

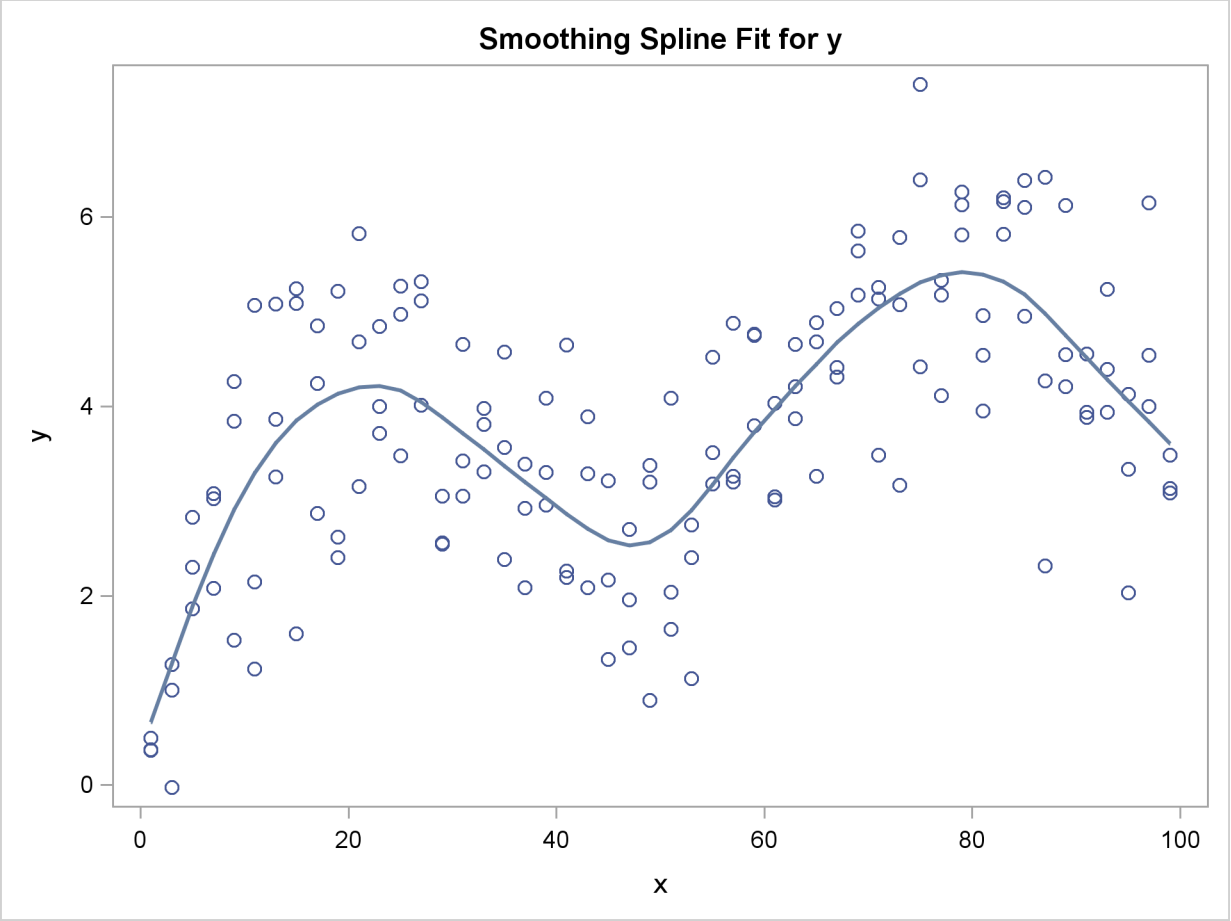

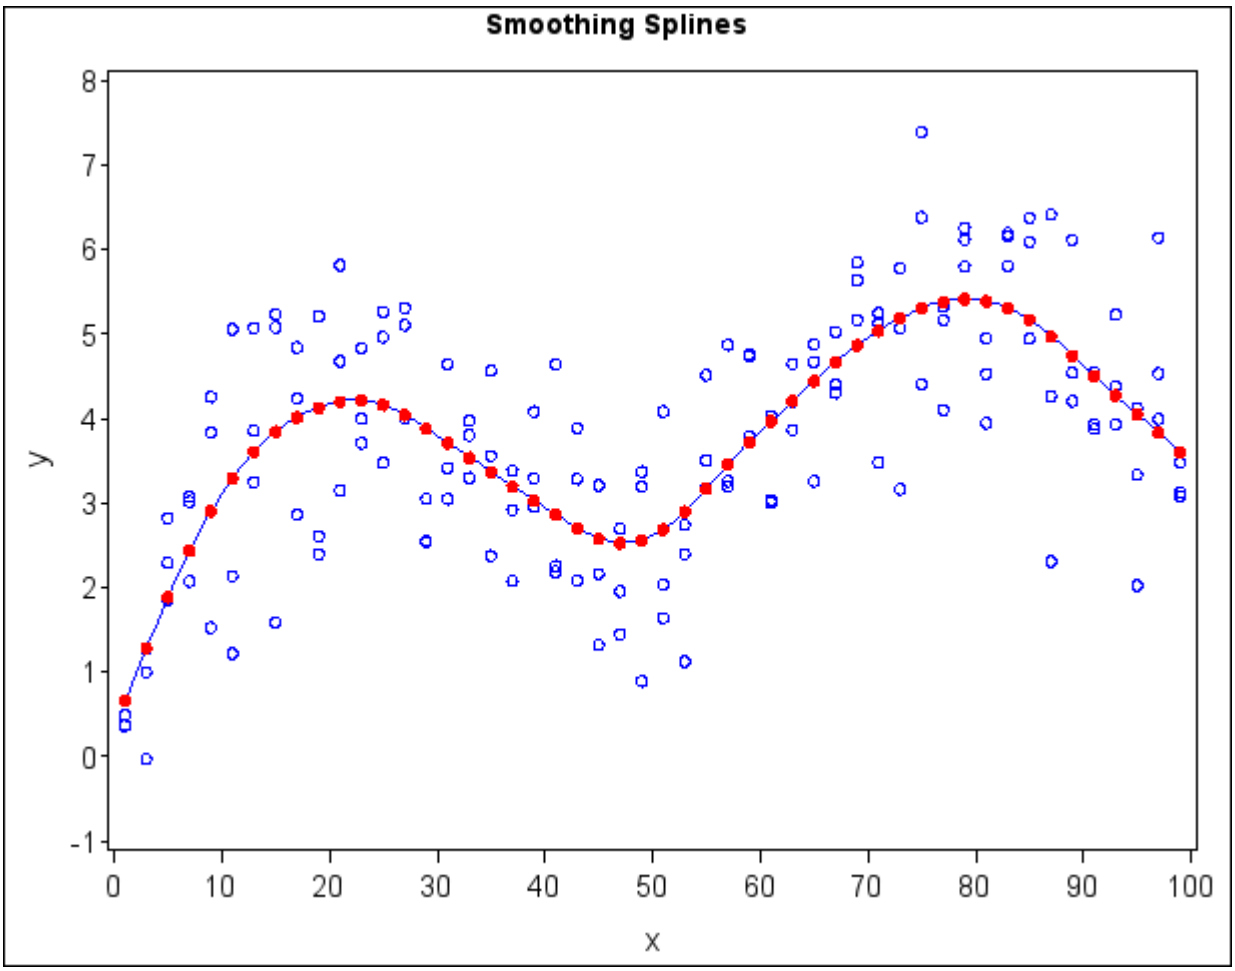

Figure 90.42 Smoothing Spline Created by PROC TRANSREG and PROC GPLOT, Overlaid

You can plot multiple nonlinear functions, one for each of several groups as defined by the levels of a CLASS variable. When you cross a SMOOTH variable with a CLASS variable, specify ZERO=NONE with the CLASS expansion. The following statements create artificial data and produce Figure 90.43:

```
title2 'Two Groups';

data x;
   do x = 1 to 100;
      Group = 1;
      do rep = 1 to 3;
         y = log(x) + sin(x / 10) + normal(7);
         output;
      end;
      group = 2;
      do rep = 1 to 3;
         y = -log(x) + cos(x / 10) + normal(7);
         output;
      end;
   end;
run;
```

```
proc transreg ss2 data=x;
   model identity(y) = class(group / zero=none) *
                       smooth(x / sm=50);
   output p;
run;

ods graphics off;
```

The ANOVA table in Figure 90.43 shows the overall model fit. The degrees of freedom are based on the trace of the transformation hat matrix, and are typically not integers. The "Smooth Transformation" table reports the degrees of freedom for each term, which includes an intercept for each group; the regression coefficients, which are always 1 with smoothing splines; the 0 to 100 smoothing parameter (like the one PROC GPLOT uses); the actual computed smoothing parameter; and the name and label for each term.

Figure 90.43 *continued*

The SMOOTH transformation is valid only with independent variables. Typically, it is used only, as in the two preceding examples, in models with a single dependent variable, a single independent variable, and optionally, a single classification variable that is crossed with the independent variable. The various standardization options such as TSTANDARD=, CENTER, Z, and REFLECT are by default not permitted when the SMOOTH transformation is part of the model.

The SMOOTH transformation can also be used in other ways, but only when you specify the NSR *a-option*. The requirement that you specify the NSR *a-option* is new with this release. (See the section "Smoothing Splines Changes and Enhancements" on page 7227.) When you specify the NSR *a-option*, and there are multiple independent variables designated as SMOOTH, PROC TRANSREG

tries to smooth the *i*th independent variable by using the *i*th dependent variable as a target. When there are more independent variables than dependent variables, the last dependent variable is reused as often as is necessary. For example, consider the following statements:

```
proc transreg nsr;
   model identity(y1-y3) = smooth(x1-x5);
   run;
```

Smoothing is based on the pairs (y1, x1), (y2, x2), (y3, x3), (y3, x4), and (y3, x5).

The SMOOTH transformation is a noniterative transformation. The smoothing of each variable occurs before the iterations begin. In contrast, SSPLINE provides an iterative smoothing spline transformation. It does not generally minimize squared error; hence, divergence is possible with SSPLINE.

Smoothing Splines Changes and Enhancements

The SMOOTH or smoothing spline transformation is the same as it has always been. However, how the results of the transformation are processed in PROC TRANSREG has changed with this release. In particular, some aspects of the syntax along the coefficients and predicted values have changed. The new behavior was required to make the smoothing splines work properly with ODS Graphics and to make SMOOTH work consistently with the new PBSPLINE (penalized B-spline; see the section "Penalized B-Splines" on page 7219) capabilities. However, you can use the new NSR *a-option*, if you want the old functionality. Here are two typical uses of the SMOOTH transformation:

```
proc transreg;
   model identity(y) = smooth(x / sm=50);
   output p;
run;

proc transreg;
   model identity(y) = class(group / zero=none) * smooth(x / sm=50);
   output p;
run;
```

For the first model, the variable x is smoothly transformed by using a smoothing parameter of SM=50, and the results are stored in the transformed variable Tx. The second model has two groups of observations corresponding to group=1 and Group=2. Separate curves are fit through each group. The results for the first group are stored in the transformed variable TGroup1x, and the results for the second group are stored in the transformed variable TGroup2x. The predicted values are stored in Py. In the first case, Py = Tx, and in the second case, Py = TGroup1x + TGroup2x. These represent the two standard usages of the SMOOTH transformation, and you can use ODS Graphics to display fit plots with a single or multiple smooth functions. For the first model, which is the most typical usage, the syntax has not changed, nor has the transformed variable. For the second model, the syntax has slightly changed, but the transformed variables have not. The details of the syntax changes are discussed later in this section. The primary change involves what happens after the SMOOTH transformation is found. Now, by default, ordinary least squares (OLS) is no longer used to find the coefficients when there are smooth transformations, and in the iteration history table the OLS R square is no longer produced.

Here is some background for the change. The first three of the four models shown next have much in common:

```
model identity(y) = smooth(x / sm=50);
model identity(y) = rank(x);
model identity(y) = log(x);
model identity(y) = spline(x);
```

Previously, the SMOOTH, RANK, and LOG transformations all requested that PROC TRANSREG preprocess the data, nonlinearly transforming x before using OLS to fit a model to the preprocessed results. All of these first three transformations of x are nonoptimal in the sense that none of them is based in any way on the OLS regression model that follows the preprocessing of the data. In contrast, the fourth model requests a spline transformation. In this model, both the nonlinear transformation and the final regression model seek to minimize the same OLS criterion. Some PROC TRANSREG transformations, such as SPLINE, MSPLINE, OPSCORE, MONOTONE, and so on, seek to minimize squared error, whereas others, such as SMOOTH, LOG, EXP, and RANK, do not. For the latter, the data are simply preprocessed before analysis. There is a philosophical difference, however, between SMOOTH and the nonoptimal transformations. The SMOOTH and PBSPLINE transformations use the dependent variable and a model (but not OLS) to compute the transformation, whereas LOG, EXP, RANK, and the other nonoptimal transformations do not. A log transformation, for example, would be the same, regardless of context, whereas the SMOOTH and PBSPLINE transformations depend on the model.

The principal change to SMOOTH, with this release of PROC TRANSREG, involves making PROC TRANSREG aware of the underlying smoothing spline model. This makes SMOOTH and PBSPLINE perform similarly, and less like LOG, EXP, RANK, and the other nonoptimal transformations. Previously, if you specified SMOOTH and then examined the regression coefficients, you would probably get an intercept very close to but not exactly 0, and the remaining coefficients would be very close to but not exactly 1. This is because PROC TRANSREG was using OLS to find the coefficients. This has changed. Now, PROC TRANSREG recognizes that the SMOOTH transformation has an implicit intercept (see the section "Implicit and Explicit Intercepts" on page 7254); hence there is no separate intercept. Furthermore, now the other parameters are exactly 1, which are the correct parameters for the non-OLS smoothing spline model. Hence, the predicted values are now the sum of the transformed variables. When there is no CLASS variable, the predicted values exactly match the transformed variable. The SMOOTH transformation is no longer a form of preprocessing; it now changes the nature of the model from OLS to a true smoothing-spline model. If you still want the old behavior, preprocessing and then OLS, you can get the old default functionality by specifying the NSR *a-option*.

The new, default functionality assumes that you either want to fit a smooth function through the data or fit separate functions, one for each level of a CLASS variable. It also recognizes the smoothing-spline model as a model with an implicit intercept. For these reasons, the syntax for models with a CLASS variable has slightly changed, as is shown next:

```
proc transreg nsr; /* old */
   model identity(y) = class(group / zero=none) |
                       smooth(x / after sm=50);
   output p;
run;

proc transreg; /* new */
   model identity(y) = class(group / zero=none) *
                       smooth(x / sm=50);
   output p;
run;
```

Previously, the AFTER *t-option* was required when you wanted to fit separate and independent functions within each group. This *t-option* specifies that PROC TRANSREG should find the smoothing spline transformations *after* it crosses the independent variable with the CLASS variable. Previously, by default, PROC TRANSREG found an overall smooth transformation and then crossed it with the CLASS variable, which is probably not what you want. You can still specify the AFTER *t-option*, but now it is assumed with CLASS * SMOOTH. If you specify AFTER without the NSR *a-option*, PROC TRANSREG suppresses the note that AFTER is assumed. It does not affect the model. If you do not want AFTER to be in effect by default, you must specify the NSR *a-option*. Also previously, you typically needed to specify the vertical bar instead of the asterisk to cross the CLASS and SMOOTH variables. The difference is that the bar adds both crossed variables and separate group intercepts to the model, whereas the asterisk adds only the crossed variables to the model. Since the SMOOTH transformation is now recognized as providing an implicit intercept, you should use the asterisk and not the vertical bar.

The default behavior of the SMOOTH transformation needed to change for several reasons. SMOOTH was originally provided as nothing more than a way to get PROC GPLOT's smoothing splines into an output data set in the transformed variables. However, with new enhancements to PROC TRANSREG such as ODS Graphics and PBSPLINE, the old method for SMOOTH did not fit well. The old method produced predicted values that were not the correct values to plot in order to show the smoothing spline fit. Now, with this change, ODS Graphics can always plot the predicted values. Also, PBSPLINE is new with this release; it and SMOOTH are similar in spirit, and for both, OLS results are not truly appropriate. Previously, PROC TRANSREG fit linear models, linear models with nonlinearly preprocessed variables, and linear models with optimal nonlinear transformations that minimized squared error. Now it also has the ability to fit non-OLS models for scatter plot smoothing.

One aspect of the SMOOTH transformation has unconditionally changed with this release. Previously, PROC TRANSREG did not evaluate the effective degrees of freedom by examining the trace of the transformation hat matrix. It simply used the number of categories in the *df* calculations, which for continuous variables is the number of observations. This made it impossible to get a sensible ANOVA test for the overall fit. With this release, the degrees of freedom are always based on the trace. This *df* change also affects the SSPLINE transformation, which finds a smooth transformation by using the same algorithm as SMOOTH. The difference is that the SMOOTH transformation occurs once, as an analysis preprocessing step, whereas SSPLINE transformations occur iteratively and in the body of the alternating least-squares algorithm.

Iteration History Changes and Enhancements

With this release, PROC TRANSREG no longer always prints an iteration history table by default, and in some cases, the table it prints is not the same as it was previously. This change is due to the increasing use of PROC TRANSREG with transformations that are not based on alternating least squares. Here is some background for the change. PROC TRANSREG's processing can be divided into three steps. In the first step, the data are read and certain transformations, such as SMOOTH, PBSPLINE, BOXCOX, RANK, LOG and the other nonoptimal transformations, are performed. These transformations are not based on OLS. In the second step, the alternating-least-squares iterations are performed according to METHOD=UNIVARIATE, MORALS, REDUNDANCY, or CANALS. It is in the second step that the alternating-least-squares transformations (SPLINE, MSPLINE, MONOTONE, OPSCORE, LINEAR, and UNTIE) are iteratively found. In the third step, the results are displayed. In some cases, the results are appropriately based on using the method of OLS applied to the optimally transformed variables. In other cases, such as with smoothing splines and penalized B-splines, OLS-based results are not appropriate. Furthermore, for many of these types of models, nothing changes in the iterations, so the computations needed to realize that nothing changes are not needed, nor is the iteration history table.

With this release, the iteration history is not printed for models where it is known that nothing will change in the iterations. Suppose the NOMISS option is specified or there are no missing data. If METHOD=UNIVARIATE, if there are no iterative transformations (SPLINE, MSPLINE, MONOTONE, OPSCORE, LINEAR, and UNTIE), and if the MAXITER= option is not specified, then by default, an iteration history table is not produced. If you want to see an iteration history, there are many things you can do, such as specifying MAXITER=, changing the method to MORALS, or changing IDENTITY to LINEAR.

With models with smoothing splines or penalized B-splines, the iteration history will not contain an R square. This is because the iterations are based on the method of alternating least squares, but the smoothing splines and penalized B-splines are not based on a least-squares model. Hence, an ordinary R square in the iterations, based on a computed intercept, which is typically not exactly zero, and a computed slope, which is typically not exactly one, will not be exactly the same as the correct R square, which is based on an intercept and slope of zero and one. The final reported results include the correct R square in the fit statistics table after the ANOVA table. If you want to see only the correct R square from the results, without the iteration history, you can specify the new RSQUARE option.

ANOVA Codings

This section illustrates several different codings of classification variables and hence several different ways of fitting two-way ANOVA models to some data. Each example fits an ANOVA model, displays the ANOVA table and parameter estimates, and displays the coded design matrix. Note throughout that the ANOVA tables and R squares are identical for all of the models, showing that the codings are equivalent. For each model, the parameter estimates are stated as a function of the cell means. The formulas are appropriate for a design such as this one, which is balanced and

orthogonal (every level and every pair of levels occurs equally often). They will not work with unequal frequencies. Since this data set has $3 \times 2 = 6$ cells, the full-rank codings all have six parameters. The following statements create the input data set, and display it in Figure 90.44:

```
title 'Two-Way ANOVA Models';

data x;
   input a b @@;
   do i = 1 to 2; input y @@; output; end;
   drop i;

Class.a3b2	1	1.0000000	6.00	6.00	0.41	0.5461	a 3 * b 2

The sum of the regression table DF's, minus one for the intercept, will be greater than the model df when there are ZERO=SUM constraints.

The parameter estimates are

$$
\begin{aligned}
\hat{\mu} &= \overline{y} = 13.3333 \\
\hat{\alpha}_1 &= (\overline{y}_{11} + \overline{y}_{12})/2 - \overline{y} = (15 + 14)/2 - 13.3333 = 1.1667 \\
\hat{\alpha}_2 &= (\overline{y}_{21} + \overline{y}_{22})/2 - \overline{y} = (5 + 16)/2 - 13.3333 = -2.8333 \\
\hat{\alpha}_3 &= (\overline{y}_{31} + \overline{y}_{32})/2 - \overline{y} = (11 + 19)/2 - 13.3333 = 1.6667 \\
\hat{\beta}_1 &= (\overline{y}_{11} + \overline{y}_{21} + \overline{y}_{31})/3 - \overline{y} = (15 + 5 + 11)/3 - 13.3333 = -3 \\
\hat{\beta}_2 &= (\overline{y}_{12} + \overline{y}_{22} + \overline{y}_{32})/3 - \overline{y} = (14 + 16 + 19)/3 - 13.3333 = 3 \\
\hat{\gamma}_{11} &= \overline{y}_{11} - (\overline{y} + \hat{\alpha}_1 + \hat{\beta}_1) = 15 - (13.3333 + 1.1667 + -3) = 3.5 \\
\hat{\gamma}_{12} &= \overline{y}_{12} - (\overline{y} + \hat{\alpha}_1 + \hat{\beta}_2) = 14 - (13.3333 + 1.1667 + 3) = -3.5 \\
\hat{\gamma}_{21} &= \overline{y}_{21} - (\overline{y} + \hat{\alpha}_2 + \hat{\beta}_1) = 5 - (13.3333 + -2.8333 + -3) = -2.5 \\
\hat{\gamma}_{22} &= \overline{y}_{22} - (\overline{y} + \hat{\alpha}_2 + \hat{\beta}_2) = 16 - (13.3333 + -2.8333 + 3) = 2.5 \\
\hat{\gamma}_{31} &= \overline{y}_{31} - (\overline{y} + \hat{\alpha}_3 + \hat{\beta}_1) = 11 - (13.3333 + 1.6667 + -3) = -1 \\
\hat{\gamma}_{32} &= \overline{y}_{32} - (\overline{y} + \hat{\alpha}_3 + \hat{\beta}_2) = 19 - (13.3333 + 1.6667 + 3) = 1
\end{aligned}
$$

The constraints are

$$\alpha_1 + \alpha_2 + \alpha_3 \equiv \beta_1 + \beta_2 \equiv 0$$

$$\gamma_{11} + \gamma_{12} \equiv \gamma_{21} + \gamma_{22} \equiv \gamma_{31} + \gamma_{32} \equiv \gamma_{11} + \gamma_{21} + \gamma_{31} \equiv \gamma_{12} + \gamma_{22} + \gamma_{32} \equiv 0$$

Only four of the five interaction constraints are needed. The fifth constraint is implied by the other four. (Given a 2×3 table with four marginal sum-to-zero constraints, you can freely fill in only two cells. The values in the other four cells are determined from the first two cells and the constraints.) A full-rank model has six estimable parameters. This less-than-full-rank model has one parameter for the intercept, two for the first main effect (plus one more as determined by the first constraint),

one for the second main effect (plus one more as determined by the second constraint), and two for the interactions (plus four more as determined by the next four constraints). Six of the twelve parameters are determined given the other six and the constraints. Notice that $\hat{\mu}, \hat{\alpha}_1, \hat{\alpha}_2, \hat{\beta}_1, \hat{\gamma}_{11}$, and $\hat{\gamma}_{21}$ match the corresponding estimates from the effects coding.

\end{aligned}
$$

The numerators in the square roots are sums of squares of the coded values for the unstandardized-orthogonal codings, and the denominators are the numbers of levels. These terms convert the estimates from the orthogonal contrast coding to the standardized-orthogonal coding. The term $\sqrt{2/2}$, which is 1 and could be dropped, is included in the preceding formulas to show the general pattern. Notice the regression tables for the orthogonal-contrast coding and the standardized-orthogonal coding. Some of the coefficients are different, but the rest of the table is the same since the coded variables for the two models differ only by a constant.

Missing Values

PROC TRANSREG can estimate missing values, with or without category or monotonicity constraints, so that the regression model fit is optimized. Several approaches to missing data handling are provided. All observations with missing values in IDENTITY, CLASS, POINT, EPOINT, QPOINT, SMOOTH, PBSPLINE, PSPLINE, and BSPLINE variables are excluded from the analysis. When METHOD=UNIVARIATE (specified in the PROC TRANSREG or MODEL statement), observations with missing values in any of the independent variables are excluded from the analysis. When you specify the NOMISS *a-option*, observations with missing values in the other analysis variables are excluded. Otherwise, missing data are estimated, and the variable means are the initial estimates.

You can specify the LINEAR, OPSCORE, MONOTONE, UNTIE, SPLINE, MSPLINE, SSPLINE, LOG, LOGIT, POWER, ARSIN, BOXCOX, RANK, and EXP transformations in any combination with nonmissing values, ordinary missing values, and special missing values, as long as the nonmissing values in each variable have positive variance. No category or order restrictions are placed on the estimates of ordinary missing values. You can force missing value estimates within a variable to be identical by using special missing values (see "DATA Step Processing" in *SAS Language Reference: Concepts*. You can specify up to 27 categories of missing values, in which within-category estimates must be the same, by coding the missing values with ._ and .A through .Z.

You can also specify an ordering of some missing value estimates. You can use the MONOTONE= *a-option* in the PROC TRANSREG or MODEL statement to indicate a range of special missing values (a subset of the list from .A to .Z) with estimates that must be weakly ordered within each variable in which they appear. For example, if MONOTONE=AI, the nine classes, .A, .B, . . . , .I, are monotonically scored and optimally scaled just as MONOTONE transformation values are scored. In this case, category but not order restrictions are placed on the missing values ._ and .J through .Z. You can also use the UNTIE= *a-option* (in the PROC TRANSREG or MODEL statement) to indicate a range of special missing values with estimates that must be weakly ordered within each variable in which they appear but can be untied.

The missing value estimation facilities enable you to have partitioned or mixed-type variables. For example, a variable can be considered part nominal and part ordinal. Nominal classes of otherwise ordinal variables are coded with special missing values. This feature can be useful with survey research. The class "unfamiliar with the product" in the variable "Rate your preference for 'Brand X' on a 1 to 9 scale, or if you are unfamiliar with the product, check 'unfamiliar with the product"' is an example. You can code "unfamiliar with the product" as a special missing value, such as .A. The 1s to 9s can be monotonically transformed, while no monotonic restrictions are placed on the quantification of the "unfamiliar with the product" class.

A variable specified for a LINEAR transformation, with special missing values and ordered categorical missing values, can be part interval, part ordinal, and part nominal. A variable specified for a MONOTONE transformation can have two independent ordinal parts. A variable specified for an UNTIE transformation can have an ordered categorical part and an ordered part without category restrictions. Many other mixes are possible.

Missing Values, UNTIE, and Hypothesis Tests

PROC TRANSREG can estimate missing data and monotonically transform variables while untying tied values. Estimates of ordinary missing values (.) are all permitted to be different. Analyses with UNTIE transformations, the UNTIE= *a-option*, and ordinary missing data estimation are all prone to degeneracy problems. Consider the following example. A perfect fit is found by collapsing all observations except the one with two missing values into a single value in y and x1. The following statements produce Figure 90.61:

```
title 'Missing Data';

data x;
   input y x1 x2 @@;
   datalines;
1 3 7    8 3 9    1 8 6    . . 9    3 3 9

10	SCORE	ROW10	.	2.7680	1	9	1	1	5.1233	1

Generally, the use of ordinary missing data estimation, the UNTIE transformation, and the UNTIE= *a-option* should be avoided, particularly with hypothesis tests. With these options, parameters are estimated based on only a single observation, and they can exert tremendous influence over the results. Each of these parameters has one model degree of freedom associated with it, so small or zero error degrees of freedom can also be a problem.

Controlling the Number of Iterations

Several *a-options* in the PROC TRANSREG or MODEL statement control the number of iterations performed. Iteration terminates when any one of the following conditions is satisfied:

- The number of iterations equals the value of the MAXITER= *a-option*.
- The average absolute change in variable scores from one iteration to the next is less than the value of the CONVERGE= *a-option*.
- The criterion change is less than the value of the CCONVERGE= *a-option*.

You can specify negative values for either convergence *a-option* if you want to define convergence only in terms of the other option. The criterion change can become negative when the data have converged, so it is numerically impossible, within machine precision, to increase the criterion. Usually, a negative criterion change is the result of very small amounts of rounding error, since the algorithms are (usually) convergent. However, there are cases where a negative criterion change is a sign of divergence, which is not necessarily an error. When you specify an SSPLINE transformation or the REITERATE or SOLVE *a-option*, divergence is perfectly normal.

When there are no monotonicity constraints and there is only one canonical variable in each set, PROC TRANSREG (with the SOLVE *a-option*) can usually find the optimal solution in only one iteration. (There are no monotonicity constraints when none of the following is specified: MONOTONE, MSPLINE, or UNTIE transformation or the UNTIE= or MONOTONE= *a-option*. There is only one canonical variable in each set when METHOD=MORALS or METHOD=UNIVARIATE, or when METHOD=REDUNDANCY with only one dependent variable, or when METHOD=CANALS and NCAN=1.)

The initialization iteration is number 0. When there are no monotonicity constraints and there is only one canonical variable in each set, the next iteration shows no change, and iteration stops. At least two iterations (0 and 1) are performed with the SOLVE *a-option* even if nothing changes in iteration 0. The MONOTONE, MSPLINE, and UNTIE variables are not transformed by the canonical initialization. Note that divergence with the SOLVE *a-option*, particularly in the second iteration, is not an error. The initialization iteration is slower and uses more memory than other iterations. However, for many models, specifying the SOLVE *a-option* can greatly decrease the amount of time required to find the optimal transformations.

You can increase the number of iterations to ensure convergence by increasing the value of the MAXITER= *a-option* and decreasing the value of the CONVERGE= *a-option*. Since the average absolute change in standardized variable scores seldom decreases below 1E–11, you should not specify a value for the CONVERGE= *a-option* less than 1E–8 or 1E–10. Most of the data changes occur during the first few iterations, but the data can still change after 50 or even 100 iterations. You can try different combinations of values for the CONVERGE= and MAXITER= *a-options* to ensure convergence without extreme overiteration. If the data do not converge with the default specifications, try CONVERGE=1E–8 and MAXITER=50, or CONVERGE=1E–10 and MAXITER=200. Note that you can specify the REITERATE *a-option* to start iterating where the previous analysis stopped.

Using the REITERATE Algorithm Option

You can use the REITERATE *a-option* to perform additional iterations when PROC TRANSREG stops before the data have adequately converged. For example, suppose that you execute the following step:

```
proc transreg data=a;
   model mspline(y) = mspline(x1-x5);
   output out=b coefficients;
run;
```

If the transformations do not converge in the default 30 iterations, you can perform more iterations without repeating the first 30 iterations, as follows:

```
proc transreg data=b reiterate;
   model mspline(y) = mspline(x1-x5);
   output out=b coefficients;
run;
```

Note that a WHERE statement is not necessary to exclude the coefficient observations. They are automatically excluded because their _TYPE_ value is not SCORE.

You can also use the REITERATE *a-option* to specify starting values other than the original values for the transformations. Providing alternate starting points might help avoid local optima. Here are two examples:

```
proc transreg data=a;
   model rank(y) = rank(x1-x5);
   output out=b;
run;

proc transreg data=b reiterate;
   /* Use ranks as the starting point. */
   model mspline(y) = mspline(x1-x5);
   output out=c coefficients;
run;

data b;
   set a;
   array tx[6] ty tx1-tx5;
   do j = 1 to 6;
      tx[j] = normal(7);
   end;
run;

proc transreg data=b reiterate;
   /* Use a random starting point. */
   model mspline(y) = mspline(x1-x5);
   output out=c coefficients;
run;
```

Note that divergence with the REITERATE *a-option*, particularly in the second iteration, is not an error since the initial transformation is not required to be a valid member of the transformation family. When you specify the REITERATE *a-option*, the iteration does not terminate when the criterion change is negative during the first 10 iterations.

Avoiding Constant Transformations

There are times when the optimal scaling produces a constant transformed variable. This can happen with the MONOTONE, UNTIE, and MSPLINE transformations when the target is negatively correlated with the original input variable. It can happen with all transformations when the target is uncorrelated with the original input variable. When this happens, the procedure modifies the target to avoid a constant transformation. This strategy avoids certain nonoptimal solutions.

If the transformation is monotonic and a constant transformed variable results, the procedure multiplies the target by –1 and tries the optimal scaling again. If the transformation is not monotonic or if the multiplication by –1 did not help, the procedure tries using a random target. If the transformation is still constant, the previous nonconstant transformation is retained. When a constant transformation is avoided by any strategy, this message is displayed: "A constant transformation was avoided for *name*."

With extreme collinearity, small amounts of rounding error might interact with the instability of the coefficients to produce target vectors that are not positively correlated with the original scaling. If a regression coefficient for a variable is zero, the formula for the target for that variable contains a zero divide. In a multiple regression model, after many iterations, one independent variable can be scaled the same way as the current scaling of the dependent variable, so the other independent variables have coefficients of zero. When the constant transformation warning appears, you should interpret your results with extreme caution, and recheck your model.

Constant Variables

Constant and almost constant variables are zeroed and ignored. When constant variables are expected and should not be zeroed, specify the NOZEROCONSTANT *a-option*.

Character OPSCORE Variables

Character OPSCORE variables are replaced by a numeric variable containing category numbers before the iterations, and the character values are discarded. Only the first eight characters are considered in determining category membership. If you want the original character variable in the output data set, give it a different name in the OPSCORE specification (OPSCORE(x / name=(x2)) and name the original variable in the ID statement (ID x;).

Convergence and Degeneracies

When you specify the SSPLINE transformation, divergence is normal. The rest of this section assumes that you did not specify SSPLINE. For all the methods available in PROC TRANSREG, the algorithms are convergent, in terms of both the criterion being optimized and the parameters being estimated. The value of the criterion being maximized (squared multiple correlation, average squared multiple correlation, or average squared canonical correlation) can, theoretically, never decrease from one iteration to the next. The values of the parameters being solved for (the scores and weights of the transformed variables) become stable after sufficient iteration.

In practice, the criterion being maximized can decrease with overiteration. When the statistic has very nearly reached its maximum, further iterations might report a decrease in the criterion in the last few decimal places. This is a normal result of very small amounts of rounding error. By default, iteration terminates when this occurs because, by default, CCONVERGE=0.0. Specifying CCONVERGE=–1, an impossible change, turns off this check for convergence.

Even though the algorithms are convergent, they might not converge to a global optimum. Also, under extreme circumstances, the solution might degenerate. Because two points always form a straight line, the algorithms sometimes try to reach this degenerate optimum. This sometimes occurs when one observation is an ordinal outlier (when one observation has the extreme rank on all variables). The algorithm can reach an optimal solution that ties all other categories producing two points. Similar results can occur when there are many missing values. More generally, whenever there are very few constraints on the scoring of one or more points, degeneracies can be a problem. In a well-behaved analysis, the maximum data change, average data change, and criterion change all decrease at a rapid rate with each iteration. When the rate of change increases for several iterations, the solution might be degenerating.

Implicit and Explicit Intercepts

Depending on several options, the model intercept is nonzero, zero, or implicit, or there is no intercept. Ordinarily, the model contains an explicit nonzero intercept, and the Intercept variable in the OUT= data set contains ones. When TSTANDARD=CENTER or TSTANDARD=Z is specified, the model contains an explicit, zero intercept and the Intercept variable contains zeros. When METHOD=CANALS, the model is fit with centered variables and the Intercept variable is set to missing.

If you specify CLASS with ZERO=NONE or BSPLINE for one or more independent variables, and TSTANDARD=NOMISS or TSTANDARD=ORIGINAL (the default), an implicit intercept model is fit. The intercept is implicit in a set of the independent variables since there exists a set of independent variables the sum of which is a column of ones. All statistics are mean corrected. The implicit intercept is not an option; it is implied by the model. Specifying SMOOTH or PBSPLINE also implies an implicit intercept model.

With METHOD=CANALS, the Intercept variable contains the *canonical intercept* for canonical coefficients observations: $\hat{\beta}_0 = \bar{\mathbf{y}}'\hat{\boldsymbol{\alpha}} - \bar{\mathbf{x}}'\hat{\boldsymbol{\beta}}$ where $\mathbf{Y}\hat{\boldsymbol{\alpha}} \approx \mathbf{X}\hat{\boldsymbol{\beta}}$.

Passive Observations

Observations can be excluded from the analysis for several reasons; these include zero weight; zero frequency; missing values in variables designated IDENTITY, CLASS, POINT, EPOINT, QPOINT, SMOOTH, PBSPLINE, PSPLINE, or BSPLINE; and missing values with the NOMISS *a-option* specified. These observations are passive in that they do not contribute to determining transformations, R square, sums of squares, degrees of freedom, and so on. However, some information can be computed for them. For example, if no independent variable values are missing, predicted values and redundancy variable values can both be computed. Residuals can be computed for observations with a nonmissing dependent and nonmissing predicted value. Canonical variables for dependent variables can be computed when no dependent variables are missing; canonical variables for independent variables can be computed when no independent variables are missing, and so on. Passive observations in the OUT= data set have a blank value for _TYPE_.

Point Models

The expanded set of independent variables generated from the POINT, EPOINT, and QPOINT expansions can be used to perform ideal point regressions (Carroll 1972) and compute ideal point coordinates for plotting in a biplot (Gabriel 1981). The three types of ideal point coordinates can all be described as transformed coefficients. Assume that m independent variables are specified in one of the three point expansions. Let $\mathbf{b}'$ be a $1 \times m$ row vector of coefficients for these variables and one of the dependent variables. Let $\mathbf{R}$ be a matrix created from the coefficients of the extra variables. When coordinates are requested with the MPC, MEC, or MQC *o-option*, $\mathbf{b}'$ and $\mathbf{R}$ are created from multiple regression coefficients. When coordinates are requested with the CPC, CEC, or CQC *o-option*, $\mathbf{b}'$ and $\mathbf{R}$ are created from canonical coefficients.

If you specify the POINT expansion in the MODEL statement, $\mathbf{R}$ is an $m \times m$ identity matrix times the coefficient for the sums of squares (_ISSQ_) variable. If you specify the EPOINT expansion, $\mathbf{R}$ is an $m \times m$ diagonal matrix of coefficients from the squared variables. If you specify the QPOINT expansion, $\mathbf{R}$ is an $m \times m$ symmetric matrix of coefficients from the squared variables on the diagonal and crossproduct variables off the diagonal. The MPC, MEC, MQC, CPC, CEC, and CQC ideal point coordinates are defined as $-0.5\mathbf{b}'\mathbf{R}^{-1}$. When $\mathbf{R}$ is singular, the ideal point coordinates are infinitely far away and are set to missing, so you should try a simpler version of the model. The version that is simpler than the POINT model is the vector model, where no extra variables are created. In the vector model, designate all independent variables as IDENTITY. Then draw vectors from the origin to the COEFFICIENTS points.

Typically, when you request ideal point coordinates, the MODEL statement should consist of a single transformation for the dependent variables (usually IDENTITY, MONOTONE, or MSPLINE) and a single expansion for the independent variables (one of POINT, EPOINT, or QPOINT).

Redundancy Analysis

Redundancy analysis (Stewart and Love 1968) is a principal component analysis of multivariate regression predicted values. These first steps show the redundancy analysis results produced by PROC TRANSREG. The specification TSTANDARD=Z sets all variables to mean zero and variance one. METHOD=REDUNDANCY specifies redundancy analysis and outputs the redundancy variables to the OUT= data set. The MREDUNDANCY *o-option* outputs two sets of redundancy analysis coefficients to the OUT= data set. The following statements produce Figure 90.62:

```
title 'Redundancy Analysis';

The _TYPE_='SCORE' observations of the Red1–Red3 variables contain the redundancy variables. The nonmissing "M REDUND" values are coefficients for predicting the redundancy variables from the independent variables. The nonmissing "R REDUND" values are coefficients for predicting the independent variables from the redundancy variables.

The next steps show how to generate the same results manually. The data set is standardized, predicted values are computed, and principal components of the predicted values are computed. The following statements produce the redundancy variables, shown in Figure 90.63:

```
proc standard data=x out=std m=0 s=1;
   title2 'Manually Generate Redundancy Variables';
run;

proc reg noprint data=std;
   model y1-y3 = x1-x4;
   output out=p p=ay1-ay3;
run; quit;

proc princomp data=p cov noprint std out=p;
   var ay1-ay3;
run;

proc print data=p(keep=Prin:);
   format _numeric_ 4.1;
run;
```

Optimal Scaling

An alternating least-squares optimal scaling algorithm can be divided into two major stages. The first major stage estimates the parameters of the linear model. These parameters are used to create the predicted values or target for each variable that can be transformed. Each target minimizes squared error (as explained in the discussion of the algorithms in *SAS Technical Report R-108*). The definition of the target depends on many factors, such as whether a variable is independent or dependent, which algorithm is used (for example, regression, redundancy, CANALS, or principal components), and so on. The definition of the target is independent of the transformation family you specify for the variable. However, the target values for a variable typically do not fit the prescribed transformation family for the variable. They might not have the right category structure; they might not have the right order; they might not be a linear combination of the columns of a B-spline basis; and so on.

The second major stage is optimal scaling. Optimal scaling can be defined as a possibly constrained, least-squares regression problem. When you specify an optimal transformation, or when missing data are estimated for any variable, the full representation of the variable is not simply a vector; it is a matrix with more than one column. The optimal scaling phase finds the vector that is a linear combination of the columns of this matrix that is closest to the target (in terms of minimum squared error), among those that do not violate any of the constraints imposed by the transformation family. Optimal scaling methods are independent of the data analysis method that generated the target. In all cases, optimal scaling can be accomplished by creating a design matrix based on the original scaling of the variable and the transformation family specified for that variable. The optimally scaled variable is a linear combination of the columns of the design matrix. The coefficients of the linear combination are found by using (possibly constrained) least squares. Many optimal scaling problems are solved without actually constructing design and projection matrices. The next two sections describe the algorithms used by PROC TRANSREG for optimal scaling. The first section discusses optimal scaling for OPSCORE, MONOTONE, UNTIE, and LINEAR transformations, including how missing values are handled. The second section addresses SPLINE and MSPLINE transformations.

OPSCORE, MONOTONE, UNTIE, and LINEAR Transformations

Two vectors of information are needed to produce the optimally scaled variable: the initial variable scaling vector **x** and the target vector **y**. For convenience, both vectors are first sorted on the values of the initial scaling vector. If you request an UNTIE transformation, the target vector is sorted within ties in the initial scaling vector. The normal SAS collating sequence for missing and nonmissing values is used. Sorting simply permits the constraints to be specified in terms of relationships among adjoining coefficients. The sorting process partitions **x** and **y** into missing and nonmissing parts $(\mathbf{x}'_m\mathbf{x}'_n)'$, and $(\mathbf{y}'_m\mathbf{y}'_n)'$.

Next, PROC TRANSREG determines category membership. Every ordinary missing value (.) forms a separate category. (Three ordinary missing values form three categories.) Every special missing value within the range specified in the UNTIE= *a-option* forms a separate category. (If UNTIE= BC and there are three .B and two .C missing values, five categories are formed from them.) For all other special missing values, a separate category is formed for each different value. (If there are four .A missing values, one category is formed from them.)

Each distinct nonmissing value forms a separate category for OPSCORE and MONOTONE transformations (1 1 1 2 2 3 form three categories). Each nonmissing value forms a separate category for all other transformations (1 1 1 2 2 3 form six categories). When category membership is determined, category means are computed. Here is an example:

x:	**(. . .A .A .B 1 1 1 2 2 3 3 3 4)′**
y:	**(5 6 2 4 2 1 2 3 4 6 4 5 6 7)′**
OPSCORE and MONOTONE means:	**(5 6 3 2 2 5 5 7)′**
other means:	**(5 6 3 2 1 2 3 4 6 4 5 6 7)′**

The category means are the coefficients of a category indicator design matrix. The category means are the Fisher (1938) optimal scores. For MONOTONE and UNTIE transformations, order constraints are imposed on the category means for the nonmissing partition by merging categories that are out of order. The algorithm checks upward until an order violation is found, and then averages downward until the order violation is averaged away. (The average of $\bar{x}_1$ computed from n_1 observations and $\bar{x}_2$ computed from n_2 observations is $(n_1\bar{x}_1 + n_2\bar{x}_2)/(n_1 + n_2)$.) The MONOTONE algorithm (Kruskal 1964, secondary approach to ties) for this example with means for the nonmissing values (2 5 5 7)′ would do the following checks: $2 < 5$: OK, $5 = 5$: OK, $5 < 7$: OK. The means are in the proper order, so no work is needed.

The UNTIE transformation (Kruskal 1964, primary approach to ties) uses the same algorithm on the means of the nonmissing values (1 2 3 4 6 4 5 6 7)′ but with different results for this example: $1 < 2$: OK, $2 < 3$: OK, $3 < 4$: OK, $4 < 6$: OK, $6 > 4$: average 6 and 4 and replace 6 and 4 by the average. The new means of the nonmissing values are (1 2 3 4 5 5 5 6 7)′. The check resumes: $4 < 5$: OK, $5 = 5$: OK, $5 = 5$: OK, $5 < 6$: OK, $6 < 7$: OK. If some of the special missing values are ordered, the upward-checking, downward-averaging algorithm is applied to them also, independently of the other missing and nonmissing partitions. When the means conform to any required category or order constraints, an optimally scaled vector is produced from the means. The following example results from a MONOTONE transformation:

x:	(. . .A .A .B 1 1 1 2 2 3 3 3 4)′
y:	(5 6 2 4 2 1 2 3 4 6 4 5 6 7)′
result:	(5 6 3 3 2 2 2 2 5 5 5 5 5 7)′

The upward-checking, downward-averaging algorithm is equivalent to creating a category indicator design matrix, solving for least-squares coefficients with order constraints, and then computing the linear combination of design matrix columns.

For the optimal transformation LINEAR and for nonoptimal transformations, missing values are handled as just described. The nonmissing target values are regressed onto the matrix defined by the nonmissing initial scaling values and an intercept. In this example, the target vector $y_n = (1\ 2\ 3\ 4\ 6\ 4\ 5\ 6\ 7)'$ is regressed onto the design matrix

$$\begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 2 & 2 & 3 & 3 & 3 & 4 \end{bmatrix}'$$

Although only a linear transformation is performed, the effect of a linear regression optimal scaling is not eliminated by the later standardization step (unless the variable has no missing values). In the presence of missing values, the linear regression is necessary to minimize squared error.

SPLINE and MSPLINE Transformations

The missing portions of variables subjected to SPLINE or MSPLINE transformations are handled the same way as for OPSCORE, MONOTONE, UNTIE, and LINEAR transformations (see the previous section). The nonmissing partition is handled by first creating a B-spline basis of the specified degree with the specified knots for the nonmissing partition of the initial scaling vector and then regressing the target onto the basis. The optimally scaled vector is a linear combination of the B-spline basis vectors. Ordinary least-squares regression coefficients are used. An algorithm for generating the B-spline basis is given in de Boor (1978, pp. 134–135). B-splines are both a computationally accurate and efficient way of constructing a basis for piecewise polynomials; however, they are not the most natural method of describing splines.

Consider an initial scaling vector $x = (1\ 2\ 3\ 4\ 5\ 6\ 7\ 8\ 9)'$ and a degree-three spline with interior knots at 3.5 and 6.5. The B-spline basis for the transformation is the left matrix, and the natural piecewise polynomial spline basis is the right matrix.

B-Spline Basis

$$\begin{bmatrix} 1.000 & 0.000 & 0.000 & 0.000 & 0 & 0 \\ 0.216 & 0.608 & 0.167 & 0.009 & 0 & 0 \\ 0.008 & 0.458 & 0.461 & 0.073 & 0 & 0 \\ 0 & 0.172 & 0.585 & 0.241 & 0.001 & 0 \\ 0 & 0.037 & 0.463 & 0.463 & 0.037 & 0 \\ 0 & 0.001 & 0.241 & 0.585 & 0.172 & 0 \\ 0 & 0 & 0.073 & 0.461 & 0.458 & 0.008 \\ 0 & 0 & 0.009 & 0.167 & 0.608 & 0.216 \\ 0 & 0 & 0.000 & 0.000 & 0.000 & 1.000 \end{bmatrix}$$

Piecewise Polynomial Splines

$$\begin{bmatrix} 1 & 1 & 1 & 1 & 0 & 0 \\ 1 & 2 & 4 & 8 & 0 & 0 \\ 1 & 3 & 9 & 27 & 0 & 0 \\ 1 & 4 & 16 & 64 & 0.125 & 0 \\ 1 & 5 & 25 & 125 & 3.375 & 0 \\ 1 & 6 & 36 & 216 & 15.625 & 0 \\ 1 & 7 & 49 & 343 & 42.875 & 0.125 \\ 1 & 8 & 64 & 512 & 91.125 & 3.375 \\ 1 & 9 & 81 & 729 & 166.375 & 15.625 \end{bmatrix}$$

The two matrices span the same column space. The natural basis has an intercept, a linear term, a quadratic term, a cubic term, and two more terms since there are two interior knots. These terms are generated (for knot k and **x** element x) by the formula $(x-k)^3 \times I_{(x>k)}$. The indicator variable $I_{(x>k)}$ evaluates to 1.0 if x is greater than k and to 0.0 otherwise. If knot k had been repeated, there would be a $(x-k)^2 \times I_{(x>k)}$ term also. Notice that the fifth column makes no contribution to the curve before 3.5, makes zero contribution at 3.5 (the transformation is continuous), and makes an increasing contribution beyond 3.5. The same pattern of results holds for the last term with knot 6.5. The coefficient of the fifth column represents the change in the cubic portion of the curve after 3.5. The coefficient of the sixth column represents the change in the cubic portion of the curve after 6.5.

The numbers in the B-spline basis do not have a simple interpretation like the numbers in the natural piecewise polynomial basis. The B-spline basis has a diagonally banded structure. The band shifts one column to the right after every knot. The number of entries in each row that can potentially be nonzero is one greater than the degree. The elements within a row always sum to one. The B-spline basis is accurate because of the smallness of the numbers and the lack of extreme collinearity inherent in the natural polynomials. B-splines are efficient because PROC TRANSREG can take advantage of the sparseness of the B-spline basis when it accumulates crossproducts. The number of required multiplications and additions to accumulate the crossproduct matrix does not increase with the number of knots but does increase with the degree of the spline, so it is much more computationally efficient to increase the number of knots than to increase the degree of the polynomial.

MSPLINE transformations are handled like SPLINE transformations except that constraints are placed on the coefficients to ensure monotonicity. When the coefficients of the B-spline basis are monotonically increasing, the transformation is monotonically increasing. When the polynomial degree is two or less, monotone coefficient splines, integrated splines (Winsberg and Ramsay 1980), and the general class of all monotone splines are equivalent.

Specifying the Number of Knots

Keep the number of knots small (usually less than 10, although you can specify more). A degree-three spline with nine knots, one at each decile, can closely follow a large variety of curves. Each spline transformation of degree p with q knots fits a model with $p+q$ parameters. The total number of parameters should be much less than the number of observations. Usually in regression analyses, it is recommended that there be at least five or ten observations for each parameter in order to get stable results. For example, when spline transformations of degree three with nine knots are requested for six variables, the number of observations in the data set should be at least 5 or 10 times 72 (since $6 \times (3+9)$ is the total number of parameters). The overall model can also have a parameter for the intercept and one or more parameters for each nonspline variable in the model.

Increasing the number of knots gives the spline more freedom to bend and follow the data. Increasing the degree also gives the spline more freedom, but to a lesser extent. Specifying a large number of knots is much better than increasing the degree beyond three.

When you specify NKNOTS=q for a variable with n observations, then each of the $q+1$ segments of the spline contains $n/(q+1)$ observations on the average. When you specify KNOTS=number-list,

make sure that there is a reasonable number of observations in each interval.

The following statements find a cubic polynomial transformation of x and no transformation of y:

```
proc transreg;
   model identity(y)$=spline(x);
   output;
run;
```

The following statements find a cubic-spline transformation for x that consists of the weighted sum of a single constant, a single straight line, a quadratic curve for the portion of the variable less than 3.0, a different quadratic curve for the portion greater than 3.0 (since the 3.0 knot is repeated), and a different cubic curve for each of the intervals: (minimum to 1.5), (1.5 to 2.4), (2.4 to 3.0), (3.0 to 4.0), and (4.0 to maximum):

```
proc transreg;
   model identity(y)=spline(x / knots=1.5 2.4 3.0 3.0 4.0);
   output;
run;
```

The transformation is continuous everywhere, its first derivative is continuous everywhere, its second derivative is continuous everywhere except at 3.0, and its third derivative is continuous everywhere except at 1.5, 2.4, 3.0, and 4.0.

The following statements find a quadratic spline transformation that consists of a polynomial $\text{x_t} = b_0 + b_1\text{x} + b_2\text{x}^2$ for the range ($\text{x} < 3.0$) and a completely different polynomial $\text{x_t} = b_3 + b_4\text{x} + b_5\text{x}^2$ for the range ($\text{x} > 3.0$):

```
proc transreg;
   model identity(y)=spline(x / knots=3 3 3 degree=2);
   output;
run;
```

The two curves are not required to be continuous at 3.0.

The following statements categorize y into 10 intervals and find a step-function transformation:

```
proc transreg;
   model identity(y)=spline(x / degree=0 nknots=9);
   output;
run;
```

One aspect of this transformation family is unlike all other optimal transformation families. The initial scaling of the data does not fit the restrictions imposed by the transformation family. This is because the initial variable can be continuous, but a discrete step-function transformation is sought. Zero-degree spline variables are categorized before the first iteration.

The following statements find a continuous, piecewise linear transformation of x:

```
proc transreg;
   model identity(y)=spline(x / degree=1 nknots=8);
   output;
run;
```

SPLINE, BSPLINE, and PSPLINE Comparisons

SPLINE is a transformation. It takes a variable as input and produces a transformed variable as output. Internally, with SPLINE, a B-spline basis is used to find the transformation, which is a linear combination of the columns of the B-spline basis. However, with SPLINE, the basis is not made available in any output.

BSPLINE is an expansion. It takes a variable as input and produces more than one variable as output. The output variables are the same B-spline basis that is used internally by SPLINE.

PSPLINE is an expansion. It takes a variable as input and produces more than one variable as output. The difference between PSPLINE and BSPLINE is that PSPLINE produces a piecewise polynomial, whereas BSPLINE produces a B-spline. A matrix consisting of a piecewise polynomial basis and an intercept spans the same space as the B-spline matrix, but the basis vectors are quite different. The numbers in the piecewise polynomials can get quite large; the numbers in the B-spline basis range between 0 and 1. There are many more zeros in the B-spline basis.

Interchanging SPLINE, BSPLINE, and PSPLINE should have no effect on the fit of the overall model except for the fact that PSPLINE is much more prone to numerical problems. Similarly, interchanging a CLASS expansion and an OPSCORE transformation should have no effect on the fit of the overall model.

Hypothesis Tests

PROC TRANSREG has a set of options for testing hypotheses in models with a single dependent variable. The TEST *a-option* produces an ANOVA table. It tests the null hypothesis that the vector of coefficients for all of the transformations is zero. The SS2 *a-option* produces a regression table with Type II tests of the contribution of each transformation to the overall model. In some cases, exact tests are provided; in other cases, the tests are approximate, liberal, or conservative.

There are two reasons why it is typically not appropriate to test hypotheses by using the output from PROC TRANSREG as input to other procedures such as the REG procedure. First, PROC REG has no way of determining how many degrees of freedom were used for each transformation. Second, the Type II sums of squares for the tests of the individual regression coefficients are not correct for the transformation regression model because PROC REG, as it evaluates the effect of each variable, cannot change the transformations of the other variables. PROC TRANSREG uses the correct degrees of freedom and sums of squares.

In an ordinary univariate linear model, there is one parameter for each independent variable, including the intercept. In the transformation regression model, many of the "variables" are used internally in the bases for the transformations. Each basis column has one parameter or *scoring* coefficient, and each linearly independent column has one model degree of freedom associated with it. Coefficients applied to transformed variables, *model coefficients*, do not enter into the degrees-of-freedom calculations. They are byproducts of the standardizations and can be absorbed into the transformations by specifying the ADDITIVE *a-option*. The word *parameter* is reserved for model and scoring coefficients that have a degree of freedom associated with them.

For expansions, there is one model parameter for each variable created by the expansion (except for all missing CLASS columns and expansions that have an implicit intercept). Each IDENTITY variable has one model parameter. If there are m POINT variables, they expand to $m + 1$ variables and hence have $m + 1$ model parameters. For m EPOINT variables, there are $2m$ model parameters. For m QPOINT variables, there are $m(m + 3)/2$ model parameters. If a variable with m categories is designated CLASS, there are $m - 1$ parameters. For BSPLINE and PSPLINE variables of DEGREE=n with NKNOTS=k, there are $n + k$ parameters. Note that one of the $n + k + 1$ BSPLINE columns and one of the m CLASS(variable / ZERO=NONE) columns are not counted due to the implicit intercept.

There are scoring parameters for missing values in nonexcluded observations. Each ordinary missing value (.) has one scoring parameter. Each different special missing value (._ and .A through .Z) within each variable has one scoring parameter. Missing values specified in the UNTIE= and MONOTONE= options follow the rules for UNTIE and MONOTONE transformations, which are described later in this chapter.

For all nonoptimal transformations (LOG, LOGIT, ARSIN, POWER, EXP, RANK, BOXCOX), there is one parameter per variable in addition to any missing value scoring parameters.

For SPLINE, OPSCORE, and LINEAR transformations, the number of scoring parameters is the number of basis columns that are used internally to find the transformations minus 1 for the intercept. The number of scoring parameters for SPLINE variables is the same as the number of model parameters for BSPLINE and PSPLINE variables. If DEGREE=n and NKNOTS=k, there are $n + k$ scoring parameters. The number of scoring parameters for OPSCORE, SMOOTH, and SSPLINE variables is the same as the number of model parameters for CLASS variables. If there are m categories, there are $m - 1$ scoring parameters. There is one parameter for each LINEAR variable. For SPLINE, OPSCORE, LINEAR, MONOTONE, UNTIE, and MSPLINE transformations, missing value scoring parameters are computed as described previously with the nonoptimal transformations.

The number of scoring parameters for MONOTONE, UNTIE, and MSPLINE transformations is less precise than for SPLINE, OPSCORE, and LINEAR transformations. One way of handling a MONOTONE transformation is to treat it as if it were the same as an OPSCORE transformation. If there are m categories, there are $m - 1$ potential scoring parameters. However, there are typically fewer than $m - 1$ unique parameter estimates, since some of those $m - 1$ scoring parameter estimates might be tied during the optimal scaling to impose the order constraints. Imposing ties on the scoring parameter estimates is equivalent to fitting a model with fewer parameters. So there are two available scoring parameter counts: $m - 1$ and a smaller number that is determined during the analysis. Using $m - 1$ as the model degrees of freedom for MONOTONE variables (treating OPSCORE and MONOTONE transformations the same way) is *conservative*, since the MONOTONE scoring

parameter estimates are more restricted than the OPSCORE scoring parameter estimates. Using the smaller count (the number of scoring parameter estimates that are different, minus 1 for the intercept) in the model degrees of freedom is *liberal*, since the data and the model together are being used to determine the number of parameters. PROC TRANSREG reports tests that use both liberal and conservative degrees of freedom to provide lower and upper bounds on the "true" p-values.

For the UNTIE transformation, the conservative scoring parameter count is the number of distinct observations, whereas the liberal scoring parameter count is the number of scoring parameter estimates that are different, minus 1 for the intercept. Hence, when you specify UNTIE, conservative tests have zero error degrees of freedom unless there are replicated observations.

For MSPLINE variables of DEGREE=n and NKNOTS=k, the conservative scoring parameter count is $n + k$, whereas the liberal parameter count is the number of scoring parameter estimates that are different, minus 1 for the intercept. A liberal degrees of freedom of 1 does not necessarily imply a linear transformation. It implies only that n plus k minus the number of ties imposed equals 1. An example of a one-degree-of-freedom nonlinear transformation is a two-piece linear transformation in which the slope of one piece is 0.

The number of scoring parameters is determined during each iteration. After the last iteration, enough information is available for the TEST *a-option* to produce an ANOVA table that reports the overall fit of the model. If you specify the SS2 *a-option*, further iterations are necessary to test the contribution of each transformation to the overall model.

The liberal tests do not compensate for overparameterization. For example, requesting a spline transformation with k knots when a linear transformation will suffice results in "liberal" tests that are actually conservative because too many degrees of freedom are being used for the transformations. To avoid this problem, use as few knots as possible.

In ordinary multiple regression, an F test of the null hypothesis that the coefficient for variable x_j is zero can be constructed by comparing two linear models. One model is the full model with all parameters, and the other is a reduced model that has all parameters except the parameter for variable x_j. The difference between the model sum of squares for the full model and the model sum of squares for the reduced model is the Type II sum of squares for the test of the null hypothesis that the coefficient for variable x_j is 0. The numerator of the F test has one degree of freedom. The mean square error for the full model is the denominator of the F test of variable x_j. Note that the estimates of the coefficients for the two models are not usually the same. When variable x_j is removed, the coefficients for the other variables change to compensate for the removal of x_j. In a transformation regression model, the transformations of the other variables must be permitted to change and the numerator degrees of freedom are not always ones. It is not correct to simply let the model coefficients for the transformed variables change and apply the new model coefficients to the old transformations computed with the old scoring parameter estimates. In a transformation regression model, further iteration is needed to test each transformation, because all the scoring parameter estimates for other variables must be permitted to change to test the effect of variable x_j. This can be quite time-consuming for a large model if the SOLVE *a-option* cannot be used to solve directly for the transformations.

Output Data Set

The OUT= output data set can contain a great deal of information; however, in most cases, the output data set contains a small portion of the entire range of available information.

Output Data Set Examples

This section provides three brief examples, illustrating some typical OUT= output data sets. See the section "Output Data Set Contents" on page 7272 for a complete list of the contents of the OUT= data set.

The first example shows the output data set from a two-way ANOVA model. The following statements produce Figure 90.66:

```

The CONTENTS Procedure

Variables in Creation Order

#	Variable	Type	Len	Label
1	_TYPE_	Char	8	
2	_NAME_	Char	32	
3	y	Num	8	
4	Py	Num	8	y Predicted Values
5	Ry	Num	8	y Residuals
6	Intercept	Num	8	Intercept
7	x1a	Num	8	x1 a
8	x2a	Num	8	x2 a
9	x1ax2a	Num	8	x1 a * x2 a
10	x1	Char	32	
11	x2	Char	32	

The _TYPE_ variable indicates observation type: score, multiple regression coefficient (parameter estimates), and marginal means. The _NAME_ variable contains the default observation labels, "ROW1", "ROW2", and so on, and contains the dependent variable name (y) for the remaining observations. If you specify an ID statement, _NAME_ contains the values of the first ID variable for score observations. The y variable is the dependent variable, Py contains the predicted values, Ry contains the residuals, and the variables Intercept through x1ax2a contain the design matrix. The x1 and x2 variables are the original CLASS variables.

The next example shows the contents of the output data set from fitting a curve through a scatter plot. The following statements produce Figure 90.67:

```
title 'Output Data Set for Curve Fitting Example';

data a;
   do x = 1 to 100;
      y = log(x) + sin(x / 10) + normal(7);
      output;
   end;
run;

proc transreg;
   model identity(y) = spline(x / nknots=9);
   output predicted out=b;
run;

proc contents position;
   ods select position;
run;

5	Py	Num	8	y Predicted Values
6	Intercept	Num	8	Intercept
7	x	Num	8	
8	TIntercept	Num	8	Intercept Transformation
9	Tx	Num	8	x Transformation

The OUT= data set contains _TYPE_ and _NAME_ variables. Since no coefficients or coordinates are requested, all observations are _TYPE_='SCORE'. The y variable is the original dependent variable, Ty is the transformed dependent variable, Py contains the predicted values, x is the original independent variable, and Tx is the transformed independent variable. The data set also contains an Intercept and transformed intercept TIntercept variable. (In this case, the transformed intercept is the same as the intercept. However, if you specify the TSTANDARD= and ADDITIVE options, these are not always the same.)

The following example shows the results from specifying METHOD=MORALS when there is more than one dependent variable:

```
title 'METHOD=MORALS Output Data Set Example';

data x;
   input y1 y2 x1 $ x2 $;
   datalines;

If you specify METHOD=MORALS with multiple dependent variables, PROC TRANSREG performs separate univariate analyses and stacks the results in the OUT= data set. For this example, the results of the first analysis are in the partition designated by _DEPVAR_='Spline(y1)' and the results of the second analysis are in the partition designated by _DEPVAR_='Spline(y2)', which are the transformation and dependent variable names. Each partition has _TYPE_='SCORE' observations for the variables and a _TYPE_='M COEFFI' observation for the coefficients. In this example, an ID variable is specified, so the _NAME_ variable contains the formatted values of the first ID variable. Since both dependent variables have to go into the same column, the dependent variable is given a new name, _DEPEND_. The dependent variable transformation is named T_DEPEND_, the predicted values variable is named P_DEPEND_, and the residuals variable is named R_DEPEND_.

The independent variables are character OPSCORE variables. By default, PROC TRANSREG replaces character OPSCORE variables with category numbers and discards the original character variables. To avoid this, the input variables are renamed from x1 and x2 to n1 and n2 and the original x1 and x2 are added to the data set as ID variables. The n1 and n2 variables contain the initial values for the OPSCORE transformations, and the Tn1 and Tn2 variables contain optimal scores. The data set also contains an Intercept and transformed intercept TIntercept variable. The regression coefficients are in the transformation columns, which also contain the variables to which they apply.

Output Data Set Contents

Table 90.7 summarizes the various matrices that can result from PROC TRANSREG processing and that appear in the OUT= data set. The exact contents of an OUT= data set depends on many options.

Table 90.7 PROC TRANSREG OUT= Data Set Contents

TYPE	Contents	Options, Default Prefix
SCORE	dependent variables	DREPLACE not specified
SCORE	independent variables	IREPLACE not specified
SCORE	transformed dependent variables	default, TDPREFIX=T
SCORE	transformed independent variables	default, TIPREFIX=T

M QPOINT	quadratic point coordinates	COORDINATES or MQC, QPOINT
C POINT	canonical point coordinates	COORDINATES or CPC, POINT
C EPOINT	canonical elliptical point coordinates	COORDINATES or CEC, EPOINT
C QPOINT	canonical quadratic point coordinates	COORDINATES or CQC, QPOINT

The independent and dependent variables are created from the original input data. Several potential differences exist between these variables and the actual input data. An intercept variable can be added, new variables can be added for POINT, EPOINT, QPOINT, CLASS, IDENTITY, PSPLINE, and BSPLINE variables, and category numbers are substituted for character OPSCORE variables. These matrices are not always what is input to the first iteration. After the expanded data set is stored for inclusion in the output data set, several things happen to the data before they are input to the first iteration: column means are substituted for missing values; zero-degree SPLINE and MSPLINE variables are transformed so that the iterative algorithms get step-function data as input, which conform to the zero-degree transformation family restrictions; and the nonoptimal transformations are performed.

Details for the UNIVARIATE Method

When you specify METHOD=UNIVARIATE (in the MODEL or PROC TRANSREG statement), PROC TRANSREG can perform several analyses, one for each dependent variable. While each dependent variable can be transformed, their independent variables are not transformed. The OUT= data set optionally contains all of the _TYPE_='SCORE' observations, optionally followed by coefficients or coordinates.

Details for the MORALS Method

When you specify METHOD=MORALS (in the MODEL or PROC TRANSREG statement), successive analyses are performed, one for each dependent variable. Each analysis transforms one dependent variable and the entire set of the independent variables. All information for the first dependent variable (scores then, optionally, coefficients) appears first. Then all information for the second dependent variable (scores then, optionally, coefficients) appears next. This arrangement is repeated for all dependent variables.

Details for the CANALS and REDUNDANCY Methods

For METHOD=CANALS and METHOD=REDUNDANCY (specified in either the MODEL or PROC TRANSREG statement), one analysis is performed that simultaneously transforms all dependent and independent variables. The OUT= data set optionally contains all of the _TYPE_='SCORE' observations, optionally followed by coefficients or coordinates.

Variable Names

As shown in the preceding examples, some variables in the output data set directly correspond to input variables, and some are created. All original optimal and nonoptimal transformation variable names are unchanged.

The names of the POINT, QPOINT, and EPOINT expansion variables are also left unchanged, but new variables are created. When independent POINT variables are present, the sum-of-squares variable _ISSQ_ is added to the output data set. For each EPOINT and QPOINT variable, a new squared variable is created by appending "_2". For example, Dim1 and Dim2 are expanded into Dim1, Dim2, Dim1_2, and Dim2_2. In addition, for each pair of QPOINT variables, a new crossproduct variable is created by combining the two names—for example, Dim1Dim2.

The names of the CLASS variables are constructed from original variable names and levels. Lengths are controlled by the CPREFIX= *a-option*. For example, when x1 and x2 both have values of 'a' and 'b', CLASS(x1 | x2 / ZERO=NONE) creates x1 main-effect variable names x1a x1b, x2 main-effect variable names x2a x2b, and interaction variable names x1ax2a x1ax2b x1bx2a x1bx2b.

PROC TRANSREG then uses these variable names when creating the transformed, predicted, and residual variable names by affixing the relevant prefix and dropping extra characters if necessary.

METHOD=MORALS Variable Names

When you specify METHOD=MORALS and only one dependent variable is present, the output data set is structured exactly as if METHOD=REDUNDANCY (see the section "Details for the CANALS and REDUNDANCY Methods" on page 7274). When more than one dependent variable is present, the dependent variables are output in the variable _DEPEND_, transformed dependent variables are output in the variable T_DEPEND_, predicted values are output in the variable P_DEPEND_, and residuals are output in the variable R_DEPEND_. You can partition the data set into BY groups, one per dependent variable, by referring to the character variable _DEPVAR_, which contains the original dependent variable names and transformations.

Duplicate Variable Names

When the same name is generated from multiple variables in the OUT= data set, new names are created by appending '2', '3', or '4', and so on, until a unique name is created. For 32-character names, the last character is replaced with a numeric suffix until a unique name is created. For example, if there are two output variables that otherwise would be named x, then x and x2 are created instead. If there are two output variables that otherwise would be named ThisIsAThirtyTwoCharacterVarName, then ThisIsAThirtyTwoCharacterVarName and ThisIsAThirtyTwoCharacterVarNam2 are created instead.

OUTTEST= Output Data Set

The OUTTEST= data set contains hypothesis test results. The OUTTEST= data set always contains ANOVA results. When you specify the SS2 *a-option*, regression tables are also output. When you specify the UTILITIES *a-option*, conjoint analysis part-worth utilities are also output. The OUTTEST= data set has the following variables:

DEPVAR is a 42-character variable that contains the dependent variable transformation and name.

TYPE is an 8-character variable that contains the table type. The first character is "U" for univariate or "M" for multivariate. The second character is blank. The third character is "A" for ANOVA, "2" for Type II sum of squares, or "U" for UTILITIES. The fourth character is blank. The fifth character is "L" for liberal tests, "C" for conservative tests, or "U" for the usual tests.

Title is an 80-character variable that contains the table title.

Variable is a 42-character variable that contains the independent variable transformations and names for regression tables and blanks for ANOVA tables.

Coefficient contains the multiple regression coefficients for regression tables and underscore special missing values for ANOVA tables.

Statistic is a 24-character variable that contains the names for statistics in other variables, such as Value.

Value contains multivariate test statistics and all other information that does not fit in one of the other columns including R square, dependent mean, adjusted R

	square, and coefficient of variation. Whenever Value is not an underscore special missing value, the Statistic variable describes the contents of the Value variable.
NumDF	contains numerator degrees of freedom for F tests.
DenDF	contains denominator degrees of freedom for F tests.
SSq	contains sums of squares.
MeanSquare	contains mean squares.
F	contains F statistics.
NumericP	contains the p-value for the F statistic, stored in a numeric variable.
P	is a 9-character variable that contains the formatted p-value for the F statistic, including the appropriate ~, <=, >=, or blank symbols.
LowerLimit	contains lower confidence limits on the parameter estimates.
UpperLimit	contains upper confidence limits on the parameter estimates.
StdError	contains standard errors. For SS2 and UTILITIES tables, standard errors are output for each coefficient with one degree of freedom.
Importance	contains the relative importance of each factor for UTILITIES tables.
Label	is a 256-character variable that contains variable labels.

There are several possible tables in the OUTTEST= data set corresponding to combinations of univariate and multivariate tests; ANOVA and regression results; and liberal, conservative, and the usual tests. Each table is composed of only a subset of the variables. Numeric variables contain underscore special missing values when they are not a column in a table. Ordinary missing values (.) appear in variables that are part of a table when a nonmissing value cannot be produced. For example, the F is missing for a test with zero degrees of freedom.

Computational Resources

This section provides information about the computational resources required to use PROC TRANSREG.

Let

n = number of observations
q = number of expanded independent variables
r = number of expanded dependent variables
k = maximum spline degree
p = maximum number of knots

More than $56(q+r)$ plus the maximum of the data matrix size, the optimal scaling work space, and the covariance matrix size bytes of array space are required. The data matrix size is $8n(q+r)$

bytes. The optimal scaling work space requires less than $8(6n + (p + k + 2)(p + k + 11))$ bytes. The covariance matrix size is $4(q + r)(q + r + 1)$ bytes.

PROC TRANSREG tries to store the original and transformed data in memory. If there is not enough memory, a utility data set is used, potentially resulting in a large increase in execution time. The amount of memory for the preceding data formulas is an underestimate of the amount of memory needed to handle most problems. These formulas give the absolute minimum amount of memory required. If a utility data set is used, and if memory can be used with perfect efficiency, then roughly the amount of memory stated previously is needed. In reality, most problems require at least two or three times the minimum.

PROC TRANSREG sorts the data once. The sort time is roughly proportional to $(q + r)n^{3/2}$.

One regression analysis per iteration is required to compute model parameters (or two canonical correlation analyses per iteration for METHOD=CANALS). The time required to accumulate the crossproducts matrix is roughly proportional to $n(q + r)^2$. The time required to compute the regression coefficients is roughly proportional to q^3.

Each optimal scaling is a multiple regression problem, although some transformations are handled with faster special-case algorithms. The number of regressors for the optimal scaling problems depends on the original values of the variable and the type of transformation. For each monotone spline transformation, an unknown number of multiple regressions is required to find a set of coefficients that satisfies the constraints. The B-spline basis is generated twice for each SPLINE and MSPLINE transformation for each iteration. The time required to generate the B-spline basis is roughly proportional to nk^2.

Unbalanced ANOVA without CLASS Variables

This section illustrates that an analysis of variance model can be formulated as a simple regression model with optimal scoring. The purpose of the example is to explain one aspect of how PROC TRANSREG works, not to propose an alternative way of performing an analysis of variance.

Finding the overall fit of a large, unbalanced analysis of variance model can be handled as an optimal scoring problem without creating large, sparse design matrices. For example, consider an unbalanced full main-effects and interactions ANOVA model with six factors. Assume that a SAS data set is created with factor-level indicator variables `c1` through `c6` and dependent variable `y`. If each factor level consists of nonblank single characters, you can create a cell indicator in a DATA step with the statement as follows:

```
x=compress(c1||c2||c3||c4||c5||c6);
```

The following statements optimally score `x` (by using the OPSCORE transformation) and do not transform `y`:

```
proc transreg;
   model identity(y)=opscore(x);
   output;
run;
```

The final R square reported is the R square for the full analysis of variance model. This R square is the same R square that would be reported by both of the following PROC GLM steps:

```
proc glm;
   class x;
   model y=x;
run;

proc glm;
   class c1-c6;
   model y=c1|c2|c3|c4|c5|c6;
run;
```

PROC TRANSREG optimally scores the classes of x, within the space of a single variable with values linearly related to the cell means, so the full ANOVA problem is reduced to a simple regression problem with an optimal independent variable. PROC TRANSREG requires only one iteration to find the optimal scoring of x but, by default, performs a second iteration, which reports no data changes.

Hypothesis Tests for Simple Univariate Models

If the dependent variable has one parameter (IDENTITY, LINEAR with no missing values, and so on) and if there are no monotonicity constraints, PROC TRANSREG fits univariate models, which can also be fit with a DATA step and PROC REG. This is illustrated with the following artificial data set:

```
data htex;
   do i = 0.5 to 10 by 0.5;
      x1 = log(i);
      x2 = sqrt(i) + sin(i);
      x3 = 0.05 * i * i + cos(i);
      y  = x1 - x2 + x3 + 3 * normal(7);
      x1 = x1 + normal(7);
      x2 = x2 + normal(7);
      x3 = x3 + normal(7);
      output;
   end;
run;
```

Both PROC TRANSREG and PROC REG are run to fit the same polynomial regression model as follows:

```
proc transreg data=htex ss2 short;
   title 'Fit a Polynomial Regression Model with PROC TRANSREG';
   model identity(y) = spline(x1);
run;
```

```
data htex2;
   set htex;
   x1_1 = x1;
   x1_2 = x1 * x1;
   x1_3 = x1 * x1 * x1;
run;

proc reg;
   title 'Fit a Polynomial Regression Model with PROC REG';
   model y = x1_1 - x1_3;
run; quit;
```

The ANOVA and regression tables from PROC TRANSREG are displayed in Figure 90.69. The ANOVA and regression tables from PROC REG are displayed in Figure 90.70. The SHORT *a-option* is specified with PROC TRANSREG to suppress the iteration history.

The PROC TRANSREG regression table differs in several important ways from the parameter estimate table produced by PROC REG. The REG procedure displays standard errors and t statistics. PROC TRANSREG displays Type II sums of squares, mean squares, and F statistics. The difference is because the numerator degrees of freedom are not always 1, so t tests are not uniformly appropriate. When the degrees of freedom for variable x_j is 1, the following relationships hold between the standard errors (s_{β_j}) and the Type II sums of squares (SS_j):

$$s_{\beta_j} = (\hat{\beta}_j^2 / F_j)^{1/2}$$

and

$$SS_j = \hat{\beta}_j^2 \times MSE / s_{\beta_j}^2$$

PROC TRANSREG does not provide tests of the individual terms that go into the transformation. (However, it could if BSPLINE or PSPLINE had been specified instead of SPLINE.) The test of **spline(x1)** is the same as the test of the overall model. The intercepts are different due to the different numbers of variables and their standardizations.

In the next example, both x1 and x2 are transformed in the first PROC TRANSREG step, and PROC TRANSREG is used instead of a DATA step to create the polynomials for PROC REG. Both PROC TRANSREG and PROC REG fit the same polynomial regression model. The following statements run PROC TRANSREG and PROC REG and produce Figure 90.71 and Figure 90.72:

```
title 'Two-Variable Polynomial Regression';

proc transreg data=htex ss2 solve;
   model identity(y) = spline(x1 x2);
run;

proc transreg noprint data=htex maxiter=0;
   /* Use PROC TRANSREG to prepare input to PROC REG */
   model identity(y) = pspline(x1 x2);
   output out=htex2;
run;

proc reg data=htex2;
   model y = x1_1-x1_3 x2_1-x2_3;
   test x1_1, x1_2, x1_3;
   test x2_1, x2_2, x2_3;
run; quit;
```

Variable         DF    Coefficient    Squares     Square    F Value    Pr > F

Intercept         1      3.5437125    35.2282    35.2282       2.47    0.1400
Spline(x1)        3      0.3644562     4.5682     1.5227       0.11    0.9546
Spline(x2)        3     -1.3551738    32.9112    10.9704       0.77    0.5315
```

There are three iteration histories: one for the overall model and two for the two independent variables. The first PROC TRANSREG iteration history shows the R square of 0.17287 for the

fit of the overall model. The second is for the following model:

```
model identity(y) = spline(x2);
```

This model excludes **spline(x1)**. The third iteration history is for the following model:

```
model identity(y) = spline(x1);
```

This model excludes **spline(x2)**. The difference between the first and second R square times the total sum of squares is the model sum of squares for **spline(x1)**:

$$(0.17287 - 0.15249) \times 224.143800 = 4.568165$$

The difference between the first and third R square times the total sum of squares is the model sum of squares for **spline(x2)**:

$$(0.17287 - 0.02604) \times 224.143800 = 32.911247$$

Figure 90.72 displays the PROC REG results. The TEST statement in PROC REG tests the null hypothesis that the vector of parameters for x1_1 x1_2 x1_3 is zero. This is the same test as the **spline(x1)** test used by PROC TRANSREG. Similarly, the PROC REG test that the vector of parameters for x2_1 x2_2 x2_3 is zero is the same as the PROC TRANSREG SPLINE(x2) test. So for models with no monotonicity constraints and no dependent variable transformations, PROC TRANSREG provides little more than a different packaging of standard least-squares methodology.

Hypothesis Tests with Monotonicity Constraints

Now consider a model with monotonicity constraints. This model has no counterpart in PROC REG. The following statements fit a monotone-spline model and produce Figure 90.73:

```
title 'Monotone Splines';

proc transreg data=htex ss2 short;
   model identity(y) = mspline(x1-x3 / nknots=3);
run;
```

The SHORT *a-option* is specified to suppress the iteration histories. Two ANOVA tables are displayed—one by using liberal degrees of freedom and one by using conservative degrees of freedom. All sums of squares and the R squares are the same for both tables. What differs are the degrees of freedom and statistics that use degrees of freedom. The liberal test has 8 model degrees of freedom and 11 error degrees of freedom, whereas the conservative test has 15 model degrees of freedom and only 4 error degrees of freedom. The "true" p-value is between 0.8462 and 0.9997, so clearly you would fail to reject the null hypothesis. Unfortunately, results are not always this clear. (See Figure 90.73.)

Hypothesis Tests with Dependent Variable Transformations

PROC TRANSREG can also provide approximate tests of hypotheses when the dependent variable is transformed, but the output is more complicated. When a dependent variable has more than one degree of freedom, the problem becomes multivariate. Hypothesis tests are performed in the context of a multivariate linear model with the number of dependent variables equal to the number of scoring parameters for the dependent variable transformation. The transformation regression model with a dependent variable transformation differs from the usual multivariate linear model in two important ways. First, the usual assumption of multivariate normality is always violated. This fact is simply ignored. This is one reason why all hypothesis tests in the presence of a dependent variable transformation should be considered approximate at best. Multivariate normality is assumed even though it is known that the assumption is violated.

The second difference concerns the usual multivariate test statistics: Pillai's trace, Wilks' lambda, Hotelling-Lawley trace, and Roy's greatest root. The first three statistics are defined in terms of all the squared canonical correlations. Here, there is only one linear combination (the transformation), and hence only one squared canonical correlation of interest, which is equal to the R square. It might seem that Roy's greatest root, which uses only the largest squared canonical correlation, is the only statistic of interest. Unfortunately, Roy's greatest root is very liberal and provides only a lower bound on the *p*-value. Approximate upper bounds are provided by adjusting the other three statistics for the one linear combination case. Wilks' lambda, Pillai's trace, and Hotelling-Lawley trace are a conservative adjustment of the usual statistics.

These statistics are normally defined in terms of the squared canonical correlations, which are the eigenvalues of the matrix $\mathbf{H}(\mathbf{H}+\mathbf{E})^{-1}$, where $\mathbf{H}$ is the hypothesis sum-of-squares matrix and

E is the error sum-of-squares matrix. Here the R square is used for the first eigenvalue, and all other eigenvalues are set to 0 since only one linear combination is used. Degrees of freedom are computed assuming that all linear combinations contribute to the lambda and trace statistics, so the *F* tests for those statistics are conservative. The *p*-values for the liberal and conservative statistics provide approximate lower and upper bounds on *p*. In practice, the adjusted Pillai's trace is very conservative—perhaps too conservative to be useful. Wilks' lambda is less conservative, and the Hotelling-Lawley trace seems to be the least conservative. The conservative statistics and the liberal Roy's greatest root provide a bound on the true *p*-value. Unfortunately, they sometimes report a bound of 0.0001 and 1.0000.

The following example has a dependent variable transformation and produces Figure 90.74:

```
title 'Transform Dependent and Independent Variables';

proc transreg data=htex ss2 solve short;
   model spline(y) = spline(x1-x3);
run;
```

The univariate results match Roy's greatest root results. Clearly, the proper action is to fail to reject the null hypothesis. However, as stated previously, results are not always this clear.

Figure 90.74 Transform Dependent and Independent Variables

```

Figure 90.74 *continued*

Adjusted Multivariate ANOVA Table Based on the Usual Degrees of Freedom

Dependent Variable Scoring Parameters=3 S=3 M=2.5 N=3

Statistic	Value	F Value	Num DF	Den DF	p
Wilks' Lambda	0.505308	0.23	27	24.006	<= 0.9998
Pillai's Trace	0.494692	0.22	27	30	<= 0.9999
Hotelling-Lawley Trace	0.978992	0.26	27	11.589	<= 0.9980
Roy's Greatest Root	0.978992	1.09	9	10	>= 0.4452

The Wilks' Lambda, Pillai's Trace, and Hotelling-Lawley Trace statistics are a conservative adjustment of the normal statistics. Roy's Greatest Root is liberal. These statistics are normally defined in terms of the squared canonical correlations which are the eigenvalues of the matrix H*inv(H+E). Here the R-Square is used for the first eigenvalue and all other eigenvalues are set to zero since only one linear combination is used. Degrees of freedom are computed assuming all linear combinations contribute to the Lambda and Trace statistics, so the F tests for those statistics are conservative. The p values for the liberal and conservative statistics provide approximate lower and upper bounds on p. A liberal test statistic with conservative degrees of freedom and a conservative test statistic with liberal degrees of freedom yield at best an approximate p value, which is indicated by a "~" before the p value.

Univariate Regression Table Based on the Usual Degrees of Freedom

Variable	DF	Coefficient	Type II Sum of Squares	Mean Square	F Value	Liberal p
Intercept	1	6.9089087	117.452	117.452	10.37	>= 0.0092

These statistics are adjusted in the same way as the multivariate statistics above.

Hypothesis Tests with One-Way ANOVA

One-way ANOVA models are fit with either an explicit or implicit intercept. In implicit intercept models, the ANOVA table of PROC TRANSREG is the correct table for a model with an intercept, and the regression table is the correct table for a model that does not have a separate explicit intercept. The PROC TRANSREG implicit intercept ANOVA table matches the PROC REG table when the NOINT *a-option* is not specified, and the PROC TRANSREG implicit intercept regression table matches the PROC REG table when the NOINT *a-option* is specified. The following statements illustrate this relationship and produce Figure 90.75:

```

```

Using the DESIGN Output Option

This example uses PROC TRANSREG and the DESIGN *o-option* to prepare an input data set with classification variables for the LOGISTIC procedure. The DESIGN *o-option* specifies that the goal is design matrix creation, not analysis. When you specify DESIGN, dependent variables are not required. The DEVIATIONS (or EFFECTS) *t-option* requests a deviations-from-means $(1, 0, -1)$ coding of the classification variables, which is the same coding the CATMOD procedure uses. PROC TRANSREG automatically creates a macro variable &_TrgInd that contains the list of independent variables created. This macro is used in the PROC LOGISTIC MODEL statement. (See Figure 90.76.) For comparison, the same analysis is also performed with PROC CATMOD. The following statements create Figure 90.76:

```
title 'Using PROC TRANSREG to Create a Design Matrix';

data a;
   do y = 1, 2;
      do a = 1 to 4;
         do b = 1 to 3;
            w = ceil(uniform(1) * 10 + 10);
            output;
         end;
      end;
   end;
run;

proc transreg data=a design;
   model class(a b / deviations);
   id y w;
   output out=coded;
run;

proc print;
   title2 'PROC TRANSREG Output Data Set';
run;

title2 'PROC LOGISTIC with Classification Variables';

proc logistic;
   freq w;
   model y = &_trgind;
run;

title2 'PROC CATMOD Should Produce the Same Results';

proc catmod data=a;
   model y = a b;
   weight w;
run;
```

Discrete Choice Experiments: DESIGN, NORESTORE, NOZERO

A discrete choice experiment is constructed consisting of four product brands, each available at three different prices, \$1.49, \$1.99, \$2.49. In addition, each choice set contains a constant "other" alternative available at \$1.49. In the fifth choice set, price is constant. PROC TRANSREG is used to code the design, and the PHREG procedure fits the multinomial logit choice model (not shown). See http://support.sas.com/resources/papers/tnote/tnote_marketresearch.html (Kuhfeld 2005) for more information about discrete choice modeling and the multinomial logit model; look for the latest "Discrete Choice" report. The following statements produce Figure 90.77:

```
title 'Choice Model Coding';

data design;
   array p[4];
   input p1-p4 @@;
   set = _n_;
   do brand = 1 to 4;
      price = p[brand];
      output;
   end;
   brand = .; price = 1.49; output; /* constant alternative */
   keep set brand price;
   datalines;
1.49 1.99 1.49 1.99 1.99 1.99 2.49 1.49 1.99 1.49 1.99 1.49
1.99 1.49 2.49 1.99 1.49 1.49 1.49 1.49 2.49 1.49 1.99 2.49
1.49 1.49 2.49 2.49 2.49 2.49 1.49 1.49 1.49 2.49 2.49 1.99
2.49 2.49 2.49 1.49 1.99 2.49 1.49 2.49 2.49 1.99 2.49 2.49
2.49 1.49 1.49 1.99 1.49 1.99 1.99 1.49 2.49 1.99 1.99 1.99
1.99 1.99 1.49 2.49 1.99 2.49 1.99 1.99 1.49 2.49 1.99 2.49
;

proc transreg data=design design norestoremissing nozeroconstant;
   model class(brand / zero=none) identity(price);
   output out=coded;
   by set;
run;

proc print data=coded(firstobs=21 obs=25);
   var set brand &_trgind;
run;
```

In the interest of space, only the fifth choice set is displayed in Figure 90.77.

Figure 90.77 The Fifth Choice Set

Choice Model Coding

Obs	set	brand	brand1	brand2	brand3	brand4	price
21	5	1	1	0	0	0	1.49
22	5	2	0	1	0	0	1.49
23	5	3	0	0	1	0	1.49
24	5	4	0	0	0	1	1.49
25	5	.	0	0	0	0	1.49

For the constant alternative (Brand = .), the brand coding is a row of zeros due to the NORESTOREMISSING *o-option*, and Price is a constant \$1.49 (instead of 0) due to the NOZEROCONSTANT.

The data set was coded by choice set (BY set;). This is a small problem. With very large problems, it might be necessary to restrict the number of observations that are coded at one time so that the procedure uses less time and memory. Coding by choice set is one option. When coding is performed after the data are merged in, coding by subject and choice set combinations is another option. Alternatively, you can specify DESIGN=*n*, where *n* is the number of observations to code at one time. For example, you can specify DESIGN=100 or DESIGN=1000 to process the data set in blocks of 100 or 1000 observations. Specify the NOZEROCONSTANT *a-option* to ensure that constant variables within blocks are not zeroed. When you specify DESIGN=*n*, or perform coding after the data are merged in, specify the dependent variable and any other variables needed for analysis as ID variables.

Centering

You can use transformation options to center and standardize the variables in several ways. For example, the following MODEL statement creates three independent variables, x, x^2, and x^3:

```
model identity(y) = pspline(x);
```

The variables are not centered.

When the CENTER *t-option* is specified, as in the following statement, the independent variable is centered before squaring and cubing:

```
model identity(y) = pspline(x / center);
```

The three independent variables are $x - \bar{x}$, $(x - \bar{x})^2$, and $(x - \bar{x})^3$.

Since operations such as squaring occur after the centering, the resulting variables are not always centered. The CENTER *t-option* is particularly useful with polynomials since centering before squaring and cubing can help reduce collinearity and numerical problems. For example, if one of your variables is year, with values all greater than 1900, squaring and cubing without centering first will create variables that are all essentially perfectly correlated.

When the TSTANDARD=CENTER *t-option* is specified, as in the following model, the three independent variables are squared and cubed and then centered:

```
model identity(y) = pspline(x / tstandard=center);
```

The three independent variables are $x - \bar{x}$, $x^2 - \overline{x^2}$, and $x^3 - \overline{x^3}$.

You can specify both the CENTER and TSTANDARD=CENTER *t-options* to center the variables, then square and cube them, and then center the results, as in the following statement:

```
model identity(y) = pspline(x / center tstandard=center);
```

The three independent variables are $x - \bar{x}$, $(x - \bar{x})^2 - \overline{(x - \bar{x})^2}$, and $(x - \bar{x})^3 - \overline{(x - \bar{x})^3}$.

Displayed Output

The display options control the amount of displayed output. The displayed output can contain the following:

- an iteration history and convergence status table (by default when there are iterations)
- an ANOVA table when the TEST, SS2, or UTILITIES *a-option* is specified
- a regression table when the SS2 *a-option* is specified
- conjoint analysis part-worth utilities when the UTILITIES *a-option* is specified
- model details when the DETAIL *a-option* is specified
- a multivariate ANOVA table when the dependent variable is transformed and the TEST or SS2 *a-option* is specified
- a multivariate regression table when the dependent variable is transformed and it is specified
- liberal and conservative ANOVA, multivariate ANOVA, regression, and multivariate regression tables when there is a MONOTONE, UNTIE, or MSPLINE transformation and the TEST or SS2 *a-option* is specified

ODS Table Names

PROC TRANSREG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 90.8. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 90.8 ODS Tables Produced by PROC TRANSREG

ODS Table Name	Description	Statement & Option
ANOVA	ANOVA	MODEL/PROC, TEST/SS2
BoxCox	Box-Cox transformation results	MODEL, BOXCOX
CANALS	CANALS iteration history	MODEL/PROC, METHOD=CANALS
ClassLevels	ANOVA	MODEL/PROC, TEST/SS2
Coef	Regression results	MODEL/PROC, SS2
ConservANOVA	ANOVA, *1	MODEL/PROC, TEST/SS2
ConservCoef	Regression results, *1	MODEL/PROC, SS2
ConservFitStatistics	Fit statistics, *1	MODEL/PROC, TEST/SS2
ConservMVANOVA	Multivariate ANOVA, *1, *2	MODEL/PROC, TEST/SS2
ConservMVCoef	Multivariate regression results, *1, *2	MODEL/PROC, SS2
ConservUtilities	Conjoint analysis utilities, *1	MODEL/PROC, UTILITIES
ConvergenceStatus	Convergence status	default
Details	Model Details	MODEL/PROC, DETAIL
Equation	Linear dependency equation	less-than-full-rank model
FitStatistics	Fit statistics like R square	MODEL/PROC, TEST/SS2
Footnotes	Iteration history footnotes	default
LiberalANOVA	ANOVA, *1	MODEL/PROC, TEST/SS2
LiberalCoef	Regression results, *1	MODEL/PROC, SS2
LiberalFitStatistics	Fit statistics, *1	MODEL/PROC, TEST/SS2
LiberalMVANOVA	Multivariate ANOVA, *1, *2	MODEL/PROC, TEST/SS2
LiberalMVCoef	Multivariate regression results, *1, *2	MODEL/PROC, SS2

MVCoef	Multivariate regression results, *2	MODEL/PROC, SS2
NObs	ANOVA	MODEL/PROC, TEST/SS2
PBSplineCriteria	Penalized B-spline criteria (nonprinting)	MODEL, PBSPLINE
RSquare	R square	MODEL/PROC, RSQUARE
Redundancy	Redundancy iteration history	MODEL/PROC, METHOD=REDUNDANCY
SplineCoef	Spline coefficients (nonprinting)	MODEL, SPLINE/MSPLINE
TestIterations	Hypothesis test iterations iteration history	MODEL/PROC, SS2
Univariate	Univariate iteration history	MODEL/PROC, METHOD=UNIVARIATE
Utilities	Conjoint analysis utilities	MODEL/PROC, UTILITIES

*1. Liberal and conservative test tables are produced when a MONOTONE, UNTIE, or MSPLINE transformation is requested.

*2. Multivariate tables are produced when the dependent variable is iteratively transformed.

ODS Graphics

To request graphics with PROC TRANSREG, you must first enable ODS Graphics by specifying the ODS GRAPHICS ON statement. See Chapter 21, "Statistical Graphics Using ODS," for more information. Some graphs are produced by default; other graphs are produced by using statements and options. You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC TRANSREG generates are listed in Table 90.9, along with the required statements and options.

Table 90.9 ODS Graphics Produced by PROC TRANSREG

ODS Graph Name	Plot Description	Statement & Option
BoxCoxFPlot	Box-Cox $F = t^2$	MODEL & PROC, BOXCOX *transform* & PLOTS(UNPACK)
BoxCoxLogLikePlot	Box-Cox Log Likelihood	MODEL & PROC, BOXCOX *transform* & PLOTS(UNPACK)
BoxCoxPlot	Box-Cox t or $F = t^2$ & Log Likelihood	MODEL, BOXCOX *transform*
BoxCoxtPlot	Box-Cox t	MODEL & PROC, BOXCOX *transform* & PLOTS(UNPACK)=BOXCOX(T)
FitPlot	Simple Regression and Separate Group Regressions	MODEL, a dependent variable that is not transformed, one non-CLASS independent variable, and at most one CLASS variable
ObservedByPredicted	Dependent Variable by Predicted Values	MODEL, PLOTS=OBSERVEDBYPREDICTED
PBSPlineCritPlot	Penalized B-Spline Criterion Plot	MODEL, PBSPLINE *transform*
PrefMapVecPlot	Preference Mapping Vector Plot	MODEL & PROC, IDENTITY *transform* & COORDINATES
PrefMapIdealPlot	Preference Mapping Ideal Point Plot	MODEL & PROC, POINT expansion & COORDINATES
ResidualPlot	Residuals	PROC, PLOTS=RESIDUALS
RMSEPlot	Box-Cox Root Mean Square Error	MODEL & PROC, BOXCOX *transform* & PLOTS=BOXCOX(RMSE)
ScatterPlot	Scatter Plot of Observed Data	MODEL, one non-CLASS independent variable, and at most one CLASS variable, PLOTS=SCATTER
TransformationPlot	Variable Transformations	PROC, PLOTS=TRANSFORMATION

The PLOTS(INTERPOLATE) Option

This section illustrates one use of the PLOTS(INTERPOLATE) option for use with ODS Graphics. The data set has two groups of observations, c = 1 and c = 2. Each group is sparse, having only five observations, so the plots of the transformations and fit functions are not smooth. A second DATA step adds additional observations to the data set, over the range of x, with y missing. These observations do not contribute to the analysis, but they are used in computations of transformed and predicted values. The resulting plots are much smoother in the latter case than in the former. The other results of the analysis are the same. The following statements produce Figure 90.78 and Figure 90.79:

```

Examples: TRANSREG Procedure

Example 90.1: Transformation Regression of Exhaust Emissions Data

In this example, the data are from an experiment in which nitrogen oxide emissions from a single cylinder engine are measured for various combinations of fuel, compression ratio, and equivalence ratio. The data are provided by Brinkman (1981).

The equivalence ratio and nitrogen oxide variables are continuous and numeric, so spline transformations of these variables are requested. The spline transformation of the dependent variable is restricted to be monotonic. Each spline is degree three with nine knots (one at each decile) in order to give PROC TRANSREG a great deal of freedom in finding transformations. The compression ratio variable has only five discrete values, so an optimal scoring is requested with monotonicity constraints. The character variable Fuel is nominal, so it is optimally scored without any monotonicity constraints. Observations with missing values are excluded with the NOMISS *a-option*. The following statements produce Output 90.1.1:

```

Output 90.1.1 *continued*

The squared multiple correlation for the initial model is approximately 0.05. PROC TRANSREG increases the R square to over 0.95 by transforming the variables. The transformation plots show how each variable is transformed. The transformation of compression ratio (TCpRatio) is nearly linear. The transformation of equivalence ratio (TEqRatio) is nearly parabolic. It can be seen from this plot that the optimal transformation of equivalence ratio is nearly uncorrelated with the original scoring. This suggests that the large increase in R square is due to this transformation. The transformation of nitrogen oxide (TNOx) is similar to a log transformation. The final plot shows the transformed dependent variable plotted as a function of the predicted values. This plot is reasonably linear, showing that the nonlinearities in the data are being accounted for fairly well by the TRANSREG model.

These results suggest the parametric model

$$\begin{aligned}\log(\text{NOX}) &= b_0 + b_1 \times \text{EqRatio} + b_2 \times \text{EqRatio}^2 + b_3 \times \text{CpRatio} \\ &\quad + \sum_j b_j \text{class}_j(\text{Fuel}) + \text{error}\end{aligned}$$

You can perform this analysis with PROC TRANSREG. The following statements produce Output 90.1.2:

```
title2 'Now fit log(NOx) = b0 + b1*EqRatio + b2*EqRatio**2 +';
title3 'b3*CpRatio + Sum b(j)*Fuel(j) + Error';

*-Fit the Parametric Model Suggested by the Nonparametric Analysis-;

The LOG transformation computes the natural log. The PSPLINE expansion expands EqRatio into a linear term, EqRatio, and a squared term, EqRatio^2. An identity transformation of CpRatio and an optimal scoring of Fuel is requested. These should provide a good parametric operationalization of the optimal transformations. The final model has an R square of 0.91 (smaller than before since the model has fewer parameters, but still quite good).

Example 90.2: Box-Cox Transformations

This example shows Box-Cox transformations with a yarn failure data set. For more information about Box-Cox transformations, including using a Box-Cox transformation in a model with no independent variable, to normalize the distribution of the data, see the section "Box-Cox Transformations" on page 7181. In this example, a simple 3^3 design was used to study the effects of different factors on the failure of a yarn manufacturing process. The design factors are as follows:

- the length of test specimens of yarn, with levels of 250, 300, and 350 mm
- the amplitude of the loading cycle, with levels of 8, 9, and 10 mmd

- the load with levels of 40, 45, and 50 grams

The measured response was time (in cycles) until failure. However, you could just as well have measured the inverse of time until failure (in other words, the failure rate). Hence, the correct metric with which to analyze the response is not apparent. You can use PROC TRANSREG to find an optimum power transformation for the analysis. The following statements create the input SAS data set:

```
title 'Yarn Strength';

proc format;
   value a -1 =   8 0 =   9 1 =  10;
   value l -1 = 250 0 = 300 1 = 350;
   value o -1 =  40 0 =  45 1 =  50;
run;

data yarn;
   input Fail Amplitude Length Load @@;
   format amplitude a. length l. load o.;
   label fail = 'Time in Cycles until Failure';
   datalines;
 674 -1 -1 -1    370 -1 -1  0    292 -1 -1  1    338  0 -1 -1

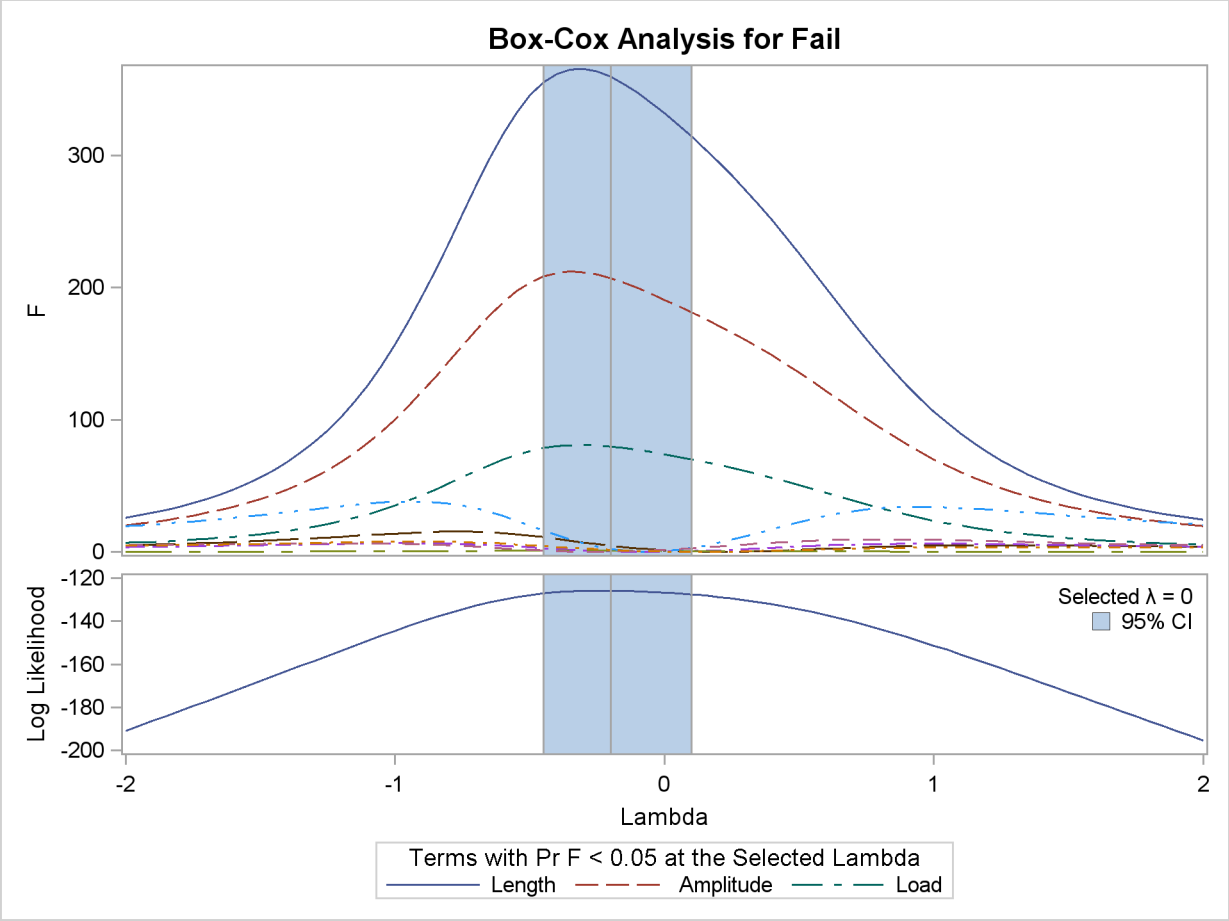
  90  1 -1  1   1414 -1  0 -1   1198 -1  0  0    634 -1  0  1
1022  0  0 -1    620  0  0  0    438  0  0  1    442  1  0 -1
 332  1  0  0    220  1  0  1   3636 -1  1 -1   3184 -1  1  0
2000 -1  1  1   1568  0  1 -1   1070  0  1  0    566  0  1  1
1140  1  1 -1    884  1  1  0    360  1  1  1
;
```



PROC TRANSREG is run to find the Box-Cox transformation. The lambda list is –2 TO 2 BY 0.05, which produces 81 lambdas, and a convenient lambda is requested. This many power parameters makes a nice graphical display with plenty of detail around the confidence interval. In the interest of space, only part of this table is displayed. The independent variables are designated with the QPOINT expansion. QPOINT, for quadratic point model, gets its name from PROC TRANSREG's ideal point modeling capabilities, which process variables for a response surface analysis. What QPOINT does is create a set of independent variables consisting of the following: the m original variables (Length Amplitude Load), the m original variables squared (Length_2 Amplitude_2 Load_2), and the $m \times (m-1)/2 = 3$ pairs of products between the m variables (LengthAmplitude LengthLoad AmplitudeLoad). The following statements produce Output 90.2.1:

```
ods graphics on;

proc transreg details data=yarn ss2
              plots=(transformation(dependent) obp);
   model BoxCox(fail / convenient lambda=-2 to 2 by 0.05) =

The optimal power parameter is –0.20, but since 0.0 is in the confidence interval, and since the CONVENIENT *t-option* was specified, the procedure chooses a log transformation. The $F = t^2$ plot shows in the vicinity of the optimal Box-Cox transformation, the parameters for the three original variables (Length Amplitude Load), particularly Length, are significant and the others become essentially zero.

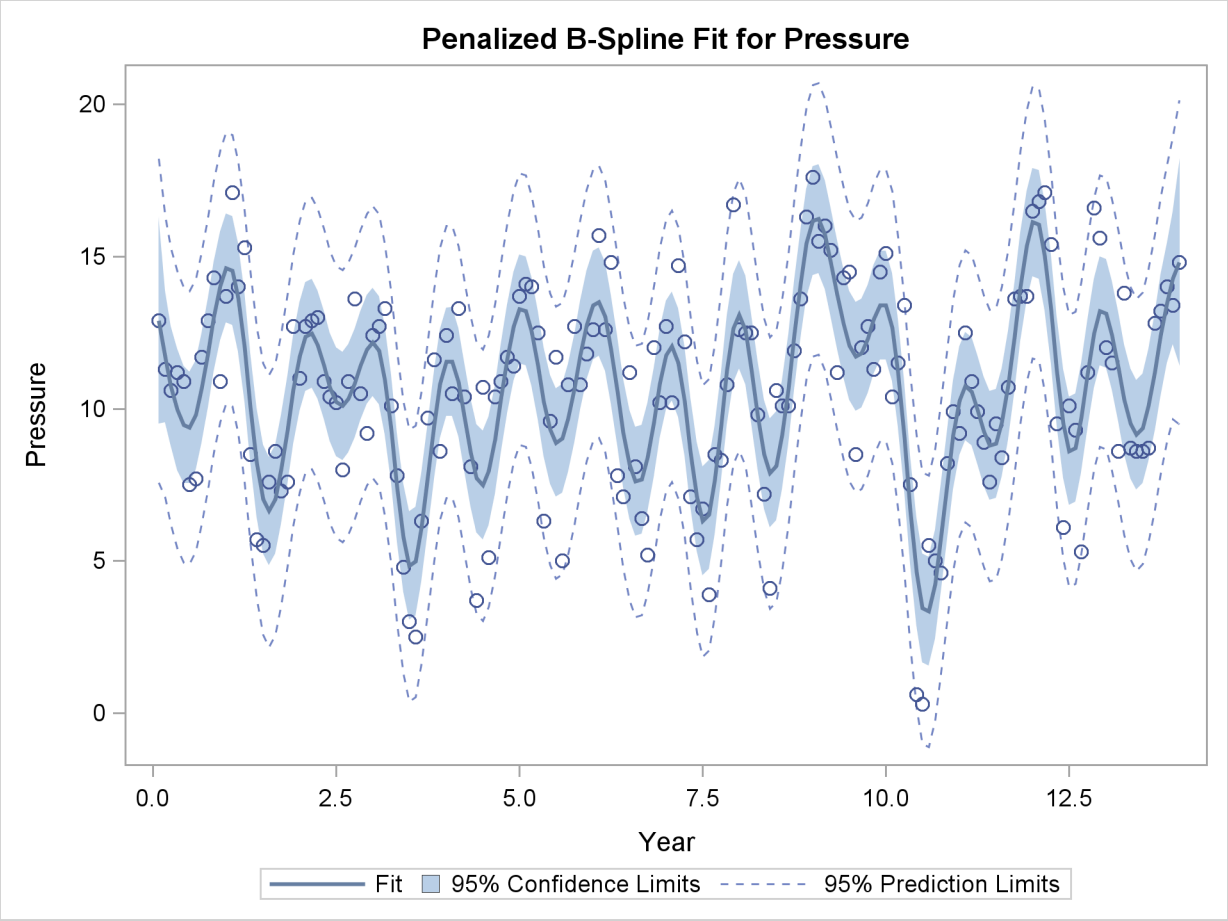
You can fit a curve through these data by using a penalized B-spline (Eilers and Marx 1996) function and the following statements:

```
ods graphics on;

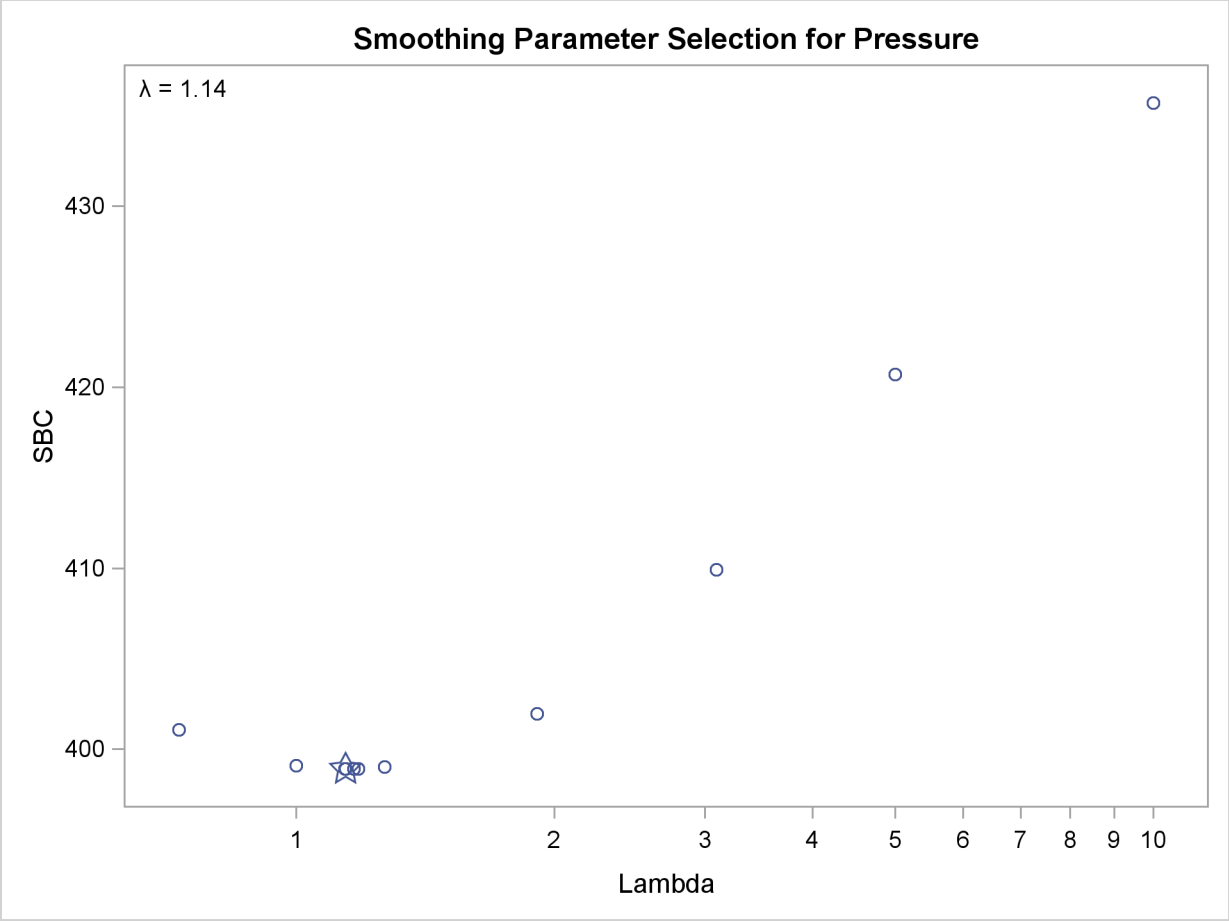


proc transreg data=enso;
   model identity(pressure) = pbspline(year);
run;
```

The dependent variable Pressure is specified along with an IDENTITY transformation, so Pressure is analyzed as is, with no transformations. The independent variable Year is specified with a PBSPLINE transformation, so a penalized B-spline model is fit. By default, a DEGREE=3 B-spline basis is used along with 100 evenly spaced knots and three evenly spaced exterior knots on each side of the data. The penalized spline function is typically much smoother than you would get by using a SPLINE transformation or a BSPLINE expansion since changes in the coefficients of the basis are penalized to make a smoother fit. The output is shown next in Output 90.3.1.

Output 90.3.1 Change in Atmospheric Pressure, AICC

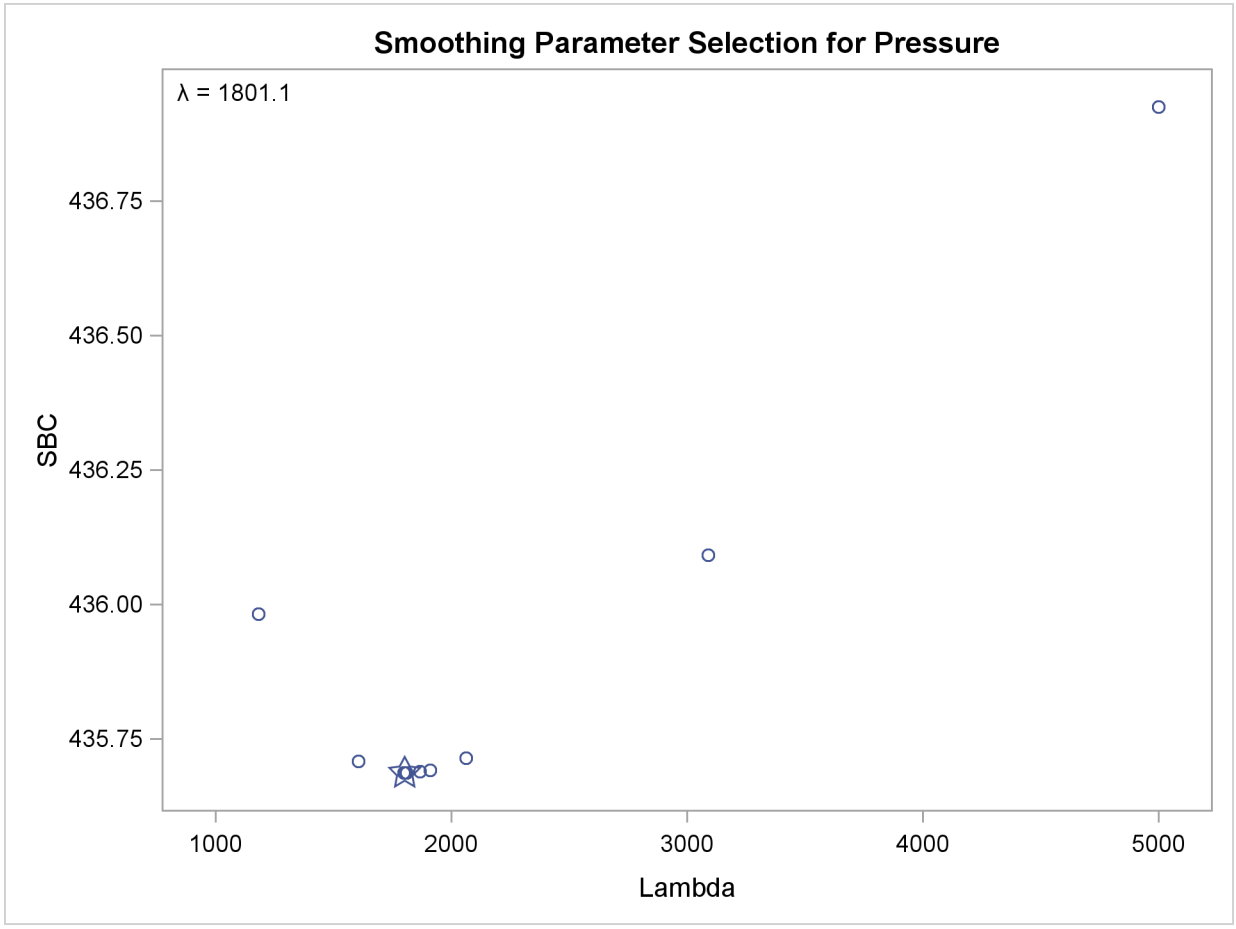
Output 90.3.1 *continued*



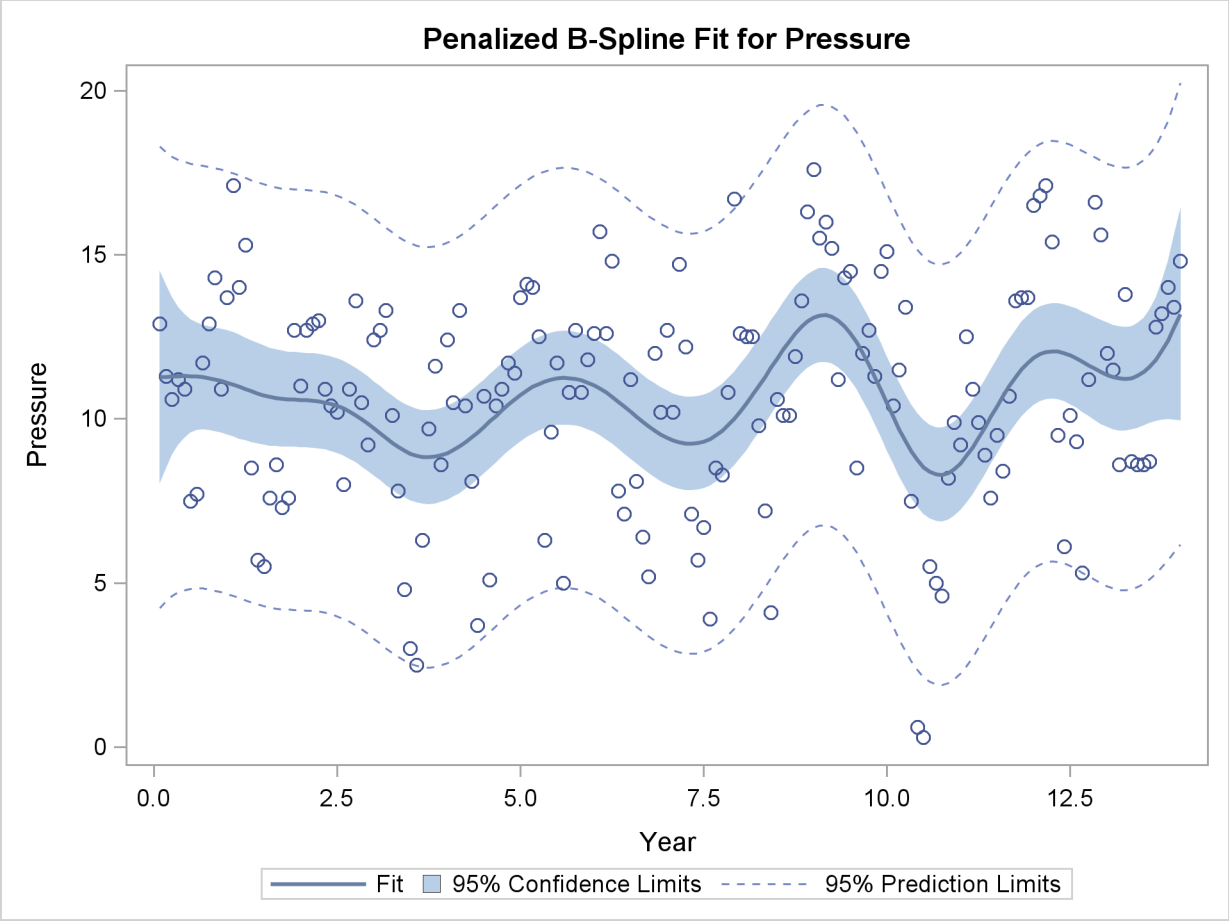
The results show a yearly cycle of pressure change. The procedure chose a smoothing parameter of $\lambda = 0.709$. With data such as these, with many peaks and valleys, it might be useful to perform another analysis, this time asking for a smoother plot. The Schwarz Bayesian criterion (SBC) is sometimes a better choice than the default criterion when you want a smoother plot. The following PROC TRANSREG step requests a penalized B-spline analysis minimizing the SBC criterion:

```
proc transreg data=enso;
   model identity(pressure) = pbspline(year / sbc);
run;
```

The plot of SBC as a function of λ is shown in Output 90.3.2.



Output 90.3.2 Change in Atmospheric Pressure, SBC



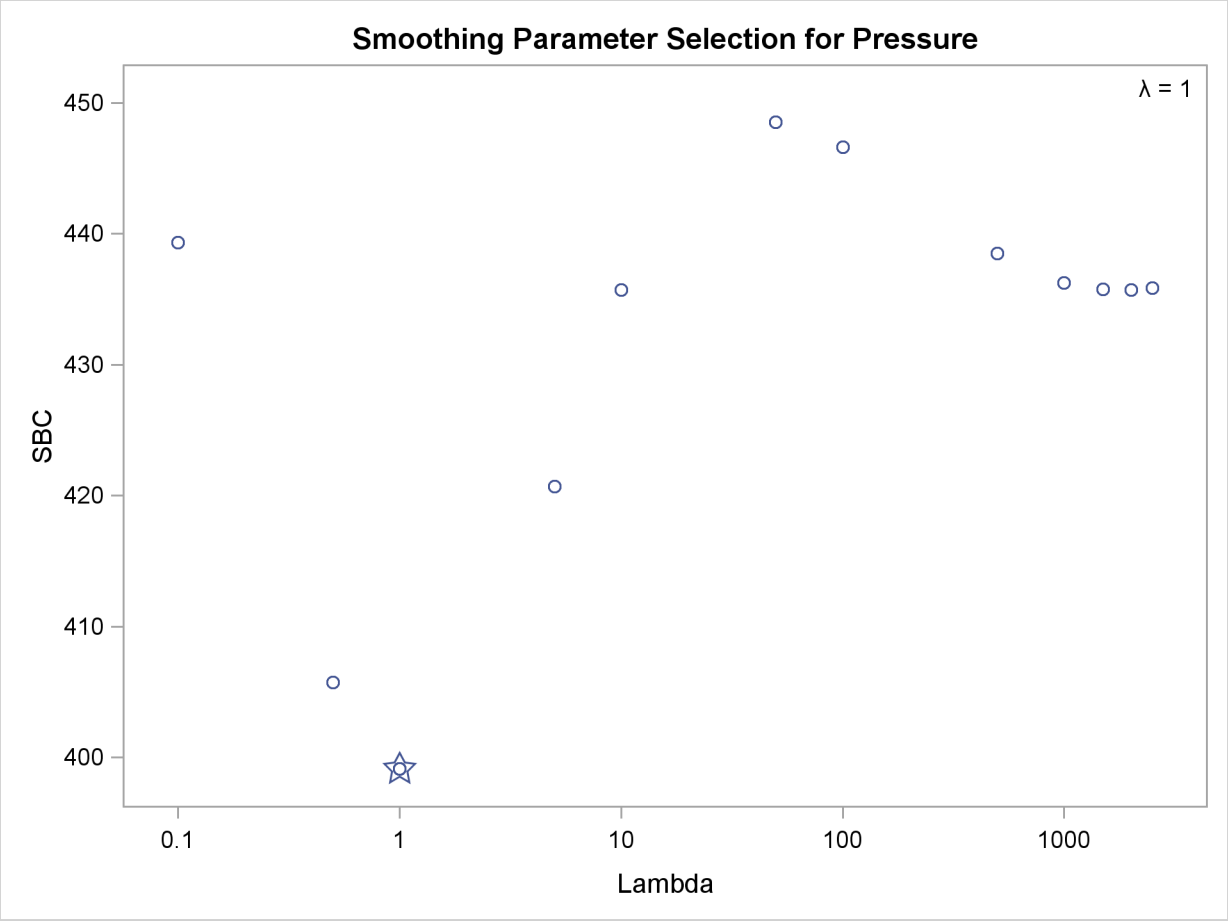
The fit plot (not shown) is essentially the same as the one shown in Output 90.3.1 due to the similar choice of smoothing parameters: $\lambda = 0.709$ versus $\lambda = 1.14$. You can analyze these data again, this time forcing PROC TRANSREG to consider only larger smoothing parameters. The specification LAMBDA=2 10000 RANGE eliminates from consideration the two lambdas that you previously saw and considers only $2 \leq \lambda \leq 10,000$. The following statements produce Output 90.3.3:

```
proc transreg data=enso;
   model identity(pressure) = pbspline(year / sbc lambda=2 10000 range);
run;
```

Output 90.3.3 Change in Atmospheric Pressure, SBC, Lambda > 1

Output 90.3.3 *continued*

The results clearly show that there is a local minimum in the SBC(λ) function at $\lambda = 1801.1$. Using this lambda results in a much smoother regression function with a longer cycle than you saw previously. This second cycle can be identified as the periodic warming of the Pacific Ocean known as "El Niño." The SBC(λ) function has at least two minima since there are at least two trends in the data. In the first analysis, PROC TRANSREG found what is probably the globally optimal solution, and in the second set of analyses, with a little nudging away from the global optimum, it found a very interesting locally optimal solution.



You can specify a list of lambdas to see SBC as a function of lambda over the range that includes both minima as follows:

```
proc transreg data=enso;
   model identity(pressure) = pbspline(year / sbc lambda=.1 .5 1 5
                                          10 50 100 500 to 2500 by 500);
   run;

ods graphics off;
```

The plot of SBC as a function of λ is shown in Output 90.3.4.

Output 90.3.4 Change in Atmospheric Pressure, SBC, Over the Range of Both Minima

Example 90.4: Nonmetric Conjoint Analysis of Tire Data

This example uses PROC TRANSREG to perform a nonmetric conjoint analysis of tire preference data. Conjoint analysis decomposes rank-ordered evaluation judgments of products or services into components based on qualitative product attributes. For each level of each attribute of interest, a numerical "part-worth utility" value is computed. The sum of the part-worth utilities for each product is an estimate of the utility for that product. The goal is to compute part-worth utilities such that the product utilities are as similar as possible to the original rank ordering. (This example is a greatly simplified introductory example.)

The stimuli for the experiment are 18 hypothetical tires. The stimuli represent different brands (Goodstone, Pirogi, Machismo),[1] prices ($69.99, $74.99, $79.99), expected tread life (50,000, 60,000, 70,000 miles), and road hazard insurance plans (Yes, No). There are $3 \times 3 \times 3 \times 2 = 54$ possible combinations. From these, 18 combinations are selected that form an efficient experimental design for a main-effects model. The combinations are then ranked from 1 (most preferred) to 18 (least preferred). In this simple example, there is one set of rankings. A real conjoint study would have many more.

[1] In real conjoint experiments, real brand names would be used.

First, the FORMAT procedure is used to specify the meanings of the factor levels, which are entered as numbers in the DATA step along with the ranks. PROC TRANSREG is used to perform the conjoint analysis. A maximum of 50 iterations is requested. The specification **monotone(Rank / reflect)** in the MODEL statement requests that the dependent variable Rank should be monotonically transformed and reflected so that positive utilities mean high preference. The variables Brand, Price, Life, and Hazard are designated as CLASS variables, and the part-worth utilities are constrained by ZERO=SUM to sum to zero within each factor. The UTILITIES *a-option* displays the conjoint analysis results.

The importance column of the utilities table shows that price is the most important attribute in determining preference (57%), followed by expected tread life (18%), brand (15%), and road hazard insurance (10%). Looking at the utilities table for the maximum part-worth utility within each attribute, you see from the results that the most preferred combination is Pirogi brand tires, at $69.99, with a 70,000-mile expected tread life and road hazard insurance. This product is not actually in the data set. The sum of the part-worth utilities for this combination is as follows:

$$20.64 = 9.50 + 1.90 + 5.87 + 2.41 + 0.96$$

The following statements produce Output 90.4.1.

Example 90.5: Metric Conjoint Analysis of Tire Data

This example, which is more detailed than the previous one, uses PROC TRANSREG to perform a metric conjoint analysis of tire preference data. Conjoint analysis can be used to decompose preference ratings of products or services into components based on qualitative product attributes. For each level of each attribute of interest, a numerical "part-worth utility" value is computed. The sum of the part-worth utilities for each product is an estimate of the utility for that product. The goal is to compute part-worth utilities such that the product utilities are as similar as possible to the original ratings. Metric conjoint analysis, as shown in this example, fits an ordinary linear model directly to data assumed to be measured on an interval scale. Nonmetric conjoint analysis, as shown in Example 90.4, finds an optimal monotonic transformation of original data before fitting an ordinary linear model to the transformed data.

This example has three parts. In the first part, an experimental design is created. In the second part, a DATA step creates descriptions of the stimuli for the experiment. The third part of the example performs the conjoint analyses.

The stimuli for the experiment are 18 hypothetical tires. The stimuli represent different brands (Goodstone, Pirogi, Machismo),[2] prices ($69.99, $74.99, $79.99), expected tread life (50,000, 60,000, 70,000 miles), and road hazard insurance plans (Yes, No).

For a conjoint study such as this, you need to create an experimental design with 3 three-level factors, 1 two-level factor, and 18 combinations or *runs*. The easiest way to get this design is with the %MktEx autocall macro. The %MktEx macro requires you to specify the number of levels of each of the four factors, followed by N=18, the number of runs. Specifying a random number seed, while not strictly necessary, helps ensure that the design is reproducible. The %MktLab macro assigns the actual factor names instead of the default names x1, x2, and so on, and it assigns formats to the factor levels. The %MktEval macro helps you evaluate the design. It shows how correlated or independent the factors are, how often each factor level appears in the design, how often each pair occurs for every factor pair, and how often each product profile or run occurs in the design. See http://support.sas.com/resources/papers/tnote/tnote_marketresearch.html (Kuhfeld 2005) for more information about experimental design and conjoint analysis; look for the latest "Conjoint Analysis" report. The following statements create, evaluate, and display the design:

```
title 'Tire Study, Experimental Design';

proc format;
   value BrandF
             1 = 'Goodstone'
             2 = 'Pirogi   '
             3 = 'Machismo ';
   value PriceF
             1 = '$69.99'
             2 = '$74.99'
             3 = '$79.99';
   value LifeF
             1 = '50,000'
```

[2] In real conjoint experiments, real brand names would be used.

```
                2 = '60,000'
                3 = '70,000';
   value HazardF
                1 = 'Yes'
                2 = 'No ';
run;

%mktex(3 3 3 2, n=18, seed=448)

%mktlab(vars=Brand Price Life Hazard, out=sasuser.TireDesign,
        statements=format Brand BrandF9. Price PriceF9.
                   Life LifeF6. Hazard HazardF3.)

%mkteval;

proc print data=sasuser.TireDesign;
run;
```

The %MktEx macro (Kuhfeld 2005) output displayed in Output 90.5.1 shows you that the design is 100% efficient, which means it is orthogonal and balanced. The %MktEval macro output displayed in Output 90.5.2 shows you that all of the factors are uncorrelated or orthogonal, the design is balanced (each level occurs once), and every pair of factor levels occurs equally often (again showing that the design is orthogonal). The *n*-way frequencies show that each product profile occurs once (there are no duplicates). The design is shown in Output 90.5.3. The design is automatically randomized (the profiles were sorted into a random order and the original levels are randomly reassigned). Orthogonality, balance, randomization, and other design concepts are discussed in detail in Kuhfeld (2005), in the "Experimental Design, Efficiency, Coding, and Choice Designs" report.

This output in Output 90.5.4 is abbreviated in the interest of conserving space; the statements actually produce stimuli for all combinations.

Output 90.5.4 Conjoint Analysis, Stimuli Descriptions

```
                                                    Subject _________

1) For your next tire purchase, how likely are you to buy this product?

   Pirogi brand tires at $79.99,
   with a 50,000 tread life guarantee,
   and without road hazard insurance.

   Definitely Would                 Definitely Would
   Not Purchase                             Purchase

   1     2     3     4     5     6     7     8     9

2) For your next tire purchase, how likely are you to buy this product?

   Machismo brand tires at $79.99,
   with a 60,000 tread life guarantee,
   and without road hazard insurance.

   Definitely Would                 Definitely Would
   Not Purchase                             Purchase

   1     2     3     4     5     6     7     8     9

3) For your next tire purchase, how likely are you to buy this product?

   Machismo brand tires at $74.99,
   with a 70,000 tread life guarantee,
   and with road hazard insurance.

   Definitely Would                 Definitely Would
   Not Purchase                             Purchase

   1     2     3     4     5     6     7     8     9

4) For your next tire purchase, how likely are you to buy this product?

   Machismo brand tires at $74.99,
   with a 50,000 tread life guarantee,
   and without road hazard insurance.

   Definitely Would                 Definitely Would
   Not Purchase                             Purchase

   1     2     3     4     5     6     7     8     9
```

The third part of the example performs the conjoint analyses. The DATA step reads the data. Only the ratings are entered, one row per subject. Real conjoint studies have many more subjects than five. The TRANSPOSE procedure transposes this (5×18) data set into an (18×5) data set that can be merged with the factor level data set sasuser.TireDesign. The next DATA step does the merge. The PRINT procedure displays the input data set.

PROC TRANSREG fits the five individual conjoint models, one for each subject. The UTILITIES *a-option* displays the conjoint analysis results. The SHORT *a-option* suppresses the iteration histories, OUTTEST=UTILS creates an output data set with all of the conjoint results, and the SEPARATORS= option requests that the labels constructed for each category contain two blanks between the variable name and the level value. The ODS SELECT statement is used to limit the displayed output. The MODEL statement specifies IDENTITY for the ratings, which specifies a metric conjoint analysis—the ratings are not transformed. The variables Brand, Price, Life, and Hazard are designated as CLASS variables, and the part-worth utilities are constrained to sum to zero within each factor.

The following statements produce Output 90.5.5:

```
title 'Tire Study, Data Entry, Preprocessing';

data Results;
   input (c1-c18) (1.);
   datalines;
233279766526376493

262189456534275794
184396375364187754
133379775526267493
;

* Create an Object by Subject Data Matrix;
proc transpose data=Results out=Results(drop=_name_) prefix=Subj;
run;

* Merge the Factor Levels with the Data Matrix;
data Both;
   merge sasuser.TireDesign Results;
run;

proc print;
   title2 'Data Set for Conjoint Analysis';
run;

title 'Tire Study, Individual Conjoint Analyses';

* Fit Each Subject Individually;
proc transreg data=Both utilities short outtest=utils separators='  ';
   ods select TestsNote FitStatistics Utilities;
   model identity(Subj1-Subj5) =
         class(Brand Price Life Hazard / zero=sum);
run;
```

The output contains two tables per subject, one with overall fit statistics and one with the conjoint analysis results.

The next steps summarize the results. Three tables are displayed, showing the following: all of the importance values, the average importance, and the part-worth utilities. The first DATA step selects the importance information from the UTILS data set. The final assignment statement stores just the variable name from the label, relying on the fact that the separator is two blanks. PROC TRANSPOSE creates the data set of importances, one row per subject, and PROC PRINT displays the results. The MEANS procedure displays the average importance of each attribute across the subjects. The next DATA step selects the part-worth utilities information from the UTILS data set. PROC TRANSPOSE creates the data set of utilities, one row per subject, and PROC PRINT displays the results. The following statements produce Output 90.5.6:

```
title 'Tire Study Results';

* Gather the Importance Values;
data Importance;
   set utils(keep=_depvar_ Importance Label);
   if n(Importance);
   label = substr(label, 1, index(label, '  '));
run;

proc transpose out=Importance2(drop=_:);
   by _depvar_;
   id Label;
run;

proc print;
   title2 'Importance Values';
run;

proc means;
   title2 'Average Importance';
run;

* Gather the Part-Worth Utilities;

Based on the importance values, price is the most important attribute for some of the respondents, but expected tread life is most important for others. On the average, price is most important, followed by expected tread life and brand. Road hazard insurance is less important. Each of the brands is preferred by some of the respondents. All respondents preferred a lower price over a higher price, a longer tread life, and road hazard insurance.

Example 90.6: Preference Mapping of Automobile Data

This example uses PROC TRANSREG to perform a preference mapping (PREFMAP) analysis (Carroll 1972) of automobile preference data after a PROC PRINQUAL principal component analysis. The PREFMAP analysis is a response surface regression that locates ideal points for each dependent variable in a space defined by the independent variables.

The data are ratings obtained from 25 judges of their preference for each of 17 automobiles. The ratings were made on a scale of zero (very weak preference) to nine (very strong preference). These judgments were made in 1980 about that year's products. There are two character variables that indicate the manufacturer and model of the automobile. The data set also contains three ratings: miles per gallon (MPG), projected reliability (Reliability), and quality of the ride (Ride). These ratings are on a scale of one (bad) to five (good). PROC PRINQUAL creates an OUT= data set containing standardized principal component scores (Prin1 and Prin2), along with the ID variables Model, MPG, Reliability, and Ride.

While this data set contains all of the information needed for the subsequent preference mapping, you can make slightly more informative plots by adding new variable labels to the principal component score variables. The default labels are 'Component 1', 'Component 2', and so on. These are by necessity rather generic since they are created before any data are read, and they must be appropriate across BY groups when a BY variable is specified. In contrast, the MDPREF plot in PROC PRINQUAL has axis labels of the form 'Component 1 (43.54%)' and 'Component 2 (23.4%)' that show the proportion of variance accounted for by each component. You can create an output data set from the MDPREF plot by using the ODS OUTPUT statement and then use only the label information from it to reset the labels in the output data set from PROC PRINQUAL. In the DATA PLOT step, the SET statement for the MD data set is specified before the SET statement for the PRESULTS data set. The `if 0` ensures that no data are actually read from it, but nevertheless the properties of the Prin1 and Prin2 variables including the variable labels are set based on the properties of those variables in the MD data set.

The first PROC TRANSREG step fits univariate regression models for MPG and Reliability. All variables are designated IDENTITY. A vector drawn in the plot of Prin1 and Prin2 from the origin to the point defined by an attribute's regression coefficients approximately shows how the autos differ on that attribute. See Carroll (1972) for more information. The Prin1 and Prin2 columns of the TResult1 OUT= data set contain the automobile coordinates (_Type_='SCORE' observations) and endpoints of the MPG and Reliability vectors (_Type_='M COEFFI' observations).

The second PROC TRANSREG step fits a univariate regression model with Ride designated IDENTITY, and Prin1 and Prin2 designated POINT. The POINT expansion creates an additional independent variable _ISSQ_, which contains the sum of Prin1 squared and Prin2 squared. The OUT= data set TResult2 contains no _Type_='SCORE' observations, only ideal point (_Type_='M

POINT') coordinates for Ride. The coordinates of both the vectors and the ideal points are output by specifying COORDINATES in the OUTPUT statement in PROC TRANSREG.

A vector model is used for MPG and Reliability because perfectly efficient and reliable automobiles do not exist in the data set. The ideal points for MPG and Reliability are far removed from the plot of the automobiles. It is more likely that an ideal point for quality of the ride is in the plot, so an ideal point model is used for the ride variable. See Carroll (1972) and Schiffman, Reynolds, and Young (1981) for discussions of the vector model and point models (including the EPOINT and QPOINT versions of the point model that are not used in this example). For the vector model, the default coordinates stretch factor of 2.5 was used. This extends the vectors by a factor of 2.5 from their standard lengths, making a better graphical display. Sometimes the default vectors are short and near the origin, and they look better when they are extended.

The following statements produce Output 90.6.1 through Output 90.6.5:

   Algorithm converged.
```

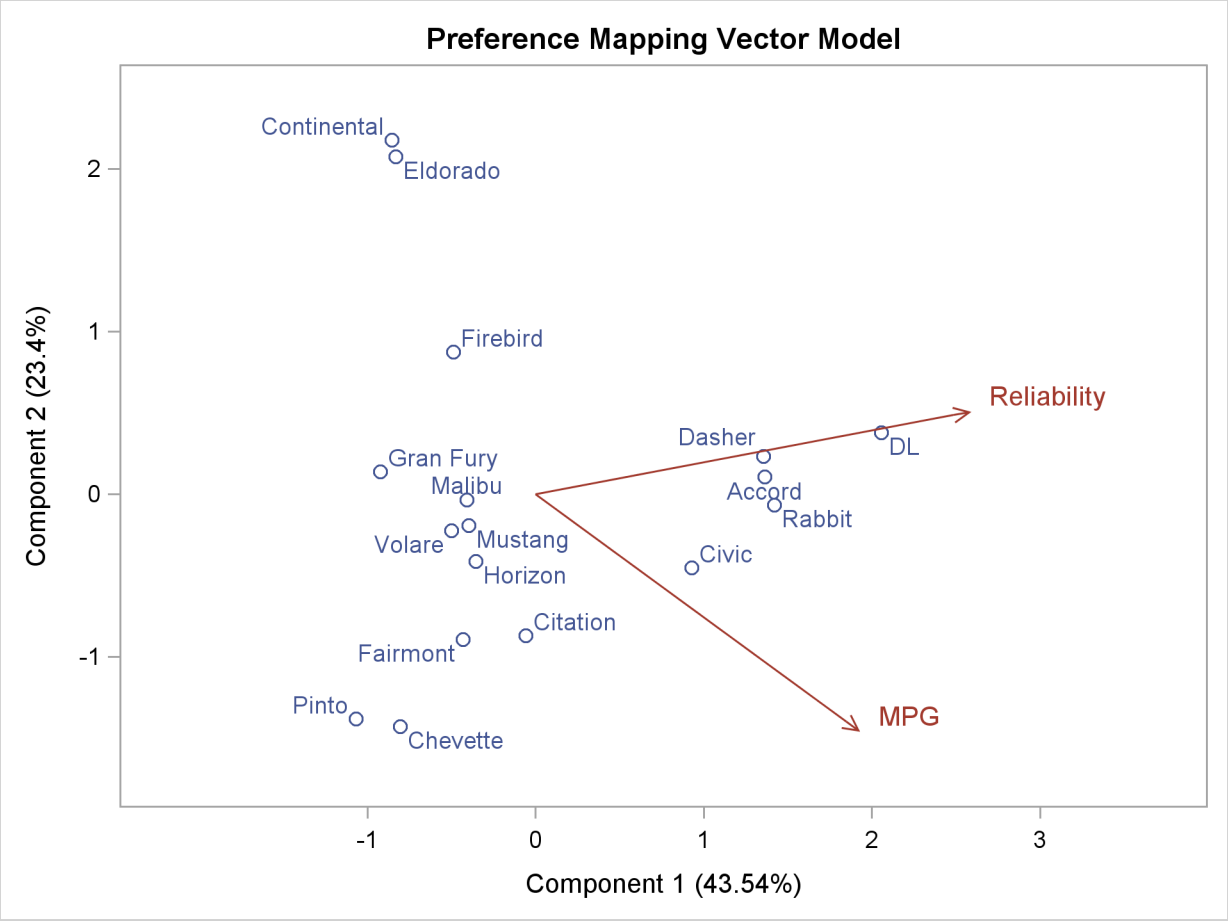
Output 90.6.2 MDPREF Plot

Output 90.6.3 shows that an unreliable-to-reliable direction extends from the left and slightly below the origin to the right and slightly above the origin. The Japanese and European automobiles are rated, on the average, as more reliable. A low MPG to good MPG direction extends from the top left of the plot to the bottom right. The smaller automobiles, on the average, get better gas mileage.

Output 90.6.3 Preference Mapping Vector Plot

```
Preference Ratings for Automobiles Manufactured in 1980
Preference Mapping (PREFMAP) Analysis

The TRANSREG Procedure



The TRANSREG Procedure Hypothesis Tests for Identity(MPG)

R-Square      0.5720

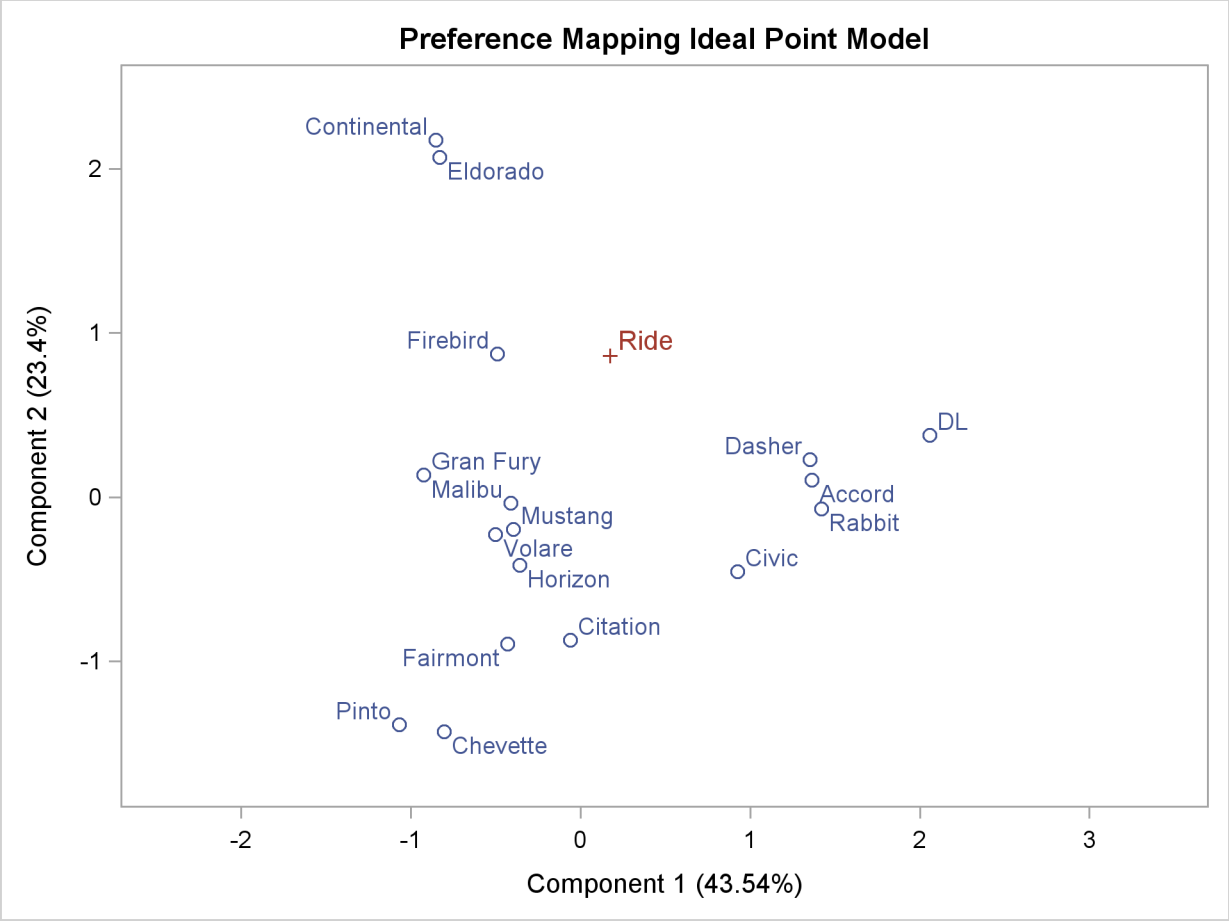
The TRANSREG Procedure Hypothesis Tests for Identity(Reliability)

R-Square      0.5086
```

Output 90.6.3 *continued*

The ideal point for Ride in Output 90.6.4 is in the top, just right of the center of the plot. Automobiles near the Ride ideal point tend to have a better ride than automobiles far away. It can be seen from the R squares that none of these ratings perfectly fits the model, so all of the interpretations are approximate.

Output 90.6.4 Preference Mapping Ideal Point Plot



```
Preference Ratings for Automobiles Manufactured in 1980
Preference Mapping (PREFMAP) Analysis

The TRANSREG Procedure

The TRANSREG Procedure Hypothesis Tests for Identity(Ride)

R-Square      0.3780
```

Output 90.6.4 *continued*

The Ride point is a "negative-negative" ideal point. The point models assume that small ratings mean the object (automobile) is similar to the rating name and large ratings imply dissimilarity to the rating name. Because the opposite scoring is used, the interpretation of the Ride point must be reversed to a negative ideal point (bad ride). However, the coefficient for the _ISSQ_ variable in Output 90.6.5 is negative, so the interpretation is reversed again, back to the original interpretation.

Output 90.6.5 Preference Mapping Ideal Point Coefficients

Overview: TREE Procedure

The TREE procedure produces a tree diagram, also known as a *dendrogram* or *phenogram*, from a data set created by the CLUSTER or VARCLUS procedure that contains the results of hierarchical clustering as a tree structure. The TREE procedure uses the data set to produce a diagram of the tree structure in the style of Johnson (1967), with the root at the top. Alternatively, the diagram can be oriented horizontally, with the root at the left. Any numeric variable in the output data set can be used to specify the heights of the clusters. PROC TREE can also create an output data set containing a variable to indicate the disjoint clusters at a specified level in the tree.

Tree diagrams are discussed in the context of cluster analysis by Duran and Odell (1974), Hartigan (1975), and Everitt (1980). Knuth (1973) provides a general treatment of tree diagrams in computer programming.

The literature on tree diagrams contains a mixture of botanical and genealogical terminology. The objects that are clustered are *leaves*. The cluster containing all objects is the *root*. A cluster containing at least two objects but not all of them is a *branch*. The general term for leaves, branches, and roots is *node*. If a cluster A is the union of clusters B and C, then A is the *parent* of B and C, and B and C are *children* of A. A leaf is thus a node with no children, and a root is a node with no parent. If every cluster has at most two children, the tree diagram is a *binary tree*. The CLUSTER procedure always produces binary trees. The VARCLUS procedure can produce tree diagrams with clusters that have many children.

Getting Started: TREE Procedure

The TREE procedure creates tree diagrams from a SAS data set containing the tree structure. You can create this type of data set with the CLUSTER or VARCLUS procedure. See Chapter 29, "The CLUSTER Procedure," and Chapter 93, "The VARCLUS Procedure," for more information.

In the following example, the VARCLUS procedure is used to divide a set of variables into hierarchical clusters and to create the SAS data set containing the tree structure. The TREE procedure then generates the tree diagrams.

The following data, from Hand et al. (1994), represent the amount of protein consumed from nine food groups for each of 25 European countries. The nine food groups are red meat (RedMeat), white meat (WhiteMeat), eggs (Eggs), milk (Milk), fish (Fish), cereal (Cereal), starch (Starch), nuts (Nuts), and fruits and vegetables (FruVeg).

The following SAS statements create the data set Protein:

```
data Protein;
   input Country $15. RedMeat WhiteMeat Eggs Milk
      Fish Cereal Starch Nuts FruVeg;
   datalines;
Albania         10.1  1.4  0.5   8.9  0.2  42.3  0.6  5.5  1.7

;
run;
```

The data set Protein contains the character variable Country and the nine numeric variables representing the food groups. The `$15.` in the INPUT statement specifies that the variable Country is a character variable with a length of 15.

The following statements cluster the variables in the data set Protein. The OUTTREE= option creates an output data set named Tree to contain the tree structure. The CENTROID option specifies the centroid clustering method, and the MAXCLUSTERS= option specifies that the largest number of clusters desired is four. The NOPRINT option suppresses the display of the output. The VAR statement specifies that all numeric variables (RedMeat—FruVeg) are used by the procedure.

```
proc varclus data=Protein outtree=Tree centroid maxclusters=4 noprint;
   var RedMeat--FruVeg;
run;
```

The output data set Tree, created by the OUTTREE= option in the previous statements, contains the following variables:

NAME	the name of the cluster
PARENT	the parent of the cluster
NCL	the number of clusters
VAREXP	the amount of variance explained by the cluster
PROPOR	the proportion of variance explained by the clusters at the current level of the tree diagram
MINPRO	the minimum proportion of variance explained by a cluster
MAXEIGEN	the maximum second eigenvalue of a cluster

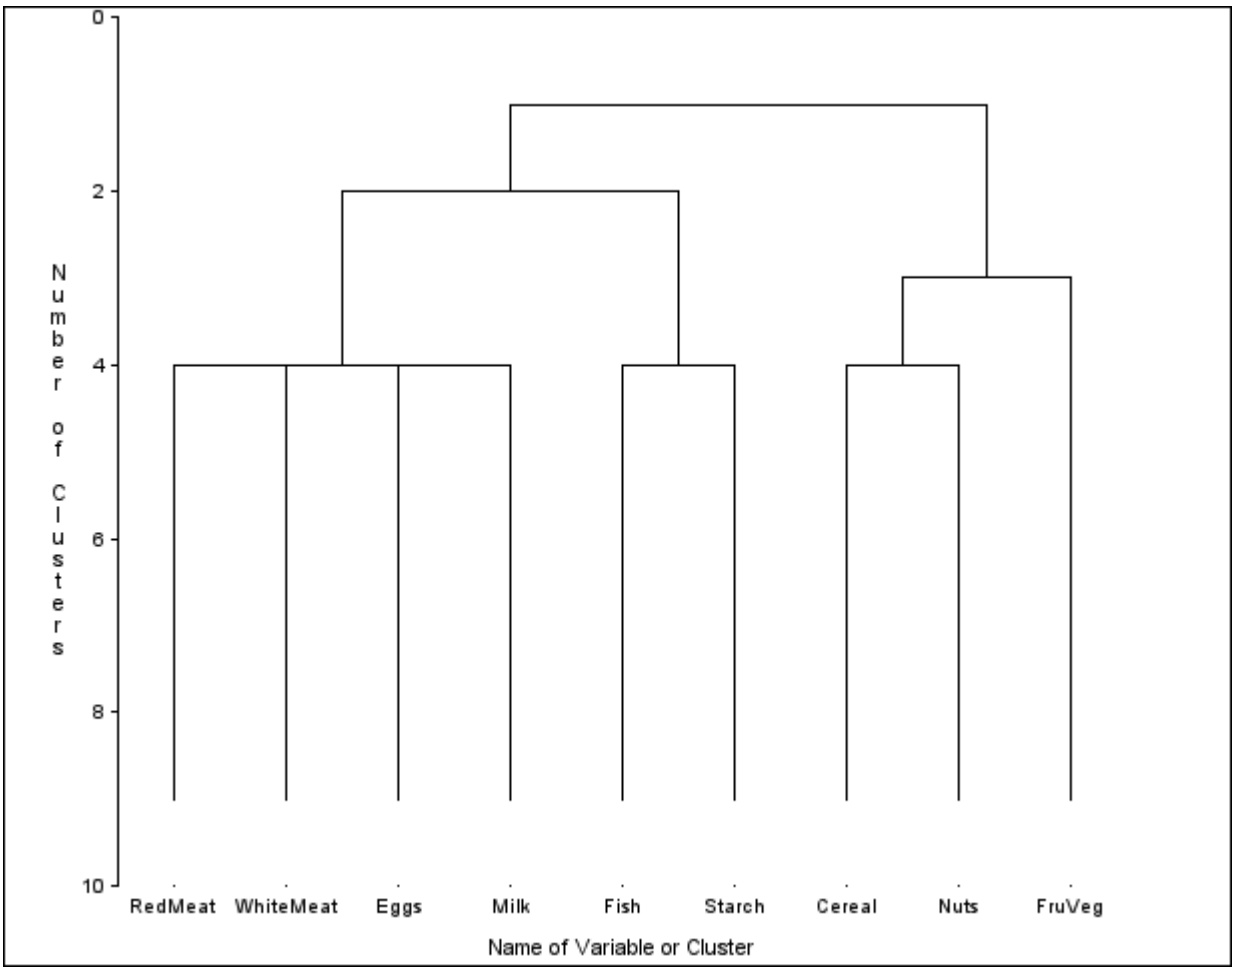
The following statements produce tree diagrams of the clusters created by PROC VARCLUS:

```
proc tree data=tree;
proc tree data=tree lineprinter;
```

PROC TREE is invoked twice. In the first invocation, the tree diagram is presented using the default graphical output. In the second invocation, the LINEPRINTER option specifies line printer output.

Figure 91.1 displays the default graphical representation of the tree diagram.

Figure 91.1 Graphical Tree Diagram from PROC TREE



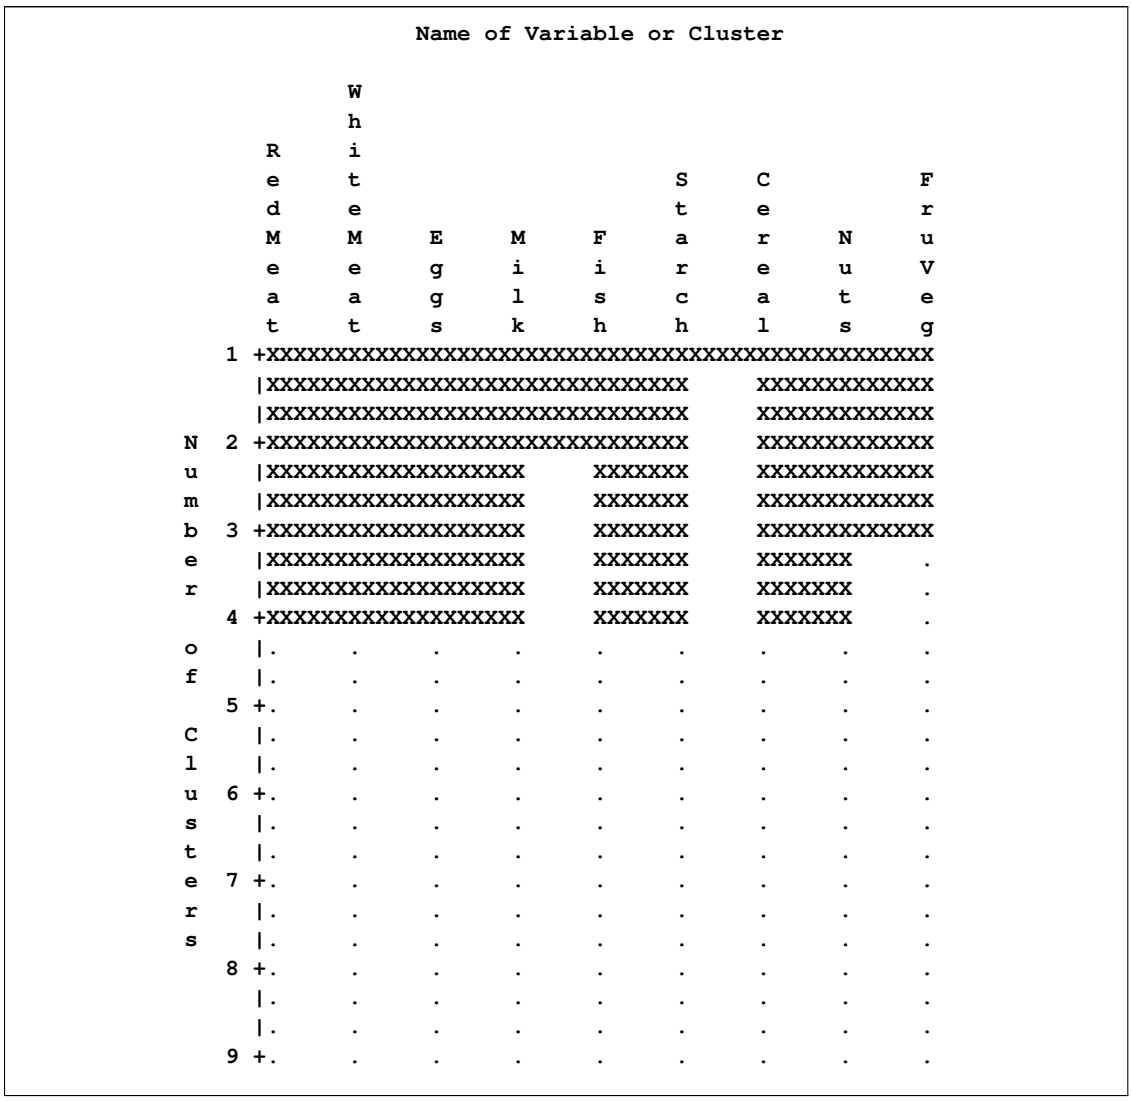


Figure 91.2 displays the same information as Figure 91.1 by using line printer output.

Figure 91.2 Line Printer Representation of the Tree Diagram

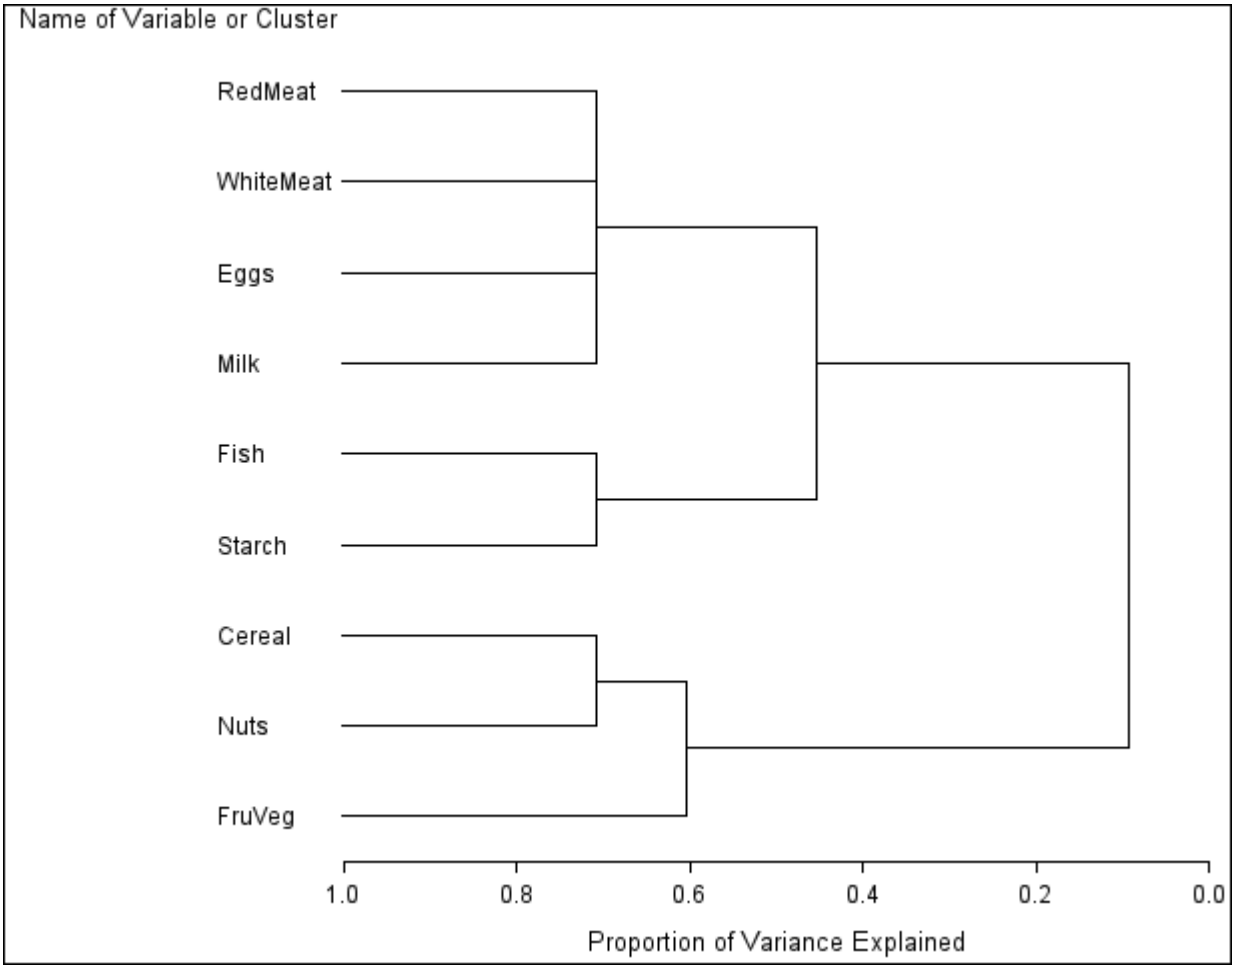
In each diagram the name of the cluster is displayed on the horizontal axis and the number of clusters is displayed on the vertical or height axis.

As you look up from the bottom of either diagram, clusters are progressively joined until a single, all-encompassing cluster is formed at the top (or root) of the tree. Clusters exist at each level of the diagram. For example, at the level where the diagram indicates three clusters, the clusters are as follows:

- Cluster 1: RedMeat WhiteMeat Eggs Milk
- Cluster 2: Fish Starch
- Cluster 3: Cereal Nuts FruVeg

As you proceed up the diagram one level, the number of clusters is two:

- Cluster 1: RedMeat WhiteMeat Eggs Milk Fish Starch
- Cluster 2: Cereal Nuts FruVeg



The following statements illustrate how you can specify the numeric variable defining the height of each node (cluster) in the tree:

```
axis1 order=(0 to 1 by 0.2);
proc tree data=Tree horizontal haxis=axis1;
   height _PROPOR_;
run;
```

The AXIS1 statement ORDER= option specifies the data values in the order in which they are to appear on the axis. The HORIZONTAL option in the PROC TREE statement orients the tree diagram horizontally. The HAXIS option specifies that the AXIS1 statement be used to customize the appearance of the horizontal axis. The HEIGHT statement specifies the variable _PROPOR_ (the proportion of variance explained) as the height variable.

The resulting tree diagram is shown in Figure 91.3.

Figure 91.3 Horizontal Tree Diagram with _PROPOR_ as the HEIGHT Variable

As you look from left to right in the diagram, objects and clusters are progressively joined until a single, all-encompassing cluster is formed at the right (or root) of the tree.

Clusters exist at each level of the diagram, represented by horizontal line segments. Each vertical line segment represents a point where leaves and branches are connected into progressively larger clusters.

For example, three clusters are formed at the leftmost point along the axis where three horizontal line segments exist. At that point, where a vertical line segment connects the Cereal-Nuts and FruVeg clusters, the proportion of variance explained is about 0.6 (_PROPOR_ = 0.6). At the next clustering level the variables Fish and Starch are clustered with variables RedMeat through Milk, resulting in a total of two clusters. The proportion of variance explained is about 0.45 at that point.

Syntax: TREE Procedure

The TREE procedure is invoked by the following statements:

```
PROC TREE < options > ;
    NAME variables ;
    HEIGHT variable ;
    PARENT variables ;
    BY variables ;
    COPY variables ;
    FREQ variable ;
    ID variable ;
```

If the input data set has been created by CLUSTER or VARCLUS, the only statement required is the PROC TREE statement. The BY, COPY, FREQ, HEIGHT, ID, NAME, and PARENT statements are described after the PROC TREE statement.

PROC TREE Statement

```
PROC TREE < options > ;
```

The PROC TREE statement starts the TREE procedure.

The options that can appear in the PROC TREE statement are summarized in Table 91.1.

Table 91.1 PROC TREE Statement Options

Option	Description
Data Sets	
DATA=	specifies input data set
DOCK=	specifies that small clusters not be counted in OUT= data set

Table 91.1 *continued*

Option	Description
LEVEL=	defines disjoint cluster in OUT= data set
NCLUSTERS=	specifies number of clusters in OUT= data set
OUT=	specifies output data set
ROOT=	displays root of a subtree
Cluster Heights	
HEIGHT=	specifies variable for the height axis
DISSIMILAR	specifies that height values indicate dissimilarity
SIMILAR	specifies that height values indicate similarity
Horizontal Trees	
HORIZONTAL	specifies that height axis be horizontal
Sort Order	
DESCENDING	reverses sort order
SORT	sorts children by HEIGHT variable
Displayed Output	
INC=	specifies increment between tick values
LINEPRINTER	displays tree by using line printer graphics
LIST	displays all nodes in tree
MAXHEIGHT=	specifies maximum value on axis
MINHEIGHT=	specifies minimum value on axis
NOPRINT	suppresses display of tree
NTICK=	specifies number of tick intervals
Graphics	
CFRAME=	specifies color of the frame
DESCRIPTION=	specifies catalog description
GOUT=	specifies catalog name
HAXIS=	customizes horizontal axis
HORDISPLAY=	displays horizontal tree with leaves on right
HPAGES=	specifies number of pages to expand tree horizontally
LINES=	specifies line color and thickness, dots at nodes
NAME=	specifies name of graph in catalog
VAXIS=	customizes vertical axis
VPAGES=	specifies number of pages to expand tree vertically
Line Printer Graphics	
PAGES=	specifies number of pages
POS=	specifies number of column positions
SPACES=	specifies number of spaces between objects
TICKPOS=	specifies number of column positions between ticks
FILLCHAR=	specifies fill character between unjoined leaves
JOINCHAR=	specifies character displayed between joined leaves
LEAFCHAR=	specifies character representing clusters with no children
TREECHAR=	specifies character representing clusters with children

CFRAME=*color*

specifies a color for the frame, which is the rectangle bounded by the axes.

DATA=*SAS-data-set*

specifies the input data set defining the tree. If you omit the DATA= option, the most recently created SAS data set is used.

DESCENDING

DES

reverses the sorting order for the SORT option.

DESCRIPTION=*entry-description*

specifies a description for the graph in the GOUT= catalog. The default is "Proc Tree Graph Output."

DISSIMILAR

DIS

specifies that the values of the HEIGHT variable are dissimilarities; that is, a large height value means that the clusters are very dissimilar or far apart.

If neither the SIMILAR nor the DISSIMILAR option is specified, PROC TREE attempts to infer from the data whether the height values are similarities or dissimilarities. If PROC TREE cannot tell this from the data, it issues an error message and does not display a tree diagram.

DOCK=*n*

causes observations in the OUT= data set assigned to output clusters with a frequency of *n* or less to be given missing values for the output variables CLUSTER and CLUSNAME. If the NCLUSTERS= option is also specified, DOCK= also prevents clusters with a frequency of *n* or less from being counted toward the number of clusters requested by the NCLUSTERS= option. By default, DOCK=0.

FILLCHAR=*'c'*

FC=*'c'*

specifies the character to display between leaves that are not joined into a cluster. The character should be enclosed in single quotes. The default is a blank. The LINEPRINTER option must also be specified.

GOUT=<*libref.*>*member-name*

specifies the catalog in which the generated graph is stored. The default is WORK.GSEG.

HAXIS=AXIS*n*

specifies that the AXIS*n* statement used to customize the appearance of the horizontal axis.

HEIGHT=*name*

H=*name*

specifies certain conventional variables to be used for the height axis of the tree diagram. For many situations, the only option you need is the HEIGHT= option. Valid values for *name* and their meanings are as follows:

HEIGHT | H specifies the _HEIGHT_ variable.

LENGTH | L	defines the height of each node as its path length from the root. This can also be interpreted as the number of ancestors of the node.
MODE | M	specifies the _MODE_ variable.
NCL | N	specifies the _NCL_ (number of clusters) variable.
RSQ | R	specifies the _RSQ_ variable.

See also the section "HEIGHT Statement" on page 7368, which can specify any variable in the input data set to be used for the height axis. In rare cases, you might need to specify either the DISSIMILAR option or the SIMILAR option.

HORDISPLAY=RIGHT

specifies that the graph be oriented horizontally, with the leaf nodes on the right side, when the HORIZONTAL option is also specified. By default, the leaf nodes are on the left side.

HORIZONTAL

HOR

displays the tree diagram with the height axis oriented horizontally. The leaf nodes are on the side specified in the HORDISPLAY= option. If you do not specify the HORIZONTAL option, the height axis is vertical, with the root at the top. When the tree takes up more than one page, horizontal orientation can make the tree diagram considerably easier to read.

HPAGES=*n1*

specifies that the original graph be enlarged to cover $n1$ pages. If you also specify the VPAGES=$n2$ option, the original graph is enlarged to cover $n1 \times n2$ graphs. For example, if HPAGES=2 and VPAGES=3, then the original graph is generated, followed by $2 \times 3 = 6$ more graphs. In these six graphs, the original is enlarged by a factor of 2 in the horizontal direction and by a factor of 3 in the vertical direction. The graphs are generated in left-to-right and top-to-bottom order.

INC=*n*

specifies the increment between tick values on the height axis. If the HEIGHT variable is _NCL_, the default is usually 1, although a different value can be specified for consistency with other options. For any other HEIGHT variable, the default is some power of 10 times 1, 2, 2.5, or 5.

JOINCHAR=*'c'*

JC=*'c'*

specifies the character displayed between leaves that are joined into a cluster. The character should be enclosed in single quotes. The default is 'X'. The LINEPRINTER option must also be specified.

LEAFCHAR=*'c'*

LC=*'c'*

specifies the character used to represent clusters having no children. The character should be enclosed in single quotes. The default is a period. The LINEPRINTER option must also be specified.

LEVEL=*n*

specifies the level of the tree defining disjoint clusters for the OUT= data set. The LEVEL= option also causes only clusters between the root and a height of n to be displayed. The clusters in the output data set are those that exist at a height of n on the tree diagram. For example, if the HEIGHT variable is _NCL_ (number of clusters) and LEVEL=5 is specified, then the OUT= data set contains five disjoint clusters. If the HEIGHT variable is _RSQ_ (R^2) and LEVEL=0.9 is specified, then the OUT= data set contains the smallest number of clusters that yields an R^2 of at least 0.9.

LINEPRINTER

specifies that the tree diagram be displayed using line printer graphics.

LINES=(<COLOR=*color***> <WIDTH=***n***> <DOTS>)**

specifies the color and the thickness of the lines of the tree, and whether a dot is drawn at each leaf node. Note that if the frame and the lines are specified to be the same color, PROC TREE selects a different color for the lines.

LIST

lists all the nodes in the tree, displaying the height, parent, and children of each node.

MAXHEIGHT=*n*

MAXH=*n*

specifies the maximum value displayed on the height axis.

MINHEIGHT=*n*

MINH=*n*

specifies the minimum value displayed on the height axis.

NAME=*name*

specifies the entry name for the generated graph in the GOUT= catalog. Note that each time another graph is generated with the same name, the name is modified by appending a number to make it unique.

NCLUSTERS=*n*

NCL=*n*

N=*n*

specifies the number of clusters desired in the OUT= data set. The number of clusters obtained might not equal the number specified if (1) there are fewer than n leaves in the tree, (2) there are more than n unconnected trees in the data set, (3) a multiway tree does not contain a level with the specified number of clusters, or (4) the DOCK= option eliminates too many clusters.

The NCLUSTERS= option uses the _NCL_ variable to determine the order in which the clusters are formed. If there is no _NCL_ variable, the height variable (as determined by the HEIGHT statement or HEIGHT= option) is used instead.

NTICK=*n*

specifies the number of tick intervals on the height axis. The default depends on the values of other options.

NOPRINT

suppresses the display of the tree. Specify the NOPRINT option if you want only to create an OUT= data set.

OUT=*SAS-data-set*

creates an output data set containing one observation for each object in the tree or subtree being processed and variables called CLUSTER and CLUSNAME showing cluster membership at any specified level in the tree. If you specify the OUT= option, you must also specify either the NCLUSTERS= or LEVEL= option in order to define the output partition level. If you want to create a permanent SAS data set, you must specify a two-level name (see "SAS Data Files" in *SAS Language Reference: Concepts*).

PAGES=*n*

specifies the number of pages over which the tree diagram (from root to leaves) is to extend. The default is 1. The LINEPRINTER option must also be specified.

POS=*n*

specifies the number of column positions on the height axis. The default depends on the value of the PAGES= option, the orientation of the tree diagram, and the values specified by the PAGESIZE= and LINESIZE= options. The LINEPRINTER option must also be specified.

ROOT=*'name'*

specifies the value of the NAME variable for the root of a subtree to be displayed if you do not want to display the entire tree. If you also specify the OUT= option, the output data set contains only objects belonging to the subtree specified by the ROOT= option.

SIMILAR

SIM

specifies that the values of the HEIGHT variable represent similarities; that is, a large height value means that the clusters are very similar or close together.

If neither the SIMILAR nor the DISSIMILAR option is specified, PROC TREE attempts to infer from the data whether the height values are similarities or dissimilarities. If PROC TREE cannot tell this from the data, it issues an error message and does not display a tree diagram.

SORT

sorts the children of each node by the HEIGHT variable, in the order of cluster formation. See the DESCENDING option on page 7363 for details.

SPACES=*s*

S=*s*

specifies the number of spaces between objects in the output. The default depends on the number of objects, the orientation of the tree diagram, and the values specified by the PAGESIZE= and LINESIZE= options. The LINEPRINTER option must also be specified.

TICKPOS=*n*

specifies the number of column positions per tick interval on the height axis. The default value is usually between 5 and 10, although a different value can be specified for consistency with other options.

TREECHAR=*'c'*

TC=*'c'*

specifies the character used to represent clusters with children. The character should be enclosed in single quotes. The default is 'X'. The LINEPRINTER option must also be specified.

VAXIS=AXIS*n*

specifies that the AXIS*n* statement be used to customize the appearance of the vertical axis.

VPAGES=*n2*

specifies that the original graph be enlarged to cover $n2$ pages. If you also specify the HPAGES=$n1$ option, the original graph is enlarged to cover $n1 \times n2$ pages. For example, if HPAGES=2 and VPAGES=3, then the original graph is generated, followed by $2 \times 3 = 6$ more graphs. In these six graphs, the original is enlarged by a factor of 2 in the horizontal direction and by a factor of 3 in the vertical direction. The graphs are generated in left-to-right and top-to-bottom order.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC TREE to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the TREE procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

COPY Statement

COPY *variables* **;**

The COPY statement specifies one or more character or numeric variables to be copied to the OUT= data set.

FREQ Statement

FREQ *variable* **;**

The FREQ statement specifies one numeric variable that tells how many clustering observations belong to the cluster. If the FREQ statement is omitted, PROC TREE uses the variable _FREQ_ to specify the number of observations per cluster. If neither the FREQ statement nor the _FREQ_ variable is present, each leaf is assumed to represent one clustering observation, and the frequency for each internal node is found by summing the frequencies of its children.

HEIGHT Statement

HEIGHT *variable* **;**

The HEIGHT statement specifies the name of a numeric variable to define the height of each node (cluster) in the tree. The height variable can also be specified by the HEIGHT= option in the PROC TREE statement. If both the HEIGHT statement and the HEIGHT= option are omitted, PROC TREE uses the variable _HEIGHT_. If the data set does not contain _HEIGHT_, PROC TREE uses the variable _NCL_. If _NCL_ is not present either, the height of each node is defined to be its path length from the root.

ID Statement

ID *variable* **;**

The ID variable is used to identify the objects (leaves) in the tree on the output. The ID variable can be a character or numeric variable of any length. If the ID statement is omitted, the variable in the NAME statement is used instead. If both the ID and NAME statements are omitted, PROC TREE uses the variable _NAME_. If the _NAME_ variable is not found in the data set, PROC TREE issues an error message and stops. The ID variable is copied to the OUT= data set.

NAME Statement

NAME *variable* **;**

The NAME statement specifies a character or numeric variable identifying the node represented by each observation. The NAME variable and the PARENT variable jointly define the tree structure. If the NAME statement is omitted, PROC TREE uses the variable _NAME_. If the _NAME_ variable is not found in the data set, PROC TREE issues an error message and stops.

PARENT Statement

PARENT *variable* **;**

The PARENT statement specifies a character or numeric variable identifying the node in the tree that is the parent of each observation. The PARENT variable must have the same formatted length as the NAME variable. If the PARENT statement is omitted, PROC TREE uses the variable _PARENT_. If the _PARENT_ variable is not found in the data set, PROC TREE issues an error message and stops.

Details: TREE Procedure

Missing Values

An observation with a missing value for the NAME variable is omitted from processing. If the PARENT variable has a missing value but the NAME variable is present, the observation is treated as the root of a tree. A data set can contain several roots and, hence, several trees.

Missing values of the HEIGHT variable are set to upper or lower bounds determined from the nonmissing values under the assumption that the heights are monotonic with respect to the tree structure.

Missing values of the FREQ variable are inferred from nonmissing values where possible; otherwise, they are treated as zero.

Output Data Set

The OUT= data set contains one observation for each leaf in the tree or subtree being processed. The variables are as follows:

- the BY variables, if any
- the ID variable, or the NAME variable if the ID statement is not used
- the COPY variables
- a numeric variable CLUSTER taking values from 1 to c, where c is the number of disjoint clusters. The cluster to which the first observation belongs is given the number 1, the cluster to which the next observation belongs that does not belong to cluster 1 is given the number 2, and so on.

- a character variable CLUSNAME giving the value of the NAME variable of the cluster to which the observation belongs

The CLUSTER and CLUSNAME variables are missing if the corresponding leaf has a nonpositive frequency.

Displayed Output

The displayed output from the TREE procedure includes the following:

- the names of the objects in the tree
- the height axis
- the tree diagram. The leaves are displayed at the bottom of the graph. Horizontal lines connect the leaves into branches, while the topmost horizontal line indicates the root.

  If the LINEPRINTER option is specified, the root (the cluster containing all the objects) is indicated by a solid line of the character specified by the TREECHAR= option (the default character is 'X'). At each level of the tree, clusters are shown by unbroken lines of the TREECHAR= symbol with the FILLCHAR= symbol (the default is a blank) separating the clusters. The LEAFCHAR= symbol (the default character is a period) represents single-member clusters.

By default, the tree diagram is oriented with the height axis vertical and the object names at the top of the diagram. If the HORIZONTAL option is specified, then the height axis is horizontal and the object names are on the left.

ODS Table Names

PROC TREE assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 91.2. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 91.2 ODS Tables Produced by PROC TREE

ODS Table Name	Description	Statement	Option
TreeListing	Listing of all nodes in the tree	PROC	LIST

Examples: TREE Procedure

Example 91.1: Mammals' Teeth

The following statements produce a data set containing the numbers of different kinds of teeth for a variety of mammals:

```
data teeth;
   title 'Mammals'' Teeth';
   input mammal $ 1-16 @21 (v1-v8) (1.);
   label V1='Right Top Incisors'
         V2='Right Bottom Incisors'
         V3='Right Top Canines'
         V4='Right Bottom Canines'
         V5='Right Top Premolars'
         V6='Right Bottom Premolars'
         V7='Right Top Molars'
         V8='Right Bottom Molars';
   datalines;
Brown Bat           23113333
Mole                32103333
Silver Hair Bat     23112333
Pigmy Bat           23112233
House Bat           23111233
Red Bat             13112233
Pika                21002233
Rabbit              21003233
Beaver              11002133
Groundhog           11002133
Gray Squirrel       11001133
House Mouse         11000033
Porcupine           11001133
Wolf                33114423
Bear                33114423
Raccoon             33114432
Marten              33114412
Weasel              33113312
Wolverine           33114412
Badger              33113312
River Otter         33114312
Sea Otter           32113312
Jaguar              33113211
Cougar              33113211
Fur Seal            32114411
Sea Lion            32114411
Grey Seal           32113322
Elephant Seal       21114411
Reindeer            04103333
Elk                 04103333
```

```
Deer                 04003333
Moose                04003333
;
run;
```

The following statements use the CLUSTER procedure to cluster the mammals by average linkage and the TREE procedure to produce a horizontal tree diagram that uses the average-linkage distance as its height axis:

```
proc cluster method=average std pseudo noeigen outtree=tree;
   id mammal;
   var v1-v8;
run;

proc tree horizontal;
run;
```

Output 91.1.1 displays the information about how the clusters are joined. For example, the cluster history shows that the observations Wolf and Bear form cluster 29, which is merged with Raccoon to form cluster 11.

Output 91.1.1 Output from PROC CLUSTER

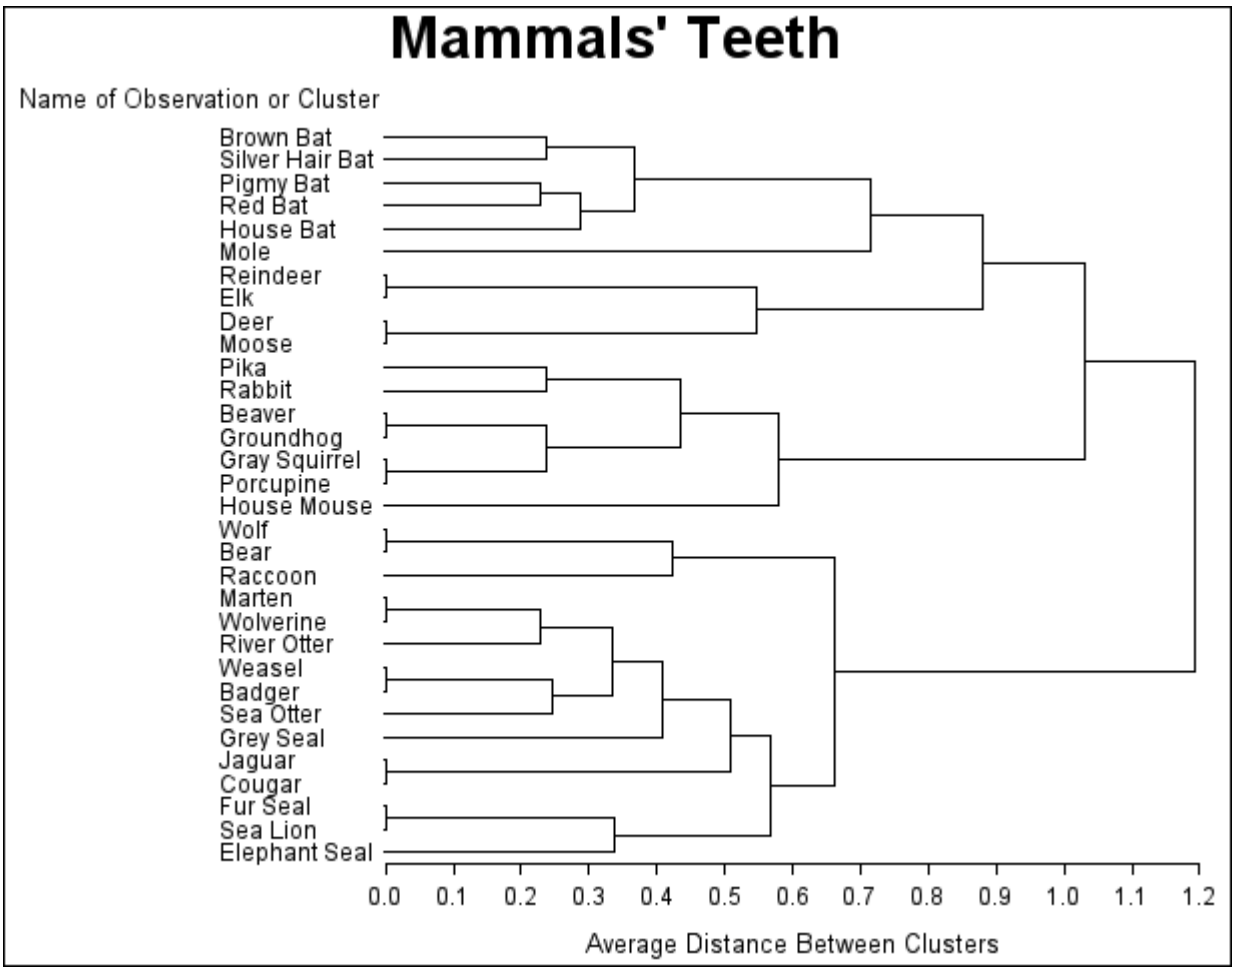
```
                              Mammals' Teeth

                          The CLUSTER Procedure
                       Average Linkage Cluster Analysis

          The data have been standardized to mean 0 and variance 1

          Root-Mean-Square Total-Sample Standard Deviation           1

           Root-Mean-Square Distance Between Observations           4
```



Output 91.1.1 *continued*

Cluster History

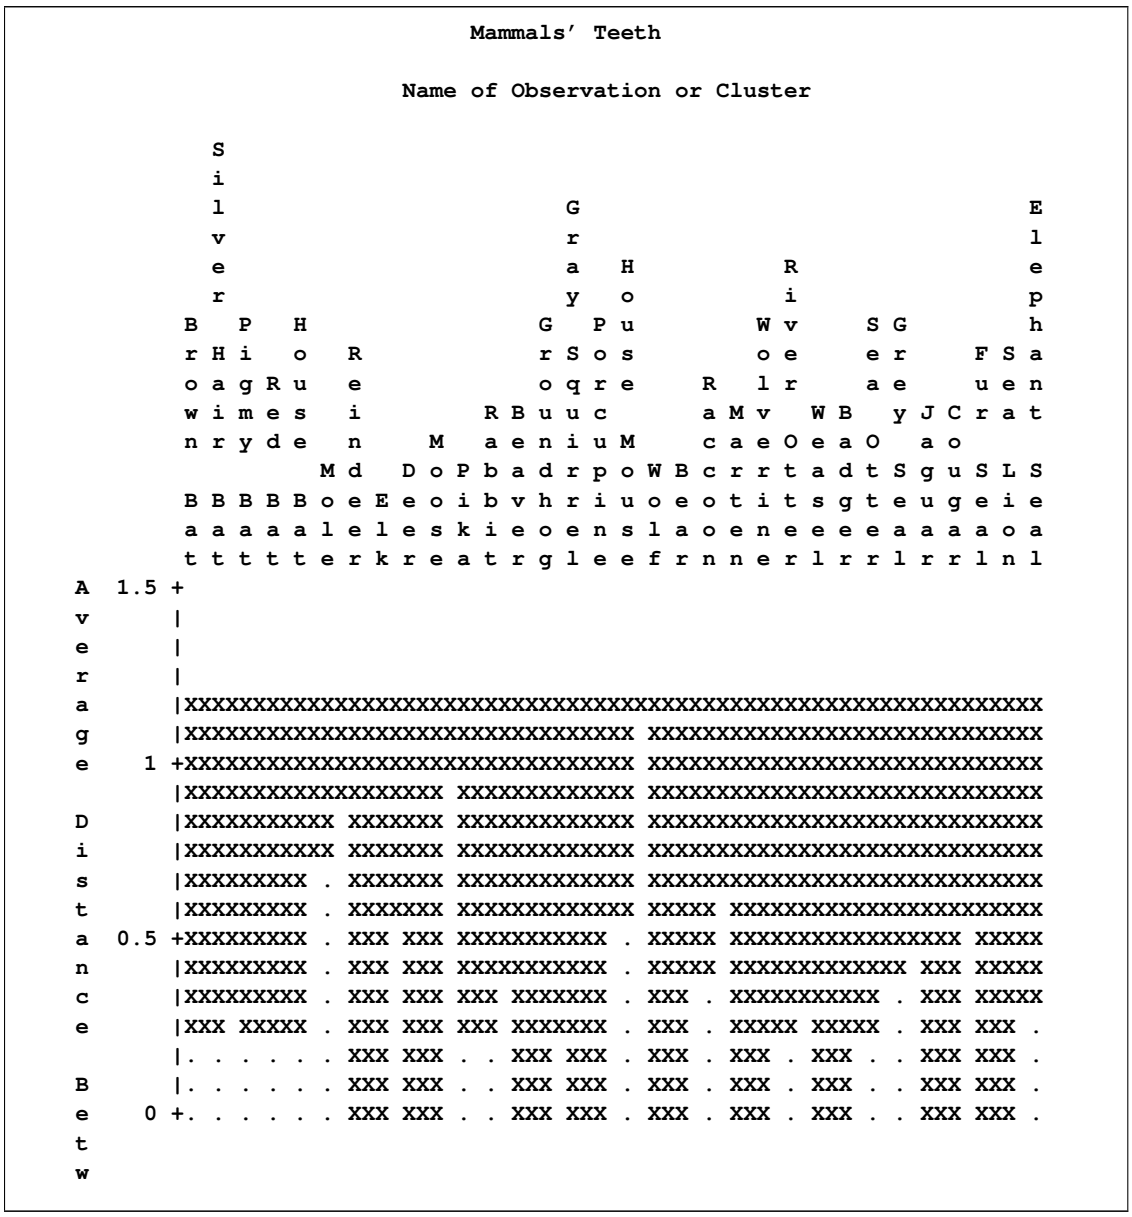
Output 91.1.2 shows the corresponding tree diagram.

Output 91.1.2 Tree Diagram of Mammal Teeth Clusters



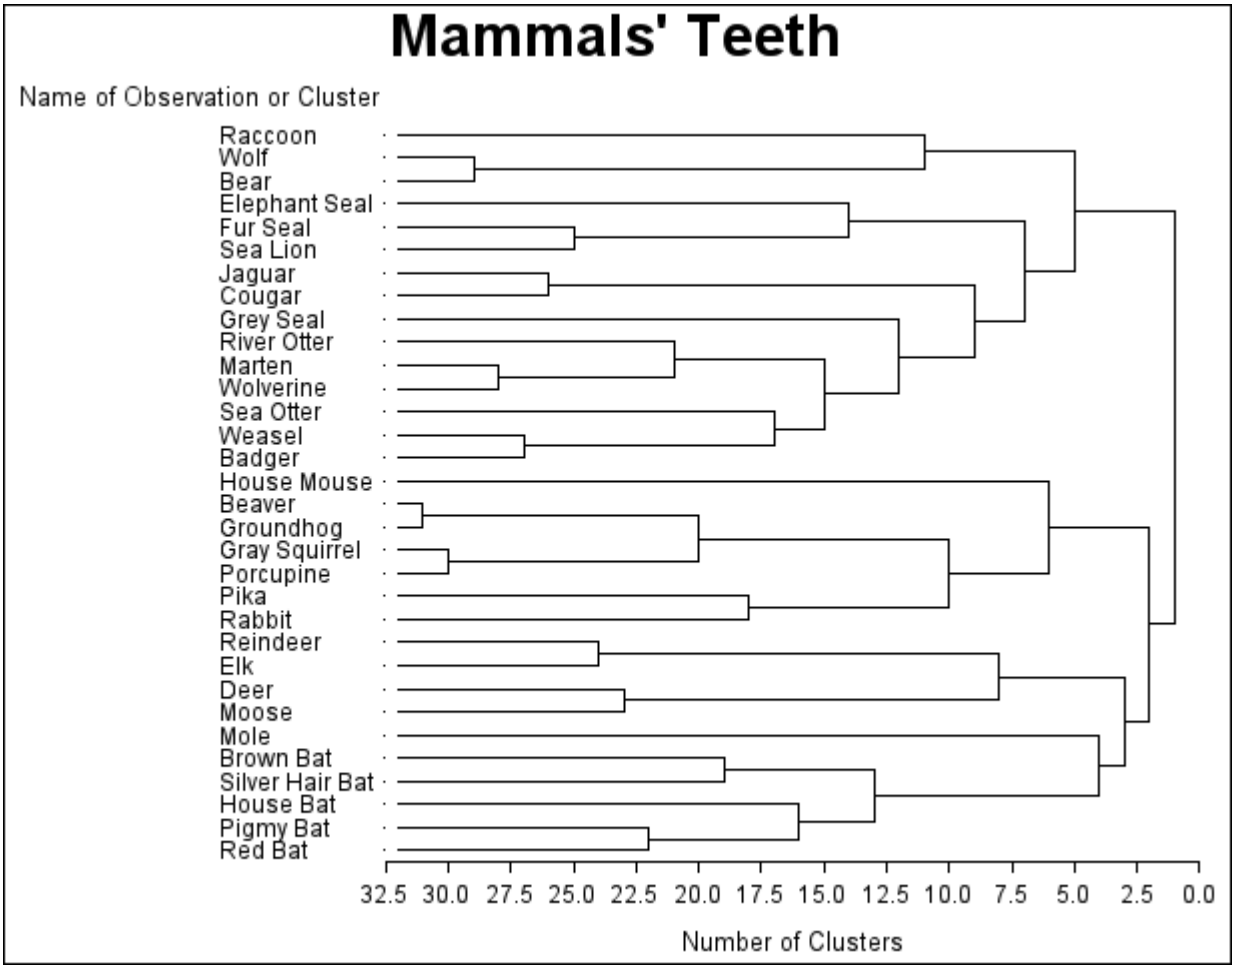
As you view the diagram in Output 91.1.2 from left to right, objects and clusters are progressively joined until a single, all-encompassing cluster is formed at the right (or root) of the tree. Clusters exist at each level of the diagram, and every vertical line connects leaves and branches into progressively larger clusters. For example, the five bats form a cluster at the 0.6 level, while the next cluster consists only of the mole. The observations `Reindeer`, `Elk`, `Deer`, and `Moose` form the next cluster at the 0.6 level, the mammals `Pika` through `House Mouse` are in the fourth cluster, The observations `Wolf`, `Bear`, and `Raccoon` form the fifth cluster, while the last cluster contains the observations `Marten` through `Elephant Seal`.

The following statements create the same tree with line printer graphics in a vertical orientation:

```
proc tree lineprinter;
run;
```

The tree is displayed in Output 91.1.3.

Output 91.1.3 PROC TREE with the LINEPRINTER Option



As you look up from the bottom of the diagram, objects and clusters are progressively joined until a single, all-encompassing cluster is formed at the top (or root) of the root. Clusters exist at each level of the diagram. For example, the unbroken line of Xs at the leftmost side of the 0.6 level indicates that the five bats have formed a cluster. The next cluster is represented by a period because it contains only one mammal, `Mole`. `Reindeer`, `Elk`, `Deer`, and `Moose` form the next cluster, indicated by Xs again. The mammals `Pika` through `House Mouse` are in the fourth cluster. The observations `Wolf`, `Bear`, and `Raccoon` form the fifth cluster, while the last cluster contains the observations `Marten` through `Elephant Seal`.

The next statements sort the clusters at each branch in order of formation and use the number of clusters as the height axis:

```
proc tree sort height=n horizontal;
run;
```

The resulting tree is displayed in Output 91.1.4.

Output 91.1.4 PROC TREE with SORT and HEIGHT= Options

Because the CLUSTER procedure always produces binary trees, the number of internal (root and branch) nodes in the tree is one less than the number of leaves. Therefore 31 clusters are formed from the 32 mammals in the input data set. These are represented by the 31 vertical line segments in the tree diagram, each at a different value along the horizontal axis.

As you examine the tree from left to right, the first vertical line segment is where `Beaver` and `Groundhog` are clustered and the number of clusters is 31. The next cluster is formed from `Gray Squirrel` and `Porcupine`. The third contains `Wolf` and `Bear`. Note how the tree graphically displays the clustering order information that was presented in tabular form by the CLUSTER procedure in Output 91.1.1.

The same clusters as in Output 91.1.2 and Output 91.1.3 can be seen at the six-cluster level of the tree diagram in Output 91.1.4, although the SORT and HEIGHT= options make them appear in a different order.

The following statements create these six clusters and save the result in the output data set part:

```
proc tree noprint out=part nclusters=6;
   id mammal;
   copy v1-v8;
proc sort;
   by cluster;
```

The PROC TREE statement produces no output but creates an output data set indicating the cluster to which each observation belongs at the six-cluster level in the tree. The following statements print part, with the results shown in Output 91.1.5:

```
proc print label uniform;
   id mammal;
   var v1-v8;
   format v1-v8 1.;
   by cluster;
run;
```

Output 91.1.5 PROC TREE OUT= Data Set

Example 91.2: Iris Data

Fisher (1936)'s iris data give sepal and petal dimensions for three different species of iris. The data are clustered by *k*th-nearest-neighbor density linkage by using the CLUSTER procedure with K=8. Observations are identified by species (`Setosa`, `Versicolor`, or `Virginica`) in the tree diagram, which is oriented with the height axis horizontal. The following statements produce the results shown in Output 91.2.1 and Output 91.2.2:

```
proc format;
   value specname
      1='Setosa    '
      2='Versicolor'
      3='Virginica ';
run;

data iris;
   title 'Fisher (1936) Iris Data';
   input SepalLength SepalWidth PetalLength PetalWidth
         Species @@;
   format Species specname.;
   label SepalLength='Sepal Length in mm.'
         SepalWidth ='Sepal Width in mm.'
         PetalLength='Petal Length in mm.'
         PetalWidth ='Petal Width in mm.';
   symbol = put(species, specname10.);
   datalines;

title 'Fisher (1936) Iris Data';
proc cluster data=iris method=twostage print=10
             outtree=tree k=8 noeigen;
   var SepalLength SepalWidth PetalLength PetalWidth;
   copy Species;
run;

proc tree data=tree horizontal lineprinter pages=1 maxh=10;
   id species;
run;
```

The PAGES=1 option specifies that the tree diagram extend over one page from tree to root. Since the HORIZONTAL option is also specified, the horizontal extent of the diagram is one page. The number of vertical pages required for the diagram is dictated by the number of leaves in the tree.

The MAXH=10 limits the values displayed on the height axis to a maximum of 10. This prunes the tree diagram so that only the portion from the leaves to level 10 is displayed. You can see this pruning effect in Output 91.2.2.

Overview: TTEST Procedure

The TTEST procedure performs *t* tests and computes confidence limits for one sample, paired observations, two independent samples, and the AB/BA crossover design. Two-sided, TOST (two one-sided test) equivalence, and upper and lower one-sided hypotheses are supported for means, mean differences, and mean ratios for either normal or lognormal data.

Table 92.1 summarizes the designs, analysis criteria, hypotheses, and distributional assumptions supported in the TTEST procedure, along with the syntax used to specify them.

Table 92.1 Features Supported in the TTEST Procedure

Feature	Syntax
Design	
One-sample	VAR statement
Paired	PAIRED statement
Two-independent-sample	CLASS statement, VAR statement
AB/BA crossover	VAR / CROSSOVER
Analysis Criterion	
Mean difference	PROC TTEST TEST=DIFF
Mean ratio	PROC TTEST TEST=RATIO
Hypothesis	
Two-sided	PROC TTEST SIDES=2
Equivalence	PROC TTEST TOST (< *lower* , > *upper*)
Lower one-sided	PROC TTEST SIDES=L
Upper one-sided	PROC TTEST SIDES=U
Distribution	
Normal	PROC TTEST DIST=NORMAL
Lognormal	PROC TTEST DIST=LOGNORMAL

FREQ and WEIGHT statements are available. Data can be input in the form of observations or, in certain cases, summary statistics. Output includes summary statistics; confidence limits for means, standard deviations, and coefficients of variation; hypothesis tests; and a variety of graphical displays, including histograms, densities, box plots, confidence intervals, Q-Q plots, profiles, and agreement plots.

PROC TTEST now uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." For specific informa-

tion about the statistical graphics available with the TTEST procedure, see the PLOTS option in the PROC TTEST statement and the section "ODS Graphics" on page 7427.

Getting Started: TTEST Procedure

One-Sample *t* Test

A one-sample *t* test can be used to compare a sample mean to a given value. This example, taken from Huntsberger and Billingsley (1989, p. 290), tests whether the mean length of a certain type of court case is more than 80 days by using 20 randomly chosen cases. The data are read by the following DATA step:

```
data time;
   input time @@;
   datalines;
 43  90  84  87  116   95  86   99   93  92
121  71  66  98   79  102  60  112  105  98
;
run;
```

The only variable in the data set, time, is assumed to be normally distributed. The trailing at signs (@@) indicate that there is more than one observation on a line. The following statements invoke PROC TTEST for a one-sample *t* test:

```
ods graphics on;

proc ttest h0=80 plots(showh0) sides=u alpha=0.1;
   var time;
run;

ods graphics off;
```

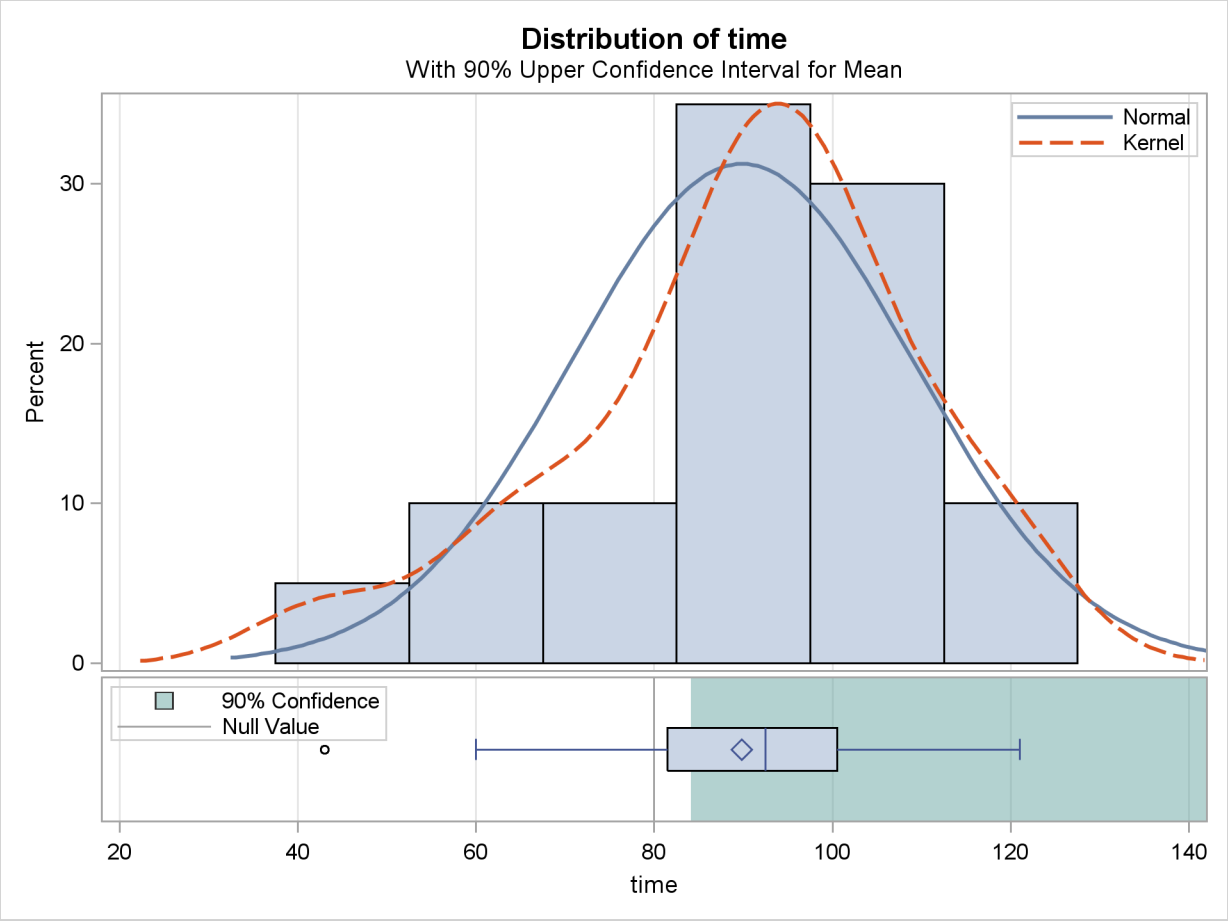
The ODS GRAPHICS statement requests graphical output. The VAR statement indicates that the time variable is being studied, while the H0= option specifies that the mean of the time variable should be compared to the null value 80 rather than the default of 0. The PLOTS(SHOWH0) option requests that this null value be displayed on all relevant graphs. The SIDES=U option reflects the focus of the research question, namely whether the mean court case length is *greater than* 80 days, rather than *different than* 80 days (in which case you would use the default SIDES=2 option). The ALPHA=0.1 option requests 90% confidence intervals rather than the default 95% confidence intervals. The output is displayed in Figure 92.1.

Figure 92.1 One-Sample *t* Test Results

The TTEST Procedure

Variable: time

N	Mean	Std Dev	Std Err	Minimum	Maximum
20	89.8500	19.1456	4.2811	43.0000	121.0



Mean	90% CL Mean		Std Dev	90% CL Std Dev	
89.8500	84.1659	Infty	19.1456	15.2002	26.2374

DF	t Value	Pr > t
19	2.30	0.0164

Summary statistics appear at the top of the output. The sample size (N), mean, standard deviation, and standard error are displayed with the minimum and maximum values of the time variable. The 90% confidence limits for the mean and standard deviation are shown next. Due to the SIDES=U option, the interval for the mean is an upper one-sided interval with a finite lower bound (84.1659 days). The limits for the standard deviation are the equal-tailed variety, per the default CI=EQUAL option in the PROC TTEST statement. At the bottom of the output are the degrees of freedom, t statistic value, and p-value for the t test. At the 10% α level, this test indicates that the mean length of the court cases is significantly greater than from 80 days ($t = 2.30$, $p = 0.0164$).

The summary panel in Figure 92.2 shows a histogram with overlaid normal and kernel densities, a box plot, the 90% confidence interval for the mean, and the null value of 80 days.

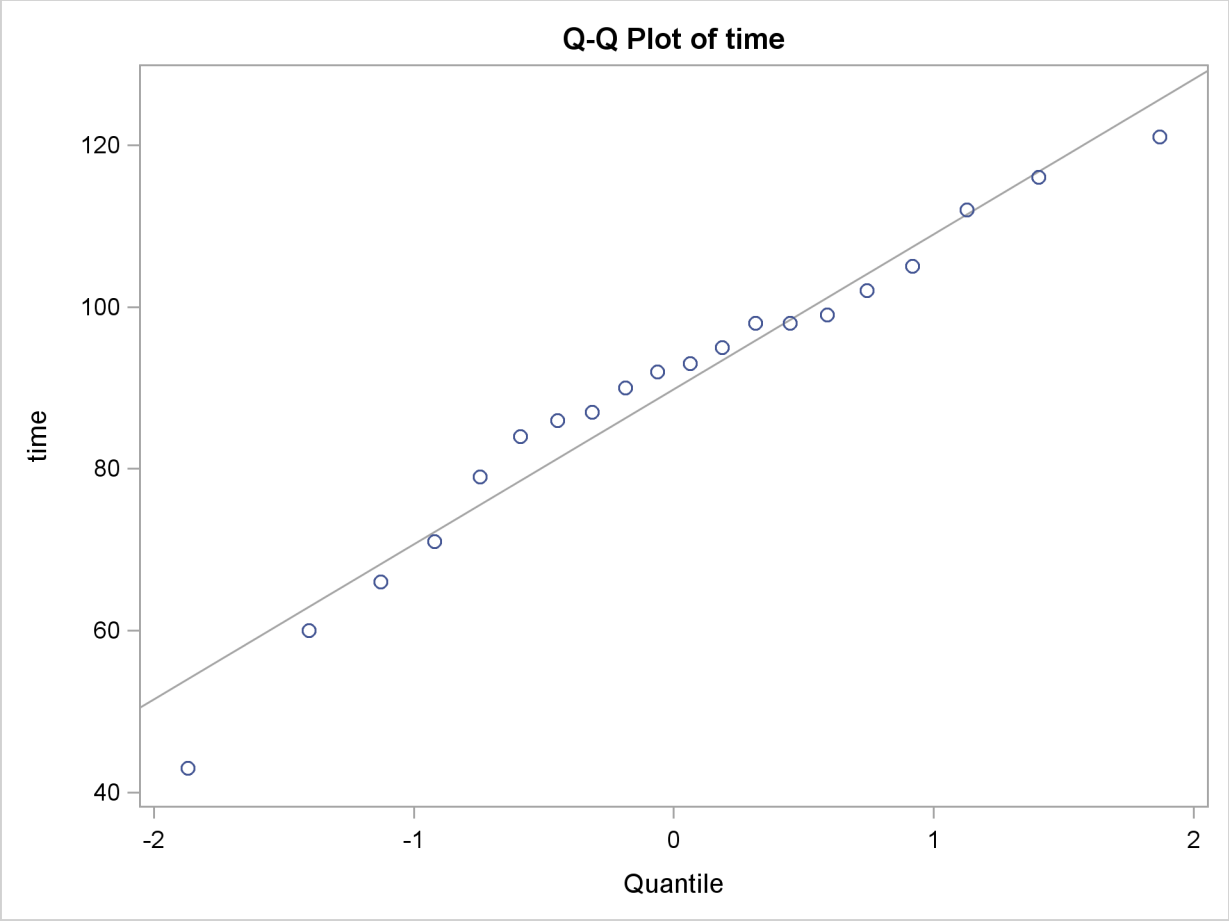


Figure 92.2 Summary Panel

The confidence interval excludes the null value, consistent with the rejection of the null hypothesis at $\alpha = 0.1$.

The Q-Q plot in Figure 92.3 assesses the normality assumption.

Figure 92.3 Q-Q Plot

The curvilinear shape of the Q-Q plot suggests a possible slight deviation from normality. You could use the UNIVARIATE procedure with the NORMAL option to numerically check the normality assumptions.

Comparing Group Means

If you want to compare values obtained from two different groups, and if the groups are independent of each other and the data are normally or lognormally distributed in each group, then a group *t* test can be used. Examples of such group comparisons include the following:

- test scores for two third-grade classes, where one of the classes receives tutoring
- fuel efficiency readings of two automobile nameplates, where each nameplate uses the same fuel
- sunburn scores for two sunblock lotions, each applied to a different group of people
- political attitude scores of males and females

In the following example, the golf scores for males and females in a physical education class are compared. The sample sizes from each population are equal, but this is not required for further analysis. The scores are thought to be approximately normally distributed within gender. The data are read by the following statements:

```
data scores;
   input Gender $ Score @@;
   datalines;
f 75  f 76  f 80  f 77  f 80  f 77  f 73
m 82  m 80  m 85  m 85  m 78  m 87  m 82
;
run;
```

The dollar sign ($) following Gender in the INPUT statement indicates that Gender is a character variable. The trailing at signs (@@) enable the procedure to read more than one observation per line.

You can use a group t test to determine whether the mean golf score for the men in the class differs significantly from the mean score for the women. If you also suspect that the distributions of the golf scores of males and females have unequal variances, then you might want to specify the COCHRAN option in order to use the Cochran approximation (in addition to the Satterthwaite approximation, which is included by default). The following statements invoke PROC TTEST for the case of unequal variances, along with both types of confidence limits for the pooled standard deviation.

```
ods graphics on;

proc ttest cochran ci=equal umpu;
   class Gender;
   var Score;
run;

ods graphics off;
```

The ODS GRAPHICS statement requests graphical output. The CLASS statement contains the variable that distinguishes the groups being compared, and the VAR statement specifies the response variable to be used in calculations. The COCHRAN option produces p-values for the unequal variance situation by using the Cochran and Cox (1950) approximation. Equal-tailed and uniformly most powerful unbiased (UMPU) confidence intervals for σ are requested by the CI= option. Output from these statements is displayed in Figure 92.4 through Figure 92.7.

Figure 92.4 Simple Statistics

The TTEST Procedure

Variable: Score

Gender	N	Mean	Std Dev	Std Err	Minimum	Maximum
f	7	76.8571	2.5448	0.9619	73.0000	80.0000
m	7	82.7143	3.1472	1.1895	78.0000	87.0000
Diff (1-2)		-5.8571	2.8619	1.5298		

Simple statistics for the two populations being compared, as well as for the difference of the means between the populations, are displayed in Figure 92.4. The Gender column indicates the population corresponding to the statistics in that row. The sample size (N), mean, standard deviation, standard error, and minimum and maximum values are displayed.

Confidence limits for means and standard deviations are shown in Figure 92.5.

Figure 92.5 Simple Statistics

Gender	Method	Mean	95% CL Mean		Std Dev
f		76.8571	74.5036	79.2107	2.5448
m		82.7143	79.8036	85.6249	3.1472
Diff (1-2)	Pooled	-5.8571	-9.1902	-2.5241	2.8619
Diff (1-2)	Satterthwaite	-5.8571	-9.2064	-2.5078	

Gender	Method	95% CL Std Dev		95% UMPU CL Std Dev	
f		1.6399	5.6039	1.5634	5.2219
m		2.0280	6.9303	1.9335	6.4579
Diff (1-2)	Pooled	2.0522	4.7242	2.0019	4.5727
Diff (1-2)	Satterthwaite				

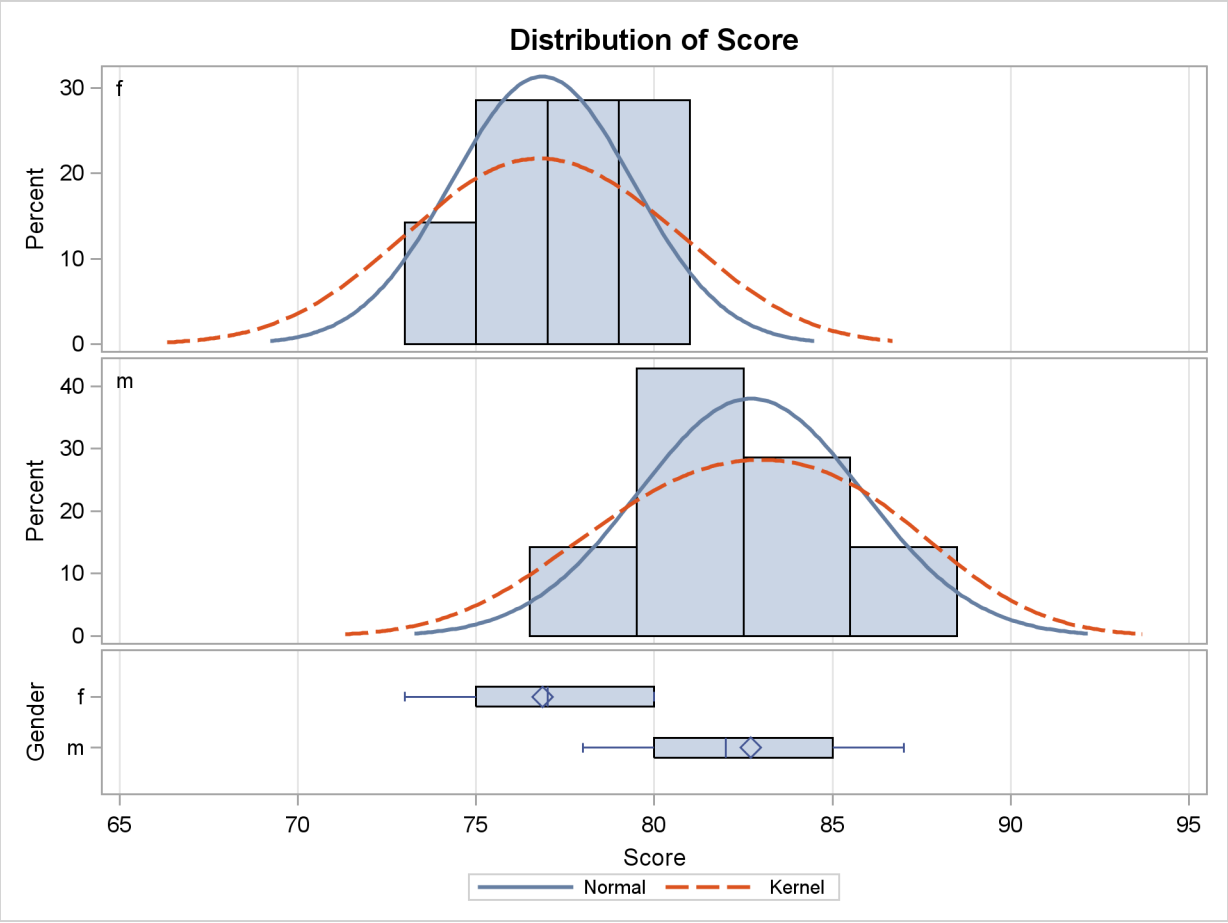
For the mean differences, both pooled (assuming equal variances for males and females) and Satterthwaite (assuming unequal variances) 95% intervals are shown. The confidence limits for the standard deviations are of the equal-tailed variety.

The test statistics, associated degrees of freedom, and p-values are displayed in Figure 92.6.

Figure 92.6 *t* Tests

Method	Variances	DF	t Value	Pr > |t|
Pooled	Equal	12	-3.83	0.0024
Satterthwaite	Unequal	11.496	-3.83	0.0026
Cochran	Unequal	6	-3.83	0.0087

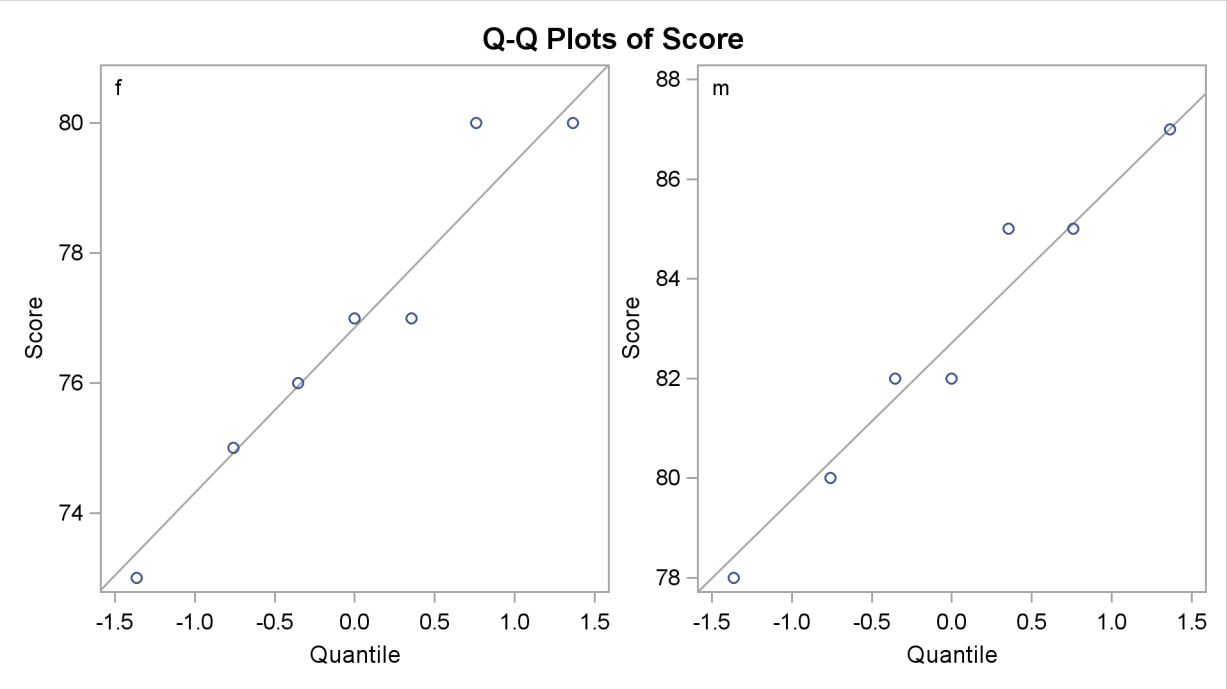
The Method column denotes which t test is being used for that row, and the Variances column indicates what assumption about variances is being made. The pooled test assumes that the two populations have equal variances and uses degrees of freedom $n_1 + n_2 - 2$, where n_1 and n_2 are the sample sizes for the two populations. The remaining two tests do not assume that the populations have equal variances. The Satterthwaite test uses the Satterthwaite approximation for degrees of freedom, while the Cochran test uses the Cochran and Cox approximation for the p-value. All three tests result in highly significant p-values, supporting the conclusion of a significant difference between males' and females' golf scores.



The "Equality of Variances" test in Figure 92.7 reveals insufficient evidence of unequal variances (the Folded F statistic $F' = 1.53$, with $p = 0.6189$).

Figure 92.7 Tests of Equality of Variances

Equality of Variances				
Method	Num DF	Den DF	F Value	Pr > F
Folded F	6	6	1.53	0.6189



The summary panel in Figure 92.8 shows comparative histograms, normal and kernel densities, and box plots, comparing the distribution of golf scores between genders.

Figure 92.8 Summary Panel

The Q-Q plots in Output 92.9 assess the normality assumption for each gender.

Figure 92.9 Q-Q Plot

The plots for both males and females show no obvious deviations from normality. You can check the assumption of normality more rigorously by using PROC UNIVARIATE with the NORMAL option; if the assumption of normality is not reasonable, you should analyze the data with the nonparametric Wilcoxon rank sum test by using PROC NPAR1WAY.

Syntax: TTEST Procedure

The following statements are available in PROC TTEST:

PROC TTEST < *options* > ;
  CLASS *variable* ;
  PAIRED *variables* ;
  BY *variables* ;
  VAR *variables* < / *options* > ;
  FREQ *variable* ;
  WEIGHT *variable* ;

No statement can be used more than once. There is no restriction on the order of the statements after the PROC TTEST statement.

PROC TTEST Statement

PROC TTEST < *options* > **;**

The PROC TTEST statement invokes the procedure. Table 92.2 summarizes the options in the PROC TTEST statement by function. The options are then described fully in alphabetical order.

Table 92.2 PROC TTEST Statement Options

Option	Description
Basic Options	
DATA=	specifies input data set
ORDER=	determines sort order of CLASS variable or CROSSOVER treatment variables
Analysis Options	
ALPHA=	specifies 1− confidence level
DIST=	specifies distributional assumption (normal or lognormal)
H0=	specifies null value
SIDES=	specifies number of sides and direction
TEST=	specifies test criterion (difference or ratio)
TOST	requests equivalence test and specifies bounds
Displayed Output	
CI=	requests confidence interval for standard deviation or CV
COCHRAN	requests Cochran t test
PLOTS	produces ODS statistical graphics
Output Ordering	
BYVAR	groups results by PAIRED or VAR variables
NOBYVAR	groups results by tables

The following options can appear in the PROC TTEST statement.

ALPHA=*p*

specifies that confidence intervals (except test-based mean confidence intervals when the TOST option is used) are to be $100(1-p)\%$ confidence intervals, where $0 < p < 1$. When the TOST option is used, the test-based mean confidence intervals are $100(1-2p)\%$ confidence intervals. By default, PROC TTEST uses ALPHA=0.05. If p is 0 or less, or 1 or more, an error message is printed.

BYVAR

groups the results by the PAIRED or VAR variables. The BYVAR option is enabled by default. Note that this represents a change from previous releases for how the results are grouped

with respect to variables and tables. Prior to SAS 9.2, multiple variables were included in each table, similar to the new NOBYVAR option.

CI=EQUAL | UMPU | NONE

CL=EQUAL | UMPU | NONE

specifies whether a confidence interval is displayed for σ and, if so, what kind. The CI=EQUAL option specifies an equal-tailed confidence interval, and it is the default. The CI=UMPU option specifies an interval based on the uniformly most powerful unbiased test of $H_0: \sigma = \sigma_0$. The CI=NONE option requests that no confidence interval be displayed for σ. The values EQUAL and UMPU together request that both types of confidence intervals be displayed. If the value NONE is specified with one or both of the values EQUAL and UMPU, NONE takes precedence. For more information, see the section "Two-Independent-Sample Design" on page 7416.

COCHRAN

requests the Cochran and Cox (1950) approximation of the probability level for the unequal variances situation. For more information, see the section "Two-Independent-Sample Design" on page 7416.

DATA=*SAS-data-set*

names the SAS data set for the procedure to use. By default, PROC TTEST uses the most recently created SAS data set. The input data set can contain summary statistics of the observations instead of the observations themselves. The number, mean, and standard deviation of the observations are required for each BY group (one sample and paired differences) or for each class within each BY group (two samples). For more information about the DATA= option, see the section "Input Data Set of Statistics" on page 7411.

DIST=LOGNORMAL | NORMAL

specifies the underlying distribution assumed for the data. The default is NORMAL, unless TEST=RATIO is specified, in which case the default is LOGNORMAL.

H0=*m*

requests tests against a null value of m, unless the TOST option is used, in which case m is merely used to derive the lower and upper equivalence bounds. For the crossover design, the value m applies for both treatment and period tests. By default, PROC TTEST uses H0=0 when TEST=DIFF (or DIST=NORMAL for a one-sample design) and H0=1 when TEST=RATIO (or DIST=LOGNORMAL for a one-sample design).

NOBYVAR

includes all PAIRED or VAR variables together in each output table. If the NOBYVAR option is not specified, then the BYVAR option is enabled, grouping the results by the PAIRED and VAR variables.

ORDER=DATA | FORMATTED | FREQ | INTERNAL | MIXED

specifies the sorting order for the levels of the classification variable (specified in the CLASS statement) and treatment variables (specified in the CROSSOVER option in the VAR statement). The default is ORDER=MIXED, which corresponds to the ordering in releases previous to SAS 9.2.

The following table shows how PROC TTEST interprets values of the ORDER= option.

Value of ORDER=	Levels Sorted By
DATA	order of appearance in the input data set
FORMATTED	external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	descending frequency count; levels with the most observations come first in the order. In the event of a tie, ORDER=MIXED is used.
INTERNAL	unformatted value
MIXED	same as ORDER=FORMATTED if the unformatted variable is character-valued; same as ORDER=INTERNAL otherwise (unformatted variable is numeric-valued)

For FORMATTED and INTERNAL, the sort order is machine dependent. For more information about sorting order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PLOTS **<** **(***global-plot-options***)** **>** **<** **=** *plot-request* **<** *(options)* **>** **>**

PLOTS **<** **(***global-plot-options***)** **>** **<** **=** **(***plot-request* **<** *(options)* **>** **<** **...** *plot-request* **<** *(options)* **>** **>)** **>**

controls the plots produced through ODS Graphics. When you specify only one plot request, you can omit the parentheses around the plot request. Here are some examples:

```
plots=none
plots=(histogram boxplot interval qq profiles agreement)
plots(unpack)=summary
plots(showh0)=interval(type=pergroup)
plots=(summary(unpack) interval(type=period))
```

You must enable ODS Graphics before requesting plots, for example, like this:

```
ods graphics on;

proc ttest plots=all;
   var oxygen;
run;

ods graphics off;
```

For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." If you have enabled ODS Graphics but do not specify the PLOTS option, then PROC TTEST produces a default set of plots. (**NOTE:** The graphical results are unavailable if your input data set contains summary statistics rather than observation values.)

For a one-sample design, the default plots are the following:

- summary plot (histogram with overlaid normal and kernel densities, box plot, and confidence interval band)
- Q-Q plot

For a two-independent-sample design, the default plots are the following:

- summary plot (comparative histograms with overlaid densities and box plots)
- Q-Q plot

For a paired design, the default plots are the following:

- summary plot (histogram, densities, box plot, and confidence interval) of the difference or ratio
- Q-Q plot of the difference or ratio
- profiles plot
- agreement plot

For a crossover design, the default plots are the following:

- comparative histograms with overlaid densities by treatment and period
- comparative box plots by treatment and period
- Q-Q plots by treatment and period
- profiles over treatment plot
- agreement of treatments plot

For more detailed descriptions of plots, see the section "Interpreting Graphs" on page 7428.

The global plot options include the following:

ONLY
suppresses the default plots. Only plots specifically requested are displayed.

SHOWH0
SHOWNULL
shows the null value (as specified by the H0= option in the PROC TTEST statement) in all relevant plots. For one-sample and paired designs, the null value can appear in SUMMARY, BOX, and INTERVAL. For two-independent-sample and crossover designs, the null value can appear only in INTERVAL.

UNPACKPANEL
UNPACK
suppresses paneling. By default, multiple plots can appear in some output panels. Specify UNPACKPANEL to get each plot in a separate panel. You can specify PLOTS(UNPACKPANEL) to unpack the default plots. You can also specify UNPACK as a suboption with SUMMARY.

The plot requests include the following:

ALL
produces all appropriate plots. You can specify other options with ALL; for example, to request all plots and specify that intervals should be for the period difference in a crossover design, specify PLOTS=(ALL INTERVAL(TYPE=PERIOD)).

AGREEMENT

AGREEMENTPLOT

requests an agreement plot. This plot is produced by default for paired and crossover designs, the only designs for which the AGREEMENT option is valid.

For paired designs, the second response in each pair is plotted against the first response. See the section "Agreement Plots for Paired Designs" on page 7428 for further details.

For crossover designs, the AGREEMENT plot request has the following options:

TYPE=PERIOD

plots the response in the second period against the response in the first period. See the section "Period Agreement Plots for Crossover Designs" on page 7428 for further details.

TYPE=TREATMENT

plots the response associated with the second treatment against the response associated with the first treatment. This is the default TYPE= option for crossover designs. See the section "Treatment Agreement Plots for Crossover Designs" on page 7429 for further details.

BOX

BOXPLOT

requests a box plot or comparative box plots. This plot is produced by default for crossover designs. For other designs, a box plot appears as part of the SUMMARY plot by default.

For one-sample and paired designs, a confidence interval for the mean is shown as a band in the background, along with the equivalence bounds if the TOST option is used in the PROC TTEST statement.

For a two-independent-sample design, comparative box plots (one for each class) are shown. For a crossover design, comparative box plots for all four combinations of the two treatments and two periods are shown.

See the section "Box Plots" on page 7429 for further details.

HISTOGRAM

HIST

HISTDENS

requests a histogram or comparative histograms with overlaid normal and kernel densities. This plot is produced by default for crossover designs. For other designs, it appears as part of the SUMMARY plot by default.

For one-sample and paired designs, the histogram and densities are based on the test criterion (which is the mean difference or ratio for a paired design). For a two-independent-sample design, comparative histograms (one for each class) are shown. For a crossover design, histograms for all four combinations of the two treatments and two periods are shown.

See the section "Histograms" on page 7429 for further details.

INTERVAL

INTERVALPLOT

requests plots of confidence interval for means.

For a two-independent-sample design, the INTERVAL plot request has the following options:

TYPE=PERGROUP

shows two separate two-sided confidence intervals, one for each class. This option cannot be used along with the SHOWH0 global plot option.

TYPE=TEST

shows pooled and Satterthwaite confidence intervals. This is the default TYPE= option for two-independent-sample designs.

For a crossover design, The INTERVAL plot request has the following options:

TYPE=PERGROUP

shows four separate two-sided intervals, one for each treatment-by-period combination. This option cannot be used along with the SHOWH0 global plot option.

TYPE=PERIOD

shows pooled and Satterthwaite confidence intervals for the period difference or ratio. This option is invalid if the IGNOREPERIOD option is used in the VAR statement.

TYPE=TREATMENT

shows pooled and Satterthwaite confidence intervals for the treatment difference or ratio. This is the default TYPE= option for crossover designs.

See the section "Confidence Intervals" on page 7429 for further details.

NONE

suppresses all plots.

PROFILES

PROFILESPLOT

requests a profiles plot. This plot is produced by default for paired and crossover designs, the only designs for which the PROFILES option is valid.

For paired designs, a line is drawn for each observation from left to right connecting the first response to the second response. See the section "Profiles for Paired Designs" on page 7430 for further details.

For crossover designs, the PROFILES plot request has the following options:

TYPE=PERIOD

shows response profiles over period, connecting the first period on the left to the second period on the right for each subject. See the section "Profiles over Period for Crossover Designs" on page 7430 for further details.

TYPE=TREATMENT
shows response profiles over treatment values, connecting the first treatment on the left to the second treatment on the right for each observation. This is the default TYPE= option for crossover designs. See the section "Profiles over Treatment for Crossover Designs" on page 7430 for further details.

QQ
QQPLOT
requests a normal quantile-quantile (Q-Q) plot. This plot is produced by default for all designs.

For two-sample designs, separate plots are shown for each class in a single panel. For crossover design, separate plots are shown for each treatment-by-period combination in a single panel.

See the section "Q-Q Plots" on page 7430 for further details.

SUMMARY
SUMMARYPLOT
requests HISTOGRAM and BOX plots together in a single panel, sharing common X axes. This plot is produced by default for one-sample, paired, and two-independent-sample designs, the only designs for which the SUMMARY option is valid. See the documentation for the BOX and HISTOGRAM plot requests for details. The SUMMARY plot request has the following option:

UNPACK
plots histograms with overlaid densities in one panel and box plots (along with confidence interval bands, if one-sample or paired design) in another. Note that specifying PLOTS(ONLY)=SUMMARY(UNPACK) is exactly the same as specifying PLOTS(ONLY)=(BOX HISTOGRAM).

SIDES=2 | L | U
SIDED=2 | L | U
SIDE=2 | L | U
specifies the number of sides (or tails) and direction of the statistical tests and test-based confidence intervals. The values are interpreted as follows:

SIDES=2 (the default) specifies two-sided tests and confidence intervals for means.

SIDES=L specifies lower one-sided tests, in which the alternative hypothesis indicates a mean less than the null value, and lower one-sided confidence intervals between minus infinity and the upper confidence limit.

SIDES=U specifies upper one-sided tests, in which the alternative hypothesis indicates a mean greater than the null value, and upper one-sided confidence intervals between the lower confidence limit and infinity.

TEST=DIFF | RATIO
specifies the test criterion. Use TEST=DIFF to test the difference of means and TEST=RATIO to test the ratio of means. The default is DIFF, unless DIST=LOGNORMAL

is specified, in which case the default is RATIO. This option is ignored for one-sample designs.

TOST (< *lower* **, >** *upper* **)**
requests Schuirman's TOST equivalence test. The *upper* equivalence bound must be specified. If TEST=DIFF, then the default value for the *lower* equivalence bound is $2m-$*upper*, where m is the value of the H0= option. If TEST=RATIO, then the default value for *lower* is $m/$*upper*.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC TTEST to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the TTEST procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* **;**

A CLASS statement giving the name of the classification (or grouping) variable must accompany the PROC TTEST statement in the two-independent-sample case. It should be omitted for the one-sample, paired, and AB/BA crossover designs. If it is used without the VAR statement, all numeric variables in the input data set (except those appearing in the CLASS, BY, FREQ, or WEIGHT statement) are included in the analysis.

The classification variable must have two, and only two, levels. PROC TTEST divides the observations into the two groups for the t test by using the levels of this variable. You can use either a numeric or a character variable in the CLASS statement.

Class levels are determined from the formatted values of the CLASS variable. Thus, you can use formats to define group levels. See the discussions of the FORMAT procedure, the FORMAT statement, formats, and informats in *SAS Language Reference: Dictionary*.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a variable that contains the frequency of occurrence of each observation. PROC TTEST treats each observation as if it appears n times, where n is the value of the FREQ variable for the observation. If the value is not an integer, only the integer portion is used. If the frequency value is less than 1 or is missing, the observation is not used in the analysis. When the FREQ statement is not specified, each observation is assigned a frequency of 1. The FREQ statement cannot be used if the DATA= data set contains statistics instead of the original observations.

PAIRED Statement

PAIRED *PairLists* **;**

The *PairLists* in the PAIRED statement identifies the variables to be compared in paired comparisons. You can use one or more *PairLists*. Variables or lists of variables are separated by an asterisk (*) or a colon (:). The asterisk requests comparisons between each variable on the left with each variable on the right. The colon requests comparisons between the first variable on the left and the first on the right, the second on the left and the second on the right, and so forth. The number of variables on the left must equal the number on the right when the colon is used. The differences are calculated by taking the variable on the left minus the variable on the right for both the asterisk and colon. A pair formed by a variable with itself is ignored. Use the PAIRED statement only for paired comparisons. The CLASS and VAR statements cannot be used with the PAIRED statement.

Examples of the use of the asterisk and the colon are shown in Table 92.3.

Table 92.3 PAIRED Statement in the TTEST Procedure

These PAIRED statements...	yield these comparisons
`PAIRED A*B;`	A-B
`PAIRED A*B C*D;`	A-B and C-D
`PAIRED (A B)*(C D);`	A-C, A-D, B-C, and B-D
`PAIRED (A B)*(C B);`	A-C, A-B, and B-C
`PAIRED (A1-A2)*(B1-B2);`	A1-B1, A1-B2, A2-B1, and A2-B2
`PAIRED (A1-A2):(B1-B2);`	A1-B1 and A2-B2

VAR Statement

VAR *variables* < / *options* > **;**

The VAR statement names the variables to be used in the analyses. One-sample comparisons are conducted when the VAR statement is used without the CROSSOVER option or CLASS statement. Two-independent-sample comparisons are conducted when the VAR statement is used with a CLASS statement.

An AB/BA crossover analysis is conducted when the CROSSOVER option is used in the VAR statement. In this case, you must specify an even number of variables. Each set of two variables represents the responses in the first and second periods of the AB/BA crossover design. For example, if you use the CROSSOVER option and specify **`VAR x1 x2 x3 x4`**, then you will get two analyses. One analysis will have x1 as the period 1 response and x2 as the period 2 response. The other analysis will have x3 as the period 1 response and x4 as the period 2 response.

The VAR statement cannot be used with the PAIRED statement. If the VAR statement is omitted, all numeric variables in the input data set (except a numeric variable appearing in the BY, CLASS, FREQ, or WEIGHT statement) are included in the analysis.

You can specify the following options after a slash (/):

CROSSOVER= (*variable1 variable2* **)**
specifies the variables representing the treatment applied in each of the two periods in an AB/BA crossover design. The treatment variables must have two, and only two, levels. For any given observation, the levels for the two variables must be different, due to the restrictions of the AB/BA crossover design. You can use either numeric or character variables.

Treatment levels are determined from the formatted values of the variables. Thus, you can use formats to define the treatment levels. See the discussions of the FORMAT procedure, the FORMAT statement, formats, and informats in *SAS Language Reference: Dictionary*.

IGNOREPERIOD
indicates that the period effect shall be ignored—that is, assumed to be equal to 0 (if TEST=DIFF) or 1 (if TEST=RATIO). This assumption increases the degrees of freedom for the test of the treatment difference by one and is usually more powerful, but it risks incorrect results if there is actually a period effect.

WEIGHT Statement

WEIGHT *variable* **;**

The WEIGHT statement weights each observation in the input data set by the value of the WEIGHT variable. The values of the WEIGHT variable can be nonintegral, and they are not truncated. Observations with negative, zero, or missing values for the WEIGHT variable are not used in the analyses. Each observation is assigned a weight of 1 when the WEIGHT statement is not used. The WEIGHT statement cannot be used with an input data set of summary statistics.

Details: TTEST Procedure

Input Data Set of Statistics

PROC TTEST accepts data containing either observation values or summary statistics. Observation values are supported for all analyses, whereas summary statistics are supported only for a subset of analyses. If the analysis involves the paired design, the AB/BA crossover design, or the lognormal distributional assumption (DIST=LOGNORMAL), then observation values must be used. The graphical results are unavailable if your input data set contains summary statistics rather than raw observed values.

PROC TTEST assumes that the DATA= data set contains statistics if it contains a character variable with name _TYPE_ or _STAT_. The TTEST procedure expects this character variable to contain the names of statistics. If both _TYPE_ and _STAT_ variables exist and are of type character, PROC TTEST expects _TYPE_ to contain the names of statistics including 'N', 'MEAN', and 'STD' for each BY group (or for each class within each BY group for two-sample *t* tests). If no 'N', 'MEAN', or 'STD' statistics exist, an error message is printed.

FREQ, WEIGHT, and PAIRED statements cannot be used with input data sets of statistics. BY, CLASS, and VAR statements are the same regardless of data set type. For paired comparisons, see the _DIF_ values for the _TYPE_=T observations in output produced by the OUTSTATS= option in the PROC COMPARE statement (see the *Base SAS Procedures Guide*).

Missing Values

An observation is omitted from the calculations if it has a missing value for either the CLASS variable, a CROSSOVER variable, a PAIRED variable, the variable to be tested (in a one-sample or two-independent-sample design), or either of the two response variables (in a crossover design). If more than one variable or pair of variables is listed in the VAR statement, a missing value in one variable or pair does not eliminate the observation from the analysis of other nonmissing variables or variable pairs.

Computational Methods

This section describes the computational formulas for the estimates, confidence limits, and tests for each analysis in the TTEST procedure. The first subsection defines some common notation. The second subsection discusses the distinction between arithmetic and geometric means. The third subsection explains the concept of the coefficient of variation. The following four subsections address the four supported designs (one-sample, paired, two-independent-sample, and AB/BA crossover). The content in each of those subsections is divided into separate discussions according to differ-

ent values of the DIST= and TEST= options in the PROC TTEST statement. The last subsection describes TOST equivalence analyses.

Common Notation

Table 92.4 displays notation for some of the commonly used symbols.

Table 92.4 Common Notation

Symbol	Description
μ	population value of (arithmetic) mean
μ_0	null value of test (value of H0= option in PROC TTEST statement)
σ^2	population variance
σ	population value of standard deviation
γ	population value of geometric mean
CV	population value of coefficient of variation (ratio of population standard deviation and population arithmetic mean)
α	value of ALPHA= option in PROC TTEST statement
$t_{p,\nu}$	pth percentile of t distribution with ν degrees of freedom (d.f.)
F_{p,ν_1,ν_2}	pth percentile of F distribution with ν_1 numerator d.f. and ν_2 denominator d.f.
$\chi^2_{p,\nu}$	pth percentile of chi-square distribution with ν d.f.

Arithmetic and Geometric Means

The *arithmetic mean* (more commonly called simply the *mean*) of the distribution of a random variable X is its expected value, $E(X)$. The arithmetic mean is the natural parameter of interest for a normal distribution because the distribution of the difference of normal random variables has a known normal distribution, and the arithmetic mean of a normal difference is equal to the difference of the individual arithmetic means. (No such convenient property holds for geometric means with normal data, with either differences or ratios.)

The usual estimate of an arithmetic mean is the sum of the values divided by the number of values:

$$\text{arithmetic mean} = \frac{1}{n}\sum_{i=1}^{n} y_i$$

The *geometric mean* of the distribution of a random variable X is $\exp(E(\log(X))$, the exponentiation of the mean of the natural logarithm. The geometric mean is the natural parameter of interest for a lognormal distribution because the distribution of a ratio of lognormal random variables has a known lognormal distribution, and the geometric mean of a lognormal ratio is equal to the ratio of the individual geometric means. (No such convenient property holds for arithmetic means with lognormal data, with either differences or ratios.)

The usual estimate of a geometric mean is the product of the values raised to the power $1/n$, where n is the number of values:

$$\text{geometric mean} = \left(\prod_{i=1}^{n} y_i \right)^{\frac{1}{n}}$$

Coefficient of Variation

The *coefficient of variation* (abbreviated "CV") of the distribution of a random variable X is the ratio of the standard deviation to the (arithmetic) mean, or $\sqrt{\text{Var}(X)}/E(X)$. Conceptually, it is a measure of the variability of X expressed in units corresponding to the mean of X.

For lognormal data, the CV is the natural measure of variability (rather than the standard deviation) because the CV is invariant to multiplication of a lognormal variable by a constant. For a two-independent-sample design, the assumption of equal CVs on a lognormal scale is analogous to the assumption of equal variances on the normal scale. When the CVs of two independent samples of lognormal data are assumed equal, the pooled estimate of variability is used.

One-Sample Design

Define the following notation:

$$\begin{aligned}
n^\star &= \text{number of observations in data set} \\
y_i &= \text{value of } i\text{th observation}, \quad i \in \{1, \ldots, n^\star\} \\
f_i &= \text{frequency of } i\text{th observation}, \quad i \in \{1, \ldots, n^\star\} \\
w_i &= \text{weight of } i\text{th observation}, \quad i \in \{1, \ldots, n^\star\} \\
n &= \text{sample size} = \sum_{i}^{n^\star} f_i
\end{aligned}$$

Normal Data (DIST=NORMAL)

The mean estimate $\bar{y}$, standard deviation estimate s, and standard error SE are computed as follows:

$$\begin{aligned}
\bar{y} &= \frac{\sum_i^{n^\star} f_i w_i y_i}{\sum_i^{n^\star} f_i w_i} \\
s &= \left(\frac{\sum_i^{n^\star} f_i w_i (y_i - \bar{y})^2}{n-1} \right)^{\frac{1}{2}} \\
\text{SE} &= \frac{s}{\sum_i^{n^\star} f_i w_i}
\end{aligned}$$

The $100(1-\alpha)\%$ confidence interval for the mean μ is

$$\begin{aligned}
&\left(\bar{y} - t_{1-\frac{\alpha}{2},n-1}\text{SE} \;,\; \bar{y} + t_{1-\frac{\alpha}{2},n-1}\text{SE}\right), && \text{SIDES=2} \\
&\left(-\infty \;,\; \bar{y} + t_{1-\alpha,n-1}\text{SE}\right), && \text{SIDES=L} \\
&\left(\bar{y} - t_{1-\alpha,n-1}\text{SE} \;,\; \infty\right), && \text{SIDES=U}
\end{aligned}$$

The t value for the test is computed as

$$t = \frac{\bar{y} - \mu_0}{\text{SE}}$$

The p-value of the test is computed as

$$p\text{-value} = \begin{cases} P\left(t^2 > F_{1-\alpha,1,n-1}\right) & , \quad \text{2-sided} \\ P\left(t < t_{\alpha,n-1}\right) & , \quad \text{lower 1-sided} \\ P\left(t > t_{1-\alpha,n-1}\right) & , \quad \text{upper 1-sided} \end{cases}$$

The equal-tailed confidence interval for the standard deviation (CI=EQUAL) is based on the acceptance region of the test of $H_0: \sigma = \sigma_0$ that places an equal amount of area ($\frac{\alpha}{2}$) in each tail of the chi-square distribution:

$$\left\{ \chi^2_{\frac{\alpha}{2},n-1} \leq \frac{(n-1)s^2}{\sigma_0^2} \leq \chi^2_{\frac{1-\alpha}{2},n-1} \right\}$$

The acceptance region can be algebraically manipulated to give the following $100(1-\alpha)\%$ confidence interval for σ^2:

$$\left(\frac{(n-1)s^2}{\chi^2_{1-\frac{\alpha}{2},n-1}} \quad , \quad \frac{(n-1)s^2}{\chi^2_{\frac{\alpha}{2},n-1}} \right)$$

Taking the square root of each side yields the $100(1-\alpha)\%$ CI=EQUAL confidence interval for σ:

$$\left(\left(\frac{(n-1)s^2}{\chi^2_{1-\frac{\alpha}{2},n-1}} \right)^{\frac{1}{2}} \quad , \quad \left(\frac{(n-1)s^2}{\chi^2_{\frac{\alpha}{2},n-1}} \right)^{\frac{1}{2}} \right)$$

The other confidence interval for the standard deviation (CI=UMPU) is derived from the uniformly most powerful unbiased test of $H_0: \sigma = \sigma_0$ (Lehmann 1986). This test has acceptance region

$$\left\{ c_1 \leq \frac{(n-1)s^2}{\sigma_0^2} \leq c_2 \right\}$$

where the critical values c_1 and c_2 satisfy

$$\int_{c_1}^{c_2} f_{n-1}(y)dy = 1 - \alpha$$

and

$$\int_{c_1}^{c_2} y f_{n-1}(y)dy = (n-1)(1-\alpha)$$

where $f_\nu(y)$ is the p.d.f. of the chi-square distribution with ν degrees of freedom. This acceptance region can be algebraically manipulated to arrive at

$$P\left\{ \frac{(n-1)s^2}{c_2} \leq \sigma^2 \leq \frac{(n-1)s^2}{c_1} \right\} = 1 - \alpha$$

where c_1 and c_2 solve the preceding two integrals. To find the area in each tail of the chi-square distribution to which these two critical values correspond, solve $c_1 = \chi^2_{1-\alpha_2,n-1}$ and $c_2 = \chi^2_{\alpha_1,n-1}$ for α_1 and α_2; the resulting α_1 and α_2 sum to α. Hence, a $100(1-\alpha)\%$ confidence interval for σ^2 is given by

$$\left(\frac{(n-1)s^2}{\chi^2_{1-\alpha_2,n-1}} \ , \ \frac{(n-1)s^2}{\chi^2_{\alpha_1,n-1}} \right)$$

Taking the square root of each side yields the $100(1-\alpha)\%$ CI=UMPU confidence interval for σ:

$$\left(\left(\frac{(n-1)s^2}{\chi^2_{1-\alpha_2,n-1}} \right)^{\frac{1}{2}} \ , \ \left(\frac{(n-1)s^2}{\chi^2_{\alpha_1,n-1}} \right)^{\frac{1}{2}} \right)$$

Lognormal Data (DIST=LOGNORMAL)

The DIST=LOGNORMAL analysis is handled by log-transforming the data and null value, performing a DIST=NORMAL analysis, and then transforming the results back to the original scale. This simple technique is based on the properties of the lognormal distribution as discussed in Johnson, Kotz, and Balakrishnan (1994, Chapter 14).

Taking the natural logarithms of the observation values and the null value, define

$$z_i = \log(y_i) \ , \ \ i \in \{1, \ldots, n^\star\}$$
$$\gamma_0 = \log(\mu_0)$$

First a DIST=NORMAL analysis is performed on z_i in place of y_i. The geometric mean estimate $\hat{\gamma}$ and CV estimate $\widehat{CV}$ of the original lognormal data are computed as follows:

$$\hat{\gamma} = \exp(\bar{y})$$
$$\widehat{CV} = \left(\exp(s^2) - 1\right)^{\frac{1}{2}}$$

The t value and p-value remain the same. The confidence limits for the geometric mean and CV on the original lognormal scale are computed from the confidence limits for the arithmetic mean and standard deviation in the DIST=NORMAL analysis on the log-transformed data, in the same way that $\hat{\gamma}$ is derived from $\bar{y}$ and $\widehat{CV}$ is derived from s.

Paired Design

Define the following notation:

$$n^\star = \text{number of observations in data set}$$
$$y_{1i} = \text{value of } i\text{th observation for first PAIRED variable, } \ i \in \{1, \ldots, n^\star\}$$
$$y_{2i} = \text{value of } i\text{th observation for second PAIRED variable, } \ i \in \{1, \ldots, n^\star\}$$
$$f_i = \text{frequency of } i\text{th observation, } \ i \in \{1, \ldots, n^\star\}$$
$$w_i = \text{weight of } i\text{th observation, } \ i \in \{1, \ldots, n^\star\}$$
$$n = \text{sample size} = \sum_i^{n^\star} f_i$$

Normal Difference (DIST=NORMAL TEST=DIFF)

The analysis is the same as the analysis for the one-sample design in the section "Normal Data (DIST=NORMAL)" on page 7413 based on the differences

$$d_i = y_{1i} - y_{2i} \quad , \quad i \in \{1, \ldots, n^\star\}$$

Lognormal Ratio (DIST=LOGNORMAL TEST=RATIO)

The analysis is the same as the analysis for the one-sample design in the section "Lognormal Data (DIST=LOGNORMAL)" on page 7415 based on the ratios

$$r_i = y_{1i}/y_{2i} \quad , \quad i \in \{1, \ldots, n^\star\}$$

Normal Ratio (DIST=NORMAL TEST=RATIO)

The hypothesis $H_0: \mu_1/\mu_2 = \mu_0$, where μ_1 and μ_2 are the means of the first and second PAIRED variables, respectively, can be rewritten as $H_0: \mu_1 - \mu_0\mu_2 = 0$. The t value and p-value are computed in the same way as in the one-sample design in the section "Normal Data (DIST=NORMAL)" on page 7413 based on the transformed values

$$z_i = y_{1i} - \mu_0 y_{2i} \quad , \quad i \in \{1, \ldots, n^\star\}$$

Estimates and confidence limits are not computed for this situation.

Two-Independent-Sample Design

Define the following notation:

$n_1^\star$ = number of observations at first class level
$n_2^\star$ = number of observations at second class level
y_{1i} = value of ith observation at first class level, $i \in \{1, \ldots, n_1^\star\}$
y_{2i} = value of ith observation at second class level, $i \in \{1, \ldots, n_2^\star\}$
f_{1i} = frequency of ith observation at first class level, $i \in \{1, \ldots, n_1^\star\}$
f_{2i} = frequency of ith observation at second class level, $i \in \{1, \ldots, n_2^\star\}$
w_{1i} = weight of ith observation at first class level, $i \in \{1, \ldots, n_1^\star\}$
w_{2i} = weight of ith observation at second class level, $i \in \{1, \ldots, n_2^\star\}$

$$n_1 = \text{sample size for first class level} = \sum_i^{n_1^\star} f_{1i}$$

$$n_2 = \text{sample size for second class level} = \sum_i^{n_2^\star} f_{2i}$$

Normal Difference (DIST=NORMAL TEST=DIFF)

Observations at the first class level are assumed to be distributed as $\mathrm{N}(\mu_1, \sigma_1^2)$, and observations at the second class level are assumed to be distributed as $\mathrm{N}(\mu_2, \sigma_2^2)$, where μ_1, μ_2, σ_1, and σ_2 are unknown.

The within-class-level mean estimates ($\bar{y}_1$ and $\bar{y}_2$), standard deviation estimates (s_1 and s_2), standard errors (SE_1 and SE_2), and confidence limits for means and standard deviations are computed in the same way as for the one-sample design in the section "Normal Data (DIST=NORMAL)" on page 7413.

The mean difference $\mu_1 - \mu_2 = \mu_d$ is estimated by

$$\bar{y}_d = \bar{y}_1 - \bar{y}_2$$

Under the assumption of equal variances ($\sigma_1^2 = \sigma_2^2$), the pooled estimate of the common standard deviation is

$$s_p = \left(\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2} \right)^{\frac{1}{2}}$$

The pooled standard error (the estimated standard deviation of $\bar{y}_d$ assuming equal variances) is

$$\mathrm{SE}_p = s_p \left(\frac{1}{\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}} + \frac{1}{\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}} \right)^{\frac{1}{2}}$$

The pooled $100(1-\alpha)\%$ confidence interval for the mean difference μ_d is

$$\begin{aligned} \left(\bar{y}_d - t_{1-\frac{\alpha}{2}, n_1+n_2-2} \mathrm{SE}_p \ , \ \bar{y}_d + t_{1-\frac{\alpha}{2}, n_1+n_2-2} \mathrm{SE}_p \right), & \quad \text{SIDES=2} \\ \left(-\infty \ , \ \bar{y}_d + t_{1-\alpha, n_1+n_2-2} \mathrm{SE}_p \right), & \quad \text{SIDES=L} \\ \left(\bar{y}_d - t_{1-\alpha, n_1+n_2-2} \mathrm{SE}_p \ , \ \infty \right), & \quad \text{SIDES=U} \end{aligned}$$

The t value for the pooled test is computed as

$$t_p = \frac{\bar{y}_d - \mu_0}{\mathrm{SE}_p}$$

The p-value of the test is computed as

$$p\text{-value} = \begin{cases} P\left(t_p^2 > F_{1-\alpha,1,n_1+n_2-2}\right) \ , & \text{2-sided} \\ P\left(t_p < t_{\alpha, n_1+n_2-2}\right) \ , & \text{lower 1-sided} \\ P\left(t_p > t_{1-\alpha, n_1+n_2-2}\right) \ , & \text{upper 1-sided} \end{cases}$$

Under the assumption of unequal variances (the Behrens-Fisher problem), the unpooled standard error is computed as

$$\mathrm{SE}_u = \left(\frac{s_1^2}{\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}} + \frac{s_2^2}{\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}} \right)^{\frac{1}{2}}$$

Satterthwaite's (1946) approximation for the degrees of freedom, extended to accommodate weights, is computed as

$$\mathrm{df}_u = \frac{\mathrm{SE}_u^4}{\frac{s_1^4}{(n_1-1)\left(\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}\right)^2} + \frac{s_2^4}{(n_2-1)\left(\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}\right)^2}}$$

The unpooled Satterthwaite $100(1-\alpha)\%$ confidence interval for the mean difference μ_d is

$$\begin{aligned}\left(\bar{y}_d - t_{1-\frac{\alpha}{2},\mathrm{df}_u}\mathrm{SE}_u \;,\; \bar{y}_d + t_{1-\frac{\alpha}{2},\mathrm{df}_u}\mathrm{SE}_u\right), &\quad \text{SIDES=2}\\ \left(-\infty \;,\; \bar{y}_d + t_{1-\alpha,\mathrm{df}_u}\mathrm{SE}_u\right), &\quad \text{SIDES=L}\\ \left(\bar{y}_d - t_{1-\alpha,\mathrm{df}_u}\mathrm{SE}_u \;,\; \infty\right), &\quad \text{SIDES=U}\end{aligned}$$

The t value for the unpooled Satterthwaite test is computed as

$$t_u = \frac{\bar{y}_d - \mu_0}{\mathrm{SE}_u}$$

The p-value of the unpooled Satterthwaite test is computed as

$$p\text{-value} = \begin{cases} P\left(t_u^2 > F_{1-\alpha,1,\mathrm{df}_u}\right) \;, & \text{2-sided}\\ P\left(t_u < t_{\alpha,\mathrm{df}_u}\right) \;, & \text{lower 1-sided}\\ P\left(t_u > t_{1-\alpha,\mathrm{df}_u}\right) \;, & \text{upper 1-sided}\end{cases}$$

When the COCHRAN option is specified in the PROC TTEST statement, the Cochran and Cox (1950) approximation of the p-value of the t_u statistic is the value of p such that

$$t_u = \frac{\left(\frac{s_1^2}{\sum_{i=1}^{n_1^\star} f_{1i}w_{1i}}\right)t_1 + \left(\frac{s_2^2}{\sum_{i=1}^{n_2^\star} f_{2i}w_{2i}}\right)t_2}{\left(\frac{s_1^2}{\sum_{i=1}^{n_1^\star} f_{1i}w_{1i}}\right) + \left(\frac{s_2^2}{\sum_{i=1}^{n_2^\star} f_{2i}w_{2i}}\right)}$$

where t_1 and t_2 are the critical values of the t distribution corresponding to a significance level of p and sample sizes of n_1 and n_2, respectively. The number of degrees of freedom is undefined when $n_1 \neq n_2$. In general, the Cochran and Cox test tends to be conservative (Lee and Gurland 1975).

The $100(1-\alpha)\%$ CI=EQUAL and CI=UMPU confidence intervals for the common population standard deviation σ assuming equal variances are computed as discussed in the section "Normal Data (DIST=NORMAL)" on page 7413 for the one-sample design, except replacing s^2 by s_p^2 and $(n-1)$ by (n_1+n_2-1).

The folded form of the F statistic, F', tests the hypothesis that the variances are equal (Steel and Torrie 1980), where

$$F' = \frac{\max(s_1^2, s_2^2)}{\min(s_1^2, s_2^2)}$$

A test of F' is a two-tailed F test because you do not specify which variance you expect to be larger. The p-value gives the probability of a greater F value under the null hypothesis that $\sigma_1^2 = \sigma_2^2$. Note that this test is not very robust to violations of the assumption that the data are normally distributed, and thus it is not recommended without confidence in the normality assumption.

Lognormal Ratio (DIST=LOGNORMAL TEST=RATIO)

The DIST=LOGNORMAL analysis is handled by log-transforming the data and null value, performing a DIST=NORMAL analysis, and then transforming the results back to the original scale.

See the section "Normal Data (DIST=NORMAL)" on page 7413 for the one-sample design for details on how the DIST=NORMAL computations for means and standard deviations are transformed into the DIST=LOGNORMAL results for geometric means and CVs. As mentioned in the section "Coefficient of Variation" on page 7413, the assumption of equal CVs on the lognormal scale is analogous to the assumption of equal variances on the normal scale.

Normal Ratio (DIST=NORMAL TEST=RATIO)

The distributional assumptions, equality of variances test, and within-class-level mean estimates ($\bar{y}_1$ and $\bar{y}_2$), standard deviation estimates (s_1 and s_2), standard errors (SE_1 and SE_2), and confidence limits for means and standard deviations are the same as in the section "Normal Difference (DIST=NORMAL TEST=DIFF)" on page 7416 for the two-independent-sample design.

The mean ratio $\mu_1/\mu_2 = \mu_r$ is estimated by

$$\hat{\mu}_r = \bar{y}_1/\bar{y}_2$$

No estimates or confidence intervals for the ratio of standard deviations are computed.

Under the assumption of equal variances ($\sigma_1^2 = \sigma_2^2$), the pooled confidence interval for the mean ratio is the Fieller (1954) confidence interval, extended to accommodate weights. Let

$$a_p = \frac{s_p^2 t^2_{1-\frac{\alpha}{2},n_1+n_2-2}}{\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}} - \bar{y}_2^2$$
$$b_p = \bar{y}_1 \bar{y}_2$$
$$c_p = \frac{s_p^2 t^2_{1-\frac{\alpha}{2},n_1+n_2-2}}{\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}} - \bar{y}_1^2$$

where s_p is the pooled standard deviation defined in the section "Normal Difference (DIST=NORMAL TEST=DIFF)" on page 7416 for the two-independent-sample design. If $a_p \geq 0$ (which occurs when $\bar{y}_2$ is too close to zero), then the pooled two-sided $100(1-\alpha)\%$ Fieller confidence interval for μ_r does not exist. If $a < 0$, then the interval is

$$\left(-\frac{b_p}{a_p} + \frac{\left(b_p^2 - a_p c_p\right)^{\frac{1}{2}}}{a_p} \; , -\frac{b_p}{a_p} - \frac{\left(b_p^2 - a_p c_p\right)^{\frac{1}{2}}}{a_p} \right)$$

For the one-sided intervals, let

$$a_p^\star = \frac{s_p^2 t^2_{1-\alpha,n_1+n_2-2}}{\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}} - \bar{y}_2^2$$
$$c_p^\star = \frac{s_p^2 t^2_{1-\alpha,n_1+n_2-2}}{\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}} - \bar{y}_1^2$$

which differ from a_p and c_p only in the use of α in place of $\alpha/2$. If $a_p^\star \geq 0$, then the pooled one-sided $100(1-\alpha)\%$ Fieller confidence intervals for μ_r do not exist. If $a_p^\star < 0$, then the intervals are

$$\left(-\infty \ , -\frac{b_p}{a_p^\star} - \frac{\left(b_p^2 - a_p^\star c_p^\star\right)^{\frac{1}{2}}}{a_p^\star} \right), \quad \text{SIDES=L}$$

$$\left(-\frac{b_p}{a_p^\star} + \frac{\left(b_p^2 - a_p^\star c_p^\star\right)^{\frac{1}{2}}}{a_p^\star} \ , \ \infty \right), \quad \text{SIDES=U}$$

The pooled t test assuming equal variances is the Sasabuchi (1988a, 1988b) test. The hypothesis $H_0\colon \mu_r = \mu_0$ is rewritten as $H_0\colon \mu_1 - \mu_0\mu_2 = 0$, and the pooled t test in the section "Normal Difference (DIST=NORMAL TEST=DIFF)" on page 7416 for the two-independent-sample design is conducted on the original y_{1i} values ($i \in \{1, \ldots, n_1^\star\}$) and transformed values of y_{2i}

$$y_{2i}^\star = \mu_0 y_{2i} \ , \ \ i \in \{1, \ldots, n_2^\star\}$$

with a null difference of 0. The t value for the Sasabuchi pooled test is computed as

$$t_p = \frac{\bar{y}_1 - \mu_0 \bar{y}_2}{s_p \left(\frac{1}{\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}} + \frac{\mu_0^2}{\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}} \right)^{\frac{1}{2}}}$$

The p-value of the test is computed as

$$p\text{-value} = \begin{cases} P\left(t_p^2 > F_{1-\alpha,1,n_1+n_2-2}\right) & , \quad \text{2-sided} \\ P\left(t_p < t_{\alpha,n_1+n_2-2}\right) & , \quad \text{lower 1-sided} \\ P\left(t_p > t_{1-\alpha,n_1+n_2-2}\right) & , \quad \text{upper 1-sided} \end{cases}$$

Under the assumption of unequal variances, the unpooled Satterthwaite-based confidence interval for the mean ratio μ_r is computed according to the method in Dilba, Schaarschmidt, and Hothorn (2006), extended to accommodate weights. The degrees of freedom are computed as

$$\mathrm{df}_u = \frac{\left(\frac{s_1^2}{\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}} + \frac{\hat{\mu}_r^2 s_2^2}{\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}} \right)^2}{\frac{s_1^4}{(n_1-1)\left(\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}\right)^2} + \frac{\hat{\mu}_r^4 s_2^4}{(n_2-1)\left(\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}\right)^2}}$$

Note that the estimate $\hat{\mu}_r = \bar{y}_1/\bar{y}_2$ is used in df_u. Let

$$a_u = \frac{s_2^2 t_{1-\frac{\alpha}{2},\mathrm{df}_u}^2}{\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}} - \bar{y}_2^2$$

$$b_u = \bar{y}_1 \bar{y}_2$$

$$c_u = \frac{s_1^2 t_{1-\frac{\alpha}{2},\mathrm{df}_u}^2}{\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}} - \bar{y}_1^2$$

where s_1 and s_2 are the within-class-level standard deviations defined in the section "Normal Difference (DIST=NORMAL TEST=DIFF)" on page 7416 for the two-independent-sample design. If $a_u \geq 0$ (which occurs when $\bar{y}_2$ is too close to zero), then the unpooled Satterthwaite-based two-sided $100(1-\alpha)\%$ confidence interval for μ_r does not exist. If $a_u < 0$, then the interval is

$$\left(-\frac{b_u}{a_u} + \frac{\left(b_u^2 - a_u c_u\right)^{\frac{1}{2}}}{a_u} \;\; , -\frac{b_u}{a_u} - \frac{\left(b_u^2 - a_u c_u\right)^{\frac{1}{2}}}{a_u} \right)$$

The t test assuming unequal variances is the test derived in Tamhane and Logan (2004). The hypothesis $H_0\colon \mu_r = \mu_0$ is rewritten as $H_0\colon \mu_1 - \mu_0\mu_2 = 0$, and the Satterthwaite t test in the section "Normal Difference (DIST=NORMAL TEST=DIFF)" on page 7416 for the two-independent-sample design is conducted on the original y_{1i} values ($i \in \{1, \ldots, n_1^\star\}$) and transformed values of y_{2i}

$$y_{2i}^\star = \mu_0 y_{2i} \quad , \quad i \in \{1, \ldots, n_2^\star\}$$

with a null difference of 0. The degrees of freedom used in the unpooled t test differs from the df_u used in the unpooled confidence interval. The mean ratio μ_0 under the null hypothesis is used in place of the estimate $\hat{\mu}_r$:

$$\mathrm{df}_u^\star = \frac{\left(\frac{s_1^2}{\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}} + \frac{\mu_0^2 s_2^2}{\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}} \right)^2}{\frac{s_1^4}{(n_1-1)\left(\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}\right)^2} + \frac{\mu_0^4 s_2^4}{(n_2-1)\left(\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}\right)^2}}$$

The t value for the Satterthwaite-based unpooled test is computed as

$$t_u = \frac{\bar{y}_1 - \mu_0 \bar{y}_2}{\left(\frac{s_1^2}{\sum_{i=1}^{n_1^\star} f_{1i} w_{1i}} + \frac{\mu_0^2 s_2^2}{\sum_{i=1}^{n_2^\star} f_{2i} w_{2i}} \right)^{\frac{1}{2}}}$$

The p-value of the test is computed as

$$p\text{-value} = \begin{cases} P\left(t_u^2 > F_{1-\alpha,1,\mathrm{df}_u^\star}\right) & , \quad \text{2-sided} \\ P\left(t_u < t_{\alpha,\mathrm{df}_u^\star}\right) & , \quad \text{lower 1-sided} \\ P\left(t_u > t_{1-\alpha,\mathrm{df}_u^\star}\right) & , \quad \text{upper 1-sided} \end{cases}$$

AB/BA Crossover Design

Let "A" and "B" denote the two treatment values. Define the following notation:

$n_1^\star$ = number of observations with treatment sequence AB
$n_2^\star$ = number of observations with treatment sequence BA
y_{11i} = response value of ith observation in sequence AB during period 1, $i \in \{1, \ldots, n_1^\star\}$
y_{12i} = response value of ith observation in sequence AB during period 2, $i \in \{1, \ldots, n_1^\star\}$
y_{21i} = response value of ith observation in sequence BA during period 1, $i \in \{1, \ldots, n_2^\star\}$
y_{22i} = response value of ith observation in sequence BA during period 2, $i \in \{1, \ldots, n_2^\star\}$

So $\{y_{11i}, \ldots, y_{11n_1^\star}\}$ and $\{y_{22i}, \ldots, y_{22n_2^\star}\}$ are all observed at treatment level A, and $\{y_{12i}, \ldots, y_{12n_2^\star}\}$ and $\{y_{21i}, \ldots, y_{21n_1^\star}\}$ are all observed at treatment level B.

Define the *period difference* for an observation as the difference between period 1 and period 2 response values:

$$\mathrm{pd}_{kji} = y_{k1i} - y_{k2i}$$

for $k \in \{1, 2\}$ and $i \in \{1, \ldots, n_k^\star\}$. Similarly, the *period ratio* is the ratio between period 1 and period 2 response values:

$$\mathrm{pr}_{kji} = y_{k1i} / y_{k2i}$$

The *crossover difference* for an observation is the difference between treatment A and treatment B response values:

$$\mathrm{cd}_{kji} = \begin{cases} y_{k1i} - y_{k2i} & , \quad k = 1 \\ y_{k2i} - y_{k1i} & , \quad k = 2 \end{cases}$$

Similarly, the *crossover ratio* is the ratio between treatment A and treatment B response values:

$$\mathrm{cr}_{kji} = \begin{cases} y_{k1i} / y_{k2i} & , \quad k = 1 \\ y_{k2i} / y_{k1i} & , \quad k = 2 \end{cases}$$

In the absence of the IGNOREPERIOD option in the PROC TTEST statement, the data are split into two groups according to treatment sequence and analyzed as a two-independent-sample design. If DIST=NORMAL, then the analysis of the treatment effect is based on the half period differences $\{\mathrm{pd}_{kji}/2\}$, and the analysis for the period effect is based on the half crossover differences $\{\mathrm{cd}_{kji}/2\}$. The computations for the normal difference analysis are the same as in the section "Normal Difference (DIST=NORMAL TEST=DIFF)" on page 7416 for the two-independent-sample design. The normal ratio analysis without the IGNOREPERIOD option is not supported for the AB/BA crossover design. If DIST=LOGNORMAL, then the analysis of the treatment effect is based on the square root of the period ratios $\{\sqrt{\mathrm{pr}_{kji}}\}$, and the analysis for the period effect is based on the square root of the crossover ratios $\{\sqrt{\mathrm{cr}_{kji}}\}$. The computations are the same as in the section "Lognormal Ratio (DIST=LOGNORMAL TEST=RATIO)" on page 7418 for the two-independent-sample design.

If the IGNOREPERIOD option is specified, then the treatment effect is analyzed as a paired analysis on the (treatment A, treatment B) response value pairs, regardless of treatment sequence. So the set of pairs is taken to be the concatenation of $\{(y_{111}, y_{121}), \ldots, (y_{11n_1^\star}, y_{12n_1^\star})\}$ and $\{(y_{221}, y_{211}), \ldots, (y_{22n_2^\star}, y_{22n_2^\star})\}$. The computations are the same as in the section "Paired Design" on page 7415.

See Senn (2002, Chapter 3) for a more detailed discussion of the AB/BA crossover design.

TOST Equivalence Test

The hypotheses for an equivalence test are

$$H_0{:}\mu < \theta_L \quad \text{or} \quad \mu > \theta_U$$
$$H_1{:}\theta_L \le \mu \le \theta_U$$

where θ_L and θ_U are the lower and upper bounds specified in the TOST option in the PROC TTEST statement, and μ is the analysis criterion (mean, mean ratio, or mean difference, depending on the analysis). Following the two one-sided tests (TOST) procedure of Schuirmann (1987), the equivalence test is conducted by performing two separate tests:

$$H_{a0}{:}\mu < \theta_L$$
$$H_{a1}{:}\mu \geq \theta_L$$

and

$$H_{b0}{:}\mu > \theta_U$$
$$H_{b1}{:}\mu \leq \theta_U$$

The overall p-value is the larger of the two p-values of those tests.

Rejection of H_0 in favor of H_1 at significance level α occurs if and only if the $100(1-2\alpha)\%$ confidence interval for μ is contained completely within (θ_L, θ_U). So, the $100(1-2\alpha)\%$ confidence interval for μ is displayed in addition to the usual $100(1-\alpha)\%$ interval.

See Phillips (1990), Diletti, Hauschke, and Steinijans (1991), and Hauschke et al. (1999) for further discussion of equivalence testing for the designs supported in the TTEST procedure.

Displayed Output

For an AB/BA crossover design, the "CrossoverVarInfo" table shows the variables specified for the response and treatment values in each period of the design.

The summary statistics in the "Statistics" table and confidence limits in the "ConfLimits" table are displayed for certain variables and/or transformations or subgroups of the variables in the analysis, depending on the design. For a one-sample design, summary statistics are displayed for all variables in the analysis. For a paired design, statistics are displayed for the difference if you specify the TEST=DIFF option in the PROC TTEST statement, or for the ratio if you specify TEST=RATIO. For a two-independent-sample design, the statistics for each of the two groups and for the difference (if TEST=DIFF) or ratio (if TEST=RATIO) are displayed. For an AB/BA crossover design, statistics are displayed for each of the four cells in the design (all four combinations of the two periods and two treatments). If the IGNOREPERIOD option is absent, then if TEST=DIFF is specified, statistics are displayed for the treatment difference within each sequence and overall, and also for the period difference. If TEST=RATIO, statistics are displayed for the treatment ratio within each sequence and overall, and also for the period ratio. If the IGNOREPERIOD option is specified in the VAR statement, then statistics are displayed for the overall treatment difference if TEST=DIFF or for the overall treatment ratio if TEST=RATIO.

The "Statistics" table displays the following summary statistics:

- the name of the variable(s), displayed if the NOBYVAR option is used in the PROC TTEST statement
- the name of the classification variable (if two-independent-sample design) or treatment and period (if AB/BA crossover design)

- N, the number of nonmissing values
- the (arithmetic) Mean, displayed if the DIST=NORMAL option is specified in the PROC TTEST statement
- the Geometric Mean, displayed if the DIST=LOGNORMAL option is specified in the PROC TTEST statement
- Std Dev, the standard deviation, displayed if the DIST=NORMAL option is specified in the PROC TTEST statement
- the Coefficient of Variation, displayed if the DIST=LOGNORMAL option is specified in the PROC TTEST statement
- Std Err, the standard error of the mean, displayed if the DIST=NORMAL option is specified in the PROC TTEST statement
- the Minimum value
- the Maximum value

The "ConfLimits" table displays the following:

- the name of the variable(s), displayed if the NOBYVAR option is used in the PROC TTEST statement
- the name of the classification variable (if two-independent-sample design) or treatment and period (if AB/BA crossover design)
- the (arithmetic) Mean, displayed if the DIST=NORMAL option is specified in the PROC TTEST statement
- the Geometric Mean, displayed if the DIST=LOGNORMAL option is specified in the PROC TTEST statement
- $100(1-\alpha)\%$ CL Mean, the lower and upper confidence limits for the mean. Separate pooled and Satterthwaite confidence limits are shown for the difference or ratio transformations in two-independent-sample designs and AB/BA crossover designs without the IGNOREPERIOD option.
- Std Dev, the standard deviation, displayed if the DIST=NORMAL option is specified in the PROC TTEST statement
- the Coefficient of Variation, displayed if the DIST=LOGNORMAL option is specified in the PROC TTEST statement
- $100(1-\alpha)\%$ CL Std Dev, the equal-tailed confidence limits for the standard deviation, displayed if the DIST=NORMAL and CI=EQUAL options are specified in the PROC TTEST statement
- $100(1-\alpha)\%$ UMPU CL Std Dev, the UMPU confidence limits for the standard deviation, displayed if the DIST=NORMAL and CI=UMPU options are specified in the PROC TTEST statement

- $100(1-\alpha)\%$ CL CV, the equal-tailed confidence limits for the coefficient of variation, displayed if the DIST=LOGNORMAL and CI=EQUAL options are specified in the PROC TTEST statement
- $100(1-\alpha)\%$ UMPU CL CV, the UMPU confidence limits for the coefficient of variation, displayed if the DIST=LOGNORMAL and CI=UMPU options are specified in the PROC TTEST statement

The confidence limits in the "EquivLimits" table and test results in the "TTests" and "EquivTests" tables are displayed only for the test criteria—that is, the variables or transformations being tested. For a one-sample design, results are displayed for all variables in the analysis. For a paired design, results are displayed for the difference if you specify the TEST=DIFF option in the PROC TTEST statement, or for the ratio if you specify TEST=RATIO. For a two-independent-sample design, the results for the difference (if TEST=DIFF) or ratio (if TEST=RATIO) are displayed. For an AB/BA crossover design, results are displayed for the treatment difference (if TEST=DIFF) or ratio (if TEST=RATIO). If the IGNOREPERIOD option is absent, then results are also displayed for the period difference (if TEST=DIFF) or ratio (if TEST=RATIO).

The "EquivLimits" table, produced only if the TOST option is specified in the PROC TTEST statement, displays the following:

- the name of the variable(s), displayed if the NOBYVAR option is used in the PROC TTEST statement
- the (arithmetic) Mean, displayed if the DIST=NORMAL option is specified in the PROC TTEST statement
- the Geometric Mean, displayed if the DIST=LOGNORMAL option is specified in the PROC TTEST statement
- Lower Bound, the lower equivalence bound for the mean specified in the TOST option in the PROC TTEST statement
- $100(1-2\alpha)\%$ CL Mean, the lower and upper confidence limits for the mean relevant to the equivalence test. Separate pooled and Satterthwaite confidence limits are shown for two-independent-sample designs and AB/BA crossover designs without the IGNOREPERIOD option.
- Upper Bound, the upper equivalence bound for the mean specified in the TOST option in the PROC TTEST statement
- Assessment, the result of the equivalence test at the significance level specified by the ALPHA= option in the PROC TTEST statement, either "Equivalent" or "Not equivalent"

The "TTests" table is produced only if the TOST option is *not* specified in the PROC TTEST statement. Separate results for pooled and Satterthwaite tests (and also the Cochran and Cox test, if the COCHRAN option is specified in the PROC TTEST statement) are displayed for two-independent-sample designs and AB/BA crossover designs without the IGNOREPERIOD option. The table includes the following results:

- the name of the variable(s), displayed if the NOBYVAR option is used in the PROC TTEST statement
- t Value, the t statistic for comparing the mean to the null value as specified by the H0= option in the PROC TTEST statement
- DF, the degrees of freedom
- the p-value, the probability of obtaining a t statistic at least as extreme as the observed t value under the null hypothesis

The "EquivTests" table is produced only if the TOST option is specified in the PROC TTEST statement. Separate results for pooled and Satterthwaite tests are displayed for two-independent-sample designs and AB/BA crossover designs without the IGNOREPERIOD option. Each test consists of two separate one-sided tests. The overall p-value is the larger p-value from these two tests. The table includes the following results:

- the name of the variable(s), displayed if the NOBYVAR option is used in the PROC TTEST statement
- Null, the lower equivalence bound for the Upper test or the upper equivalence bound for the Lower test, as specified by the TOST option in the PROC TTEST statement
- t Value, the t statistic for comparing the mean to the Null value
- DF, the degrees of freedom
- the p-value, the probability of obtaining a t statistic at least as extreme as the observed t value under the null hypothesis

The "Equality" table gives the results of the test of equality of variances. It is displayed for two-independent-sample designs and AB/BA crossover designs without the IGNOREPERIOD option. The table includes the following results:

- the name of the variable(s), displayed if the NOBYVAR option is used in the PROC TTEST statement
- Num DF and Den DF, the numerator and denominator degrees of freedom
- F Value, the F' (folded) statistic
- Pr > F, the probability of a greater F' value. This is the two-tailed p-value.

ODS Table Names

PROC TTEST assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 92.5. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 92.5 ODS Tables Produced by PROC TTEST

ODS Table Name	Description	Syntax
ConfLimits	$100(1-\alpha)\%$ confidence limits for means, standard deviations, and/or coefficients of variation	by default
Equality	Tests for equality of variance	CLASS statement or VAR / CROSSOVER
EquivLimits	$100(1-2\alpha)\%$ confidence limits for means	PROC TTEST TOST
EquivTests	Equivalence t tests	PROC TTEST TOST
Statistics	Univariate summary statistics	by default
TTests	t tests	by default

ODS Graphics

ODS Graph Names

To request graphics with PROC TTEST, you must first enable ODS Graphics by specifying the **ODS GRAPHICS ON** statement. See Chapter 21, "Statistical Graphics Using ODS," for more information. You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC TTEST generates are listed in Table 92.6, along with the required statements and options.

Table 92.6 ODS Graphics Produced by PROC TTEST

ODS Graph Name	Plot Description	Option
AgreementOfPeriods	Plot of period 2 against period 1 response values for an AB/BA crossover design	VAR / CROSSOVER PLOTS=AGREEMENT(TYPE=PERIOD)
AgreementOfTreatments	Plot of second treatment against first treatment response values for an AB/BA crossover design	VAR / CROSSOVER PLOTS=AGREEMENT
AgreementPlot	Plot of second response against first response for a paired design	PAIRED statement PLOTS=AGREEMENT
BoxPlot	Box plots, also with confidence band for one-sample or paired design	PLOTS=BOX PLOTS=SUMMARY(UNPACK)
Histogram	Histograms with overlaid kernel densities, and also normal densities if DIST=NORMAL	PLOTS=HISTOGRAM PLOTS=SUMMARY(UNPACK)
Interval	Confidence intervals for means	PLOTS=INTERVAL

Table 92.6 *continued*

ODS Graph Name	Plot Description	Option
ProfilesOverPrd	Plot of response profiles over periods 1 and 2 for an AB/BA crossover design	VAR / CROSSOVER PLOTS=PROFILES(TYPE=PERIOD)
ProfilesOverTrt	Plot of response profiles over first and second treatments for an AB/BA crossover design	VAR / CROSSOVER PLOTS=PROFILES
ProfilesPlot	Plot of response profiles over first and second response values for a paired design	PAIRED statement PLOTS=PROFILES
QQPlot	Normal quantile-quantile plots	PLOTS=QQ
SummaryPanel	Histograms with overlaid kernel densities (and also normal densities if DIST=NORMAL) and box plots (and also with confidence band for one-sample or paired design)	PLOTS=SUMMARY

Interpreting Graphs

Agreement Plots for Paired Designs

For paired designs, the second response of each pair is plotted against the first response, with the mean shown as a large bold symbol. If the WEIGHT statement is used, then the mean is the weighted mean. A diagonal line with slope=0 and y-intercept=1 is overlaid. The location of the points with respect to the diagonal line reveals the strength and direction of the difference or ratio. The tighter the clustering along the same direction as the line, the stronger the positive correlation of the two measurements for each subject. Clustering along a direction perpendicular to the line indicates negative correlation.

Period Agreement Plots for Crossover Designs

The response in the second period is plotted against the response in the first period, with plot symbols distinguishing the two treatment sequences and the two sequence means shown larger in bold. If the WEIGHT statement is used, then the means are weighted means. A diagonal line with slope=0 and y-intercept=1 is overlaid.

In the absence of a strong period effect, the points from each sequence will appear as mirror images about the diagonal line, farther apart with stronger treatment effects. Deviations from symmetry about the diagonal line indicate a period effect. The spread of points within each treatment sequence is an indicator of between-subject variability. The tighter the clustering along the same direction as the line (within each treatment sequence), the stronger the positive correlation of the

two measurements for each subject. Clustering along a direction perpendicular to the line indicates negative correlation.

The period agreement plot is usually less informative than the treatment agreement plot. The exception is when the period effect is stronger than the treatment effect.

Treatment Agreement Plots for Crossover Designs

The response associated with the second treatment is plotted against the response associated with the first treatment, with plot symbols distinguishing the two treatment sequences and the two sequence means shown larger in bold. If the WEIGHT statement is used, then the means are weighted means. A diagonal line with slope=0 and y-intercept=1 is overlaid.

The location of the points with respect to the diagonal line reveals the strength and direction of the treatment effect. Substantial location differences between the two sequences indicates a strong period effect. The spread of points within each treatment sequence is an indicator of between-subject variability. The tighter the clustering along the same direction as the line (within each treatment sequence), the stronger the positive correlation of the two measurements for each subject. Clustering along a direction perpendicular to the line indicates negative correlation.

Box Plots

The box is drawn from the 25th percentile (lower quartile) to the 75th percentile (upper quartile). The vertical line inside the box shows the location of the median. If DIST=NORMAL, then a diamond symbol shows the location of the mean. The whiskers extend to the minimum and maximum observations, and circles beyond the whiskers identify outliers.

For one-sample and paired designs, a confidence interval for the mean is shown as a band in the background. If the analysis is an equivalence analysis (with the TOST option in the PROC TTEST statement), then the interval is a $100(1-2\alpha)\%$ confidence interval shown along with the equivalence bounds. The inclusion of this interval completely within the bounds is indicative of a significant p-value. If the analysis is not an equivalence analysis, then the confidence level is $100(1-\alpha)\%$. If the SHOWH0 global plot option is used, then the null value for the test is shown. If the WEIGHT statement is used, then weights are incorporated in the confidence intervals.

Histograms

The WEIGHT statement is ignored in the computation of the normal and kernel densities.

Confidence Intervals

If the analysis is an equivalence analysis (with the TOST option in the PROC TTEST statement), then unless the TYPE=PERGROUP option is used, the interval is a $100(1-2\alpha)\%$ mean confidence interval shown along with the equivalence bounds. The inclusion of this interval completely within the bounds is indicative of a significant p-value.

If the analysis is not an equivalence analysis, or if the TYPE=PERGROUP option is used, then the confidence level is $100(1-\alpha)\%$. If the SHOWH0 global plot option is used, then the null value for the test is shown.

If the SIDES=L or SIDES=U option is used in the PROC TTEST statement, then the unbounded side of the one-sided interval is represented with an arrowhead. Note that the actual location of the arrowhead is irrelevant.

If the WEIGHT statement is used, then weights are incorporated in the confidence intervals.

Profiles for Paired Designs

For paired designs, a line is drawn for each observation from left to right connecting the first response to the second response. The mean first response and mean second response are connected with a bold line. If the WEIGHT statement is used, then the means are weighted means. The more extreme the slope, the stronger the effect. A wide spread of profiles indicates high between-subject variability. Consistent positive slopes indicate strong positive correlation. Widely varying slopes indicate lack of correlation, while consistent negative slopes indicate strong negative correlation.

Profiles over Period for Crossover Designs

For each observation, the response for the first period is connected to the response for second period, regardless of the treatment applied in each period. The means for each treatment sequence are shown in bold. If the WEIGHT statement is used, then the means are weighted means.

In the absence of a strong period effect, the profiles for each sequence will appear as mirror images about an imaginary horizontal line in the center. Deviations from symmetry about this imaginary horizontal line indicate a period effect. A wide spread of profiles within sequence indicates high between-subject variability.

The TYPE=PERIOD plot is usually less informative than the TYPE=TREATMENT plot. The exception is when the period effect is stronger than the treatment effect.

Profiles over Treatment for Crossover Designs

For each observation, the response for the first treatment is connected to the response for the second treatment, regardless of the periods in which they occur. The means for each treatment sequence are shown in bold. If the WEIGHT statement is used, then the means are weighted means.

In general, the more extreme the slope, the stronger the treatment effect. Slope differences between the two treatment sequences measure the period effect. A wide spread of profiles within sequence indicates high between-subject variability.

Q-Q Plots

Q-Q plots are useful for diagnosing violations of the normality and homoscedasticity assumptions. If the data in a Q-Q plot come from a normal distribution, the points will cluster tightly around the

reference line. You can use the UNIVARIATE procedure with the NORMAL option to numerically check the normality assumption.

Examples: TTEST Procedure

Example 92.1: Using Summary Statistics to Compare Group Means

This example, taken from Huntsberger and Billingsley (1989), compares two grazing methods using 32 steers. Half of the steers are allowed to graze continuously while the other half are subjected to controlled grazing time. The researchers want to know if these two grazing methods affect weight gain differently. The data are read by the following DATA step:

```
data graze;
   length GrazeType $ 10;
   input GrazeType $ WtGain @@;
   datalines;
controlled  45   controlled  62
controlled  96   controlled 128
controlled 120   controlled  99
controlled  28   controlled  50
controlled 109   controlled 115
controlled  39   controlled  96
controlled  87   controlled 100
controlled  76   controlled  80
continuous  94   continuous  12
continuous  26   continuous  89
continuous  88   continuous  96
continuous  85   continuous 130
continuous  75   continuous  54
continuous 112   continuous  69
continuous 104   continuous  95
continuous  53   continuous  21
;
run;
```

The variable GrazeType denotes the grazing method: “controlled” is controlled grazing and “continuous” is continuous grazing. The dollar sign ($) following GrazeType makes it a character variable, and the trailing at signs (@@) tell the procedure that there is more than one observation per line.

If you have summary data—that is, just means and standard deviations, as computed by PROC MEANS—then you can still use PROC TTEST to perform a simple *t* test analysis. This example demonstrates this mode of input for PROC TTEST. Note, however, that graphics are unavailable when summary statistics are used as input.

The MEANS procedure is invoked to create a data set of summary statistics with the following statements:

```
proc sort;
   by GrazeType;
proc means data=graze noprint;
   var WtGain;
   by GrazeType;
   output out=newgraze;
run;
```

The NOPRINT option eliminates all printed output from the MEANS procedure. The VAR statement tells PROC MEANS to compute summary statistics for the WtGain variable, and the BY statement requests a separate set of summary statistics for each level of GrazeType. The OUTPUT OUT= statement tells PROC MEANS to put the summary statistics into a data set called newgraze so that it can be used in subsequent procedures. This new data set is displayed in Output 92.1.1 by using PROC PRINT as follows:

```
proc print data=newgraze;
run;
```

The _STAT_ variable contains the names of the statistics, and the GrazeType variable indicates which group the statistic is from.

Output 92.1.1 Output Data Set of Summary Statistics

Obs	GrazeType	_TYPE_	_FREQ_	_STAT_	WtGain
1	continuous	0	16	N	16.000
2	continuous	0	16	MIN	12.000
3	continuous	0	16	MAX	130.000
4	continuous	0	16	MEAN	75.188
5	continuous	0	16	STD	33.812
6	controlled	0	16	N	16.000
7	controlled	0	16	MIN	28.000
8	controlled	0	16	MAX	128.000
9	controlled	0	16	MEAN	83.125
10	controlled	0	16	STD	30.535

The following statements invoke PROC TTEST with the newgraze data set, as denoted by the DATA= option:

```
proc ttest data=newgraze;
   class GrazeType;
   var WtGain;
run;
```

The CLASS statement contains the variable that distinguishes between the groups being compared, in this case GrazeType. The summary statistics and confidence intervals are displayed first, as shown in Output 92.1.2.

Output 92.1.2 Summary Statistics and Confidence Limits

The TTEST Procedure

Variable: WtGain

GrazeType	N	Mean	Std Dev	Std Err	Minimum	Maximum
continuous	16	75.1875	33.8117	8.4529	12.0000	130.0
controlled	16	83.1250	30.5350	7.6337	28.0000	128.0
Diff (1-2)		-7.9375	32.2150	11.3897		

GrazeType	Method	Mean	95% CL Mean		Std Dev
continuous		75.1875	57.1705	93.2045	33.8117
controlled		83.1250	66.8541	99.3959	30.5350
Diff (1-2)	Pooled	-7.9375	-31.1984	15.3234	32.2150
Diff (1-2)	Satterthwaite	-7.9375	-31.2085	15.3335	

GrazeType	Method	95% CL Std Dev	
continuous		.	.
controlled		.	.
Diff (1-2)	Pooled	25.7434	43.0609
Diff (1-2)	Satterthwaite		

In Output 92.1.2, The GrazeType column specifies the group for which the statistics are computed. For each class, the sample size, mean, standard deviation and standard error, and maximum and minimum values are displayed. The confidence bounds for the mean are also displayed; however, since summary statistics are used as input, the confidence bounds for the standard deviation of the groups are not calculated.

Output 92.1.3 shows the results of tests for equal group means and equal variances.

Output 92.1.3 *t* Tests

Method	Variances	DF	t Value	Pr > |t|
Pooled	Equal	30	-0.70	0.4912
Satterthwaite	Unequal	29.694	-0.70	0.4913

Equality of Variances

Method	Num DF	Den DF	F Value	Pr > F
Folded F	15	15	1.23	0.6981

A group test statistic for the equality of means is reported for both equal and unequal variances. Both tests indicate a lack of evidence for a significant difference between grazing methods ($t = -0.70$ and $p = 0.4912$ for the pooled test, $t = -0.70$ and $p = 0.4913$ for the Satterthwaite test). The equality of variances test does not indicate a significant difference in the two variances

($F' = 1.23, p = 0.6981$). Note that this test assumes that the observations in both data sets are normally distributed; this assumption can be checked in PROC UNIVARIATE by using the NORMAL option with the raw data.

Although the ability to use summary statistics as input is useful if you lack access to the original data, some of the output that would otherwise be produced in an analysis on the original data is unavailable. There are also limitations on the designs and distributional assumptions that can be used with summary statistics as input. For more information, see the section "Input Data Set of Statistics" on page 7411.

Example 92.2: One-Sample Comparison with the FREQ Statement

This example examines children's reading skills. The data consist of Degree of Reading Power (DRP) test scores from 44 third-grade children and are taken from Moore (1995, p. 337). Their scores are given in the following DATA step:

```
data read;
   input score count @@;
   datalines;
40 2   47 2   52 2   26 1   19 2
25 2   35 4   39 1   26 1   48 1
14 2   22 1   42 1   34 2   33 2
18 1   15 1   29 1   41 2   44 1
51 1   43 1   27 2   46 2   28 1
49 1   31 1   28 1   54 1   45 1
;
run;
```

The following statements invoke the TTEST procedure to test if the mean test score is equal to 30.

```
ods graphics on;

proc ttest data=read h0=30;
   var score;
   freq count;
run;

ods graphics off;
```

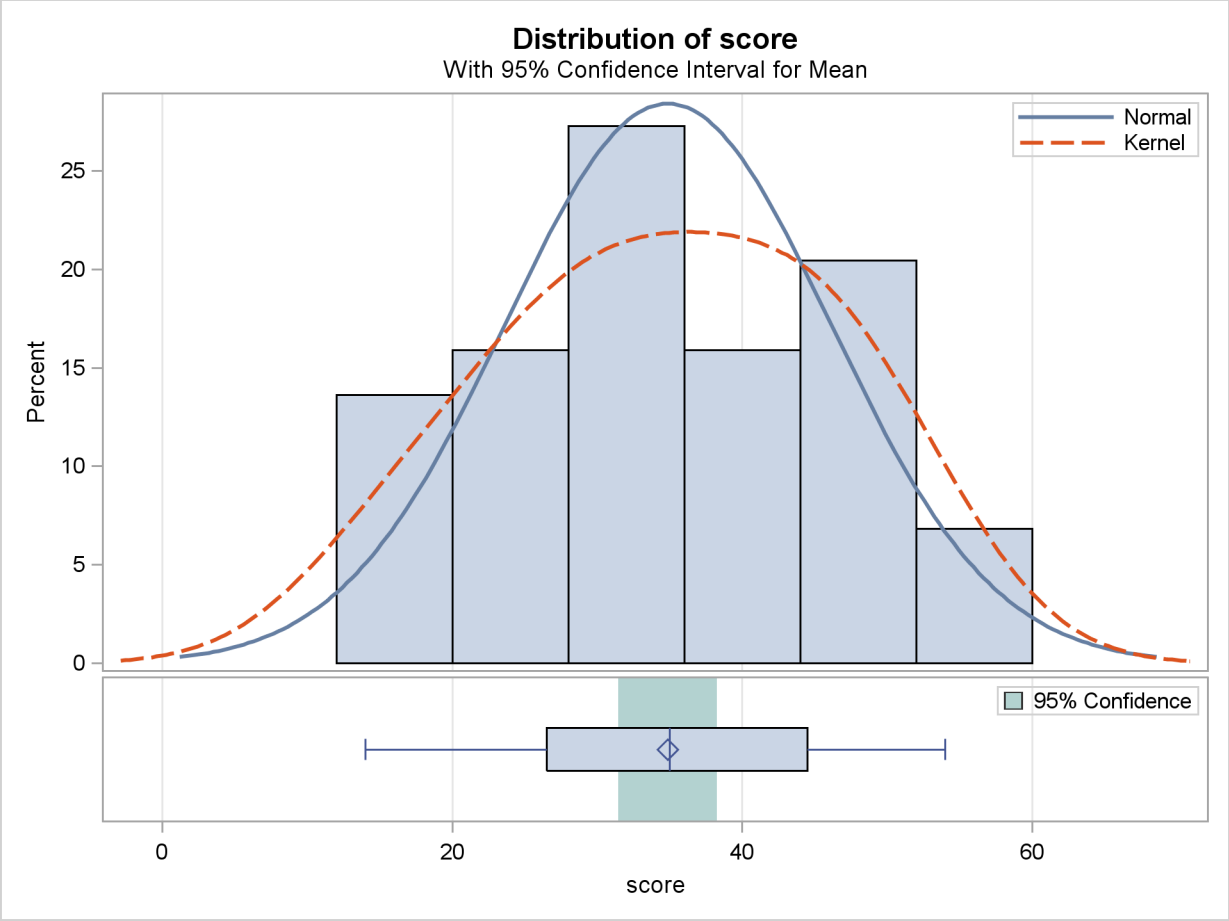
The ODS GRAPHICS statement requests graphical output. The count variable contains the frequency of occurrence of each test score; this is specified in the FREQ statement. The output, shown in Output 92.2.1, contains the results.

Output 92.2.1 TTEST Results

The TTEST Procedure

Variable: score

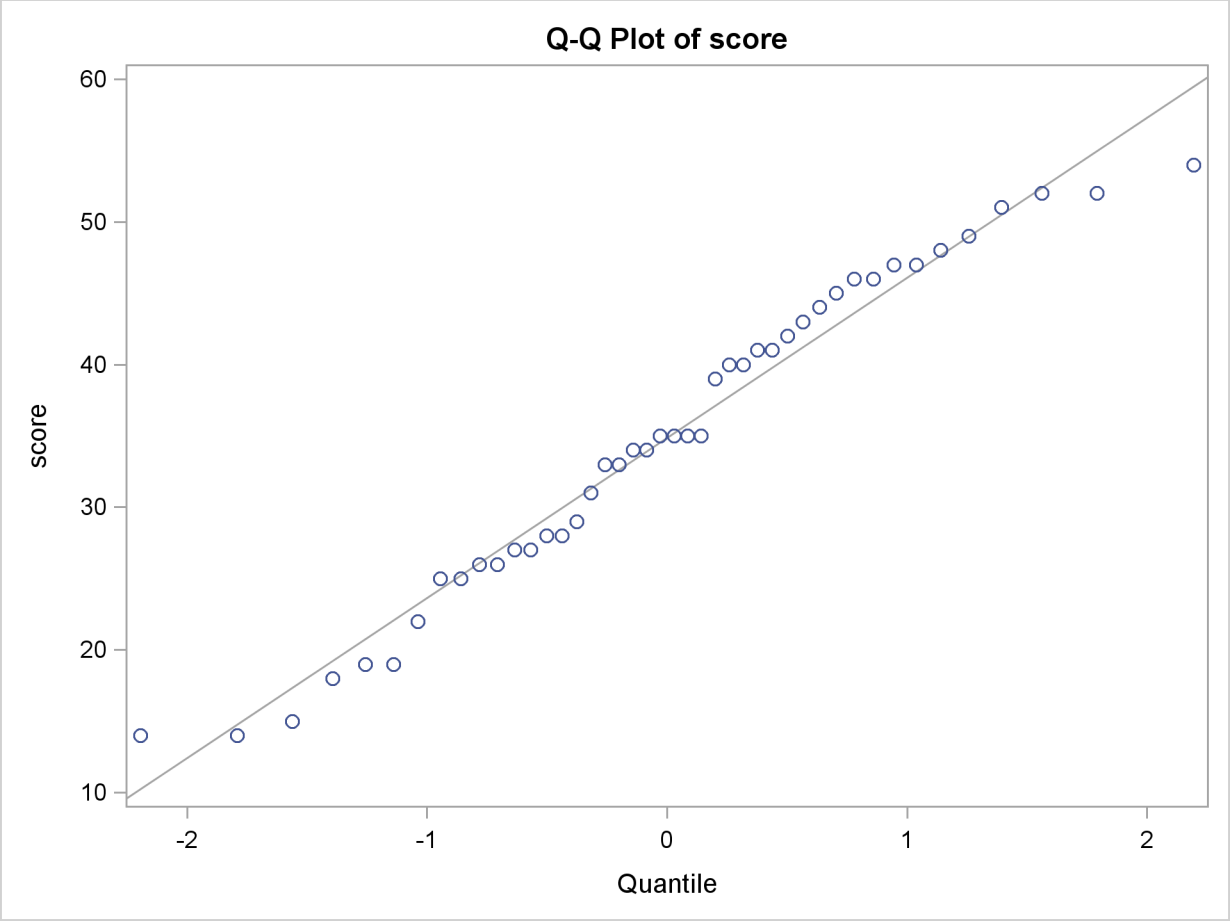
N	Mean	Std Dev	Std Err	Minimum	Maximum
44	34.8636	11.2303	1.6930	14.0000	54.0000



Mean	95% CL Mean		Std Dev	95% CL Std Dev	
34.8636	31.4493	38.2780	11.2303	9.2788	14.2291

DF	t Value	Pr > |t|
43	2.87	0.0063

The SAS log states that 30 observations and two variables have been read. However, the sample size given in the TTEST output is N=44. This is due to specifying the count variable in the FREQ statement. The test is significant ($t = 2.87$, $p = 0.0063$) at the 5% level, so you can conclude that the mean test score is different from 30.



The summary panel in Output 92.2.2 shows a histogram with overlaid normal and kernel densities, a box plot, and the 95% confidence interval for the mean.

Output 92.2.2 Summary Panel

The Q-Q plot in Output 92.2.3 assesses the normality assumption.

Output 92.2.3 Q-Q Plot

The tight clustering of the points around the diagonal line is consistent with the normality assumption. You could use the UNIVARIATE procedure with the NORMAL option to numerically check the normality assumption.

Example 92.3: Paired Comparisons

When it is not feasible to assume that two groups of data are independent, and a natural pairing of the data exists, it is advantageous to use an analysis that takes the correlation into account. Using this correlation results in higher power to detect existing differences between the means. The differences between paired observations are assumed to be normally distributed. Some examples of this natural pairing are as follows:

- pre- and post-test scores for a student receiving tutoring
- fuel efficiency readings of two fuel types observed on the same automobile
- sunburn scores for two sunblock lotions, one applied to the individual's right arm, one to the left arm
- political attitude scores of husbands and wives

In this example, taken from the *SUGI Supplemental Library User's Guide, Version 5 Edition*, a stimulus is being examined to determine its effect on systolic blood pressure. Twelve men participate in the study. Each man's systolic blood pressure is measured both before and after the stimulus is applied. The following statements input the data:

```
data pressure;
      input SBPbefore SBPafter @@;
      datalines;
120 128   124 131   130 131   118 127
140 132   128 125   140 141   135 137
126 118   130 132   126 129   127 135
;
run;
```

The variables SBPbefore and SBPafter denote the systolic blood pressure before and after the stimulus, respectively.

The statements to perform the test follow:

```
ods graphics on;

proc ttest;
   paired SBPbefore*SBPafter;
run;

ods graphics off;
```

The ODS GRAPHICS statement requests graphical output. The PAIRED statement is used to test whether the mean change in systolic blood pressure is significantly different from zero. The tabular output is displayed in Output 92.3.1.

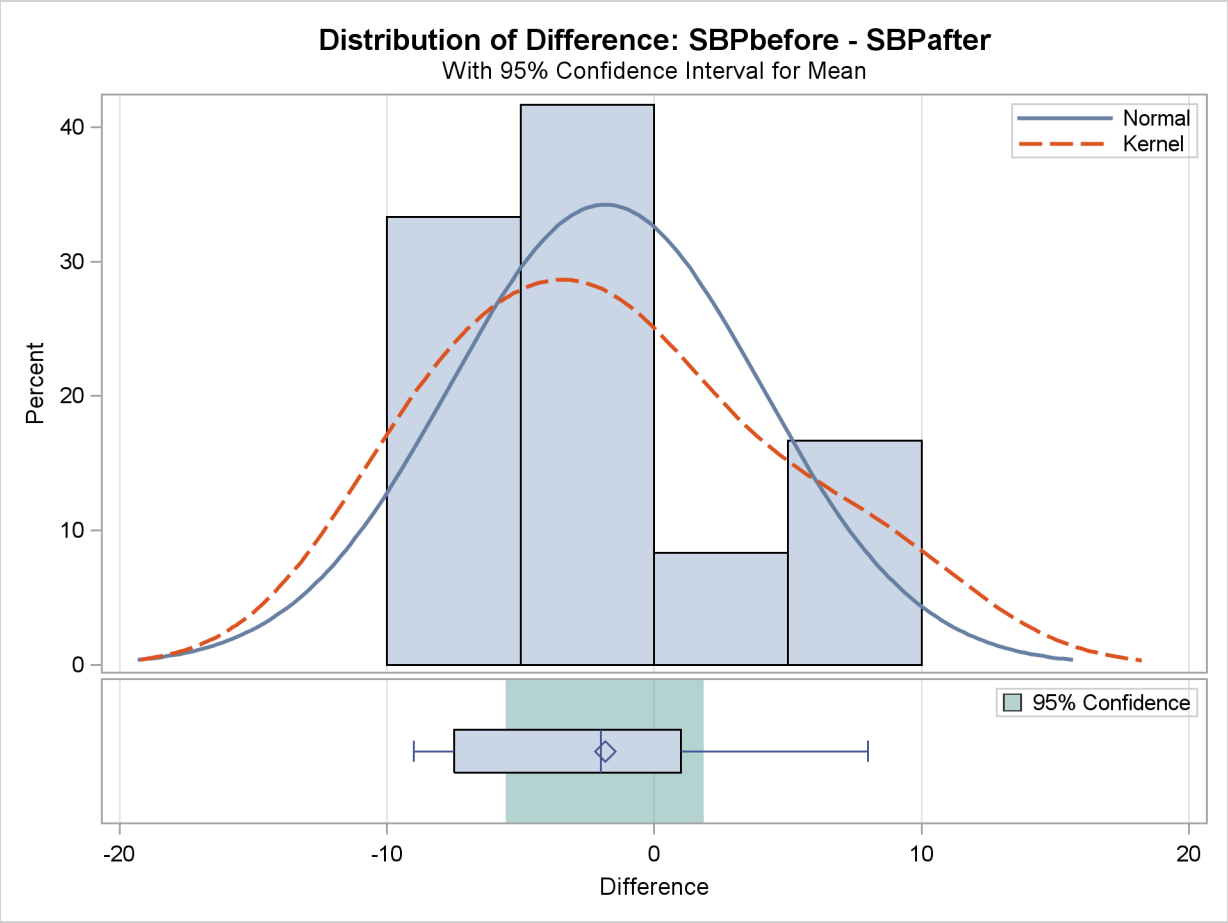
Output 92.3.1 TTEST Results

The TTEST Procedure

Difference: SBPbefore - SBPafter

N	Mean	Std Dev	Std Err	Minimum	Maximum
12	-1.8333	5.8284	1.6825	-9.0000	8.0000

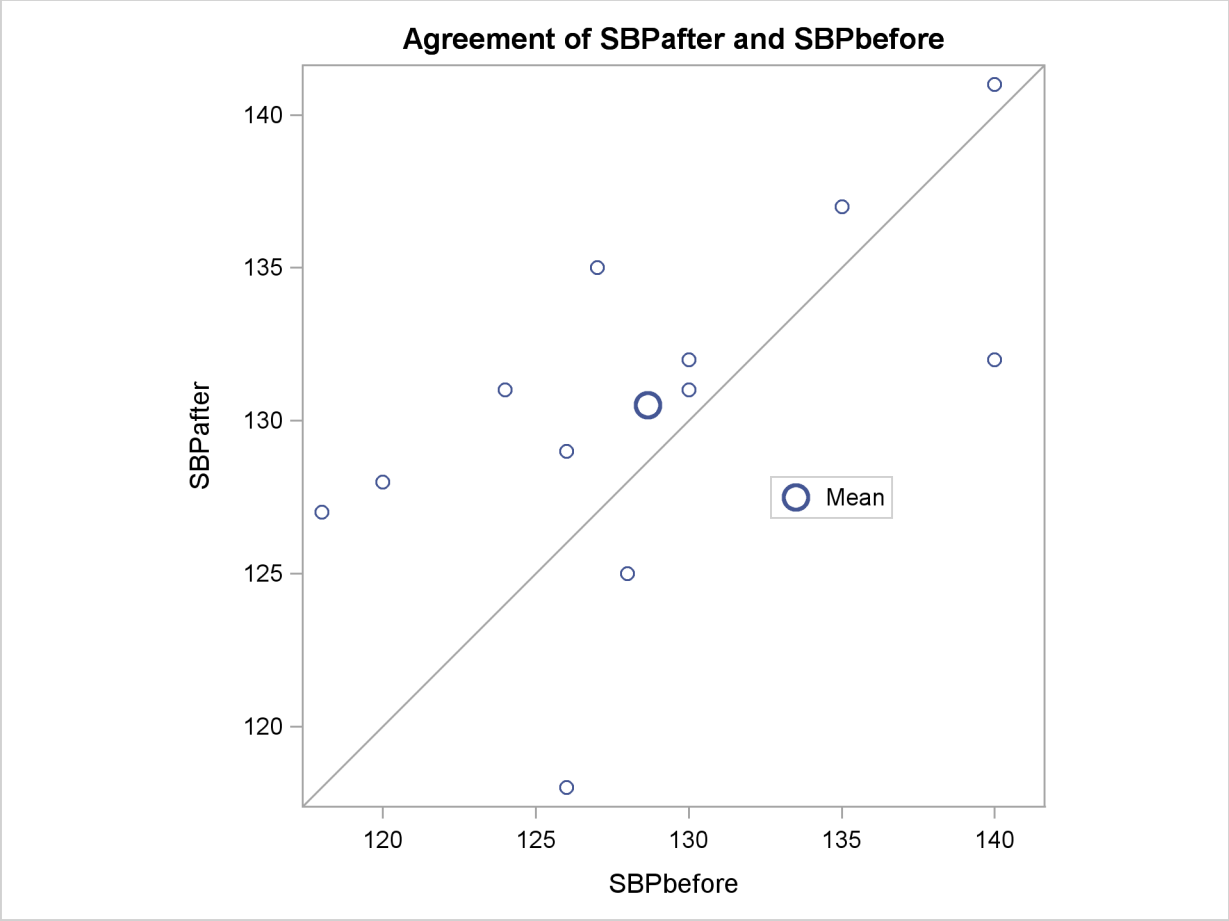
Mean	95% CL Mean		Std Dev	95% CL Std Dev	
-1.8333	-5.5365	1.8698	5.8284	4.1288	9.8958



DF	t Value	Pr > |t|
11	-1.09	0.2992

The variables SBPbefore and SBPafter are the paired variables with a sample size of 12. The summary statistics of the difference are displayed (mean, standard deviation, and standard error) along with their confidence limits. The minimum and maximum differences are also displayed. The *t* test

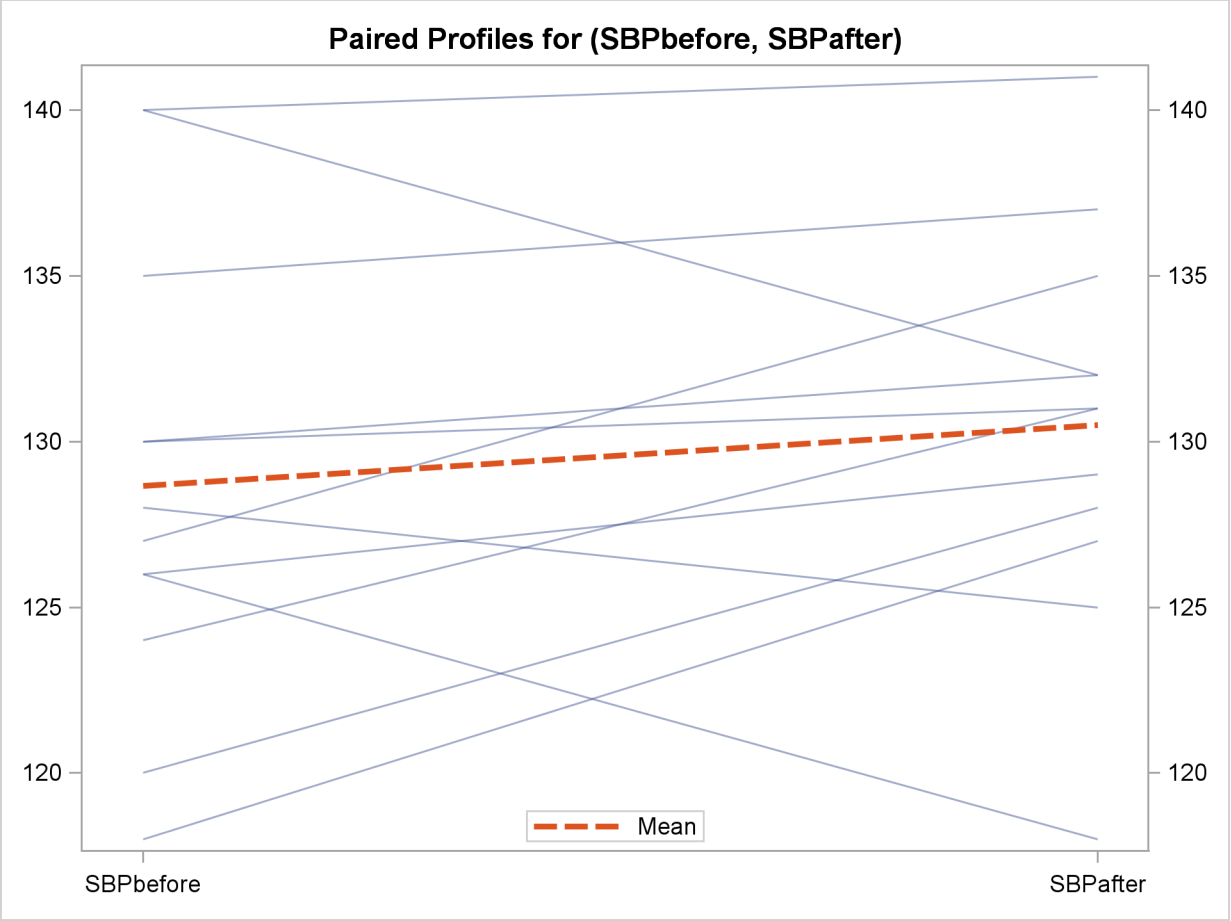
is not significant ($t = -1.09$, $p = 0.2992$), indicating that the stimuli did not significantly affect systolic blood pressure.



The summary panel in Output 92.3.2 shows a histogram, normal and kernel densities, box plot, and $100(1-\alpha)\% = 95\%$ confidence interval of the SBPbefore − SBPafter difference.

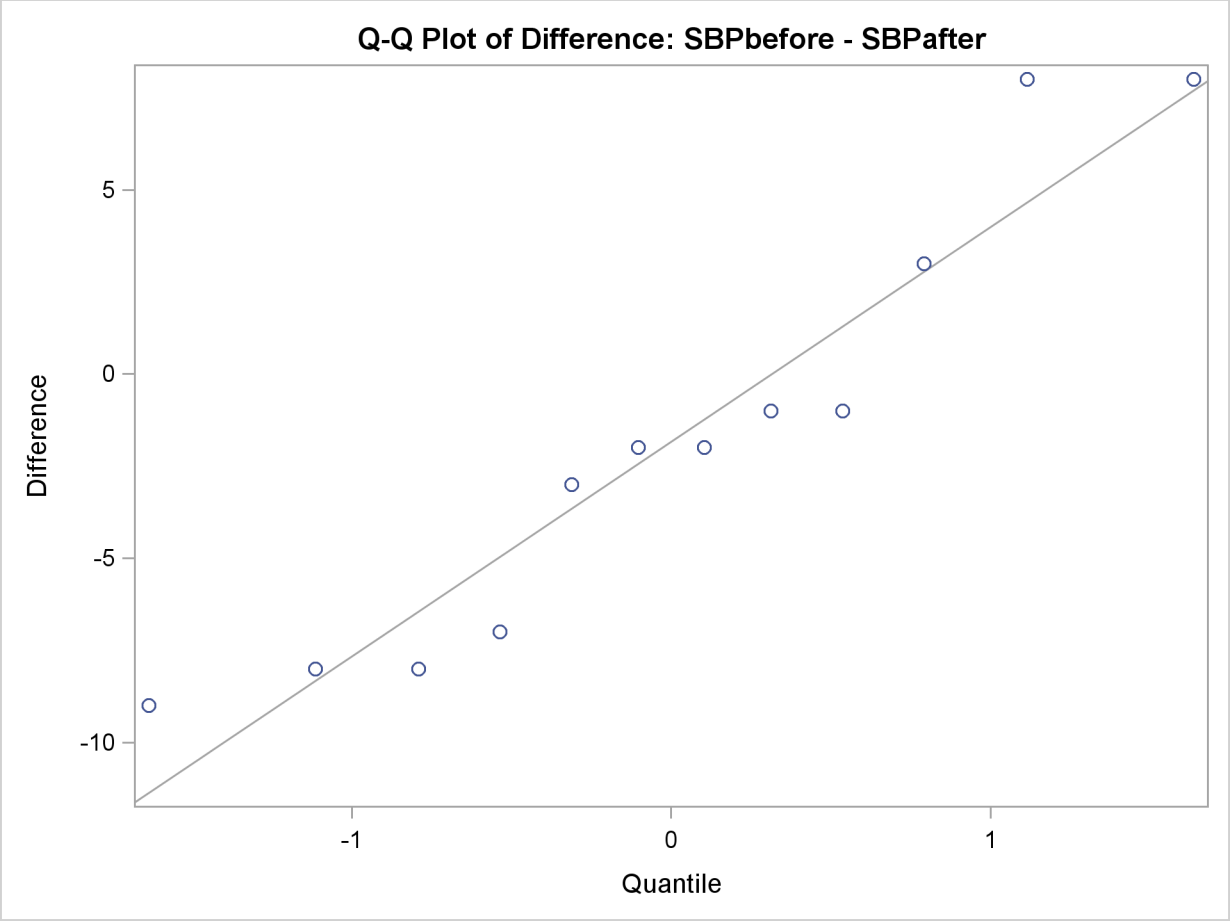
Output 92.3.2 Summary Panel

The agreement plot in Output 92.3.3 reveals that only three men have higher blood pressure before the stimulus than after.



Output 92.3.3 Agreement of Treatments

But the differences for these men are relatively large, keeping the mean difference only slightly negative.



The profiles plot in Output 92.3.4 is a different view of the same information contained in Output 92.3.3, plotting the blood pressure from before to after the stimulus.

Output 92.3.4 Profiles over Treatments

The Q-Q plot in Output 92.3.5 assesses the normality assumption.

Output 92.3.5 Q-Q Plot

The Q-Q plot shows no obvious deviations from normality. You can check the assumption of normality more rigorously by using PROC UNIVARIATE with the NORMAL option.

Example 92.4: AB/BA Crossover Design

Senn (2002, Chapter 3) discusses a study comparing the effectiveness of two bronchodilators, formoterol ("for") and salbutamol ("sal"), in the treatment of childhood asthma. A total of 13 children are recruited for an AB/BA crossover design. A random sample of 7 of the children are assigned to the treatment sequence for/sal, receiving a dose of formoterol upon an intial visit ("period 1") and then a dose of salbutamol upon a later visit ("period 2"). The other 6 children are assigned to the sequence sal/for, receiving the treatments in the reverse order but otherwise in a similar manner. Periods 1 and 2 are sufficiently spaced so that no carryover effects are suspected. After a child inhales a dose of a bronchodilator, peak expiratory flow (PEF) is measured. Higher PEF indicates greater effectiveness. The data are assumed to be approximately normally distributed.

The data set is generated with the following statements:

```
data asthma;
   input Drug1 $ Drug2 $ PEF1 PEF2 @@;
   datalines;
for sal 310 270   for sal 310 260  for sal 370 300
for sal 410 390   for sal 250 210  for sal 380 350
for sal 330 365
sal for 370 385   sal for 310 400  sal for 380 410
sal for 290 320   sal for 260 340  sal for 90  220
;
run;
```

You can display the data by using the following statements, which produce Output 92.4.1:

```
proc print data=asthma;
run;
```

Output 92.4.1 Asthma Study Data

Obs	Drug1	Drug2	PEF1	PEF2
1	for	sal	310	270
2	for	sal	310	260
3	for	sal	370	300
4	for	sal	410	390
5	for	sal	250	210
6	for	sal	380	350
7	for	sal	330	365
8	sal	for	370	385
9	sal	for	310	400
10	sal	for	380	410
11	sal	for	290	320
12	sal	for	260	340
13	sal	for	90	220

The variables PEF1 and PEF2 represent the responses for the first and second periods, respectively. The variables Drug1 and Drug2 represent the treatment in each period.

You can analyze this crossover design by using the CROSSOVER option after a slash (/) in the VAR statement:

```
ods graphics on;

proc ttest data=asthma plots=interval;
   var PEF1 PEF2 / crossover= (Drug1 Drug2);
run;

ods graphics off;
```

The ODS GRAPHICS statement requests graphical output. With the default PROC TTEST options TEST=DIFF and DIST=NORMAL and the lack of the IGNOREPERIOD option in the VAR statement, both the treatment difference and the period difference are assessed. The PROC TTEST default options H0=0, SIDES=2, and ALPHA=0.05 specify a two-sided analysis with 95% confidence limits comparing treatment and period differences to a default difference of zero. The

default CI=EQUAL option in the PROC TTEST statement requests equal-tailed confidence intervals for standard deviations. The PLOTS=INTERVAL option produces TYPE=TREATMENT confidence intervals, in addition to the default plots AGREEMENT(TYPE=TREATMENT), BOX, HISTOGRAM, PROFILES(TYPE=TREATMENT), and QQ.

Output 92.4.2 summarizes the response and treatment variables for each period.

Output 92.4.2 Crossover Variable Information

The TTEST Procedure

Response Variables: PEF1, PEF2

Crossover Variable Information

Period	Response	Treatment
1	PEF1	Drug1
2	PEF2	Drug2

Output 92.4.3 displays basic summary statistics (sample size, mean, standard deviation, standard error, minimum, and maximum) for each of the four cells in the design, the treatment difference within each treatment sequence, the overall treatment difference, and the overall period difference.

Output 92.4.3 Statistics

Sequence	Treatment	Period	N	Mean	Std Dev	Std Err
1	for	1	7	337.1	53.7631	20.3206
2	for	2	6	345.8	70.8814	28.9372
2	sal	1	6	283.3	105.4	43.0245
1	sal	2	7	306.4	64.7247	24.4636
1	Diff (1-2)		7	30.7143	32.9682	12.4608
2	Diff (1-2)		6	62.5000	44.6934	18.2460
Both	Diff (1-2)			46.6071	19.3702	10.7766
Both		Diff (1-2)		-15.8929	19.3702	10.7766

Sequence	Treatment	Period	Minimum	Maximum
1	for	1	250.0	410.0
2	for	2	220.0	410.0
2	sal	1	90.0000	380.0
1	sal	2	210.0	390.0
1	Diff (1-2)		-35.0000	70.0000
2	Diff (1-2)		15.0000	130.0
Both	Diff (1-2)			
Both		Diff (1-2)		

The treatment difference "Diff (1-2)" corresponds to the "for" treatment minus the "sal" treatment, because "for" appears before "sal" in the output, according to the ORDER=MIXED default PROC TTEST option. Its mean estimate is 46.6071, favoring formoterol over salbutamol. The standard deviation (Std Dev) reported for a "difference" is actually the pooled standard deviation across both

treatment sequence (for/sal and sal/for), assuming equal variances. The standard error (Std Err) is the standard deviation of the mean estimate.

The top half of the table in Output 92.4.4 shows 95% two-sided confidence limits for the means for the same criteria addressed in the table in Output 92.4.3.

Output 92.4.4 Confidence Limits

Sequence	Treatment	Period	Method	Mean	95% CL Mean	
1	for	1		337.1	287.4	386.9
2	for	2		345.8	271.4	420.2
2	sal	1		283.3	172.7	393.9
1	sal	2		306.4	246.6	366.3
1	Diff (1-2)			30.7143	0.2238	61.2048
2	Diff (1-2)			62.5000	15.5972	109.4
Both	Diff (1-2)		Pooled	46.6071	22.8881	70.3262
Both	Diff (1-2)		Satterthwaite	46.6071	21.6585	71.5558
Both		Diff (1-2)	Pooled	-15.8929	-39.6119	7.8262
Both		Diff (1-2)	Satterthwaite	-15.8929	-40.8415	9.0558

Sequence	Treatment	Period	Method	Std Dev	95% CL Std Dev	
1	for	1		53.7631	34.6446	118.4
2	for	2		70.8814	44.2447	173.8
2	sal	1		105.4	65.7841	258.5
1	sal	2		64.7247	41.7082	142.5
1	Diff (1-2)			32.9682	21.2445	72.5982
2	Diff (1-2)			44.6934	27.8980	109.6
Both	Diff (1-2)		Pooled	19.3702	13.7217	32.8882
Both	Diff (1-2)		Satterthwaite			
Both		Diff (1-2)	Pooled	19.3702	13.7217	32.8882
Both		Diff (1-2)	Satterthwaite			

For the mean differences, both pooled (assuming equal variances for both treatment sequences) and Satterthwaite (assuming unequal variances) intervals are shown. For example, the pooled confidence limits for the overall treatment mean difference (for − sal) assuming equal variances are 22.8881 and 70.3262.

The bottom half of Output 92.4.4 shows 95% equal-tailed confidence limits for the standard deviations within each cell and for the treatment difference within each sequence. It also shows confidence limits for the pooled common standard deviation assuming equal variances. Note that the pooled standard deviation of 19.3702 and associated confidence limits 13.7217 and 32.8882 apply to both difference tests (treatment and period), since each of those tests involves the same pooled standard deviation.

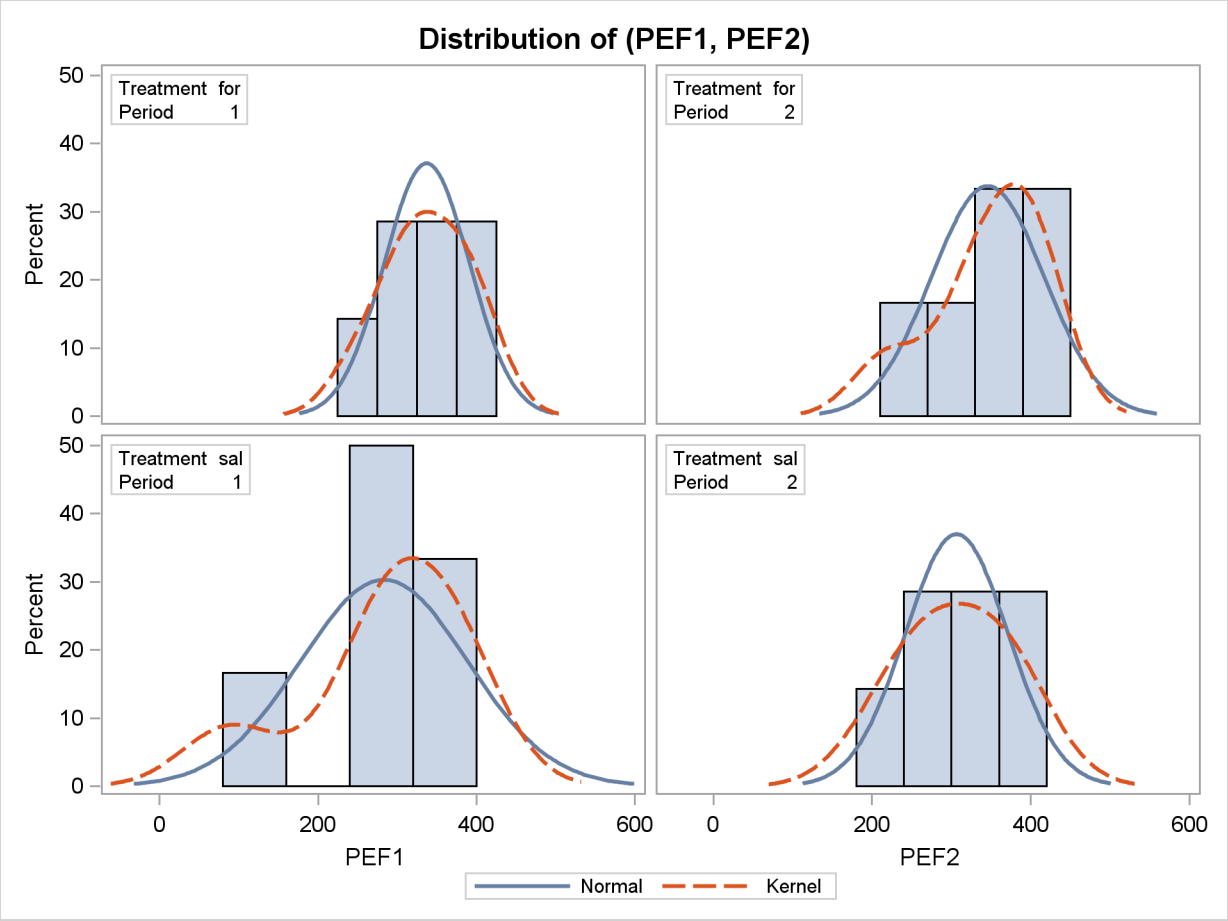
Output 92.4.5 shows the results of t tests of treatment and period differences.

Output 92.4.5 *t* Tests

Treatment	Period	Method	Variances	DF	t Value	Pr > |t|
Diff (1-2)		Pooled	Equal	11	4.32	0.0012
Diff (1-2)		Satterthwaite	Unequal	9.1017	4.22	0.0022
	Diff (1-2)	Pooled	Equal	11	-1.47	0.1683
	Diff (1-2)	Satterthwaite	Unequal	9.1017	-1.44	0.1838

Both pooled and Satterhthwaite versions of the test of treatment difference are highly significant ($p = 0.0012$ and $p = 0.0022$), and both versions of the test of period difference are insignificant ($p = 0.1683$ and $p = 0.1838$).

The folded F test of equal variances in each treatment sequence is shown in Output 92.4.6.

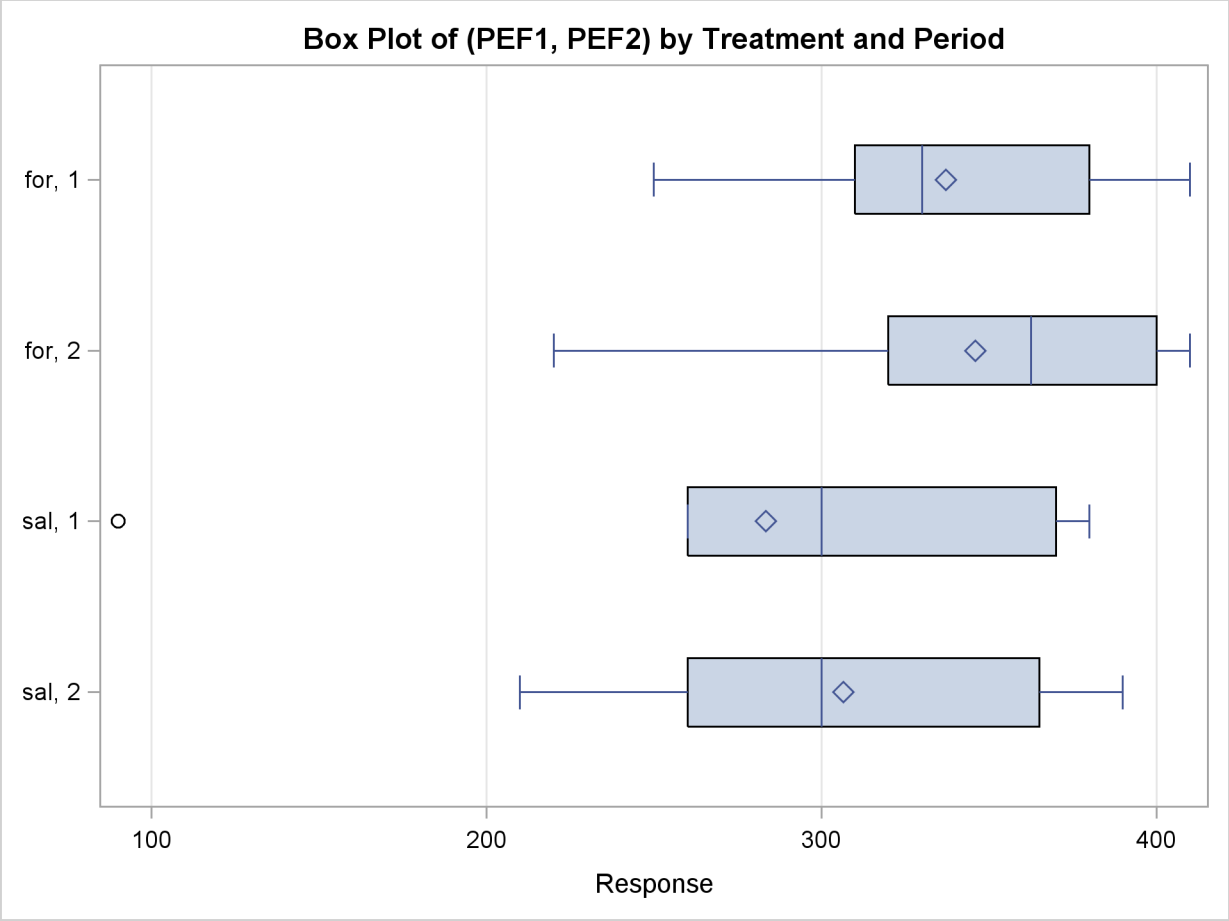


Output 92.4.6 Equality of Variances Test

Equality of Variances				
Method	Num DF	Den DF	F Value	Pr > F
Folded F	5	6	1.84	0.4797

The insignificant result ($p = 0.48$) implies a lack of evidence for unequal variances. However, it does not demonstrate equal variances, and it is not very robust to deviations from normality.

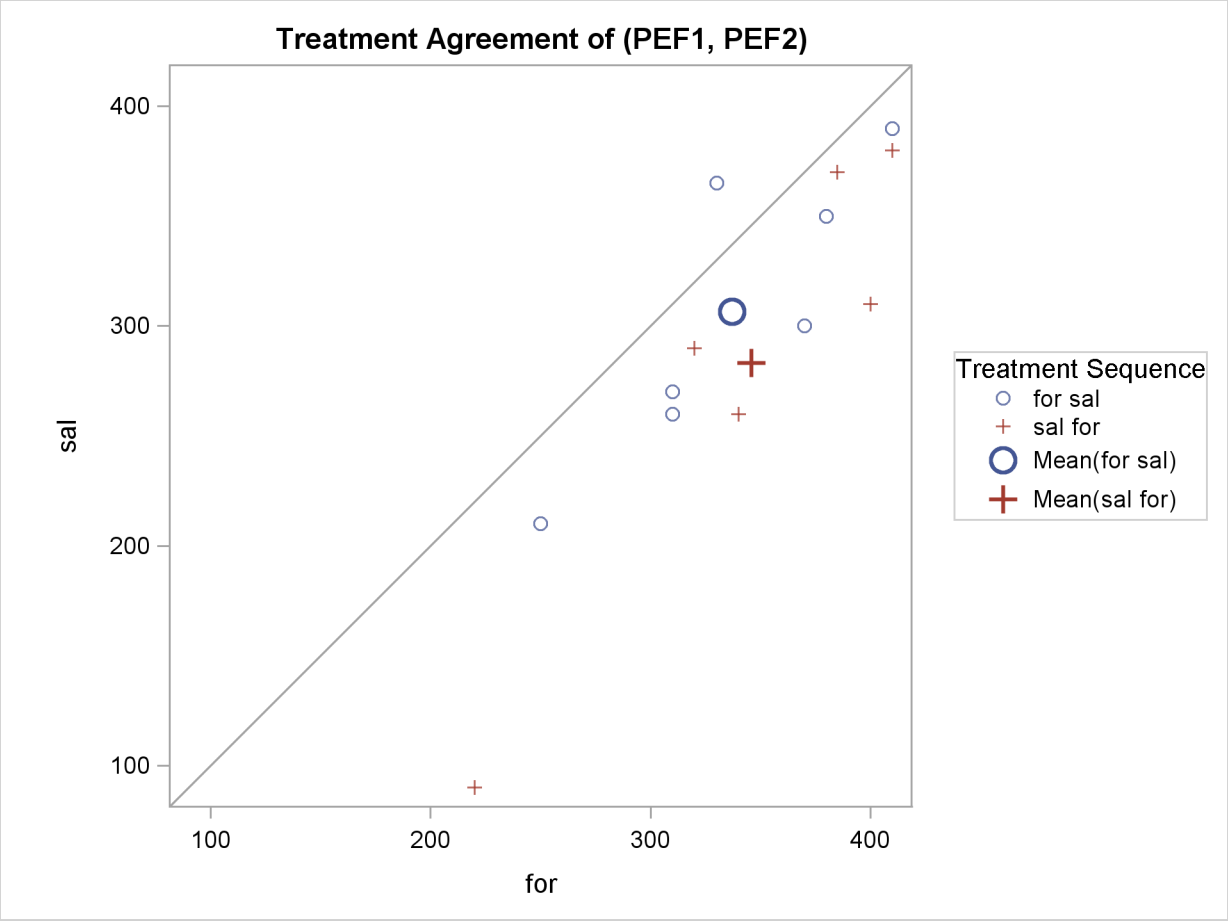
Output 92.4.7 shows the distribution of the response variables PEF1 and PEF2 within each of the four cells (combinations of two treatments and two periods) of the AB/BA crossover design, in terms of histograms and normal and kernel density estimates.



Output 92.4.7 Comparative Histograms

The distributions for the first treatment sequence (for/sal) appear to be somewhat symmetric, and the distributions for the sal/for sequence appear to be skewed to the left.

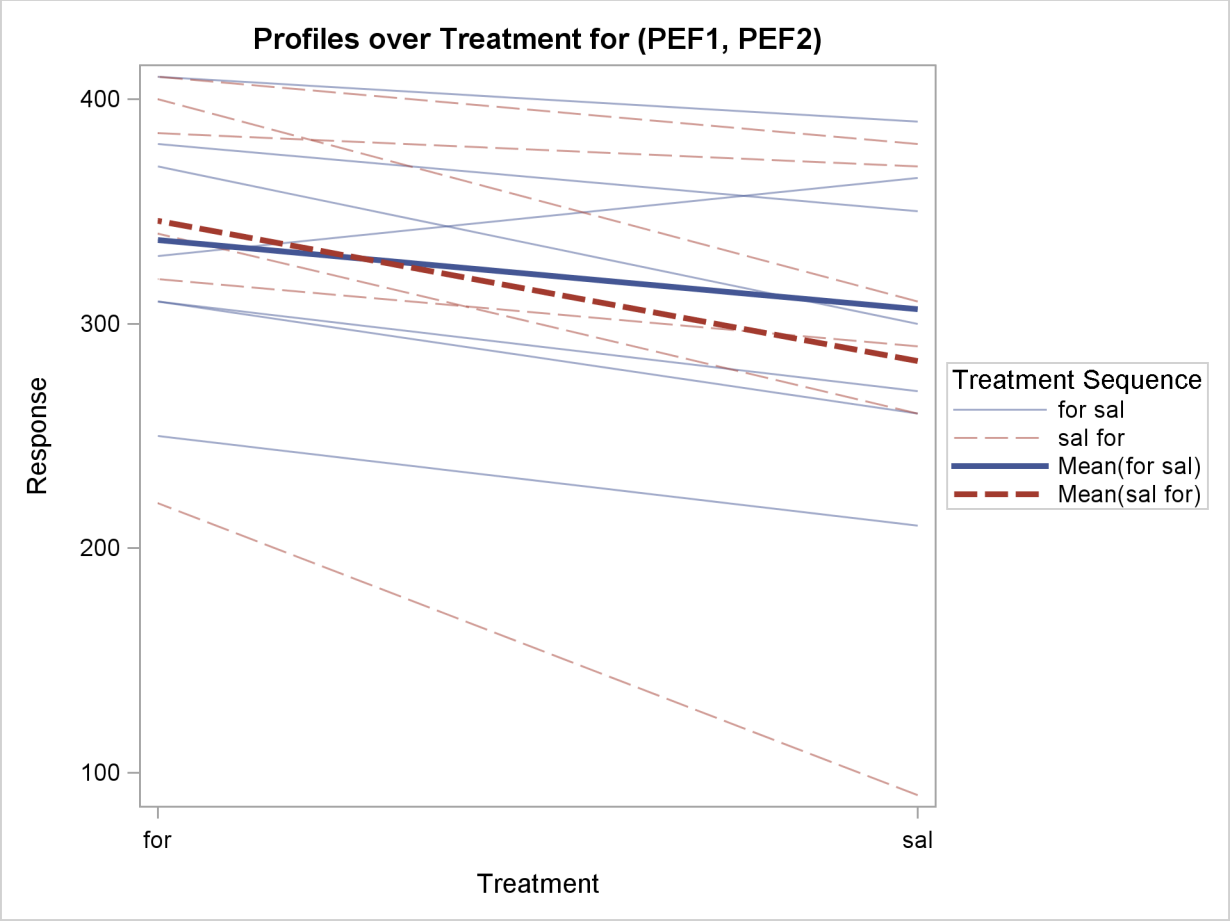
Output 92.4.8 shows a similar distributional summary but in terms of box plots.



Output 92.4.8 Comparative Box Plots

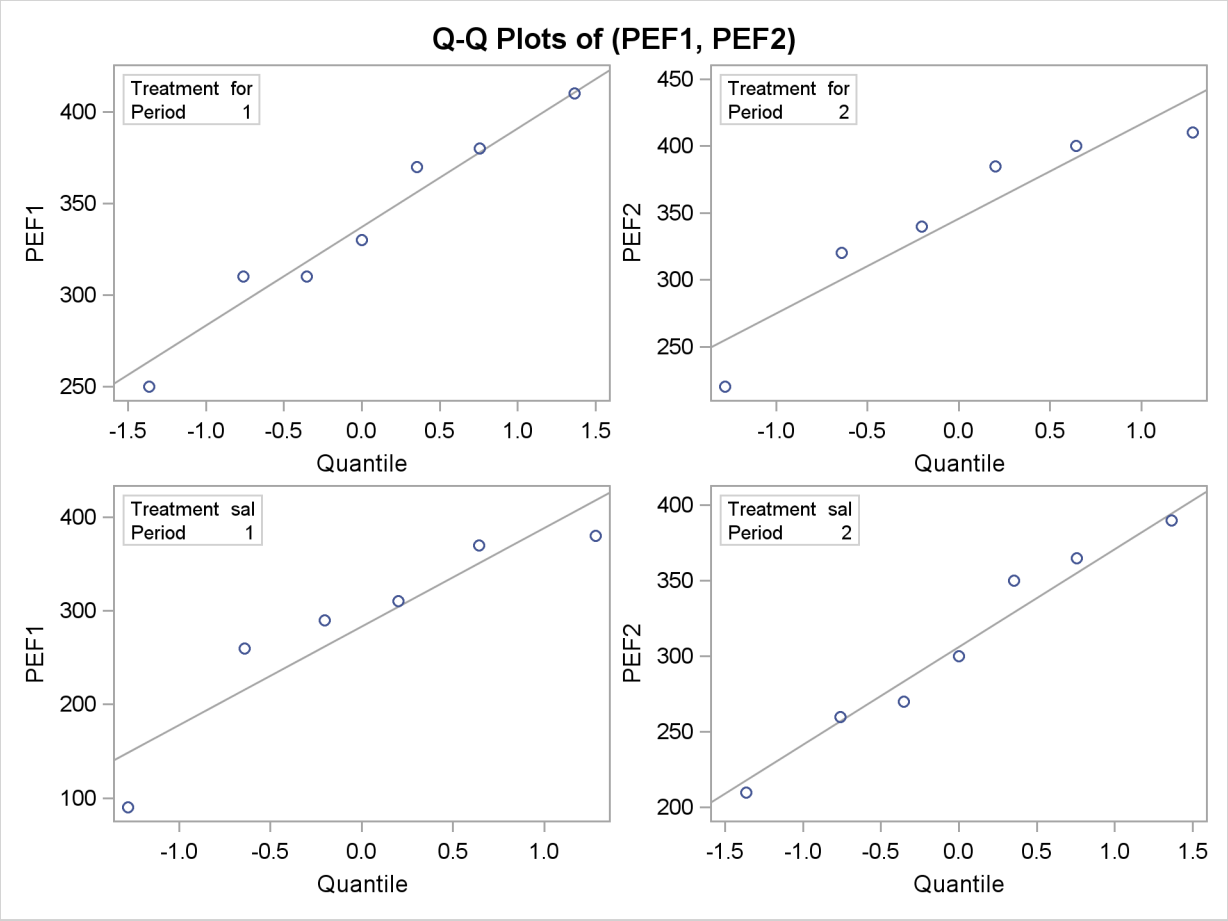
The relative locations of means and medians in each box plot corroborate the fact that the distributions for the sal/for sequence are skewed to the left. The distributions for the for/sal sequence appear to be skewed slightly to the right. The box plot for the salbutamol treatment in the first period shows an outlier (the circle on the far left side of the plot).

The treatment agreement plot in Output 92.4.9 reveals that only a single observation has a higher peak expiratory flow for salbutamol.



Output 92.4.9 Agreement of Treatments Plot

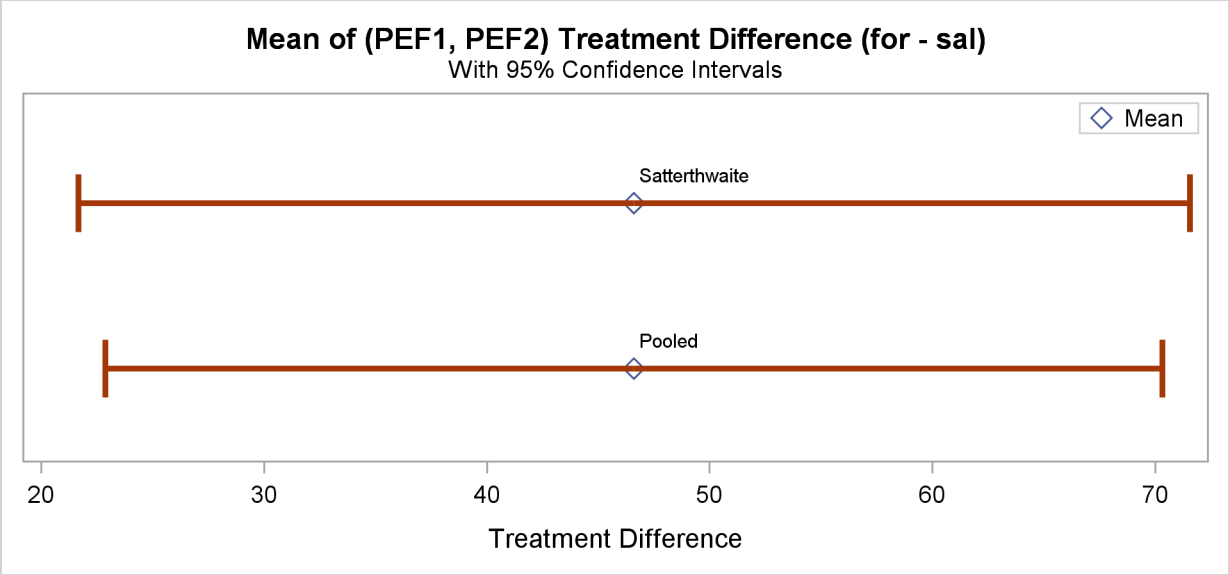
The mean for the sal/for treatment sequence is farther from the diagonal equivalence line, revealing that the treatment difference is more pronounced for the 6 observations in the sal/for sequence than for the 7 observations in the for/sal sequence. This fact is also seen numerically in Output 92.4.3 and Output 92.4.4, which show within-sequence treatment differences of 30.7 for for/sal and 62.5 for sal/for.



The profiles over treatment plot in Output 92.4.10 is a different view of the same information contained in Output 92.4.9, plotting the profiles from formoterol to salbutamol treatments. The lone observation for which the peak expiratory flow is higher for salbutamol appears as the only line with negative slope.

Output 92.4.10 Profiles over Treatment

The Q-Q plots in Output 92.4.11 assess normality assumption within each of the four cells of the design.



Output 92.4.11 Q-Q Plots

The two Q-Q plots for the sal/for sequence (lower left and upper right) suggest some possible normality violations in the tails, but the sample size is too small to make any strong conclusions. You could use the UNIVARIATE procedure with the NORMAL option to numerically check the normality assumptions.

Finally, Output 92.4.12 shows both pooled and Satterthwaite two-sided 95% confidence intervals for the treatment difference.

Output 92.4.12 Confidence Intervals for Treatment Difference

The pooled interval is slightly smaller than the Satterthwaite interval. (This is not always the case.)

Example 92.5: Equivalence Testing with Lognormal Data

Wellek (2003, p. 212) discusses an average bioequivalence study comparing the AUC (area under serum-concentration curve) measurements for two different drugs, denoted "Test" and "Reference," over a period of 20 hours. This example looks at a portion of Wellek's data, conducting an equivalence analysis with a paired design that uses AUC values on the original scale (assumed to be lognormally distributed). Each subject in the study received the Test drug upon one visit and then the Reference drug upon a later visit, sufficiently spaced so that no carryover effects would occur.

The goal is to test whether the geometric mean AUC ratio between Test and Reference is between 0.8 and 1.25, corresponding to the traditional FDA (80%, 125%) equivalence criterion. See the section "Arithmetic and Geometric Means" on page 7412 for a discussion of the use of geometric means for lognormal data.

The following SAS statements generate the data set:

```
data auc;
input TestAUC RefAUC @@;
datalines;
103.4 90.11  59.92 77.71  68.17 77.71  94.54 97.51
69.48 58.21  72.17 101.3  74.37 79.84  84.44 96.06
96.74 89.30  94.26 97.22  48.52 61.62  95.68 85.80
;
run;
```

You can display the data by using the following statements, which produce Output 92.5.1:

```
proc print data=auc;
run;
```

Output 92.5.1 AUC Data for Test and Reference Drugs

Obs	Test AUC	RefAUC
1	103.40	90.11
2	59.92	77.71
3	68.17	77.71
4	94.54	97.51
5	69.48	58.21
6	72.17	101.30
7	74.37	79.84
8	84.44	96.06
9	96.74	89.30
10	94.26	97.22
11	48.52	61.62
12	95.68	85.80

The TestAUC and RefAUC variables represent the AUC measurements for each subject under the Test and Reference drugs, respectively. Use the following SAS statements to perform the equivalence analysis:

```
ods graphics on;

proc ttest data=auc dist=lognormal tost(0.8, 1.25);
   paired TestAUC*RefAUC;
run;

ods graphics off;
```

The ODS GRAPHICS statement requests graphical output. The DIST=LOGNORMAL option specifies the lognormal distributional assumption and requests an analysis in terms of geometric mean and coefficient of variation. The TOST option specifies the equivalence bounds 0.8 and 1.25.

Output 92.5.2 shows basic summary statistics for the ratio of TestAUC to RefAUC.

Output 92.5.2 Summary Statistics

The TTEST Procedure

Ratio: TestAUC / RefAUC

N	Geometric Mean	Coefficient of Variation	Minimum	Maximum
12	0.9412	0.1676	0.7124	1.1936

The geometric mean ratio of 0.9412 is the sample mean of the log-transformed data exponentiated

to bring it back to the original scale. So the plasma concentration over the 20-hour period is slightly lower for the Test drug than for the Reference drug. The CV of 0.1676 is the ratio of the standard deviation to the (arithmetic) mean.

Output 92.5.3 shows the $100(1-\alpha)\% = 95\%$ confidence limits for the geometric mean ratio (0.8467 and 1.0462) and CV (0.1183 and 0.2884).

Output 92.5.3 Confidence Limits

Geometric Mean	95% CL Mean		Coefficient of Variation	95% CL CV	
0.9412	0.8467	1.0462	0.1676	0.1183	0.2884

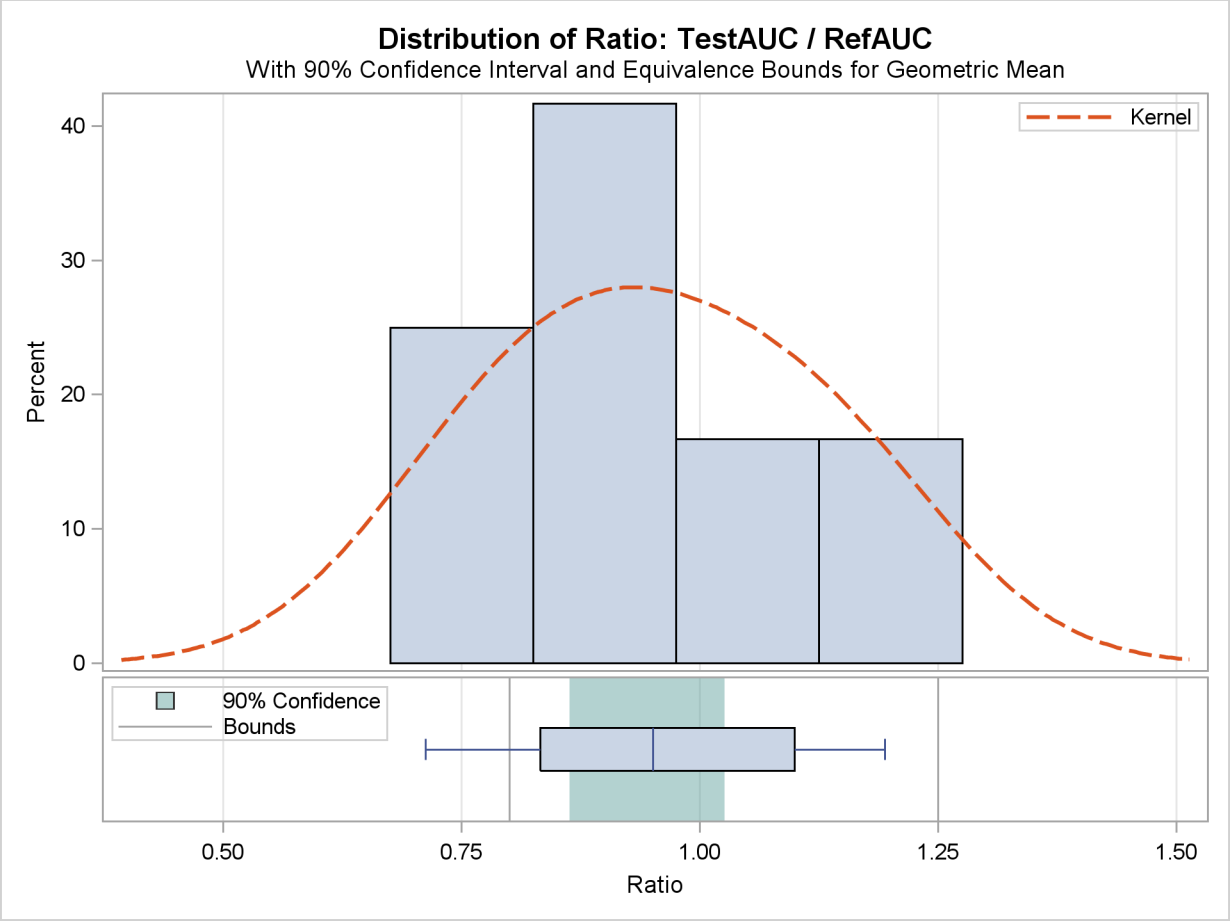
Output 92.5.4 shows the $100(1-2\alpha)\% = 90\%$ confidence limits for the geometric mean ratio, 0.8634 and 1.0260.

Output 92.5.4 Equivalence Limits

Geometric Mean	Lower Bound		90% CL Mean		Upper Bound	Assessment
0.9412	0.8	<	0.8634	1.0260 <	1.25	Equivalent

The assessment of "Equivalent" reflects the fact that these limits are contained within the equivalence bounds 0.8 and 1.25. This result occurs if and only if the p-value of the test is less than the α value specified in the ALPHA= option in the PROC TTEST statement, and it is the reason that $100(1-2\alpha)\%$ confidence limits are shown in addition to the usual $100(1-\alpha)\%$ limits.

Output 92.5.5 shows the p-values for the two one-sided tests against the upper and lower equivalence bounds.

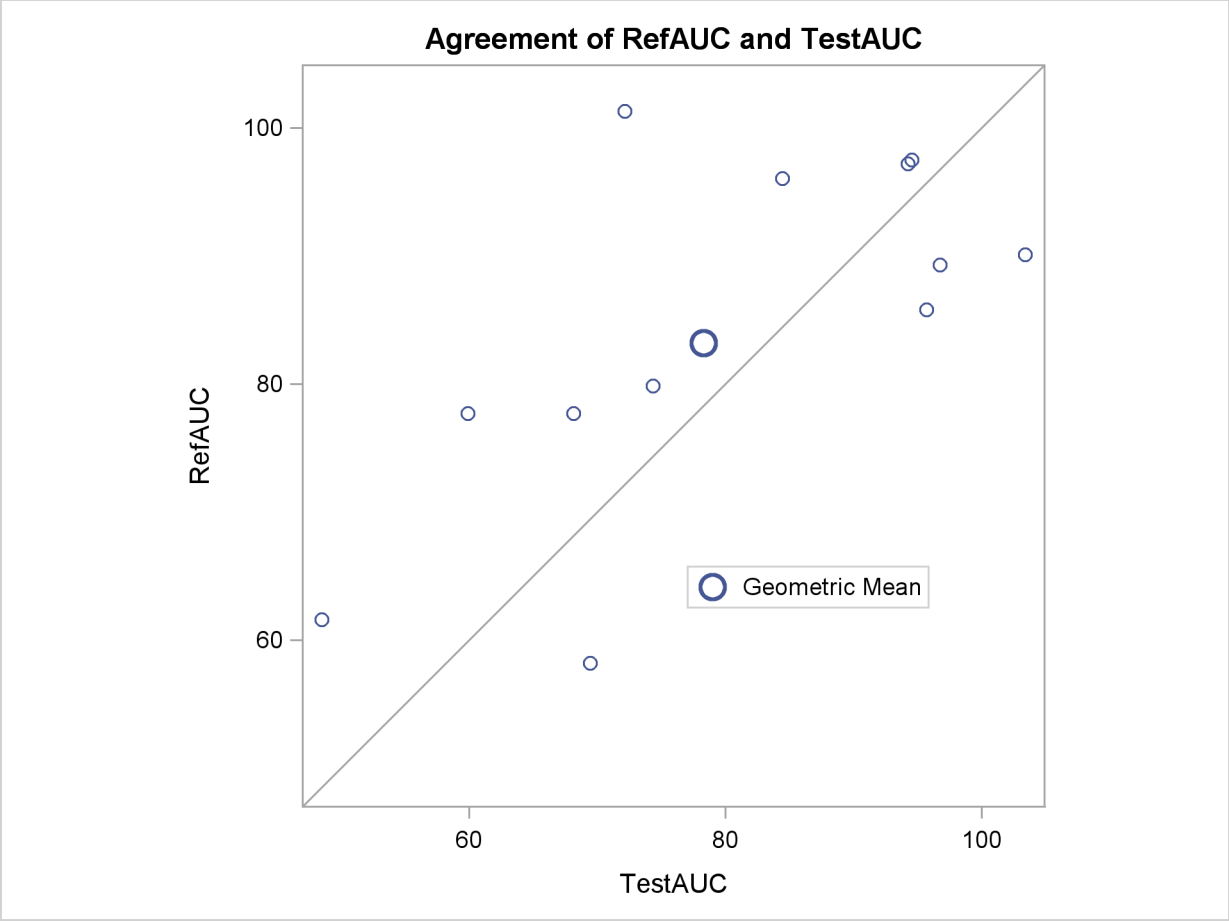


Output 92.5.5 TOST Equivalence Test

Test	Null	DF	t Value	P-Value
Upper	0.8	11	3.38	0.0031
Lower	1.25	11	-5.90	<.0001
Overall				0.0031

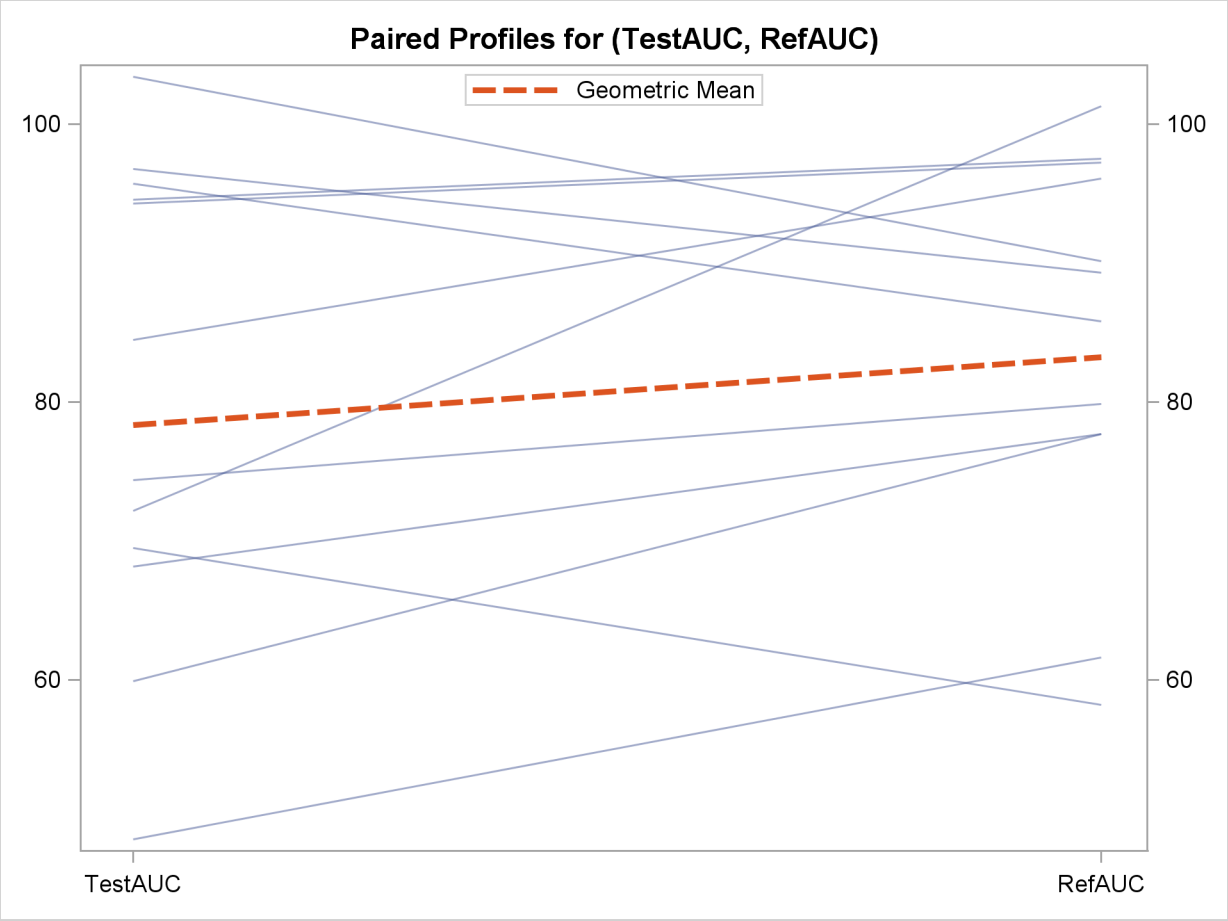
The overall p-value of 0.0031, the larger of the two one-sided p-values, indicates significant evidence of equivalence between the Test and Reference drugs.

The summary panel in Output 92.5.6 shows a histogram, kernel density, box plot, and $100(1-2\alpha)\% = 90\%$ confidence interval of the Test-to-Reference ratio of AUC, along with the equivalence bounds.



Output 92.5.6 Summary Panel

The confidence interval is closer to the lower equivalence bound than the upper bound and contained entirely within the bounds.



The agreement plot in Output 92.5.7 reveals that the only four subjects with higher AUC for the Test drug are at the far lower or far upper end of the AUC distribution. This might merit further investigation.

Output 92.5.7 Agreement Plot

The profiles plot in Output 92.5.8 is a different view of the same information contained in Output 92.5.7, plotting the AUC from Test to Reference drug.

Output 92.5.8 Profiles Plot

Overview: VARCLUS Procedure

The VARCLUS procedure divides a set of numeric variables into disjoint or hierarchical clusters. Associated with each cluster is a linear combination of the variables in the cluster. This linear combination can be either the first principal component (the default) or the centroid component (if you specify the CENTROID option). The first principal component is a weighted average of the variables that explains as much variance as possible. See Chapter 69, "The PRINCOMP Procedure," for further details. Centroid components are unweighted averages of either the standardized variables (the default) or the raw variables (if you specify the COVARIANCE option). The VARCLUS

procedure tries to maximize the variance that is explained by the cluster components, summed over all the clusters.

The cluster components are oblique, not orthogonal, even when the cluster components are first principal components. In an ordinary principal component analysis, all components are computed from the same variables, and the first principal component is orthogonal to the second principal component and to every other principal component. In the VARCLUS procedure, each cluster component is computed from a different set of variables than all the other cluster components. The first principal component of one cluster might be correlated with the first principal component of another cluster. Hence, the VARCLUS algorithm is a type of oblique component analysis.

As in principal component analysis, either the correlation or the covariance matrix can be analyzed. If correlations are used, all variables are treated as equally important. If covariances are used, variables with larger variances have more importance in the analysis.

The VARCLUS procedure creates an output data set that can be used with the SCORE procedure to compute component scores for each cluster. A second output data set can be used by the TREE procedure to draw a tree diagram of hierarchical clusters.

The VARCLUS procedure can be used as a variable-reduction method. A large set of variables can often be replaced by the set of cluster components with little loss of information. A given number of cluster components does not generally explain as much variance as the same number of principal components on the full set of variables, but the cluster components are usually easier to interpret than the principal components, even if the latter are rotated.

For example, an educational test might contain 50 items. The VARCLUS procedure can be used to divide the items into, say, five clusters. Each cluster can then be treated as a subtest, with the subtest scores given by the cluster components. If the cluster components are centroid components of the covariance matrix, each subtest score is simply the sum of the item scores for that cluster.

The VARCLUS algorithm is both divisive and iterative. By default, the VARCLUS procedure begins with all variables in a single cluster. It then repeats the following steps:

1. A cluster is chosen for splitting. Depending on the options specified, the selected cluster has either the smallest percentage of variation explained by its cluster component (using the PROPORTION= option) or the largest eigenvalue associated with the second principal component (using the MAXEIGEN= option).

2. The chosen cluster is split into two clusters by finding the first two principal components, performing an orthoblique rotation (raw quartimax rotation on the eigenvectors; Harris and Kaiser 1964), and assigning each variable to the rotated component with which it has the higher squared correlation.

3. Variables are iteratively reassigned to clusters to try to maximize the variance accounted for by the cluster components. You can require the reassignment algorithms to maintain a hierarchical structure for the clusters.

The procedure stops splitting when either of the following conditions holds:

- The number of clusters is greater than or equal to the maximum number of clusters as specified by the MAXCLUSTERS= option is reached.
- Every cluster satisfies the stopping criteria specified by the PROPORTION= (percentage of variation explained) and/or the MAXEIGEN= (second eigenvalue) options.

By default, VARCLUS stops splitting when every cluster has only one eigenvalue greater than one, thus satisfying the most popular criterion for determining the sufficiency of a single underlying dimension.

The iterative reassignment of variables to clusters proceeds in two phases. The first is a nearest component sorting (NCS) phase, similar in principle to the nearest centroid sorting algorithms described by Anderberg (1973). In each iteration, the cluster components are computed, and each variable is assigned to the component with which it has the highest squared correlation. The second phase involves a search algorithm in which each variable is tested to see if assigning it to a different cluster increases the amount of variance explained. If a variable is reassigned during the search phase, the components of the two clusters involved are recomputed before the next variable is tested. The NCS phase is much faster than the search phase but is more likely to be trapped by a local optimum.

If principal components are used, the NCS phase is an alternating least-squares method and converges rapidly. The search phase can be very time-consuming for a large number of variables. But if the default initialization method is used, the search phase is rarely able to substantially improve the results of the NCS phase, so the search takes few iterations. If random initialization is used, the NCS phase might be trapped by a local optimum from which the search phase can escape.

If centroid components are used, the NCS phase is not an alternating least-squares method and might not increase the amount of variance explained; therefore it is limited, by default, to one iteration.

You can have VARCLUS do the clustering hierarchically by restricting the reassignment of variables such that the clusters maintain a tree structure. In this case, when a cluster is split, a variable in one of the two resulting clusters can be reassigned to the other cluster resulting from the split but not to a cluster that is not part of the original cluster (the one that is split).

Getting Started: VARCLUS Procedure

This example demonstrates how you can cluster variables using the VARCLUS procedure.

The following data are job ratings of police officers. The officers were rated by their supervisors on 13 job skills on a scale from 1 to 9. There is also an overall rating that is not used in this analysis. The following DATA step creates the SAS data set JobRat:

```
data JobRat;
   input
      (Communication_Skills
       Problem_Solving
       Learning_Ability
       Judgement_under_Pressure
       Observational_Skills
       Willingness_to_Confront_Problems
       Interest_in_People
       Interpersonal_Sensitivity
       Desire_for_Self_Improvement
       Appearance
       Dependability
       Physical_Ability
       Integrity
       Overall_Rating)
      (1.);
datalines;
26838853879867
74758876857667
56757863775875
67869777988997

... more lines ...

99997899799799
99899899899899
76656399567486
;
```

The following statements cluster the variables:

```
proc varclus data=JobRat maxclusters=3;
   var Communication_Skills--Integrity;
run;
```

The DATA= option specifies the SAS data set JobRat as input.

The MAXCLUSTERS=3 option specifies that no more than three clusters be computed. By default, PROC VARCLUS splits and optimizes clusters until all clusters have a second eigenvalue less than one. In this example, the default setting would produce only two clusters, but going to three clusters produces a more interesting result.

The VAR statement lists the numeric variables (Communication_Skills–Integrity) to be used in the analysis. The overall rating is omitted from the list of variables.

Although the VARCLUS procedure displays output for one cluster, two clusters, and three clusters, the following figures display only the final analysis for three clusters.

For each cluster, Figure 93.1 displays the number of variables in the cluster, the cluster variation, the total explained variation, and the proportion of the total variance explained by the variables in the cluster. The variance explained by the variables in a cluster is similar to the variance explained

by a factor in common factor analysis, but it includes contributions only from the variables in the cluster rather than from all variables.

The line labeled "Total variation explained" in Figure 93.1 gives the sum of the explained variation over all clusters. The final "Proportion" represents the total explained variation divided by the sum of cluster variation. This value, 0.6715, indicates that about 67% of the total variation in the data can be accounted for by the three cluster components.

Figure 93.1 Cluster Summary for Three Clusters from the VARCLUS Procedure

Oblique Principal Component Cluster Analysis

Cluster Summary for 3 Clusters

Cluster	Members	Cluster Variation	Variation Explained	Proportion Explained	Second Eigenvalue
1	6	6	3.771349	0.6286	0.7093
2	5	5	3.575933	0.7152	0.5035
3	2	2	1.382005	0.6910	0.6180

Total variation explained = 8.729286 Proportion = 0.6715

Figure 93.2 shows how the variables are clustered. Figure 93.2 also displays the R-square value of each variable with its own cluster and the R-square value with its nearest cluster. The R-square value for a variable with the nearest cluster should be low if the clusters are well separated. The last column displays the ratio of $(1 - R^2_{own})/(1 - R^2_{nearest})$ for each variable. Small values of this ratio indicate good clustering.

Figure 93.2 R-Square Values from the VARCLUS Procedure

3 Clusters		R-squared with		
Cluster	Variable	Own Cluster	Next Closest	1-R**2 Ratio
Cluster 1	Communication_Skills	0.6403	0.3599	0.5620
	Problem_Solving	0.5412	0.2895	0.6458

Figure 93.3 displays the standardized scoring coefficients that are used to compute the first principal component of each cluster. Since each variable is assigned to one and only one cluster, each row of the scoring coefficients contains only one nonzero value.

Figure 93.3 Standardized Scoring Coefficients from the VARCLUS Procedure

Standardized Scoring Coefficients

Inter-Cluster Correlations

Cluster	1	2	3
1	1.00000	0.60851	0.59223
2	0.60851	1.00000	0.48711
3	0.59223	0.48711	1.00000

The VARCLUS procedure next displays the summary table of statistics for the cluster history (Figure 93.5). The first three columns give the number of clusters, the total variation explained by clusters, and the proportion of variation explained by clusters, respectively.

As displayed in the first row of Figure 93.5, the variation explained by the first principal component of all the variables is 6.547402, and the proportion of variation explained is 0.5036.

When the number of clusters is two, the total variation explained is 7.967753, and the proportion of variation explained by the two clusters is 0.6129. The larger second eigenvalue of the clusters is 0.937902, so by default, the VARCLUS procedure would stop splitting clusters at this point. But because the MAXCLUSTERS=3 option was specified in this example, the VARCLUS procedure continues to the three-cluster solution.

When the number of clusters increases to three, the total variation explained is 8.729286, and the proportion of variation explained by the two clusters is 0.6715. The largest second eigenvalue of the clusters is 0.709323. The statistical improvement from increasing the number of clusters from two to three seems modest, but the interpretabilty of the three clusters argues for the three-cluster solution.

Figure 93.5 also displays the minimum proportion of variance explained by a cluster, the minimum R square for a variable, and the maximum $(1 - R^2)$ ratio for a variable. The last quantity is the maximum ratio of the value $1 - R^2$ for a variable's own cluster to the value $1 - R^2$ for its nearest cluster.

Figure 93.5 Final Cluster Summary Table from the VARCLUS Procedure

Number of Clusters	Total Variation Explained by Clusters	Proportion of Variation Explained by Clusters	Minimum Proportion Explained by a Cluster	Maximum Second Eigenvalue in a Cluster	Minimum R-squared for a Variable	Maximum 1-R**2 Ratio for a Variable
1	6.547402	0.5036	0.5036	1.772715	0.2995	
2	7.967753	0.6129	0.5475	0.937902	0.3123	0.8026
3	8.729286	0.6715	0.6286	0.709323	0.5412	0.6875

Syntax: VARCLUS Procedure

The following statements are available in PROC VARCLUS:

PROC VARCLUS < *options* > **;**
VAR *variables* **;**
SEED *variables* **;**
PARTIAL *variables* **;**
WEIGHT *variables* **;**
FREQ *variables* **;**
BY *variables* **;**

Usually you need only the VAR statement in addition to the PROC VARCLUS statement. The following sections give detailed syntax information about each of the statements, beginning with the PROC VARCLUS statement. The remaining statements are listed in alphabetical order.

PROC VARCLUS Statement

PROC VARCLUS < *options* > **;**

The PROC VARCLUS statement starts the VARCLUS procedure. By default, VARCLUS clusters the numeric variables in the most recently created SAS data set, starting with one cluster and splitting clusters until all clusters have at most one eigenvalue greater than one.

VARCLUS chooses a cluster to split based on two options: MAXEIGEN= and PROPORTION=.

1. If you specify *either* or *both* of these two options, then *only* the specified options affect the choice of the cluster to split.
2. If you specify *neither* of these options, the criterion for choice of cluster to split depends on the CENTROID option:
   a) If you specify CENTROID, VARCLUS splits the cluster with the smallest percentage of variation explained by its cluster component, as if you had specified the PROPORTION= option.
   b) If you do not specify CENTROID, VARCLUS splits the cluster with the largest eigenvalue associated with the second principal component, as if you had specified the MAXEIGEN= option.

The final number of clusters is controlled by three options: MAXCLUSTERS=, MAXEIGEN=, and PROPORTION=.

1. If you specify *any* of these three options, then *only* the options you specify affect the final number of clusters.
2. If you specify *none* of these options, VARCLUS continues to split clusters until the default splitting criterion is satisfied. The default splitting criterion depends on the CENTROID option:

a) If you specify CENTROID, the default splitting criterion is PROPORTION=0.75.

b) If you do not specify CENTROID, splitting is based on the MAXEIGEN= criterion, with a default depending on the COVARIANCE option:

   i. For analyzing a correlation matrix (no COVARIANCE option), the default value for MAXEIGEN= is one.

   ii. For analyzing a covariance matrix (using the COVARIANCE option), the default value for MAXEIGEN= is the average variance of the variables being clustered.

VARCLUS continues to split clusters until any of the following conditions holds:

- The number of cluster equals the value specified for MAXCLUSTERS=.
- No cluster qualifies for splitting according to the MAXEIGEN= or PROPORTION= criterion.
- A cluster was chosen for splitting, but after iteratively reassigning variables to clusters, one of the cluster has no members.

Table 93.1 summarizes the options available in the PROC VARCLUS statement.

Table 93.1 Options Available in the PROC VARCLUS Statement

Option	Description
Data Sets	
DATA=	specifies the input SAS data set
OUTSTAT=	specifies the output SAS data set containing statistics
OUTTREE=	specifies the output SAS data set for use with PROC TREE
Input Data Processing	
COVARIANCE	uses the covariance matrix instead of the correlation matrix
NOINT	omits intercept
VARDEF=	specifies the divisor for variances
Number of Clusters	
MAXCLUSTERS=	specifies the maximum number of clusters
MINCLUSTERS=	specifies the minimum number of clusters
MAXEIGEN=	specifies the maximum second eigenvalue in a cluster
PROPORTION=	specifies the minimum proportion of variance explained by a cluster component
Clustering Methods	
CENTROID	uses centroid components instead of principal components
HIERARCHY	clusters hierarchically
INITIAL=	specifies the initialization method
MAXITER=	specifies the maximum iterations during the alternating least-squares phase
MAXSEARCH=	specifies the maximum iterations during the search phase
MULTIPLEGROUP	performs a multiple group component analysis
RANDOM=	specifies the random number seed
Control Displayed Output	
CORR	displays the correlation matrix
NOPRINT	suppresses displayed output

Table 93.1 *continued*

Option	Description
SHORT	suppresses display of large matrices
SIMPLE	displays means and standard deviations
SUMMARY	suppresses all default displayed output except the final summary table
TRACE	displays the cluster to which each variable is assigned during the iterations

The following list gives details on these options. The list is in alphabetical order.

CENTROID

uses centroid components rather than principal components. You should specify centroid components if you want the cluster components to be unweighted averages of the standardized variables (the default) or the unstandardized variables (if you specify the COVARIANCE option). It is possible to obtain locally optimal clusterings in which a variable is not assigned to the cluster component with which it has the highest squared correlation. You cannot specify both the CENTROID and MAXEIGEN= options.

CORR

C

displays the correlation matrix.

COVARIANCE

COV

analyzes the covariance matrix instead of the correlation matrix. The COVARIANCE option causes variables with a large variance to have more effect on the cluster components than variables with a small variance.

DATA=*SAS-data-set*

specifies the input data set to be analyzed. The data set can be an ordinary SAS data set or TYPE=CORR, UCORR, COV, UCOV, FACTOR, or SSCP. If you do not specify the DATA= option, the most recently created SAS data set is used. See Appendix A, "Special SAS Data Sets," for more information about types of SAS data sets.

HIERARCHY

HI

requires the clusters at different levels to maintain a hierarchical structure. To draw a tree diagram, use the OUTTREE= option and the TREE procedure.

INITIAL=GROUP

INITIAL=INPUT

INITIAL=RANDOM

INITIAL=SEED

specifies the method for initializing the clusters. If the INITIAL= option is omitted and the MINCLUSTERS= option is greater than 1, the initial cluster components are obtained by extracting the required number of principal components and performing an orthoblique rotation (raw quartimax rotation on the eigenvectors; Harris and Kaiser 1964). The following list describes the values for the INITIAL= option:

GROUP obtains the cluster membership of each variable from an observation in the DATA= data set where the _TYPE_ variable has a value of "GROUP". In this observation, the variables to be clustered must each have an integer value ranging from one to the number of clusters. You can use this option only if the DATA= data set is a TYPE=CORR, UCORR, COV, UCOV, or FACTOR data set. You can use a data set created either by a previous run of PROC VARCLUS or in a DATA step.

INPUT obtains scoring coefficients for the cluster components from observations in the DATA= data set where the _TYPE_ variable has a value of "SCORE". You can use this option only if the DATA= data set is a TYPE=CORR, UCORR, COV, UCOV, or FACTOR data set, You can use scoring coefficients from the FACTOR procedure or a previous run of the VARCLUS procedure, or you can enter other coefficients in a DATA step.

RANDOM assigns variables randomly to clusters.

SEED initializes each cluster component to be one of the variables named in the SEED statement. Each variable listed in the SEED statement becomes the sole member of a cluster, and the other variables are initially unassigned. If you do not specify the SEED statement, the first MINCLUSTERS= variables in the VAR statement are used as seeds.

MAXCLUSTERS=*n*

MAXC=*n*

specifies the largest number of clusters desired. The default value is the number of variables. VARCLUS stops splitting clusters after the number of clusters reaches the value of the MAXCLUSTERS= option, regardless of what other splitting options are specified.

MAXEIGEN=*n*

specifies that when choosing a cluster to split, VARCLUS should choose the cluster with the largest second eigenvalue, provided that its second eigenvalue is greater than the MAXEIGEN= value. The MAXEIGEN= option cannot be used with the CENTROID or MULTIPLEGROUP options.

If you do not specify MAXEIGEN=, the default behavior depends on other options as follows:

- If you specify PROPORTION=, CENTROID, or MULTIPLEGROUP, cluster splitting does not depend on the second eigenvalue.
- Otherwise, if you specify MAXCLUSTERS=, the default value for MAXEIGEN= is zero.
- Otherwise, the default value for MAXEIGEN= is either 1.0 if the correlation matrix is analyzed, or the average variance if the COVARIANCE option is specified.

If you specify both MAXEIGEN= and MAXCLUSTERS=, the number of clusters will never exceed the value of the MAXCLUSTERS= option.

If you specify both MAXEIGEN= and PROPORTION=, VARCLUS first looks for a cluster to split based on the MAXEIGEN= criterion. If no cluster meets that criterion, VARCLUS then looks for a cluster to split based on the PROPORTION= criterion.

MAXITER=*n*

specifies the maximum number of iterations during the NCS phase. The default value is 1 if you specify the CENTROID option; the default is 10 otherwise.

MAXSEARCH=*n*

specifies the maximum number of iterations during the search phase. The default is 1000 divide by the number of variables.

MINCLUSTERS=*n*

MINC=*n*

specifies the smallest number of clusters desired. The default value is 2 for INITIAL=RANDOM or INITIAL=SEED; otherwise, VARCLUS begins with one cluster and tries to split it in accordance with the PROPORTION= and/or MAXEIGEN= options.

MULTIPLEGROUP

MG

performs a multiple group component analysis (Harman 1976). You specify which variables belong to which clusters. No clusters are split, and no variables are reassigned to a different cluster. The input data set must be TYPE=CORR, UCORR, COV, UCOV, FACTOR, or SSCP and must contain an observation with _TYPE_="GROUP" defining the variable groups. Specifying the MULTIPLEGROUP option is equivalent to specifying all of the following options: INITIAL=GROUP, MINC=1, MAXITER=0, MAXSEARCH=0, PROPORTION=0, and MAXEIGEN=large number.

NOINT

requests that no intercept be used; covariances or correlations are not corrected for the mean. If you specify the NOINT option, the OUTSTAT= data set is TYPE=UCORR.

NOPRINT

suppresses displayed output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 20, "Using the Output Delivery System."

OUTSTAT=*SAS-data-set*

creates an output data set to contain statistics including means, standard deviations, correlations, cluster scoring coefficients, and the cluster structure. If you want to create a permanent SAS data set, you must specify a two-level name. The OUTSTAT= data set is TYPE=UCORR if the NOINT option is specified. For more information about permanent SAS data sets, see "SAS Files" and "DATA Step Concepts" in *SAS Language Reference: Concepts*. For information about types of SAS data sets, see Appendix A, "Special SAS Data Sets."

OUTTREE=*SAS-data-set*

creates an output data set to contain information on the tree structure that can be used by the TREE procedure to display a tree diagram. The OUTTREE= option implies the HIERARCHY option. See Example 93.1 for use of the OUTTREE= option. If you want to create a permanent SAS data set, you must specify a two-level name. For more information on permanent SAS data sets, see "SAS Files" and "DATA Step Concepts" in *SAS Language Reference: Concepts*.

PROPORTION=*n*

PERCENT=*n*

specifies that when choosing a cluster to split, VARCLUS should choose the cluster with the smallest proportion of variation explained, provided that its proportion of variation explained is less than the PROPORTION= value. Values greater than 1.0 are considered to be percentages, so PROPORTION=0.75 and PERCENT=75 are equivalent.

However, if you specify both MAXEIGEN= and PROPORTION=, VARCLUS first looks for a cluster to split based on the MAXEIGEN= criterion. If no cluster meets that criterion, VARCLUS then looks for a cluster to split based on the PROPORTION= criterion.

If you do not specify PROPORTION=, the default behavior depends on other options as follows:

- If you specify MAXEIGEN=, cluster splitting does not depend on the proportion of variation explained.
- Otherwise, if you specify CENTROID and MAXCLUSTERS=, the default value for PROPORTION= is one.
- Otherwise, if you specify CENTROID, without MAXCLUSTERS=, the default value is PROPORTION=0.75 or PERCENT=75.
- Otherwise, cluster splitting does not depend on the proportion of variation explained.

If you specify both PROPORTION= and MAXCLUSTERS=, the number of clusters will never exceed the value of the MAXCLUSTERS= option.

RANDOM=*n*

specifies a positive integer as a starting value for use with REPLACE=RANDOM. If you do not specify the RANDOM= option, the time of day is used to initialize the pseudo-random number sequence.

SHORT

suppresses display of the cluster structure, scoring coefficient, and intercluster correlation matrices.

SIMPLE

S

displays means and standard deviations.

SUMMARY

suppresses all default displayed output except the final summary table.

TRACE

displays the cluster to which each variable is assigned during the iterations.

VARDEF=DF

VARDEF=N

VARDEF=WDF

VARDEF=WEIGHT | WGT

specifies the divisor to be used in the calculation of variances and covariances. The default value is VARDEF=DF. The values and associated divisors are displayed in the following table.

Value	Divisor	Formula
DF	degrees of freedom	$n - i$
N	number of observations	n
WDF	sum of weights minus one	$(\sum_j w_j) - 1$
WEIGHT | WGT	sum of weights	$\sum_j w_j$

In the preceding table, $i = 0$ if the NOINT option is specified, and $i = 1$ otherwise.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC VARCLUS to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for PROC VARCLUS. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

FREQ Statement

FREQ *variable* **;**

If a variable in your data set represents the frequency of occurrence for the other values in the observation, include the variable's name in a FREQ statement. The procedure then treats the data set

as if each observation appears *n* times, where *n* is the value of the FREQ variable for the observation. If the value of the FREQ variable is less than 1, the observation is not used in the analysis. Only the integer portion of the value is used. The total number of observations is considered equal to the sum of the FREQ variable.

PARTIAL Statement

PARTIAL *variable* **;**

If you want to base the clustering on partial correlations, list the variables to be partialed out in the PARTIAL statement.

SEED Statement

SEED *variables* **;**

The SEED statement specifies variables to be used as seeds to initialize the clusters. It is not necessary to use INITIAL=SEED if the SEED statement is present, but if any other INITIAL= option is specified, the SEED statement is ignored.

VAR Statement

VAR *variables* **;**

The VAR statement specifies the variables to be clustered. If you do not specify the VAR statement and do not specify TYPE=SSCP, all numeric variables not listed in other statements (except the SEED statement) are processed. The default VAR variable list does not include the variable INTERCEPT if the DATA= data set is TYPE=SSCP. If the variable INTERCEPT is explicitly specified in the VAR statement with a TYPE=SSCP data set, the NOINT option is enabled.

WEIGHT Statement

WEIGHT *variables* **;**

If you want to specify relative weights for each observation in the input data set, place the weights in a variable in the data set and specify the name in a WEIGHT statement. This is often done when the variance associated with each observation is different and the values of the weight variable are proportional to the reciprocals of the variances. The WEIGHT variable can take nonintegral values. An observation is used in the analysis only if the value of the WEIGHT variable is greater than zero.

Details: VARCLUS Procedure

Missing Values

Observations containing missing values are omitted from the analysis.

Using the VARCLUS procedure

Default options for the VARCLUS procedure often provide satisfactory results. If you want to change the final number of clusters, use one or more of the MAXCLUSTERS=, MAXEIGEN=, or PROPORTION= options. The MAXEIGEN= and PROPORTION= options usually produce similar results but occasionally cause different clusters to be selected for splitting. The MAXEIGEN= option tends to choose clusters with a large number of variables, while the PROPORTION= option is more likely to select a cluster with a small number of variables.

Execution time

The VARCLUS procedure usually requires more computer time than principal factor analysis, but it can be faster than some of the iterative factoring methods. If you have more than 30 variables, you might want to reduce execution time by one or more of the following methods:

- Specify the MINCLUSTERS= and MAXCLUSTERS= options if you know how many clusters you want.
- Specify the HIERARCHY option.
- Specify the SEED statement if you have some prior knowledge of what clusters to expect.

If computer time is not a limiting factor, you might want to try one of the following methods to obtain a better solution:

- If the clustering algorithm has not converged, specify larger values for MAXITER= and MAXSEARCH=.
- Try several factoring and rotation methods with PROC FACTOR to use as input to PROC VARCLUS.
- Run PROC VARCLUS several times, specifying INITIAL=RANDOM.

Output Data Sets

OUTSTAT= Data Set

The OUTSTAT= data set is TYPE=CORR, and it can be used as input to the SCORE procedure or a subsequent run of PROC VARCLUS. The OUSTAT= data set contains the following variables:

- BY variables
- _NCL_, a numeric variable giving the number of clusters
- _TYPE_, a character variable indicating the type of statistic the observation contains
- _NAME_, a character variable containing a variable name or a cluster name, which is of the form CLUS*n*, where *n* is the number of the cluster
- the variables that are clustered

The values of the _TYPE_ variable are listed in the following table.

Table 93.2 _TYPE_

TYPE	**Contents**
MEAN	means
STD	standard deviations
USTD	uncorrected standard deviations, produced when the NOINT option is specified
N	number of observations
CORR	correlations
UCORR	uncorrected correlation matrix, produced when the NOINT option is specified
MEMBERS	number of members in each cluster
VAREXP	variance explained by each cluster
PROPOR	proportion of variance explained by each cluster
GROUP	number of the cluster to which each variable belongs
RSQUARED	squared multiple correlation of each variable with its cluster component
SCORE	standardized scoring coefficients
USCORE	scoring coefficients to be applied without subtracting the mean from the raw variables, produced when the NOINT option is specified
STRUCTUR	cluster structure
CCORR	correlations between cluster components

The observations with _TYPE_="MEAN", "STD", "N", and "CORR" have missing values for the _NCL_ variable. All other values of the _TYPE_ variable are repeated for each cluster solution, with different solutions distinguished by the value of the _NCL_ variable. If you want to specify the OUTSTAT= data set with the SCORE procedure, you can use a DATA step to select observations with the _NCL_ variable missing or equal to the desired number of clusters as follows:

```
data Coef2;
   set Coef;
   if _ncl_ = . or _ncl_ = 3;
   drop _ncl_;
run;

proc score data=NewScore score=Coef2; run;
```

PROC SCORE standardizes the new data by subtracting the original variable means that are stored in the _TYPE_='MEAN' observations, and dividing by the original variable standard deviations from the _TYPE_='STD' observations. Then PROC SCORE multiplies the standardized variables by the coefficients from the _TYPE_='SCORE' observations to get the cluster scores.

OUTTREE= Data Set

The OUTTREE= data set contains one observation for each variable clustered plus one observation for each cluster of two or more variables—that is, one observation for each node of the cluster tree. The total number of output observations is between n and $2n-1$, where n is the number of variables clustered.

The OUTTREE= data set contains the following variables:

- BY variables, if any
- _NAME_, a character variable giving the name of the node. If the node is a cluster, the name is CLUSn, where n is the number of the cluster. If the node is a single variable, the variable name is used.
- _PARENT_, a character variable giving the value of _NAME_ of the parent of the node. If the node is the root of the tree, _PARENT_ is blank.
- _LABEL_, a character variable giving the label of the node. If the node is a cluster, the label is CLUSn, where n is the number of the cluster. If the node is a single variable, the variable label is used.
- _NCL_, the number of clusters
- _VAREXP_, the total variance explained by the clusters at the current level of the tree
- _PROPOR_, the total proportion of variance explained by the clusters at the current level of the tree
- _MINPRO_, the minimum proportion of variance explained by a cluster component
- _MAXEIG_, the maximum second eigenvalue of a cluster

Computational Resources

Let

n = number of observations
v = number of variables
c = number of clusters

It is assumed that, at each stage of clustering, the clusters all contain the same number of variables.

Time

The time required for the VARCLUS procedure to analyze a given data set varies greatly depending on the number of clusters requested, the number of iterations in both the alternating least-squares and search phases, and whether centroid or principal components are used.

The time required to compute the correlation matrix is roughly proportional to nv^2.

Default cluster initialization requires time roughly proportional to v^3. Any other method of initialization requires time roughly proportional to cv^2.

In the alternating least-squares phase, each iteration requires time roughly proportional to cv^2 if centroid components are used or

$$\left(c + 5\frac{v}{c^2}\right) v^2$$

if principal components are used.

In the search phase, each iteration requires time roughly proportional to v^3/c if centroid components are used or v^4/c^2 if principal components are used. The HIERARCHY option speeds up each iteration after the first split by as much as $c/2$.

Memory

The amount of memory, in bytes, needed by the VARCLUS procedure is approximately

$$v^2 + 2vc + 20v + 15c$$

Interpreting VARCLUS Procedure Output

Because the VARCLUS algorithm is a type of oblique component analysis, its output is similar to the output from the FACTOR procedure for oblique rotations. The scoring coefficients have the same meaning in both PROC VARCLUS and PROC FACTOR; they are coefficients applied

to the standardized variables to compute component scores. The cluster structure is analogous to the factor structure containing the correlations between each variable and each cluster component. A cluster pattern is not displayed because it would be the same as the cluster structure, except that zeros would appear in the same places in which zeros appear in the scoring coefficients. The intercluster correlations are analogous to interfactor correlations; they are the correlations among cluster components.

The VARCLUS procedure also displays a cluster summary and a cluster listing. The cluster summary gives the number of variables in each cluster and the variation explained by the cluster component. The latter is similar to the variation explained by a factor but includes contributions from only the variables in that cluster rather than from all variables, as in PROC FACTOR. The proportion of variance explained is obtained by dividing the variance explained by the total variance of variables in the cluster. If the cluster contains two or more variables and the CENTROID option is not used, the second largest eigenvalue of the cluster is also displayed.

The cluster listing gives the variables in each cluster. Two squared correlations are calculated for each cluster. The column labeled "Own Cluster" gives the squared correlation of the variable with its own cluster component. This value should be higher than the squared correlation with any other cluster unless an iteration limit has been exceeded or the CENTROID option has been used. The larger the squared correlation is, the better. The column labeled "Next Closest" contains the next-highest squared correlation of the variable with a cluster component. This value is low if the clusters are well separated. The column labeled "1–R**2 Ratio" gives the ratio of one minus the "Own Cluster" R square to one minus the "Next Closest" R square. A small "1–R**2 Ratio" indicates a good clustering.

Displayed Output

The following items are displayed for each cluster solution unless the NOPRINT or SUMMARY option is specified. The CLUSTER SUMMARY table includes the following columns:

- the Cluster number
- Members, the number of members in the cluster
- Cluster Variation of the variables in the cluster
- Variation Explained by the cluster component. This statistic is based only on the variables in the cluster rather than on all variables.
- Proportion Explained, the result of dividing the variation explained by the cluster variation
- Second Eigenvalue, the second largest eigenvalue of the cluster. This is displayed if the cluster contains more than one variable and the CENTROID option is not specified

The VARCLUS procedure also displays the following:

- Total variation explained, the sum across clusters of the variation explained by each cluster

- Proportion, the total explained variation divided by the total variation of all the variables

The cluster listing includes the following columns:

- Variable, the variables in each cluster
- R square with Own Cluster, the squared correlation of the variable with its own cluster component; and R square with Next Closest, the next highest squared correlation of the variable with a cluster component. Own Cluster values should be higher than the R square with any other cluster unless an iteration limit is exceeded or you specify the CENTROID option. Next Closest should be a low value if the clusters are well separated.
- 1−R**2 Ratio, the ratio of one minus the value in the Own Cluster column to one minus the value in the Next Closest column. The occurrence of low ratios indicates well-separated clusters.

If the SHORT option is not specified, the VARCLUS procedure also displays the following tables:

- Standardized Scoring Coefficients, standardized regression coefficients for predicting cluster components from variables
- Cluster Structure, the correlations between each variable and each cluster component
- Inter-Cluster Correlations, the correlations between the cluster components

If the analysis includes partitions for two or more numbers of clusters, a final summary table is displayed. Each row of the table corresponds to one partition. The columns include the following:

- Number of Clusters
- Total Variation Explained by Clusters
- Proportion of Variation Explained by Clusters
- Minimum Proportion (of variation) Explained by a Cluster
- Maximum Second Eigenvalue in a Cluster
- Minimum R square for a Variable
- Maximum 1−R**2 Ratio for a Variable

ODS Table Names

The VARCLUS procedure assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These ODS table names are listed in Table 93.3. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 93.3 ODS Tables Produced by the VARCLUS procedure

ODS Table Name	Description	Option
ClusterQuality	Cluster quality	default
ClusterStructure	Cluster structure	default
ClusterSummary	Cluster summary	default
ConvergenceStatus	Convergence status	default
Corr	Correlations between variables	CORR
DataOptSummary	Data and options summary table	default
InterClusterCorr	Correlations between cluster components	default
IterHistory	Iteration history	TRACE
RSquare	R-squares between variables and clusters	default
SimpleStatistics	Means and standard deviations	SIMPLE
StdScoreCoef	Standardized scoring coefficients	default

Example: VARCLUS Procedure

Example 93.1: Correlations among Physical Variables

The data in this example are correlations among eight physical variables as given by Harman (1976). The first PROC VARCLUS run clusters on the basis of principal components. The second run clusters on the basis of centroid components. The third analysis is hierarchical, and the TREE procedure is used to display a tree diagram. The following statements create the data set and perform the analysis:

```
data phys8(type=corr);
   title 'Eight Physical Measurements on 305 School Girls';
   title2 'Harman: Modern Factor Analysis, 3rd Ed, p22';
   label ArmSpan='Arm Span'              Forearm='Length of Forearm'
         LowerLeg='Length of Lower Leg' BitDiam='Bitrochanteric Diameter'
         Girth='Chest Girth'            Width='Chest Width';
   input _Name_ $ 1-8
         (Height ArmSpan Forearm LowerLeg Weight BitDiam
          Girth Width)(7.);
   _Type_='corr';
   datalines;
Height     1.0    .846   .805   .859   .473   .398   .301   .382
ArmSpan    .846   1.0    .881   .826   .376   .326   .277   .415
Forearm    .805   .881   1.0    .801   .380   .319   .237   .345
LowerLeg   .859   .826   .801   1.0    .436   .329   .327   .365
Weight     .473   .376   .380   .436   1.0    .762   .730   .629
BitDiam    .398   .326   .319   .329   .762   1.0    .583   .577
Girth      .301   .277   .237   .327   .730   .583   1.0    .539
Width      .382   .415   .345   .365   .629   .577   .539   1.0
;

proc varclus data=phys8;
run;
```

The PROC VARCLUS statement invokes the procedure. By default, the VARCLUS procedure clusters using principal components.

As displayed in Output 93.1.1, when there is only one cluster, the cluster component (by default, the first principal component) explains 58.41% of the total variation of the eight variables.

The cluster is split because the second eigenvalue is greater than 1 (the default value of the MAXEIGEN option).

The two resulting cluster components explain 80.33% of the variation in the original variables. The cluster summary table shows that the variables Height, ArmSpan, Forearm, and LowerLeg have been assigned to the first cluster, and that the variables Weight, BitDiam, Girth, and Width have been assigned to the second cluster.

The standardized scoring coefficients in Output 93.1.1 show that each cluster component has similar scores for each of its associated variables. This suggests that the principal cluster component solution should be similar to the centroid cluster component solution, which follows in the next PROC VARCLUS run.

The cluster structure table displays high correlations between the variables and their own cluster component. The correlations between the variables and the opposite cluster component are all moderate.

The intercluster correlation table shows that the two cluster components have a moderate correlation of 0.44513.

Output 93.1.1 Principal Component Clusters

```

In the following statements, the CENTROID option in the PROC VARCLUS statement specifies that cluster centroids be used as the basis for clustering:

```
proc varclus data=phys8 centroid;
run;
```

The first cluster component, which, in the centroid method, is an unweighted sum of the standardized variables, explains 57.89% of the variation in the data. This value is near the maximum possible variance explained, 58.41%, which is attained by the first principal component shown previously in Output 93.1.1.

The default behavior in the centroid method is to split any cluster with less than 75% of the total cluster variance explained by the centroid component. Since the centroid component for the one-cluster solution explains only 57.89% of the variation as shown in Output 93.1.2, the variables are split into two clusters. The resulting clusters are the same two clusters created by the principal component method. Recall that this outcome was suggested by the similar standardized scoring coefficients in the principal cluster component solution.

In the two-cluster solution, the centroid component of the second cluster explains only 72.75% of the total variation of the cluster. Since this percentage is less than 75%, the second cluster is split.

In the R-square table for two clusters, the Width variable has a weaker relation to its cluster than any other variable. In the three-cluster solution this variable is in a cluster of its own.

Each cluster component is an unweighted average of the cluster's standardized variables. Thus, the coefficients for each of the cluster's associated variables are identical in the centroid cluster component solution.

The centroid method stops at the three-cluster solution. The three centroid components account for 86.15% of the variability in the eight variables, and all cluster components account for at least 79.44% of the total variation in the corresponding cluster. Additionally, the smallest squared corre-

lation between the variables and their own cluster component is 0.7482.

Note that if the PROPORTION= option were set to a value between 0.5789 (the proportion of variance explained in the one-cluster solution) and 0.7275 (the minimum proportion of variance explained in the two-cluster solution), the VARCLUS procedure would stop at the two-cluster solution, and the centroid solution would find the same clusters as the principal components solution, although the cluster components would be slightly different.

Output 93.1.2 Centroid Component Clusters

In the following statements, the MAXC= option computes all clustering solutions, from one to eight clusters. The SUMMARY option suppresses all output except the final cluster quality table, and the OUTTREE= option saves the results of the analysis to an output data set and forces the clusters to be hierarchical. The TREE procedure is invoked to produce a graphical display of the clusters as follows:

```
proc varclus data=phys8 maxc=8 summary outtree=tree;
run;

title  h=10pct 'Eight Physical Measurements on 305 School Girls';
title2 h=5pct 'Harman: Modern Factor Analysis, 3rd Ed, p22';
goptions htext=4pct ftext="Albany AMT";
axis1 order=(0.5 to 1 by 0.1);
axis2 label=none;
proc tree horizontal haxis=axis1 vaxis=axis2;
   height _propor_;
   id _label_;
run;
```

The results from PROC VARCLUS are shown in Output 93.1.3.

1	4.672880	0.5841	0.5841	1.770983	0.3810	
2	6.426502	0.8033	0.7293	0.476418	0.6329	0.4380
3	6.895347	0.8619	0.7954	0.418369	0.7421	0.3634
4	7.271218	0.9089	0.8773	0.238000	0.8652	0.2548
5	7.509218	0.9387	0.8773	0.236135	0.8652	0.1665
6	7.740000	0.9675	0.9295	0.141000	0.9295	0.2560
7	7.881000	0.9851	0.9405	0.119000	0.9405	0.2093
8	8.000000	1.0000	1.0000	0.000000	1.0000	0.0000

The principal component method first separates the variables into the same two clusters that were created in the first PROC VARCLUS run. Note that, in creating the third cluster, the principal component method identifies the variable Width. This is the same variable that is put into its own cluster in the preceding centroid method example. The tree diagram in Output 93.1.4 displays the cluster hierarchy.

Output 93.1.4 Tree Diagram from PROC TREE

It appears from the diagram that there are two, or possibly three, clusters present. However, the MAXC=8 option forces the VARCLUS procedure to split the clusters until each variable is in its own cluster.

Overview: VARCOMP Procedure

The VARCOMP procedure handles general linear models that have random effects. Random effects are classification effects with levels that are assumed to be randomly selected from an infinite population of possible levels. PROC VARCOMP estimates the contribution of each of the random effects to the variance of the dependent variable.

A single MODEL statement specifies the dependent variables and the effects: main effects, interactions, and nested effects. The effects must be composed of classification variables; no continuous variables are allowed on the right side of the equal sign.

You can specify certain effects as fixed (nonrandom) by putting them first in the MODEL statement and indicating the number of fixed effects with the FIXED= option. An intercept is always fitted and assumed fixed. Except for the effects specified as fixed, all other effects are assumed to be random. Their contribution to the model can be thought of as an observation from a distribution that is normally and independently distributed.

The dependent variables are grouped based on the similarity of their missing values. Each group of dependent variables is then analyzed separately. The columns of the design matrix $\mathbf{X}$ are formed in the same order in which the effects are specified in the MODEL statement. A singular parameterization involving just 0–1 dummy variables is used, as in the GLM procedure.

You can specify four general methods of estimation in the PROC VARCOMP statement by using the METHOD= option. They are TYPE1 (based on computation of Type I sum of squares for each effect), MIVQUE0, maximum likelihood (METHOD=ML), and restricted maximum likelihood (METHOD=REML). A fifth method, METHOD=GRR, provides a specialized analysis for gauge repeatability and reproducibility (R&R) studies. See the section "Gauge Repeatability and Reproducibility Analysis" on page 7503 for further details. Note that this method, along with the CL option in the MODEL statement for confidence limits, applies only to certain designs, namely balanced one-way or two-way designs. The other four general methods apply to any random-effects model and design.

Other procedures, such as PROC GLM, PROC MIXED, and PROC GLIMMIX, fit similar random effects models. The VARCOMP procedure is usually more computationally efficient for certain special designs and models. See the section "Relationship to PROC MIXED" on page 7508 for a more precise comparison with the MIXED procedure in particular.

The GAUGE application in SAS/QC software provides a graphical interface for computing many of the same statistics as METHOD=GRR in PROC VARCOMP.

Getting Started: VARCOMP Procedure

Analyzing the Cure Rate of Rubber

This example, using data from Hicks (1973), concerns an experiment to determine the sources of variability in cure rates of rubber. The goal of the experiment was to find out if the different laboratories contributed more to the variance of cure rates than did the different batches of raw materials. This information would be useful in trying to control the cure rate of the final product because it would provide insight into the sources of the variability in cure rates. The rubber used was cured at three temperatures, which were taken to be fixed. Three laboratories were chosen at random, and three different batches of raw material were tested at each combination of temperature and laboratory. The following statements read the data into the SAS data set Cure.

```
data Cure;
   input Lab Temp Batch $ Cure @@;

;
```

The variables Lab, Temp, and Batch contain levels of laboratory, temperature, and batch, respectively. The Cure variable contains the response values.

The following SAS statements perform a restricted maximum likelihood variance component analysis.

```
title 'Analyzing the Cure Rate of Rubber';
proc varcomp method=reml data=cure;
   class temp lab batch;
   model cure=temp|lab batch(lab temp) / fixed=1;
run;
```

The FIXED=1 option indicates that the first factor, Temp, is fixed. The effect specification Temp|Lab is equivalent to putting the three terms Temp, Lab, and Temp*Lab in the model. Batch(Lab Temp) is equivalent to putting Batch(Temp*Lab) in the MODEL statement. The results of this analysis are displayed in Figure 94.1 through Figure 94.4.

2	13.0893125570	0.3176048001	0	2.0738906134	0.6026217204
3	13.0893125555	0.3176017115	0	2.0738685461	0.6026234568

Convergence criteria met.

The "REML Iterations" table in Figure 94.2 displays the iteration history, which includes the value of the objective function associated with REML and the values of the variance components at each iteration.

Figure 94.3 REML Estimates

REML Estimates

Variance Component	Estimate
Var(Lab)	0.31760
Var(Temp*Lab)	0
Var(Batch(Temp*Lab))	2.07387
Var(Error)	0.60262

Figure 94.3 displays the REML estimates of the variance components.

Figure 94.4 Covariance Matrix for REML Estimates

Asymptotic Covariance Matrix of Estimates

	Var(Lab)	Var(Temp*Lab)
Var(Lab)	0.32452	0
Var(Temp*Lab)	0	0
Var(Batch(Temp*Lab))	-0.04998	0
Var(Error)	1.026E-12	0

Asymptotic Covariance Matrix of Estimates

	Var(Batch(Temp*Lab))	Var(Error)
Var(Lab)	-0.04998	1.026E-12
Var(Temp*Lab)	0	0
Var(Batch(Temp*Lab))	0.45042	-0.0022417
Var(Error)	-0.0022417	0.0089668

The "Asymptotic Covariance Matrix of Estimates" table in Figure 94.4 displays the asymptotic covariance matrix of the REML estimates.

The results of the analysis show that the variance attributable to Batch(Temp*Lab) (with a variance component of 2.0739) is considerably larger than the variance attributable to Lab (0.3176). Therefore, attempts to reduce the variability of cure rates should concentrate on improving the homogeneity of the batches of raw material used rather than standardizing the practices or equipment within the laboratories. Also, note that since the Batch(Temp*Lab) variance is considerably larger than the experimental error (Var(Error)=0.6026), the Batch(Temp*Lab) variability plays an important part in the overall variability of the cure rates.

Syntax: VARCOMP Procedure

The following statements are available in PROC VARCOMP:

```
PROC VARCOMP < options > ;
   CLASS variables ;
   MODEL dependent = < effects > < / options > ;
   BY variables ;
```

Only one MODEL statement is allowed. The BY, CLASS, and MODEL statements are described after the PROC VARCOMP statement.

PROC VARCOMP Statement

PROC VARCOMP < *options* > **;**

This statement invokes the VARCOMP procedure. You can specify the following options in the PROC VARCOMP statement.

DATA=*SAS-data-set*
specifies the input SAS data set to use. If this option is omitted, the most recently created SAS data set is used.

EPSILON=*number*
specifies the convergence value of the objective function for METHOD=ML or METHOD=REML. By default, EPSILON=1E−8.

MAXITER=*number*
specifies the maximum number of iterations for METHOD=ML or METHOD=REML. By default, MAXITER=50.

METHOD=TYPE1 | MIVQUE0 | ML | REML | GRR < *(options)* >
specifies which of the five methods (TYPE1, MIVQUE0, ML, REML, or GRR) you want to use. By default, METHOD=MIVQUE0. METHOD=GRR provides a specialized analysis only for certain designs, whereas the other four methods apply to any random-effects model and design. You can specify the following options in parentheses after METHOD=GRR.

SPECLIMITS=*(LSL,USL,*< *k*>*)*

SL=*(LSL,USL,*< *k*>*)*
specifies the specification limits for the first random factor, which is regarded as the product being tested in the gauge R&R study. The lower limit *(LSL)* must be smaller than the upper limit *(USL)*. The value *k* is optional. The default value is 6, which corresponds to the number of standard deviations between the "natural" tolerance limits containing the middle 99.73% of a normal process. *SPECLIMITS=(LSL,USL,k)* requests the estimates of the parameters PTR(LSL,USL,k) and Cp(LSL,USL,k) to be displayed.

RATIO
specifies that certain additional ratios of variance components should also be computed and displayed, such as proportion of total variance due to the process. These ratios are listed in Table 94.4.

For more information see the section "Computational Methods" on page 7502.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC VARCOMP to obtain separate analyzes on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The *variables* are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the VARCOMP procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variables* **;**

The CLASS statement specifies the classification variables to be used in the analysis. All effects in the MODEL statement must be composed of effects that appear in the CLASS statement. Classification variables can be either numeric or character; if they are character, only the first 16 characters are used.

Numeric classification variables are not restricted to integers since a variable's format determines the levels. For more information, see the discussion of the FORMAT statement in *SAS Language Reference: Dictionary*.

MODEL Statement

MODEL *dependent* = < *effects* > < / *options* > **;**

The MODEL statement gives the dependent variables and independent effects. If you specify more than one dependent variable, a separate analysis is performed for each one. The independent effects are limited to main effects, interactions, and nested effects; no continuous effects are allowed. All

independent effects must be composed of effects that appear in the CLASS statement. Effects are specified in the VARCOMP procedure in the same way as described for the ANOVA procedure. Only one MODEL statement is allowed.

The following options are available in the MODEL statement.

FIXED=*n*

specifies that the first *n* effects in the MODEL statement are fixed effects. The remaining effects are assumed to be random. By default, PROC VARCOMP assumes that all effects are random in the model. Keep in mind that if you use bar notation and, for example, specify Y=A|B / FIXED=2, then A*B is considered a random effect.

CL

specifies that confidence limits for all of the parameters of interest should be computed and displayed. Note that this option applies only to balanced one-way or two-way designs for METHOD=TYPE1 or GRR.

ALPHA=*α*

specifies the level of significance α for $(1-\alpha)100\%$ two-sided confidence limits. The value of α must be between 0 and 1. By default, α is equal to 0.05.

Details: VARCOMP Procedure

Missing Values

If an observation has a missing value for any variable used in the independent effects, then the analyses of all dependent variables omit this observation. An observation is deleted from the analysis of a given dependent variable if the observation's value for that dependent variable is missing. Note that a missing value in one dependent variable does not eliminate an observation from the analysis of the other dependent variables.

During processing, PROC VARCOMP groups the dependent variables on their missing values across observations so that sums of squares and crossproducts can be computed in the most efficient manner.

Fixed and Random Effects

Central to the idea of variance components models is the idea of fixed and random effects. Each effect in a variance components model must be classified as either a fixed or a random effect. Fixed effects arise when the levels of an effect constitute the entire population in which you are interested. For example, if a plant scientist is comparing the yields of three varieties of soybeans, then Variety would be a fixed effect, providing that the scientist was concerned about making inferences

about only these three varieties of soybeans. Similarly, if an industrial experiment focused on the effectiveness of two brands of a machine, Machine would be a fixed effect only if the experimenter's interest did not go beyond the two machine brands.

On the other hand, an effect is classified as a random effect when you want to make inferences about an entire population, and the levels in your experiment represent only a sample from that population. Psychologists comparing test results between different groups of subjects would consider Subject as a random effect. Depending on the psychologists' particular interest, the Group effect might be either fixed or random. For example, if the groups are based on the sex of the subject, then Sex would be a fixed effect. But if the psychologists are interested in the variability in test scores due to different teachers, then they might choose a random sample of teachers as being representative of the total population of teachers, and Teacher would be a random effect. Note that, in the soybean example presented earlier, if the scientists are interested in making inferences about the entire population of soybean varieties and randomly choose three varieties for testing, then Variety would be a random effect.

If all the effects in a model (except for the intercept) are considered random effects, then the model is called a *random-effects model*; likewise, a model with only fixed effects is called a *fixed-effects model*. The more common case, where some factors are fixed and others are random, is called a *mixed model*. In PROC VARCOMP, by default, effects are assumed to be random. You specify which effects are fixed by using the FIXED= option in the MODEL statement. In general, if an interaction or nested effect contains any effect that is random, then the interaction or nested effect should be considered a random effect as well.

In the linear model, each level of a fixed effect contributes a fixed amount to the expected value of the dependent variable. What makes a random effect different is that each level of a random effect contributes an amount that is viewed as a sample from a population of normally distributed variables, each with mean 0, and an unknown variance, much like the usual random error term that is a part of all linear models. The estimate of the variance associated with the random effect is known as the *variance component* because it measures the part of the overall variance contributed by that effect. Thus, PROC VARCOMP estimates the variance of the random variables that are associated with the random effects in your model, and the variance components tell you how much each of the random factors contributes to the overall variability in the dependent variable.

Negative Variance Component Estimates

The variance components estimated by PROC VARCOMP should theoretically be nonnegative because they are assumed to represent the variance of a random variable. Nevertheless, when you are using METHOD=MIVQUE0, TYPE1, or GRR, some estimates of variance components might become negative. (Due to the nature of the algorithms used for METHOD=ML and METHOD=REML, negative estimates are constrained to zero.) These negative estimates might arise for a variety of reasons:

- The variability in your data might be large enough to produce a negative estimate, even though the true value of the variance component is positive.

- Your data might contain outliers. Refer to Hocking (1983) for a graphical technique for detecting outliers in variance components models by using the SAS System.
- A different model for interpreting your data might be appropriate. Under some statistical models for variance components analysis, negative estimates are an indication that observations in your data are negatively correlated. Refer to Hocking (1984) for further information about these models.

Assuming you are satisfied that the model that PROC VARCOMP is using is appropriate for your data, it is common practice to treat negative variance components as if they are zero.

Computational Methods

Four methods of estimation can be specified in the PROC VARCOMP statement by using the METHOD= option. They are described in the following sections.

The Type I Method

This method (METHOD=TYPE1) computes the Type I sum of squares for each effect, equates each mean square involving only random effects to its expected value, and solves the resulting system of equations (Gaylor, Lucas, and Anderson 1970). The $\mathbf{X}'\mathbf{X} \mid \mathbf{X}'\mathbf{Y}$ matrix is computed and adjusted in segments whenever memory is not sufficient to hold the entire matrix.

The MIVQUE0 Method

Based on the technique suggested by Hartley, Rao, and LaMotte (1978), the MIVQUE0 method (METHOD=MIVQUE0) produces unbiased estimates that are invariant with respect to the fixed effects of the model and that are locally best quadratic unbiased estimates given that the true ratio of each component to the residual error component is zero. The technique is similar to TYPE1 except that the random effects are adjusted only for the fixed effects. This affords a considerable timing advantage over the TYPE1 method; thus, MIVQUE0 is the default method used in PROC VARCOMP. The $\mathbf{X}'\mathbf{X}|\mathbf{X}'\mathbf{Y}$ matrix is computed and adjusted in segments whenever memory is not sufficient to hold the entire matrix. Each element (i, j) of the form

$$\mathrm{SSQ}(\mathbf{X}_i'\mathbf{M}\mathbf{X}_j)$$

is computed, where

$$\mathbf{M} = \mathbf{I} - \mathbf{X}_0(\mathbf{X}_0'\mathbf{X}_0)^{-}\mathbf{X}_0'$$

and where $\mathbf{X}_0$ is part of the design matrix for the fixed effects, $\mathbf{X}_i$ is part of the design matrix for one of the random effects, and SSQ is an operator that takes the sum of squares of the elements. For more information refer to Rao (1971, 1972) and Goodnight (1978).

The Maximum Likelihood Method

The maximum likelihood method (METHOD=ML) computes maximum likelihood estimates of the variance components; refer to Searle, Casella, and McCulloch (1992). The computing algorithm makes use of the W-transformation developed by Hemmerle and Hartley (1973) and Goodnight and Hemmerle (1979). The procedure uses a Newton-Raphson algorithm, iterating until the log-likelihood objective function converges.

The objective function for METHOD=ML is $\ln(|\mathbf{V}|) + \mathbf{r}'\mathbf{V}^{-1}\mathbf{r}$, where

$$\mathbf{V} = \sigma_0^2\mathbf{I} + \sum_{i=1}^{n_r} \sigma_i^2 \mathbf{X}_i \mathbf{X}_i'$$

and where σ_0^2 is the residual variance, n_r is the number of random effects in the model, σ_i^2 represents the variance components, $\mathbf{X}_i$ is part of the design matrix for one of the random effects, and

$$\mathbf{r} = \mathbf{y} - \mathbf{X}_0(\mathbf{X}_0'\mathbf{V}^{-1}\mathbf{X}_0)^{-}\mathbf{X}_0'\mathbf{V}^{-1}\mathbf{y}$$

is the vector of residuals.

The Restricted Maximum Likelihood Method

The restricted maximum likelihood method (METHOD=REML) is similar to the maximum likelihood method, but it first separates the likelihood into two parts: one that contains the fixed effects and one that does not (Patterson and Thompson 1971). The procedure uses a Newton-Raphson algorithm, iterating until convergence is reached for the log-likelihood objective function of the portion of the likelihood that does not contain the fixed effects. Using notation from earlier methods, the objective function for METHOD=REML is $\ln(|\mathbf{V}|) + \mathbf{r}'\mathbf{V}^{-1}\mathbf{r} + \ln(|\mathbf{X}_0'\mathbf{V}^{-1}\mathbf{X}_0|)$. Refer to Searle, Casella, and McCulloch (1992) for additional details.

The GRR Method

Based on the technique suggested by Burdick, Borror, and Montgomery (2005), the GRR method (METHOD=GRR) produces minimum variance unbiased estimators.

Gauge Repeatability and Reproducibility Analysis

In a typical gauge R&R experiment, each operator (O_j) makes multiple observations on each of several similar parts (P_i) from a monitored process. The statistical model used to describe the response variable is the balanced two-factor crossed random model with interaction

$$y_{ijk} = \mu_y + P_i + O_j + (PO)_{ij} + E_{ijk}$$

where $i = 1, \ldots, p$, $j = 1, \ldots, o$, $k = 1, \ldots, r$, μ_y is an unknown constant, and $P_i, O_j, (PO)_{ij}, E_{ijk}$ are jointly independent normal random variables with means of zero and variances $\mathrm{Var}(P)$, $\mathrm{Var}(O)$, $\mathrm{Var}(PO)$, and $\mathrm{Var}(E)$, respectively. The corresponding SAS statements are as follows:

```
proc varcomp method=grr;
   class P O;
   model y = P|O;
run;
```

The first random effect in the MODEL statement is assumed to be the "Part" effect and the second is "Operator."

The ANOVA table for the preceding model is shown in Table 94.1.

Table 94.1 GRR Analysis of Variance

Source	DF	Mean Square	Expected Mean Square
Parts(P)	$p-1$	S_P^2	$\mathrm{Var}(E)+r\mathrm{Var}(PO)+or\mathrm{Var}(P)$
Operators(O)	$o-1$	S_O^2	$\mathrm{Var}(E)+r\mathrm{Var}(PO)+pr\mathrm{Var}(O)$
P×O	$(p-1)(o-1)$	S_{PO}^2	$\mathrm{Var}(E)+r\mathrm{Var}(PO)$
Error(E)	$po(r-1)$	S_E^2	$\mathrm{Var}(E)$

The gauge R&R parameters of interest are given in Table 94.2 in terms of $\mathrm{Var}(P)$, $\mathrm{Var}(O)$, $\mathrm{Var}(PO)$, and $\mathrm{Var}(E)$.

Table 94.2 Gauge R&R Parameters

Parameter	Formula
Variance of the monitored process	$\gamma_P = \mathrm{Var}(P)$
Variance of the measurement system	$\gamma_M = \mathrm{Var}(O)+\mathrm{Var}(PO)+\mathrm{Var}(E)$
Total variance of the response variable	$\gamma_y = \mathrm{Var}(y) = \gamma_P+\gamma_M$
Ratio of process variance to measurement variance	$\gamma_R = \gamma_P/\gamma_M$
Proportion of total variance due to the process	$\rho_P = \gamma_P/\gamma_y = \frac{\gamma_R}{1+\gamma_R}$
Proportion of total variance due to the measurement	$\rho_M = \gamma_M/\gamma_y = 1-\rho_P$
Signal-to-noise ratio	$\mathrm{SNR} = \sqrt{2\times\gamma_R}$
Discrimination ratio	$\mathrm{DR} = 1+2\gamma_R$

For a one-way model, $\gamma_M = \mathrm{Var}(E)$, and for a two-way model with no interaction, $\gamma_M = \mathrm{Var}(O)+\mathrm{Var}(E)$.

If you use the SPECLIMITS option to give specification limits, the two parameters in Table 94.3 will also be estimated and displayed.

Table 94.3 Gauge R&R Parameters Related to Specification Limits

Parameter	Formula
Precision-to-tolerance ratio	$\mathrm{PTR(LSL, USL, k)} = k\sqrt{\gamma_M}/(\mathrm{USL}-\mathrm{LSL})$
Process capability ratio	$\mathrm{Cp(LSL, USL, k)} = (\mathrm{USL}-\mathrm{LSL})/(k\sqrt{\gamma_P})$

Here, USL and LSL are the specification limits, and the value k corresponds to the number of standard deviations between the "natural" tolerance limits of a normal process.

If you use the RATIO option, the ratios in Table 94.4 will also be estimated and displayed.

Table 94.4 Gauge R&R Ratios

Ratio	Formula
Ratio of process variance to total variance	$\text{Var}(P)/\gamma_y$
Ratio of operator variance to total variance	$\text{Var}(O)/\gamma_y$
Ratio of process by operator variance to total variance	$\text{Var}(PO)/\gamma_y$
Ratio of process variance to residual variance	$\text{Var}(P)/\text{Var}(E)$
Ratio of operator variance to residual variance	$\text{Var}(O)/\text{Var}(E)$
Ratio of process by operator variance to residual variance	$\text{Var}(PO)/\text{Var}(E)$

Confidence Limits

When you are analyzing a balanced one-way or two-way design, then if you specify the CL option with METHOD=TYPE1 or GRR, the VARCOMP procedure will compute confidence limits by using modified large-sample (MLS) methods, as discussed in Burdick, Borror, and Montgomery (2005).

The formulas for these confidence limits are very complicated. Those for a balanced two-way crossed random model with interaction are given in Table 94.5. Refer to Burdick, Borror, and Montgomery (2005) for the formulas for one-way or balanced two-way with no interaction models.

Note that confidence limits for parameters such as variances and their ratios might not contain the corresponding point estimates, since negative confidence bounds are increased to zero.

Table 94.5 $100(1-\alpha)\%$ MLS Confidence Limits

Parameter	Lower Bound	Upper Bound
γ_P	$\hat{\gamma}_P - \sqrt{V_{LP}}/(or)$	$\hat{\gamma}_P + \sqrt{V_{UP}}/(or)$
γ_M	$\hat{\gamma}_M - \sqrt{V_{LM}}/(pr)$	$\hat{\gamma}_M + \sqrt{V_{UM}}/(pr)$
γ_y	$\hat{\gamma}_y - \sqrt{V_{LT}}/(por)$	$\hat{\gamma}_y + \sqrt{V_{UT}}/(por)$
γ_R	L_R	U_R
ρ_P	$L_R/(1+L_R)$	$U_R/(1+U_R)$
ρ_M	$1/(1+U_R)$	$1/(1+L_R)$

The terms in Table 94.5 are defined as follows:

$$
\begin{aligned}
V_{LP} &= G_1^2 S_P^4 + H_3^2 S_{PO}^4 + G_{13} S_P^2 S_{PO}^2 \\
V_{UP} &= H_1^2 S_P^4 + G_3^2 S_{PO}^4 + H_{13} S_P^2 S_{PO}^2 \\
V_{LM} &= G_2^2 S_O^4 + G_3^2 (p-1)^2 S_{PO}^4 + G_4^2 p^2 (r-1)^2 S_E^4 \\
V_{UM} &= H_2^2 S_O^4 + H_3^2 (p-1)^2 S_{PO}^4 + H_4^2 p^2 (r-1)^2 S_E^4 \\
V_{LT} &= G_1^2 p^2 S_P^4 + G_2^2 o^2 S_O^4 + G_3^2 (po-p-o)^2 S_{PO}^4 + G_4^2 (po)^2 (r-1)^2 S_E^4 \\
V_{UT} &= H_1^2 p^2 S_P^4 + H_2^2 o^2 S_O^4 + H_3^2 (po-p-o)^2 S_{PO}^4 + H_4^2 (po)^2 (r-1)^2 S_E^4 \\
L_R &= \frac{p(1-G_1)(S_P^2 - F_1 S_{PO}^2)}{po(r-1)S_E^2 + o(1-G_1)F_3 S_O^2 + o(p-1)S_{PO}^2} \\
U_R &= \frac{p(1+H_1)(S_P^2 - F_2 S_{PO}^2)}{po(r-1)S_E^2 + o(1+H_1)F_4 S_O^2 + o(p-1)S_{PO}^2} \\
G_1 &= 1 - F_{\alpha/2:\infty,p-1} \\
G_2 &= 1 - F_{\alpha/2:\infty,o-1} \\
G_3 &= 1 - F_{\alpha/2:\infty,(p-1)(o-1)} \\
G_4 &= 1 - F_{\alpha/2:\infty,po(r-1)} \\
H_1 &= F_{1-\alpha/2:\infty,p-1} - 1 \\
H_2 &= F_{1-\alpha/2:\infty,o-1} - 1 \\
H_3 &= F_{1-\alpha/2:\infty,(p-1)(o-1)} - 1 \\
H_4 &= F_{1-\alpha/2:\infty,po(r-1)} - 1 \\
F_1 &= F_{1-\alpha/2:p-1,(p-1)(o-1)} \\
F_2 &= F_{\alpha/2:p-1,(p-1)(o-1)} \\
F_3 &= F_{1-\alpha/2:p-1,o-1} \\
F_4 &= F_{\alpha/2:p-1,o-1} \\
G_{13} &= \frac{(F_1-1)^2 - G_1^2 F_1^2 - H_3^2}{F_1} \\
H_{13} &= \frac{(1-F_2)^2 - H_1^2 F_2^2 - G_3^2}{F_2}
\end{aligned}
$$

The symbol $F_{\alpha:df1,df2}$ represents the percentile of an F distribution with *df1* and *df2* degrees of freedom and area α to the left.

Displayed Output

PROC VARCOMP displays the following items:

- Class Level Information for verifying the levels in your data
- Number of observations read from the data set and number of observations used in the analysis

- for METHOD=TYPE1, an analysis-of-variance table with Source, DF, Type I Sum of Squares, Type I Mean Square, and Expected Mean Square, and a table of Type I variance component estimates
- for METHOD=MIVQUE0, the SSQ Matrix containing sums of squares of partitions of the $\mathbf{X}'\mathbf{X}$ crossproducts matrix adjusted for the fixed effects
- for METHOD=ML and METHOD=REML, the iteration history, including the objective function, a table of variance component estimates, and the estimated Asymptotic Covariance Matrix of the variance components
- for METHOD=GRR, an analysis-of-variance table with Source, DF, GRR Sum of Squares, GRR Mean Square, and Expected Mean Square, and a table of GRR parameter estimates. If the CL option is specified, confidence limits for each parameter estimate will also be displayed.

ODS Table Names

PROC VARCOMP assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 94.6. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 94.6 ODS Tables Produced by PROC VARCOMP

ODS Table Name	Description	Statement
ANOVA	Type 1 analysis of variance	METHOD=TYPE1 or GRR
AsyCov	Asymptotic covariance matrix of estimates	METHOD=ML or REML
ClassLevels	Class level information	default
ConvergenceStatus	Convergence status	METHOD=ML or REML
DepVar	Dependent variable	METHOD=TYPE1, REML, ML, or GRR
DependentInfo	Dependent variable info (multiple variables)	
Estimates	Variance component estimates	default
IterHistory	Iteration history	METHOD=ML or REML
NObs	Number of observations	default
SSCP	Sum of squares matrix	METHOD=MIVQUE0

In situations where multiple dependent variables are analyzed that differ in their missing value pattern, separate names for ANOVA*n*, AsyCov*n*, Estimates*n*, IterHistory*n*, and SSCP*n* tables are no longer required. The results are combined into a single output data set. For METHOD=TYPE1, ML, or REML, the variable Dependent in the output data set identifies the dependent variable. For METHOD=MIVQUE0, a variable is added to the output data set for each dependent variable.

Relationship to PROC MIXED

The MIXED procedure effectively performs the same analyzes as PROC VARCOMP and many others, including Type I, Type II, and Type III tests of fixed effects, confidence limits, customized contrasts, and least squares means. Furthermore, continuous variables are permitted as both fixed and random effects in PROC MIXED, and numerous other covariance structures besides variance components are available. The VARCOMP procedure is more computationally efficient for some special designs and models.

To translate PROC VARCOMP code into PROC MIXED code, move all random effects to the RANDOM statement in PROC MIXED. For example, the syntax for the example in the section "Getting Started: VARCOMP Procedure" on page 7494 is as follows:

```
proc mixed;
   class Temp Lab Batch;
   model Cure = Temp;
   random Lab Temp*Lab Batch(Lab Temp);
run;
```

REML is the default estimation method in PROC MIXED, and you can specify other methods by using the METHOD= option.

Examples: VARCOMP Procedure

Example 94.1: Using the Four General Estimation Methods

In this example, a and b are classification variables and y is the dependent variable. a is declared fixed, and b and a*b are random. Note that this design is unbalanced because the cell sizes are not all the same. PROC VARCOMP is invoked four times, once for each of the general estimation methods. The data are from Hemmerle and Hartley (1973). The following statements produce Output 94.1.1.

```
data a;
   input a b y @@;
   datalines;
1 1 237   1 1 254   1 1 246   1 2 178   1 2 179
2 1 208   2 1 178   2 1 187   2 2 146   2 2 145   2 2 141
3 1 186   3 1 183   3 2 142   3 2 125   3 2 136
;

proc varcomp method=type1 data=a;
   class a b;
   model y=a|b / fixed=1;
run;
```

Output 94.1.1 VARCOMP Procedure: Method=TYPE1

Variance Components Estimation Procedure

Class Level Information

Class	Levels	Values
a	3	1 2 3
b	2	1 2

Corrected Total	15	24270		

Type 1 Estimates

Variance Component	Estimate
Var(b)	1448.4
Var(a*b)	27.42659
Var(Error)	78.63333

The "Class Level Information" table in Output 94.1.1 displays the levels of each variable specified in the CLASS statement. You can check this table to make sure the data are input correctly.

The Type I analysis of variance in Output 94.1.1 consists of a sequential partition of the total sum of squares. The mean square is the sum of squares divided by the degrees of freedom, and the expected mean square is the expected value of the mean square under the mixed model. The "Q" notation in the expected mean squares refers to a quadratic form in parameters of the parenthesized effect.

The Type I estimates of the variance components in Output 94.1.1 result from solving the linear system of equations established by equating the observed mean squares to their expected values.

The following statements are the same as before, except that the estimation method is MIVQUE0 instead of the default TYPE1. They produce Output 94.1.2.

```
proc varcomp method=mivque0 data=a;
   class a b;
   model y=a|b / fixed=1;
run;
```

Output 94.1.2 VARCOMP Procedure: Method=MIVQUE0

```
                  Variance Components Estimation Procedure

                              MIVQUE(0) SSQ Matrix

Source                    b                  a*b                Error                    y

b                  60.84000            20.52000             7.80000             89295.4
a*b                20.52000            20.52000             7.80000             30181.3
Error               7.80000             7.80000            13.00000             12533.5

                              MIVQUE(0) Estimates

                         Variance Component                  y

                         Var(b)                         1466.1
                         Var(a*b)                     -35.49170
                         Var(Error)                   105.73660
```

The MIVQUE0 estimates in Output 94.1.2 result from solving the equations established by the MIVQUE0 SSQ matrix. Note that the estimate of the variance component for the interaction effect, Var(a*b), is negative for this example.

The following statements use METHOD=ML to invoke maximum likelihood estimation. They produce Output 94.1.3.

```
proc varcomp method=ml data=a;
   class a b;
   model y=a|b / fixed=1;
run;
```

Output 94.1.3 VARCOMP Procedure: Method=ML

```
                  Variance Components Estimation Procedure

                          Maximum Likelihood Iterations

Iteration        Objective           Var(b)         Var(a*b)       Var(Error)

        0    78.3850371200       1031.49070                0    74.3909717935
        1    78.2637043807   732.3606453635                0    77.4011688154
        2    78.2635471161   723.6867470850                0    77.5301774839
        3    78.2635471152   723.6658365289                0    77.5304926877

       Convergence criteria met.
```

Output 94.1.3 *continued*

Maximum Likelihood Estimates

Variance Component	Estimate
Var(b)	723.66584
Var(a*b)	0
Var(Error)	77.53049

Asymptotic Covariance Matrix of Estimates

	Var(b)	Var(a*b)	Var(Error)
Var(b)	537826.1	0	-107.33905
Var(a*b)	0	0	0
Var(Error)	-107.33905	0	858.71104

The "Maximum Likelihood Iterations" table in Output 94.1.3 shows that the Newton-Raphson algorithm used by PROC VARCOMP requires three iterations to converge.

The ML estimate of Var(a*b) is zero for this example, and the other two estimates are smaller than their Type I and MIVQUE0 counterparts.

One benefit of using likelihood-based methods is that an approximate covariance matrix is available from the matrix of second derivatives evaluated at the ML solution. This covariance matrix is valid asymptotically and can be unreliable in small samples.

Here the variance component estimates for B and the Error are negatively correlated, and the elements for Var(a*b) are set to zero because the estimate equals zero. Also, the very large variance for Var(b) indicates a lot of uncertainty about the estimate for Var(b), and one contributing explanation is that B has only two levels in this data set.

Finally, the following statements use the restricted maximum likelihood (REML) for estimation. They produce Output 94.1.4.

```
proc varcomp method=reml data=a;
   class a b;
   model y=a|b / fixed=1;
run;
```

Output 94.1.4 VARCOMP Procedure: Method=REML

Variance Components Estimation Procedure

REML Iterations

Iteration	Objective	Var(b)	Var(a*b)	Var(Error)
0	63.4134144942	1269.52701	0	91.5581191305
1	63.0446869787	1601.84199	32.7632417174	76.9355562461
2	63.0311530508	1468.82932	27.2258186561	78.7548276319
3	63.0311265148	1464.33646	26.9564053003	78.8431476502
4	63.0311265127	1464.36727	26.9588525177	78.8423898761

Convergence criteria met.

REML Estimates

Variance Component	Estimate
Var(b)	1464.4
Var(a*b)	26.95885
Var(Error)	78.84239

Asymptotic Covariance Matrix of Estimates

	Var(b)	Var(a*b)	Var(Error)
Var(b)	4401703.8	1.29359	-273.39651
Var(a*b)	1.29359	3559.1	-502.85157
Var(Error)	-273.39651	-502.85157	1249.7

The "REML Iterations" table in Output 94.1.4 shows that the REML optimization requires four iterations to converge.

The REML estimates in Output 94.1.4 are all larger than the corresponding ML estimates (adjusting for potential downward bias) and are fairly similar to the Type I estimates.

The "Asymptotic Covariance Matrix of Estimates" table in Output 94.1.4 shows that the Error variance component estimate is negatively correlated with the other two variance component estimates, and the estimated variances are all larger than their ML counterparts.

Example 94.2: Using the GRR Method

In this example from Houf and Burman (1988), the response variable is the thermal performance of a module measured in Celsius degrees per watt. Each of three operators measures 10 parts three times. It is assumed that parts and operators are selected at random from larger populations. The following statements produce Output 94.2.1.

```
data Houf;
   input a b y @@;
   datalines;
1  1 37    1  1 38    1 1 37
1  2 41    1  2 41    1 2 40

The GRR analysis of variance in Output 94.2.2 is the same as for the Type I analysis when the design is balanced.

Finally, the estimates of the GRR parameters of interest and their confidence limits are displayed in Output 94.2.3.

Output 94.2.3 Parameter Estimates Using Method=GRR

GRR Estimates

Parameter	Estimate	95% Confidence Limits	
Var(a)	48.29259	22.69452	161.63918
Var(b)	0.56461	0.07296	25.75077
Var(a*b)	0.72798	0.33273	1.79272
Var(Error)	0.51111	0.36816	0.75754
Gamma Y	50.09630	24.48844	166.22217
Gamma P	48.29259	22.69452	161.63918
Gamma M	1.80370	1.20623	27.01724
Gamma R	26.77413	1.69168	105.60895
SNR	7.31767	1.83939	14.53334
PTR(18,58,6)	0.20145	0.16474	0.77967
Cp(18,58,6)	0.95933	0.52437	1.39942
DR	54.54825	4.38336	212.21791
Rho P	0.96400	0.62848	0.99062
Rho M	0.03600	0.0093801	0.37152
Var(a)/Gamma Y	0.96400	0.62848	0.99062
Var(b)/Gamma Y	0.01127	0.0008700	0.34151
Var(a*b)/Gamma Y	0.01453	0.0027083	0.04744
Var(a)/Var(Error)	94.48551	40.19199	327.32469
Var(b)/Var(Error)	1.10467	0.13662	50.37744
Var(a*b)/Var(Error)	1.42432	0.55232	3.74691

You can draw the following inferences from the results of the analysis. Most of the variation is due to differences between parts because of the relative larger value of Gamma R. The measurement system is nearly inadequate because the PTR exceeds 20%. However, the measurement system is of value in monitoring the process since the SNR is greater than five. Refer to Burdick, Borror, and Montgomery (2003) for more information about interpreting gauge R&R studies.

Overview: VARIOGRAM Procedure

The VARIOGRAM procedure computes empirical measures of spatial continuity for two-dimensional spatial data. These measures are a function of the distances between the sample data pairs. When the data are free of nonrandom (or systematic) surface trends, the estimated continuity measures are the empirical semivariance and covariance. These measures can be used in subsequent analysis to perform spatial prediction. The procedure plots empirical semivariograms, which can also be saved to an output data set to enable parameter estimation for theoretical semivariogram or covariance models. Both isotropic and anisotropic measures are available.

In addition, PROC VARIOGRAM provides the Moran I and Geary c spatial autocorrelation statistics. The procedure also produces the OUTPAIR= and OUTDISTANCE= data sets that contain information about the semivariogram analysis.

The VARIOGRAM procedure now uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." For more information about the graphics available in PROC VARIOGRAM, see the section "ODS Graphics" on page 7569.

Introduction to Spatial Prediction

Many activities in science and technology involve measurements of one or more quantities at given spatial locations, with the goal of predicting the measured quantities at unsampled locations. Application areas include reservoir prediction in mining and petroleum exploration, as well as modeling in a broad spectrum of fields (for example, environmental health, environmental pollution, natural resources and energy, hydrology, risk analysis). Often, the unsampled locations are on a regular grid, and the predictions are used to produce surface plots or contour maps.

The preceding tasks fall within the scope of *spatial prediction*, which, in general, is any prediction method that incorporates spatial dependence. The study of these tasks involves naturally occurring uncertainties that cannot be ignored. Stochastic analysis frameworks and methods are used to account for these uncertainties. Hence, the terms *stochastic spatial prediction* and *stochastic modeling* are also used to characterize this type of analysis.

A popular method of spatial prediction is *ordinary kriging*, which produces both predicted values and associated standard errors. Ordinary kriging requires the complete specification (the form and parameter values) of the spatial dependence characterizing the spatial process. For this purpose, models for the spatial dependence are expressed in terms of the distance between any two locations in the spatial domain of interest. These models take the form of a covariance or semivariance function.

Spatial prediction, then, involves two steps. First, you model the covariance or semivariance of the spatial process. These measures are typically not known in advance. This step involves computing an empirical estimate, as well as determining both the mathematical form and the values of any parameters for a theoretical form of the dependence model. Second, you use this dependence model to solve the kriging system at a specified set of spatial points, resulting in predicted values and associated standard errors.

SAS/STAT software has two procedures corresponding to these steps for spatial prediction of two-dimensional data. The VARIOGRAM procedure is used in the first step (that is, calculating and modeling the dependence model), and the KRIGE2D procedure performs the kriging operations to produce the final predictions.

This introduction concludes with a note on terminology. You might commonly encounter the terms *estimation* and *prediction* used interchangeably by experts in different fields; this could be a source of confusion. A precise statistical vernacular uses the term *estimation* to refer to inferences about the value of fixed but unknown parameters, whereas *prediction* concerns inferences about the value of random variables—see, for example, Cressie (1993, p. 106). In light of these definitions, kriging methods are clearly predictive techniques, since they are concerned with making inferences about the value of a spatial random field at observed or unobserved locations. The SAS/STAT suite of procedures for spatial analysis and prediction (VARIOGRAM, KRIGE2D, and SIM2D) follows the statistical vernacular in the use of the terms *estimation* and *prediction*.

Getting Started: VARIOGRAM Procedure

PROC VARIOGRAM uses your data to compute the empirical semivariogram. This computation refers to the steps you take to derive the empirical semivariance from the data, and then to produce the corresponding semivariogram plot.

You can proceed further with the semivariogram analysis if the data are free of systematic trends. In that case, you can use the empirical outcome to determine a theoretical semivariogram model by using automated or visual methods. The model characterizes the type of theoretical semivariance function you will use to describe spatial dependence in your data set.

Some of the following graphical displays are requested by using the ODS GRAPHICS statement. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." For specific information about the graphics available in the VARIOGRAM procedure, see the section "ODS Graphics" on page 7569.

Preliminary Spatial Data Analysis

The following data set simulates measurements of coal seam thickness (in feet) taken over an approximately square area. The coordinates are offsets from a point in the southwest corner of the measurement area, with the north and east distances in units of thousands of feet.

```

;
```

It is instructive to see the locations of the measured points in the area where you want to perform spatial prediction. It is desirable to have the sampling locations scattered evenly throughout the prediction area. If the locations are not scattered evenly, the prediction error might be unacceptably large where measurements are sparse.

You can run PROC VARIOGRAM in this preliminary analysis to determine potential problems. In the following statements, the NOVARIOGRAM option in the COMPUTE statement specifies that only the descriptive summaries and a plot of the raw data should be produced.

```
ods graphics on;

proc variogram data=thick plots=pairs(thr=30);
   compute novariogram nhc=20;
   coordinates xc=East yc=North;
   var Thick;
run;
```

PROC VARIOGRAM produces the table in Figure 95.1 that shows the number of Thick observations read and used. This table provides you with useful information in case you have missing values in the input data.

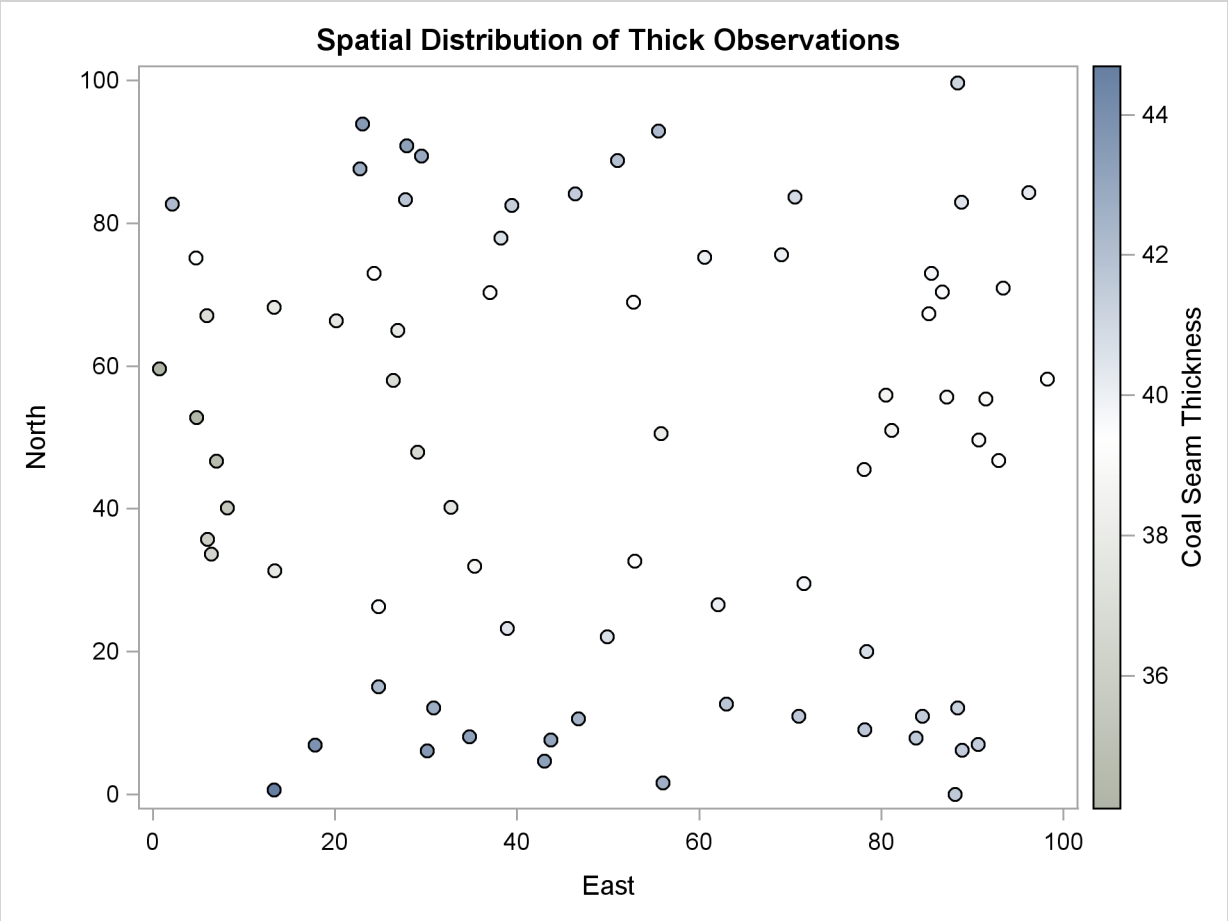

Figure 95.1 Number of Observations for the thick Data Set

```
                    The VARIOGRAM Procedure
                   Dependent Variable: Thick

              Number of Observations Read          75
              Number of Observations Used          75
```

Then, the scatter plot of the observed data is produced as shown in Figure 95.2. According to the figure, while the locations are not ideally spread around the prediction area, there are not any extended areas lacking measurements. The same graph also provides the values of the measured variable by using colored markers.

Figure 95.2 Scatter Plot of the Observations Spatial Distribution

The following is a crucial step. Any obvious surface trend must be removed before you compute the empirical semivariogram and proceed to estimate a model of spatial dependence (the theoretical semivariogram model). You can observe in Figure 95.2 the small-scale variation typical of spatial data, but a first inspection indicates no obvious major systematic trend.

Assuming, therefore, that the data are free of surface trends, you can work with the original thickness rather than residuals obtained from a trend removal process. The following analysis also assumes that the spatial characterization is independent of the direction of the line connecting any two equidistant pairs of data; this is a property known as isotropy. See "Example 95.2: An Anisotropic Case Study with Surface Trend in the Data" on page 7574 for a more detailed approach to trend analysis and the issue of anisotropy.

Following the previous exploratory analysis, you then need to classify each data pair as a member of a distance interval (lag). PROC VARIOGRAM performs this grouping with two required options for semivariogram computation: the LAGDISTANCE= and MAXLAGS= options. These options are based on your assessment of how to group the data pairs within distance classes.

The meaning of the required LAGDISTANCE= option is as follows. Classify all pairs of points into intervals according to their pairwise distance. The width of each distance interval is the LAGDISTANCE= value. The meaning of the required MAXLAGS= option is simply the number of intervals you consider. The problem is that given only the scatter plot of the measurement locations, it is not clear what values to give to the LAGDISTANCE= and MAXLAGS= options.

Ideally, you would like a sufficient number of distance classes that capture the extent to which your data are correlated, and that each contain a minimum of data pairs to increase the accuracy in your computations. A rule of thumb used in semivariogram computations is that you should have at least 30 pairs per lag class. This is an empirical arbitrary threshold; see the section "Choosing the Size of Classes" on page 7555 for further details.

In the preliminary analysis, you use the option NHC= in the COMPUTE statement to help you experiment with these numbers and choose values for the LAGDISTANCE= and MAXLAGS= options. Here, in particular, you requested NHC=20 to preview a classification that uses 20 distance classes across your spatial domain. A zero lag class is always considered; therefore the output shows the number of distance classes to be one more than the number you specified.

Based on your selection of the NHC= option, the NOVARIOGRAM option produces a pairwise distances table from your observations shown in Figure 95.3, and the corresponding histogram in Figure 95.4. For illustration purposes, you also specified in the code a threshold of minimum data pairs per distance class in the PAIRS option as THR=30. As a result, a reference line appears in the histogram so that you can visually identify any lag classes with pairs that fall below your specified threshold.

Figure 95.3 Pairwise Distance Intervals Table

Pairwise Distance Intervals

Lag Class	Bounds		Number of Pairs	Percentage of Pairs
0	0.00	3.48	7	0.25%
1	3.48	10.45	81	2.92%
2	10.45	17.42	138	4.97%
3	17.42	24.39	167	6.02%
4	24.39	31.36	204	7.35%
5	31.36	38.33	210	7.57%
6	38.33	45.30	213	7.68%
7	45.30	52.27	253	9.12%
8	52.27	59.24	237	8.54%
9	59.24	66.20	280	10.09%
10	66.20	73.17	252	9.08%
11	73.17	80.14	230	8.29%
12	80.14	87.11	217	7.82%
13	87.11	94.08	154	5.55%
14	94.08	101.05	71	2.56%
15	101.05	108.02	41	1.48%
16	108.02	114.99	14	0.50%
17	114.99	121.96	5	0.18%
18	121.96	128.93	1	0.04%
19	128.93	135.89	0	0.00%
20	135.89	142.86	0	0.00%

The NOVARIOGRAM option also produces a table with useful facts about the pairs and the distances between the most remote data in selected directions, shown in Figure 95.5. In particular, the lag distance value is calculated based on your selection of the NHC= option. The last three table entries report the overall maximum distance among your data pairs, as well as the maximum distances in the main axes directions (that is, the vertical or N–S axis, and the horizontal or E–W axis). This information is also provided in the inset of Figure 95.4. When you specify a threshold in the PAIRS suboption of the PLOTS= option, as in this example, the threshold also appears in the table. Then, the line that follows indicates the highest lag class with the following property: Each one of the distance classes that lie farther away from this lag features a pairs population below the specified threshold.

With the preceding information you can determine appropriate values for the LAGDISTANCE= and MAXLAGS= options in the COMPUTE statement. In particular, the classification that uses 20 distance classes is satisfactory, and you can choose LAGDISTANCE=7 after following the suggestion in Figure 95.5.

Figure 95.4 Distribution of Pairwise Distances

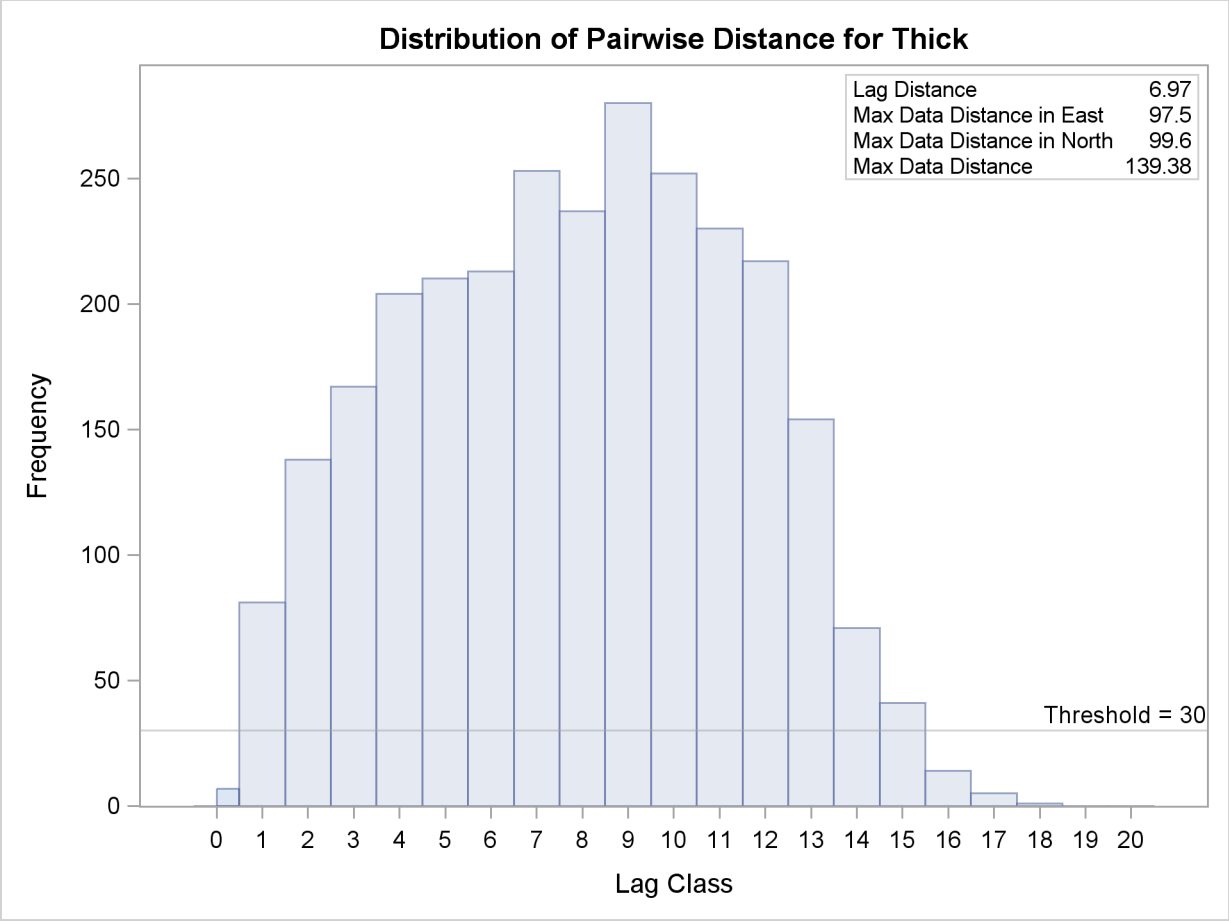

Figure 95.5 Pairs Information Table

Pairs Information

Number of Lags	21
Lag Distance	6.97
Minimum Pairs Threshold	30
Highest Lag With Pairs > Threshold	15
Maximum Data Distance in East	97.50
Maximum Data Distance in North	99.60
Maximum Data Distance	139.38

The MAXLAGS= option needs to be specified based on the spatial extent to which your data are correlated. Unless you know this size, in the present omnidirectional case you can assume the correlation extent to be roughly equal to half the overall maximum distance between data points.

The table in Figure 95.5 suggests that this number corresponds to 139,380 feet, which is most likely on or close to a diagonal direction (that is, the northeast–southwest or northwest–southeast direction). Hence, you can expect the correlation extent in this scale to be around $139.4/2 = 69,700$ feet. Consequently, this is the distance up to which you should consider lag classes for the empirical semivariogram computations. Given your lag size selection, Figure 95.3 indicates that this distance corresponds to about 10 lags; hence you can set MAXLAGS=10.

Overall, for a specific NHC= choice of class count, you can expect your choice of MAXLAGS= to be approximately half the number of the lag classes (see the section "Spatial Extent of the Empirical Semivariogram" on page 7556 for more details).

Once you have starting values for the LAGDISTANCE= and MAXLAGS= options, you can run the VARIOGRAM procedure multiple times to inspect and compare the results you get by specifying different values for these options.

Empirical Semivariogram Computation

Using the values of LAGDISTANCE=7 and MAXLAGS=10 computed previously, rerun PROC VARIOGRAM without the NOVARIOGRAM option in order to compute the empirical semivariogram. You specify the CL option in the COMPUTE statement to calculate the 95% confidence limits for the classical semivariance. The section "COMPUTE Statement" on page 7533 describes how to use the ALPHA= option to specify a different confidence level.

Also, you can request a robust version of the semivariance with the ROBUST option in the COMPUTE statement. PROC VARIOGRAM produces a plot showing both the classical and the robust empirical semivariograms. See the details of the PLOT option to specify different instances of plots of the empirical semivariogram. In addition, ask for the autocorrelation Moran's I and Geary's c statistics under the assumption of randomization using binary weights. The following statements implement all of the preceding requests:

```
proc variogram data=thick outv=outv;
   compute lagd=7 maxlag=10 cl robust
           autocorr(assum=random);
   coordinates xc=East yc=North;
   var Thick;
run;

ods graphics off;
```

Figure 95.6 displays the PROC VARIOGRAM output empirical semivariogram table for the preceding code.

9	281	62.89	8.2792	6.8445	0.5774	5.713	7.9763
10	250	69.93	8.1440	6.3577	0.5686	5.243	7.4722

Figure 95.7 shows the output from the requested autocorrelation analysis. This includes the observed (computed) Moran's I and Geary's c coefficients, the expected value and standard deviation for each coefficient, the corresponding Z score, and the p-value in the Pr $>|$ Z $|$ column. The low p-values suggest strong autocorrelation for both statistics types. Note that a two-sided p-value is reported, which is the probability that the observed coefficient lies farther away from $|$ Z $|$ on either side of the coefficient's expected value—that is, lower than $-Z$ or higher than Z. The sign of Z for both Moran's I and Geary's c coefficients indicates positive autocorrelation in the Thick data values; see the section "Interpretation" on page 7564 for more details.

Figure 95.7 Output Table for the Autocorrelation Statistics

Autocorrelation Statistics

Assumption	Coefficient	Observed	Expected	Std Dev	Z	Pr > |Z|
Randomization	Moran's I	1.0833	-0.0135	0.147	7.47	<.0001
Randomization	Geary's c	0.0185	1.0000	0.228	-4.30	<.0001

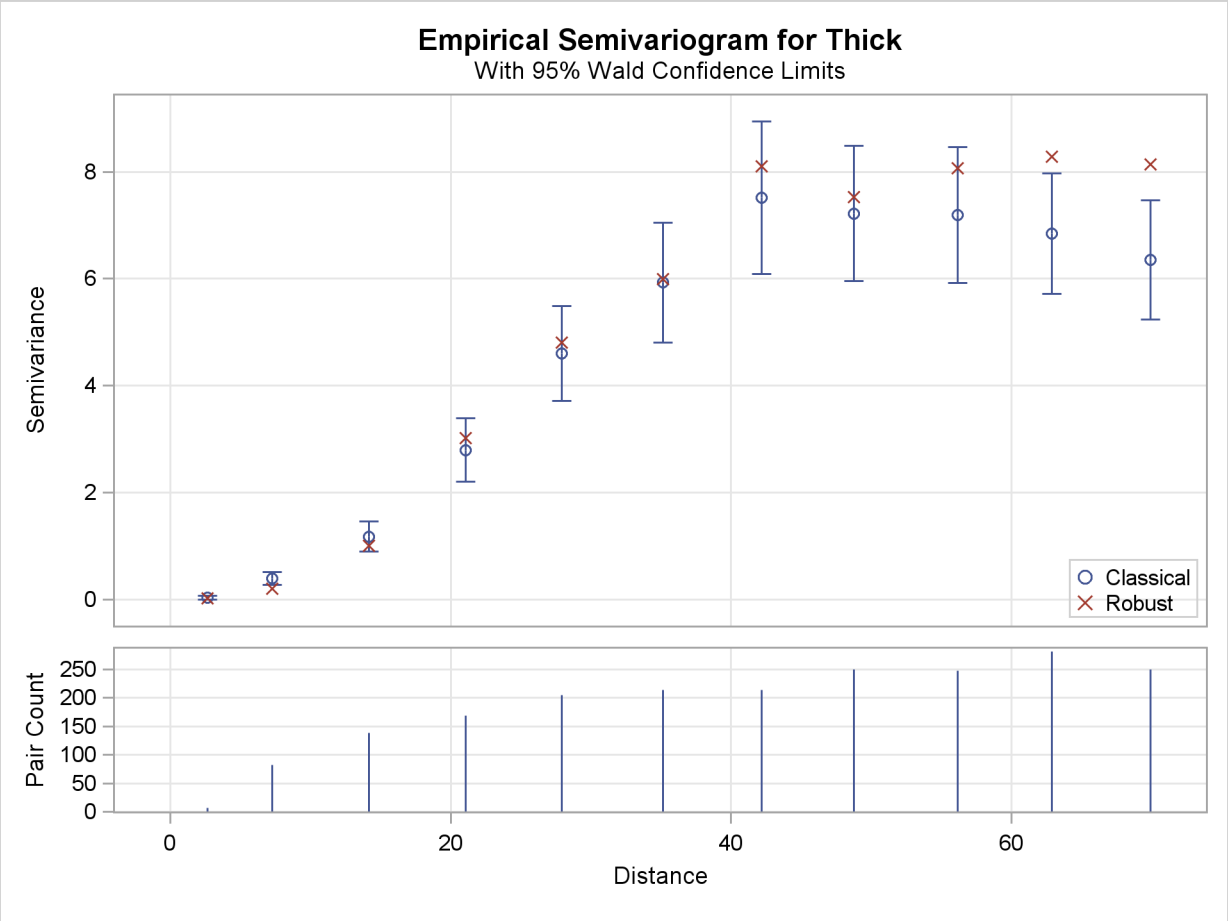

Figure 95.8 shows both the classical and robust empirical semivariograms. In addition, the plot features the approximate 95% confidence limits for the classical semivariance. The figure exhibits a typical behavior of the computed semivariance uncertainty, where in general the variance increases with distance from the origin at Distance=0.

The needle plot in the lower part of the Figure 95.8 provides the number of pairs that were used in the computation of the empirical semivariance for each lag class shown. Note that in general this is a pairwise distribution that is different from the distribution depicted in Figure 95.4. First, the number of pairs shown in the needle plot depends on the particular criteria you specify in the

COMPUTE statement of PROC VARIOGRAM. Second, the distances shown for each lag on the Distance axis are not the midpoints of the lag classes as in the pairwise distances plot, but rather the average distance from the origin Distance=0 of all pairs in a given lag class.

"Example 95.1: Theoretical Semivariogram Model Fitting" on page 7570 continues from this point to show how to choose a theoretical model for the thickness spatial dependence.

Figure 95.8 Classical and Robust Empirical Semivariograms for Coal Seam Thickness Data

Syntax: VARIOGRAM Procedure

The following statements are available in PROC VARIOGRAM:

PROC VARIOGRAM *options* ;
  BY *variables* ;
  COMPUTE *computation-options* ;
  COORDINATES *coordinate-variables* ;
  DIRECTIONS *directions-list* ;
  VAR *analysis-variables-list* ;

The COMPUTE and COORDINATES statements are required.

Table 95.1 outlines the options available in PROC VARIOGRAM classified by function.

Table 95.1 Options Available in the VARIOGRAM Procedure

Task	Statement	Option
Data Set Options		
Specify input data set	PROC VARIOGRAM	DATA=
Suppress normal display of results	PROC VARIOGRAM	NOPRINT
Write autocorrelation weights information	PROC VARIOGRAM	OUTACWEIGHTS=
Write distance histogram information	PROC VARIOGRAM	OUTDISTANCE=
Write pairwise point information	PROC VARIOGRAM	OUTPAIR=
Write spatial continuity measures	PROC VARIOGRAM	OUTVAR=
Specify plot display and options	PROC VARIOGRAM	PLOTS
Declaring the Role of Variables		
Specify variables to define analysis subgroups	BY	
Specify the analysis variables	VAR	
Specify the *x*, *y* coordinates in the DATA= data set	COORDINATES	XCOORD= YCOORD=
Controlling Continuity Measure Computations		
Specify the confidence level	COMPUTE	ALPHA=
Specify the angle tolerances for angle classes	COMPUTE	ANGLETOL=
Compute autocorrelation statistics	COMPUTE	AUTOCORRELATION
Specify the bandwidths for angle classes	COMPUTE	BANDWIDTH=
Compute semivariance estimate variance	COMPUTE	CL
Specify the minimum distance that indicates any two distinct points are not collocated	COMPUTE	DEPSILON=
Specify the basic lag distance	COMPUTE	LAGDISTANCE=
Specify the tolerance around the lag distance	COMPUTE	LAGTOLERANCE=
Specify the maximum number of lags in computations	COMPUTE	MAXLAGS=
Specify the number of angle classes	COMPUTE	NDIRECTIONS=
Suppress computation of all continuity measures	COMPUTE	NOVARIOGRAM
Compute robust semivariance	COMPUTE	ROBUST
Controlling Distance Histogram Data Set		
Specify the distance histogram data set	PROC VARIOGRAM	OUTDISTANCE=
Specify the number of histogram classes	COMPUTE	NHCLASSES=
Controlling Pairwise Information Data Set		
Specify the pairwise data set	PROC VARIOGRAM	OUTPAIR=
Specify the maximum distance for the pairwise data set	COMPUTE	OUTPDISTANCE=

PROC VARIOGRAM Statement

PROC VARIOGRAM *options* **;**

You can specify the following options in the PROC VARIOGRAM statement.

DATA=*SAS-data-set*
specifies a SAS data set containing the x and y coordinate variables and the VAR statement variables.

NOPRINT
suppresses the normal display of results. The NOPRINT option is useful when you want only to create one or more output data sets with the procedure. Note that this option temporarily disables the Output Delivery System (ODS); see the section "ODS Graphics" on page 7569 for more information.

OUTACWEIGHTS=*SAS-data-set*
OUTACW=*SAS-data-set*
OUTA=*SAS-data-set*
specifies a SAS data set in which to store the autocorrelation weights information for each pair of points in the DATA= data set. This option should be used with caution when the DATA= data set is large. If n denotes the number of observations in the DATA= data set, the OUTACWEIGHTS= data set contains $[n(n-1)]/2$ observations.

See the section "OUTACWEIGHTS=*SAS-data-set*" on page 7565 for details.

OUTDISTANCE=*SAS-data-set*
OUTDIST=*SAS-data-set*
OUTD=*SAS-data-set*
specifies a SAS data set in which to store summary distance information. This data set contains a count of all pairs of data points within a given distance interval. The number of distance intervals is controlled by the NHCLASSES= option in the COMPUTE statement. The OUTDISTANCE= data set is useful for plotting modified histograms of the count data for determining appropriate lag distances.

See the section "OUTDIST=*SAS-data-set*" on page 7566 for details.

OUTPAIR=*SAS-data-set*
OUTP=*SAS-data-set*
specifies a SAS data set in which to store distance and angle information for each pair of points in the DATA= data set. This option should be used with caution when the DATA= data set is large. If n denotes the number of observations in the DATA= data set, the OUTPAIR= data set contains $[n(n-1)]/2$ observations unless you restrict it with the OUTPDISTANCE= option in the COMPUTE statement. The OUTPDISTANCE= option in the COMPUTE statement excludes pairs of points when the distance between the pairs exceeds the OUTPDISTANCE= value.

See the section "OUTPAIR=*SAS-data-set*" on page 7566 for details.

OUTVAR=*SAS-data-set*

OUTVR=*SAS-data-set*

specifies a SAS data set in which to store the continuity measures.

See the section "OUTVAR=*SAS-data-set*" on page 7567 for details.

PLOTS <(*global-plot-options***) > < = *plot-request* < *(options)* > >**

PLOTS <(*global-plot-options***) > < = (***plot-request* < *(options)* > **< ...** *plot-request* < *(options)* > **>) >**

controls the plots produced through ODS Graphics. When you specify only one plot request, you can omit the parentheses around the plot request. Here are some examples:

```
plots=none
plots=observ
plots=(observ semivar)
plots(unpack)=semivar
plots=(semivar(cla unpack) semivar semivar(rob))
```

You must enable ODS Graphics before requesting plots, for example, like this:

```
ods graphics on;

proc variogram data=thick;
   compute novariogram;
   coordinates xc=East yc=North;
   var Thick;
run;

ods graphics off;
```

For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." If you have enabled ODS Graphics but do not specify the PLOTS= option or have specified PLOTS=ALL, then PROC VARIOGRAM produces a default set of plots, which might be different for different COMPUTE statement options, as discussed in the following.

- If you specify NOVARIOGRAM in the COMPUTE statement, the VARIOGRAM procedure produces a scatter plot of your observations spatial distribution, as well as the histogram of the pairwise distances of your data. For an example of the observations plot, see Figure 95.2. For an example of the pairwise distances plot, see Figure 95.4.
- If you do not specify NOVARIOGRAM in the COMPUTE statement, the VARIOGRAM procedure computes the empirical semivariogram for the specified LAGDISTANCE= and MAXLAGS= options. The observations plot appears by default in this case, too. The VARIOGRAM procedure also produces a plot of the classical empirical semivariogram. If you further specify ROBUST in the COMPUTE statement, then the VARIOGRAM procedure instead produces a plot of both the classical and robust empirical semivariograms, in addition to the observations plot. For an example of the empirical semivariograms plot, see Output 95.3.4.

The *global-plot-options* include the following:

ONLY

suppresses the default plots. Only plots specifically requested are displayed.

UNPACKPANEL

UNPACK

suppresses paneling. By default, multiple plots can appear in some output panels. Specify UNPACKPANEL to get each plot in a separate panel. You can specify PLOTS(UNPACKPANEL) to unpack the default plots. You can also specify UNPACKPANEL as a suboption with the SEMIVAR option.

The following individual *plot-requests* and plot *options* are available:

ALL

produces all appropriate plots. You can specify other options with ALL. For example, to request all default plots and an additional classical empirical semivariogram, specify PLOTS=(ALL SEMIVAR(CLA)).

EQUATE

specifies that all appropriate plots be produced in a way that the axes coordinates have equal size units.

NONE

suppresses all plots.

OBSERVATIONS < (*observations-plot-options*) >

OBSERV < (*observations-plot-options*) >

OBS < (*observations-plot-options*) >

produces the observed data plot. Only one observations plot will be created if you specify the OBSERVATIONS option more than once within a PLOTS option.

The OBSERVATIONS option has the following suboptions:

GRADIENT

specifies that observations be displayed as circles colored by the observed measurement.

OUTLINE

specifies that observations be displayed as circles with a border but with a completely transparent fill.

OUTLINEGRADIENT

is the same as OBSERVATIONS(GRADIENT) except that a border is shown around each observation.

SHOWMISSING

specifies that observations with missing values be displayed in addition to the observations with nonmissing values. By default, missing values locations are not shown on the plot. If you specify multiple instances of the OBSERVATIONS option, and you specify the SHOWMISSING suboption in any of those, then the resulting observations plot will display the observations with missing values.

For the GRADIENT, OUTLINE, and OUTLINEGRADIENT suboptions: The OUTLINEGRADIENT is the default suboption if you do not specify any of those three. If you specify multiple instances of the OBSERVATIONS option or multiple suboptions for OBSERVATIONS, then the resulting observations plot will honor the last specified GRADIENT, OUTLINE, or OUTLINEGRADIENT suboption.

PAIRS < (*pairs-plot-options*) >
specifies that the pairwise distances histogram be produced. By default, the horizontal axis displays the lag class number. The vertical axis shows the frequency (count) of pairs in the lag classes. Notice that the zero lag class width is half the width of the other classes.

The PAIRS option has the following suboptions:

MIDPOINT
MID
specifies that the plot created with the PAIRS option display the lag class midpoint value on the horizontal axis, rather than the default lag class number. The midpoint value is the actual distance of a lag class center from the assumed origin point at distance zero (see also the illustration in Figure 95.14).

NOINSET
NOI
specifies that the plot created with the PAIRS option be produced without the default inset that provides additional information about the pairs distribution.

THRESHOLD=*minimum pairs*
THR=*minimum pairs*
specifies that a reference line appear in the plot created with the PAIRS option to indicate the *minimum pairs* frequency of data pairs. You can use this line as an exploratory tool when you want to select lag classes that contain at least THRESHOLD point pairs. The option helps you to identify visually any portion of the PAIRS distribution that lies below the specified THRESHOLD value.

Only one pairwise distances histogram will be created if you specify the PAIRS option within a PLOTS option. If you specify multiple instances of the PAIRS option, the resulting plot will have the following features:

- If the MIDPOINT or NOINSET suboption has been specified in any of the instances, it will be activated in the resulting plot.
- If you have specified the THRESHOLD= suboption more than once, then the THRESHOLD= value specified last will prevail.

SEMIVARIOGRAM < (*semivar-plot-options*) >
SEMIVAR < (*semivar-plot-options*) >
specifies that the empirical semivariogram plot be produced. You can specify the SEMIVAR option multiple times in the same PLOTS option to request instances of plots with the following *semivar-plot-options*:

ALL | CLASSICAL | ROBUST

ALL | CLA | ROB

specifies a single type of empirical semivariogram (classical or robust) to plot, or specifies that all the available types be included in the same plot. The default is ALL.

UNPACKPANEL

UNPACK

specifies that paneled semivariogram plots be displayed separately. By default, plots appear in a panel, when appropriate.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC VARIOGRAM to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The *variables* are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement options NOTSORTED or DESCENDING in the BY statement for the VARIOGRAM procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

COMPUTE Statement

COMPUTE *computation-options* **;**

The COMPUTE statement provides a number of options that control the computation of the semivariance, the robust semivariance, and the covariance.

ALPHA=*number*

specifies a parameter to obtain the confidence level for constructing confidence limits in the classical empirical semivariance estimation. The value of *number* must be between 0 and 1, and the confidence level is $1-number$. The default is ALPHA=0.05, which corresponds to the default confidence level of 95%. If the CL option is not specified, ALPHA= is ignored.

ANGLETOLERANCE=*angle tolerance*

ANGLETOL=*angle tolerance*

ATOL=*angle tolerance*

specifies the tolerance, in degrees, around the angles determined by the NDIRECTIONS= specification. The default is $180^\circ/(2n_d)$, where n_d is the NDIRECTIONS= specification. If you do not specify the NDIRECTIONS= option or the DIRECTIONS statement, ANGLETOLERANCE= is ignored.

See the section "Theoretical and Computational Details of the Semivariogram" on page 7544 for further information.

Experimental

AUTOCORRELATION < (*autocorrelation-options***) >**

AUTOCORR < (*autocorrelation-options***) >**

AUTOC < (*autocorrelation-options***) >**

specifies that autocorrelation statistics be calculated. You can further specify the following *autocorrelation-options* in parentheses following the experimental AUTOCORRELATION option.

ASSUMPTION < = *assumption-options* >

ASSUM < = *assumption-options* >

specifies the type of autocorrelation assumption to use. The *assumption-options* can be one of the following:

NORMALITY | NORMAL | NOR

specifies use of the normality assumption.

RANDOMIZATION | RANDOM | RAN

specifies use of the randomization assumption.

The default is ASSUMPTION=NORMALITY.

STATISTICS < = (*stats-options*) >

STATS < = (*stats-options*) >

specifies the autocorrelation statistics in detail. The *stats-options* can be one or more of the following:

ALL

applies all available types of autoregression statistics.

GEARY | GEA

specifies use of the Geary c statistics.

MORAN | MOR

specifies use of the Moran I statistics.

The default is STATISTICS=ALL.

WEIGHTS < = *weights-options* >

WEI < = *weights-options* >

specifies the scheme used for the computation of the autocorrelation weights. You can choose one of the following *weights-options*:

BINARY < (*binary-option*) >

specifies that binary weights be used. You also have the following *binary-option*:

ROWAVERAGING | ROWAVG | ROW

specifies that asymmetric autocorrelation weights be assigned to data pairs. For each observation, if there are nonzero weights, the ROWAVG option standardizes those weights so that they sum to 1. No row averaging is performed by default.

DISTANCE < (*distance-options*) >

specifies that autocorrelation weights be assigned based on the point pair distances. You also have the following *distance-options*:

NORMALIZE | NORMAL | NOR

specifies that normalized pair distances be used in the distance-based weights expression. The distances are normalized with respect to the maximum pairwise distance h_b, as it is defined in the section "Computation of the Distribution Distance Classes" on page 7553. By default, nonnormalized values are used in the computations.

POWER | POW

specifies the power to which the pair distance is raised in the distance-based weights expression. POWER is a nonnegative number, and its default value is POWER=1.

ROWAVERAGING | ROWAVG | ROW

specifies that asymmetric autocorrelation weights be assigned to data pairs. For each observation, if there are nonzero weights, the ROWAVG option standardizes those weights so that they sum to 1. No row averaging is performed by default.

SCALE | SCA

specifies the scaling factor in the distance-based weights expression. SCALE is a nonnegative number, and its default value is SCALE=1.

The default is WEIGHTS=BINARY. See the section "Autocorrelation Statistics (Experimental)" on page 7560 for further details about the autocorrelation weights.

When you specify the AUTOCORRELATION option with no *autocorrelation-options*, PROC VARIOGRAM computes by default both the Moran I and Geary c statistics with p-values computed under the normality assumption with binary weights.

If you specify more than one ASSUMPTION in the *autocorrelation-options*, all but the last specified ASSUMPTION will be ignored. The same holds if you specify more than one POWER= or SCALE= parameter in the WEIGHT=DISTANCE *distance-options*.

If you specify the WEIGHT=BINARY option in the AUTOCORRELATION option and the NOVARIOGRAM option at the same time, then you must also specify the LAGDISTANCE= option in the COMPUTE statement. See the section "Autocorrelation Weights" on page 7560 for more information.

BANDWIDTH=*bandwidth distance*

BANDW=*bandwidth distance*

specifies the bandwidth, or perpendicular distance cutoff for determining the angle class for a given pair of points. The distance classes define a series of cylindrically shaped areas, while the angle classes radially cut these cylindrically shaped areas. For a given angle class $(\theta_1 - \delta\theta_1, \theta_1 + \delta\theta_1)$, as you proceed out radially, the area encompassed by this angle class becomes larger. The BANDWIDTH= option restricts this area by excluding all points with a perpendicular distance from the line $\theta = \theta_1$ that is greater than the BANDWIDTH= value. See Figure 95.15 for a visual representation of the bandwidth.

If you do not specify the BANDWIDTH= option, no restriction occurs. If you do not specify the NDIRECTIONS= option or the DIRECTIONS statement, BANDWIDTH= is ignored.

CL

requests confidence limits for the classical semivariance estimate. The confidence limits' lower bound is always nonnegative, adhering to the behavior of the theoretical semivariance. You can control the confidence level with the ALPHA= option.

DEPSILON=*distance value*

DEPS=*distance value*

specifies the distance value for declaring that two distinct points are zero distance apart. Such pairs, if they occur, cause numeric problems. If you specify DEPSILON=$\Delta\varepsilon$, then pairs of points P_1 and P_2 for which the distance between them $\mid P_1P_2 \mid < \Delta\varepsilon$ are excluded from the continuity measure calculations. The default value of the DEPSILON= option is 100 times the machine precision; this product is approximately 1E–10 on most computers.

LAGDISTANCE=*distance unit*

LAGDIST=*distance unit*

LAGD=*distance unit*

specifies the basic distance unit defining the lags. For example, a specification of LAGDISTANCE=x results in lag distance classes that are multiples of x. For a given pair of points P_1 and P_2, the distance between them, denoted $\mid P_1P_2 \mid$, is calculated. If $\mid P_1P_2 \mid = x$, then this pair is in the first lag class. If $\mid P_1P_2 \mid = 2x$, then this pair is in the second lag class, and so on.

For irregularly spaced data, the pairwise distances are unlikely to fall exactly on multiples of the LAGDISTANCE= value. A distance tolerance of δx is used to accommodate a spread of distances around multiples of x (the LAGTOLERANCE= option specifies the distance tolerance). For example, if $\mid P_1P_2 \mid$ is within $x \pm \delta x$, you would place this pair in the first lag class; if $\mid P_1P_2 \mid$ is within $2x \pm \delta x$, you would place this pair in the second lag class, and so on.

You can experiment and determine the candidate values for the LAGDISTANCE= option by plotting the pairwise distance histogram for different numbers of histogram classes, using the NHC= option.

A LAGDISTANCE= value is required for the semivariance and the autocorrelation computations. You need not specify LAGDISTANCE= only when you specify the NOVARIOGRAM option without the AUTOCORRELATION option.

See the section "Theoretical and Computational Details of the Semivariogram" on page 7544 for more information.

LAGTOLERANCE=*tolerance number*

LAGTOL=*tolerance number*

LAGT=*tolerance number*

specifies the tolerance around the LAGDISTANCE= value for grouping distance pairs into lag classes. See the description of the LAGDISTANCE= option for information about the use of the LAGTOLERANCE= option, and the section "Theoretical and Computational Details of the Semivariogram" on page 7544 for more details.

If you do not specify the LAGTOLERANCE= option, a default value of $\frac{1}{2}$ times the LAGDISTANCE= value is used.

MAXLAGS=*number of lags*

MAXLAG=*number of lags*

MAXL=*number of lags*

specifies the maximum number of lag classes used in constructing the continuity measures. This option excludes any pair of points P_1 and P_2 for which the distance between them, $| P_1 P_2 |$, exceeds the MAXLAGS= value times the LAGDISTANCE= value.

You can determine candidate values for the MAXLAGS= option by plotting or displaying the OUTDISTANCE= data set.

A MAXLAGS= value is required unless you specify the NOVARIOGRAM option.

NDIRECTIONS=*number of directions*

NDIR=*number of directions*

ND=*number of directions*

specifies the number of angle classes to use in computing the continuity measures. This option is useful when there is potential anisotropy in the spatial continuity measures. Anisotropy is a field property where the characterization of spatial continuity depends on the data pair orientation (or angle between the N–S direction and the axis defined by the data pair). Isotropy is the absence of this effect; that is, the description of spatial continuity depends only on the distance between the points, not the angle.

The angle classes formed from the NDIRECTIONS= option start from N–S and proceed clockwise. For example, NDIRECTIONS=3 produces three angle classes. In terms of compass points, these classes are centered at 0° (or its reciprocal, 180°), 60° (or its reciprocal, 240°), and 120° (or its reciprocal, 300°). For irregularly spaced data, the angles between pairs are unlikely to fall exactly in these directions, so an angle tolerance of $\delta\theta$ is used (the ANGLETOLERANCE= option specifies the angle tolerance). If NDIRECTIONS=n_d, the base angle is $\theta = 180°/n_d$, and the angle classes are

$$(k\theta - \delta\theta, k\theta + \delta\theta) \quad k = 0, \ldots, n_d - 1$$

If you do not specify the NDIRECTIONS= option, no angles are formed. This is the omnidirectional case where the spatial continuity measures are assumed to be isotropic.

The NDIRECTIONS= option is useful for exploring possible anisotropy. The DIRECTIONS statement, described in the section "DIRECTIONS Statement" on page 7539, provides greater control over the angle classes.

See the section "Theoretical and Computational Details of the Semivariogram" on page 7544 for more information.

NHCLASSES=*number of histogram classes*

NHCLASS=*number of histogram classes*

NHC=*number of histogram classes*

specifies the number of distance classes to consider in the spatial domain in the exploratory stage of the empirical semivariogram computation. The actual number of classes is one more than the NHCLASSES= value, since a special lag zero class is also computed. The NHC= option is used to produce the distance intervals table, the histogram of pairwise distances, and the OUTDISTANCE= data set. See the OUTDISTANCE= option as well as the section "OUTDIST=*SAS-data-set*" on page 7566 and the section "Theoretical and Computational Details of the Semivariogram" on page 7544 for more information.

The default value of the NHCLASSES= option is 10.

NOVARIOGRAM

prevents the computation of the continuity measures. This option is useful for preliminary analysis, or when you require only the OUTDISTANCE= or OUTPAIR= data sets.

OUTPDISTANCE=*distance limit*

OUTPDIST=*distance limit*

OUTPD=*distance limit*

specifies the cutoff distance for writing observations to the OUTPAIR= data set. If you specify OUTPDISTANCE=d_{max}, the distance $\mid P_1 P_2 \mid$ between each pair of points P_1 and P_2 is checked against d_{max}. If $\mid P_1 P_2 \mid > d_{max}$, the observation for this pair is not written to the OUTPAIR= data set. If you do not specify the OUTPDISTANCE= option, all distinct pairs are written. This option is ignored if you do not specify an OUTPAIR= data set.

ROBUST

requests that a robust version of the semivariance be calculated in addition to the classical semivariance.

COORDINATES Statement

COORDINATES *coordinate-variables* **;**

The following two options give the names of the variables in the DATA= data set containing the values of the x and y coordinates of the data.

Only one COORDINATES statement is allowed, and it is applied to all the analysis variables. In other words, it is assumed that all the VAR variables have the same x and y coordinates.

XCOORD=*(variable-name)*

XC=*(variable-name)*

X=*(variable-name)*

gives the name of the variable containing the x coordinate of the data in the DATA= data set.

YCOORD=*(variable-name)*

YC=*(variable-name)*

Y=*(variable-name)*

gives the name of the variable containing the y coordinate of the data in the DATA= data set.

DIRECTIONS Statement

DIRECTIONS *directions-list* **;**

You use the DIRECTIONS statement to define angle classes. You can specify angle classes as a list of angles, separated by commas, with optional angle tolerances and bandwidths within parentheses following the angle. You must specify at least one angle.

If you do not specify the optional angle tolerance, the default value of 45° is used. If you do not specify the optional bandwidth, no bandwidth is checked. If you specify a bandwidth, you must also specify an angle tolerance.

For example, suppose you want to compute three separate semivariograms at angles $\theta_1 = 0°, \theta_2 = 60°$, and $\theta_3 = 120°$, with corresponding angle tolerances $\delta\theta_1 = 22.5°, \delta\theta_2 = 12.5°$, and $\delta\theta_3 = 22.5°$, with bandwidths 50 and 40 distance units on the first two angle classes and no bandwidth check on the last angle class.

The appropriate DIRECTIONS statement is as follows:

```
directions 0.0(22.5,50), 60.0(12.5,40),120(22.5);
```

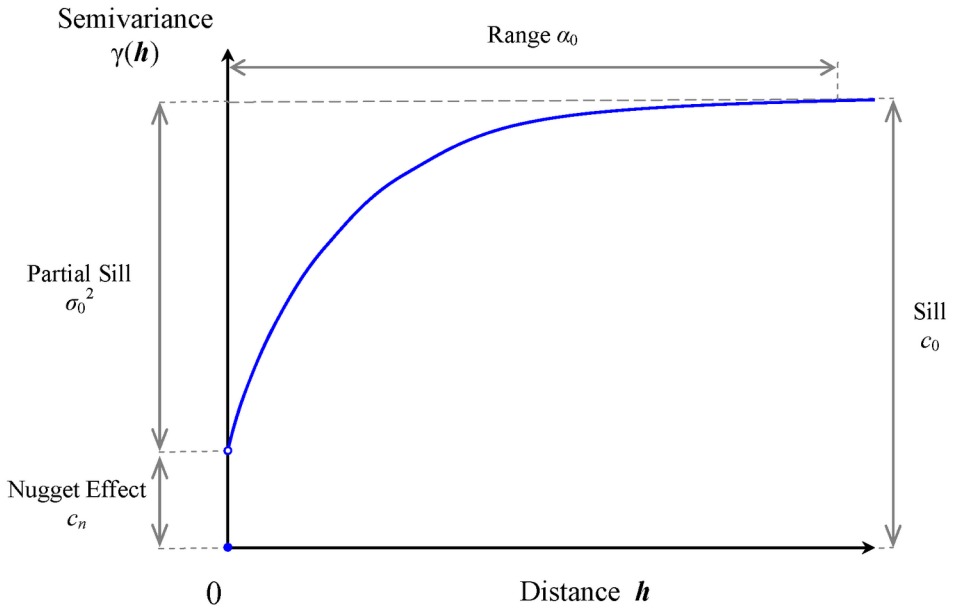
VAR Statement

VAR *analysis-variables-list* **;**

Use the VAR statement to specify the analysis variables. You can specify only numeric variables. If you do not specify a VAR statement, all numeric variables in the DATA= data set that are not in the COORDINATES statement are used.

Details: VARIOGRAM Procedure

Theoretical Semivariogram Models



The VARIOGRAM procedure computes the empirical (also known as *sample* or *experimental*) semivariogram from a set of point measurements. Semivariograms are used in the first steps of spatial prediction as tools that provide insight into the spatial continuity and structure of a random process. Naturally occurring randomness is accounted for by describing a process in terms of the *spatial random field* (SRF) concept (Christakos 1992). An SRF is a collection of random variables throughout your spatial domain of prediction. For some of them you already have measurements, and your data set constitutes part of a single realization of this SRF. Based on your sample, spatial prediction aims to provide you with values of the SRF at locations where no measurements are available.

Prediction of the SRF values at unsampled locations by techniques such as ordinary kriging requires the use of a theoretical semivariogram or covariance model. Due to the randomness involved in stochastic processes, the theoretical semivariance cannot be computed. Instead, it is possible that the empirical semivariance can provide an estimate of the theoretical semivariance, which can then be used to characterize the spatial structure of the process.

It is critical to note that the empirical semivariance provides an estimate of its theoretical counterpart only when the SRF satisfies stationarity conditions. These conditions imply that the SRF has a constant (or zero) expected value. Consequently, your data need to be sampled from a trend-free random field and need to have a constant mean, as assumed in "Example 95.1: Theoretical Semivariogram Model Fitting" on page 7570. Equivalently, your data could be residuals of an initial sample that has had a surface trend removed, as portrayed in "Example 95.2: An Anisotropic Case Study with Surface Trend in the Data" on page 7574. For a closer look at stationarity, see the section "Stationarity" on page 7546. For details about different stationarity types and conditions see, for example, Chilès and Delfiner (1999, Section 1.1.4).

When you obtain a valid empirical estimate of the theoretical semivariance, it is then necessary to choose a type of theoretical semivariogram model based on that estimate. Commonly used theoretical semivariogram shapes rise monotonically as a function of distance. The shape is typically characterized in terms of particular parameters; these are the *range* a_0, the *sill* (or *scale*) c_0, and the *nugget effect* c_n. Figure 95.9 displays a theoretical semivariogram of a spherical semivariance model, and points out the semivariogram characteristics.

Figure 95.9 A Theoretical Semivariogram of Spherical Type and Its Characteristics

Specifically, the sill is the semivariogram upper bound. The range a_0 denotes the distance at which the semivariogram reaches the sill. When the semivariogram increases asymptotically toward its sill value, as occurs in the exponential and Gaussian semivariogram models, the term *effective* (or *practical*) range is also used. The effective range r_ϵ is defined as the distance at which the semivariance value achieves 95% of the sill. In particular, for these models the relationship between the range and effective range is $r_\epsilon = 3a_0$ (exponential model) and $r_\epsilon = \sqrt{3}a_0$ (Gaussian model).

The nugget effect c_n represents a discontinuity of the semivariogram that can be present at the origin. It is typically attributed to microscale effects or measurement errors. The semivariance is always 0 at distance $\boldsymbol{h} = 0$; hence, the nugget effect demonstrates itself as a jump in the semivariance as soon as $\boldsymbol{h} > 0$ (note in Figure 95.9 the discontinuity of the function at $\boldsymbol{h} = 0$ in the presence of a nugget effect).

The sill c_0 comprises the nugget effect, if present, and the *partial sill* ${\sigma_0}^2$; that is, $c_0 = c_n + {\sigma_0}^2$. If the SRF $Z(\boldsymbol{s})$ is second-order stationary (see the section "Stationarity" on page 7546), the estimate of the sill is an estimate of the constant variance $\mathrm{Var}[Z(\boldsymbol{s})]$ of the field. Nonstationary processes have variances that depend on the location $\boldsymbol{s}$. Their semivariance increases with distance, hence their semivariograms do not have a sill.

Not every function is a suitable candidate for a theoretical semivariogram model. The semivariance function $\gamma_z(\boldsymbol{h})$, as defined in the following section, is a so-called *conditionally negative-definite* function that satisfies (Cressie 1993, p. 60)

$$\sum_{i=1}^{m}\sum_{j=i}^{m} q_i q_j \gamma_z(\boldsymbol{s}_i - \boldsymbol{s}_j) \leq 0$$

for any number m of locations $\boldsymbol{s}_i$, $\boldsymbol{s}_j$ in $\mathcal{R}^2$ with $\boldsymbol{h} = \boldsymbol{s}_i - \boldsymbol{s}_j$, and any real numbers q_i such that $\sum_{i=1}^{m} q_i = 0$. Permissible, commonly used theoretical semivariogram models include the ones shown in Table 95.2.

Table 95.2 Some Permissible Theoretical Semivariogram Models ($a_0 > 0$)

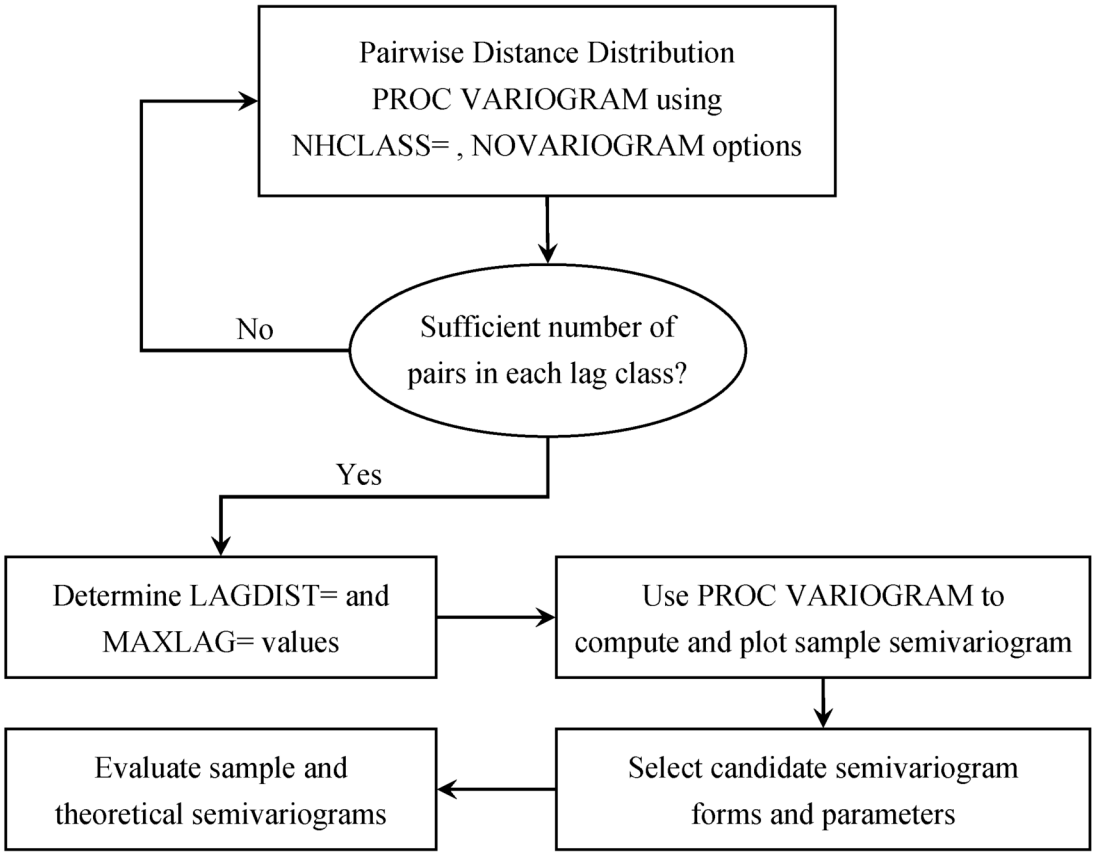
Model Type	Semivariance
Exponential	$\gamma_z(\boldsymbol{h}) = \begin{cases} 0 & , \text{if } \mid \boldsymbol{h} \mid = 0 \\ c_n + {\sigma_0}^2 \left[1 - \exp\left(-\frac{\mid \boldsymbol{h} \mid}{a_0}\right)\right] & , \text{if } 0 < \mid \boldsymbol{h} \mid \end{cases}$
Gaussian	$\gamma_z(\boldsymbol{h}) = \begin{cases} 0 & , \text{if } \mid \boldsymbol{h} \mid = 0 \\ c_n + {\sigma_0}^2 \left[1 - \exp\left(-\frac{\mid \boldsymbol{h} \mid^2}{a_0^2}\right)\right] & , \text{if } 0 < \mid \boldsymbol{h} \mid \end{cases}$
Power	$\gamma_z(\boldsymbol{h}) = \begin{cases} 0 & , \text{if } \mid \boldsymbol{h} \mid = 0 \\ c_n + {\sigma_0}^2 \boldsymbol{h}^{a_0} & , \text{if } 0 < \mid \boldsymbol{h} \mid \end{cases}$
Spherical	$\gamma_z(\boldsymbol{h}) = \begin{cases} 0 & , \text{if } \mid \boldsymbol{h} \mid = 0 \\ c_n + {\sigma_0}^2 \left[\frac{3}{2}\frac{\mid \boldsymbol{h} \mid}{a_0} - \frac{1}{2}\left(\frac{\mid \boldsymbol{h} \mid}{a_0}\right)^3\right] & , \text{if } 0 < \mid \boldsymbol{h} \mid \leq a_0 \\ c_0, & , \text{if } a_0 < \mid \boldsymbol{h} \mid \end{cases}$

You can review these models in further detail in the section "Theoretical Semivariogram Models" on page 2947 in the KRIGE2D procedure documentation.

The theoretical semivariogram models are used to describe the spatial structure of random processes. Based on their shape and characteristics, the semivariograms of these models can provide a plethora of information (Christakos 1992, Section 7.3):

- Examination of the semivariogram variation in different directions provides information about the isotropy of the random process (see also the discussion about isotropy in the following section).
- The semivariogram range determines the zone of influence extending from any given location. Values at surrounding locations within this zone are correlated with the value at the specific location by means of the particular semivariogram.
- The semivariogram behavior at large distances indicates the degree of stationarity of the process. In particular, an asymptotic behavior suggests a stationary process, whereas either a linear increase and slow convergence to the sill or a fast increase is an indicator of nonstationarity.
- The semivariogram behavior close to the origin indicates the degree of regularity of the process variation. Specifically, a parabolic behavior at the origin implies a very regular spatial variation, whereas a linear behavior characterizes a nonsmooth process. The presence of a nugget effect is additional evidence of irregularity in the process.
- The semivariogram behavior within the range provides description of potential periodicities or anomalies in the spatial process.

A brief note on terminology: In some fields (for example, geostatistics) the term homogeneity is sometimes used instead of stationarity in spatial analysis, whereas in statistics homogeneity is defined differently (Banerjee, Carlin, and Gelfand 2004, Section 2.1.3). In particular, the alternative terminology characterizes as homogeneous the stationary SRF in $\mathcal{R}^n, n > 1$, whereas it retains the term stationary for such SRF in $\mathcal{R}^1$ (SRF in $\mathcal{R}^1$ are also known as *random processes*). Often, studies in a single dimension refer to temporal processes; hence, you might see time-stationary random processes called "temporally stationary" or simply stationary, and stationary SRF in $\mathcal{R}^n, n > 1$, characterized as "spatially homogeneous" or simply homogeneous. This distinction made by the alternative nomenclature is more evident in spatiotemporal random fields (S/TRF), where the different terms clarify whether stationarity applies in the spatial or the temporal part of the S/TRF.



Typically, you choose a theoretical semivariogram model to fit the empirical semivariance in an automated manner. For this task you can use methods such as least squares, maximum likelihood, and robust methods (Cressie 1993, Section 2.6). "Example 95.1: Theoretical Semivariogram Model Fitting" on page 7570 illustrates the fitting process by using ordinary and weighted least squares methods. A different approach is manual fitting, where a theoretical semivariogram model is chosen based on visual inspection of the empirical semivariogram; see, for example, Hohn (1988, p. 25).

In some cases, you might see that using a combination of theoretical models results in a more accurate fit onto the empirical semivariance than using a single model. This is known as model nesting. Nested models, anisotropic models, and the nugget effect increase the scope of theoretical models available. All these concepts are discussed in the section "Theoretical Semivariogram Models" on page 2947 in the KRIGE2D procedure documentation.

Overall, Goovaerts (1997, Section 4.2.4) suggests that fitting a theoretical model should aim to capture the major spatial features. An accurate fit is desirable, but overfitting does not offer advantages, because you might find yourself trying to model possibly spurious details of the empirical semivariogram.

Note the general flow of investigation. The empirical semivariogram is computed after a suitable choice is made for the LAGDISTANCE= and MAXLAGS= options. For computations in more than one directions you can further use the NDIR= option or the DIRECTIONS statement. Potential theoretical models (which can also incorporate nesting, anisotropy, and the nugget effect) are then plotted against the empirical semivariogram and evaluated. The flow of this analytical process is illustrated in Figure 95.10. After a suitable theoretical model is determined, it is used in PROC KRIGE2D for the prediction stage. The prediction analysis is presented in detail in the section "Details of Ordinary Kriging" on page 2962 in the KRIGE2D procedure documentation.

Figure 95.10 Flowchart for Variogram Selection

Theoretical and Computational Details of the Semivariogram

Let $\{Z(\boldsymbol{s}), \boldsymbol{s} \in D \subset \mathcal{R}^2\}$ be a spatial random field (SRF) with n measured values $z_i = Z(\boldsymbol{s}_i)$ at respective locations $\boldsymbol{s}_i$, $i = 1, \ldots, n$. You use the VARIOGRAM procedure because you want to gain insight into the spatial continuity and structure of $Z(\boldsymbol{s})$. A good measure of the spatial continuity of $Z(\boldsymbol{s})$ is defined by means of the variance of the difference $Z(\boldsymbol{s}_i) - Z(\boldsymbol{s}_j)$, where $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$ are locations in D. Specifically, if you consider $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$ to be spatial increments such that $\boldsymbol{h} = \boldsymbol{s}_j - \boldsymbol{s}_i$, then the variance function based on the increments $\boldsymbol{h}$ is independent of the actual locations $\boldsymbol{s}_i, \boldsymbol{s}_j$. Most commonly, the continuity measure used in practice is one half of this variance, better known as the *semivariance* function:

$$\gamma_z(\boldsymbol{h}) = \frac{1}{2}\mathrm{Var}[Z(\boldsymbol{s}+\boldsymbol{h}) - Z(\boldsymbol{s})]$$

or, equivalently,

$$\gamma_z(\boldsymbol{h}) = \frac{1}{2}\left(\mathrm{E}\{[Z(\boldsymbol{s}+\boldsymbol{h}) - Z(\boldsymbol{s})]^2\} - \{\mathrm{E}[Z(\boldsymbol{s}+\boldsymbol{h})] - \mathrm{E}[Z(\boldsymbol{s})]\}^2\right)$$

The plot of semivariance as a function of $\boldsymbol{h}$ is the *semivariogram*. In extension to its meaning, you might commonly see the term *semivariogram* used instead of the term *semivariance*, as well.

Assume that the SRF $Z(\boldsymbol{s})$ is free of nonrandom (or systematic) surface trends. Then, the expected value $\mathrm{E}[Z(\boldsymbol{s})]$ of $Z(\boldsymbol{s})$ will be a constant for all $\boldsymbol{s} \in \mathcal{R}^2$, and the semivariance expression is simplified to the following:

$$\gamma_z(\boldsymbol{h}) = \frac{1}{2}\mathrm{E}\{[Z(\boldsymbol{s}+\boldsymbol{h}) - Z(\boldsymbol{s})]^2\}$$

Given the preceding assumption, you can compute an estimate $\hat{\gamma}_z(\boldsymbol{h})$ of the semivariance $\gamma_z(\boldsymbol{h})$ from a finite set of points in a practical way by using the formula

$$\hat{\gamma}_z(\boldsymbol{h}) = \frac{1}{2 \mid N(\boldsymbol{h}) \mid} \sum_{N(\boldsymbol{h})} [Z(\boldsymbol{s}_i) - Z(\boldsymbol{s}_j)]^2$$

where the sets $N(\boldsymbol{h})$ contain all the neighboring pairs at distance $\boldsymbol{h}$:

$$N(\boldsymbol{h}) = \{i, j : \boldsymbol{s}_i - \boldsymbol{s}_j = \boldsymbol{h}\}$$

and $\mid N(\boldsymbol{h}) \mid$ is the number of such pairs (i, j).

The expression for $\hat{\gamma}_z(\boldsymbol{h})$ is called the *empirical semivariance* (Matheron 1963). This is the quantity that PROC VARIOGRAM computes, and its corresponding plot is the *empirical semivariogram*. According to Cressie (1993, p. 96), the estimate $\hat{\gamma}_z(\boldsymbol{h})$ has approximate variance

$$\mathrm{Var}[\hat{\gamma}_z(\boldsymbol{h})] \simeq \frac{2[\gamma_z(\boldsymbol{h})]^2}{N(\boldsymbol{h})}$$

The empirical semivariance $\hat{\gamma}_z(\boldsymbol{h})$ is also referred to as *classical*. This name is used so that it can be distinguished from the *robust semivariance* estimate $\bar{\gamma}_z(\boldsymbol{h})$ and the corresponding *robust semivariogram*. The robust semivariance was introduced by Cressie and Hawkins (1980) and is described by Cressie (1993, p. 75) as:

$$\bar{\gamma}_z(\boldsymbol{h}) = \frac{\Psi^4(\boldsymbol{h})}{2[0.457 + 0.494/N(\boldsymbol{h})]}$$

In the preceding expression the parameter $\Psi(\boldsymbol{h})$ is defined as:

$$\Psi(\boldsymbol{h}) = \frac{1}{N(\boldsymbol{h})} \sum_{P_i P_j \in N(\boldsymbol{h})} [Z(\boldsymbol{s}_i) - Z(\boldsymbol{s}_j)]^{\frac{1}{2}}$$

Note that if your data include a surface trend, then the empirical semivariance $\hat{\gamma}_z(\boldsymbol{h})$ is not an estimate of the theoretical semivariance function $\gamma_z(\boldsymbol{h})$. Instead, rather than the spatial increments variance, it represents a different quantity known as *pseudo-semivariance*, and its corresponding plot is a *pseudo-semivariogram*. In principle, pseudo-semivariograms do not provide measures of the spatial continuity. They can thus lead to misinterpretations of the $Z(\boldsymbol{s})$ spatial structure, and are consequently unsuitable for the purpose of spatial prediction. For further information, see the detailed discussion in the section "Empirical Semivariograms and Surface Trends" on page 7559. Under certain conditions you might be able to gain some insight about the spatial continuity with a pseudo-semivariogram. This case is presented in "Example 95.3: Analysis without Surface Trend Removal" on page 7587.

Stationarity

In the combined presence of the previous two assumptions—that is, when $\mathrm{E}[Z(\boldsymbol{s})]$ is constant and spatial increments are used to define $\gamma_z(\boldsymbol{h})$—the SRF $Z(\boldsymbol{s})$ is characterized as *intrinsically stationary* (Cressie 1993, p. 40).

The expected value $\mathrm{E}[Z(\boldsymbol{s})]$ is the first statistical moment of the SRF $Z(\boldsymbol{s})$. The second statistical moment of the SRF $Z(\boldsymbol{s})$ is the *covariance* function between two points $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$ in $Z(\boldsymbol{s})$, and it is defined as

$$C_z(\boldsymbol{s}_i, \boldsymbol{s}_j) = \mathrm{E}\left([Z(\boldsymbol{s}_i) - \mathrm{E}[Z(\boldsymbol{s}_i)]]\left[Z(\boldsymbol{s}_j) - \mathrm{E}[Z(\boldsymbol{s}_j)]\right]\right)$$

Note that when $\boldsymbol{s}_i = \boldsymbol{s}_j = \boldsymbol{s}$, the covariance expression provides the variance at $\boldsymbol{s}$.

The assumption of a constant $\mathrm{E}[Z(\boldsymbol{s})] = m$ means that the expected value is invariant with respect to translations of the spatial location $\boldsymbol{s}$. The covariance is considered invariant to such translations when it depends only on the distance $\boldsymbol{h} = \boldsymbol{s}_i - \boldsymbol{s}_j$ between any two points $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$. If both of these conditions are true, then the preceding expression becomes

$$C_z(\boldsymbol{s}_i, \boldsymbol{s}_j) = C_z(\boldsymbol{s}_i - \boldsymbol{s}_j) = C_z(\boldsymbol{h}) = \mathrm{E}\left([Z(\boldsymbol{s}) - m][Z(\boldsymbol{s} + \boldsymbol{h}) - m]\right)$$

When both $\mathrm{E}[Z(\boldsymbol{s})]$ and $C(\boldsymbol{s}_i, \boldsymbol{s}_j)$ are invariant to spatial translations, the SRF $Z(\boldsymbol{s})$ is characterized as *second-order stationary* (Cressie 1993, p. 53).

In a second-order stationary SRF the quantity $C(\boldsymbol{h})$ is the same for any two points that are separated by distance $\boldsymbol{h}$. Based on the preceding formula, for $\boldsymbol{h} = 0$ you can see that the variance is constant throughout a second-order stationary SRF. Hence, second-order stationarity is a stricter condition than intrinsic stationarity.

Under the assumption of second-order stationarity, the semivariance definition at the beginning of this section leads to the conclusion that

$$\gamma_z(\boldsymbol{h}) = C(\mathbf{0}) - C(\boldsymbol{h})$$

which relates the theoretical semivariance and covariance. Note that the empirical estimates of these quantities are not related in exactly the same way, as indicated in Schabenberger and Gotway (2005, Section 4.2.1).

Ergodicity

In addition to the constant $\mathrm{E}[Z(\boldsymbol{s})]$ and the assumption of intrinsic stationarity, *ergodicity* is a necessary third hypothesis to estimate the empirical semivariance. Assume that for the SRF $Z(\boldsymbol{s})$ you have measurements z_i whose sample mean is estimated by $\bar{Z}$. The hypothesis of ergodicity dictates that $\bar{Z} = \mathrm{E}[Z(\boldsymbol{s})]$.

In general, an SRF $Z(\boldsymbol{s})$ is characterized as ergodic if the statistical moments of its realizations coincide with the corresponding ones of the SRF. In spatial analysis we are often interested in the first two statistical moments, and consequently a more relaxed ergodicity assumption is made only for them. See Christakos (1992, Section 2.12) for the use of the ergodicity hypothesis in SRF, and Cressie (1993, p. 57) for a more detailed discussion of ergodicity.

The semivariogram analysis makes implicit use of the ergodicity hypothesis. The VARIOGRAM procedure works with the residual centered values $V(\boldsymbol{s}_i) = v_i = z_i - \bar{Z}, i = 1, \ldots, n$, where it is assumed that the sample mean $\bar{Z}$ is the constant expected value $\mathrm{E}[Z(\boldsymbol{s})]$ of $Z(\boldsymbol{s})$. This is equivalent to using the original values, since $V(\boldsymbol{s}_i) - V(\boldsymbol{s}_j) = Z(\boldsymbol{s}_i) - Z(\boldsymbol{s}_j)$, which shows the property of the semivariance to filter out the mean. See the section "Semivariance Computation" on page 7558 for the exact expressions PROC VARIOGRAM uses to compute the empirical classical $\hat{\gamma}_z(\boldsymbol{h})$ and robust $\bar{\gamma}_z(\boldsymbol{h})$ semivariances.

Anisotropy

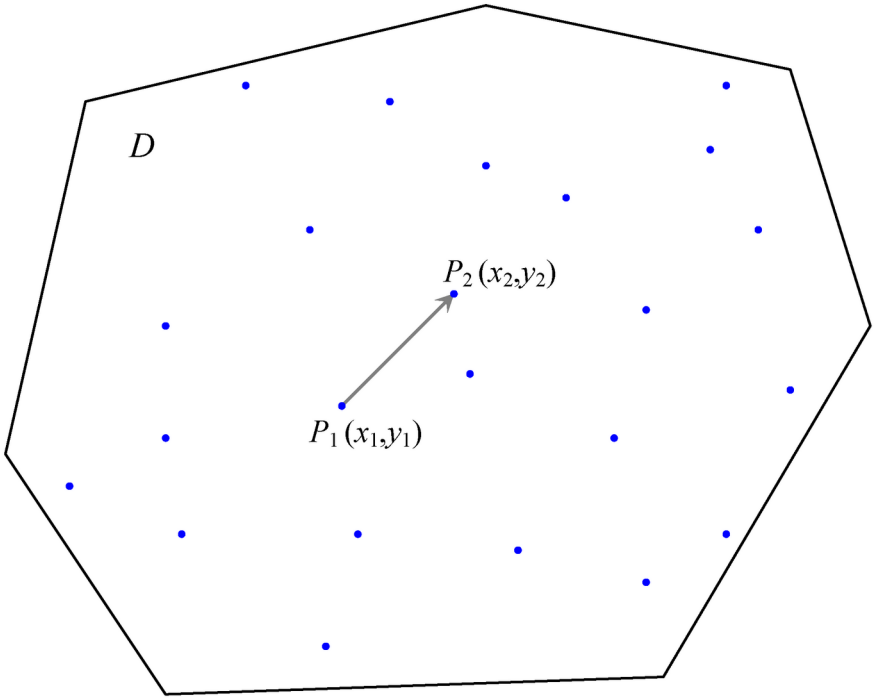
Semivariance is defined on the basis of the spatial increment vector $\boldsymbol{h}$. If the variance characteristics of $Z(\boldsymbol{s})$ are independent of the spatial direction, then $Z(\boldsymbol{s})$ is called *isotropic*; if not, then $Z(\boldsymbol{s})$ is called *anisotropic*. In the case of isotropy, the semivariogram depends only on the length h of $\boldsymbol{h}$ and $\gamma_z(\boldsymbol{h}) = \gamma_z(h)$. Anisotropy is characterized as *geometric*, when the range a_0 of the semivariogram varies in different directions, and *zonal*, when the semivariogram sill c_0 depends on the spatial direction. Either type or both types of anisotropy can be present.

In the more general case, an SRF can be anisotropic. For an accurate characterization of the spatial structure it is necessary to perform individual analyses in multiple directions. Goovaerts (1997, p. 98) suggests an initial investigation in at least one direction more than the working spatial dimensions—for example, at least three different directions in $\mathcal{R}^2$. Olea (2006) supports exploring as many directions as possible when the data set allows.

You might not know in advance whether you have anisotropy or not. If the semivariogram characteristics do not change in different directions, then you assume the SRF is isotropic. If your directional analysis reveals anisotropic behavior in particular directions, then you proceed to focus your analysis on these directions. For example, in an anisotropic SRF in $\mathcal{R}^2$ you should expect to find two distinct directions where you observe the *major axis* and the *minor axis* of anisotropy. The major axis direction is the one in which the semivariogram has maximum range, and hence has the strongest spatial continuity. Conversely, in the minor axis direction the SRF has minimum range and the weakest spatial continuity. See "Example 95.2: An Anisotropic Case Study with Surface Trend in the Data" on page 7574 for a detailed demonstration of a case with anisotropy when you are using PROC VARIOGRAM.

You can find some additional information about anisotropy analysis in the section "Anisotropic Models" on page 2955 in the KRIGE2D procedure documentation.

Pair Formation



The basic starting point in computing the empirical semivariance is the enumeration of pairs of points for the spatial data. Figure 95.11 shows the spatial domain D and the set of n measurements z_i, $i = 1, \ldots, n$, that have been sampled at the indicated locations in D. Two data points P_1 and P_2, with coordinates $\boldsymbol{s}_1 = (x_1, y_1)$ and $\boldsymbol{s}_2 = (x_2, y_2)$, respectively, are selected for illustration.

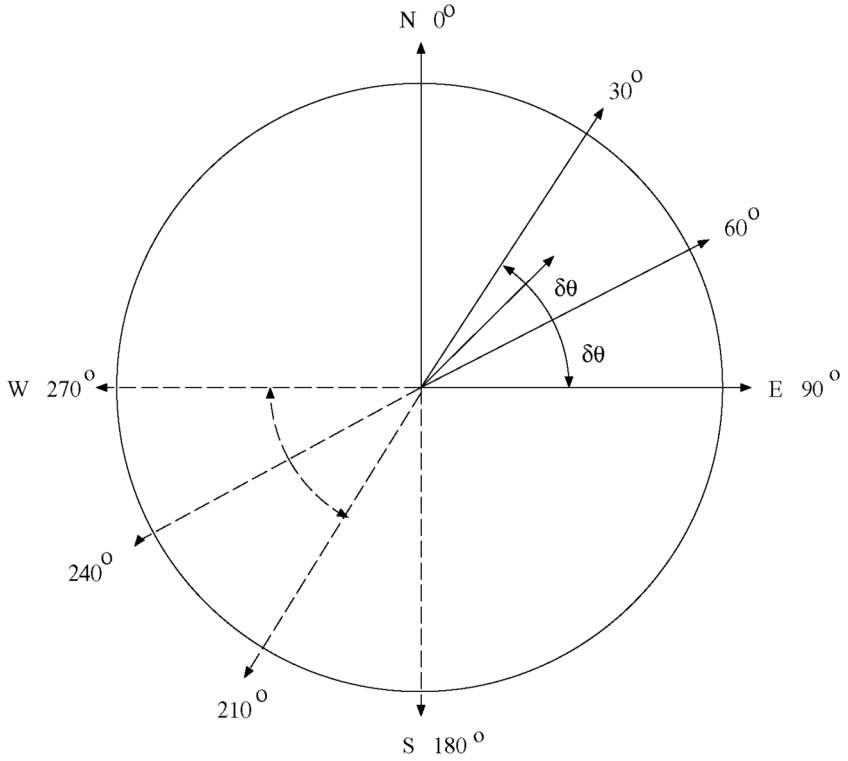
A vector, or directed line segment, is drawn between these points. If the length $\mid P_i P_j \mid = \mid \boldsymbol{s}_2 - \boldsymbol{s}_1 \mid = (x_2 - x_1)^2 + (y_2 - y_1)^2$ of this vector is smaller than the specified DEPSILON= value, then the pair is excluded from the continuity measure calculations as the two points P_1 and P_2 are considered to be at zero distance apart (or *collocated*). Spatial collocation might appear due to different scales in sampling, observations made at the same spatial location at different time instances, and errors in the data sets. PROC VARIOGRAM excludes such pairs from the pairwise distance and semivariance computations because they can cause numeric problems in spatial analysis.

If this pair is not discarded on the basis of collocation, it is then classified—first by orientation of the directed line segment $\boldsymbol{s}_2 - \boldsymbol{s}_1$, and then by its length $\mid P_i P_j \mid$. For example, it is unlikely for actual data that the distance $\mid P_i P_j \mid$ between any pair of data points P_i and P_j located at $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$, respectively, would exactly satisfy $\mid P_i P_j \mid = \mid \boldsymbol{h} \mid = h$ in the preceding computation of $\hat{\gamma}_z(\boldsymbol{h})$. A similar argument can be made for the orientation of the segment $\boldsymbol{s}_2 - \boldsymbol{s}_1$. Consequently, the pair $P_1 P_2$ is placed into an angle and distance class.

The following subsections give more details about the nature of these classifications. You will also find extensive discussions about the size and the number of classes to consider for the computation of the empirical semivariogram.

Figure 95.11 Selection of Points P_1 and P_2 in Spatial Domain D

Angle Classification



Suppose you specify NDIR=3 in the COMPUTE statement in PROC VARIOGRAM. This results in three angle classes defined by midpoint angles between 0° and 180°: $0° \pm \delta\theta$, $60° \pm \delta\theta$, and $120° \pm \delta\theta$, where $\delta\theta$ is the angle tolerance. If you do not specify an angle tolerance by using the ATOL= option in the COMPUTE statement, the following default value is used:

$$\delta\theta = \frac{180°}{2 \times \text{NDIR}}$$

For example, if NDIR=3, the default angle tolerance is $\delta\theta = 30°$. When the directed line segment P_1P_2 in Figure 95.11 is superimposed on the coordinate system showing the angle classes, its angle is approximately 45°, measured clockwise from north. In particular, it falls within $[60° - \delta\theta, 60° + \delta\theta) = [30°, 90°)$, the second angle class (Figure 95.12).

Note that if the designated points P_1 and P_2 are labeled in the opposite order, the orientation is in the opposite direction—that is, approximately 225° instead of approximately 45°. This does not affect angle class selection; the angle classes $[60° - \delta\theta, 60° + \delta\theta)$ and $[240° - \delta\theta, 240° + \delta\theta)$ are the same.

Figure 95.12 Selected Pair $P_1 P_2$ Falls within the Second Angle Class

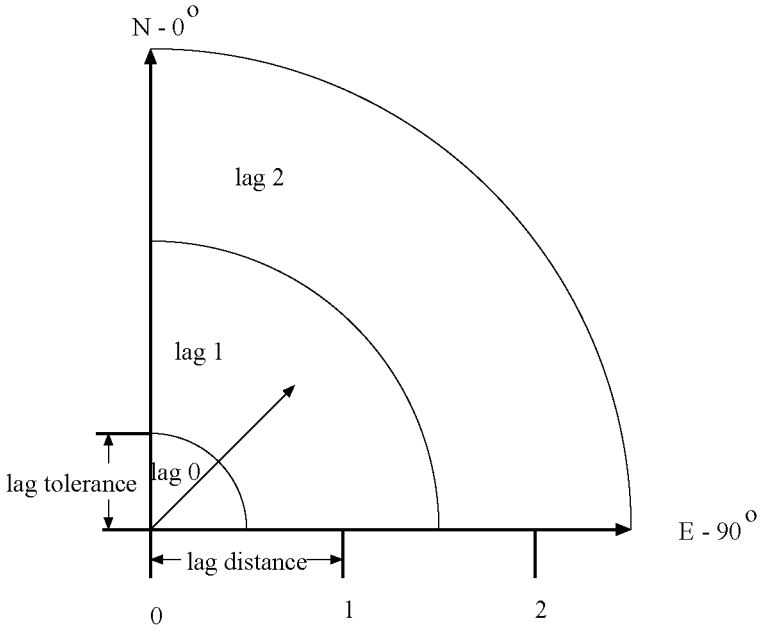
If you specify an angle tolerance less than the default, such as ATOL=15°, some point pairs might be excluded. For example, the selected point pair $P_1 P_2$ in Figure 95.12, while closest to the 60° axis, might lie outside $[60 - \delta\theta, 60 + \delta\theta) = [45°, 75°)$. In this case, the point pair $P_1 P_2$ would be excluded from the semivariance computation. This setting can be desirable if you want to reduce interference between neighboring angles. An angle tolerance that is too small might result in too few point pairs in some distance classes for the empirical semivariance estimation (see also the discussion in the section "Choosing the Size of Classes" on page 7555).

On the other hand, you can specify an angle tolerance *greater* than the default. This can result in a point pair being counted in more than one angle classes. This has a smoothing effect on the variogram and is useful when there is a small amount of data or the available data are sparsely located. However, in cases of anisotropy the smoothing effect might have the side effect of amplifying weaker anisotropy in some direction and weakening stronger anisotropy in another (Deutsch and Journel 1992, p. 59).

Changes in the values of the BANDW= option have a similar effect. See the section "Bandwidth Restriction" on page 7552 for an explanation of how BANDW= functions.

An alternative way to specify angle classes and angle tolerances is with the DIRECTIONS statement. The DIRECTIONS statement is useful when angle classes are not equally spaced. When you use the DIRECTIONS statement, you should also specify the angle tolerance, too. The default value of the angle tolerance is 45° when a DIRECTIONS statement is used instead of the NDIRECTIONS= option in the COMPUTE statement. This might not be appropriate for a particular set of angle classes. See the section "DIRECTIONS Statement" on page 7539 for more details.

Distance Classification



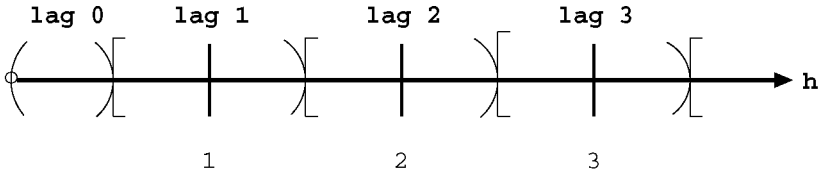
The distance class for a point pair $P_1 P_2$ is determined as follows. The directed line segment $P_1 P_2$ is superimposed on the coordinate system showing the distance or lag classes. These classes are determined by the LAGDISTANCE= option in the COMPUTE statement. Denoting the length of the line segment by $\mid P_1 P_2 \mid$ and the LAGDISTANCE= value by Δ, the lag class L is determined by

$$L(P_1 P_2) = \left\lfloor \frac{\mid P_1 P_2 \mid +0.5}{\Delta} \right\rfloor$$

where $\lfloor x \rfloor$ denotes the largest integer $\leq x$.

When the directed line segment $P_1 P_2$ is superimposed on the coordinate system showing the distance classes, it is seen to fall in the first lag class; see Figure 95.13 for an illustration for $\Delta = 1$.

Figure 95.13 Selected Pair $P_1 P_2$ Falls within the First Lag Class



Because pairwise distances are positive, lag class zero is smaller than lag classes $1, \cdots,$ MAXLAG-1. For example, if you specify LAGDISTANCE=1 and MAXLAG=10, and you do not specify a LAGTOL= value in the COMPUTE statement in PROC VARIOGRAM, the 10 lag classes generated by the preceding equation are

$$[0, 0.5), [0.5, 1.5), [1.5, 2.5), \cdots, [8.5, 9.5)$$

This is because the default lag tolerance is half the LAGDISTANCE= value, resulting in no gaps between the distance class intervals. This is shown in Figure 95.14.

Figure 95.14 Lag Distance Axis Showing Lag Classes

On the other hand, if you do specify a distance tolerance with the LAGTOL= option in the COMPUTE statement, a further check is performed to see if the point pair falls within this tolerance of the nearest lag. In the preceding example, if you specify LAGDISTANCE=1 and MAXLAG=10 (as before) and also specify LAGTOL=0.25, the intervals become

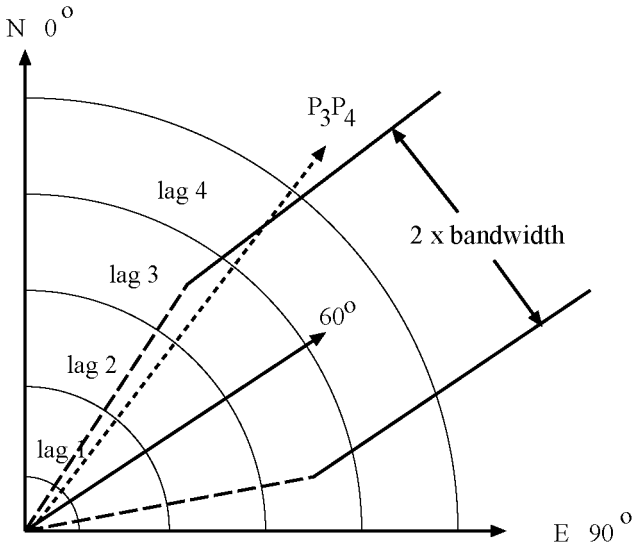
$$[0, 0.25), [0.75, 1.25), [1.75, 2.25), \cdots, [8.75, 9.25)$$

Note that this specification results in gaps in the lag classes; a point pair $P_1 P_2$ might fall in an interval such as

$$\mid P_1 P_2 \mid \in [1.25, 1.75)$$

and hence be excluded from the semivariance calculation. The maximum LAGTOL= value allowed is half the LAGDISTANCE= value; no overlap of the distance classes is allowed.

In the section "Computation of the Distribution Distance Classes" on page 7553 there is a more extensive discussion of practical aspects in the specification of the LAGDISTANCE= and MAXLAGS= options.



Bandwidth Restriction

Because the areal segments generated from the angle and distance classes increase in area as the lag distance increases, it is sometimes desirable to restrict this area (Deutsch and Journel 1992, p. 45). If you specify the BANDW= option in the COMPUTE statement, the lateral, or perpendicular, distance from the axis defining the angle classes is fixed.

For example, suppose two points P_3, P_4 are picked from the domain in Figure 95.11 and are superimposed on the grid defining distance and angle classes, as shown in Figure 95.15.

The endpoint of vector $P_3 P_4$ falls within the angle class around 60° and the 5th lag class; however, it falls outside the restricted area defined by the bandwidth. Hence, it is excluded from the semivariance calculation.

Figure 95.15 Selected Pair $P_3 P_4$ Falls Outside Bandwidth Limit

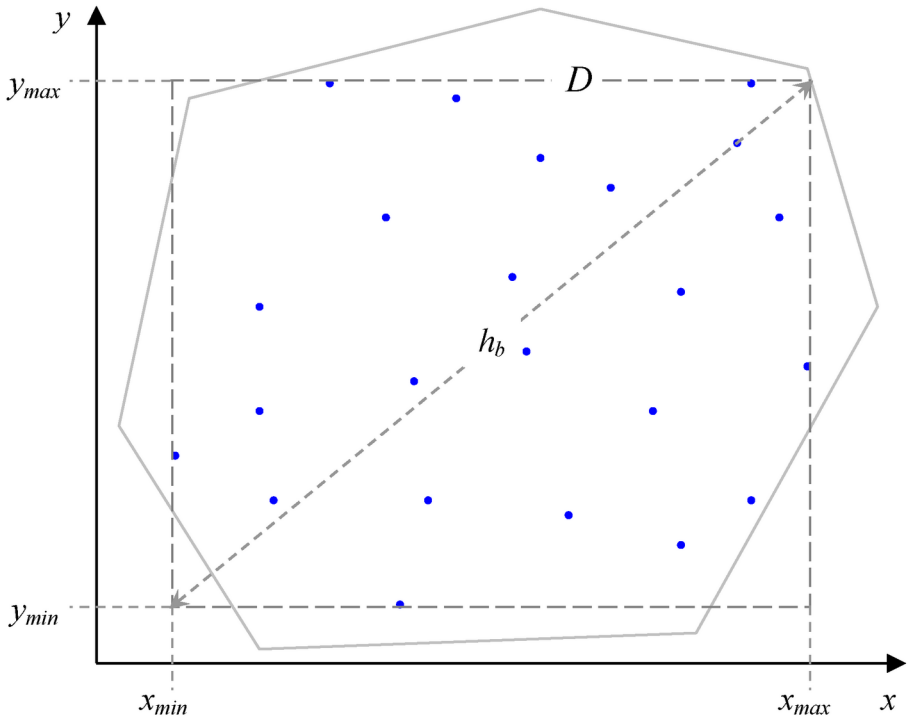
Finally, a pair $P_i P_j$ that falls in a lag class larger than the value of the MAXLAGS= option is excluded from the semivariance calculation.

The BANDW= option complements the angle and lag tolerances in determining how point pairs are included in distance classes. Clearly, the number of pairs within each angle/distance class is strongly affected by the angle and lag tolerances and whether BANDW= has been specified. See also the section "Angle Classification" on page 7549 for more details about the effects these rules can have, since BANDW= operates in a manner similar to the ATOL= option.

Computation of the Distribution Distance Classes

This section deals with theoretical considerations and practical aspects when you specify the LAGDISTANCE= and MAXLAGS= options. In principle, these values depend on the amount and spatial distribution of your experimental data.

The value of the LAGDISTANCE= option regulates how many pairs of data are contained within each distance class. In effect, this information defines the pairwise distance distribution (see the following subsection). Your choice of MAXLAGS= specifies how many of these lags you want to include in the empirical semivariogram computation. Adjusting the values of these parameters is a crucial part of your analysis. Based on your observations sample, they determine whether you have sufficient points for a descriptive empirical semivariogram, and they can affect the accuracy of the estimated semivariance, too.



The simplest way of determining the distribution of pairwise distances is to determine the maximum distance h_{max} between any pair of points in your data, and then to divide this distance by some number N of intervals to produce distance classes of length $\delta = h_{max}/N$. The distance $\mid P_1 P_2 \mid$ between each pair of points P_1, P_2 is computed, and the pair $P_1 P_2$ is counted in the kth distance class if $\mid P_1 P_2 \mid \in [(k-1)\delta, k\delta)$ for $k = 1, \cdots, N$.

The actual computation is a slight variation of this. A bound, rather than the actual maximum distance, is computed. This bound is the length of the diagonal of a bounding rectangle for the data points. This bounding rectangle is found by using the maximum and minimum x and y coordinates, $x_{max}, x_{min}, y_{max}, y_{min}$, and forming the rectangle determined by the following points:

(x_{min}, y_{max})	(x_{max}, y_{max})
(x_{min}, y_{min})	(x_{max}, y_{min})

See Figure 95.16 for an illustration of the bounding rectangle applied to the data of the domain D in Figure 95.11. PROC VARIOGRAM provides you with the sizes of $x_{max} - x_{min}$, $y_{max} - y_{min}$, and h_b. For example, in Figure 95.4 in the preliminary analysis, the specified parameters named "Max Data Distance in East," "Max Data Distance in North," and "Max Data Distance" correspond to the lengths $x_{max} - x_{min}$, $y_{max} - y_{min}$, and h_b, respectively.

Figure 95.16 Bounding Rectangle to Determine Maximum Pairwise Distance in Domain D

The pairwise distance bound, denoted by h_b, is given by

$$h_b = \sqrt{(x_{max} - x_{min})^2 + (y_{max} - y_{min})^2}$$

Using h_b, the interval $(0, h_b]$ is divided into $N + 1$ subintervals, where N is the value of the NHCLASSES= option specified in the COMPUTE statement, or $N = 10$ (default) if the NHCLASSES= option is not specified. The basic distance unit is $h_0 = \frac{h_b}{N}$; the distance intervals are centered on $h_0, 2h_0, \cdots, Nh_0$, with a distance tolerance of $\pm\frac{h_0}{2}$. The extra subinterval is $(0, h_0/2)$ and corresponds to the 0th lag. It is half the length of the remaining subintervals, and it often contains the smallest number of pairs. Figure 95.14 shows an example where the lag classes correspond to $h_0 = 1$. This method of partitioning the interval $(0, h_b]$ is used in the empirical semivariogram computation.

Choosing the Size of Classes

When you start with a data sample, the VARIOGRAM procedure computes all the distinct point pairs in the sample. The OUTPAIR= output data set, described in the section "OUTPAIR=*SAS-data-set*" on page 7566, contains information about these pairs. The point pairs are then categorized in classes. The size of each class depends on the common distance that separates consecutive classes. In PROC VARIOGRAM you need to provide this distance value with the LAGDISTANCE= option. Practically, you can define the distance between classes to be about the size of the average sampling distance (Olea 2006).

Under a more scrutinized approach, before you specify a value for the LAGDISTANCE= option, it is helpful to be aware of two issues. First, you should have an estimate of how many classes of data pairs you will need. Each class contributes one point to the empirical semivariogram. Therefore, you need enough classes for an adequate number of points, so that your empirical semivariogram can suggest a suitable theoretical model shape for the description of the spatial continuity. Second, you should keep in mind that a larger number of data pairs in a class can contribute to a more accurate estimate of the corresponding semivariogram point.

The first consideration is a more general issue, and both this and the following subsection address it in detail. Based on the second consideration, the class size problem translates into having a sufficient number of data pairs in each class to produce an accurate semivariance estimate. However, only empirical rules of thumb exist to guide you with this choice. Examples of minimum pairs empirical rules include the suggestion by Journel and Huijbregts (1978, p. 194) to use at least 30 point pairs for each lag class. Also, in a different approach, Chilès and Delfiner (1999, p. 38) increase this number to 50 point pairs.

Obviously, smaller data samples will provide fewer data pairs in the sample. According to Olea (2006), it is difficult to properly estimate a semivariogram with fewer than 50 measurements. The preceding minimum pairs practical rules are useful in cases where small samples are involved. When you work with a relatively small sample, the key is to specify the value of LAGDISTANCE= such that you can strike a balance between the number of the classes you can form and their pairs count. In the coal seam thickness example of the section "Preliminary Spatial Data Analysis" on page 7520, it is not possible to create a desirable large number of classes and maintain an adequate size for each one. On the other hand, there is no practical need to invoke these rules in the case of the much larger sample of ozone concentrations in "Example 95.2: An Anisotropic Case Study with Surface Trend in the Data" on page 7574.

The spatial distribution of the sample might also affect the grouping of pairs into classes. For example, data that are sampled in clusters might prove difficult to classify according to the preceding practical rules. One strategy to address this problem is to accept fewer than 30 pairs for the underpopulated distance classes. Then, at the stage when you determine what theoretical semivariogram model to use, either disregard the corresponding empirical semivariogram points or use them and accept the increased uncertainty.

The VARIOGRAM procedure can help you decide on a suitable class size before you proceed with the empirical semivariogram computation. First, provide a number for the class count by specifying the NHCLASSES= value. Run the procedure with the option NOVARIOGRAM in the COMPUTE statement and examine the distribution data pairs. Use different values of NHCLASSES= to investigate how this will affect the data pairs distribution in each distance class. The pairwise distance intervals table (for example, Figure 95.3) shows the number of pairs in each distance class in the "Number of Pairs" column, and you can use the preceding rule of thumb to adjust the NHCLASSES= value accordingly.

PROC VARIOGRAM displays a rounded value of the distance between the lag bounds as the "Lag Distance" parameter in the pairs information table (see Figure 95.5) or the pairwise distances histogram (see Figure 95.4), which you can use for the LAGDISTANCE= specification. However, this is only one tool. For the semivariogram computation you can specify your own LAGDISTANCE= value based on your experience. Smaller LAGDISTANCE= values result in fewer data pairs in the classes. In that sense, you might find smaller values useful when you work with large samples so that you obtain more semivariogram points. Also, if the LAGDISTANCE= value is too large, you might end up "wasting" too many point pairs in fewer classes at the expense of computing fewer semivariogram points and no significant accuracy gains in the estimation.

As explained earlier, depending on the sample size and its spatial distribution you might have classes with fewer points than what the practical rules advise. Most commonly, the deficient distance classes are the limiting ones close to the origin $\boldsymbol{h} = 0$, as well as the most remote ones at large $\boldsymbol{h}$. The classes near the origin correspond to lags 0 and 1. They are crucial, because the empirical semivariogram in small distances $\boldsymbol{h}$ characterizes the process smoothness and can be further used to detect the presence of a nugget effect. However, as discussed in the section "Distance Classification" on page 7551, lag 0 is half the size of the rest of the classes by definition, so it can be expected to violate the rule of thumb for the number of pairs in a class.

The classes located at higher and extreme distances within a spatial domain are often not accounted for in the empirical semivariogram. The fewer pairs that can be formed in these distances do not allow for an accurate assessment of the spatial correlation, as is explained in the following section.

Spatial Extent of the Empirical Semivariogram

Given your choice for the LAGDISTANCE= value in your spatial domain, the following paragraphs provide guidelines on how many classes to consider when you compute the empirical semivariogram.

Obviously, you want to include no more classes beyond the limit where the pairs count falls below the minimum pairs empirical rule threshold, as discussed in the preceding subsection. PROC VARIOGRAM provides you with a visual way to inspect this upper limit, if you decide to make use of the minimum pairs empirical rule. In particular, specify your threshold choice for the minimum pairs per class by using the THRESHOLD= parameter for the PLOT=PAIRS option.

Then, the procedure produces in the pairwise distances histogram a reference line at the specified THRESHOLD=, which leaves below the line all lags whose pairs count is lower than the threshold value; see, for example, Figure 95.4. The last lag class whose pair population is above the THRESHOLD= is reported in the pairs information table as "Highest Lag With Pairs > Threshold." Note that this value is not a recommendation for the MAXLAGS= option, but rather is an upper limit for your choice. Detailed information about the pairs count in each class is displayed in the corresponding pairwise distance intervals table, as Figure 95.3 demonstrates.

The preceding suggests that you have an upper limit indication, but you still need some criterion to decide how many lags to include in the semivariogram estimation. The criterion is the extent of spatial dependence in your domain.

Spatial dependence can exist beyond your domain limits. However, you do not have data past your domain scale to define a range for larger-scale spatial dependencies. As you look for pairs of data that are gradually farther apart, the number of pairs naturally decreases with distance. The pairs at the more distant classes might be so few that they are likely to be independent with respect to the spatial dependence scale that you can detect. These will only contribute added noise if you include the largest distances in your empirical semivariogram plot. Note that in the same sense, you cannot explore in detail spatial dependencies in scales smaller than an average minimum distance between your data. The nugget effect is then used to represent microscale correlations whose effect is evident in your working scale.

You specify the spatial dependence extent with commonly used measures such as the *correlation range* (or *correlation length*) ϵ and the *correlation radius* h_c. Both are defined in a similar manner. The correlation range ϵ is the distance at which the covariance is 5% of its value at $\boldsymbol{h} = 0$, and shows that beyond ϵ the covariance is considered to be negligible. The correlation radius h_c is the distance at which the covariance is about half the variance at $\boldsymbol{h} = 0$, and indicates the distance over which significant correlations prevail (Christakos 1992, p. 76). The physical meanings of these measures are similar to that of the semivariogram range. Also, the effective range r_ϵ used in asymptotically increasing semivariance models has essentially the same definition as the correlation range ϵ (see the section "Theoretical Semivariogram Models" on page 7540).

A rough estimate of the correlation extent measures might be available from previous studies of a similar site, or from prior information about related measurements. In such an event, you typically want to consider a maximum pairwise distance that does not exceed the length of two or three correlation radii, or one and a half correlation ranges. You can then specify the MAXLAGS= value on the basis of the lags that fit in that distance.

When there are no estimates of correlation extent measures, you can use first use a crude measure to get started with your analysis: You can typically expect MAXLAGS= to be about half of the lag classes shown in the pairwise distances histogram.

Then, if necessary, you can refine your MAXLAGS= choice by using the following maximum lags rule of thumb: Journel and Huijbregts (1978, p. 194) advise considering lags up to about half of the extreme distance between data in the direction of interest. The VARIOGRAM procedure assists you in this task by providing the overall extreme data distance h_b, as well as the extreme data distances in the vertical and horizontal axes directions. For example, h_b is reported in the pairs information table as "Maximum Data Distance" (see Figure 95.5), and in the pairwise distances histogram as "Max Data Distance" (see Figure 95.4).

Overall, you do not want to deviate significantly from the maximum lags rule of thumb. As was stated earlier, a MAXLAGS= value that takes you well beyond the half-extreme distance between data in a given direction might give you limited accuracy in the empirical semivariance estimates at higher distances. At the other end, a value of MAXLAGS= that is too small might lead you to omit important information about the spatial structure that potentially lies within the range of distances you skipped.

Semivariance Computation

With the classification of a point pair $P_i P_j$ into an angle/distance class, as shown earlier in this section, the semivariance computation proceeds as follows.

Denote all pairs $P_i P_j$ belonging to angle class $[\theta_k - \delta\theta_k, \theta_k + \delta\theta_k)$ and distance class $L = L(P_i P_j)$ as $N(\theta_k, L)$. For example, based on Figure 95.12 and Figure 95.13, $P_1 P_2$ belongs to $N(60°, 1)$.

Let $\mid N(\theta_k, L) \mid$ denote the *number* of such pairs. The component of the standard (or method of moments) semivariance corresponding to angle/distance class $N(\theta_k, L)$ is given by

$$\hat{\gamma}(h_k) = \frac{1}{2 \mid N(\theta_k, L) \mid} \sum_{P_i P_j \in N(\theta_k, L)} [V(\boldsymbol{s}_i) - V(\boldsymbol{s}_j)]^2$$

where h_k is the average distance in class $N(\theta_k, L)$; that is,

$$h_k = \frac{1}{\mid N(\theta_k, L) \mid} \sum_{P_i P_j \in N(\theta_k, L)} \mid P_i P_j \mid$$

The robust version of the semivariance is given by

$$\bar{\gamma}(h_k) = \frac{\Psi^4(h_k)}{2[0.457 + 0.494/N(\theta_k, L)]}$$

where

$$\Psi(h_k) = \frac{1}{N(\theta_k, L)} \sum_{P_i P_j \in N(\theta_k, L)} [V(\boldsymbol{s}_i) - V(\boldsymbol{s}_j)]^{\frac{1}{2}}$$

This robust version of the semivariance is computed when you specify the ROBUST option in the COMPUTE statement in PROC VARIOGRAM.

PROC VARIOGRAM computes and writes to the OUTVAR= data set the quantities $h_k, \theta_k, L, N(\theta_k, L), \hat{\gamma}(h)$, and $\bar{\gamma}(h)$.

Empirical Semivariograms and Surface Trends

It was stressed in the beginning of the section "Theoretical and Computational Details of the Semivariogram" on page 7544 that if your data are not free of nonrandom surface trends, then the empirical semivariance $\hat{\gamma}_z(\boldsymbol{h})$ you obtain from PROC VARIOGRAM represents a pseudo-semivariance rather than an estimate of the theoretical semivariance $\gamma_z(\boldsymbol{h})$.

In practice, two major difficulties appear. First, you might have no knowledge of underlying surface trends in your SRF $Z(\boldsymbol{s})$. It can be possible to have this information when you deal with a repetitive phenomenon (Chilès and Delfiner 1999, p. 123), or if you work within a subdomain of a broader region with known characteristics; often, though, this is not the case. Second, even if you suspect the existence of an underlying nonrandom trend, its precise nature might be unknown (Cressie 1993, p. 114, 162).

Based on the last remark, the criteria to define the exact form of a surface trend can be subjective. However, statistical methods can identify the presence and remove an estimate of such a trend. Different trend forms can be estimated in your SRF depending on the trend estimation model that you choose. This choice can lead to different degrees of smoothing in the residual random fluctuations. It might also have an effect on the residuals spatial structure characterization, as trend removals with different models are essentially different operations acting upon the values of your original observations. Note the comment by Chilès and Delfiner (1999, Section 2.7.3) that there are as many semivariograms of residuals as there are ways of estimating the trend. The same source also examines the introduction of bias in the semivariance of the residuals as a side effect of trend removal processes. This bias is small when you examine distances close to the origin $\boldsymbol{h} = 0$, and can increase with distance.

Keeping in mind the preceding remarks, an approach you can take is to use one of the many predictive modeling tools in SAS/STAT software to estimate the unknown trend. Then you use PROC VARIOGRAM to analyze the residuals after you remove the trend. If the resulting model does not require too many degrees of freedom (such as if you use a low-order polynomial), then this approach might be sufficient. The section "Analysis with Surface Trend Removal" on page 7578 demonstrates how to use PROC GLM (see Chapter 39, "The GLM Procedure") for that purpose.

Apart from the standard semivariogram analysis, you can attempt to fit a theoretical semivariogram model to your empirical semivariogram if (a) either the analysis itself or your knowledge of the SRF does not clearly suggest the presence of any surface trend, or (b) the analysis can indicate a potentially trend-free direction, along which your data will have a constant mean.

For example, you might observe overall similar values in your data. This can be an indication that your data are free of nonrandom trends, or that a very mild trend is present. The case falls under the preceding option (a). A very mild trend still allows a good determination of the semivariance at short distances according to Chilès and Delfiner (1999, p. 125), and this can be sufficient for your spatial prediction goal. An analysis of this type is assumed in the section "Preliminary Spatial Data Analysis" on page 7520.

If you observe similar values locally across a particular direction, this an instance of option (b). Olea (2006) suggests recognizing a trend-free direction as being perpendicular to the axis of the maximum dip in the values of $Z(\boldsymbol{s})$. If you suspect that there is at least one such direction in your data, then run PROC VARIOGRAM for a series of directions in the angular vicinity. The trend-free direction, if it exists, will coincide with the one whose pseudo-semivariogram exhibits minimal

increase with distance; see "Example 95.3: Analysis without Surface Trend Removal" on page 7587 for a demonstration of this approach. However, you cannot test $Z(\boldsymbol{s})$ for anisotropy in this case, because you can investigate the semivariogram only in the single trend-free direction (Olea 1999, p. 76). Chilès and Delfiner (1999, Section 2.7.4) suggest fitting a theoretical model in a trend-free direction only if the hypothesis of an isotropic semivariogram appears reasonable in your analysis.

As a result, you need to be very cautious when you choose to perform semivariogram analysis on data you have not previously examined for surface trends. In this event, both of the options (a) and (b) that were reviewed in the preceding paragraphs rely mostly on empirical and subjective criteria. As noted in this section, a degree of subjectivity exists in the selection of the surface trend itself. This fact suggests that a significant part of the semivariogram analysis is based on meta-statistical decisions, as well as on your understanding of your data and the physical considerations that govern your study. In any case, as shown in the section "Theoretical and Computational Details of the Semivariogram" on page 7544, your semivariogram analysis relies fundamentally on the use of trend-free data.

Autocorrelation Statistics (Experimental)

Spatial autocorrelation measures offer you additional insight into the interdependence of spatial data. These measures quantify the correlation of an SRF $Z(\boldsymbol{s})$ with itself at different locations, and they can be very useful whether you have information at exact locations (point-referenced data) or measurements characterizing an area type such as counties, census tracts, zip codes, etc. (areal data).

As in the semivariogram computation, a key issue for the autocorrelation statistics is that you work with a set z_i of measurements, $i = 1, \ldots, n$, that are free of nonrandom surface trends and have a constant mean.

Autocorrelation Weights

In general, the choice of a weighting scheme is subjective. You can obtain different results by using different schemes, options and parameters. PROC VARIOGRAM offers you considerable flexibility in choosing weights that are appropriate for prior considerations such as different hypotheses about neighboring areas, definition of the neighborhood structure, and accounting for natural barriers or other spatial characteristics; see the discussion in Cliff and Ord (1981, p. 17). As stressed for all types of spatial analysis, it is important to have good knowledge of your data. In the autocorrelation statistics, this knowledge will help you avoid spurious correlations when you choose the weights.

The starting point is to assign individual weights to each one of the n data values z_i, $i = 1, \ldots, n$, with respect to the rest. An $n \times n$ matrix of weights is thus defined, such that for any two locations $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$, the weight w_{ij} denotes the effect of the value z_i at location $\boldsymbol{s}_i$ on the value z_j at location $\boldsymbol{s}_j$. Depending on the nature of your study, the weights w_{ij} need not be symmetric; that is, it can be that $w_{ij} \neq w_{ji}$.

Binary and Nonbinary Weights

The weights w_{ij} can be either binary or nonbinary values. Binary values of 1 or 0 are assigned if the SRF $Z(\boldsymbol{s}_i)$ at one location $\boldsymbol{s}_i$ is deemed to be connected or not, respectively, to its value $Z(\boldsymbol{s}_j)$ at another location $\boldsymbol{s}_j$. Nonbinary values can be used in the presence of more refined measures of connectivity between any two data points P_i and P_j. PROC VARIOGRAM offers a choice between a binary and a distance-based nonbinary weighting scheme.

In the binary weighting scheme the weight $w_{ij} = 1$, if the data pair at $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$ is closer than the user-defined distance LAGDISTANCE=, and $w_{ij} = 0$, if $i = j$ or in any other case. For that reason, in the COMPUTE statement, if you specify the WEIGHTS=BINARY suboption of the AUTOCORRELATION option when the NOVARIOGRAM option is also specified, then you must also specify the LAGDISTANCE= option.

The nonbinary weighting scheme is based on the pair distances and is invoked with the WEIGHTS=DISTANCE suboption of the AUTOCORRELATION option. PROC VARIOGRAM uses a variation of the Pareto form functional to set the weights. Namely, the autocorrelation weight for every point pair P_i and P_j located at $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$, respectively, is defined as

$$w_{ij} = s\frac{1}{1+\mid \boldsymbol{h} \mid^p}$$

where $\boldsymbol{h} = \boldsymbol{s}_i - \boldsymbol{s}_j$, and $p \geq 0, s \geq 0$ are user-defined parameters for the adjustment of the weights.

In particular, the power parameter p is specified in the POWER= option of the DISTANCE suboption within the AUTOCORRELATION option. The default value for this parameter is $p = 1$. Also, the scaling parameter s is specified by the SCALE= option in the DISTANCE suboption of the AUTOCORRELATION option. The default value for the scaling parameter is $s = 1$. You can use the p and s parameters to adjust the actual values of the weights according to your needs. Note that variations in the scaling parameter s do not affect the computed values of the Moran's I and Geary's c autocorrelation coefficients that are introduced in the section "Autocorrelation Statistics Types" on page 7562.

Nonbinary Weights with Normalized Distances

PROC VARIOGRAM offers additional flexibility in the DISTANCE weighting scheme through an option to use normalized pair distances. You can invoke this feature by specifying the NORMALIZE option in the DISTANCE suboption of the AUTOCORRELATION option. In this case, the distances used in the definition of the weights are normalized by the maximum pairwise distance h_b (see the section "Computation of the Distribution Distance Classes" on page 7553 and Figure 95.16); the weights are then defined as $w_{ij} = s/[1 + (\mid \boldsymbol{h} \mid / h_b)^p]$.

Note that h_b most likely has a different value for different data sets. Hence, it is suggested that you avoid using the weights you obtain from the preceding equation and a data set for comparisons with the weights you derive from different data sets.

Symmetric and Asymmetric Weights

The weighting schemes presented in the preceding paragraphs are symmetric; that is, $w_{ij} = w_{ji}$ for every data pair at locations $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$. However, you can also define asymmetric weights w'_{ij} such that

$$\sum_{j \in J} w'_{ij} = 1$$

for $i = 1, 2, \cdots, n$, where $w'_{ij} = w_{ij} / \sum_{j \in J} w_{ij}$, $i = 1, 2, \cdots, n$. In the distance-based scheme, J is the set of all locations that form point pairs with the point at $\boldsymbol{s}_i$. In the binary scheme, J is the set of the locations that are connected to $\boldsymbol{s}_i$ based on your selection of the LAGDISTANCE= option; see Cliff and Ord (1981, p. 18). The weights w'_{ij} are *row-averaged* (or *standardized* by the count of their connected neighbors). You can apply row averaging in weights when you specify the ROWAVG option within either the BINARY or DISTANCE suboptions in the AUTOCORRELATION option.

Autocorrelation Statistics Types

One measure of spatial autocorrelation provided by PROC VARIOGRAM is Moran's I statistic, which was introduced by Moran (1950) and is defined as

$$I = \frac{n}{(n-1)S^2 W} \sum_i \sum_j w_{ij} v_i v_j$$

where $S^2 = (n-1)^{-1} \sum_i v_i^2$, and $W = \sum_i \sum_{j \neq i} w_{ij}$.

Another measure of spatial autocorrelation in PROC VARIOGRAM is Geary's c statistic (Geary 1954), defined as

$$c = \frac{1}{2S^2 W} \sum_i \sum_j w_{ij} (z_i - z_j)^2$$

Note that Moran's I coefficient makes use of the centered variable, whereas the Geary's c expression uses the noncentered values in the summation.

Inference on these two statistic types comes from approximate tests based on the asymptotic distribution of I and c, which both tend to a normal distribution as n increases. To this end, PROC VARIOGRAM calculates the means and variances of I and c. The outcome depends on the assumption made regarding the distribution $Z(\boldsymbol{s})$. In particular, you can choose to investigate any of the statistics under the *normality* (also known as *Gaussianity*) or the *randomization* assumption. Cliff and Ord (1981) provided the equations for the means and variances of the I and c distributions, as described in the following.

The normality assumption asserts that the random field $Z(\boldsymbol{s})$ follows a normal distribution of constant mean ($\bar{Z}$) and variance, from which the z_i values are drawn. In this case, the I statistics yield

$$\mathrm{E}_g[I] = -\frac{1}{n-1}$$

and

$$\mathrm{E}_g[I^2] = \frac{1}{(n+1)(n-1)W^2}(n^2 S_1 - nS_2 + 3W^2)$$

where $S_1 = 0.5\sum_i \sum_{j\neq i}(w_{ij} + w_{ji})^2$ and $S_2 = \sum_i(\sum_j w_{ij} + \sum_j w_{ji})^2$. The corresponding moments for the c statistics are

$$\mathrm{E}_g[c] = 1$$

and

$$\mathrm{Var}_g[c] = \frac{(2S_1 + S_2)(n-1) - 4W^2}{2(n+1)W^2}$$

According to the randomization assumption, the I and c observations are considered in relation to all the different values that I and c could take, respectively, if the n z_i values were repeatedly randomly permuted around the domain D. The moments for the I statistics are now

$$\mathrm{E}_r[I] = -\frac{1}{n-1}$$

and

$$\mathrm{E}_r[I^2] = \frac{A_1 + A_2}{(n-1)(n-2)(n-3)W^2}$$

where $A_1 = n[(n^2 - 3n + 3)S_1 - nS_2 + 3W^2]$, $A_2 = -b_2[n(n-1)S_1 - 2nS_2 + 6W^2]$. The factor $b_2 = m_4/(m_2{}^2)$ is the coefficient of kurtosis that uses the sample moments $m_k = \frac{1}{n}\sum_i v_i^k$ for $k = 2, 4$. Finally, the c statistics under the randomization assumption are given by

$$\mathrm{E}_r[c] = 1$$

and

$$\mathrm{Var}_r[c] = \frac{B_1 + B_2 + B_3}{n(n-2)(n-3)W^2}$$

with $B_1 = (n-1)S_1[n^2 - 3n + 3 - (n-1)b_2]$, $B_2 = -\frac{1}{4}(n-1)S_2[n^2 + 3n - 6 - (n^2 - n + 2)b_2]$, and $B_3 = W^2[n^2 - 3 - b_2(n-1)^2]$.

Note that when you specify LAGDISTANCE= to be larger than the maximum data distance in your domain, the binary weighting scheme used by the VARIOGRAM procedure leads to all weights $w_{ij} = 1, i \neq j$. In this extreme case the preceding definitions can show that the variances of the I and c statistics become zero under either the normality or the randomization assumption.

A similar effect might occur when you have collocated observations (see the section "Pair Formation" on page 7548). The Moran's I and Geary's c statistics allow for the inclusion of such pairs in the computations. Hence, contrary to the semivariance analysis, PROC VARIOGRAM does not exclude pairs of collocated data from the autocorrelation statistics.

Interpretation

For Moran's I coefficient, $I > \mathrm{E}[I]$ indicates positive autocorrelation. Positive autocorrelation suggests that neighboring values $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$ tend to have similar feature values z_i and z_j, respectively. When $I < \mathrm{E}[I]$, this is a sign of negative autocorrelation, or dissimilar values at neighboring locations. A measure of strength of the autocorrelation is the size of the absolute difference $| I - \mathrm{E}[I] |$.

Geary's c coefficient interpretation is analogous to that of Moran's I. The only difference is that $c > \mathrm{E}[c]$ indicates negative autocorrelation and dissimilarity, whereas $c < \mathrm{E}[c]$ signifies positive autocorrelation and similarity of values.

The VARIOGRAM procedure uses the mathematical definitions in the preceding section to provide the observed and expected values, and the standard deviation of the autocorrelation coefficients in the autocorrelation statistics table. The Z scores for each type of statistics are computed as follows:

$$Z_I = \frac{I - \mathrm{E}[I]}{\sqrt{\mathrm{Var}[I]}}$$

for Moran's I coefficient, and

$$Z_c = \frac{c - \mathrm{E}[c]}{\sqrt{\mathrm{Var}[c]}}$$

for Geary's c coefficient. PROC VARIOGRAM also reports the two-sided p-value for each coefficient under the null hypothesis that the sample values are not autocorrelated. Smaller p-values correspond to stronger autocorrelation for both the I and c statistics. However, the p-value does not tell you whether the autocorrelation is positive or negative. Based on the preceding remarks, you have positive autocorrelation when $Z_I > 0$ or $Z_c < 0$, and you have negative autocorrelation when $Z_I < 0$ or $Z_c > 0$.

Computational Resources

The fundamental computation of the VARIOGRAM procedure is binning: for each pair of observations in the input data set, a distance class and an angle class are determined and recorded. Let N_d denote the number of distance classes, N_a denote the number of angle classes, and N_v denote the number of VAR variables. The memory requirements for these operations are proportional to $N_d \times N_a \times N_v$. This is typically small.

The CPU time required for the computations is proportional to the number of pairs of observations, or to $N^2 \times N_v$, where N is the number of observations in the input data set.

Output Data Sets

The VARIOGRAM procedure produces four data sets: the OUTACWEIGHTS=*SAS-data-set*, the OUTDIST=*SAS-data-set*, the OUTPAIR=*SAS-data-set*, and the OUTVAR=*SAS-data-set*. These data sets are described in the following sections.

OUTACWEIGHTS=*SAS-data-set*

The OUTACWEIGHTS= data set contains one observation for each pair of points P_1, P_2 in the original data set, where P_1 is different from P_2, with information about the data distance and autocorrelation weight of each point pair.

Note that the OUTACWEIGHTS= data set can be very large, even for a moderately sized DATA= data set. For example, if the DATA= data set has NOBS=500, then the OUTACWEIGHTS= data set has NOBS(NOBS $-$ 1)/2=124,750 observations.

When you perform autocorrelation computations, the OUTACWEIGHTS= data set is a practical way to save the autocorrelation weights for further use.

The OUTACWEIGHTS= data set contains the following variables:

- ACWGHT12, the autocorrelation weight for the pair P_1, P_2
- ACWGHT21, the autocorrelation weight for the pair P_2, P_1
- DISTANCE, the distance between the data in the pair

- V1, the variable value for the first point in the pair
- V2, the variable value for the second point in the pair
- VARNAME, the variable name for the current VAR= variable
- X1, the x coordinate of the first point in the pair
- X2, the x coordinate of the second point in the pair
- Y1, the y coordinate of the first point in the pair
- Y2, the y coordinate of the second point in the pair

When the autocorrelation weights are symmetric, the pair P_1, P_2 has the same weight as the pair P_2, P_1. For this reason, in the case of symmetric weights the OUTACWEIGHTS= data set contains only the autocorrelation weights ACWGHT12.

OUTDIST=*SAS-data-set*

The OUTDIST= data set contains counts for a modified histogram showing the distribution of pairwise distances. This data set provides you with information related to the choice of values for the LAGDISTANCE= option in the COMPUTE statement.

To request an OUTDIST= data set, specify the OUTDIST= data set in the PROC VARIOGRAM statement and the NOVARIOGRAM option in the COMPUTE statement. The NOVARIOGRAM option prevents any semivariogram or covariance computation from being performed.

The following variables are written to the OUTDIST= data set:

- COUNT, the number of pairs falling into this lag class
- LAG, the lag class value
- LB, the lower bound of the lag class interval
- UB, the upper bound of the lag class interval
- PER, the percent of all pairs falling in this lag class
- VARNAME, the name of the current VAR= variable

OUTPAIR=*SAS-data-set*

The OUTPAIR= data set contains one observation for each distinct pair of points P_1, P_2 in the original data set, unless you specify the OUTPDISTANCE= option in the COMPUTE statement.

If you specify OUTPDISTANCE=D_{max} in the COMPUTE statement, all pairs P_1, P_2 in the original data set that satisfy the relation $| P_1 P_2 | \leq D_{max}$ are written to the OUTPAIR= data set.

Note that the OUTPAIR= data set can be very large even for a moderately sized DATA= data set.

For example, if the DATA= data set has NOBS=500, then the OUTPAIR= data set has NOBS(NOBS − 1)/2=124,750 if no OUTPDISTANCE= restriction is given in the COMPUTE statement.

The OUTPAIR= data set contains information about the distance and orientation of each point pair, and you can use it for specialized continuity measure calculations.

The OUTPAIR= data set contains the following variables:

- AC, the angle class value
- COS, the cosine of the angle between pairs
- DC, the distance (lag) class
- DISTANCE, the distance between the data in pairs
- V1, the variable value for the first point in the pair
- V2, the variable value for the second point in the pair
- VARNAME, the variable name for the current VAR= variable
- X1, the x coordinate of the first point in the pair
- X2, the x coordinate of the second point in the pair
- Y1, the y coordinate of the first point in the pair
- Y2, the y coordinate of the second point in the pair

OUTVAR=*SAS-data-set*

The OUTVAR= data set contains the standard and robust versions of the sample semivariance, the covariance, and other information in each lag class.

The OUTVAR= data set contains the following variables:

- ANGLE, the angle class value (clockwise from N to S)
- ATOL, the angle tolerance for the lag/angle class
- AVERAGE, the average variable value for the lag/angle class
- BANDW, the bandwidth for the lag/angle class
- COUNT, the number of pairs in the lag/angle class
- COVAR, the covariance value for the lag/angle class
- DISTANCE, the average lag distance for the lag/angle class

- LAG, the lag class value (in LAGDISTANCE= units)
- RVARIO, the sample robust semivariance value for the lag/angle class
- VARIOG, the sample semivariance value for the lag/angle class
- VARNAME, the name of the current VAR= variable

The robust semivariance estimate, RVARIO, is not included in the data set if the user has not specified the option ROBUST in the DIRECTIONS statement.

The bandwidth variable, BANDW, is not included in the data set if no bandwidth specification is given in the COMPUTE statement or in a DIRECTIONS statement.

The OUTVAR= data set contains a line where the LAG variable is -1. The AVERAGE variable in this line displays the sample mean value $\bar{Z}$ of the SRF $Z(\boldsymbol{s})$, and the COVAR variable shows the sample variance $\mathrm{Var}[Z(\boldsymbol{s})]$.

Displayed Output

In addition to the output data sets, the VARIOGRAM procedure produces several output objects. Most of those are produced depending on whether you specify either NOVARIOGRAM or LAGDISTANCE= and MAXLAGS= in the COMPUTE statement. The VARIOGRAM procedure output objects are the following:

- a default "Number of Observations" table that displays the number of observations read from the input data set and the number of observations used in the analysis
- a default map showing the spatial distribution of the observations of the current variable in the VAR statement. The observations are displayed by default with circled markers whose color indicates the VAR value at the corresponding location.
- a table with basic information about the lags and the extreme distance between data pairs, when NOVARIOGRAM is specified
- a table that describes the distribution of data pairs in distance intervals, when NOVARIOGRAM is specified
- a histogram plot of the pairwise distance distribution, when NOVARIOGRAM is specified). The plot also displays a reference line at a user-specified pairs frequency threshold when you specify the THRESHOLD= parameter in the PLOT=PAIRS option. The option PLOT=PAIRS(NOINSET) forces the informational inset that appears in the plot to hide.
- empirical semivariogram details, when NOVARIOGRAM is not specified and LAGDISTANCE= and MAXLAGS= are specified. This table also includes the semivariance estimate variance and confidence limits when CL is specified, and estimates of the robust semivariance when ROBUST is specified.

- plots of the appropriate empirical semivariograms, when NOVARIOGRAM is not specified and LAGDISTANCE= and MAXLAGS= are specified. If you perform the analysis in more than one direction simultaneously, the output is a panel comprising the empirical semivariogram plots for the specified angles. If the semivariograms are nonpaneled, then each plot includes in the lower part a needle plot of the contributing pairs distribution.
- a table that provides autocorrelation statistics, when the options AUTOCORRELATION and LAGDISTANCE= are specified

ODS Table Names

Each table created by PROC VARIOGRAM has a name associated with it, and you must use this name to reference the table when using ODS Graphics. These names are listed in Table 95.4.

Table 95.4 ODS Tables Produced by PROC VARIOGRAM

ODS Table Name	Description	Statement	Option
AutoCorrStats	Autocorrelation statistics information	COMPUTE	AUTOCORR
DistanceIntervals	Pairwise distances matrix	COMPUTE	NOVARIOGRAM
NObs	Number of observations read and used	PROC	default output
PairsInformation	General information about the pairs distribution in classes and data maximum distances in selected directions	COMPUTE	NOVARIOGRAM
SemivariogramTable	Empirical semivariance classes, parameters, and estimates	COMPUTE	LAGD=, MAXLAGS=

ODS Graphics

This section describes the use of the Output Delivery System (ODS) for creating graphics with the VARIOGRAM procedure.

To request these graphs, you must specify the ODS GRAPHICS statement. For additional control of the graphics that are displayed, see the PLOTS= option in the section "PROC VARIOGRAM Statement" on page 7529. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

ODS Graph Names

PROC VARIOGRAM assigns a name to each graph it creates by using ODS Graphics. You can use these names to reference the graphs when using ODS Graphics. The names are listed in Table 95.5.

Table 95.5 ODS Graphics Produced by PROC VARIOGRAM

ODS Graph Name	Plot Description	Statement	Option
ObservationsPlot	Scatter plot of observed data and colored markers indicating observed values	PROC	PLOTS=OBSERV
PairDistPlot	Histogram of the pairwise distance distribution	PROC	PLOTS=PAIRS
Semivariogram	Plots of empirical classical and robust (optional) semivariograms	PROC	PLOTS=SEMIVAR
SemivariogramPanel	Panel of empirical classical and robust (optional) semivariogram plots	PROC	PLOTS=SEMIVAR

To request these graphs, you must specify the ODS GRAPHICS statement in addition to the statements indicated in Table 95.5. For more information about the ODS GRAPHICS statement, see Chapter 21, "Statistical Graphics Using ODS."

Examples: VARIOGRAM Procedure

Example 95.1: Theoretical Semivariogram Model Fitting

This example continues the introduction study presented in the section "Getting Started: VARIOGRAM Procedure" on page 7519 by fitting a theoretical semivariogram model to the estimated classical sample semivariogram in Figure 95.8. You will use PROC NLIN to perform the model fit and to compare two different approaches: the ordinary least squares (OLS) and the weighted least squares (WLS) fitting methods.

A review of the coal seam thickness empirical semivariogram in Figure 95.8 shows first a slow, then rapid rise from the origin, suggesting a Gaussian-type form:

$$\gamma_z(h) = c_0\left[1 - \exp\left(-\frac{h^2}{a_0^2}\right)\right]$$

as shown in the section "Theoretical Semivariogram Models" on page 7540.

By experimentation, you find that a sill of $c_0 = 7.5$ and a range of $a_0 = 30,000$ feet (effective range $r_\epsilon = \sqrt{3}a_0 \approx 52,000$ feet) provide a reasonable fit of the preceding semivariogram model. You can use these values as initial guesses in the least squares fitting process. For the fitting you need the output data set that is produced by the parameters used in the section "Theoretical Semivariogram Models" on page 7540. The following statements skip the autocorrelation statistics and the creation of plots, and produce the required output data for the semivariogram table. Note that for the fitting

process you need information about the semivariance variance, which you obtain by specifying the CL option in the COMPUTE statement.

```
title 'Theoretical Semivariogram Model Fitting Example';
ods graphics on;

proc variogram data=thick outv=outv plots=none;
   compute lagd=7 maxlag=10 robust cl;
   coordinates xc=East yc=North;
   ods output SemivariogramTable=sv;
   var Thick;
run;
```

Since MAXLAG=10, you computed the empirical semivariogram at 11 points (see also Figure 95.8). You would like to obtain a smooth theoretical semivariogram plot, so you need to estimate the theoretical model at more points on the horizontal (distance) axis. The following statements create a sequence of such distance points from 0 to 70,000 feet and space them 500 feet apart:

```
data pv;
   do Distance = 0 to 70 by 0.5;
      Semivariance = .;
      output;
   end;
run;

data sv; set sv pv; by Distance;
run;
```

PROC NLIN performs its own analysis based on the Gaussian model you provided as input. By invoking the NLIN procedure twice, as shown in the following statements, you obtain the estimates for the theoretical model parameters for the OLS and WLS fitting methods. Notice in the WLS case that the weights are defined as the inverse of the computed semivariance variance.

```
proc nlin data=sv;
   parms Range=30
         Sill=7.5;
   model Semivariance =
         Sill*(1-exp(-Distance*Distance/(Range*Range)));
   output out=OLS p=OLS;
run;

proc nlin data=sv;
   parms Range=30
         Sill=7.5;
   model Semivariance =
         Sill*(1-exp(-Distance*Distance/(Range*Range)));
   _weight_ = 1/SemivarianceStdErr/SemivarianceStdErr;
   output out=WLS p=WLS;
run;
```

Output 95.1.1 shows part of the NLIN procedure output that displays the model parameters statistics for the OLS methods.

Output 95.1.1 Ordinary Least Squares Fitting Parameter Estimates

Theoretical Semivariogram Model Fitting Example

The NLIN Procedure

Parameter	Estimate	Approx Std Error	Approximate 95% Confidence Limits	
Range	27.1706	1.9211	22.8247	31.5165
Sill	7.1628	0.2781	6.5337	7.7919

The corresponding PROC NLIN output for the WLS method is displayed in the following Output 95.1.2.

Output 95.1.2 Weighted Least Squares Fitting Parameter Estimates

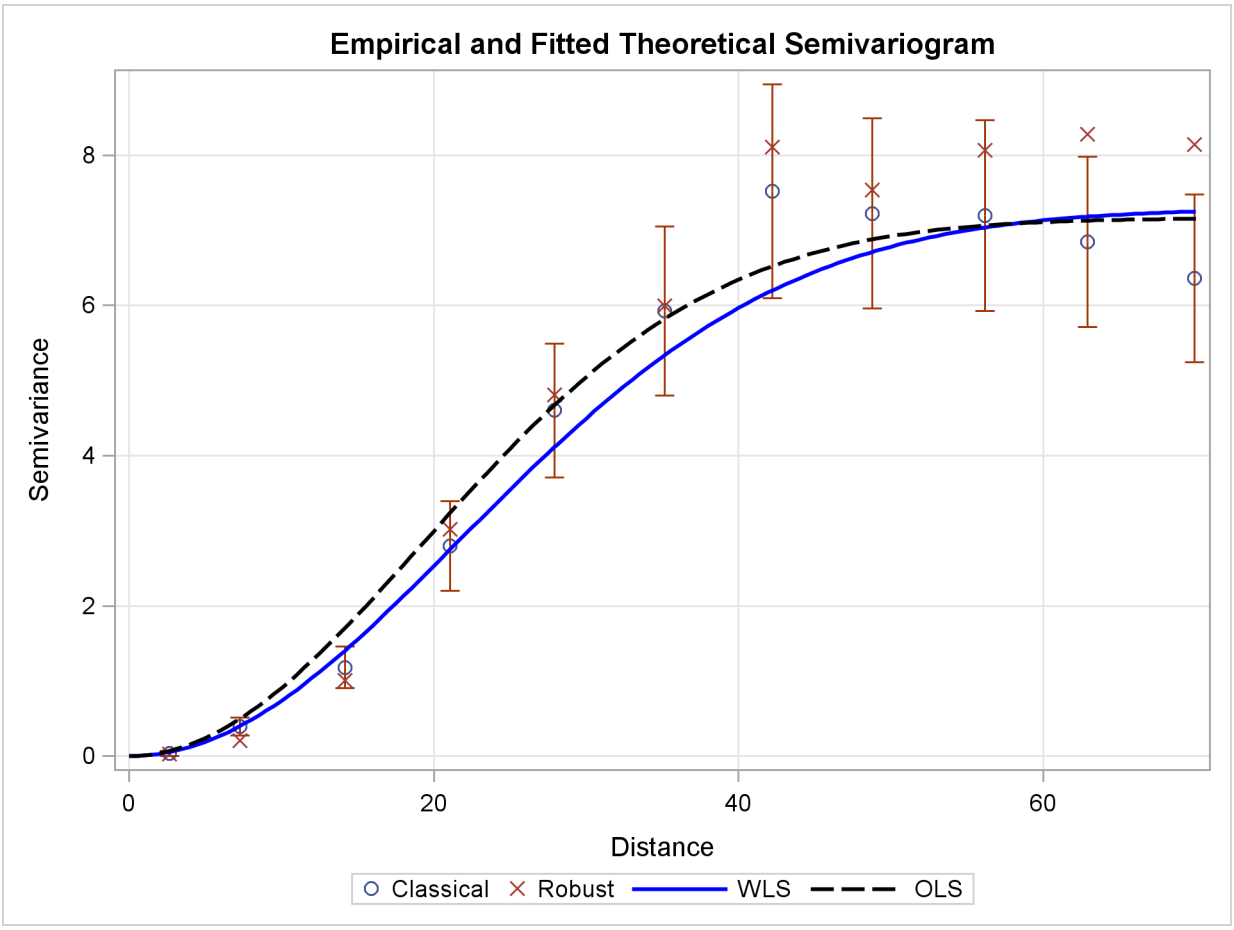
Theoretical Semivariogram Model Fitting Example

The NLIN Procedure

Parameter	Estimate	Approx Std Error	Approximate 95% Confidence Limits	
Range	30.6239	1.7382	26.6917	34.5560
Sill	7.2881	0.4082	6.3646	8.2116

Finally, you visualize the outcome of the fitting analysis. You start with a DATA step to arrange the WLS and OLS data in the same data set. Then you use the SGPLOT procedure to produce a plot showing the empirical and fitted theoretical semivariograms. This sequence is exhibited in the following statements:

```
data pv;
   merge WLS OLS;
run;



proc sgplot data=pv;
   title "Empirical and Fitted Theoretical Semivariogram";
   xaxis label = "Distance" grid;
   yaxis label = "Semivariance" grid;
   scatter y=Semivariance x=Distance /
           markerattrs = GraphData1(symbol=circle)
           name = 'SemiVarClassical'
           yerrorupper = UpperCLSemivariance
           yerrorlower = LowerCLSemivariance;
   scatter y=RobustSemivariance x=Distance /
           markerattrs = GraphData2(symbol=X)
           name = 'SemiVarRobust';
```

```
   series x=Distance y=WLS /
          lineattrs = (thickness=2px color=blue)
          name = 'SemivarPredWgh';
   series x=Distance y=OLS /
          lineattrs = (thickness=2px color=black
                       pattern=MediumDash)
          name = 'SemivarPredUnw';
   discretelegend 'SemiVarClassical' 'SemiVarRobust'
                  'SemivarPredWgh' 'SemivarPredUnw';
run;

ods graphics off;
```

Output 95.1.3 demonstrates the difference between the ordinary and weighted least squares fitting results: WLS achieves a more accurate fit closer to the empirical points with the smaller variances, because the weights are expressed as the inverse of these variances. In the presence of a sizable population per distance class, you expect the points with lower variance to be situated close to the origin, as the semivariance variance expression suggests in the section "Theoretical and Computational Details of the Semivariogram" on page 7544. Hence, you expect in general the WLS method to perform with increased accuracy at short distances because it acknowledges the smaller variance at small $\boldsymbol{h}$. In contrast, the OLS approach performs a least squares overall best fit as it assumes constant variance.

Output 95.1.3 Fitted Theoretical and Empirical Semivariogram for Coal Seam Thickness Data

The WLS method is preferred over the OLS method because it is important to obtain accurate estimates of the spatial continuity closer to the origin $\boldsymbol{h} = 0$. Another advantage of WLS over OLS is that OLS falsely assumes that the differences in the optimization process are normally distributed and independent. However, WLS has the disadvantage that the weights depend on the fitting parameters.

Other fitting methods include maximum likelihood approaches that rely crucially on the normality assumption for the data distribution, and the generalized least squares method, which offers better accuracy but is computationally more demanding. You can find extensive discussions of these issues in Cressie (1993, Section 2.3), Jian, Olea, and Yu (1996), Stein (1988), and Schabenberger and Gotway (2005).

Example 95.2: An Anisotropic Case Study with Surface Trend in the Data

This example shows how to examine data for nonrandom surface trends and anisotropy. You will use simulated data where the variable is atmospheric ozone (O_3) concentrations measured in Dobson units (DU). The coordinates are offsets from a point in the southwest corner of the measurement area, with the east and north distances in units of kilometers (km). You will be working with 300 measurements in a square area of 100 km $\times$ 100 km.

The following statements read the data set.

```
title 'Semivariogram in Anisotropic Case With Trend Removal Example';

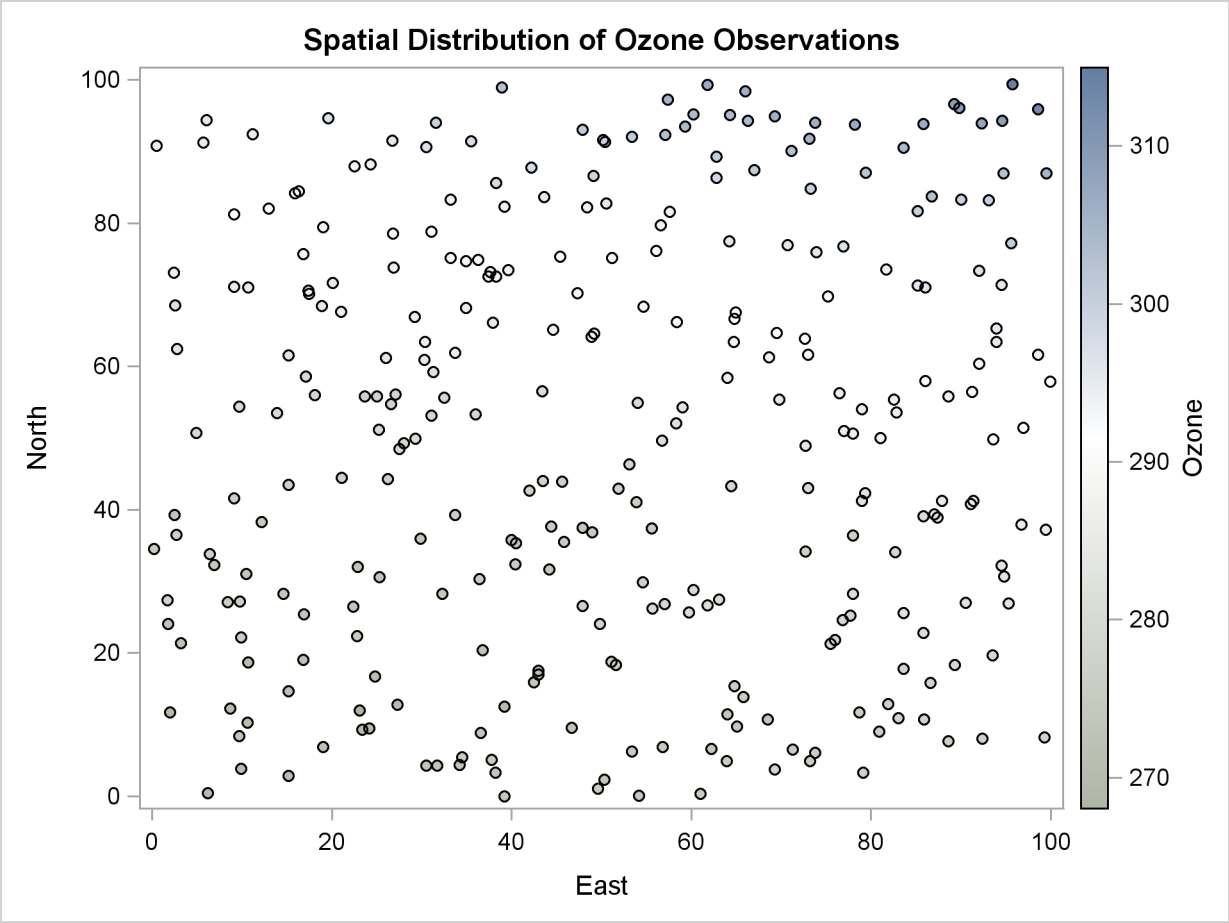
   ;
run;
```



The initial step is to explore the data set by inspecting the data spatial distribution. Run PROC VARIOGRAM, specifying the NOVARIOGRAM option in the COMPUTE statement as follows:

```
ods graphics on;

proc variogram data=ozoneSet;
   compute novariogram nhc=35;
   coord xc=East yc=North;
   var Ozone;
run;
```

The result is a scatter plot of the observed data shown in Output 95.2.1. The scatter plot suggests an almost uniform spread of the measurements throughout the prediction area. No direct inference can be made about the existence of a surface trend in the data. However, the apparent stratification of ozone values in the northeast–southwest direction might indicate a nonrandom trend.

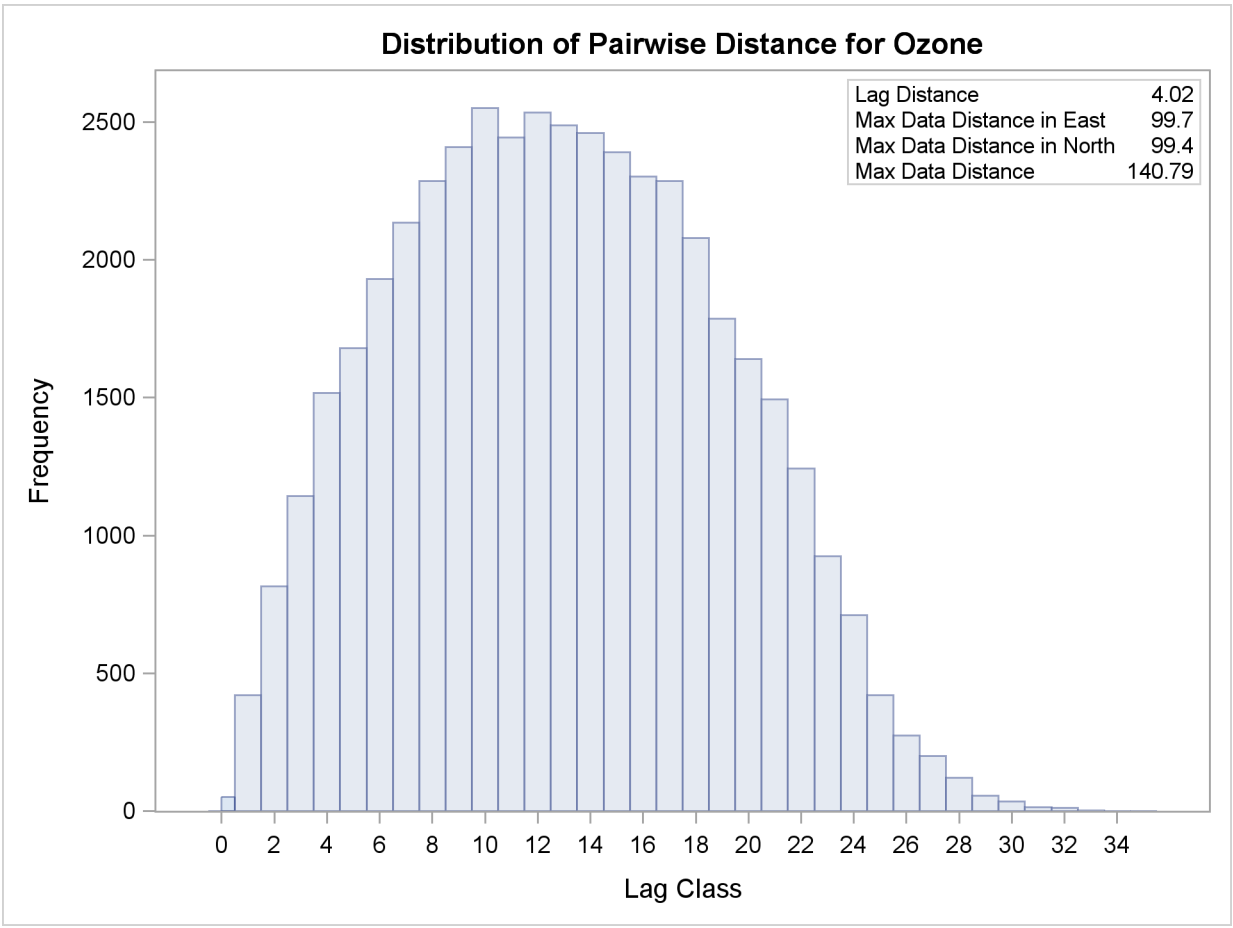
Output 95.2.1 Ozone Observation Data Scatter Plot

You will need to define the size and count of the data classes by specifying suitable values for the LAGDISTANCE= and MAXLAGS= options, respectively. Compared to the smaller sample of thickness data used in "Example 95.1: Theoretical Semivariogram Model Fitting" on page 7570, the larger size of the ozoneSet data results in more densely populated distance classes for the same

value of the NHC= option. Once you experiment with a variety of values for the NHC= option, you can adjust LAGDISTANCE= to have a relatively small number. Then you can account for a large value of MAXLAGS= so that you obtain many sample semivariogram points within your data correlation range. Specifying these values requires some exploration, for which you might need to return to this point from a later stage in your semivariogram analysis. For illustration purposes you now specify NHC=35.

Your choice of NHC=35 yields the pairwise distance intervals table in Output 95.2.2 and the corresponding histogram in Output 95.2.3.

Output 95.2.2 Pairwise Distance Intervals Table



Pairwise Distance Intervals

Lag Class	Bounds		Number of Pairs	Percentage of Pairs
0	0.00	2.01	52	0.12%
1	2.01	6.03	420	0.94%
2	6.03	10.06	815	1.82%
3	10.06	14.08	1143	2.55%
4	14.08	18.10	1518	3.38%
5	18.10	22.12	1680	3.75%
6	22.12	26.15	1931	4.31%
7	26.15	30.17	2135	4.76%
8	30.17	34.19	2285	5.09%
9	34.19	38.21	2408	5.37%
10	38.21	42.24	2551	5.69%
11	42.24	46.26	2444	5.45%
12	46.26	50.28	2535	5.65%
13	50.28	54.30	2487	5.55%
14	54.30	58.33	2460	5.48%
15	58.33	62.35	2391	5.33%
16	62.35	66.37	2302	5.13%
17	66.37	70.39	2285	5.09%
18	70.39	74.41	2079	4.64%
19	74.41	78.44	1786	3.98%
20	78.44	82.46	1640	3.66%
21	82.46	86.48	1493	3.33%
22	86.48	90.50	1243	2.77%
23	90.50	94.53	925	2.06%
24	94.53	98.55	710	1.58%
25	98.55	102.57	421	0.94%
26	102.57	106.59	274	0.61%
27	106.59	110.62	200	0.45%
28	110.62	114.64	120	0.27%
29	114.64	118.66	55	0.12%
30	118.66	122.68	35	0.08%
31	122.68	126.71	14	0.03%
32	126.71	130.73	11	0.02%
33	130.73	134.75	2	0.00%
34	134.75	138.77	0	0.00%
35	138.77	142.80	0	0.00%

Notice the overall high pair count in the majority of classes in Output 95.2.2. You can see that even for higher values of NHC= the classes are still sufficiently populated for your semivariogram analysis according to the rule of thumb stated in the section "Choosing the Size of Classes" on page 7555. Based on the displayed information in Output 95.2.3, you specify LAGDISTANCE=4 km. You can further experiment with smaller lag sizes to obtain more points in your sample semivariogram.

You will return to the MAXLAGS= specification later. The important step now is to investigate the presence of trends in the measurement. The following section makes a suggestion about how to remove surface trends from your data, and then continues the semivariogram analysis with the detrended data.

Output 95.2.3 Distribution of Pairwise Distances for Ozone Observation Data

Analysis with Surface Trend Removal

You can use a SAS/STAT predictive modeling procedure to extract surface trends from your original data. If your goal is spatial prediction, you can continue processing the detrended data for the prediction tasks, and at the end you can reinstate the trend at the prediction locations to report your analysis results.

In general, the exact form of the trend is unknown, as discussed in the section "Empirical Semivariograms and Surface Trends" on page 7559. In this case, the spatial distribution of the measurements shown in Figure 95.2.1 suggests that you can use a quadratic model to describe the surface trend like the one that follows:

$$T(\text{East}, \text{North}) = f_0 + f_1\,[\text{East}] + f_2\,[\text{East}]^2 + f_3\,[\text{North}] + f_4\,[\text{North}]^2$$

The following statements show how to invoke the GLM procedure for your ozone data, and how to extract the preceding trend from them:

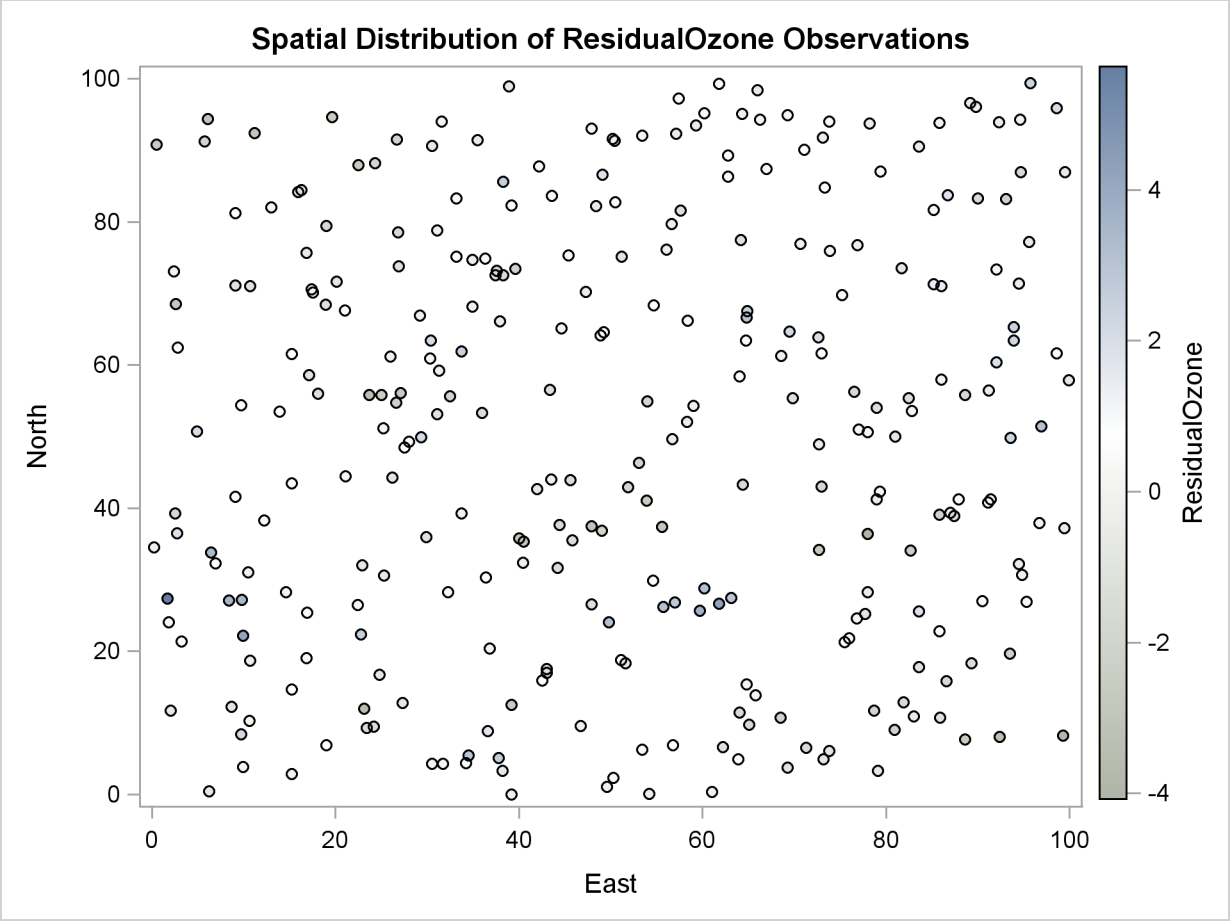
```
proc glm data=ozoneSet;
   model ozone = East East*East North North*North;
   output out=gmout predicted=pred residual=ResidualOzone;
run;
```

Among other output, PROC GLM produces estimates for the parameters $f_0, \ldots, f_4$ in the preceding trend model. Output 95.2.4 shows the table with the parameter estimates. In this table, the coefficient f_0 corresponds to the intercept estimate, and the rest of the coefficients correspond to their matching variables; for example, the estimate in the line of "East*East" refers to f_2 in the preceding model. For more information about the syntax and the PROC GLM output, see Chapter 39, "The GLM Procedure."

Output 95.2.4 Parameter Estimates for the Surface Trend Model

Semivariogram in Anisotropic Case With Trend Removal Example

The GLM Procedure



Dependent Variable: Ozone

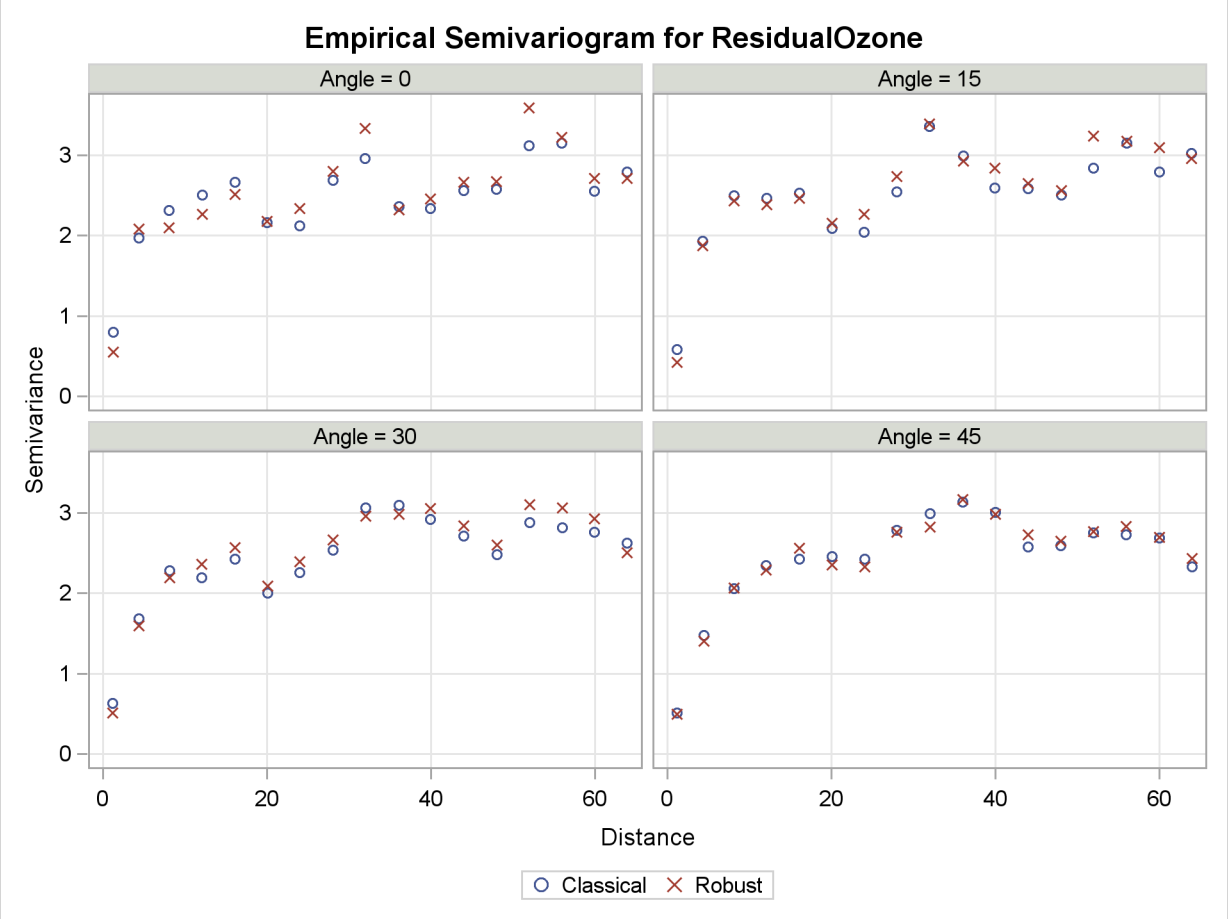
Parameter	Estimate	Standard Error	t Value	Pr > |t|
Intercept	270.6798273	0.40595731	666.77	<.0001
East	0.0065148	0.01360281	0.48	0.6323
East*East	0.0010726	0.00012987	8.26	<.0001
North	-0.0369159	0.01297491	-2.85	0.0047
North*North	0.0035587	0.00012659	28.11	<.0001

The detrending process leaves you with the GMOUT data set, which contains the ResidualOzone data residuals. You can run PROC VARIOGRAM again as follows, with the NOVARIOGRAM option to inspect the detrended residuals. Note that you ask only for the OBSERVATIONS plot, shown in Output 95.2.5.

```
proc variogram data=gmout plots(only)=observ;
  compute novariogram nhc=35;
  coord xc=East yc=North;
  var ResidualOzone;
run;
```

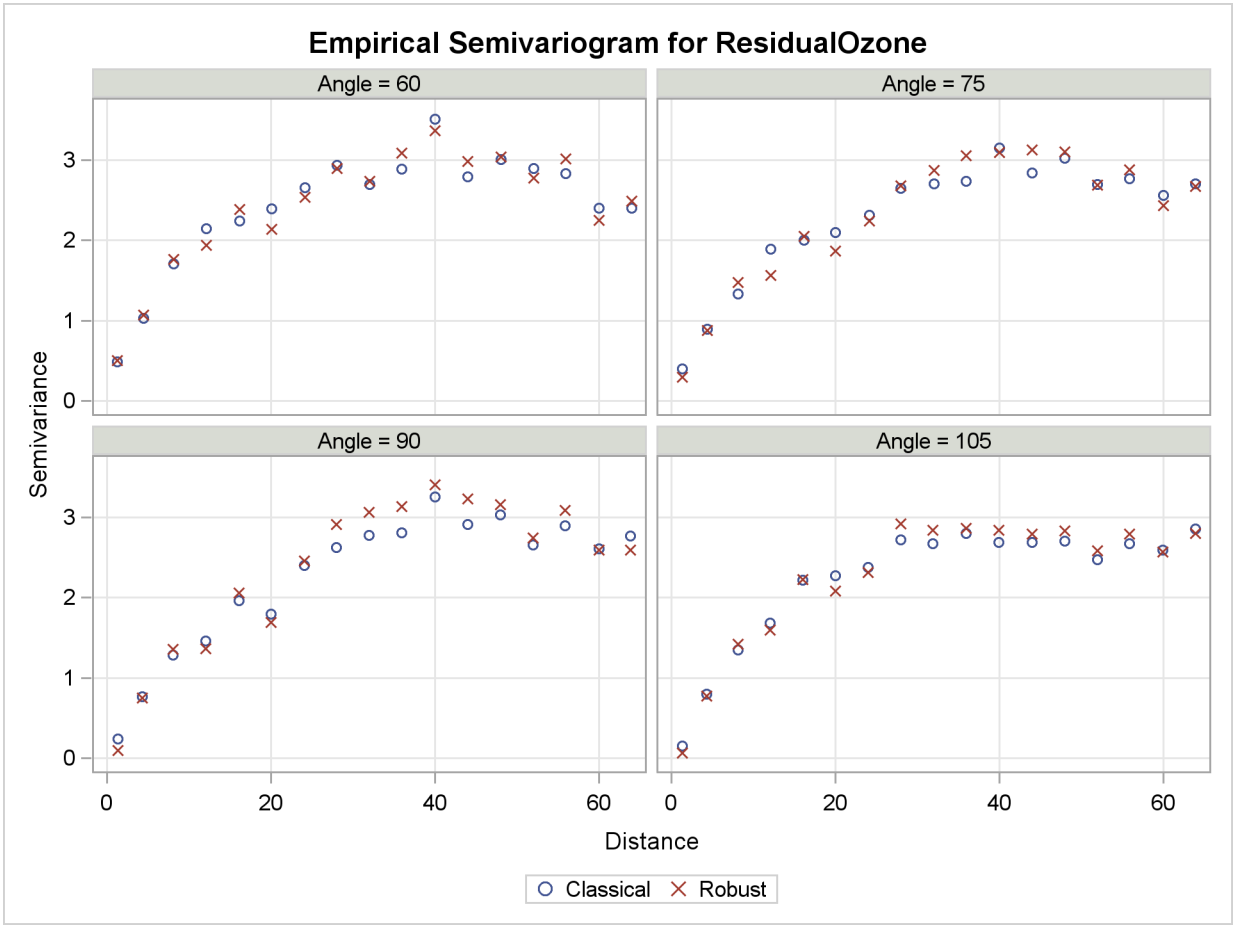
Output 95.2.5 Ozone Residual Observation Data Scatter Plot

Before you proceed with the empirical semivariogram computation and model fitting, examine your data for anisotropy. This investigation is necessary to portray the spatial structure of your SRF accurately. If anisotropy exists, it will manifest itself as different ranges and/or sills for the empirical semivariograms in different directions.



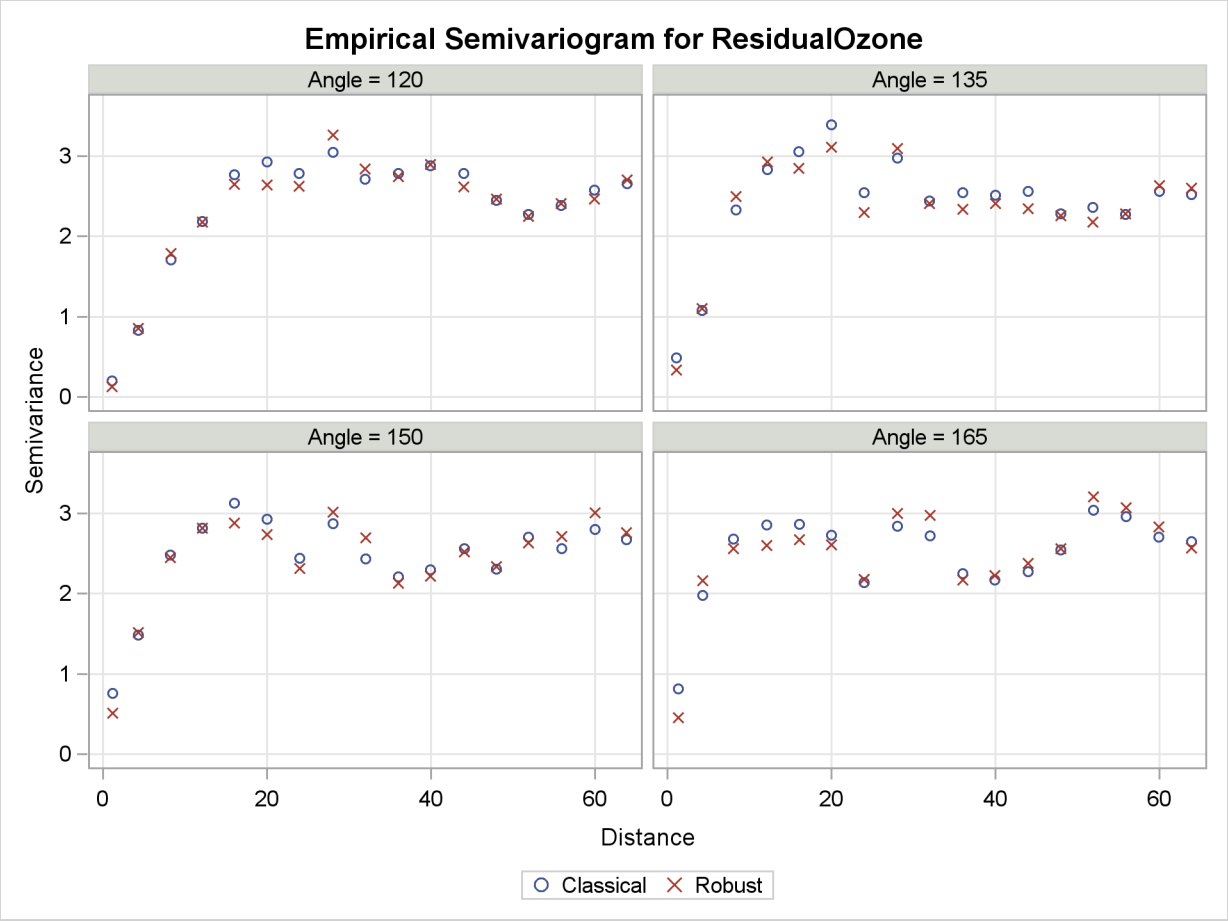
You want detail in your analysis, so you ask for the empirical semivariance in 12 directions by specifying NDIRECTIONS=12. Based on the NDIRECTIONS= option, empirical semivariograms are produced in increments of the base angle $\theta = 180°/12 = 15°$.

You also choose ANGLETOLERANCE=22.5 and BANDWIDTH=20. A different choice of values will produce different empirical semivariograms, because these options can regulate the number of pairs that are included in a class. You do not want these parameters to have values that are too small, so that you can allow for an adequate number of point pairs per class. On the other hand, the higher the values of these parameters, the more data pairs coming from closely neighboring directions will be included in each lag. In this case, there is a risk of losing information along the particular direction. This can be a side effect because you will incorporate data pairs from a broader spectrum of angles, and thus potentially amplify weaker anisotropy or weaken stronger anisotropy, as noted in the section "Angle Classification" on page 7549. You can experiment with different ANGLETOLERANCE= and BANDWIDTH= values to reach this balance with your data, if necessary.



With the following statements you ask to display only the SEMIVAR plots in the specified number of directions. Multiple empirical semivariograms are placed by default in panels, as Output 95.2.6 shows. If you want an individual plot for each angle, then you need to further specify the plot option SEMIVAR(UNPACK).

```
proc variogram data=gmout plot(only)=semivar;
   compute lagd=4 maxlag=16 ndir=12 atol=22.5 bandw=20 robust;
   coord xc=East yc=North;
   var ResidualOzone;
run;
```



Output 95.2.6 Ozone Empirical Semivariograms with $0° \leq \theta < 180°$ and $\delta\theta = 15°$

Output 95.2.6 *continued*

Output 95.2.6 *continued*

Note that in some of the directions, such as for $\theta = 0°$, the directional plots tend to exhibit a somewhat noisy structure. This behavior can be due to the pairs distribution across the particular direction. Specifically, based on the LAGDISTANCE= choice there might be insufficient pairs present in a class. Also, depending on the ANGLETOLERANCE= and BANDWIDTH= values, too many pairs might be considered from neighboring angles that potentially follow a modified structure. These are factors that can increase the variability in the semivariance estimate. A different explanation might lie in the existence of outliers in the data set; this aspect is further explored in "Example 95.5: A Box Plot of the Square Root Difference Cloud" on page 7600.

This behavior is relatively mild here and should not obstruct your goal to study anisotropy in your data. You can also perform individual computations in any direction. By doing so, you can fine-tune the computation parameters and attempt to obtain smoother estimates of the sample semivariance.

Further in this study, the directional plots in Output 95.2.6 suggest that during shifting from $\theta = 0°$ to $\theta = 90°$, the empirical semivariogram range increases. Beyond the angle $\theta = 90°$, the range starts decreasing again until the whole circle is traversed at 180° and small range values are encountered around the N–S direction at $\theta = 0°$. Note that the sill seems to remain overall the same. This analysis suggests that there is anisotropy in the ozone concentrations, with the major axis oriented at about $\theta = 90°$ and the minor axis situated perpendicular to the major axis at $\theta = 0°$.

The multidirectional analysis requires that for a given LAGDISTANCE= you also specify a MAXLAGS= value. Since the ozone correlation range might be unknown (as assumed here), you can apply the rule of thumb that suggests use of the half-extreme data distance in the direction of interest, as explained in the section "Spatial Extent of the Empirical Semivariogram" on page 7556. Following the information displayed in Output 95.2.3, for different directions this distance varies between $99.4/2 = 49.7$ and $140.8/2 = 70.4$ km. In turn, the pairwise distances table in Output 95.2.2 indicates that within this range of distances you can specify MAXLAG= to be between 12 and 17 lags. In this example you specify MAXLAG=16.

At this point you are ready to continue with fitting theoretical semivariogram models to the empirical semivariogram in the selected directions of $\theta = 0°$ and $\theta = 90°$. This process follows the exact steps shown in "Example 95.1: Theoretical Semivariogram Model Fitting" on page 7570. You apply weighted least squares fitting. In the following, PROC NLIN is used for the simultaneous theoretical semivariogram fitting in both directions of interest. By trying out different models, you see that an exponential one is suitable for your empirical data:

$$\gamma_z(h) = c_0 \left[1 - \exp\left(-\frac{h}{a_0} \right) \right]$$

where $\gamma_z(0) = 0$ and $a_0 > 0$. First, you run PROC VARIOGRAM to create the necessary input information for PROC NLIN. The NLIN procedure needs information about the semivariance variance, which you obtain when you specify the CL option in the COMPUTE statement. You use the following statements:

```
proc variogram data=gmout plot=none;
   compute lagd=4 maxlag=16 robust cl;
   directions 0(22.5,10) 90(22.5,10);
   coord xc=East yc=North;
   ods output SemivariogramTable=svg;
   var ResidualOzone;
run;
```

You also request a vector of points throughout the Distance axis where PROC NLIN estimates the theoretical model values for the two selected directions. Note that essentially you need such a vector for each one of these directions. Then, the output of PROC VARIOGRAM is combined with the added Distance points into the PROC NLIN input data set, as shown in the following statements:

```
data pv;
   do Angle = 0 to 90 by 90;
      do Distance = 0 to 64 by 0.5;
         Semivariance = .;
         output;
      end;
   end;
run;

data svg; set svg pv; by Angle Distance;
run;
```

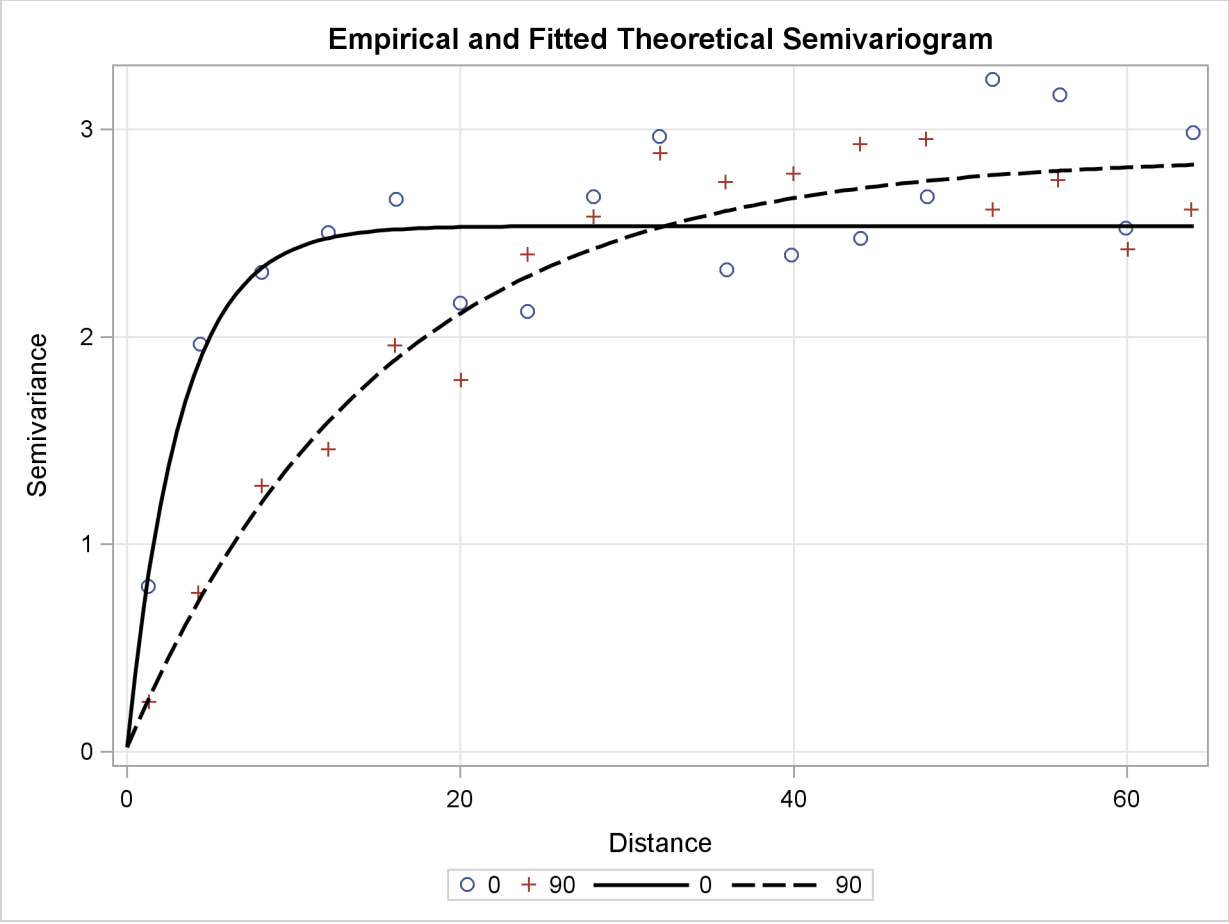
PROC NLIN requires initial values for the fitting parameters. For the $\theta = 0°$ direction, Output 95.2.6 suggests that a range $a_{00,init} = 4$ km (effective range $r_{\epsilon 0} = 12$ km) and a partial sill ${\sigma_0}^2{}_{0,init} = 2.5$ can be used. Output 95.2.6 indicates that in the direction of $\theta = 90°$, a range of $a_{090,init} = 16$ km (effective range $r_{\epsilon 9}0 = 48$ km) and a partial sill ${\sigma_0}^2{}_{90,init} = 3$ can be used. Both cases indicate that there is no significant nugget effect present. The nugget effect is initialized to the value $c_{ninit} = 0$. Note that you use one nugget effect value for all directions; that is, it is considered isotropic. The following statements implement these considerations, and PROC SGPLOT is eventually called to create the sample and theoretical semivariogram plots:

```
proc nlin data=svg;
   parms Nugget=0 Range0=4   PartSill0=2.5
                  Range90=16 PartSill90=3;
   if (Angle=0) then
      y = Nugget + PartSill0*(1-exp(-Distance/Range0));
   else if (Angle=90) then
      y = Nugget + PartSill90*(1-exp(-Distance/Range90));
   model Semivariance = y;
   _weight_ = 1/SemivarianceStdErr/SemivarianceStdErr;
   output out=WLS p=WLSprediction;
run;

proc sgplot data=WLS;
   title "Empirical and Fitted Theoretical Semivariogram";
   xaxis label = "Distance" grid;
   yaxis label = "Semivariance" grid;
   scatter y=Semivariance x=Distance /
           name='SemiVarClassical'
           group=Angle;
   series x=Distance y=WLSprediction /
          lineattrs=(thickness=2px color=black)
          name='SemivarPredWgh'
          group=Angle;
   discretelegend 'SemiVarClassical' 'SemivarPredWgh';
run;

ods graphics off;
```

Output 95.2.7 shows the PROC NLIN estimates of the fitting parameters. From this table, you can easily compute the estimates for the sills in $\theta = 0°$ and $\theta = 90°$, which are $c_{00} = 2.5339$ and $c_{090} = 2.8703$, respectively. The fitted and empirical semivariograms are displayed in Output 95.2.8.



Output 95.2.7 Weighted Least Squares Fitting Parameter Estimates for the Selected Directions $\theta = 0°$ and $\theta = 90°$

Semivariogram in Anisotropic Case With Trend Removal Example

The NLIN Procedure

Parameter	Estimate	Approx Std Error	Approximate 95% Confidence Limits	
Nugget	0.0214	0.1517	-0.2888	0.3316
Range0	3.2073	1.1413	0.8730	5.5415
PartSill0	2.5125	0.1677	2.1696	2.8554
Range90	15.0962	2.7113	9.5510	20.6414
PartSill90	2.8489	0.1740	2.4930	3.2048

Output 95.2.8 Fitted Theoretical and Empirical Semivariogram for the Ozone Data in the $\theta = 0°$ and $\theta = 90°$ Directions

Conclusively, your semivariogram analysis on the detrended ozone data suggests that the ozone SRF exhibits anisotropy in the perpendicular directions of N–S ($\theta = 0°$) and E–W ($\theta = 90°$). The sills in the two directions of anisotropy are similar in size, whereas the range in the major axis is about 4.5 times larger than the minor axis range.

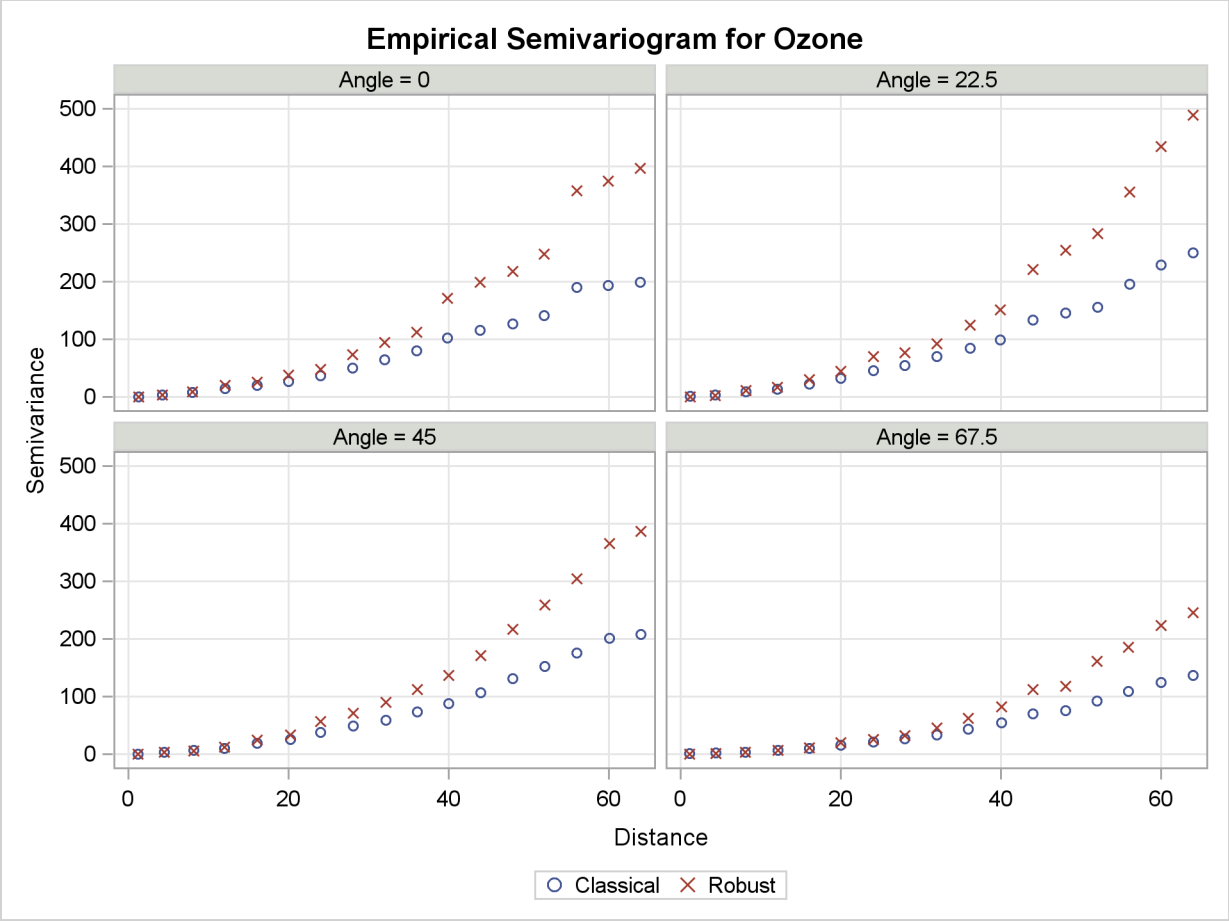
Example 95.3: Analysis without Surface Trend Removal

This example uses PROC VARIOGRAM without removing potential surface trends in a data set, in order to investigate a distinguished spatial direction in the data. In doing so, this example also serves as a guide to examine under which circumstances you might be able to bypass the effect of a trend on a semivariogram. Typically, though, for theoretical semivariogram estimations you follow the analysis presented in "Example 95.2: An Anisotropic Case Study with Surface Trend in the Data" on page 7574.

As explained in the section "Details: VARIOGRAM Procedure" on page 7540, when you compute the empirical semivariance for data that contain underlying surface trends, the outcome is the pseudo-semivariance. Pseudo-semivariograms are not estimates of the theoretical semivariogram; hence, they do not provide any information about the spatial continuity of your SRF.

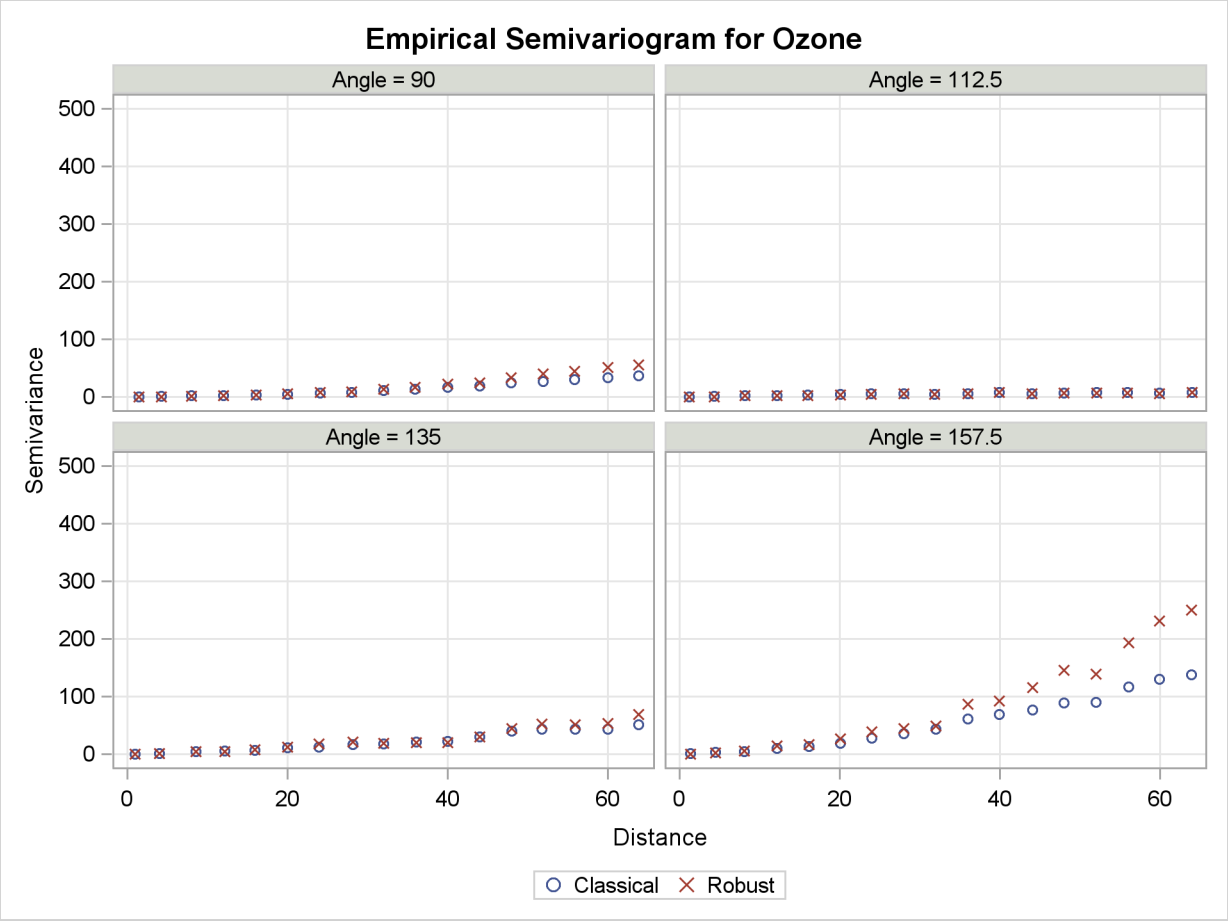
However, in the section "Empirical Semivariograms and Surface Trends" on page 7559 it is mentioned that you might still be able to perform a semivariogram analysis with potentially non-trend-free data, if you suspect that your measurements might be trend-free across one or more specific directions. The example demonstrates this approach.

Reconsider the ozone data presented at the beginning of "Example 95.2: An Anisotropic Case Study with Surface Trend in the Data" on page 7574. The spatial distribution of the data is shown in Figure 95.2.1, and the pairwise distance distribution for NHC=35 is illustrated in Figure 95.2.3. This exploratory analysis suggested a LAGDISTANCE=4 km, and Figure 95.2.2 indicated that for this LAGDISTANCE= you can consider a value of MAXLAGS=16.



Recall from the section "Empirical Semivariograms and Surface Trends" on page 7559 that you need to investigate the empirical semivariogram of the data in a few different directions, in order to identify a trend-free direction. If such a direction exists, then you can proceed with this special type of analysis. The following statements employ NDIRECTIONS=8 to examine eight directions:

```
title 'Semivariogram Without Trend Removal Example';
ods graphics on;



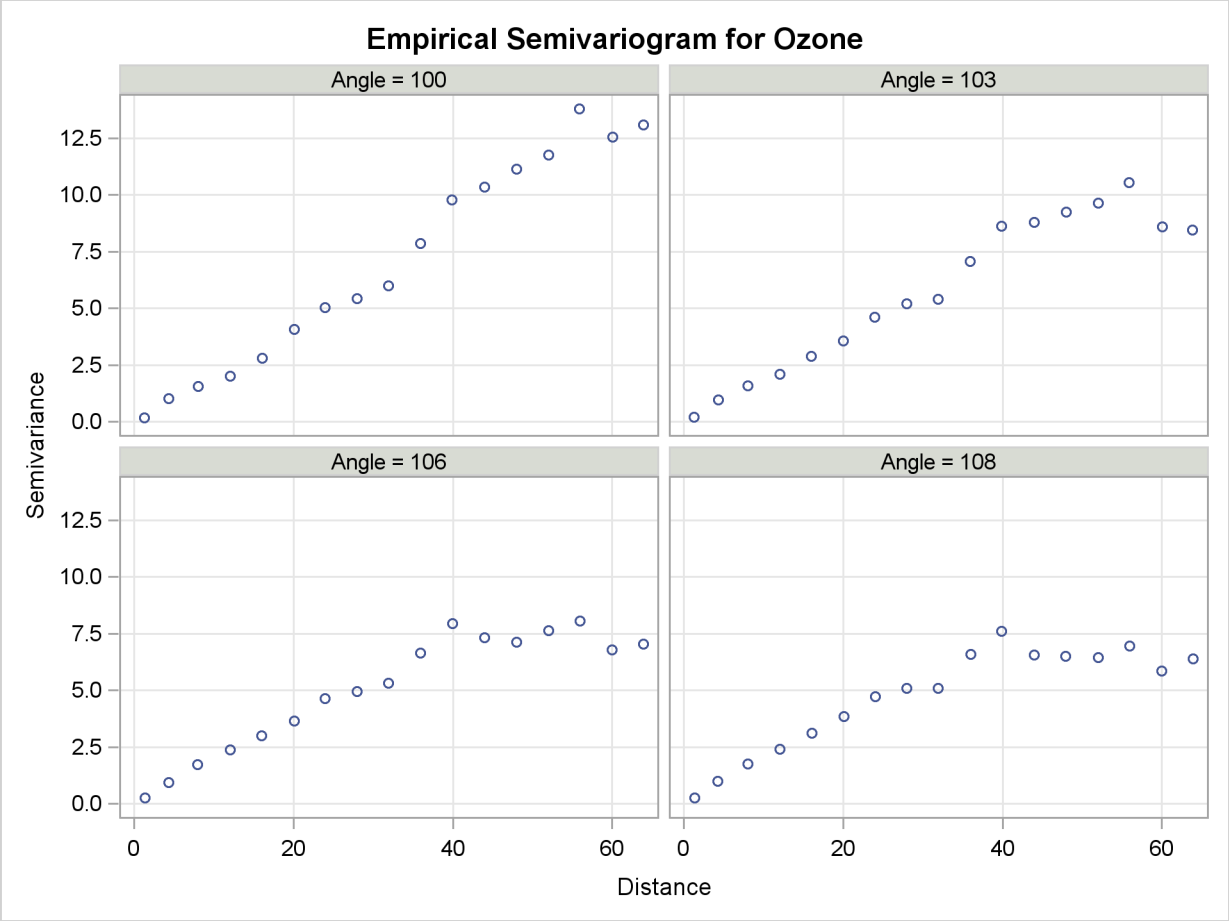
proc variogram data=ozoneSet plot(only)=semivar;
   compute lagd=4 maxlag=16 ndirections=8 robust;
   coord xc=East yc=North;
   var Ozone;
run;
```

By default, the range of 180° is divided into eight equally distanced angles: $\theta = 0°$, $\theta = 22.5°$, $\theta = 45°$, $\theta = 67.5°$, $\theta = 90°$, $\theta = 112.5°$, $\theta = 135°$, and $\theta = 157.5°$. The resulting empirical semivariograms for these angles are shown in Output 95.3.1.

Output 95.3.1 Ozone Empirical Semivariograms with $0° \leq \theta < 180°$ and $\delta\theta = 22.5°$

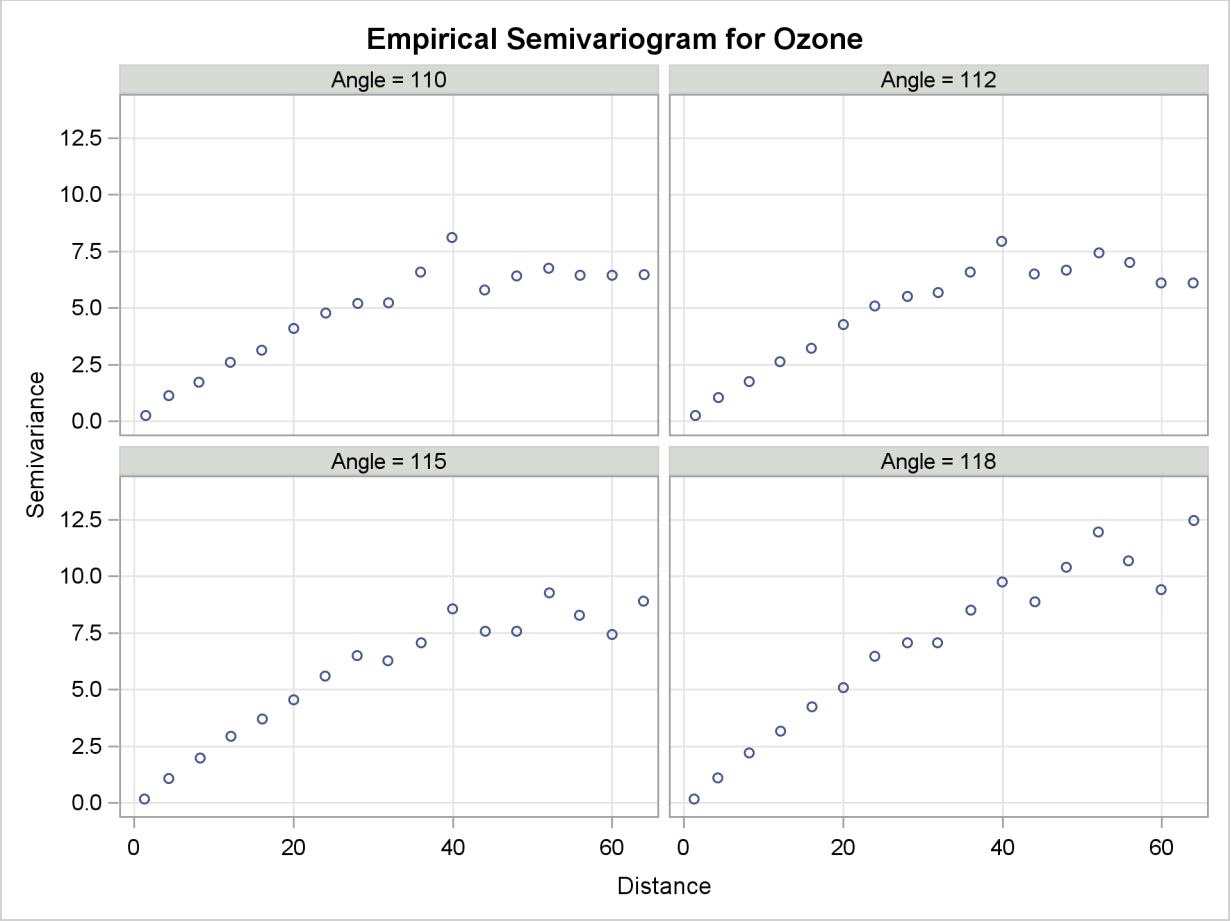
Output 95.3.1 *continued*

The figures in Output 95.3.1 suggest that in all directions there is an overall continuing increase with distance of the semivariance. As explained in the section "Theoretical Semivariogram Models" on page 7540, this can be an indication of systematic trends in the data. However, in the direction of $\theta = 112.5°$ there is a clear indication that the increase rate, if any, is smaller than the corresponding rates across the rest of the directions. You then want to search whether there exists a trend-free direction in the neighborhood of this angle.



Run PROC VARIOGRAM again, specifying several directions within an interval of angles where you want to close in and suspect the existence of a trend-free direction. In the following step you use an ANGLETOL=15°, which is smaller than the default value of 22.5°, as well as a BANDWIDTH=10 km. The smaller values help with minimization of the interference with neighboring directions, as discussed in the section "Angle Classification" on page 7549.

The aforementioned considerations are addressed in the following statements:



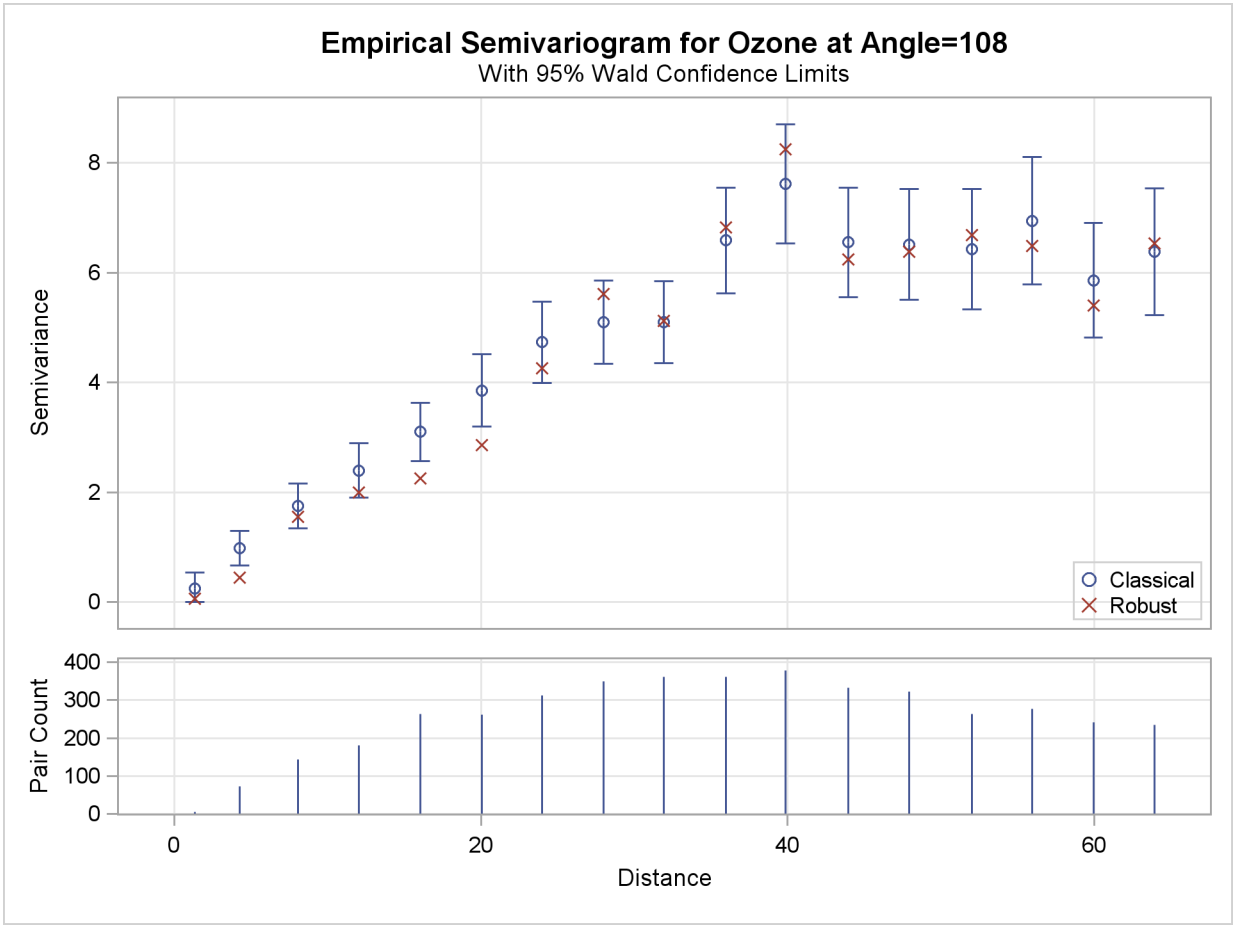
```
proc variogram data=ozoneSet plot(only)=semivar(cla);
   compute lagd=4 maxlag=16 robust;
   directions 100(15,10) 103(15,10)
              106(15,10) 108(15,10)
              110(15,10) 112(15,10)
              115(15,10) 118(15,10);
   coord xc=East yc=North;
   var Ozone;
run;
```

Your analysis has brought you to examine a narrow strip of angles within $\theta = 100°$ and $\theta = 118°$. The pseudo-semivariograms in Output 95.3.2 and Output 95.3.3 indicate that at the boundaries of this strip, the angles display increasing semivariance with distance. On the other hand, within this interval there are directions across which the semivariance is tentatively reaching a sill, and these are potential candidates to be trend-free directions.

Output 95.3.2 Ozone Empirical Semivariograms in 100°, 103°, 106°, and 108°

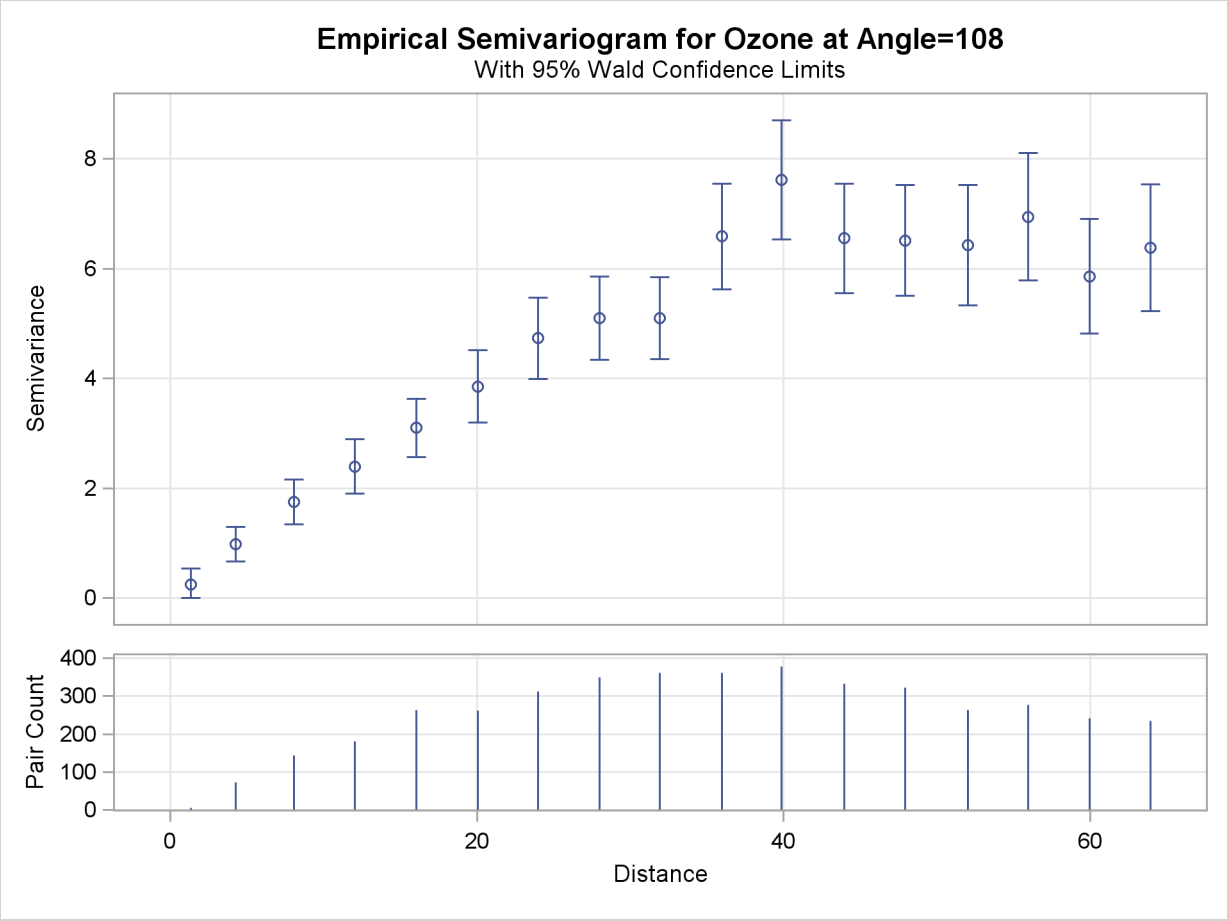
Output 95.3.3 Ozone Empirical Semivariograms in 110°, 112°, 115°, and 118°

You could further investigate this angle spectrum in more detail. For example, you can monitor additional angles in between, or use a smaller LAGDISTANCE= and increased MAXLAGS= values to single out the most qualified candidate. For the purpose of this example, you can consider the direction $\theta = 108°$ to very likely be the trend-free one you are looking for.



From a physical standpoint, it is also mentioned in the section "Empirical Semivariograms and Surface Trends" on page 7559 that you should expect the trend-free direction, if it exists, to be perpendicular to the direction of the maximum dip in the values of the ozone field. If you cross-examine the ozone data distribution in Output 95.2.1, the figure suggests that this direction exists and is slightly tilted clockwise with respect to the E–W axis. This direction emerges from the mild stratification of the ozone values in your data distribution. The ozone concentrations across it are similar when compared to surrounding directions, and as such, it has been identified as a trend-free direction.

Your next step is to obtain the empirical semivariogram in the suspected trend-free direction of $\theta = 108°$, and to perform a theoretical model fit as shown in "Example 95.1: Theoretical Semivariogram Model Fitting" on page 7570 and "Example 95.2: An Anisotropic Case Study with Surface Trend in the Data" on page 7574.



First, assume that you want to inspect the classical and robust empirical semivariograms in the selected direction, as well as a separate plot of the classical one and its confidence limits. Use the PLOT option as shown in the following statements to produce the two empirical semivariograms for your selected angle. The resulting plots are displayed in Output 95.3.4 and Output 95.3.5.

```
proc variogram data=ozoneSet
               plot(only)=(semivar semivar(cla));
   compute lagd=4 maxlag=16 robust cl;
   directions 108(15,10);
   coord xc=East yc=North;
   ods output SemivariogramTable=sv;
   var ozone;
run;
```

Output 95.3.4 Ozone Classical and Robust Empirical Semivariograms in $\theta = 108°$

Output 95.3.5 Ozone Classical Empirical Semivariogram in $\theta = 108°$

Then, you create a vector of points on the Distance axis to provide enough theoretical model estimation locations for a smooth plot. Also, you combine this data set with the output of PROC VARIOGRAM to create the input data set for PROC NLIN. The statements you use are as follows:

```
data pv;
   do Distance = 0 to 64 by 0.5;
      Semivariance = .;
      output;
   end;
run;

data sv; set sv pv; by Distance;
run;
```

Finally, as in the previous examples, you employ PROC NLIN to fit a theoretical model to the empirical semivariogram shown in Output 95.3.5. Note that you have not omitted specifying the CL option earlier in the COMPUTE statement in PROC VARIOGRAM, so that you can provide PROC NLIN with semivariance variance information. The semivariance exhibits a slow, almost linear rise at short distances and seems to be reaching the sill fast, rather than asymptotically.

You can accommodate this behavior by using the following spherical model:

$$\gamma_z(h) = \begin{cases} c_n + {\sigma_0}^2 \left[\frac{3}{2}\frac{h}{a_0} - \frac{1}{2}(\frac{h}{a_0})^3 \right], & \text{for } 0 < h \leq a_0 \\ c_0, & \text{for } a_0 < h \end{cases}$$

where $\gamma_z(0) = 0$ and $a_0 > 0$. PROC NLIN requires initial values for the model parameters. A reasonable initial choice for the sill value is about 7, and for the range $a_{0init} = 40$ km. Though there does not seem to be a nugget effect, you use an initial value $c_{ninit} = 0$ and you initialize the partial sill by using ${\sigma_0}^2{}_{init} = 7$. The following statements implement these considerations. Consequently, PROC SGPLOT is invoked to create the empirical and theoretical semivariogram plots.

```
proc nlin data=sv;
   parms Nugget=0 Range=40 PartSill=7;
   if (Distance<Range)
      then y = Nugget + PartSill*(1.5*(Distance/Range) -
                                  0.5*(Distance/Range)**3);
      else y = Nugget + PartSill;
   model Semivariance = y;
   _weight_ = 1/SemivarianceStdErr/SemivarianceStdErr;
   output out=WLS p=WLSprediction;
run;

proc sgplot data=WLS;
   title "Empirical and Fitted Theoretical Semivariogram";
   xaxis label = "Distance" grid;
   yaxis label = "Semivariance" grid;
   scatter y=Semivariance x=Distance /
           markerattrs = GraphData1(symbol=circle)
           name='SemiVarClassical';
   series x=Distance y=WLSprediction /
          lineattrs = (thickness=2px color=black)
          name = 'SemivarPredWgh';
   discretelegend 'SemiVarClassical' 'SemivarPredWgh';
run;

ods graphics off;
```

PROC NLIN fits the requested model, for which the range, partial sill, and nugget effect estimates are shown in Figure 95.3.6. Clearly, there is an almost negligible nugget effect based on the weighted least squares PROC NLIN analysis. From the fitted values the estimate for the theoretical semivariogram sill is $c_0 = 6.55601$. Figure 95.3.7 displays the fitted and empirical semivariograms in the selected direction $\theta = 108°$.

Output 95.3.6 Weighted Least Squares Fitting Parameter Estimates for $\theta = 108°$

Semivariogram Without Trend Removal Example

The NLIN Procedure

Parameter	Estimate	Approx Std Error	Approximate 95% Confidence Limits	
Nugget	0.00991	0.1111	−0.2284	0.2482
Range	47.0906	2.7872	41.1126	53.0685
PartSill	6.5461	0.2208	6.0725	7.0197

Output 95.3.7 Fitted Theoretical and Empirical Semivariogram for Ozone Data in the Direction $\theta = 108°$

A comparative look at the empirical and fitted semivariograms in Output 95.3.7 and Output 95.2.8 suggests that the analysis of the trend-free ResidualOzone produces a different outcome from that of the original Ozone values. In fact, a more suitable comparison can be made between the semivariograms in the assumed trend-free direction $\theta = 108°$ of the current scenario, and the one shown in Output 95.2.6 in the nearly identical direction $\theta = 105°$. It might seem unreasonable that these two semivariograms are produced both in the same ozone study and in a narrow band of directions free

of apparent surface trends, yet they bear no resemblance. However, the lack of similarity in these plots stems from operating on two different data sets where the outcome depends on the actual data values.

More specifically, in the eyes of semivariogram analysis the trend-free ozone set and the original ozone measurements are treated as different quantities. The process of detrending the original Ozone values is a transformation of these values into the trend-free ones of ResidualOzone. Any existing spatial correlation in the original data is not directly memorized into the transformed data, but is rather affected by the transformation features. In principle, the emerging data set has its own characteristics, as demonstrated in this example.

A final remark concerns the issue of isotropy. Based on the details presented in the section "Empirical Semivariograms and Surface Trends" on page 7559, your knowledge of the spatial structure of the ozoneSet data set is limited to the selected trend-free direction you indicated in the present example. You can generalize this outcome for all spatial directions only if you consider the hypothesis of isotropy in the ozone field to be reasonable. Note that you cannot infer the assumption of anisotropy in the present example based on the analysis in the section "Analysis with Surface Trend Removal" on page 7578. Again, the reason is that you currently use the observed Ozone values, whereas the ResidualOzone data in the previous example emerged from a transformation of the current data. Hence, you have essentially two data sets that do not necessarily share the same properties.

Example 95.4: Covariogram and Semivariogram

The covariance that was reviewed in the section "Stationarity" on page 7546 is an alternative measure of spatial continuity that can be used instead of the semivariance. In a similar manner to the empirical semivariance that was presented in the section "Theoretical and Computational Details of the Semivariogram" on page 7544, you can also compute the empirical covariance. The covariograms are plots of this quantity and can be used to fit permissible theoretical covariance models, in correspondence to the semivariogram analysis presented in the section "Theoretical Semivariogram Models" on page 7540. This example displays a comparative view of the empirical covariogram and semivariogram, and examines some additional aspects of these two measures.

You consider 500 simulations of an SRF $Z(\boldsymbol{s})$ in a square domain of 100×100 (10^6 km^2). The following DATA step defines the data locations:

```
title 'Covariogram and Semivariogram Example';
data dataCoord;
   retain seed 837591;
   do i=1 to 100;
      East = round(100*ranuni(seed),0.1);
      North = round(100*ranuni(seed),0.1);
      output;
   end;
run;
```

For the simulations you use PROC SIM2D, which produces Gaussian simulations of SRFs with user-specified covariance structure—see Chapter 79, "The SIM2D Procedure." The Gaussian SRF

implies full knowledge of the SRF expected value $\mathrm{E}[Z(\boldsymbol{s})]$ and variance $\mathrm{Var}[Z(\boldsymbol{s})]$ at every location $\boldsymbol{s}$. The following statements simulate an isotropic, second-order stationary SRF with constant expected value and variance throughout the simulation domain:

```
ods graphics on;

proc sim2d outsim=dataSims;
   simulate numreal=500 seed=79750
            nugget=2 scale=6 range=10 form=exp;
   mean 30;
   grid gdata=dataCoord xc=East yc=North;
run;
```

Here, the SIMULATE statement accommodates the simulation parameters. The NUMREAL= option specifies that you want to perform 500 simulations, and the SEED= option specifies the seed for the simulation random number generator. You use the MEAN statement to specify the expected value $\mathrm{E}[Z(\boldsymbol{s})] = 30$ units of Z. You also specify two variance components. The first is the nugget effect, and you use the NUGGET= option to set it to $c_n = 2$. The second is the partial sill ${\sigma_0}^2 = 6$ that you specify with the SCALE= option. The two variance components make up the total SRF variance $\mathrm{Var}[Z(\boldsymbol{s})] = c_n + {\sigma_0}^2 = 8$. You assume an exponential covariance structure to describe the field spatial continuity, where ${\sigma_0}^2$ is the sill value, and its range $a_0 = 10$ km (effective range $a_\epsilon = 3a_0 = 30$ km) is specified by the RANGE= option. The option FORM= specifies the covariance structure type.

The empirical semivariance and covariance are computed by the VARIOGRAM procedure, and are available either in the ODS output semivariogram table (as variables Semivariance and Covariance, respectively) or in the OUTVAR= data set. In the following statements you obtain these variables by using the OUTVAR= data set of the VARIOGRAM procedure:

```
proc variogram data=dataSims outv=outv noprint;
   compute lagd=3 maxlag=18;
   coord xc=gxc yc=gyc;
   by _ITER_;
   var svalue;
run;
```

For each distance lag you take the average of the empirical measures over the number of simulations. PROC SORT is used to prepare the input data for PROC MEANS, which produces these averages and stores them in the dataAvgs data set. This sequence is performed with the following statements:

```
proc sort data=outv;
   by lag;
run;

proc means data=outv n mean noprint;
   var Distance variog covar;
   by lag;
   output out=dataAvgs mean(variog)=Semivariance
                       mean(covar)=Covariance
                       mean(Distance)=Distance;
run;
```

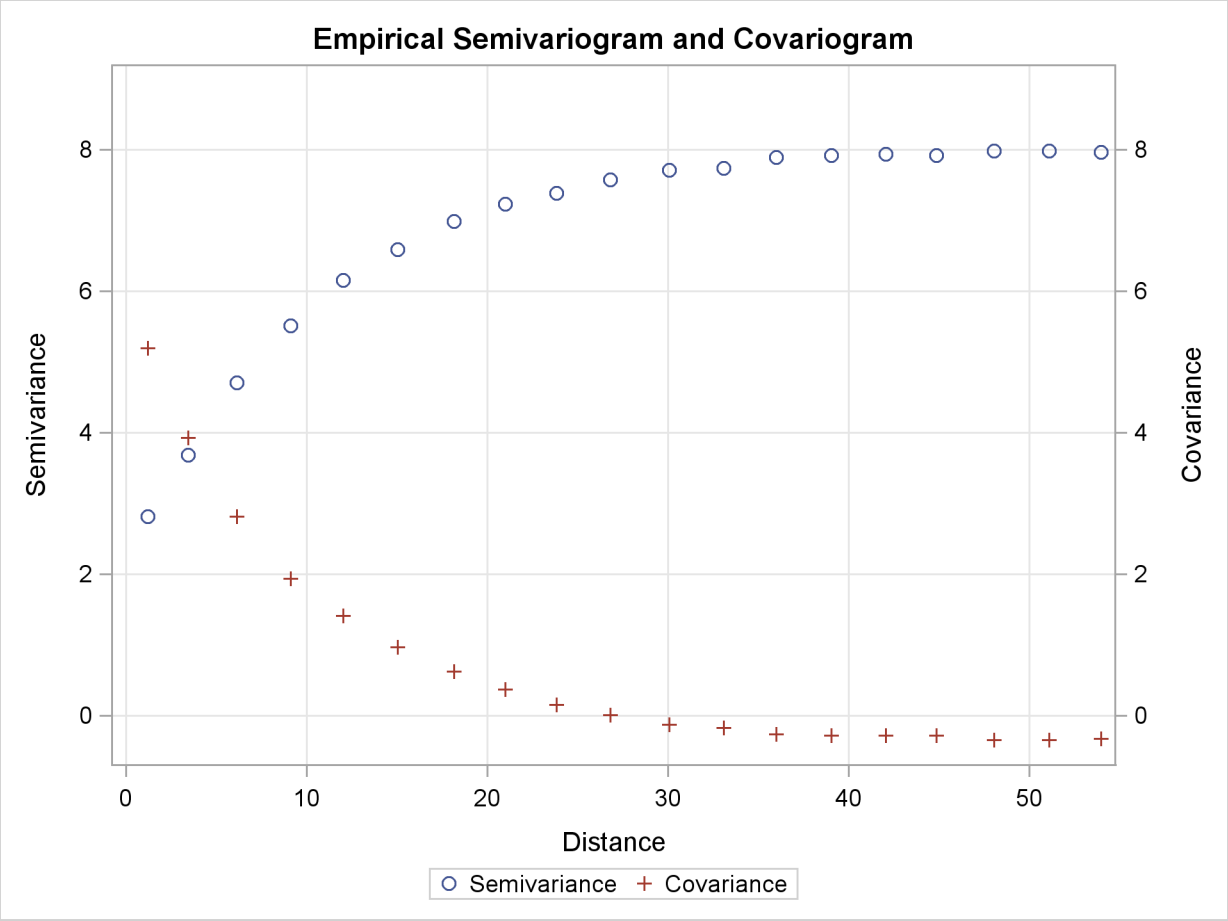
The SGPLOT procedure is used to create the plot of the average empirical semivariogram and covariogram, as in the following statements:

```
proc sgplot data=dataAvgs;
   title "Empirical Semivariogram and Covariogram";
   xaxis label = "Distance" grid;
   yaxis  label = "Semivariance" min=-0.5 max=9 grid;
   y2axis label = "Covariance"   min=-0.5 max=9;
   scatter y=Semivariance x=Distance /
           markerattrs = GraphData1
           name='Semivar'
           legendlabel='Semivariance';
   scatter y=Covariance x=Distance /
           y2axis
           markerattrs = GraphData2
           name='Covar'
           legendlabel='Covariance';
   discretelegend 'Semivar' 'Covar';
run;

ods graphics off;
```

The plot of the average empirical semivariance and covariance of the preceding analysis is shown in Output 95.4.1. Note that the high number of simulations led to averages of empirical continuity measures that accurately approximate the simulated SRF characteristics. Specifically, the empirical semivariogram and covariogram both exhibit clearly exponential behavior. The semivariogram sill is approximately at the specified variance $\mathrm{Var}[Z(\boldsymbol{s})] = 8$ of the SRF.

The simulated SRF is second-order stationary, so you expect at each lag the sum of the empirical semivariance and covariance to approximate the field variance $\mathrm{Var}[Z(\boldsymbol{s})]$, as explained in the section "Stationarity" on page 7546. This behavior is evident in Output 95.4.1.



We conclude with a discussion of basic reasons why the empirical semivariogram analysis is commonly preferred to the empirical covariance analysis. A first reason comes from the assumptions that are necessary to compute each of these two measures. The condition of intrinsic stationarity that is required in order to define the empirical semivariogram is less restrictive than the condition of second-order stationarity that is required in order to consider the covariance function as a parameter of the process.

Also, an empirical semivariogram can indicate whether a nugget effect is present in your data sample, whereas the empirical covariogram itself might not reveal this information. This point is illustrated in Output 95.4.1, where you expect to see that $C(\mathbf{0}) = \mathrm{Var}[Z(\boldsymbol{s})]$, but the empirical covariogram cannot have a point at exactly $\boldsymbol{h} = \mathbf{0}$. There is a practical way to investigate for a nugget effect when you use empirical covariograms. Recall that the OUTVAR= data set provides you with the sample variance (shown in the COVAR column for LAG=-1), as the following statement shows:

```
/* Obtain the sample variance from the data set ----------------*/

proc print data=dataAvgs (obs=1);
```

Output 95.4.1 Average Empirical Semivariogram and Covariogram from 500 Simulations

Output 95.4.2 is a partial output of the dataAvgs data set, which contains averages of the OUTVAR= data set, and shows the computed average $C(\mathbf{0})$ in the Covariance column. The combination of the empirical covariogram and the $C(\mathbf{0})$ value can help you fit a theoretical covariance model that will include any nugget effect, if present. See also the discussion in Schabenberger and Gotway (2005, Section 4.2.2) about the Matérn definition of the covariance function that is related to this issue. In particular, this definition provides for an additional variance component in the covariance expression at $\boldsymbol{h} = \mathbf{0}$ to account for the corresponding nugget effect in the semivariogram.

Output 95.4.2 Partial Outcome of the dataAvgs Data Set

Empirical Semivariogram and Covariogram

Obs	LAG	_TYPE_	_FREQ_	Semivariance	Covariance	Distance
1	-1	0	500	.	7.74832	.

In addition to the preceding points, if the SRF is nonstationary, the empirical semivariogram indicates that the SRF variance will increase with distance $\boldsymbol{h}$, as Output 95.3.1 shows in "Example 95.3: Analysis without Surface Trend Removal" on page 7587. In that case it makes no sense to compute the empirical covariogram. Specifically, the covariogram could provide you with an estimate of the sample variance, which is not sufficient to indicate that the SRF might not be stationary (see also Chilès and Delfiner 1999, p. 31).

Finally, the definitions of the empirical semivariance and covariance in the section "Theoretical and Computational Details of the Semivariogram" on page 7544 clearly show that the sample mean $\bar{Z}$ and the SRF expected value $\mathrm{E}[Z(\boldsymbol{s})]$ are not important for the computation of the semivariance, but either one is necessary for the covariance. Hence, the semivariance expression filters the mean, which is especially useful when it is unknown. On the other hand, if $\mathrm{E}[Z(\boldsymbol{s})]$ is unknown and the empirical covariance is computed based on the sample mean $\bar{Z}$, this can induce additional bias in the covariance computation.

Example 95.5: A Box Plot of the Square Root Difference Cloud

The Gaussian form chosen for the semivariogram in the section "Getting Started: VARIOGRAM Procedure" on page 7519 is based on consideration of the plots of the sample semivariogram. For the coal thickness data, the Gaussian form appears to be a reasonable choice.

However, it can often happen that a plot of the sample variogram shows so much scatter that no particular form is evident. The cause of this scatter can be one or more outliers in the pairwise differences of the measured quantities.

A method of identifying potential outliers is discussed in Cressie (1993, Section 2.2.2). This example illustrates how to use the OUTPAIR= data set from PROC VARIOGRAM to produce a square root difference cloud, which is useful in detecting outliers.

For the SRF $Z(\boldsymbol{s}), \boldsymbol{s} \in \mathcal{R}^2$, the square root difference cloud for a particular direction $\boldsymbol{e}$ is given by

$$| Z(s_i + he) - Z(s_i) |^{\frac{1}{2}}$$

for a given lag distance h. In the actual computation, all pairs $P_1 P_2$ of points P_1, P_2 within a distance tolerance around h and an angle tolerance around the direction $\boldsymbol{e}$ are used. This generates a number of point pairs for each lag class h. The spread of these values gives an indication of outliers.

Following the example in the section "Getting Started: VARIOGRAM Procedure" on page 7519, this example uses a basic LAGDISTANCE=7, with a distance tolerance of 3.5, and a direction of N–S, with an angle tolerance ATOL=30°.

First, use PROC VARIOGRAM to produce an OUTPAIR= data set. Then use a DATA step to subset this data by choosing pairs within 30° of N–S. In addition, compute lag class and square root difference variables, as the following statements show:

```
title 'Square Root Difference Cloud Example';
data thick;
   input East North Thick @@;
   label Thick='Coal Seam Thickness';

   ;

ods graphics on;

proc variogram data=thick outp=outp noprint;
   compute novariogram;
   coordinates xc=East yc=North;
   var Thick;
run;

data sqroot;
   set outp;
   /*- Include only points +/- 30 degrees of N-S -------*/
   where abs(cos) < 0.5;
   /*- Unit lag of 7, distance tolerance of 3.5 --------*/
   lag_class=int(distance/7 + 0.5000001);
   sqr_diff=sqrt(abs(v1-v2));
run;

proc sort data=sqroot;
   by lag_class;
run;
```

Next, summarize the results by using the MEANS procedure. The statements follow, and the output is shown in Output 95.5.1.

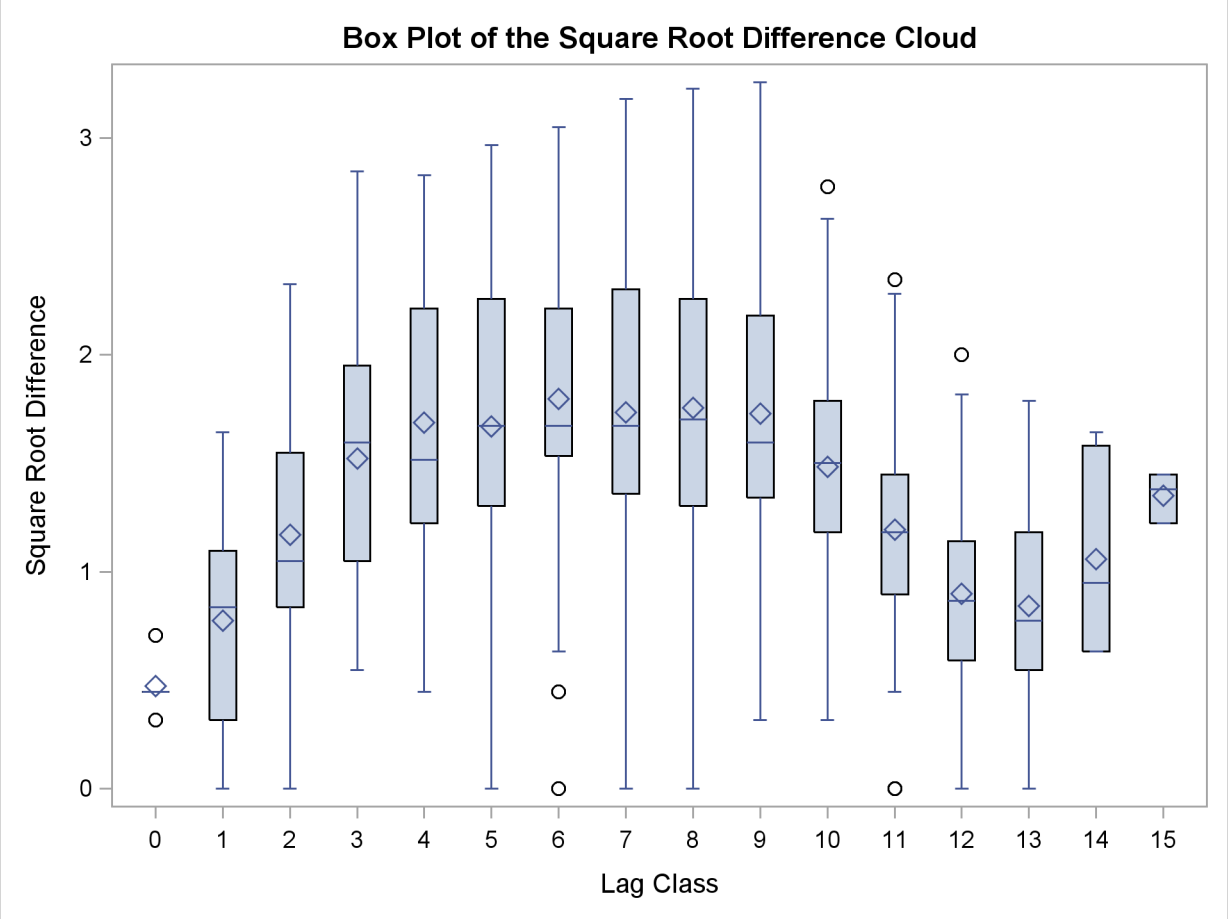
```
proc means data=sqroot noprint n mean std;
   var sqr_diff;
   by lag_class;
   output out=msqrt n=n mean=mean std=std;
run;
title2 'Summary of Results';

proc print data=msqrt;
   id lag_class;
   var n mean std;
run;
```

Output 95.5.1 Summary of Results

Square Root Difference Cloud Example
Summary of Results

lag_class	n	mean	std
0	5	0.47300	0.14263
1	31	0.77338	0.41467
2	51	1.17052	0.47800
3	58	1.52287	0.51454
4	65	1.68625	0.58465
5	65	1.66963	0.68582
6	80	1.79693	0.62929
7	88	1.73334	0.73191
8	83	1.75528	0.68767
9	108	1.72901	0.58274
10	80	1.48268	0.48695
11	84	1.19242	0.47037
12	68	0.89765	0.42510
13	38	0.84223	0.44249
14	7	1.05653	0.42548
15	3	1.35076	0.11472



Finally, present the results in a box plot by using the SGPLOT procedure. The box plot facilitates the detection of outliers. The statements are as follows:

```
proc sgplot data=sqroot;
   xaxis label = "Lag Class";
   yaxis label = "Square Root Difference";
   title "Box Plot of the Square Root Difference Cloud";
   vbox sqr_diff /category=lag_class;
run;

ods graphics off;
```

Output 95.5.2 suggests that there do not appear to be any outliers adversely affecting the empirical semivariogram in the N–S direction for the coal seam thickness data. The conclusion from Output 95.5.2 is consistent with our previous semivariogram analysis of the same data set in the section "Getting Started: VARIOGRAM Procedure" on page 7519. The effect of the isolated outliers in lag classes 6 and 10–12 in Output 95.5.2 is demonstrated as the divergence between the classical and robust empirical semivariance estimates in the higher distances in Output 95.8. The difference in these estimates comes from the definition of the robust semivariance estimator $\bar{\gamma}_z(\boldsymbol{h})$ (see the section "Theoretical and Computational Details of the Semivariogram" on page 7544), which imposes a smoothing effect on the outlier influence.

Output 95.5.2 Box Plot of the Square Root Difference Cloud

Introduction to Special SAS Data Sets

All SAS/STAT procedures create SAS data sets. Any table generated by a procedure can be saved to a data set by using the Output Delivery System (ODS), and many procedures also have syntax that enables you to save other statistics to data sets. Some of these data sets are organized according to certain conventions so that they can be read by a SAS/STAT procedure for further analysis. Such specially organized data sets are recognized by the TYPE= data set attribute.

The CORR procedure (see the *Base SAS Procedures Guide: Statistical Procedures*), for example, can create a data set with the attribute TYPE=CORR containing a correlation matrix. This TYPE=CORR data set can be read by the REG or FACTOR procedure, among others. If the original data set is large, using a special SAS data set in this way can save computer time by avoiding the recomputation of the correlation matrix in subsequent analyses.

PROC REG, for example, can create a TYPE=EST data set containing estimated regression coefficients. If you need to make predictions for new observations, you can use the SCORE procedure to read both the TYPE=EST data set and a data set containing the new observations. PROC SCORE can then compute predicted values or residuals without repeating the entire regression analysis. See Chapter 76, "The SCORE Procedure," for an example.

A special SAS data set might contain different kinds of statistics. A special variable called _TYPE_ is used to distinguish the various statistics. For example, in a TYPE=CORR data set, an observation in which _TYPE_='MEAN' contains the means of the variables in the analysis, and an observation in which _TYPE_='STD' contains the standard deviations. Correlations appear in observations with _TYPE_='CORR'. Another special variable, _NAME_, is needed to identify the row of the correlation matrix. Thus, the correlation between variables X and Y is given by the value of the variable X in the observation for which _TYPE_='CORR' and _NAME_='Y', or by the value of the variable Y in the observation for which _TYPE_='CORR' and _NAME_='X'.

The special data sets created by SAS/STAT procedures can generally be used directly by other procedures without modification. However, if you create an output data set with PROC CORR and use the NOCORR option to omit the correlation matrix from the OUT= data set, you need to set the TYPE= option either in parentheses following the OUT= data set name in the PROC CORR statement or in parentheses following the DATA= option in any other procedure that recognizes the special TYPE= attribute. In either case, the TYPE= option should be set to COV, CSSCP, or SSCP according to what type of matrix is stored in the data set and what data set types are accepted as input by the other procedures you plan to use. If you do not follow these steps and you use the TYPE=CORR data set with no correlation matrix as input to another procedure, the procedure might issue an error message indicating that the correlation matrix is missing from the data set.

You can create special SAS data sets directly in a DATA step by specifying the TYPE= option in parentheses after the data set name in the DATA statement. See "Example A.2: Creating a TYPE=CORR Data Set in a DATA Step" on page 7612 for an example. If you use a DATA step with a SET statement to modify a special SAS data set, you must specify the TYPE= option in the DATA statement. The TYPE= attribute of the data set in the SET statement is *not* automatically copied to the data set being created. You can determine the TYPE= attribute of a data set by using the CONTENTS procedure (see "Example A.1: A TYPE=CORR Data Set Produced by PROC CORR" on page 7611 and the *Base SAS Procedures Guide* for details).

Table A.1 summarizes the TYPE= data sets that can be used as input to SAS/STAT procedures. Table A.2 summarizes the TYPE= data sets that are created by SAS/STAT procedures and the statements each procedure uses to create its special output data sets. Most procedures accept ordinary SAS data sets and create ordinary output SAS data sets with no TYPE= specification in addition to the special data sets shown in the tables. When you specify a data set with a type that the procedure does not recognize, the procedure prints an error message and stops executing.

Table A.1 SAS/STAT Procedures That Accept Special Input Data Sets Types

Procedure	Special TYPE= Data Sets Accepted
ACECLUS	ACE, CORR, COV, SSCP, UCORR, UCOV
BOXPLOT	BOXPLOT, CHARTSUM

Special SAS Data Sets

TYPE=ACE Data Sets

A TYPE=ACE data set is created by the ACECLUS procedure, and it contains the approximate within-cluster covariance estimate, as well as eigenvalues and eigenvectors from a canonical analysis, among other statistics. It can be used as input to the ACECLUS procedure to initialize another execution of PROC ACECLUS. It can also be used to compute canonical variable scores with PROC SCORE and as input to PROC FACTOR, specifying METHOD=SCORE, to rotate the canonical variables. See Chapter 22, "The ACECLUS Procedure," for details.

TYPE=BOXPLOT Data Sets

A TYPE=BOXPLOT data set is created by and used by the BOXPLOT procedure. The data set contains the group summary statistics and outlier values required for constructing a schematic box plot. Each observation in a TYPE=BOXPLOT data set records the value of a single feature of one group's box-and-whiskers plot, such as its mean. Consequently, a TYPE=BOXPLOT data set contains multiple observations per group. These must appear consecutively in the data set. The _TYPE_ variable identifies the feature whose value is recorded in a given observation. _TYPE_ values of 'N', 'MIN', 'Q1', 'MEDIAN', 'MEAN', 'Q3', and 'MAX 'are required for each group. See Chapter 24, "The BOXPLOT Procedure," for details.

TYPE=CHARTSUM Data Sets

A TYPE=CHARTSUM data set is created by and used by the BOXPLOT procedure. The data set contains group summary statistics associated with box-and-whiskers plots. See Chapter 24, "The BOXPLOT Procedure," for details.

TYPE=CORR Data Sets

A TYPE=CORR data set usually contains a correlation matrix and possibly other statistics including means, standard deviations, and the number of observations in the original SAS data set from which the correlation matrix was computed. Using PROC CORR with an output data set option (OUTP=, OUTS=, OUTK=, OUTH=, or OUT=) produces a TYPE=CORR data set. (For a complete description of the CORR procedure, see the *Base SAS Procedures Guide: Statistical Procedures*.) The CALIS, CANCORR, CANDISC, DISCRIM, PRINCOMP, and VARCLUS procedures

can also create a TYPE=CORR data set with additional statistics. A TYPE=CORR data set containing a correlation matrix can be used as input for the ACECLUS, CALIS, CANCORR, CANDISC, DISCRIM, FACTOR, PRINCOMP, REG, SCORE, STEPDISC, and VARCLUS procedures. The variables in a TYPE=CORR data set are as follows:

- the BY variable or variables, if a BY statement is used with the procedure
- _TYPE_, a character variable of length eight with values identifying the type of statistic in each observation, such as 'MEAN', 'STD', 'N', and 'CORR'
- _NAME_, a character variable with values identifying the variable with which a given row of the correlation matrix is associated
- other variables that were analyzed by the CORR procedure or other procedures

The usual values of the _TYPE_ variable are as follows:

TYPE	Contents
MEAN	mean of each variable analyzed
STD	standard deviation of each variable
N	number of observations used in the analysis. PROC CORR records the number of nonmissing values for each variable unless the NOMISS option is used. If the NOMISS option is specified, or if the CALIS, CANCORR, CANDISC, PRINCOMP, or VARCLUS procedure is used to create the data set, observations with one or more missing values are omitted from the analysis, so this value is the same for each variable and provides the number of observations with no missing values. If a FREQ statement is used with the procedure that creates the data set, the number of observations is the sum of the relevant values of the variable in the FREQ statement. Procedures that read a TYPE=CORR data set use the smallest value in the observation with _TYPE_='N' as the number of observations in the analysis.
SUMWGT	sum of the observation weights if a WEIGHT statement is used with the procedure that creates the data set. The values are determined analogously to those of the _TYPE_='N' observation.
CORR	correlations with the variable named by the _NAME_ variable

There might be additional observations in a TYPE=CORR data set depending on the particular procedure and options used.

If you create a TYPE=CORR data set yourself, the data set need not contain the observations with _TYPE_='MEAN', 'STD', 'N', or 'SUMWGT', unless you intend to use one of the discriminant procedures. Procedures assume that all of the means are 0.0 and that the standard deviations are 1.0 if this information is not in the TYPE=CORR data set. If _TYPE_='N' does not appear, most procedures assume that the number of observations is 10,000; significance tests and other statistics that depend on the number of observations are, of course, meaningless. In the CALIS and CANCORR procedures, you can use the EDF= option instead of including a _TYPE_='N' observation.

A correlation matrix is symmetric; that is, the correlation between X and Y is the same as the correlation between Y and X. The CALIS, CANCORR, CANDISC, CORR, DISCRIM, PRINCOMP, and VARCLUS procedures output the entire correlation matrix. If you create the data set yourself, you need to include only one of the two occurrences of the correlation between two variables; the other can be given a missing value.

If you create a TYPE=CORR data set yourself, the _TYPE_ and _NAME_ variables are not necessary except for use with the discriminant procedures and PROC SCORE. If there is no _TYPE_ variable, then all observations are assumed to contain correlations. If there is no _NAME_ variable, the first observation is assumed to correspond to the first variable in the analysis, the second observation to the second variable, and so on. However, if you omit the _NAME_ variable, you will not be able to analyze arbitrary subsets of the variables or list the variables in a VAR or MODEL statement in a different order.

Example A.1: A TYPE=CORR Data Set Produced by PROC CORR

See Figure A.1 for an example of a TYPE=CORR data set produced by the following SAS statements. Figure A.2 displays partial output from PROC CONTENTS, which indicates that the "Data Set Type" is 'CORR'.

TYPE=COV Data Sets

A TYPE=COV data set is similar to a TYPE=CORR data set except that it has _TYPE_='COV' observations containing covariances instead of or in addition to _TYPE_='CORR' observations containing correlations. The CALIS and PRINCOMP procedures create a TYPE=COV data set if the COV option is used. You can also create a TYPE=COV data set by using PROC CORR with the COV and NOCORR options and specifying the data set option TYPE=COV in parentheses following the name of the output data set. You can use only the OUTP= or OUT= option to create a TYPE=COV data set with PROC CORR. Another way to create a TYPE=COV data set is to read a covariance matrix in a data set, in the same manner as shown in "Example A.2: Creating a TYPE=CORR Data Set in a DATA Step" on page 7612 for a TYPE=CORR data set. TYPE=COV data sets are used by the same procedures that use TYPE=CORR data sets.

TYPE=CSSCP Data Sets

A TYPE=CSSCP data set contains a corrected sum of squares and crossproducts (CSSCP) matrix. TYPE=CSSCP data sets are created by using the CORR procedure with the CSSCP option and specifying the data set option TYPE=CSSCP in parentheses following the name of the OUTP= or OUT= data set. You can also create TYPE=CSSCP data sets in a DATA step; in this case, TYPE=CSSCP must be specified as a data set option. The variables in a TYPE=CSSCP data set are the same as those found in a TYPE=SSCP data set, except that there is not a variable called Intercept or a row with _NAME_='Intercept'. TYPE=CSSCP data sets are read by only the CANDISC, DISCRIM, and STEPDISC procedures. Formulas useful for illustrating differences between corrected and uncorrected matrices in some special SAS data sets are shown in the section "Definitional Formulas" on page 7619.

TYPE=DISTANCE Data Sets

PROC DISTANCE creates a TYPE=DISTANCE or TYPE=SIMILAR data set, depending on the METHOD= option. TYPE=DISTANCE can be used as an input data set to PROC MODECLUS or PROC CLUSTER, but TYPE=SIMILAR cannot be used as an input to any procedures. The proximity measures are stored as a lower triangular matrix or a square matrix in the OUT= data set (depending on the SHAPE= option). See Chapter 32, "The DISTANCE Procedure," for details. You can also create a TYPE=DISTANCE data set in a DATA step by reading or computing a lower triangular or symmetric matrix of dissimilarity values, such as a chart of mileage between cities. The number of observations must be equal to the number of variables used in the analysis. This type of data set is used as input by the CLUSTER and MODECLUS procedures. PROC CLUSTER ignores the upper triangular portion of a TYPE=DISTANCE data set and assumes that all main diagonal values are zero, even if they are missing. PROC MODECLUS uses the entire distance matrix and does not require the matrix to be symmetric. See Chapter 29, "The CLUSTER Procedure," and Chapter 57, "The MODECLUS Procedure," for examples and details.

TYPE=EST Data Sets

A TYPE=EST data set contains parameter estimates. The CALIS, CATMOD, LIFEREG, LOGISTIC, NLIN, ORTHOREG, PHREG, PROBIT, and REG procedures create TYPE=EST data sets when the OUTEST= option is specified. A TYPE=EST data set produced by PROC LIFEREG, PROC ORTHOREG, or PROC REG can be used with PROC SCORE to compute residuals or predicted values. The variables in a TYPE=EST data set include the following:

- the BY variables, if a BY statement is used
- _TYPE_, a character variable of length eight, that indicates the type of estimate. The values depend on which procedure created the data set. Usually a value of 'PARM' or 'PARMS' indicates estimated regression coefficients, and a value of 'COV' or 'COVB' indicates estimated covariances of the parameter estimates. Some procedures, such as PROC NLIN, have other values of _TYPE_ for special purposes.
- _NAME_, a character variable that contains the values of the names of the rows of the covariance matrix when the procedure outputs the covariance matrix of the parameter estimates
- variables that contain the parameter estimates, usually the same variables that appear in the VAR statement or in any MODEL statement. See Chapter 25, "The CALIS Procedure," Chapter 28, "The CATMOD Procedure," and Chapter 60, "The NLIN Procedure," for details on the variable names used in output data sets created by those procedures.

Other variables can be included depending on the particular procedure and options used.

Example A.3: A TYPE=EST Data Set Produced by PROC REG

Figure A.4 shows the TYPE=EST data set produced by the following statements:

```
proc reg data=SocEcon outest=regest covout;
   full:   model house=pop school employ services / noprint;
   empser: model house=employ services / noprint;
run; quit;

proc print data=regest;
run;
```

TYPE=FACTOR Data Sets

A TYPE=FACTOR data set is created by PROC FACTOR when the OUTSTAT= option is specified. The CALIS, CANCORR, FACTOR, PRINCOMP, SCORE, and VARCLUS procedures can use TYPE=FACTOR data sets as input. The variables are the same as in a TYPE=CORR data set. The statistics include means, standard deviations, sample size, correlations, eigenvalues, eigenvectors, factor patterns, residual correlations, scoring coefficients, and others depending on the options specified. See Chapter 33, "The FACTOR Procedure," for details. When the NOINT option is used

with the OUTSTAT= option in PROC FACTOR, the value of the _TYPE_ variable is set to 'USCORE' instead of 'SCORE' to indicate that the scoring coefficients have not been corrected for the mean. If this data set is used with PROC SCORE, the value of the _TYPE_ variable tells PROC SCORE whether or not to subtract the mean from the scoring coefficients.

TYPE=LINEAR Data Sets

A TYPE=LINEAR data set contains the coefficients of a linear function of the variables in observations with _TYPE_='LINEAR'. PROC DISCRIM stores linear discriminant function coefficients in a TYPE=LINEAR data set when you specify METHOD=NORMAL (the default method), POOL=YES, and an OUTSTAT= data set; the data set can be used in a subsequent invocation of PROC DISCRIM to classify additional observations. Many other statistics can be included depending on the options used. See Chapter 31, "The DISCRIM Procedure," for details.

TYPE=LOGISMOD Data Sets

A TYPE=LOGISMOD data set contains information about a logistic regression model fit by PROC LOGISTIC. PROC LOGISTIC both creates and reads TYPE=LOGISMOD data sets. See Chapter 51, "The LOGISTIC Procedure," for details.

TYPE=MIXED Data Sets

A TYPE=MIXED data set contains coefficients of either a linear or a quadratic function, or both if there are BY groups. PROC DISCRIM produces a TYPE=MIXED data set when you specify METHOD=NORMAL (the default method), POOL=TEST, and an OUTSTAT= data set. See Chapter 31, "The DISCRIM Procedure," for details.

TYPE=QUAD Data Sets

A TYPE=QUAD data set contains the coefficients of a quadratic function of the variables in observations with _TYPE_='QUAD'. PROC DISCRIM stores quadratic discriminant function coefficients in a TYPE=QUAD data set when you specify METHOD=NORMAL (the default method), POOL=NO, and an OUTSTAT= data set; the data set can be used in a subsequent invocation of PROC DISCRIM to classify additional observations. Many other statistics can be included depending on the options used. See Chapter 31, "The DISCRIM Procedure," for details.

TYPE=RAM Data Sets

PROC CALIS creates and accepts as input a TYPE=RAM data set. This data set contains the model specification and the computed parameter estimates. A TYPE=RAM data set is intended to be reused as an input data set to specify good initial values in subsequent analyses by PROC CALIS. See Chapter 25, "The CALIS Procedure," for details.

TYPE=SSCP Data Sets

A TYPE=SSCP data set contains an uncorrected sum of squares and crossproducts (SSCP) matrix. TYPE=SSCP data sets are produced by PROC REG when the OUTSSCP= option is specified in the PROC REG statement. You can also create a TYPE=SSCP data set by using PROC CORR with the SSCP option and specifying the data set option TYPE=SSCP in parentheses following the name of the OUTP= or OUT= data set. You can also create TYPE=SSCP data sets in a DATA step; in this case, TYPE=SSCP must be specified as a data set option.

The variables in a TYPE=SSCP data set include those found in a TYPE=CORR data set. In addition, there is a variable called Intercept that contains crossproducts for the intercept (sums of the variables). The SSCP matrix is stored in observations with _TYPE_='SSCP', including a row with _NAME_='Intercept'. PROC REG also outputs an observation with _TYPE_='N'. PROC CORR includes observations with _TYPE_='MEAN' and _TYPE_='STD' as well. TYPE=SSCP data sets are used by the same procedures that use TYPE=CORR data sets.

Example A.4: A TYPE=SSCP Data Set Produced by PROC REG

The following statements create a TYPE=SSCP data set from the SocEcon input data set created in "Example A.1: A TYPE=CORR Data Set Produced by PROC CORR" on page 7611:

```
proc reg data=SocEcon outsscp=regsscp;
   model house=pop school employ services / noprint;
run; quit;

proc print data=regsscp;
run;
```

The data set is created by PROC REG and is displayed in Figure A.5.

Figure A.5 A TYPE=SSCP Data Set Produced by PROC REG

Five Socioeconomic Variables

Obs	_TYPE_	_NAME_	Intercept	Pop	School	Employ	Services	House
1	SSCP	Intercept	12.0	74900	137.30	28000	1450	204000
2	SSCP	Pop	74900.0	597670000	857640.00	220440000	10959000	1278700000
3	SSCP	School	137.3	857640	1606.05	324130	18152	2442100
4	SSCP	Employ	28000.0	220440000	324130.00	82280000	4191000	486600000
5	SSCP	Services	1450.0	10959000	18152.00	4191000	320500	30910000
6	SSCP	House	204000.0	1278700000	2442100.00	486600000	30910000	3914000000
7	N		12.0	12	12.00	12	12	12

TYPE=TREE Data Sets

Some clustering procedures produce TYPE=TREE data sets. For example, in PROC CLUSTER, a TYPE=TREE data set contains one observation for each observation in the input data set, plus one observation for each cluster of two or more observations (that is, one observation for each node of the cluster tree). The total number of output observations is usually $2n - 1$, where n is the number of input observations. The density methods might produce fewer output observations when the number of clusters cannot be reduced to one.

In PROC VARCLUS, the OUTTREE= data set contains one observation for each variable clustered plus one observation for each cluster of two or more variables—that is, one observation for each node of the cluster tree. The total number of output observations is between n and $2n - 1$, where n is the number of variables clustered. See Chapter 29, "The CLUSTER Procedure," and Chapter 93, "The VARCLUS Procedure," for details.

TYPE=UCORR Data Sets

A TYPE=UCORR data set is almost identical to a TYPE=CORR data set, except that the correlations are uncorrected for the mean. The corresponding value of the _TYPE_ variable is 'UCORR' instead of 'CORR'. Uncorrected standard deviations are in observations with _TYPE_='USTD'. A TYPE=UCORR data set can be used as input for every SAS/STAT procedure that uses a TYPE=CORR data set, except for the CANDISC, DISCRIM, and STEPDISC procedures. TYPE=UCORR data sets can be created by the CALIS, CANCORR, PRINCOMP, and VARCLUS procedures.

TYPE=UCOV Data Sets

A TYPE=UCOV data set is similar to a TYPE=COV data set, except that the covariances are uncorrected for the mean. Also, the corresponding value of the _TYPE_ variable is 'UCOV' instead of 'COV'. A TYPE=UCOV data set can be used as input for every SAS/STAT procedure that uses a TYPE=COV data set, except for the CANDISC, DISCRIM, and STEPDISC procedures. TYPE=UCOV data sets can be created by the CALIS and PRINCOMP procedures.

TYPE=WEIGHT Data Sets

The CALIS procedure creates and accepts as input a TYPE=WEIGHT data set. This data set contains the weight matrix used in generalized, weighted, or diagonally weighted least squares estimation. See Chapter 25, "The CALIS Procedure," for details.

Definitional Formulas

This section contrasts corrected and uncorrected SSCP, COV, and CORR matrices by showing how these matrices can be computed. In the following formulas, assume that the data consist of two variables, X and Y, with n observations.

$$\text{SSCP} = \begin{bmatrix} n & \sum X & \sum Y \\ \sum X & \sum X^2 & \sum XY \\ \sum Y & \sum XY & \sum Y^2 \end{bmatrix}$$

$$\text{CSSCP} = \begin{bmatrix} \sum(X-\bar{X})^2 & \sum(X-\bar{X})(Y-\bar{Y}) \\ \sum(X-\bar{X})(Y-\bar{Y}) & \sum(Y-\bar{Y})^2 \end{bmatrix}$$

$$\text{COV} = \frac{\text{CSSCP}}{n-1} = \frac{1}{n-1}\begin{bmatrix} \sum(X-\bar{X})^2 & \sum(X-\bar{X})(Y-\bar{Y}) \\ \sum(X-\bar{X})(Y-\bar{Y}) & \sum(Y-\bar{Y})^2 \end{bmatrix}$$

$$\text{UCOV} = \frac{1}{n}\begin{bmatrix} \sum X^2 & \sum XY \\ \sum XY & \sum Y^2 \end{bmatrix}$$

$$\text{CORR} = \begin{bmatrix} 1 & \dfrac{\sum(X-\bar{X})(Y-\bar{Y})}{\sqrt{\sum(X-\bar{X})^2\sum(Y-\bar{Y})^2}} \\ \dfrac{\sum(X-\bar{X})(Y-\bar{Y})}{\sqrt{\sum(X-\bar{X})^2\sum(Y-\bar{Y})^2}} & 1 \end{bmatrix}$$

$$\text{UCORR} = \begin{bmatrix} 1 & \dfrac{\sum XY}{\sqrt{\sum X^2\sum Y^2}} \\ \dfrac{\sum XY}{\sqrt{\sum X^2\sum Y^2}} & 1 \end{bmatrix}$$

Your Turn

We welcome your feedback.

- If you have comments about this book, please send them to **`yourturn@sas.com`**. Include the full title and page numbers (if applicable).
- If you have comments about the software, please send them to **`suggest@sas.com`**.

SAS® Publishing Delivers!

Whether you are new to the work force or an experienced professional, you need to distinguish yourself in this rapidly changing and competitive job market. SAS® Publishing provides you with a wide range of resources to help you set yourself apart. Visit us online at support.sas.com/bookstore.

SAS® Press

Need to learn the basics? Struggling with a programming problem? You'll find the expert answers that you need in example-rich books from SAS Press. Written by experienced SAS professionals from around the world, SAS Press books deliver real-world insights on a broad range of topics for all skill levels.

support.sas.com/saspress

SAS® Documentation

To successfully implement applications using SAS software, companies in every industry and on every continent all turn to the one source for accurate, timely, and reliable information: SAS documentation. We currently produce the following types of reference documentation to improve your work experience:

- Online help that is built into the software.
- Tutorials that are integrated into the product.
- Reference documentation delivered in HTML and PDF – **free** on the Web.
- Hard-copy books.
