreviated as NUMR or NR.

OUTSEED

requests that the seed values be included in the OUT= data set. The variable Seed is added to the OUT= data set. The first value of Seed is the SEED= value specified in the PROC SIMNORMAL statement (or obtained from the system clock); subsequent values are produced by the random number generator.

OUTCOND

requests that the values of the conditioning variables be included in the OUT= data set. These values are constant for the data set or within a BY group. Note that specifying OUTCOND can greatly increase the size of the OUT= data set. This increase depends on the number of conditioning variables.

SINGULAR1=*number*

specifies the first singularity criterion, which is applied to the Cholesky decomposition of the covariance matrix. The SINGULAR1= value must be in the range $(0, 1)$. The default value is 10^{-8}. SINGULAR1 can be abbreviated SING1.

SINGULAR2=*number*

specifies the second singularity criterion, which is applied to the sweeping of the covariance or correlation matrix to obtain the conditional covariance. The SINGULAR2=option is applicable only when a CONDITION statement is given. The SINGULAR2= value must be in the range $(0, 1)$. The default value is 10^{-8}. SINGULAR2 can be abbreviated SING2.

BY Statement

BY *variables* **;**

A BY statement can be used with the SIMNORMAL procedure to obtain separate simulations for each covariance structure defined by the BY variables. When a BY statement appears, the procedure expects the input DATA= data set to be sorted in the order of the BY variables. If a CONDITION statement is used along with a BY statement, there must be a _TYPE_='COND' observation within each BY group. Note that if a BY statement is specified, the number of realizations specified by the NUMREAL= option are produced for each BY group.

CONDITION Statement

CONDITION | COND *variables* **;**

A CONDITION statement specifies the conditioning variables. The presence of a CONDITION statement requests that a conditional simulation be performed.

The lack of a CONDITIONAL statement simply means that an unconditional simulation for the VAR variables is to be performed.

If a CONDITION statement is given, the variables listed must be numeric variables in the DATA= data set. This requires a conditioning value for each of the CONDITION variables. This value is supplied by adding a _TYPE_='COND' observation for each CONDITION variable. Such observations are added to the DATA= data set by a DATA step.

Note that a data set created by the CORR procedure is automatically given the TYPE=COV, UCOV, CORR, or UCORR attribute, so you do not have to specify the TYPE= option in the DATA= option in the PROC SIMNORMAL statement. However, when adding the conditioning values by using a DATA step with a SET statement, you must use the TYPE=COV, UCOV, CORR, or UCORR attribute in the new data set. See the section "Getting Started: SIMNORMAL Procedure" on page 6194 for an example in which the TYPE is set.

VAR Statement

VAR *variables* **;**

Use the VAR statement to specify the analysis variables. Only numeric variables can be specified. If a VAR statement is not given, all numeric variables in the DATA= data set that are not in the CONDITION or BY statement are used.

OUT= Output Data Set

The SIMNORMAL procedure produces a single output data set: the OUT=*SAS-data-set*.

The OUT= data set contains the following variables:

- all variables listed in the VAR statement
- all variables listed in the BY statement, if one is given
- Rnum, which is the realization number within the current BY group
- Seed, which is current seed value, if the OUTSEED option is specified

- all variables listed in the CONDITION statement, if a CONDITION statement is given and the OUTCOND option is specified

The number of observations is determined by the value of the NUMREAL= option. If there are no BY groups, the number of observations in the OUT= data set is equal to the value of the NUMREAL= option. If there are BY groups, there are number of observations equals the value of the NUMREAL= option for each BY group.

Computational Details: SIMNORMAL Procedure

Introduction

There are a number of approaches to simulating a set of dependent random variables. In the context of spatial random fields, these include sequential indicator methods, turning bands, and the Karhunen-Loeve expansion. See Christakos (1992, Chapter 8) and Duetsch and Journel (1992, Chapter 5) for details.

In addition, there is the LU decomposition method, a particularly simple and computationally efficient for normal or Gaussian variates. For a given covariance matrix, the $LU = LL^T$ decomposition is computed once, and the simulation proceeds by repeatedly generating a vector of independent $N(0, 1)$ random variables and multiplying by the L matrix.

One problem with this technique is that memory is required to hold the covariance matrix of all the analysis and conditioning variables in core.

Unconditional Simulation

It is a simple matter to produce an $N(0, 1)$ random number, and by stacking k such numbers in a column vector you obtain a vector with independent standard normal components $W \sim N_k(0, I)$. The meaning of the terms *independence* and *randomness* in the context of a deterministic algorithm required for the generation of these numbers is somewhat subtle; see Knuth (1973, Vol. 2, Chapter 3) for a discussion of these issues.

Rather than $W \sim N_k(0, I)$, what is required is the generation of a vector $Z \sim N_k(0, V)$—that is,

$$Z = \begin{bmatrix} Z_1 \\ Z_2 \\ \vdots \\ Z_k \end{bmatrix}$$

with covariance matrix

$$V = \begin{pmatrix} \sigma_{11} & \sigma_{12} & \cdots & \sigma_{1k} \\ \sigma_{21} & \sigma_{22} & \cdots & \sigma_{2k} \\ & \ddots & & \\ \sigma_{k1} & \sigma_{k2} & \cdots & \sigma_{kk} \end{pmatrix}$$

where

$$\sigma_{ij} = \text{Cov}(Z_i, Z_j)$$

If the covariance matrix is symmetric and positive definite, it has a Cholesky root L such that V can be factored as

$$V = LL^T$$

where L is lower triangular. See Ralston and Rabinowitz (1978, Chapter 9, Section 3-3) for details. This vector Z can be generated by the transformation $Z = LW$. Note that this is where the assumption of multivariate normality is crucial. If $W \sim N_k(0, I_k)$, then $Z = LW$ is also normal or Gaussian. The mean of Z is

$$\text{E}(Z) = L(\text{E}(W)) = 0$$

and the variance is

$$\text{Var}(Z) = \text{Var}(LW) = \text{E}(LWW^TL^T) = L\text{E}(WW^T)L^T = LL^T = V$$

Finally, let $Y_k = Z_k + \mu_k$; that is, you add a mean term to each variable Z_k. The covariance structure of the $Y_k's$ remains the same. Unconditional simulation is done by simply repeatedly generating k $N(0, 1)$ random numbers, stacking them, and performing the transformation

$$W \longmapsto Z = LW \longmapsto Y = Z + \mu$$

Conditional Simulation

For a conditional simulation, this distribution of

$$Y = \begin{bmatrix} Y_1 \\ Y_2 \\ \vdots \\ Y_k \end{bmatrix}$$

must be conditioned on the values of the CONDITION variables. The relevant general result concerning conditional distributions of multivariate normal random variables is the following. Let $X \sim N_m(\mu, \Sigma)$, where

$$X = \begin{bmatrix} X_1 \\ X_2 \end{bmatrix}$$

$$\mu = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix}$$

$$\Sigma = \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{pmatrix}$$

and where X_1 is $k \times 1$, X_2 is $n \times 1$, Σ_{11} is $k \times k$, Σ_{22} is $n \times n$, and $\Sigma_{12} = \Sigma_{21}^T$ is $k \times n$, with $k + n = m$. The full vector X has simply been partitioned into two subvectors, X_1 and X_2, and Σ has been similarly partitioned into covariances and cross covariances.

With this notation, the distribution of X_1 conditioned on $X_2 = x_2$ is $N_k(\tilde{\mu}, \tilde{\Sigma})$, with

$$\tilde{\mu} = \mu_1 + \Sigma_{12}\Sigma_{22}^{-1}(x_2 - \mu_2)$$

and

$$\tilde{\Sigma} = \Sigma_{11} - \Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}$$

See Searle (1971, pp. 46–47) for details.

Using the SIMNORMAL procedure corresponds with the conditional simulation as follows. Let $Y_1, \cdots, Y_k$ be the VAR variables as before (k is the number of variables in the VAR list). Let the mean vector for Y be denoted by $\mu_1 = E(Y)$. Let the CONDITION variables be denoted by $C_1, \cdots, C_n$ (where n is the number of variables in the COND list). Let the mean vector for C be denoted by $\mu_2 = E(C)$ and the conditioning values be denoted by

$$c = \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_n \end{bmatrix}$$

Then stacking

$$X = \begin{bmatrix} Y \\ C \end{bmatrix}$$

the variance of X is

$$V = \mathrm{Var}(X) = \Sigma = \begin{pmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{pmatrix}$$

where $V_{11} = \text{Var}(Y)$, $V_{12} = \text{Cov}(Y, C)$, and $V_{22} = \text{Var}(C)$. By using the preceeding general result, the relevant covariance matrix is

$$\tilde{V} = V_{11} - V_{12}V_{22}^{-1}V_{21}$$

and the mean is

$$\tilde{\mu} = \mu_1 + V_{12}V_{22}^{-1}(c - \mu_2)$$

By using $\tilde{V}$ and $\tilde{\mu}$, simulating $(Y|C = c) \sim N_k(\tilde{\mu}, \tilde{V})$ now proceeds as in the unconditional case.

Overview: STDIZE Procedure

The STDIZE procedure standardizes one or more numeric variables in a SAS data set by subtracting a location measure and dividing by a scale measure. A variety of location and scale measures are provided, including estimates that are resistant to outliers and clustering. Some of the well-known standardization methods such as mean, median, standard deviation, range, Huber's estimate, Tukey's biweight estimate, and Andrew's wave estimate are available in the STDIZE procedure.

In addition, you can multiply each standardized value by a constant and add a constant. Thus, the final output value is

$$result = add + multiply \times \frac{original - location}{scale}$$

where

result	= final output value
add	= constant to add (ADD= option)
multiply	= constant to multiply by (MULT= option)
original	= original input value
location	= location measure
scale	= scale measure

PROC STDIZE can also find quantiles in one pass of the data, a capability that is especially useful for very large data sets. With such data sets, the UNIVARIATE procedure might have high or excessive memory or time requirements.

Getting Started: STDIZE Procedure

The following example demonstrates how you can use the STDIZE procedure to obtain location and scale measures of your data.

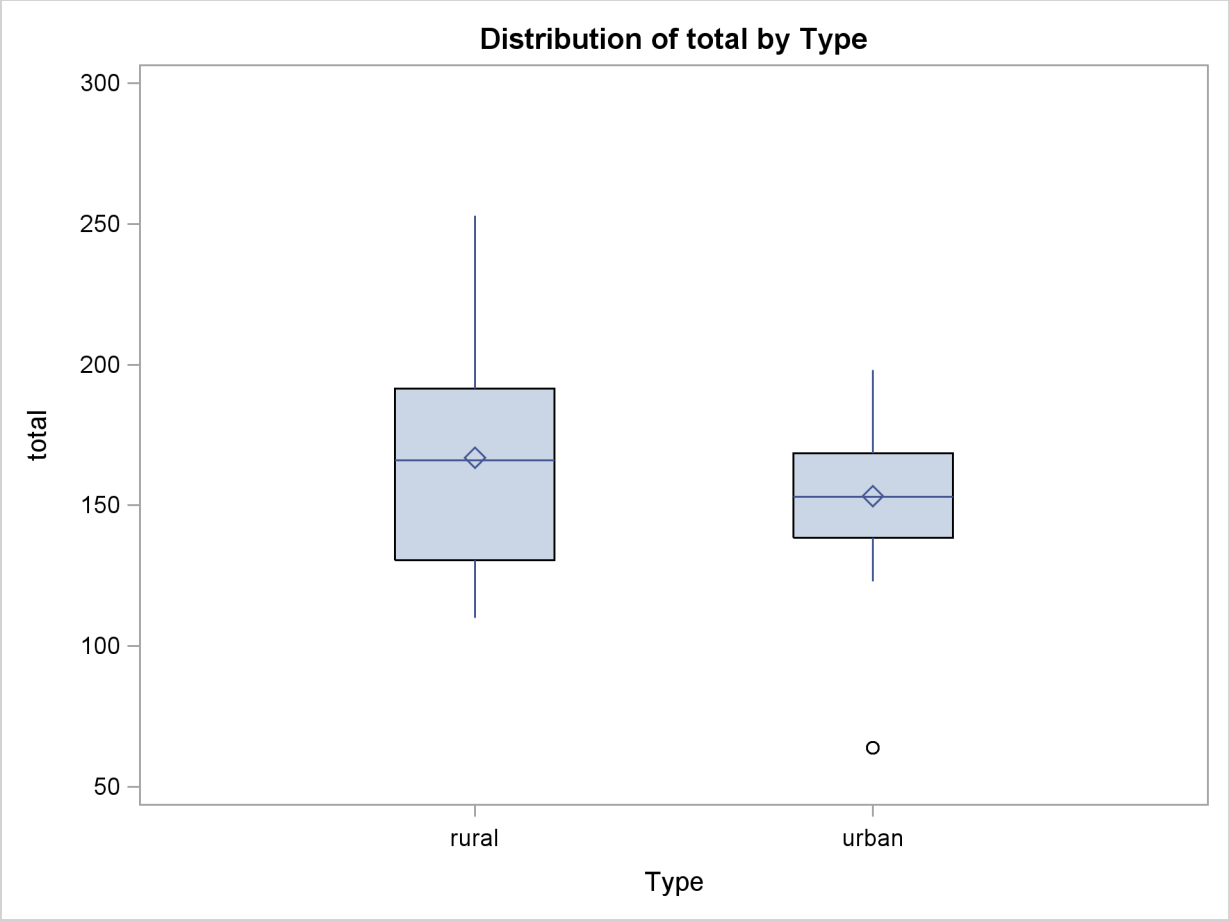
In the following hypothetical data set, a random sample of grade twelve students is selected from a number of coeducational schools. Each school is classified as one of two types: Urban or Rural. There are 40 observations.

The variables are id (student identification), Type (type of school attended: 'urban'=urban area and 'rural'=rural area), and total (total assessment scores in History, Geometry, and Chemistry).

The following DATA step creates the SAS data set TotalScores.

```
data TotalScores;
   title 'High School Scores Data';
   input id Type $  total;
   datalines;
 1      rural        135
 2      rural        125
 3      rural        223
 4      rural        224
 5      rural        133
 6      rural        253
 7      rural        144
 8      rural        193
 9      rural        152
10      rural        178
11      rural        120
12      rural        180
```

```
13      rural        154
14      rural        184
15      rural        187
16      rural        111
17      rural        190
18      rural        128
19      rural        110
20      rural        217
21      urban        192
22      urban        186
23      urban         64
24      urban        159
25      urban        133
26      urban        163
27      urban        130
28      urban        163
29      urban        189
30      urban        144
31      urban        154
32      urban        198
33      urban        150
34      urban        151
35      urban        152
36      urban        151
37      urban        127
38      urban        167
39      urban        170
40      urban        123
;
```



Suppose you now want to standardize the total scores in different types of schools prior to any further analysis. Before standardizing the total scores, you can use the box plot from PROC BOXPLOT to summarize the total scores for both types of schools.

To request this graph, you must specify the ODS GRAPHICS statement as follows. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

```
ods graphics on;
proc boxplot data=TotalScores;
   plot total*Type / boxstyle=schematic noserifs;
run;
ods graphics off;
```

The PLOT statement in the PROC BOXPLOT statement creates the schematic plots (without the serifs) when you specify **boxstyle=schematic noserifs**. Figure 81.1 displays a box plot for each type of school.

Figure 81.1 Schematic Plots from PROC BOXPLOT

Inspection reveals that one urban score is a low outlier. Also, if you compare the lengths of two box plots, there seems to be twice as much dispersion for the rural scores as for the urban scores.

The following PROC UNIVARIATE statement reports the information about the extreme values of the Score variable for each type of school:

```
proc univariate data=TotalScores;
   var total;
   by Type;
run;
```

Figure 81.2 displays the table from PROC UNIVARIATE for the lowest and highest five total scores for urban schools. The outlier (Obs = 3), marked in Figure 81.2 by the symbol '0', has a score of 64.

Figure 81.2 Table for Extreme Observations When Type=urban

High School Scores Data

Type=urban

The UNIVARIATE Procedure
Variable: total

Extreme Observations

----Lowest----		----Highest---	
Value	Obs	Value	Obs
64	23	170	39
123	40	186	22
127	37	189	29
130	27	192	21
133	25	198	32

The following PROC STDIZE procedure requests the METHOD=STD option for computing the location and scale measures:

```
proc stdize data=totalscores method=std pstat;
   title2 'METHOD=STD';
   var total;
   by Type;
run;
```

Figure 81.3 displays the table of location and scale measures from the PROC STDIZE statement. PROC STDIZE uses the sample mean as the location measure and the sample standard deviation as the scale measure for standardizing. The PSTAT option displays a table containing these two measures.

Figure 81.3 Location and Scale Measures Table When METHOD=STD

High School Scores Data
METHOD=STD

Type=rural

The STDIZE Procedure

Location and Scale Measures

Location = mean Scale = standard deviation

Name	Location	Scale	N
total	167.050000	41.956713	20

Figure 81.3 *continued*

```
                          High School Scores Data
                                 METHOD=STD

---------------------------------- Type=urban ----------------------------------

                             The STDIZE Procedure

              Location and Scale Measures

              Location = mean     Scale = standard deviation

              Name          Location            Scale           N

              total       153.300000        30.066768          20
```

The ratio of the scale of rural scores to the scale of urban scores is approximately 1.4 (41.96/30.07). This ratio is smaller than the dispersion ratio observed in the previous schematic plots.

The STDIZE procedure provides several location and scale measures that are resistant to outliers. The following statements invoke three different standardization methods and display the tables for the location and scale measures:

```
proc stdize data=totalscores method=mad pstat;
   title2 'METHOD=MAD';
   var total;
   by Type;
run;

proc stdize data=totalscores method=iqr pstat;
   title2 'METHOD=IQR';
   var total;
   by Type;
run;

proc stdize data=totalscores method=abw(4) pstat;
   title2 'METHOD=ABW(4)';
   var total;
   by Type;
run;
```

Figure 81.4 displays the table of location and scale measures when the standardization method is median absolute deviation (MAD). The location measure is the median, and the scale measure is the median absolute deviation from the median. The ratio of the scale of rural scores to the scale of urban scores is approximately 2.06 (32.0/15.5) and is close to the dispersion ratio observed in the previous schematic plots.

Figure 81.4 Location and Scale Measures Table When METHOD=MAD

```
                          High School Scores Data
                                 METHOD=MAD

---------------------------------- Type=rural ----------------------------------

                            The STDIZE Procedure

              Location and Scale Measures

           Location = median     Scale = median abs dev from median

              Name          Location            Scale            N

              total       166.000000        32.000000          20

                          High School Scores Data
                                 METHOD=MAD

---------------------------------- Type=urban ----------------------------------

                            The STDIZE Procedure

              Location and Scale Measures

           Location = median     Scale = median abs dev from median

              Name          Location            Scale            N

              total       153.000000        15.500000          20
```

Figure 81.5 displays the table of location and scale measures when the standardization method is IQR. The location measure is the median, and the scale measure is the interquartile range. The ratio of the scale of rural scores to the scale of urban scores is approximately 2.03 (61/30) and is, in fact, the dispersion ratio observed in the previous schematic plots.

Figure 81.5 Location and Scale Measures Table When METHOD=IQR

```
                          High School Scores Data
                                 METHOD=IQR

---------------------------------- Type=rural ----------------------------------

                            The STDIZE Procedure

              Location and Scale Measures

              Location = median     Scale = interquartile range

              Name          Location            Scale            N

              total       166.000000        61.000000          20
```

Figure 81.5 *continued*

```
                          High School Scores Data
                                METHOD=IQR

---------------------------------- Type=urban ----------------------------------

                            The STDIZE Procedure

              Location and Scale Measures

              Location = median     Scale = interquartile range

              Name          Location            Scale            N

              total       153.000000        30.000000          20
```

Figure 81.6 displays the table of location and scale measures when the standardization method is ABW, for which the location measure is the biweight 1-step M-estimate, and the scale measure is the biweight A-estimate. Note that the initial estimate for ABW is MAD. The following steps help to decide the value of the tuning constant:

1. For rural scores, the location estimate for MAD is 166.0, and the scale estimate for MAD is 32.0. The maximum of the rural scores is 253 (not shown), and the minimum is 110 (not shown). Thus, the tuning constant needs to be 3 so that it does not reject any observation that has a score between 110 to 253.

2. For urban scores, the location estimate for MAD is 153.0, and the scale estimate for MAD is 15.5. The maximum of the rural scores is 198, and the minimum (also an outlier) is 64. Thus, the tuning constant needs to be 4 so that it rejects the outlier (64) but includes the maximum (198) as an normal observation.

3. The maximum of the tuning constants, obtained in steps 1 and 2, is 4.

See Goodall (1983, Chapter 11) for details about the tuning constant. The ratio of the scale of rural scores to the scale of urban scores is approximately 2.06 (32.0/15.5). It is also close to the dispersion ratio observed in the previous schematic plots.

                          High School Scores Data
                               METHOD=ABW(4)

---------------------------------- Type=urban ----------------------------------

                            The STDIZE Procedure

              Location and Scale Measures

     Location = biweight 1-step M-estimate     Scale = biweight A-estimate

              Name          Location            Scale            N

              total       156.014608        28.615980          20
```

The preceding analysis shows that METHOD=MAD, METHOD=IQR, and METHOD=ABW all provide better dispersion ratios than METHOD=STD does.

You can recompute the standard deviation after deleting the outlier from the original data set for comparison. The following statements create a data set NoOutlier that excludes the outlier from the TotalScores data set and invoke PROC STDIZE with METHOD=STD.

```
   data NoOutlier;
      set totalscores;
      if (total = 64) then delete;
   run;

proc stdize data=NoOutlier method=std pstat;
   title2 'after removing outlier, METHOD=STD';
   var total;
   by Type;
run;
```

Figure 81.7 displays the location and scale measures after deleting the outlier. The lack of resistance of the standard deviation to outliers is clearly illustrated: if you delete the outlier, the sample standard deviation of urban scores changes from 30.07 to 22.09. The new ratio of the scale of rural scores to the scale of urban scores is approximately 1.90 (41.96/22.09).

Figure 81.7 Location and Scale Measures Table When METHOD=STD without the Outlier

```
                          High School Scores Data
                      after removing outlier, METHOD=STD

---------------------------------- Type=rural ----------------------------------

                             The STDIZE Procedure

               Location and Scale Measures

               Location = mean     Scale = standard deviation

               Name          Location            Scale            N

               total       167.050000        41.956713          20

                          High School Scores Data
                      after removing outlier, METHOD=STD

---------------------------------- Type=urban ----------------------------------

                             The STDIZE Procedure

               Location and Scale Measures

               Location = mean     Scale = standard deviation

               Name          Location            Scale            N

               total       158.000000        22.088207          19
```

Syntax: STDIZE Procedure

The following statements are available in the STDIZE procedure:

PROC STDIZE < *options* > ;
  BY *variables* ;
  FREQ *variable* ;
  LOCATION *variables* ;
  SCALE *variables* ;
  VAR *variables* ;
  WEIGHT *variable* ;

The PROC STDIZE statement is required. The BY, LOCATION, FREQ, VAR, SCALE, and WEIGHT statements are described in alphabetical order following the PROC STDIZE statement.

PROC STDIZE Statement

PROC STDIZE < *options* > **;**

The PROC STDIZE statement invokes the procedure. You can specify the following options in the PROC STDIZE statement. Table 81.1 summarizes the options.

Table 81.1 Summary of PROC STDIZE Statement Options

Option	Description
Specify standardization methods	
METHOD=	specifies the name of the standardization method
INITIAL=	specifies the method for computing initial estimates for the A estimates
Unstandardize variables	
UNSTD	unstandardizes variables when you also specify the METHOD=IN option
Process missing values	
NOMISS	omits observations with any missing values from computation
MISSING=	specifies the method or a numeric value for replacing missing values
REPLACE	replaces missing data with zero in the standardized data
REPONLY	replaces missing data with the location measure (does not standardize the data)
Specify data set details	
DATA=	specifies the input data set
KEEPLEN	specifies that output variables inherit the length of the analysis variable
OUT=	specifies the output data set
OUTSTAT=	specifies the output statistic data set
Specify computational settings	
VARDEF=	specifies the variances divisor
NMARKERS=	specifies the number of markers when you also specify PCTLMTD=ONEPASS
MULT=	specifies the constant to multiply each value by after standardizing
ADD=	specifies the constant to add to each value after standardizing and multiplying by the value specified in the MULT= option
FUZZ=	specifies the relative fuzz factor for writing the output

Table 81.1 *continued*

Option	Description
Specify percentiles	
PCTLDEF=	specifies the definition of percentiles when you also specify the PCTLMTD=ORD_STAT option
PCTLMTD=	specifies the method used to estimate percentiles
PCTLPTS=	writes observations containing percentiles to the data set specified in the OUTSTAT= option
Normalize scale estimators	
NORM	normalizes the scale estimator to be consistent for the standard deviation of a normal distribution
SNORM	normalizes the scale estimator to have an expectation of approximately 1 for a standard normal distribution
Specify output	
PSTAT	displays the location and scale measures

These options and their abbreviations are described (in alphabetical order) in the remainder of this section.

ADD=*c*

specifies a constant, c, to add to each value after standardizing and multiplying by the value you specify in the MULT= option. The default value is 0.

DATA=*SAS-data-set*

specifies the input data set to be standardized. If you omit the DATA= option, the most recently created data set is used.

FUZZ=*c*

specifies the relative fuzz factor. The default value is 1E–14. For the OUT= data set, the score is computed as follows:

$$\text{if } |\text{Result}| < m \times c, \text{ then Result} = 0$$

where m is the constant specified in the MULT= option, or 1 if MULT= option is not specified.

For the OUTSTAT= data set and the Location and Scale table, the scale and location values are computed as follows:

$$\text{if Scale} < |\text{Location}| \times c, \text{ Scale} = 0$$

Otherwise,

$$\text{if } |\text{Location}| < m \times c, \text{ Location} = 0$$

INITIAL=*method*

specifies the method for computing initial estimates for the A estimates (ABW, AWAVE, and AHUBER). You cannot specify the following methods for initial estimates: INITIAL=ABW, INITIAL=AHUBER, INITIAL=AWAVE, and INITIAL=IN. The default is INITIAL=MAD.

KEEPLEN

specifies that output variables inherit the length of the analysis variable that PROC STDIZE uses to derive them. PROC STDIZE stores numbers in double-precision without this option.

Caution: The KEEPLEN option causes the output variables to permanently lose numeric precision by truncating or rounding the value. However, the precision of the output variables will match that of the input.

METHOD=*name*

specifies the name of the method for computing location and scale measures. Valid values for *name* are as follows: MEAN, MEDIAN, SUM, EUCLEN, USTD, STD, RANGE, MIDRANGE, MAXABS, IQR, MAD, ABW, AHUBER, AWAVE, AGK, SPACING, L, and IN.

For details about these methods, see the descriptions in the section "Standardization Methods" on page 6229. The default is METHOD=STD.

MISSING=*method* | *value*

specifies the method (or a numeric value) for replacing missing values. If you omit the MISSING= option, the REPLACE option replaces missing values with the location measure given by the METHOD= option. Specify the MISSING= option when you want to replace missing values with a different value. You can specify any name that is valid in the METHOD= option except the name IN. The corresponding location measure is used to replace missing values.

If a numeric value is given, the value replaces missing values after standardizing the data. However, you can specify the REPONLY option with the MISSING= option to suppress standardization for cases in which you want only to replace missing values.

MULT=*c*

specifies a constant, *c*, by which to multiply each value after standardizing. The default value is 1.

NMARKERS=*n*

specifies the number of markers used when you specify the one-pass algorithm (PCTLMTD=ONEPASS). The value *n* must be greater than or equal to 5. The default value is 105.

NOMISS

omits observations with missing values for any of the analyzed variables from calculation of the location and scale measures. If you omit the NOMISS option, all nonmissing values are used.

NORM

normalizes the scale estimator to be consistent for the standard deviation of a normal distribution when you specify the option METHOD=AGK, METHOD=IQR, METHOD=MAD, or METHOD=SPACING.

OUT=*SAS-data-set*

specifies the name of the SAS data set created by PROC STDIZE. The output data set is a copy of the DATA= data set except that the analyzed variables have been standardized.

Note that analyzed variables are those specified in the VAR statement or, if there is no VAR statement, all numeric variables not listed in any other statement. See the section "Output Data Sets" on page 6234 for more information.

If you want to create a permanent SAS data set, you must specify a two-level name. See *SAS Language Reference: Concepts* for more information about permanent SAS data sets.

If you omit the OUT= option, PROC STDIZE creates an output data set named according to the DATA*n* convention.

OUTSTAT=*SAS-data-set*
specifies the name of the SAS data set containing the location and scale measures and other computed statistics. See the section "Output Data Sets" on page 6234 for more information.

PCTLDEF=*percentiles*
specifies which of five definitions is used to calculate percentiles when you specify the option PCTLMTD=ORD_STAT. By default, PCTLDEF=5. Note that the option PCTLMTD=ONEPASS implies PCTLDEF=5. See the section "Computational Methods for the PCTLDEF= Option" on page 6232 for details about percentile definition.

You cannot use PCTLDEF= when you compute weighted quantiles.

PCTLMTD=ORD_STAT | ONEPASS | P2
specifies the method used to estimate percentiles. Specify the PCTLMTD=ORD_STAT option to compute the percentiles by the order statistics method.

The PCTLMTD=ONEPASS option modifies an algorithm invented by Jain and Chlamtac (1985). See the section "Computing Quantiles" on page 6232 for more details about this algorithm.

PCTLPTS=*n*
writes percentiles to the OUTSTAT= data set. Values of *n* can be any decimal number between 0 and 100, inclusive.

A requested percentile is identified by the _TYPE_ variable in the OUTSTAT= data set with a value of P*n*. For example, suppose you specify the option PCTLPTS=10, 30. The corresponding observations in the OUTSTAT= data set that contain the 10th and the 30th percentiles would then have values _TYPE_=P10 and _TYPE_=P30, respectively.

PSTAT
displays the location and scale measures.

REPLACE
replaces missing data with the value 0 in the standardized data (this value corresponds to the location measure before standardizing). To replace missing data by other values, see the preceding description of the MISSING= option. You cannot specify both the REPLACE and REPONLY options.

REPONLY
replaces missing data only; PROC STDIZE does not standardize the data. Missing values are replaced with the location measure unless you also specify the MISSING=*value* option, in

which case missing values are replaced with *value*. You cannot specify both the REPLACE and REPONLY options.

SNORM

normalizes the scale estimator to have an expectation of approximately 1 for a standard normal distribution when you specify the METHOD=SPACING option.

UNSTD

UNSTDIZE

unstandardizes variables when you specify the METHOD=IN(*ds*) option. The location and scale measures, along with constants for addition and multiplication that the unstandardization is based on, are identified by the _TYPE_ variable in the *ds* data set.

The *ds* data set must have a _TYPE_ variable and contain the following two observations: a _TYPE_= 'LOCATION' observation and a _TYPE_= 'SCALE' observation. The variable _TYPE_ can also contain the optional observations, 'ADD' and 'MULT'; if these observations are not found in the *ds* data set, the constants specified in the ADD= and MULT= options (or their default values) are used for unstandardization.

See the section "OUTSTAT= Data Set" on page 6234 for details about the statistics that each value of _TYPE_ represents. The formula used for unstandardization is as follows: If the final output value from the previous standardization is calculated as

$$result = add + multiply \times \frac{original - location}{scale}$$

The unstandardized variable is computed as

$$original = scale \times \frac{result - add}{multiply} + location$$

VARDEF=DF | N | WDF | WEIGHT | WGT

specifies the divisor to be used in the calculation of variances. By default, VARDEF=DF. The values and associated divisors are as follows.

Value	Divisor	Formula
DF	degrees of freedom	$n - 1$
N	number of observations	n
WDF	sum of weights minus 1	$(\sum_i w_i) - 1$
WEIGHT | WGT	sum of weights	$\sum_i w_i$

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC STDIZE to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for PROC STDIZE. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

When you specify the option METHOD=IN(*ds*), the following rules are applied to BY-group processing:

- If the *ds* data set does not contain any of the BY variables, the entire DATA= data set is standardized by the location and scale measures (along with the constants for addition and multiplication) in the *ds* data set.
- If the *ds* data set contains some, but not all, of the BY variables or if some BY variables do not have the same type or length in the *ds* data set that they have in the DATA= data set, PROC STDIZE displays an error message and stops.
- If all of the BY variables appear in the *ds* data set with the same type and length as in the DATA= data set, each BY group in the DATA= data set is standardized using the location and scale measures (along with the constants for addition and multiplication) from the corresponding BY group in the *ds* data set. The BY groups in the *ds* data set must be in the same order in which they appear in the DATA= data set. All BY groups in the DATA= data set must also appear in the *ds* data set. If you do not specify the NOTSORTED option, some BY groups can appear in the *ds* data set but not in the DATA= data set; such BY groups are not used in standardizing data.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide.*

FREQ Statement

FREQ *variable* **;**

If one variable in the input data set represents the frequency of occurrence for other values in the observation, specify the variable name in a FREQ statement. PROC STDIZE treats the data set as if each observation appeared *n* times, where *n* is the value of the FREQ variable for the observation. Nonintegral values of the FREQ variable are truncated to the largest integer less than the FREQ value. If the FREQ variable has a value that is less than 1 or is missing, the observation is not used in the analysis.

NOTRUNCATE

NOTRUNC

specifies that frequency values are not truncated to integers.

The nonintegral values of the FREQ variable can be used for the following standardization methods: AGK, ABW, AHUBER, AWAVE, EUCLEN, IQR, L, MAD, MEAN, MEDIAN, SPACING, STD, SUM, and USTD. Note only when PCTLMTD=ORD_STAT is specified that the nonintegral frequency values will be used for the MAD, MEDIAN, or IQR method; if PCTLMTD=ONEPASS is specified, the NOTRUNCATE option is ignored.

LOCATION Statement

LOCATION *variables* **;**

The LOCATION statement specifies a list of numeric variables that contain location measures in the input data set specified by the METHOD=IN option.

SCALE Statement

SCALE *variables* **;**

The SCALE statement specifies the list of numeric variables containing scale measures in the input data set specified by the METHOD=IN option.

VAR Statement

VAR *variable* **;**

The VAR statement lists numeric variables to be standardized. If you omit the VAR statement, all numeric variables not listed in the BY, FREQ, and WEIGHT statements are used.

WEIGHT Statement

WEIGHT *variable* **;**

The WEIGHT statement specifies a numeric variable in the input data set with values that are used to weight each observation. Only one variable can be specified.

The WEIGHT variable values can be nonintegers. An observation is used in the analysis only if the value of the WEIGHT variable is greater than zero.

The WEIGHT variable applies only when you specify the following standardization methods: AGK, EUCLEN, IQR, L, MAD, MEAN, MEDIAN, STD, SUM, and USTD. Note that weights are used for the METHOD=MAD, MEDIAN, or IQR only when PCTLMTD=ORD_STAT is specified; if PCTLMTD=ONEPASS is specified, the WEIGHT statement is ignored.

PROC STDIZE uses the value of the WEIGHT variable to calculate the following statistics:

The sample mean and sample variances are computed as

$$\overline{x}_w = \sum_i w_i x_i / \sum_i w_i \quad \text{(sample mean)}$$

$$us_w^2 = \sum_i w_i x_i^2 / d \quad \text{(uncorrected sample variances)}$$

$$s_w^2 = \sum_i w_i (x_i - \overline{x}_w)^2 / d \quad \text{(sample variances)}$$

where w_i is the weight value of the ith observation, x_i is the value of the ith observation, and d is the divisor controlled by the VARDEF= option (see the VARDEF= option for details).

MEAN — the weighted mean, $\overline{x}_w$

SUM — the weighted sum, $\sum_i w_i x_i$

USTD — the weighted uncorrected standard deviation, $\sqrt{us_w^2}$

STD — the weighted standard deviation, $\sqrt{s_w^2}$

EUCLEN — the weighted Euclidean length, computed as the square root of the weighted uncorrected sum of squares:

$$\sqrt{\sum_i w_i x_i^2}$$

MEDIAN — the weighted median. See the section "Weighted Percentiles" on page 6233 for the formulas and descriptions.

MAD — the weighted median absolute deviation from the weighted median. See the section "Weighted Percentiles" on page 6233 for the formulas and descriptions.

IQR — the weighted median, 25th percentile, and the 75th percentile. See the section "Weighted Percentiles" on page 6233 for the formulas and descriptions.

AGK — the AGK estimate. This estimate is documented further in the ACECLUS procedure as the METHOD=COUNT option. See the discussion of the WEIGHT statement in Chapter 22, "The ACECLUS Procedure," for information about how the WEIGHT variable is applied to the AGK estimate.

L — the L_p estimate. This estimate is documented further in the FASTCLUS procedure as the LEAST= option. See the discussion of the WEIGHT statement in Chapter 34, "The FASTCLUS Procedure," for information about how the WEIGHT variable is used to compute weighted cluster means. Note that the number of clusters is always 1.

Details: STDIZE Procedure

Standardization Methods

The following table lists standardization methods and their corresponding location and scale measures available with the METHOD= option.

Table 81.2 Available Standardization Methods

Method	Location	Scale
MEAN	mean	1
MEDIAN	median	1
SUM	0	sum
EUCLEN	0	Euclidean length
USTD	0	standard deviation about origin
STD	mean	standard deviation
RANGE	minimum	range
MIDRANGE	midrange	range/2
MAXABS	0	maximum absolute value
IQR	median	interquartile range
MAD	median	median absolute deviation from median
ABW(c)	biweight 1-step M-estimate	biweight A-estimate
AHUBER(c)	Huber 1-step M-estimate	Huber A-estimate
AWAVE(c)	Wave 1-step M-estimate	Wave A-estimate
AGK(p)	mean	AGK estimate (ACECLUS)
SPACING(p)	mid-minimum spacing	minimum spacing
L(p)	L(p)	L(p)
IN(ds)	read from data set	read from data set

For METHOD=ABW(c), METHOD=AHUBER(c), or METHOD=AWAVE(c), c is a positive numeric tuning constant.

For METHOD=AGK(p), p is a numeric constant giving the proportion of pairs to be included in the estimation of the within-cluster variances.

For METHOD=SPACING(p), p is a numeric constant giving the proportion of data to be contained in the spacing.

For METHOD=L(p), p is a numeric constant greater than or equal to 1 specifying the power to which differences are to be raised in computing an L(p) or Minkowski metric.

For METHOD=IN(ds), ds is the name of a SAS data set that meets either of the following two conditions:

- contains a _TYPE_ variable. The observation that contains the location measure corresponds to the value _TYPE_= 'LOCATION', and the observation that contains the scale measure corresponds to the value _TYPE_= 'SCALE'. You can also use a data set created by the OUTSTAT= option from another PROC STDIZE statement as the *ds* data set. See the section "Output Data Sets" on page 6234 for the contents of the OUTSTAT= data set.
- contains the location and scale variables specified by the LOCATION and SCALE statements

PROC STDIZE reads in the location and scale variables in the *ds* data set by first looking for the _TYPE_ variable in the *ds* data set. If it finds this variable, PROC STDIZE continues to search for all variables specified in the VAR statement. If it does not find the _TYPE_ variable, PROC STDIZE searches for the location variables specified in the LOCATION statement and the scale variables specified in the SCALE statement.

The variable _TYPE_ can also contain the optional observations, 'ADD' and 'MULT'. If these observations are found in the *ds* data set, the values in the observation of _TYPE_ = 'MULT' are the multiplication constants, and the values in the observation of _TYPE_ = 'ADD' are the addition constants; otherwise, the constants specified in the ADD= and MULT= options (or their default values) are used.

For robust estimators, refer to Goodall (1983) and Iglewicz (1983). The MAD method has the highest breakdown point (50%), but it is somewhat inefficient. The ABW, AHUBER, and AWAVE methods provide a good compromise between breakdown and efficiency. The L(p) location estimates are increasingly robust as p drops from 2 (corresponding to least squares, or mean estimation) to 1 (corresponding to least absolute value, or median estimation). However, the L(p) scale estimates are not robust.

The SPACING method is robust to both outliers and clustering (Jannsen et al. 1995) and is, therefore, a good choice for cluster analysis or nonparametric density estimation. The mid-minimum spacing method estimates the mode for small p. The AGK method is also robust to clustering and more efficient than the SPACING method, but it is not as robust to outliers and takes longer to compute. If you expect g clusters, the argument to METHOD=SPACING or METHOD=AGK should be $\frac{1}{g}$ or less. The AGK method is less biased than the SPACING method for small samples. As a general guide, it is reasonable to use AGK for samples of size 100 or less and SPACING for samples of size 1000 or more, with the treatment of intermediate sample sizes depending on the available computer resources.

Computation of the Statistics

Formulas for statistics of METHOD=MEAN, METHOD=MEDIAN, METHOD=SUM, METHOD=USTD, METHOD=STD, METHOD=RANGE, and METHOD=IQR are given in the chapter "Elementary Statistics Procedures" (*Base SAS Procedures Guide*).

Note that the computations of median and upper and lower quartiles depend on the PCTLMTD= option.

The other statistics listed in Table 81.2, except for METHOD=IN, are described as follows:

EUCLEN — Euclidean length.
$\sqrt{\sum_{i=1}^{n} x_i^2}$, where x_i is the ith observation and n is the total number of observations in the sample.

L(p) — Minkowski metric. This metric is documented as the LEAST=p option in the PROC FASTCLUS statement of the FASTCLUS procedure (see Chapter 34, "The FASTCLUS Procedure").

If you specify METHOD=L(p) in the PROC STDIZE statement, your results are similar to those obtained from PROC FASTCLUS if you specify the LEAST=p option with MAXCLUS=1 (and use the default values of the MAXITER= option). The difference between the two types of calculations concerns the maximum number of iterations. In PROC STDIZE, it is a criterion for convergence on all variables; in PROC FASTCLUS, it is a criterion for convergence on a single variable.

The location and scale measures for L(p) are output to the OUTSEED= data set in PROC FASTCLUS.

MIDRANGE — (maximum + minimum)/2

ABW(c) — Tukey's biweight. Refer to Goodall (1983, pp. 376–378, p. 385) for the biweight 1-step M-estimate. Also refer to Iglewicz (1983, pp. 416–418) for the biweight A-estimate.

AHUBER(c) — Hubers. Refer to Goodall (1983, pp. 371–374) for the Huber 1-step M-estimate. Also refer to Iglewicz (1983, pp. 416–418) for the Huber A-estimate of scale.

AWAVE(c) — Andrews' wave. Refer to Goodall (1983, p. 376) for the Wave 1-step M-estimate. Also refer to Iglewicz (1983, pp. 416 –418) for the Wave A-estimate of scale.

AGK(p) — The noniterative univariate form of the estimator described by Art, Gnanadesikan, and Kettenring (1982).

The AGK estimate is documented in the section on the METHOD= option in the PROC ACECLUS statement of the ACECLUS procedure (also see the section "Background" on page 660 in Chapter 22, "The ACECLUS Procedure"). Specifying METHOD=AGK(p) in the PROC STDIZE statement is the same as specifying METHOD=COUNT and P=p in the PROC ACECLUS statement.

SPACING(p) — The absolute difference between two data values. The minimum spacing for a proportion p is the minimum absolute difference between two data values that contain a proportion p of the data between them. The mid-minimum spacing is the mean of these two data values.

Computing Quantiles

PROC STDIZE offers two methods for computing quantiles: the one-pass approach and the order-statistics approach (like that used in the UNIVARIATE procedure).

The one-pass approach used in PROC STDIZE modifies the P^2 algorithm for histograms proposed by Jain and Chlamtac (1985). The primary difference comes from the movement of markers. The one-pass method allows a marker to move to the right (or left) by more than one position (to the largest possible integer) as long as it does not result in two markers being in the same position. The modification is necessary in order to incorporate the FREQ variable.

You might obtain inaccurate results if you use the one-pass approach to estimate quantiles beyond the quartiles (that is, when you estimate quantiles < P25 or > P75). A large sample size (10,000 or more) is often required if the tail quantiles (quantiles <= P10 or >= P90) are requested. Note that, for variables with highly skewed or heavy-tailed distributions, tail quantile estimates might be inaccurate.

The order-statistics approach for estimating quantiles is faster than the one-pass method but requires that the entire data set be stored in memory. The accuracy in estimating the quantiles is comparable for both methods when the requested percentiles are between the lower and upper quartiles. The default is PCTLMTD=ORD_STAT if enough memory is available; otherwise, PCTLMTD=ONEPASS.

Computational Methods for the PCTLDEF= Option

You can specify one of five methods for computing quantile statistics when you use the order-statistics approach (PCTLMTD=ORD_STAT); otherwise, the PCTLDEF=5 method is used when you use the one-pass approach (PCTLMTD=ONEPASS).

Percentile Definitions Let n be the number of nonmissing values for a variable, and let $x_1, x_2, \ldots, x_n$ represent the ordered values of the variable. For the tth percentile, let $p = t/100$. In the following definitions numbered 1, 2, 3, and 5, let

$$np = j + g$$

where j is the integer part and g is the fractional part of np. For definition 4, let

$$(n+1)p = j + g$$

Given the preceding definitions, the tth percentile, y, is defined as follows:

PCTLDEF=1 weighted average at x_{np}

$$y = (1-g)x_j + gx_{j+1}$$

where x_0 is taken to be x_1

PCTLDEF=2 observation numbered closest to np

$$y = x_i$$

where i is the integer part of $np + 1/2$ if $g \neq 1/2$. If $g = 1/2$, then
$y = x_j$ if j is even, or
$y = x_{j+1}$ if j is odd

PCTLDEF=3 empirical distribution function

$$y = x_j \text{ if } g = 0$$

$$y = x_{j+1} \text{ if } g > 0$$

PCTLDEF=4 weighted average aimed at $x_{p(n+1)}$

$$y = (1 - g)x_j + gx_{j+1}$$

where x_{n+1} is taken to be x_n

PCTLDEF=5 empirical distribution function with averaging

$$y = (x_j + x_{j+1})/2 \text{ if } g = 0$$

$$y = x_{j+1} \text{ if } g > 0$$

Weighted Percentiles

When you specify a WEIGHT statement, or specify the NOTRUNCATE option in a FREQ statement, the percentiles are computed differently. The $100p$th weighted percentile y is computed from the empirical distribution function with averaging

$$y = \begin{cases} \frac{1}{2}(x_i + x_{i+1}) & \text{if } \sum_{j=1}^{i} w_j = pW \\ x_{i+1} & \text{if } \sum_{j=1}^{i} w_j < pW < \sum_{j=1}^{i+1} w_j \end{cases}$$

where w_i is the weight associated with x_i, and where $W = \sum_{i=1}^{n} w_i$ is the sum of the weights.

For PCTLMTD= ORD_STAT, the PCTLDEF= option is not applicable when a WEIGHT statement is used, or when a NOTRUNCATE option is specified in a FREQ statement. However, in this case, if all the weights are identical, the weighted percentiles are the same as the percentiles that would be computed without a WEIGHT statement and with PCTLDEF=5.

For PCTLMTD= ONEPASS, the quantile computation currently does not use any weights.

Missing Values

Missing values can be replaced by the location measure or by any specified constant (see the REPLACE option and the MISSING= option). You can also suppress standardization if you want only to replace missing values (see the REPONLY option).

If you specify the NOMISS option, PROC STDIZE omits observations with any missing values in the analyzed variables from computation of the location and scale measures.

Output Data Sets

OUT= Data Set

The output data set is a copy of the DATA= data set except that the analyzed variables have been standardized. Analyzed variables are those listed in the VAR statement or, if there is no VAR statement, all numeric variables not listed in any other statement.

OUTSTAT= Data Set

The new data set contains the following variables:

- the BY variables, if any
- _TYPE_, a character variable
- the analyzed variables

Each observation in the new data set contains a type of statistic as indicated by the _TYPE_ variable. The values of the _TYPE_ variable are as follows:

LOCATION	location measure of each variable
SCALE	scale measure of each variable
ADD	constant specified in the ADD= option. This value is the same for each variable.
MULT	constant specified in the MULT= option. This value is the same for each variable.
N	total number of nonmissing positive frequencies of each variable
NORM	norm measure of each variable. This observation is produced only when you specify the NORM option with METHOD=AGK, METHOD=IQR, METHOD=MAD, or METHOD=SPACING or when you specify the SNORM option with METHOD=SPACING.
NObsRead	number of physical records read
NObsUsed	number of physical records used in the analysis
NObsMiss	number of physical records containing missing values
P*n*	percentiles of each variable, as specified by the PCTLPTS= option. The argument n is any real number such that $0 \leq n \leq 100$
SumFreqsRead	sum of the frequency variable (or the sum of NObsUsed ones when there is no frequency variable) for all observations read
SumFreqsUsed	sum of the frequency variable (or the sum of NObsUsed ones when there is no frequency variable) for all observations used in the analysis

SumWeightsRead — sum of the weight variable (or the sum of NObsUsed ones when there is no weight variable) for all observations read

SumWeightsUsed — sum of the weight variable (or the sum of NObsUsed ones when there is no weight variable) for all observations used in the analysis

Displayed Output

If you specify the PSTAT option, PROC STDIZE displays the following statistics for each variable:

- the name of the variable, Name
- the location estimate, Location
- the scale estimate, Scale
- the norm estimate, Norm (when you specify the NORM option with METHOD=AGK, METHOD=IQR, METHOD=MAD, or METHOD=SPACING or when you specify the SNORM option with METHOD=SPACING)
- sum of nonmissing positive frequencies, N
- sum of nonmissing positive weights if the WEIGHT statement is specified, Sum of Weights

ODS Table Names

PROC STDIZE assigns a name to the single table it creates. You can use this name to reference the table when using the Output Delivery System (ODS) to select a table or create an output data set. This name is listed in Table 81.3. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 81.3 ODS Table Produced by PROC STDIZE

ODS Table Name	Description	Statement	Option
Statistics	Location and Scale Measures	PROC	PSTAT

Example: STDIZE Procedure

Example 81.1: Standardization of Variables in Cluster Analysis

To illustrate the effect of standardization in cluster analysis, this example uses the Fish data set described in the "Getting Started" section of Chapter 34, "The FASTCLUS Procedure." The numbers are measurements taken on 159 fish caught from the same lake (Laengelmavesi) near Tampere in Finland; this data set is available from the Data Archive of the *Journal of Statistics Education*. The complete data set is displayed in Chapter 82, "The STEPDISC Procedure."

The species (bream, parkki, pike, perch, roach, smelt, and whitefish), weight, three different length measurements (measured from the nose of the fish to the beginning of its tail, the notch of its tail, and the end of its tail), height, and width of each fish are recorded. The height and width are recorded as percentages of the third length variable.

Several new variables are created in the Fish data set: Weight3, Height, Width, and logLengthRatio. The weight of a fish indicates its size—a heavier pike tends to be larger than a lighter pike. To get a one-dimensional measure of the size of a fish, take the cubic root of the weight (Weight3). The variables Height, Width, Length1, Length2, and Length3 are rescaled in order to adjust for dimensionality. The logLengthRatio variable measures the tail length.

Because the new variables Weight3–logLengthRatio depend on the variable Weight, observations with missing values for Weight are not added to the data set. Consequently, there are 157 observations in the SAS data set Fish.

Before you perform a cluster analysis on coordinate data, it is necessary to consider scaling or transforming the variables since variables with large variances tend to have a larger effect on the resulting clusters than variables with small variances do.

This example uses three different approaches to standardize or transform the data prior to the cluster analysis. The first approach uses several standardization methods provided in the STDIZE procedure. However, since standardization is not always appropriate prior to the clustering (refer to Milligan and Cooper (1987) for a Monte Carlo study on various methods of variable standardization), the second approach performs the cluster analysis with no standardization. The third approach invokes the ACECLUS procedure to transform the data into a within-cluster covariance matrix.

The clustering is performed by the FASTCLUS procedure to find seven clusters. Note that the variables Length2 and Length3 are eliminated from this analysis since they both are significantly and highly correlated with the variable Length1. The correlation coefficients are 0.9958 and 0.9604, respectively. An output data set is created, and the FREQ procedure is invoked to compare the clusters with the species classification.

The DATA step is as follows, after the initial PROC FORMAT step:

```
proc format;
   value specfmt
      1='Bream'
      2='Roach'
      3='Whitefish'
      4='Parkki'
      5='Perch'
      6='Pike'
      7='Smelt';
data Fish (drop=HtPct WidthPct);
   title 'Fish Measurement Data';
   input Species Weight Length1 Length2 Length3 HtPct
         WidthPct @@;

   if Weight <= 0 or Weight=. then delete;
   Weight3=Weight**(1/3);
   Height=HtPct*Length3/(Weight3*100);
   Width=WidthPct*Length3/(Weight3*100);
   Length1=Length1/Weight3;
   Length2=Length2/Weight3;
   Length3=Length3/Weight3;
   logLengthRatio=log(Length3/Length1);

   format Species specfmt.;
   symbol = put(Species, specfmt2.);

The following macro, Std, standardizes the Fish data. The macro reads a single argument, mtd, which selects the METHOD= specification to be used in PROC STDIZE.

```
/*--- macro for standardization ---*/

%macro Std(mtd);
title2 "Data are standardized by PROC STDIZE with METHOD= &mtd";
   proc stdize data=fish out=sdzout method=&mtd;
      var Length1 logLengthRatio Height Width Weight3;
   run;
%mend Std;
```

The following macro, FastFreq, includes a PROC FASTCLUS statement for performing cluster analysis and a PROC FREQ statement for crosstabulating species with the cluster membership information that is derived from the previous PROC FASTCLUS statement. The macro reads a single argument, ds, which selects the input data set to be used in PROC FASTCLUS.

```
/*--- macro for clustering and crosstabulating ---*/
/*--- cluster membership with species           ---*/
%macro FastFreq(ds);
   proc fastclus data=&ds out=clust maxclusters=7 maxiter=100 noprint;
      var Length1 logLengthRatio Height Width Weight3;
   run;

   proc freq data=clust;
      tables species*cluster;
   run;
%mend FastFreq;
```

The following analysis (labeled 'Approach 1') includes 18 different methods of standardization followed by clustering. Since there is a large amount of output from this approach, only results from METHOD=STD, METHOD=RANGE, METHOD=AGK(0.14), and METHOD=SPACING(0.14) are shown. The following statements produce Output 81.1.1 through Output 81.1.4.

```
/*********************************************************/
/*                                                       */

Table 81.4 displays a table summarizing each classification results. In this table, the first column represents the standardization method, the second column represents the number of clusters that the seven species are classified into, and the third column represents the total number of observations that are misclassified.

MAD	4	35
ABW(5)	6	34
AWAVE(5)	6	29
AGK(0.14)	7	28
SPACING(0.14)	7	25
L(1)	6	41
L(1.5)	5	33
L(2)	5	33
untransformed	5	71
PROC ACECLUS	5	71

Consider the results displayed in Output 81.1.1. In that analysis, the method of standardization is STD, and the number of clusters and the number of misclassifications are computed as shown in Table 81.5.

Table 81.5 Computations of Numbers of Clusters and Misclassification When Standardization Method Is STD

Species	Cluster Number	Misclassification in Each Species
Bream	6	0
Roach	7	0
Whitefish	7	3
Parkki	5	0
Perch	7	29
Pike	1	0
Smelt	3	1

In Output 81.1.1, the bream species is classified as cluster 6 since all 34 bream are categorized into cluster 6 with no misclassification. A similar pattern is seen with the roach, parkki, pike, and smelt species.

For the whitefish species, two fish are categorized into cluster 2, one fish is categorized into cluster 4, and three fish are categorized into cluster 7. Because the majority of this species is categorized

into cluster 7, it is recorded in Table 81.5 as being classified as cluster 7 with 3 misclassifications. A similar pattern is seen with the perch species: it is classified as cluster 7 with 29 misclassifications.

In summary, when the standardization method is STD, seven species of fish are classified into only five clusters and the total number of misclassified observations is 33.

The result of this analysis demonstrates that when variables are standardized by the STDIZE procedure with methods including RANGE, MIDRANGE, MAXABS, AGK(0.14), and SPACING(0.14), the FASTCLUS procedure produces the correct number of clusters and less misclassification than it does when other standardization methods are used. The SPACING method attains the best result, probably because the variables Length1 and Height both exhibit marked groupings (bimodality) in their distributions.

Overview: STEPDISC Procedure

Given a classification variable and several quantitative variables, the STEPDISC procedure performs a stepwise discriminant analysis to select a subset of the quantitative variables for use in discriminating among the classes. The set of variables that make up each class is assumed to be multivariate normal with a common covariance matrix. The STEPDISC procedure can use forward selection, backward elimination, or stepwise selection (Klecka 1980). The STEPDISC procedure is a useful prelude to further analyses with the CANDISC procedure or the DISCRIM procedure.

With PROC STEPDISC, variables are chosen to enter or leave the model according to one of two criteria:

- the significance level of an F test from an analysis of covariance, where the variables already chosen act as covariates and the variable under consideration is the dependent variable

- the squared partial correlation for predicting the variable under consideration from the CLASS variable, controlling for the effects of the variables already selected for the model

Forward selection begins with no variables in the model. At each step, PROC STEPDISC enters the variable that contributes most to the discriminatory power of the model as measured by Wilks' lambda, the likelihood ratio criterion. When none of the unselected variables meet the entry criterion, the forward selection process stops.

Backward elimination begins with all variables in the model except those that are linearly dependent on previous variables in the VAR statement. At each step, the variable that contributes least to the discriminatory power of the model as measured by Wilks' lambda is removed. When all remaining variables meet the criterion to stay in the model, the backward elimination process stops.

Stepwise selection begins, like forward selection, with no variables in the model. At each step, the model is examined. If the variable in the model that contributes least to the discriminatory power of the model as measured by Wilks' lambda fails to meet the criterion to stay, then that variable is removed. Otherwise, the variable not in the model that contributes most to the discriminatory power of the model is entered. When all variables in the model meet the criterion to stay and none of the other variables meet the criterion to enter, the stepwise selection process stops. Stepwise selection is the default method of variable selection.

It is important to realize that, in the selection of variables for entry, only one variable can be entered into the model at each step. The selection process does not take into account the relationships between variables that have not yet been selected. Thus, some important variables could be excluded in the process. Also, Wilks' lambda might not be the best measure of discriminatory power for your application. However, if you use PROC STEPDISC carefully, in combination with your knowledge of the data and careful cross validation, it can be a valuable aid in selecting variables for a discrimination model.

As with any stepwise procedure, it is important to remember that when many significance tests are performed, each at a level of, for example, 5% (0.05), the overall probability of rejecting at least one true null hypothesis is much larger than 5%. If you want to prevent including any variables that do not contribute to the discriminatory power of the model in the population, you should specify a very small significance level. In most applications, all variables considered have some discriminatory power, however small. To choose the model that provides the best discrimination by using the sample estimates, you need only to guard against estimating more parameters than can be reliably estimated with the given sample size.

Costanza and Afifi (1979) use Monte Carlo studies to compare alternative stopping rules that can be used with the forward selection method in the two-group multivariate normal classification problem. Five different numbers of variables, ranging from 10 to 30, are considered in the studies. The comparison is based on conditional and estimated unconditional probabilities of correct classification. They conclude that the use of a moderate significance level, in the range of 10 to 25 percent, often performs better than the use of a much larger or a much smaller significance level.

The significance level and the squared partial correlation criteria select variables in the same order, although they might select different numbers of variables. Increasing the sample size tends to increase the number of variables selected when you are using significance levels, but it has little effect on the number selected by using squared partial correlations.

See Chapter 10, "Introduction to Discriminant Procedures," for more information about discriminant analysis.

Getting Started: STEPDISC Procedure

The data in this example are measurements of 159 fish caught in Finland's lake Laengelmavesi; this data set is available from the Puranen. For each of the seven species (bream, roach, whitefish, parkki, perch, pike, and smelt) the weight, length, height, and width of each fish are tallied. Three different length measurements are recorded: from the nose of the fish to the beginning of its tail, from the nose to the notch of its tail, and from the nose to the end of its tail. The height and width are recorded as percentages of the third length variable. PROC STEPDISC will select a subset of the six quantitative variables that might be useful for differentiating between the fish species. This subset is used in conjunction with PROC CANDISC and PROC DISCRIM to develop discrimination models.

The following steps create the data set fish and use PROC STEPDISC to select a subset of potential discriminator variables. By default, PROC STEPDISC uses stepwise selection on all numeric variables that are not listed in other statements, and the significance levels for a variable to enter the subset and to stay in the subset are set to 0.15. The following statements produce Figure 82.1 through Figure 82.5:

```

```

```
proc stepdisc data=fish;
   class Species;
run;
```

PROC STEPDISC begins by displaying summary information about the analysis (see Figure 82.1). This information includes the number of observations with nonmissing values, the number of classes in the classification variable (specified by the CLASS statement), the number of quantitative variables under consideration, the significance criteria for variables to enter and to stay in the model, and the method of variable selection being used. The frequency of each class is also displayed.

Figure 82.1 Summary Information

Fish Measurement Data

The STEPDISC Procedure

The Method for Selecting Variables is STEPWISE

Total Sample Size	158	Variable(s) in the Analysis	6
Class Levels	7	Variable(s) Will Be Included	0
		Significance Level to Enter	0.15
		Significance Level to Stay	0.15

Number of Observations Read	159
Number of Observations Used	158

Class Level Information

Species	Variable Name	Frequency	Weight	Proportion
Bream	Bream	34	34.0000	0.215190
Parkki	Parkki	11	11.0000	0.069620
Perch	Perch	56	56.0000	0.354430
Pike	Pike	17	17.0000	0.107595
Roach	Roach	20	20.0000	0.126582
Smelt	Smelt	14	14.0000	0.088608
Whitefish	Whitefish	6	6.0000	0.037975

For each entry step, the statistics for entry are displayed for all variables not currently selected (see Figure 82.2). The variable selected to enter at this step (if any) is displayed, as well as all the variables currently selected. Next are multivariate statistics that take into account all previously selected variables and the newly entered variable.

Figure 82.2 Step 1: Variable HEIGHT Selected for Entry

Fish Measurement Data

The STEPDISC Procedure
Stepwise Selection: Step 1

Statistics for Entry, DF = 6, 151

Variable	R-Square	F Value	Pr > F	Tolerance
Weight	0.3750	15.10	<.0001	1.0000
Length1	0.6017	38.02	<.0001	1.0000
Length2	0.6098	39.32	<.0001	1.0000
Length3	0.6280	42.49	<.0001	1.0000
Height	0.7553	77.69	<.0001	1.0000
Width	0.4806	23.29	<.0001	1.0000

Variable Height will be entered.

Variable(s) That Have Been Entered

Height

Multivariate Statistics

Statistic	Value	F Value	Num DF	Den DF	Pr > F
Wilks' Lambda	0.244670	77.69	6	151	<.0001
Pillai's Trace	0.755330	77.69	6	151	<.0001
Average Squared Canonical Correlation	0.125888				

For each removal step (Figure 82.3), the statistics for removal are displayed for all variables currently entered. The variable to be removed at this step (if any) is displayed. If no variable meets the criterion to be removed and the maximum number of steps as specified by the MAXSTEP= option has not been attained, then the procedure continues with another entry step.

Figure 82.3 Step 2: No Variable Is Removed; Variable Length2 Added

Fish Measurement Data

The STEPDISC Procedure
Stepwise Selection: Step 2

Statistics for Removal, DF = 6, 151

Variable	R-Square	F Value	Pr > F
Height	0.7553	77.69	<.0001

No variables can be removed.

Figure 82.3 *continued*

Statistics for Entry, DF = 6, 150

Variable	Partial R-Square	F Value	Pr > F	Tolerance
Weight	0.7388	70.71	<.0001	0.4690
Length1	0.9220	295.35	<.0001	0.6083
Length2	0.9229	299.31	<.0001	0.5892
Length3	0.9173	277.37	<.0001	0.5056
Width	0.8783	180.44	<.0001	0.3699

Variable Length2 will be entered.

Variable(s) That Have Been Entered

Length2 Height

Multivariate Statistics

Statistic	Value	F Value	Num DF	Den DF	Pr > F
Wilks' Lambda	0.018861	157.04	12	300	<.0001
Pillai's Trace	1.554349	87.78	12	302	<.0001
Average Squared Canonical Correlation	0.259058				

The stepwise procedure terminates either when no variable can be removed and no variable can be entered or when the maximum number of steps as specified by the MAXSTEP= option has been attained. In this example at step 7 no variables can be either removed or entered (Figure 82.4). Steps 3 through 6 are not displayed in this document.

Figure 82.4 Step 7: No Variables Entered or Removed

Fish Measurement Data

The STEPDISC Procedure
Stepwise Selection: Step 7

Statistics for Removal, DF = 6, 146

Variable	Partial R-Square	F Value	Pr > F
Weight	0.4521	20.08	<.0001
Length1	0.2987	10.36	<.0001
Length2	0.5250	26.89	<.0001
Length3	0.7948	94.25	<.0001
Height	0.7257	64.37	<.0001
Width	0.5757	33.02	<.0001

No variables can be removed.

PROC STEPDISC ends by displaying a summary of the steps.

Figure 82.5 Step Summary

No further steps are possible.

Fish Measurement Data

The STEPDISC Procedure

Stepwise Selection Summary

Step	Number In	Entered	Removed	Partial R-Square	F Value	Pr > F	Wilks' Lambda	Pr < Lambda	Average Squared Canonical Correlation	Pr > ASCC
1	1	Height		0.7553	77.69	<.0001	0.24466983	<.0001	0.12588836	<.0001
2	2	Length2		0.9229	299.31	<.0001	0.01886065	<.0001	0.25905822	<.0001
3	3	Length3		0.8826	186.77	<.0001	0.00221342	<.0001	0.38427100	<.0001
4	4	Width		0.5775	33.72	<.0001	0.00093510	<.0001	0.45200732	<.0001
5	5	Weight		0.4461	19.73	<.0001	0.00051794	<.0001	0.49488458	<.0001
6	6	Length1		0.2987	10.36	<.0001	0.00036325	<.0001	0.51744189	<.0001

All the variables in the data set are found to have potential discriminatory power. These variables are used to develop discrimination models in both the CANDISC and DISCRIM procedure chapters.

Syntax: STEPDISC Procedure

The following statements are available in PROC STEPDISC:

PROC STEPDISC < *options* > ;
CLASS *variable* ;
BY *variables* ;
FREQ *variable* ;
VAR *variables* ;
WEIGHT *variable* ;

The BY, CLASS, FREQ, VAR, and WEIGHT statements are described after the PROC STEPDISC statement.

PROC STEPDISC Statement

PROC STEPDISC < *options* > **;**

The PROC STEPDISC statement invokes the STEPDISC procedure. The options listed in Table 82.1 are available in the PROC STEPDISC statement.

Table 82.1 STEPDISC Procedure Options

Option	Description
Input Data Set	
DATA=	specifies input SAS data set
Method Details	
MAXMACRO=	specifies maximum macro variable lists
METHOD=	specifies method
SINGULAR=	specifies singularity
Control Stepwise Selection	
SLENTRY=	specifies entry significance
SLSTAY=	specifies staying significance
PR2ENTRY=	specifies entry partial R square
PR2STAY=	specifies staying partial R square
INCLUDE=	forces inclusion of variables
MAXSTEP=	specifies maximum number of steps
START=	specifies variables to begin
STOP=	specifies number of variables in final model
Control Displayed Output	
ALL	displays all
BCORR	displays between correlations
BCOV	displays between covariances
BSSCP	displays between SSCPs
PCORR	displays pooled correlations
PCOV	displays pooled covariances
PSSCP	displays pooled SSCPs
SHORT	suppresses output
SIMPLE	displays descriptive statistics
STDMEAN	displays standardized class means
TCORR	displays total correlations
TCOV	displays total covariances
TSSCP	displays total SSCPs
WCORR	displays within correlations
WCOV	displays within covariances
WSSCP	displays within SSCPs

ALL

activates all of the display options.

BCORR

displays between-class correlations.

BCOV

displays between-class covariances. The between-class covariance matrix equals the between-class SSCP matrix divided by $n(c-1)/c$, where n is the number of observations and c is the number of classes. The between-class covariances should be interpreted in comparison with the total-sample and within-class covariances, not as formal estimates of population parameters.

BSSCP

displays the between-class SSCP matrix.

DATA=*SAS-data-set*

specifies the data set to be analyzed. The data set can be an ordinary SAS data set or one of several specially structured data sets created by statistical procedures available with SAS/STAT software. These specially structured data sets include TYPE=CORR, COV, CSSCP, and SSCP. If the DATA= option is omitted, the procedure uses the most recently created SAS data set.

INCLUDE=*n*

includes the first n variables in the VAR statement in every model. By default, INCLUDE=0.

MAXMACRO=*n*

specifies the maximum number of macro variables with independent variable lists to create. By default, MAXMACRO=100. PROC STEPDISC saves the list of selected variables in a macro variable, &_StdVar. Suppose your input variable list consists of x1-x10; then &_StdVar would be set to x1 x3 x4 x10 if, for example, the first, third, fourth, and tenth variables were selected for the model. This list can be used, for example, in a subsequent procedure's VAR statement as follows:

```
var &_stdvar;
```

With BY processing, one macro variable is created for each BY group, and the macro variables are indexed by the BY-group number. The MAXMACRO= option can be used to either limit or increase the number of these macro variables in processing data sets with many BY groups. The macro variables are created as follows:

With no BY processing, PROC STEPDISC creates the following:

_StdVar	selected variables
_StdVar1	selected variables
_StdNumBys	number of BY groups (1)
_StdNumMacroBys	number of _StdVar*i* macro variables actually made (1)

With BY processing, PROC STEPDISC creates the following:

_StdVar	selected variables for BY group 1
_StdVar1	selected variables for BY group 1
_StdVar2	selected variables for BY group 2
.	
.	
.	
_StdVar*m*	selected variables for BY group m, where a number is substituted for m
_StdNumBys	n, the number of BY groups
_StdNumMacroBys	the number m of _StdVar*i* macro variables actually made. This value might be less than _StdNumbys = n, and it is less than or equal to the MAXMACRO= value.

MAXSTEP=*n*

specifies the maximum number of steps. By default, MAXSTEP= two times the number of variables in the VAR statement.

METHOD=BACKWARD | BW

METHOD=FORWARD | FW

METHOD=STEPWISE | SW

specifies the method used to select the variables in the model. The BACKWARD method specifies backward elimination, FORWARD specifies forward selection, and STEPWISE specifies stepwise selection. By default, METHOD=STEPWISE.

PCORR

displays pooled within-class correlations (partial correlations based on the pooled within-class covariances).

PCOV

displays pooled within-class covariances.

PR2ENTRY=*p*

PR2E=*p*

specifies the partial R square for adding variables in the forward selection mode, where $p \leq 1$.

PR2STAY=*p*

PR2S=*p*

specifies the partial R square for retaining variables in the backward elimination mode, where $p \leq 1$.

PSSCP

displays the pooled within-class corrected SSCP matrix.

SHORT

suppresses the displayed output from each step.

SIMPLE

displays simple descriptive statistics for the total sample and within each class.

SINGULAR=*p*

specifies the singularity criterion for entering variables, where $0 < p < 1$. PROC STEPDISC precludes the entry of a variable if the squared multiple correlation of the variable with the variables already in the model exceeds $1 - p$. With more than one variable already in the model, PROC STEPDISC also excludes a variable if it would cause any of the variables already in the model to have a squared multiple correlation (with the entering variable and the other variables in the model) exceeding $1 - p$. By default, SINGULAR= 1E–8.

SLENTRY=*p*

SLE=*p*

specifies the significance level for adding variables in the forward selection mode, where $0 \leq p \leq 1$. The default value is 0.15.

SLSTAY=*p*

SLS=*p*

specifies the significance level for retaining variables in the backward elimination mode, where $0 \leq p \leq 1$. The default value is 0.15.

START=*n*

specifies that the first n variables in the VAR statement be used to begin the selection process. When you specify METHOD=FORWARD or METHOD=STEPWISE, the default value is 0; when you specify METHOD=BACKWARD, the default value is the number of variables in the VAR statement.

STDMEAN

displays total-sample and pooled within-class standardized class means.

STOP=*n*

specifies the number of variables in the final model. The STEPDISC procedure stops the selection process when a model with n variables is found. This option applies only when you specify METHOD=FORWARD or METHOD=BACKWARD. When you specify METHOD=FORWARD, the default value is the number of variables in the VAR statement; when you specify METHOD=BACKWARD, the default value is 0.

TCORR

displays total-sample correlations.

TCOV

displays total-sample covariances.

TSSCP

displays the total-sample corrected SSCP matrix.

WCORR
displays within-class correlations for each class level.

WCOV
displays within-class covariances for each class level.

WSSCP
displays the within-class corrected SSCP matrix for each class level.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC STEPDISC to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for PROC STEPDISC. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* **;**

The values of the CLASS variable define the groups for analysis. Class levels are determined by the formatted values of the CLASS variable. The CLASS variable can be numeric or character. A CLASS statement is required.

FREQ Statement

FREQ *variable* **;**

If a variable in the data set represents the frequency of occurrence for the other values in the observation, include the name of the variable in a FREQ statement. The procedure then treats the data set as if each observation appears n times, where n is the value of the FREQ variable for the observation. The total number of observations is considered to be equal to the sum of the FREQ variable when the procedure determines degrees of freedom for significance probabilities.

If the value of the FREQ variable is missing or is less than one, the observation is not used in the analysis. If the value is not an integer, the value is truncated to an integer.

VAR Statement

VAR *variables* **;**

The VAR statement specifies the quantitative variables eligible for selection. The default is all numeric variables not listed in other statements.

WEIGHT Statement

WEIGHT *variable* **;**

To use relative weights for each observation in the input data set, place the weights in a variable in the data set and specify the name in a WEIGHT statement. This is often done when the variance associated with each observation is different and the values of the WEIGHT variable are proportional to the reciprocals of the variances. If the value of the WEIGHT variable is missing or is less than zero, then a value of zero for the weight is assumed.

The WEIGHT and FREQ statements have a similar effect except that the WEIGHT statement does not alter the degrees of freedom.

Details: STEPDISC Procedure

Missing Values

Observations containing missing values are omitted from the analysis.

Input Data Sets

The input data set can be an ordinary SAS data set or one of several specially structured data sets created by statistical procedures available with SAS/STAT software. For more information about these data sets, see Appendix A, "Special SAS Data Sets." The BY variable in these data sets becomes the CLASS variable in PROC STEPDISC. These specially structured data sets include the following:

- TYPE=CORR data sets created by PROC CORR by using a BY statement
- TYPE=COV data sets created by PROC PRINCOMP by using both the COV option and a BY statement
- TYPE=CSSCP data sets created by PROC CORR by using the CSSCP option and a BY statement, where the OUT= data set is assigned TYPE=CSSCP with the TYPE= data set option
- TYPE=SSCP data sets created by PROC REG by using both the OUTSSCP= option and a BY statement

When the input data set is TYPE=CORR, TYPE=COV, or TYPE=CSSCP, the STEPDISC procedure reads the number of observations for each class from the observations with _TYPE_='N' and the variable means in each class from the observations with _TYPE_='MEAN'. The procedure then reads the within-class correlations from the observations with _TYPE_='CORR', the standard deviations from the observations with _TYPE_='STD' (data set TYPE=CORR), the within-class covariances from the observations with _TYPE_='COV' (data set TYPE=COV), or the within-class corrected sums of squares and crossproducts from the observations with _TYPE_='CSSCP' (data set TYPE=CSSCP).

When the data set does not include any observations with _TYPE_='CORR' (data set TYPE=CORR), _TYPE_='COV' (data set TYPE=COV), or _TYPE_='CSSCP' (data set TYPE=CSSCP) for each class, PROC STEPDISC reads the pooled within-class information from the data set. In this case, the STEPDISC procedure reads the pooled within-class correlations from the observations with _TYPE_='PCORR', the pooled within-class standard deviations from the observations with _TYPE_='PSTD' (data set TYPE=CORR), the pooled within-class covariances

from the observations with _TYPE_='PCOV' (data set TYPE=COV), or the pooled within-class corrected SSCP matrix from the observations with_TYPE_='PSSCP' (data set TYPE=CSSCP).

When the input data set is TYPE=SSCP, the STEPDISC procedure reads the number of observations for each class from the observations with _TYPE_='N', the sum of weights of observations from the variable INTERCEPT in observations with _TYPE_='SSCP' and _NAME_='INTERCEPT', the variable sums from the variable=*variablenames* in observations with _TYPE_='SSCP' and _NAME_='INTERCEPT', and the uncorrected sums of squares and crossproducts from the variable=*variablenames* in observations with _TYPE_='SSCP' and _NAME_=*variablenames*.

Computational Resources

In the following discussion, let

$$
\begin{aligned}
n &= \text{number of observations} \\
c &= \text{number of class levels} \\
v &= \text{number of variables in the VAR list} \\
l &= \text{length of the CLASS variable} \\
t &= v + c - 1
\end{aligned}
$$

Memory Requirements

The amount of memory in bytes for temporary storage needed to process the data is

$$c(4v^2 + 28v + 3l + 4c + 72) + 16v^2 + 92v + 4t^2 + 20t + 4l$$

Additional temporary storage of 72 bytes at each step is also required to store the results.

Time Requirements

The following factors determine the time requirements of a stepwise discriminant analysis:

- The time needed for reading the data and computing covariance matrices is proportional to nv^2. The STEPDISC procedure must also look up each class level in the list. This is faster if the data are sorted by the CLASS variable. The time for looking up class levels is proportional to a value ranging from n to $n \ln(c)$.
- The time needed for stepwise discriminant analysis is proportional to the number of steps required to select the set of variables in the discrimination model. The number of steps required depends on the data set itself and the selection method and criterion used in the procedure. Each forward or backward step takes time proportional to $(v + c)^2$.

Displayed Output

The displayed output from PROC STEPDISC includes the class level information table. For each level of the classification variable, the following information is provided: the output data set variable name, frequency sum, weight sum, and the proportion of the total sample.

The optional output from PROC STEPDISC includes the following:

The optional output includes the following:

- Within-class SSCP matrices for each group
- Pooled within-class SSCP matrix
- Between-class SSCP matrix
- Total-sample SSCP matrix
- Within-class covariance matrices for each group
- Pooled within-class covariance matrix
- Between-class covariance matrix, equal to the between-class SSCP matrix divided by $n(c-1)/c$, where n is the number of observations and c is the number of classes
- Total-sample covariance matrix
- Within-class correlation coefficients and Pr $> |r|$ to test the hypothesis that the within-class population correlation coefficients are zero
- Pooled within-class correlation coefficients and Pr $> |r|$ to test the hypothesis that the partial population correlation coefficients are zero
- Between-class correlation coefficients and Pr $> |r|$ to test the hypothesis that the between-class population correlation coefficients are zero
- Total-sample correlation coefficients and Pr $> |r|$ to test the hypothesis that the total population correlation coefficients are zero
- Simple statistics, including N (the number of observations), sum, mean, variance, and standard deviation for the total sample and within each class
- Total-sample standardized class means, obtained by subtracting the grand mean from each class mean and dividing by the total-sample standard deviation
- Pooled within-class standardized class means, obtained by subtracting the grand mean from each class mean and dividing by the pooled within-class standard deviation

At each step, the following statistics are displayed:

- for each variable considered for entry or removal: partial R-square, the squared (partial) correlation, the F statistic, and Pr $>$ F, the probability level, from a one-way analysis of covariance
- the minimum tolerance for entering each variable. A variable is entered only if its tolerance and the tolerances for all variables already in the model are greater than the value specified in the SINGULAR= option. The tolerance for the entering variable is $1 - R^2$ from regressing the entering variable on the other variables already in the model. The tolerance for a variable already in the model is $1 - R^2$ from regressing that variable on the entering variable and the other variables already in the model. With m variables already in the model, for each entering variable, $m + 1$ multiple regressions are performed by using the entering variable and each of the m variables already in the model as a dependent variable. These $m + 1$ tolerances are computed for each entering variable, and the minimum tolerance is displayed for each.

  The tolerance is computed by using the total-sample correlation matrix. It is customary to compute tolerance by using the pooled within-class correlation matrix (Jennrich 1977), but it is possible for a variable with excellent discriminatory power to have a high total-sample tolerance and a low pooled within-class tolerance. For example, PROC STEPDISC enters a variable that yields perfect discrimination (that is, produces a canonical correlation of one), but a program that uses pooled within-class tolerance does not.
- the variable label, if any
- the name of the variable chosen
- the variables already selected or removed
- Wilks' lambda and the associated F approximation with degrees of freedom and Pr $<$ F, the associated probability level after the selected variable has been entered or removed. Wilks' lambda is the likelihood ratio statistic for testing the hypothesis that the means of the classes on the selected variables are equal in the population (see the section "Multivariate Tests" on page 102 in Chapter 4, "Introduction to Regression Procedures.") Lambda is close to zero if any two groups are well separated.
- Pillai's trace and the associated F approximation with degrees of freedom and Pr $>$ F, the associated probability level after the selected variable has been entered or removed. Pillai's trace is a multivariate statistic for testing the hypothesis that the means of the classes on the selected variables are equal in the population (see the section "Multivariate Tests" on page 102 in Chapter 4, "Introduction to Regression Procedures").
- Average squared canonical correlation (ASCC). The ASCC is Pillai's trace divided by the number of groups minus 1. The ASCC is close to 1 if all groups are well separated and if all or most directions in the discriminant space show good separation for at least two groups.
- Summary to give statistics associated with the variable chosen at each step. The summary includes the following:
  - Step number
  - Variable entered or removed

- Number in, the number of variables in the model
- Partial R-square
- the F value for entering or removing the variable
- Pr $>$ F, the probability level for the F statistic
- Wilks' lambda
- Pr $<$ Lambda based on the F approximation to Wilks' lambda
- Average squared canonical correlation
- Pr $>$ ASCC based on the F approximation to Pillai's trace
- the variable label, if any

ODS Table Names

PROC STEPDISC assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 82.2 along with the PROC STEPDISC statement options needed to produce the table. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 82.2 ODS Tables Produced by PROC STEPDISC

ODS Table Name	Description	Option
BCorr	Between-class correlations	BCORR
BCov	Between-class covariances	BCOV
BSSCP	Between-class SSCP matrix	BSSCP
Counts	Number of observations, variables, classes, df	default
CovDF	Nonprinting table of df for covariance matrices	any *COV option
Levels	Class level information	default
Messages	Entry/removal messages	default
Multivariate	Multivariate statistics	default
NObs	Number of observations	default
PCorr	Pooled within-class correlations	PCORR
PCov	Pooled within-class covariances	PCOV
PSSCP	Pooled within-class SSCP matrix	PSSCP
PStdMeans	Pooled standardized class means	STDMEAN
SimpleStatistics	Simple statistics	SIMPLE
Steps	Stepwise selection entry/removal	default
Summary	Stepwise selection summary	default
TCorr	Total-sample correlations	TCORR
TCov	Total-sample covariances	TCOV
TSSCP	Total-sample SSCP matrix	TSSCP
TStdMeans	Total standardized class means	STDMEAN
Variables	Variable lists	default
WCorr	Within-class correlations	WCORR
WCov	Within-class covariances	WCOV
WSSCP	Within-class SSCP matrices	WSSCP

Example: STEPDISC Procedure

Example 82.1: Performing a Stepwise Discriminant Analysis

The iris data published by Fisher (1936) have been widely used for examples in discriminant analysis and cluster analysis. The sepal length, sepal width, petal length, and petal width are measured in millimeters on 50 iris specimens from each of three species: *Iris setosa*, *I. versicolor*, and *I. virginica*.

```

;
```

A stepwise discriminant analysis is performed by using stepwise selection.

In the PROC STEPDISC statement, the BSSCP and TSSCP options display the between-class SSCP matrix and the total-sample corrected SSCP matrix. By default, the significance level of an F test from an analysis of covariance is used as the selection criterion. The variable under consideration is the dependent variable, and the variables already chosen act as covariates. The following SAS statements produce Output 82.1.1 through Output 82.1.8:

```
%let _stdvar = ;
proc stepdisc data=iris bsscp tsscp;
   class Species;
   var SepalLength SepalWidth PetalLength PetalWidth;
run;
```

Output 82.1.2 *continued*

Total-Sample SSCP Matrix

Variable	Label	SepalLength	SepalWidth	PetalLength	PetalWidth
Sepal Length	Sepal Length in mm.	10216.83333	-632.26667	18987.30000	7692.43333
SepalWidth	Sepal Width in mm.	-632.26667	2830.69333	-4911.88000	-1812.42667
Petal Length	Petal Length in mm.	18987.30000	-4911.88000	46432.54000	19304.58000
PetalWidth	Petal Width in mm.	7692.43333	-1812.42667	19304.58000	8656.99333

In step 1, the tolerance is 1.0 for each variable under consideration because no variables have yet entered the model. The variable PetalLength is selected because its F statistic, 1180.161, is the largest among all variables.

Output 82.1.3 Iris Data: Stepwise Selection Step 1

Fisher (1936) Iris Data

The STEPDISC Procedure
Stepwise Selection: Step 1

Statistics for Entry, DF = 2, 147

Variable	Label	R-Square	F Value	Pr > F	Tolerance
SepalLength	Sepal Length in mm.	0.6187	119.26	<.0001	1.0000
SepalWidth	Sepal Width in mm.	0.4008	49.16	<.0001	1.0000
PetalLength	Petal Length in mm.	0.9414	1180.16	<.0001	1.0000
PetalWidth	Petal Width in mm.	0.9289	960.01	<.0001	1.0000

Variable PetalLength will be entered.

Variable(s) That Have Been Entered

PetalLength

Multivariate Statistics

Statistic	Value	F Value	Num DF	Den DF	Pr > F
Wilks' Lambda	0.058628	1180.16	2	147	<.0001
Pillai's Trace	0.941372	1180.16	2	147	<.0001
Average Squared Canonical Correlation	0.470686				

In step 2, with the variable PetalLength already in the model, PetalLength is tested for removal before a new variable is selected for entry. Since PetalLength meets the criterion to stay, it is used as a covariate in the analysis of covariance for variable selection. The variable SepalWidth is selected because its F statistic, 43.035, is the largest among all variables not in the model and because its associated tolerance, 0.8164, meets the criterion to enter. The process is repeated in steps 3 and 4. The variable PetalWidth is entered in step 3, and the variable SepalLength is entered in step 4.

PetalWidth	Petal Width in mm.	0.2570	24.90	<.0001

No variables can be removed.

Output 82.1.8 Iris Data: Stepwise Selection Summary

No further steps are possible.

Fisher (1936) Iris Data

The STEPDISC Procedure

Stepwise Selection Summary

Step	Number In	Entered	Removed	Label	Partial R-Square	F Value	Pr > F	Wilks' Lambda	Pr < Lambda
1	1	PetalLength		Petal Length in mm.	0.9414	1180.16	<.0001	0.05862828	<.0001
2	2	SepalWidth		Sepal Width in mm.	0.3709	43.04	<.0001	0.03688411	<.0001
3	3	PetalWidth		Petal Width in mm.	0.3229	34.57	<.0001	0.02497554	<.0001
4	4	SepalLength		Sepal Length in mm.	0.0615	4.72	0.0103	0.02343863	<.0001

Step	Number In	Entered	Removed	Average Squared Canonical Correlation	Pr > ASCC
1	1	PetalLength		0.47068586	<.0001
2	2	SepalWidth		0.55995394	<.0001
3	3	PetalWidth		0.59495691	<.0001
4	4	SepalLength		0.59594941	<.0001

PROC STEPDISC automatically creates a list of the selected variables and stores it in a macro variable. You can submit the following statement to see the list of selected variables:

```
* print the macro variable list;
%put &_stdvar;
```

The macro variable _StdVar contains the following variable list:

```
SepalLength SepalWidth PetalLength PetalWidth
```

You could use this macro variable if you want to analyze these variables in subsequent steps as follows:

```
proc discrim data=iris;
   class Species;
   var &_stdvar;
run;
```

The results of this step are not shown.

Overview: SURVEYFREQ Procedure

The SURVEYFREQ procedure produces one-way to *n*-way frequency and crosstabulation tables from sample survey data. These tables include estimates of population totals, population proportions, and their standard errors. Confidence limits, coefficients of variation, and design effects are also available. The procedure provides a variety of options to customize the table display.

For one-way frequency tables, PROC SURVEYFREQ provides Rao-Scott chi-square goodness-of-fit tests, which are adjusted for the sample design. You can test a null hypothesis of equal proportions for a one-way frequency table, or you can input custom null hypothesis proportions for the test. For two-way tables, PROC SURVEYFREQ provides design-adjusted tests of independence, or no association, between the row and column variables. These tests include the Rao-Scott chi-square test, the Rao-Scott likelihood ratio test, the Wald chi-square test, and the Wald log-linear chi-square test. For 2×2 tables, PROC SURVEYFREQ computes estimates and confidence limits for risks (or row proportions), the risk difference, the odds ratio, and relative risks.

PROC SURVEYFREQ computes variance estimates based on the sample design used to obtain the survey data. The design can be a complex multistage survey design with stratification, clustering, and unequal weighting. PROC SURVEYFREQ provides a choice of variance estimation methods, which include Taylor series linearization, balanced repeated replication (BRR), and the jackknife.

Getting Started: SURVEYFREQ Procedure

The following example shows how you can use PROC SURVEYFREQ to analyze sample survey data. The example uses data from a customer satisfaction survey for a student information system (SIS), which is a software product that provides modules for student registration, class scheduling, attendance, grade reporting, and other functions.

The software company conducted a survey of school personnel who use the SIS. A probability sample of SIS users was selected from the study population, which included SIS users at middle schools and high schools in the three-state area of Georgia, South Carolina, and North Carolina. The sample design for this survey was a two-stage stratified design. A first-stage sample of schools

was selected from the list of schools in the three-state area that use the SIS. The list of schools, or the first-stage sampling frame, was stratified by state and by customer status (whether the school was a new user of the system or a renewal user). Within the first-stage strata, schools were selected with probability proportional to size and with replacement, where the size measure was school enrollment. From each sample school, five staff members were randomly selected to complete the SIS satisfaction questionnaire. These staff members included three teachers and two administrators or guidance department members.

The SAS data set SIS_Survey contains the survey results, as well as the sample design information needed to analyze the data. This data set includes an observation for each school staff member responding to the survey. The variable Response contains the staff member's response about overall satisfaction with the system.

The variable State contains the school's state, and the variable NewUser contains the school's customer status ('New Customer' or 'Renewal Customer'). These two variables determine the first-stage strata from which schools were selected. The variable School contains the school identification code and identifies the first-stage (primary) sampling units, or clusters. The variable SamplingWeight contains the overall sampling weight for each respondent. Overall sampling weights were computed from the selection probabilities at each stage of sampling and were adjusted for nonresponse.

Other variables in the data set SIS_Survey include SchoolType and Department. The variable SchoolType identifies the school as a high school or a middle school. The variable Department identifies the staff member as a teacher, or an administrator or guidance department member.

The following PROC SURVEYFREQ statements request a one-way frequency table for the variable Response:

```
title 'Student Information System Survey';
proc surveyfreq data=SIS_Survey;
   tables  Response;
   strata  State NewUser;
   cluster School;
   weight  SamplingWeight;
run;
```

The PROC SURVEYFREQ statement invokes the procedure and identifies the input data set to be analyzed. The TABLES statement requests a one-way frequency table for the variable Response. The table request syntax for PROC SURVEYFREQ is very similar to the table request syntax for PROC FREQ. This example shows a request for a single one-way table, but you can also request two-way tables and multiway tables. As in PROC FREQ, you can request more than one table in the same TABLES statement, and you can use multiple TABLES statements in the same invocation of the procedure.

The STRATA, CLUSTER, and WEIGHT statements provide sample design information for the procedure, so that the analysis is done according to the sample design used for the survey, and the estimates apply to the study population. The STRATA statement names the variables State and NewUser, which identify the first-stage strata. Note that the design for this example also includes stratification at the second stage of selection (by type of school personnel), but you specify only the first-stage strata for PROC SURVEYFREQ. The CLUSTER statement names the variable School, which identifies the clusters or primary sample units (PSUs). The WEIGHT statement names the sampling weight variable.

Figure 83.1 and Figure 83.2 display the output produced by PROC SURVEYFREQ, which includes the "Data Summary" table and the one-way table, "Table of Response." The "Data Summary" table is produced by default unless you specify the NOSUMMARY option. This table shows there are 6 strata, 370 clusters or schools, and 1850 observations or respondents in the SIS_Survey data set. The sum of the sampling weights is approximately 39,000, which estimates the total number of school personnel in the study area that use the SIS.

Figure 83.1 SIS_Survey Data Summary

Student Information System Survey

The SURVEYFREQ Procedure

Data Summary

Number of Strata	6
Number of Clusters	370
Number of Observations	1850
Sum of Weights	38899.6482

Figure 83.2 displays the one-way table of Response, which provides estimates of the population total (weighted frequency) and the population percentage for each category, or level, of the variable Response. The response level 'Very Unsatisfied' has a frequency of 304, which means that 304 sample respondents fall into this category. It is estimated that 17.17% of all school personnel in the study population fall into this category, and the standard error of this estimate is 1.29%. Note that the estimates apply to the population of all SIS users in the study area, as opposed to describing only the sample of 1850 respondents. The estimate of the total number of school personnel that are 'Very Unsatisfied' is 6,678, with a standard deviation of 502. The standard errors computed by PROC SURVEYFREQ are based on the multistage stratified design of the survey. This differs from some of the traditional analysis procedures, which assume the design is simple random sampling from an infinite population.

Figure 83.2 One-Way Table of Response

Table of Response

Response	Frequency	Weighted Frequency	Std Dev of Wgt Freq	Percent	Std Err of Percent
Very Unsatisfied	304	6678	501.61039	17.1676	1.2872
Unsatisfied	326	6907	495.94101	17.7564	1.2712
Neutral	581	12291	617.20147	31.5965	1.5795
Satisfied	455	9309	572.27868	23.9311	1.4761
Very Satisfied	184	3714	370.66577	9.5483	0.9523
Total	1850	38900	129.85268	100.000	

The following PROC SURVEYFREQ statements request confidence limits for the percentages and a chi-square goodness-of-fit test for the one-way table of Response:

```
proc surveyfreq data=SIS_Survey nosummary;
   tables  Response / cl nowt chisq;
   strata  State  NewUser;
   cluster School;
   weight  SamplingWeight;
 run;
```

The NOSUMMARY option in the PROC statement suppresses the "Data Summary" table. In the TABLES statement, the CL option requests confidence limits for the percentages in the one-way table. The NOWT option suppresses display of the weighted frequencies and their standard deviations. The CHISQ option requests a Rao-Scott chi-square goodness-of-fit test.

Figure 83.3 shows the one-way table of Response, which includes confidence limits for the percentages. The 95% confidence limits for the percentage of users that are 'Very Unsatisfied' are 14.64% and 19.70%. To change the α level of the confidence limits, which equals 5% by default, you can use the ALPHA= option. Like the other estimates and standard errors produced by PROC SURVEYFREQ, these confidence limit computations take into account the complex sample design of the survey, and the results apply to the entire study population.

Figure 83.3 Confidence Limits for Response Percentages

Student Information System Survey

The SURVEYFREQ Procedure

Table of Response

Response	Frequency	Percent	Std Err of Percent	95% Confidence Limits for Percent	
Very Unsatisfied	304	17.1676	1.2872	14.6364	19.6989
Unsatisfied	326	17.7564	1.2712	15.2566	20.2562
Neutral	581	31.5965	1.5795	28.4904	34.7026
Satisfied	455	23.9311	1.4761	21.0285	26.8338
Very Satisfied	184	9.5483	0.9523	7.6756	11.4210
Total	1850	100.000			

Figure 83.4 shows the chi-square goodness-of-fit results for the table of Response. The null hypothesis for this test is equal proportions for the levels of the one-way table. (To test a null hypothesis of specified proportions instead of equal proportions, you can use the TESTP= option to specify null hypothesis proportions.)

The chi-square test invoked by the CHISQ option is the Rao-Scott design-adjusted chi-square test, which takes the sample design into account and provides inferences for the entire study population. To produce the Rao-Scott chi-square statistic, PROC SURVEYFREQ first computes the usual Pearson chi-square statistic based on the weighted frequencies, and then adjusts this value with a design correction. An F approximation is also provided. For the table of Response, the F value is 30.0972 with a p-value of <0.0001, which indicates rejection of the null hypothesis of equal proportions for all response levels.

Figure 83.4 Chi-Square Goodness-of-Fit Test for Response

Rao-Scott Chi-Square Test	
Pearson Chi-Square	251.8105
Design Correction	2.0916
Rao-Scott Chi-Square	120.3889
DF	4
Pr > ChiSq	<.0001
F Value	30.0972
Num DF	4
Den DF	1456
Pr > F	<.0001

Sample Size = 1850

Continuing to analyze the SIS_Survey data, the following PROC SURVEYFREQ statements request a two-way table of SchoolType by Response:

```
proc surveyfreq data=SIS_Survey nosummary;
   tables  SchoolType * Response;
   strata  State NewUser;
   cluster School;
   weight  SamplingWeight;
run;
```

The STRATA, CLUSTER, and WEIGHT statements do not change from the one-way table analysis, because the sample design and the input data set are the same. These SURVEYFREQ statements request a different table but specify the same sample design information.

Figure 83.5 shows the two-way table produced for SchoolType by Response. The first variable named in the two-way table request, SchoolType, is referred to as the *row variable*, and the second variable, Response, is referred to as the *column variable*. Two-way tables display all column variable levels for each row variable level. This two-way table lists all levels of the column variable Response for each level of the row variable SchoolType, 'Middle School' and 'High School'. Also SchoolType = 'Total' shows the distribution of Response overall for both types of schools. And Response = 'Total' provides totals over all levels of response, for each type of school and overall. To suppress these totals, you can specify the NOTOTAL option.

Figure 83.5 Two-Way Table of SchoolType by Response

Student Information System Survey

The SURVEYFREQ Procedure

Table of SchoolType by Response

SchoolType	Response	Frequency	Weighted Frequency	Std Dev of Wgt Freq	Percent	Std Err of Percent

	Very Satisfied	94	1952	302.17144	5.0193	0.7758
	Total	750	15758	1000	40.5089	2.5691
High School	Very Unsatisfied	188	4183	431.30589	10.7521	1.1076
	Unsatisfied	217	4518	446.31768	11.6137	1.1439
	Neutral	347	7434	574.17175	19.1119	1.4726
	Satisfied	258	5245	498.03221	13.4845	1.2823
	Very Satisfied	90	1762	255.67158	4.5290	0.6579
	Total	1100	23142	1003	59.4911	2.5691
Total	Very Unsatisfied	304	6678	501.61039	17.1676	1.2872
	Unsatisfied	326	6907	495.94101	17.7564	1.2712
	Neutral	581	12291	617.20147	31.5965	1.5795
	Satisfied	455	9309	572.27868	23.9311	1.4761
	Very Satisfied	184	3714	370.66577	9.5483	0.9523
	Total	1850	38900	129.85268	100.000	

By default, without any other TABLES statement options, a two-way table displays the frequency, the weighted frequency and its standard deviation, and the percentage and its standard error for each table cell, or combination of row and column variable levels. But there are several options available to customize your table display by adding more information or by suppressing some of the default information.

The following PROC SURVEYFREQ statements request a two-way table of SchoolType by Response that displays row percentages, and also request a chi-square test of association between the two variables:

```
proc surveyfreq data=SIS_Survey nosummary;
   tables  SchoolType * Response / row nowt chisq;
   strata  State NewUser;
   cluster School;
   weight  SamplingWeight;
run;
```

The ROW option in the TABLES statement requests row percentages, which give the distribution of Response within each level of the row variable SchoolType. The NOWT option suppresses display of the weighted frequencies and their standard deviations. The CHISQ option requests a Rao-Scott chi-square test of association between SchoolType and Response.

Figure 83.6 displays the two-way table of SchoolType by Response. For middle schools, it is estimated that 25.79% of school personnel are satisfied with the student information system and 12.39% are very satisfied. For high schools, these estimates are 22.67% and 7.61%, respectively.

Figure 83.7 displays the chi-square test results. The Rao-Scott chi-square statistic equals 9.04, and the corresponding F value is 2.26 with a p-value of 0.0605. This indicates an association between school type (middle school or high school) and satisfaction with the student information system at the 10% significance level.

Syntax: SURVEYFREQ Procedure

The following statements are available in PROC SURVEYFREQ:

PROC SURVEYFREQ < *options* > ;
BY *variables* ;
CLUSTER *variables* ;
REPWEIGHTS *variables* < / *options* > ;
STRATA *variables* < / *option* > ;
TABLES *requests* < / *options* > ;
WEIGHT *variable* ;

The PROC SURVEYFREQ statement invokes the procedure, identifies the data set to be analyzed, and specifies the variance estimation method. The PROC SURVEYFREQ statement is required.

The TABLES statement specifies frequency or crosstabulation tables and requests tests and statistics for those tables. The STRATA statement lists the variables that form the strata in a stratified sample design. The CLUSTER statement specifies cluster identification variables in a clustered sample design. The WEIGHT statement names the sampling weight variable. The REPWEIGHTS statement names replicate weight variables for BRR or jackknife variance estimation. The BY statement requests completely separate analyses of groups defined by the BY variables.

All statements can appear multiple times except the PROC SURVEYFREQ statement and the WEIGHT statement, which can appear only once.

The rest of this section gives detailed syntax information for the BY, CLUSTER, REPWEIGHTS, STRATA, TABLES, and WEIGHT statements in alphabetical order after the description of the PROC SURVEYFREQ statement.

PROC SURVEYFREQ Statement

PROC SURVEYFREQ < *options* > **;**

The PROC SURVEYFREQ statement invokes the procedure. In this statement, you identify the data set to be analyzed, specify the variance estimation method, and provide sample design information. The DATA= option names the input data set to be analyzed. The VARMETHOD= option specifies the variance estimation method, which is the Taylor series method by default. For Taylor series variance estimation, you can include a finite population correction factor in the analysis by providing either the sampling rate or population total with the RATE= or TOTAL= option. If your design is stratified, with different sampling rates or totals for different strata, then you can input these stratum rates or totals in a SAS data set that contains the stratification variables.

You can specify the following options in the PROC SURVEYFREQ statement.

DATA=*SAS-data-set*
names the SAS data set to be analyzed by PROC SURVEYFREQ. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

MISSING
treats missing values as a valid (nonmissing) category for all categorical variables, which include TABLES, STRATA, and CLUSTER variables.

By default, if you do not specify the MISSING option, an observation is excluded from the analysis if it has a missing value for any STRATA or CLUSTER variable. Additionally, PROC SURVEYFREQ excludes an observation from a frequency or crosstabulation table if that observation has a missing value for any of the variables in the table request, unless you specify the MISSING option. For more information, see the section "Missing Values" on page 6323.

NOMCAR
includes observations with missing values of TABLES variables in the variance computation as *not missing completely at random* (NOMCAR) for Taylor series variance estimation. When you specify the NOMCAR option, PROC SURVEYFREQ computes variance estimates by analyzing the nonmissing values as a domain or subpopulation, where the entire population includes both nonmissing and missing domains. See the section "Missing Values" on page 6323 for details.

By default, PROC SURVEYFREQ completely excludes an observation from a frequency or crosstabulation table (and the corresponding variance computations) if that observation has a missing value for any of the variables in the table request, unless you specify the MISSING option. Note that the NOMCAR option has no effect when you specify the MISSING option, which treats missing values as a valid nonmissing level.

The NOMCAR option applies only to Taylor series variance estimation. The replication methods, which you request with the VARMETHOD=BRR and VARMETHOD=JACKKNIFE options, do not use the NOMCAR option.

NOSUMMARY

suppresses the display of the "Data Summary" table, which PROC SURVEYFREQ produces by default. For details about this table, see the section "Data Summary Table" on page 6356.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the order in which the values of the frequency and crosstabulation table variables are displayed. PROC SURVEYFREQ interprets values of the ORDER= option as follows:

DATA	orders values according to their order in the input data set.
FORMATTED	orders values by their formatted values (in ascending order). This order is operating-environment dependent.
FREQ	orders values by their descending frequency counts. The frequency count of a variable value is its (nonweighted) frequency of occurrence or sample size, and not its weighted frequency.
INTERNAL	orders values by their unformatted values, which yields the same order that the SORT procedure does. This order is operating-environment dependent.

By default, ORDER=INTERNAL.

PAGE

displays only one table per page. Otherwise, PROC SURVEYFREQ displays multiple tables per page as space permits.

RATE=*value* | *SAS-data-set*

R=*value* | *SAS-data-set*

specifies the sampling rate as a nonnegative *value*, or identifies an input data set that gives the stratum sampling rates in a variable named _RATE_. PROC SURVEYFREQ uses this information to compute a finite population correction for Taylor series variance estimation. The procedure does not use the RATE= option for BRR or jackknife variance estimation, which you request with the VARMETHOD=BRR or VARMETHOD=JACKKNIFE option.

If your sample design has multiple stages, you should specify the *first-stage sampling rate*, which is the ratio of the number of primary sampling units (PSUs) selected to the total number of PSUs in the population.

For a nonstratified sample design, or for a stratified sample design with the same sampling rate in all strata, you should specify a nonnegative *value* for the RATE= option. If your design is stratified with different sampling rates in different strata, then you should name a SAS data set that contains the stratification variables and the stratum sampling rates. See the section "Population Totals and Sampling Rates" on page 6322 for details.

The sampling rate *value* must be a nonnegative number. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC SURVEYFREQ converts that number to a proportion. The procedure treats the value 1 as 100%, and not the percentage form 1%.

If you do not specify the RATE= or TOTAL= option, then the Taylor series variance estimation does not include a finite population correction. You cannot specify both the TOTAL= option and the RATE= option in the same PROC SURVEYFREQ statement.

TOTAL=*value* | *SAS-data-set*

N=*value* | *SAS-data-set*

specifies the total number of primary sampling units (PSUs) in the study population as a positive *value*, or identifies an input data set that gives the stratum population totals in a variable named _TOTAL_. PROC SURVEYFREQ uses this information to compute a finite population correction for Taylor series variance estimation. The procedure does not use the TOTAL= option for BRR or jackknife variance estimation, which you request with the VARMETHOD=BRR or VARMETHOD=JACKKNIFE option.
