Overview: STATESPACE Procedure

The STATESPACE procedure has largely been superseded by the newer SSM procedure. PROC SSM fits and forecasts very general linear state space models. It supports irregularly spaced time series and replicated longitudinal data, in addition to supporting regular fixed-period time series. The SSM procedure also provides a powerful expressive language for specifying state space models, and allows programming statements to define model elements through user-written functions of unlimited complexity. The SSM procedure also provides more modern estimation, filtering, and forecasting algorithms than the older STATESPACE procedure. See Chapter 27, “The SSM Procedure,” for information about PROC SSM.

Although the SSM procedure should be preferred to the STATESPACE procedure for most state space modeling applications, the STATESPACE procedure should be considered if you wish to perform automated multivariate forecasting using a state space model selected through the modeling strategy proposed by Akaike (1976). This strategy employs an initial sequence of unrestricted vector autoregressive (VAR) models, selection of an initial VAR model using Akaike’s information criterion (AIC), followed by a canonical correlation analysis for the automatic identification of the state space model to use to forecast the vector of time series.

The operation of the STATESPACE procedure and the form of state space model it supports are described in the following.

The STATESPACE procedure uses the state space model to analyze and forecast multivariate time series. The STATESPACE procedure is appropriate for jointly forecasting several related time series that have dynamic interactions. By taking into account the autocorrelations among all the variables in a set, it is possible that the STATESPACE procedure may give better forecasts than methods that model each series separately.

By default, the STATESPACE procedure automatically selects a state space model appropriate for the time series, making the procedure a good tool for automatic forecasting of multivariate time series. Alternatively, you can specify the state space model by giving the form of the state vector and the state transition and innovation matrices.

The methods used by the STATESPACE procedure assume that the time series are jointly stationary. Nonstationary series must be made stationary by some preliminary transformation, usually by differencing. The STATESPACE procedure enables you to specify differencing of the input data. When differencing is specified, the STATESPACE procedure automatically integrates forecasts of the differenced series to produce forecasts of the original series.

The State Space Model

The state space model represents a multivariate time series through auxiliary variables, some of which might not be directly observable. These auxiliary variables are called the state vector. The state vector summarizes all the information from the present and past values of the time series that is relevant to the prediction of future values of the series. The observed time series are expressed as linear combinations of the state variables. The state space model is also called a Markovian representation, or a canonical representation, of a multivariate time series process. The state space approach to modeling a multivariate stationary time series is summarized in Akaike (1976).
The state space form encompasses a very rich class of models. Any Gaussian multivariate stationary time series can be written in a state space form, provided that the dimension of the predictor space is finite. In particular, any autoregressive moving average (ARMA) process has a state space representation and, conversely, any state space process can be expressed in an ARMA form (Akaike 1974). More details on the relation of the state space and ARMA forms are given in the section “Relation of ARMA and State Space Forms” on page 2096.

Let \( x_t \) be the \( r \times 1 \) vector of observed variables, after differencing (if differencing is specified) and subtracting the sample mean. Let \( z_t \) be the state vector of dimension \( s \), \( s \geq r \), where the first \( r \) components of \( z_t \) consist of \( x_t \). Let the notation \( x_{t+k|t} \) represent the conditional expectation (or prediction) of \( x_{t+k} \) based on the information available at time \( t \). Then the last \( s - r \) elements of \( z_t \) consist of elements of \( x_{t+k|t} \), where \( k > 0 \) is specified or determined automatically by the procedure.

There are various forms of the state space model in use. The form of the state space model used by the STATESPACE procedure is based on Akaike (1976). The model is defined by the following state transition equation:

\[
z_{t+1} = F z_t + G e_{t+1}
\]

In the state transition equation, the \( s \times s \) coefficient matrix \( F \) is called the transition matrix; it determines the dynamic properties of the model.

The \( s \times r \) coefficient matrix \( G \) is called the input matrix; it determines the variance structure of the transition equation. For model identification, the first \( r \) rows and columns of \( G \) are set to an \( r \times r \) identity matrix.

The input vector \( e_t \) is a sequence of independent normally distributed random vectors of dimension \( r \) with mean \( 0 \) and covariance matrix \( \Sigma_{ee} \). The random error \( e_t \) is sometimes called the innovation vector or shock vector.

In addition to the state transition equation, state space models usually include a measurement equation or observation equation that gives the observed values \( x_t \) as a function of the state vector \( z_t \). However, since PROC STATESPACE always includes the observed values \( x_t \) in the state vector \( z_t \), the measurement equation in this case merely represents the extraction of the first \( r \) components of the state vector.

The measurement equation used by the STATESPACE procedure is

\[
x_t = [I_r, 0] z_t
\]

where \( I_r \) is an \( r \times r \) identity matrix. In practice, PROC STATESPACE performs the extraction of \( x_t \) from \( z_t \) without reference to an explicit measurement equation.

In summary:

- \( x_t \): an observation vector of dimension \( r \).
- \( z_t \): a state vector of dimension \( s \), whose first \( r \) elements are \( x_t \) and whose last \( s - r \) elements are conditional prediction of future \( x_t \).
- \( F \): an \( s \times s \) transition matrix.
- \( G \): an \( s \times r \) input matrix, with the identity matrix \( I_r \) forming the first \( r \) rows and columns.
- \( e_t \): a sequence of independent normally distributed random vectors of dimension \( r \) with mean \( 0 \) and covariance matrix \( \Sigma_{ee} \).
How PROC STATESPACE Works

The design of the STATESPACE procedure closely follows the modeling strategy proposed by Akaike (1976). This strategy employs canonical correlation analysis for the automatic identification of the state space model.

Following Akaike (1976), the procedure first fits a sequence of unrestricted vector autoregressive (VAR) models and computes Akaike’s information criterion (AIC) for each model. The vector autoregressive models are estimated using the sample autocovariance matrices and the Yule-Walker equations. The order of the VAR model that produces the smallest Akaike information criterion is chosen as the order (number of lags into the past) to use in the canonical correlation analysis.

The elements of the state vector are then determined via a sequence of canonical correlation analyses of the sample autocovariance matrices through the selected order. This analysis computes the sample canonical correlations of the past with an increasing number of steps into the future. Variables that yield significant correlations are added to the state vector; those that yield insignificant correlations are excluded from further consideration. The importance of the correlation is judged on the basis of another information criterion proposed by Akaike. See the section “Canonical Correlation Analysis Options” on page 2081 for details. If you specify the state vector explicitly, these model identification steps are omitted.

After the state vector is determined, the state space model is fit to the data. The free parameters in the $F$, $G$, and $\Sigma_{ee}$ matrices are estimated by approximate maximum likelihood. By default, the $F$ and $G$ matrices are unrestricted, except for identifiability requirements. Optionally, conditional least squares estimates can be computed. You can impose restrictions on elements of the $F$ and $G$ matrices.

After the parameters are estimated, the Kalman filtering technique is used to produce forecasts from the fitted state space model. If differencing was specified, the forecasts are integrated to produce forecasts of the original input variables.

Getting Started: STATESPACE Procedure

The following introductory example uses simulated data for two variables X and Y. The following statements generate the X and Y series.

```plaintext
data in;
  x=10;  y=40;
  x1=0;  y1=0;
  a1=0;  b1=0;
  iseed=123;
  do t=-100 to 200;
    a=rannor(iseed);
    b=rannor(iseed);
    dx = 0.5*x1 + 0.3*y1 + a - 0.2*a1 - 0.1*b1;
    dy = 0.3*x1 + 0.5*y1 + b;
    x = x + dx + .25;
    y = y + dy + .25;
    if t >= 0 then output;
    x1 = dx;  y1 = dy;
    a1 = a;  b1 = b;
  end;
```
The simulated series X and Y are shown in Figure 28.1.

Figure 28.1 Example Series

Automatic State Space Model Selection

The STATESPACE procedure is designed to automatically select the best state space model for forecasting the series. You can specify your own model if you want, and you can use the output from PROC STATESPACE to help you identify a state space model. However, the easiest way to use PROC STATESPACE is to let it choose the model.

Stationarity and Differencing

Although PROC STATESPACE selects the state space model automatically, it does assume that the input series are stationary. If the series are nonstationary, then the process might fail. Therefore the first step is to examine your data and test to see if differencing is required. (See the section “Stationarity and Differencing” on page 2086 for further discussion of this issue.)
The series shown in Figure 28.1 are nonstationary. In order to forecast X and Y with a state space model, you must difference them (or use some other detrending method). If you fail to difference when needed and try to use PROC STATESPACE with nonstationary data, an inappropriate state space model might be selected, and the model estimation might fail to converge.

The following statements identify and fit a state space model for the first differences of X and Y, and forecast X and Y 10 periods ahead:

```plaintext
proc statespace data=in out=out lead=10;
  var x(1) y(1);
  id t;
run;
```

The DATA= option specifies the input data set and the OUT= option specifies the output data set for the forecasts. The LEAD= option specifies forecasting 10 observations past the end of the input data. The VAR statement specifies the variables to forecast and specifies differencing. The notation X(1) Y(1) specifies that the state space model analyzes the first differences of X and Y.

**Descriptive Statistics and Preliminary Autoregressions**

The first page of the printed output produced by the preceding statements is shown in Figure 28.2.

+ is > 2*std error, - is < -2*std error, . is between
Descriptive statistics are printed first, giving the number of nonmissing observations after differencing and the sample means and standard deviations of the differenced series. The sample means are subtracted before the series are modeled (unless the NOCENTER option is specified), and the sample means are added back when the forecasts are produced.

Let \( X_t \) and \( Y_t \) be the observed values of \( X \) and \( Y \), and let \( x_t \) and \( y_t \) be the values of \( X \) and \( Y \) after differencing and subtracting the mean difference. The series \( x_t \) modeled by the STATESPACE procedure is

\[
\mathbf{x}_t = \begin{bmatrix} x_t \\ y_t \end{bmatrix} = \begin{bmatrix} (1 - B)X_t - 0.144316 \\ (1 - B)Y_t - 0.164871 \end{bmatrix}
\]

where \( B \) represents the backshift operator.

After the descriptive statistics, PROC STATESPACE prints the Akaike information criterion (AIC) values for the autoregressive models fit to the series. The smallest AIC value, in this case 5.517 at lag 2, determines the number of autocovariance matrices analyzed in the canonical correlation phase.

A schematic representation of the autocorrelations is printed next. This indicates which elements of the autocorrelation matrices at different lags are significantly greater than or less than 0.

The second page of the STATESPACE printed output is shown in Figure 28.3.

**Figure 28.3** Partial Autocorrelations and VAR Model

<table>
<thead>
<tr>
<th>Schematic Representation of Partial Autocorrelations</th>

</tr>
<tr>
<td>( y )</td>
</tr>
</tbody>
</table>

Figure 28.3 shows a schematic representation of the partial autocorrelations, similar to the autocorrelations shown in Figure 28.2. The selection of a second order autoregressive model by the AIC statistic looks reasonable in this case because the partial autocorrelations for lags greater than 2 are not significant.

Next, the Yule-Walker estimates for the selected autoregressive model are printed. This output shows the coefficient matrices of the vector autoregressive model at each lag.
Selected State Space Model Form and Preliminary Estimates

After the autoregressive order selection process has determined the number of lags to consider, the canonical correlation analysis phase selects the state vector. By default, output for this process is not printed. You can use the CANCORR option to print details of the canonical correlation analysis. See the section “Canonical Correlation Analysis Options” on page 2081 for an explanation of this process.

After the state vector is selected, the state space model is estimated by approximate maximum likelihood. Information from the canonical correlation analysis and from the preliminary autoregression is used to form preliminary estimates of the state space model parameters. These preliminary estimates are used as starting values for the iterative estimation process.

The form of the state vector and the preliminary estimates are printed next, as shown in Figure 28.4.

*Figure 28.4* first prints the state vector as \( X[T;T] \ Y[T;T] \ X[T+1;T] \). This notation indicates that the state vector is

\[
z_t = \begin{bmatrix} x_{t|t} \\ y_{t|t} \\ x_{t+1|t} \end{bmatrix}
\]
The notation $x_{t+1|t}$ indicates the conditional expectation or prediction of $x_{t+1}$ based on the information available at time $t$, and $x_t$ and $y_t$ are $x_t$ and $y_t$, respectively.

The remainder of Figure 28.4 shows the preliminary estimates of the transition matrix $F$, the input matrix $G$, and the covariance matrix $\Sigma_{ee}$.

**Estimated State Space Model**

The next page of the STATESPACE output prints the final estimates of the fitted model, as shown in Figure 28.5. This output has the same form as in Figure 28.4, but it shows the maximum likelihood estimates instead of the preliminary estimates.

0 & 1 \\
0.257 & 0.202
\end{bmatrix}
\begin{bmatrix}
e_{t+1} \\
e_{t+1}
\end{bmatrix}
$$

The next page of the STATESPACE output lists the estimates of the free parameters in the $F$ and $G$ matrices with standard errors and $t$ statistics, as shown in Figure 28.6.
Convergence Failures

The maximum likelihood estimates are computed by an iterative nonlinear maximization algorithm, which might not converge. If the estimates fail to converge, warning messages are printed in the output.

If you encounter convergence problems, you should recheck the stationarity of the data and ensure that the specified differencing orders are correct. Attempting to fit state space models to nonstationary data is a common cause of convergence failure. You can also use the MAXIT= option to increase the number of iterations allowed, or experiment with the convergence tolerance options DETTOL= and PARMTOL=.

Forecast Data Set

The following statements print the output data set. The WHERE statement excludes the first 190 observations from the output, so that only the forecasts and the last 10 actual observations are printed.

```
proc print data=out;
  id t;
  where t > 190;
run;
```

The PROC PRINT output is shown in Figure 28.7.
The OUT= data set produced by PROC STATESPACE contains the VAR and ID statement variables. In addition, for each VAR statement variable, the OUT= data set contains the variables FORi, RESi, and STDi. These variables contain the predicted values, residuals, and forecast standard errors for the ith variable in the VAR statement list. In this case, X is listed first in the VAR statement, so FOR1 contains the forecasts of X, while FOR2 contains the forecasts of Y.

The following statements plot the forecasts and actuals for the series.

```sas
proc sgplot data=out noautolegend;
  where t > 150;
  series x=t y=for1 / markers
        markerattrs=(symbol=circle color=blue)
        lineattrs=(pattern=solid color=blue);
  series x=t y=for2 / markers
        markerattrs=(symbol=circle color=blue)
        lineattrs=(pattern=solid color=blue);
  series x=t y=x / markers
        markerattrs=(symbol=circle color=red)
        lineattrs=(pattern=solid color=red);
  series x=t y=y / markers
        markerattrs=(symbol=circle color=red)
        lineattrs=(pattern=solid color=red);
  reline 200.5 / axis=x;
run;
```

The forecast plot is shown in Figure 28.8. The last 50 observations are also plotted to provide context, and a reference line is drawn between the historical and forecast periods.
Controlling Printed Output

By default, the STATESPACE procedure produces a large amount of printed output. The NOPRINT option suppresses all printed output. You can suppress the printed output for the autoregressive model selection process with the PRINTOUT=NONE option. The descriptive statistics and state space model estimation output are still printed when PRINTOUT=NONE is specified. You can produce more detailed output with the PRINTOUT=LONG option and by specifying the printing control options CANCORR, COVB, and PRINT.

Specifying the State Space Model

Instead of allowing the STATESPACE procedure to select the model automatically, you can use FORM and RESTRICT statements to specify a state space model.
Specifying the State Vector

Use the FORM statement to control the form of the state vector. You can use this feature to force PROC STATESPACE to estimate and forecast a model different from the model it would select automatically. You can also use this feature to reestimate the automatically selected model (possibly with restrictions) without repeating the canonical correlation analysis.

The FORM statement specifies the number of lags of each variable to include in the state vector. For example, the statement FORM X 3; forces the state vector to include $x_{t+1}$, $x_{t+2}$, and $x_{t+3}$. The following statement specifies the state vector $(x_{t+1}, y_{t+1}, x_{t+2})$, which is the same state vector selected in the preceding example:

```
form x 2 y 1;
```

You can specify the form for only some of the variables and allow PROC STATESPACE to select the form for the other variables. If only some of the variables are specified in the FORM statement, canonical correlation analysis is used to determine the number of lags included in the state vector for the remaining variables not specified by the FORM statement. If the FORM statement includes specifications for all the variables listed in the VAR statement, the state vector is completely defined and the canonical correlation analysis is not performed.

Restricting the F and G matrices

After you know the form of the state vector, you can use the RESTRICT statement to fix some parameters in the F and G matrices to specified values. One use of this feature is to remove insignificant parameters by restricting them to 0.

In the introductory example shown in the preceding section, the $F_{2,3}$ parameter is not significant. (The parameters estimation output shown in Figure 28.6 gives the $t$ statistic for $F_{2,3}$ as $-0.06$. $F_{3,3}$ and $F_{3,1}$ also have low significance with $t < 2$.)

The following statements reestimate this model with $F_{2,3}$ restricted to 0. The FORM statement is used to specify the state vector and thus bypass the canonical correlation analysis.

```
proc statespace data=in out=out lead=10;
   var x(1) y(1);
   id t;
   form x 2 y 1;
   restrict f(2,3)=0;
run;
```

The final estimates produced by these statements are shown in Figure 28.10.

Syntax: STATESPACE Procedure

The STATESPACE procedure uses the following statements:

PROC STATESPACE options ;
  BY variable . . . ;
  FORM variable value . . . ;
  ID variable ;
  INITIAL F (row,column)=value . . . G(row,column)=value . . . ;
  RESTRICT F (row,column)=value . . . G (row,column)=value . . . ;
  VAR variable (difference, difference, . . .) . . . ;
Table 28.1 summarizes the statements and options used by PROC STATESPACE.

PROC STATESPACE Statement

PROC STATESPACE options ;

The following options can be specified in the PROC STATESPACE statement.

Printing Options

NOPRINT

suppresses all printed output.

Input Data Options

DATA=SAS-data-set

specifies the name of the SAS data set to be used by the procedure. If the DATA= option is omitted, the most recently created SAS data set is used.

LAGMAX=k

specifies the number of lags for which the sample autocovariance matrix is computed. The LAGMAX= option controls the number of lags printed in the schematic representation of the autocorrelations.

The sample autocovariance matrix of lag \( i \), denoted as \( C_i \), is computed as

\[
C_i = \frac{1}{N-1} \sum_{t=1+i}^{N} x_t x'_{t-i}
\]

where \( x_t \) is the differenced and centered data and \( N \) is the number of observations. (If the NOCENTER option is specified, 1 is not subtracted from \( N \).) LAGMAX= \( k \) specifies that \( C_0 \) through \( C_k \) are computed. The default is LAGMAX=10.

NOCENTER

prevents subtraction of the sample mean from the input series (after any specified differencing) before the analysis.
Options for Preliminary Autoregressive Models

**ARMAX**\(=n\)
specifies the maximum order of the preliminary autoregressive models. The **ARMAX**\(=\) option controls the autoregressive orders for which information criteria are printed, and controls the number of lags printed in the schematic representation of partial autocorrelations. The default is **ARMAX**\(=10\). See the section “Preliminary Autoregressive Models” on page 2087 for details.

**MINIC**
writes to the **OUTAR**= data set only the preliminary Yule-Walker estimates for the VAR model that produces the minimum AIC. See the section “OUTAR= Data Set” on page 2098 for details.

**OUTAR**\(=SAS\text{-data-set}\)
writes the Yule-Walker estimates of the preliminary autoregressive models to a SAS data set. See the section “OUTAR= Data Set” on page 2098 for details.

**PRINTOUT**\(=\text{SHORT} | \text{LONG} | \text{NONE}\)
determines the amount of detail printed. **PRINTOUT**\(=\text{LONG}\) prints the lagged covariance matrices, the partial autoregressive matrices, and estimates of the residual covariance matrices from the sequence of autoregressive models. **PRINTOUT**\(=\text{NONE}\) suppresses the output for the preliminary autoregressive models. The descriptive statistics and state space model estimation output are still printed when **PRINTOUT**\(=\text{NONE}\) is specified. **PRINTOUT**\(=\text{SHORT}\) is the default.

Canonical Correlation Analysis Options

**CANCORR**
prints the canonical correlations and information criterion for each candidate state vector considered. See the section “Canonical Correlation Analysis Options” on page 2081 for details.

**DIMMAX**\(=n\)
specifies the upper limit to the dimension of the state vector. The **DIMMAX**\(=\) option can be used to limit the size of the model selected. The default is **DIMMAX**\(=10\).

**PASTMIN**\(=n\)
specifies the minimum number of lags to include in the canonical correlation analysis. The default is **PASTMIN**\(=0\). See the section “Canonical Correlation Analysis Options” on page 2081 for details.

**SIGCORR**\(=\text{value}\)
specifies the multiplier of the degrees of freedom for the penalty term in the information criterion used to select the state space form. The default is **SIGCORR**\(=2\). The larger the value of the **SIGCORR**\(=\) option, the smaller the state vector tends to be. Hence, a large value causes a simpler model to be fit. See the section “Canonical Correlation Analysis Options” on page 2081 for details.

State Space Model Estimation Options

**COVB**
prints the inverse of the observed information matrix for the parameter estimates. This matrix is an estimate of the covariance matrix for the parameter estimates.
DETTOL=\textit{value}
specifies the convergence criterion. The DETTOL= and PARMTOL= option values are used together
to test for convergence of the estimation process. If, during an iteration, the relative change of the
parameter estimates is less than the PARMTOL= value and the relative change of the determinant of
the innovation variance matrix is less than the DETTOL= value, then iteration ceases and the current
estimates are accepted. The default is DETTOL=1E–5.

ITPRINT
prints the iterations during the estimation process.

KLAG=\textit{n}
sets an upper limit for the number of lags of the sample autocovariance matrix used in computing
the approximate likelihood function. If the data have a strong moving average character, a larger
KLAG= value might be necessary to obtain good estimates. The default is KLAG=15. See the section
“Parameter Estimation” on page 2093 for details.

MAXIT=\textit{n}
sets an upper limit to the number of iterations in the maximum likelihood or conditional least squares
estimation. The default is MAXIT=50.

NOEST
suppresses the final maximum likelihood estimation of the selected model.

OUTMODEL=\textit{SAS-data-set}
writes the parameter estimates and their standard errors to a SAS data set. See the section “OUT-
MODEL= Data Set” on page 2099 for details.

PARMTOL=\textit{value}
specifies the convergence criterion. The DETTOL= and PARMTOL= option values are used together
to test for convergence of the estimation process. If, during an iteration, the relative change of the
parameter estimates is less than the PARMTOL= value and the relative change of the determinant of
the innovation variance matrix is less than the DETTOL= value, then iteration ceases and the current
estimates are accepted. The default is PARMTOL=0.001.

RESIDEST
computes the final estimates by using conditional least squares on the raw data. This type of estimation
might be more stable than the default maximum likelihood method but is usually more computationally
expensive. See the section “Parameter Estimation” on page 2093 for details about the conditional least
squares method.

SINGULAR=\textit{value}
specifies the criterion for testing for singularity of a matrix. A matrix is declared singular if a scaled
pivot is less than the SINGULAR= value when sweeping the matrix. The default is SINGULAR=1E–7.

**Forecasting Options**

BACK=\textit{n}
starts forecasting \textit{n} periods before the end of the input data. The BACK= option value must not be
greater than the number of observations. The default is BACK=0.
**INTERVAL=interval**

specifies the time interval between observations. The INTERVAL= value is used in conjunction with the ID variable to check that the input data are in order and have no missing periods. The INTERVAL= option is also used to extrapolate the ID values past the end of the input data. See Chapter 4, “Date Intervals, Formats, and Functions,” for details about the INTERVAL= values allowed.

**INTPER=n**

specifies that each input observation corresponds to \( n \) time periods. For example, the options INTERVAL=MONTH and INTPER=2 specify bimonthly data and are equivalent to specifying INTERVAL=MONTH2. If the INTERVAL= option is not specified, the INTPER= option controls the increment used to generate ID values for the forecast observations. The default is INTPER=1.

**LEAD=n**

specifies how many forecast observations are produced. The forecasts start at the point set by the BACK= option. The default is LEAD=0, which produces no forecasts.

**OUT=SAS-data-set**

writes the residuals, actual values, forecasts, and forecast standard errors to a SAS data set. See the section “OUT= Data Set” on page 2097 for details.

**PRINT**

prints the forecasts.

---

**BY Statement**

```
BY variable . . . ;
```

A BY statement can be used with the STATESPACE procedure to obtain separate analyses on observations in groups defined by the BY variables.

---

**FORM Statement**

```
FORM variable value . . . ;
```

The FORM statement specifies the number of times a variable is included in the state vector. Values can be specified for any variable listed in the VAR statement. If a value is specified for each variable in the VAR statement, the state vector for the state space model is entirely specified, and automatic selection of the state space model is not performed.

The FORM statement forces the state vector, \( z_t \), to contain a specific variable a given number of times. For example, if \( Y \) is one of the variables in \( x_t \), then the statement

```
form y 3;
```

forces the state vector to contain \( Y_t, Y_{t+1|t}, \) and \( Y_{t+2|t} \), possibly along with other variables.
The following statements illustrate the use of the FORM statement:

```plaintext
proc statespace data=in;
  var x y;
  form x 3 y 2;
run;
```

These statements fit a state space model with the following state vector:

\[
    z_t = \begin{bmatrix}
        x_{t}|t \\
        y_{t}|t \\
        x_{t+1}|t \\
        y_{t+1}|t \\
        x_{t+2}|t
    \end{bmatrix}
\]

**ID Statement**

```plaintext
ID variable ;
```

The ID statement specifies a variable that identifies observations in the input data set. The variable specified in the ID statement is included in the OUT= data set. The values of the ID variable are extrapolated for the forecast observations based on the values of the INTERVAL= and INTPER= options.

**INITIAL Statement**

```plaintext
INITIAL F (row,column)= value . . . G(row, column)= value . . . ;
```

The INITIAL statement gives initial values to the specified elements of the \(F\) and \(G\) matrices. These initial values are used as starting values for the iterative estimation.

Parts of the \(F\) and \(G\) matrices represent fixed structural identities. If an element specified is a fixed structural element instead of a free parameter, the corresponding initialization is ignored.

The following is an example of an INITIAL statement:

```plaintext
initial f(3,2)=0 g(4,1)=0 g(5,1)=0;
```

**RESTRICT Statement**

```plaintext
RESTRICT F(row,column)= value . . . G(row, column)= value . . . ;
```

TheRESTRICT statement restricts the specified elements of the \(F\) and \(G\) matrices to the specified values.

To use the restrict statement, you need to know the form of the model. Either specify the form of the model with the FORM statement, or do a preliminary run (perhaps with the NOEST option) to find the form of the model that PROC STATESPACE selects for the data.
The following is an example of a RESTRICT statement:

\[
\text{restrict } f(3,2)=0 \ g(4,1)=0 \ g(5,1)=0 ;
\]

Parts of the \( F \) and \( G \) matrices represent fixed structural identities. If a restriction is specified for an element that is a fixed structural element instead of a free parameter, the restriction is ignored.

**VAR Statement**

\[
\text{VAR variable (difference, difference, \ldots) \ldots ;}
\]

The VAR statement specifies the variables in the input data set to model and forecast. The VAR statement also specifies differencing of the input variables. The VAR statement is required.

Differencing is specified by following the variable name with a list of difference periods separated by commas. See the section “Stationarity and Differencing” on page 2086 for more information about differencing of input variables.

The order in which variables are listed in the VAR statement controls the order in which variables are included in the state vector. Usually, potential inputs should be listed before potential outputs.

For example, assuming the input data are monthly, the following VAR statement specifies modeling and forecasting of the one period and seasonal second difference of \( X \) and \( Y \):

\[
\text{var } x(1,12) \ y(1,12);
\]

In this example, the vector time series analyzed is

\[
x_t = \left\{ \frac{(1 - B)(1 - B^{12})X_t - \bar{x}}{(1 - B)(1 - B^{12})Y_t - \bar{y}} \right\}
\]

where \( B \) represents the back shift operator and \( \bar{x} \) and \( \bar{y} \) represent the means of the differenced series. If the NOCENTER option is specified, the mean differences are not subtracted.

**Details: STATESPACE Procedure**

**Missing Values**

The STATESPACE procedure does not support missing values. The procedure uses the first contiguous group of observations with no missing values for any of the VAR statement variables. Observations at the beginning of the data set with missing values for any VAR statement variable are not used or included in the output data set.
Stationarity and Differencing

The state space model used by the STATESPACE procedure assumes that the time series are stationary. Hence, the data should be checked for stationarity. One way to check for stationarity is to plot the series. A graph of series over time can show a time trend or variability changes.

You can also check stationarity by using the sample autocorrelation functions displayed by the ARIMA procedure. The autocorrelation functions of nonstationary series tend to decay slowly. See Chapter 7, “The ARIMA Procedure,” for more information.

Another alternative is to use the STATIONARITY= option in the IDENTIFY statement in PROC ARIMA to apply Dickey-Fuller tests for unit roots in the time series. See Chapter 7, “The ARIMA Procedure,” for more information about Dickey-Fuller unit root tests.

The most popular way to transform a nonstationary series to stationarity is by differencing. Differencing of the time series is specified in the VAR statement. For example, to take a simple first difference of the series X, use this statement:

```plaintext
var x(1);
```

In this example, the change in X from one period to the next is analyzed. When the series has a seasonal pattern, differencing at a period equal to the length of the seasonal cycle can be desirable. For example, suppose the variable X is measured quarterly and shows a seasonal cycle over the year. You can use the following statement to analyze the series of changes from the same quarter in the previous year:

```plaintext
var x(4);
```

To difference twice, add another differencing period to the list. For example, the following statement analyzes the series of second differences \(X_t - X_{t-1} - (X_{t-1} - X_{t-2}) = X_t - 2X_{t-1} + X_{t-2}\):

```plaintext
var x(1,1);
```

The following statement analyzes the seasonal second difference series:

```plaintext
var x(1,4);
```

The series that is being modeled is the 1-period difference of the 4-period difference:
\[(X_t - X_{t-4}) - (X_{t-1} - X_{t-5}) = X_t - X_{t-1} - X_{t-4} + X_{t-5}\].

Another way to obtain stationary series is to use a regression on time to detrend the data. If the time series has a deterministic linear trend, regressing the series on time produces residuals that should be stationary. The following statements write residuals of X and Y to the variable RX and RY in the output data set DETREND.

```plaintext
data a;
  set a;
  t=_n_;
run;
```
proc reg data=a;
  model x y = t;
  output out=detrend r=rx ry;
run;

You then use PROC STATESPACE to forecast the detrended series RX and RY. A disadvantage of this method is that you need to add the trend back to the forecast series in an additional step. A more serious disadvantage of the detrending method is that it assumes a deterministic trend. In practice, most time series appear to have a stochastic rather than a deterministic trend. Differencing is a more flexible and often more appropriate method.

There are several other methods to handle nonstationary time series. For more information and examples, see Brockwell and Davis (1991).

---

**Preliminary Autoregressive Models**

After computing the sample autocovariance matrices, PROC STATESPACE fits a sequence of vector autoregressive models. These preliminary autoregressive models are used to estimate the autoregressive order of the process and limit the order of the autocovariances considered in the state vector selection process.

**Yule-Walker Equations for Forward and Backward Models**

Unlike a univariate autoregressive model, a multivariate autoregressive model has different forms, depending on whether the present observation is being predicted from the past observations or from the future observations.

Let $x_t$ be the $r$-component stationary time series given by the VAR statement after differencing and subtracting the vector of sample means. (If the NOCENTER option is specified, the mean is not subtracted.) Let $n$ be the number of observations of $x_t$ from the input data set.

Let $e_t$ be a vector white noise sequence with mean vector 0 and variance matrix $\Sigma_p$, and let $n_t$ be a vector white noise sequence with mean vector 0 and variance matrix $\Omega_p$. Let $p$ be the order of the vector autoregressive model for $x_t$.

The forward autoregressive form based on the past observations is written as follows:

$$x_t = \sum_{i=1}^{p} \Phi_i^p x_{t-i} + e_t$$

The backward autoregressive form based on the future observations is written as follows:

$$x_t = \sum_{i=1}^{p} \Psi_i^p x_{t+i} + n_t$$

Letting $E$ denote the expected value operator, the autocovariance sequence for the $x_t$ series, $\Gamma_i$, is

$$\Gamma_i = E x_t x_{t-i}$$
The Yule-Walker equations for the autoregressive model that matches the first \( p \) elements of the autocovariance sequence are

\[
\begin{bmatrix}
\Gamma_0 & \Gamma_1 & \cdots & \Gamma_{p-1} \\
\Gamma_1' & \Gamma_0 & \cdots & \Gamma_{p-2} \\
\vdots & \vdots & \ddots & \vdots \\
\Gamma_{p-1}' & \Gamma_{p-2} & \cdots & \Gamma_0
\end{bmatrix}
\begin{bmatrix}
\Phi_1^p \\
\Phi_2^p \\
\vdots \\
\Phi_p^p
\end{bmatrix}
= 
\begin{bmatrix}
\Gamma_1 \\
\Gamma_2 \\
\vdots \\
\Gamma_p
\end{bmatrix}
\]

and

\[
\begin{bmatrix}
\Gamma_0 & \Gamma_1' & \cdots & \Gamma_{p-1}' \\
\Gamma_1 & \Gamma_0 & \cdots & \Gamma_{p-2}' \\
\vdots & \vdots & \ddots & \vdots \\
\Gamma_{p-1} & \Gamma_{p-2} & \cdots & \Gamma_0
\end{bmatrix}
\begin{bmatrix}
\Psi_1^p \\
\Psi_2^p \\
\vdots \\
\Psi_p^p
\end{bmatrix}
= 
\begin{bmatrix}
\Gamma_1' \\
\Gamma_2' \\
\vdots \\
\Gamma_p'
\end{bmatrix}
\]

Here \( \Phi_i^p \) are the coefficient matrices for the past observation form of the vector autoregressive model, and \( \Psi_i^p \) are the coefficient matrices for the future observation form. More information about the Yule-Walker equations in the multivariate setting can be found in Whittle (1963); Ansley and Newbold (1979).

The innovation variance matrices for the two forms can be written as follows:

\[
\Sigma_p = \Gamma_0 - \sum_{i=1}^{p} \Phi_i^p \Gamma_i'
\]

\[
\Omega_p = \Gamma_0 - \sum_{i=1}^{p} \Psi_i^p \Gamma_i
\]

The autoregressive models are fit to the data by using the preceding Yule-Walker equations with \( \Gamma_i \) replaced by the sample covariance sequence \( C_i \). The covariance matrices are calculated as

\[
C_i = \frac{1}{N-1} \sum_{t=i+1}^{N} x_t x_{t-i}^\prime
\]

Let \( \hat{\Phi}_p, \hat{\Psi}_p, \hat{\Sigma}_p, \) and \( \hat{\Omega}_p \) represent the Yule-Walker estimates of \( \Phi_p, \Psi_p, \Sigma_p, \) and \( \Omega_p \), respectively. These matrices are written to an output data set when the OUTAR= option is specified.

When the PRINTOUT=LONG option is specified, the sequence of matrices \( \hat{\Sigma}_p \) and the corresponding correlation matrices are printed. The sequence of matrices \( \hat{\Sigma}_p \) is used to compute Akaike information criteria for selection of the autoregressive order of the process.

**Akaike Information Criterion**

The Akaike information criterion (AIC) is defined as \(-2(\text{maximum of log likelihood}) + 2(\text{number of parameters})\). Since the vector autoregressive models are estimates from the Yule-Walker equations, not by maximum
likelihood, the exact likelihood values are not available for computing the AIC. However, for the vector autoregressive model the maximum of the log likelihood can be approximated as

$$\ln(L) \approx -\frac{n}{2} \ln(|\hat{\Sigma}_p|)$$

Thus, the AIC for the order $p$ model is computed as

$$AIC_p = n \ln(|\hat{\Sigma}_p|) + 2p r^2$$

You can use the printed AIC array to compute a likelihood ratio test of the autoregressive order. The log-likelihood ratio test statistic for testing the order $p$ model against the order $p-1$ model is

$$-n \ln(|\hat{\Sigma}_p|) + n \ln(|\hat{\Sigma}_{p-1}|)$$

This quantity is asymptotically distributed as a $\chi^2$ with $r^2$ degrees of freedom if the series is autoregressive of order $p-1$. It can be computed from the AIC array as

$$AIC_{p-1} - AIC_p + 2r^2$$

You can evaluate the significance of these test statistics with the PROBCHI function in a SAS DATA step or with a $\chi^2$ table.

**Determining the Autoregressive Order**

Although the autoregressive models can be used for prediction, their primary value is to aid in the selection of a suitable portion of the sample covariance matrix for use in computing canonical correlations. If the multivariate time series $x_t$ is of autoregressive order $p$, then the vector of past values to lag $p$ is considered to contain essentially all the information relevant for prediction of future values of the time series.

By default, PROC STATESPACE selects the order $p$ that produces the autoregressive model with the smallest $AIC_p$. If the value $p$ for the minimum $AIC_p$ is less than the value of the PASTMIN= option, then $p$ is set to the PASTMIN= value. Alternatively, you can use the ARMAX= and PASTMIN= options to force PROC STATESPACE to use an order you select.

**Significance Limits for Partial Autocorrelations**

The STATESPACE procedure prints a schematic representation of the partial autocorrelation matrices that indicates which partial autocorrelations are significantly greater than or significantly less than 0. **Figure 28.11** shows an example of this table.

<table>

</tr>
</tbody>
</table>

* + is > 2*std error, - is < -2*std error, . is between
The partial autocorrelations are from the sample partial autoregressive matrices \( \hat{\Phi}^p \). The standard errors used for the significance limits of the partial autocorrelations are computed from the sequence of matrices \( \hat{\Omega}^p \) and \( \hat{\Sigma}^p \).

Under the assumption that the observed series arises from an autoregressive process of order \( p - 1 \), the \( p \)th sample partial autoregressive matrix \( \hat{\Phi}^p \) has an asymptotic variance matrix \( \frac{1}{n} \hat{\Omega}^{-1}^p \hat{\Sigma}^p \).

The significance limits for \( \hat{\Phi}^p \) used in the schematic plot of the sample partial autoregressive sequence are derived by replacing \( \hat{\Omega}^p \) and \( \hat{\Sigma}^p \) with their sample estimators to produce the variance estimate, as follows:

\[
\bar{\text{Var}} \left( \hat{\Phi}^p \right) = \left( \frac{1}{n-rp} \right) \hat{\Omega}^{-1}^p \hat{\Sigma}^p
\]

---

**Canonical Correlation Analysis**

Given the order \( p \), let \( p_t \) be the vector of current and past values relevant to prediction of \( x_{t+1} \):

\[
p_t = (x'_t, x'_{t-1}, \ldots, x'_{t-p})'
\]

Let \( f_t \) be the vector of current and future values:

\[
f_t = (x'_t, x'_{t+1}, \ldots, x'_{t+p})'
\]

In the canonical correlation analysis, consider submatrices of the sample covariance matrix of \( p_t \) and \( f_t \). This covariance matrix, \( V \), has a block Hankel form:

\[
V = \begin{bmatrix}
C_0 & C'_1 & C'_2 & \cdots & C'_p \\
C'_1 & C'_2 & C'_3 & \cdots & \vdots \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
C'_p & C'_{p+1} & C'_{p+2} & \cdots & C'_{2p}
\end{bmatrix}
\]

**State Vector Selection Process**

The canonical correlation analysis forms a sequence of potential state vectors \( z^j_t \). Examine a sequence \( f^j_t \) of subvectors of \( f_t \), form the submatrix \( V^j \) that consists of the rows and columns of \( V \) that correspond to the components of \( f^j_t \), and compute its canonical correlations.

The smallest canonical correlation of \( V^j \) is then used in the selection of the components of the state vector. The selection process is described in the following discussion. For more details about this process, see Akaike (1976).

In the following discussion, the notation \( x_{t+k|t} \) denotes the wide sense conditional expectation (best linear predictor) of \( x_{t+k} \), given all \( x_s \) with \( s \) less than or equal to \( t \). In the notation \( x_{i,t+1} \), the first subscript denotes the \( i \)th component of \( x_{t+1} \).

The initial state vector \( z^1_t \) is set to \( x_t \). The sequence \( f^1_t \) is initialized by setting

\[
f^1_t = (x'_t, x_{1,t+1|t})' = (x'_t, x_{1,t+1|t})'
\]
That is, start by considering whether to add $x_{1,t+1|t}$ to the initial state vector $z^1_t$.

The procedure forms the submatrix $V^1$ that corresponds to $f^1_t$ and computes its canonical correlations. Denote the smallest canonical correlation of $V^1$ as $\rho_{min}$. If $\rho_{min}$ is significantly greater than 0, $x_{1,t+1|t}$ is added to the state vector.

If the smallest canonical correlation of $V^1$ is not significantly greater than 0, then a linear combination of $f_t^1$ is uncorrelated with the past, $p_t$. Assuming that the determinant of $C_0$ is not 0, (that is, no input series is a constant), you can take the coefficient of $x_{1,t+1|t}$ in this linear combination to be 1. Denote the coefficients of $z^1_t$ in this linear combination as $\ell$. This gives the relationship:

$$x_{1,t+1|t} = \ell' x_t$$

Therefore, the current state vector already contains all the past information useful for predicting $x_{1,t+1}$ and any greater leads of $x_{1,t}$. The variable $x_{1,t+1|t}$ is not added to the state vector, nor are any terms $x_{1,t+k|t}$ considered as possible components of the state vector. The variable $x_1$ is no longer active for state vector selection.

The process described for $x_{1,t+1|t}$ is repeated for the remaining elements of $f_t$. The next candidate for inclusion in the state vector is the next component of $f_t$ that corresponds to an active variable. Components of $f_t$ that correspond to inactive variables that produced a zero $\rho_{min}$ in a previous step are skipped.

Denote the next candidate as $x_{l,t+k|t}$. The vector $f_{l}^j$ is formed from the current state vector and $x_{l,t+k|t}$ as follows:

$$f_{l}^j = (z_t^j, x_{l,t+k|t})'$$

The matrix $V^j$ is formed from $f_{l}^j$ and its canonical correlations are computed. The smallest canonical correlation of $V^j$ is judged to be either greater than or equal to 0. If it is judged to be greater than 0, $x_{l,t+k|t}$ is added to the state vector. If it is judged to be 0, then a linear combination of $f_{l}^j$ is uncorrelated with the $p_t$, and the variable $x_l$ is now inactive.

The state vector selection process continues until no active variables remain.

**Testing Significance of Canonical Correlations**

For each step in the canonical correlation sequence, the significance of the smallest canonical correlation $\rho_{min}$ is judged by an information criterion from Akaike (1976). This information criterion is

$$-n \ln(1 - \rho_{min}^2) - \lambda (r(p + 1) - q + 1)$$

where $q$ is the dimension of $f_{l}^j$ at the current step, $r$ is the order of the state vector, $p$ is the order of the vector autoregressive process, and $\lambda$ is the value of the SIGCORR= option. The default is SIGCORR=2. If this information criterion is less than or equal to 0, $\rho_{min}$ is taken to be 0; otherwise, it is taken to be significantly greater than 0. (Do not confuse this information criterion with the AIC.)

Variables in $x_{t+p|t}$ are not added in the model, even with positive information criterion, because of the singularity of $V$. You can force the consideration of more candidate state variables by increasing the size of the $V$ matrix by specifying a PASTMIN= option value larger than $p$. 
Printing the Canonical Correlations

To print the details of the canonical correlation analysis process, specify the CANCORR option in the PROC STATESPACE statement. The CANCORR option prints the candidate state vectors, the canonical correlations, and the information criteria for testing the significance of the smallest canonical correlation.

Bartlett’s $\chi^2$ and its degrees of freedom are also printed when the CANCORR option is specified. The formula used for Bartlett’s $\chi^2$ is

$$\chi^2 = -(n - .5(r(p + 1) - q + 1))\ln(1 - \rho_{min}^2)$$

with $r(p + 1) - q + 1$ degrees of freedom.

Figure 28.12 shows the output of the CANCORR option for the introductory example shown in the “Getting Started: STATESPACE Procedure” on page 2068.

```
proc statespace data=in out=out lead=10 cancorr;
  var x(1) y(1);
  id t;
run;
```

![Figure 28.12 Canonical Correlations Analysis](image)

New variables are added to the state vector if the information criteria are positive. In this example, $y_{t+1|t}$ and $x_{t+2|t}$ are not added to the state space vector because the information criteria for these models are negative.

If the information criterion is nearly 0, then you might want to investigate models that arise if the opposite decision is made regarding $\rho_{min}$. This investigation can be accomplished by using a FORM statement to specify part or all of the state vector.

Preliminary Estimates of F

When a candidate variable $x_{t,t+k|t}$ yields a zero $\rho_{min}$ and is not added to the state vector, a linear combination of $f^j_t$ is uncorrelated with the $p_j$. Because of the method used to construct the $f^j_t$ sequence, the coefficient of $x_{t,t+k|t}$ in $l$ can be taken as 1. Denote the coefficients of $z^j_t$ in this linear combination as $l$.

This gives the relationship:

$$x_{t,t+k|t} = l^Tz^j_t$$

The vector $l$ is used as a preliminary estimate of the first $r$ columns of the row of the transition matrix $F$ corresponding to $x_{t,t+k-1|t}$. 
Parameter Estimation

The model is $z_{t+1} = Fz_t + Ge_{t+1}$, where $e_t$ is a sequence of independent multivariate normal innovations with mean vector $\theta$ and variance $\Sigma_{ee}$. The observed sequence $x_t$ composes the first $r$ components of $z_t$, and thus $x_t = Hz_t$, where $H$ is the $r \times s$ matrix $[I_r \ 0]$.

Let $E$ be the $r \times n$ matrix of innovations:

$$E = \begin{bmatrix} e_1 & \cdots & e_n \end{bmatrix}$$

If the number of observations $n$ is reasonably large, the log likelihood $L$ can be approximated up to an additive constant as follows:

$$L = -\frac{n}{2} \ln(|\Sigma_{ee}|) - \frac{1}{2} \text{trace}(\Sigma_{ee}^{-1}EE')$$

The elements of $\Sigma_{ee}$ are taken as free parameters and are estimated as follows:

$$S_0 = \frac{1}{n} EE'$$

Replacing $\Sigma_{ee}$ by $S_0$ in the likelihood equation, the log likelihood, up to an additive constant, is

$$L = -\frac{n}{2} \ln(|S_0|)$$

Letting $B$ be the backshift operator, the formal relation between $x_t$ and $e_t$ is

$$x_t = H(I - BF)^{-1}Ge_t$$

$$e_t = (H(I - BF)^{-1}G)^{-1}x_t = \sum_{i=0}^{\infty} \Xi_i x_{t-i}$$

Letting $C_i$ be the $i$th lagged sample covariance of $x_t$ and neglecting end effects, the matrix $S_0$ is

$$S_0 = \sum_{i,j=0}^{\infty} \Xi_i C_{-i+j} \Xi_j'$$

For the computation of $S_0$, the infinite sum is truncated at the value of the KLAG= option. The value of the KLAG= option should be large enough that the sequence $\Xi_i$ is approximately 0 beyond that point.

Let $\theta$ be the vector of free parameters in the $F$ and $G$ matrices. The derivative of the log likelihood with respect to the parameter $\theta$ is

$$\frac{\partial L}{\partial \theta} = -\frac{n}{2} \text{trace} \left( S_0^{-1} \frac{\partial S_0}{\partial \theta} \right)$$

The second derivative is

$$\frac{\partial^2 L}{\partial \theta \partial \theta'} = \frac{n}{2} \left( \text{trace} \left( S_0^{-1} \frac{\partial S_0}{\partial \theta'} S_0^{-1} \frac{\partial S_0}{\partial \theta} \right) - \text{trace} \left( S_0^{-1} \frac{\partial^2 S_0}{\partial \theta \partial \theta'} \right) \right)$$
Near the maximum, the first term is unimportant and the second term can be approximated to give the following second derivative approximation:

$$\frac{\partial^2 L}{\partial \theta \partial \theta'} \approx -n \text{trace} \left( S_0^{-1} \frac{\partial^2 E}{\partial \theta \partial \theta'} \right)$$

The first derivative matrix and this second derivative matrix approximation are computed from the sample covariance matrix $C_0$ and the truncated sequence $\Xi_i$. The approximate likelihood function is maximized by a modified Newton-Raphson algorithm that employs these derivative matrices.

The matrix $S_0$ is used as the estimate of the innovation covariance matrix, $\Sigma_{ee}$. The negative of the inverse of the second derivative matrix at the maximum is used as an approximate covariance matrix for the parameter estimates. The standard errors of the parameter estimates printed in the parameter estimates tables are taken from the diagonal of this covariance matrix. The parameter covariance matrix is printed when the COVB option is specified.

If the data are nearly nonstationary, a better estimate of $\Sigma_{ee}$ and the other parameters can sometimes be obtained by specifying the RESIDEST option. The RESIDEST option estimates the parameters by using conditional least squares instead of maximum likelihood.

The residuals are computed using the state space equation and the sample mean values of the variables in the model as start-up values. The estimate of $S_0$ is then computed using the residuals from the $i$th observation on, where $i$ is the maximum number of times any variable occurs in the state vector. A multivariate Gauss-Marquardt algorithm is used to minimize $|S_0|$. See Harvey (1981a) for a further description of this method.

**Forecasting**

Given estimates of $F$, $G$, and $\Sigma_{ee}$, forecasts of $x_t$ are computed from the conditional expectation of $z_t$.

In forecasting, the parameters $F$, $G$, and $\Sigma_{ee}$ are replaced with the estimates or by values specified in the RESTRICT statement. One-step-ahead forecasting is performed for the observation $x_t$, where $t \leq n - b$. Here $n$ is the number of observations and $b$ is the value of the BACK= option. For the observation $x_t$, where $t > n - b$, $m$-step-ahead forecasting is performed for $m = t - n + b$. The forecasts are generated recursively with the initial condition $z_0 = 0$.

The $m$-step-ahead forecast of $z_{t+m}$ is $z_{t+m|t}$, where $z_{t+m|t}$ denotes the conditional expectation of $z_{t+m}$ given the information available at time $t$. The $m$-step-ahead forecast of $x_{t+m}$ is $x_{t+m|t} = Hz_{t+m|t}$, where the matrix $H = [I, 0]$.

Let $\Psi_i = F^i G$. Note that the last $s - r$ elements of $z_t$ consist of the elements of $x_u|t$ for $u > t$.

The state vector $z_{t+m}$ can be represented as

$$z_{t+m} = F^m z_t + \sum_{i=0}^{m-1} \Psi_i e_{t+m-i}$$

Since $e_{t+i|t} = 0$ for $i > 0$, the $m$-step-ahead forecast $z_{t+m|t}$ is

$$z_{t+m|t} = F^m z_t = Fz_{t+m-1|t}$$
Therefore, the $m$-step-ahead forecast of $x_{t+m}$ is
\[ x_{t+m|t} = Hz_{t+m|t} \]

The $m$-step-ahead forecast error is
\[ z_{t+m} - z_{t+m|t} = \sum_{i=0}^{m-1} \Psi_i e_{t+m-i} \]

The variance of the $m$-step-ahead forecast error is
\[ V_{z,m} = \sum_{i=0}^{m-1} \Psi_i \Sigma_{ee} \Psi_i' \]

Letting $V_{z,0} = 0$, the variance of the $m$-step-ahead forecast error of $z_{t+m}$, $V_{z,m}$, can be computed recursively as follows:
\[ V_{z,m} = V_{z,m-1} + \Psi_{m-1} \Sigma_{ee} \Psi_{m-1}' \]

The variance of the $m$-step-ahead forecast error of $y_{t+m}$ is the $r \times r$ left upper submatrix of $V_{z,m}$; that is,
\[ V_{x,m} = HV_{z,m}H' \]

Unless the NOCENTER option is specified, the sample mean vector is added to the forecast. When differencing is specified, the forecasts $x_{t+m|t}$ plus the sample mean vector are integrated back to produce forecasts for the original series.

Let $y_t$ be the original series specified by the VAR statement, with some 0 values appended that correspond to the unobserved past observations. Let $B$ be the backshift operator, and let $\Delta(B)$ be the $s \times s$ matrix polynomial in the backshift operator that corresponds to the differencing specified by the VAR statement. The off-diagonal elements of $\Delta_i$ are 0. Note that $\Delta_0 = I_s$, where $I_s$ is the $s \times s$ identity matrix. Then $z_t = \Delta(B)y_t$.

This gives the relationship
\[ y_t = \Delta^{-1}(B)z_t = \sum_{i=0}^{\infty} \Lambda_i z_{t-i} \]

where $\Delta^{-1}(B) = \sum_{i=0}^{\infty} \Lambda_i B^i$ and $\Lambda_0 = I_s$.

The $m$-step-ahead forecast of $y_{t+m}$ is
\[ y_{t+m|t} = \sum_{i=0}^{m-1} \Lambda_i z_{t+m-i|t} + \sum_{i=m}^{\infty} \Lambda_i z_{t+i|t} \]

The $m$-step-ahead forecast error of $y_{t+m}$ is
\[ \sum_{i=0}^{m-1} \Lambda_i (z_{t+m-i} - z_{t+m-i|t}) = \sum_{i=0}^{m-1} \left( \sum_{u=0}^{i} \Lambda_u \Psi_i - u \right) e_{t+m-i} \]
Letting \( V_{y,0} = 0 \), the variance of the \( m \)-step-ahead forecast error of \( y_{t+m} \), \( V_{y,m} \), is

\[
V_{y,m} = \sum_{i=0}^{m-1} \left( \sum_{u=0}^{i} \Lambda_u \Psi_{i-u} \right) \Sigma_{ee} \left( \sum_{u=0}^{i} \Lambda_u \Psi_{i-u} \right)'
\]

\[
= V_{y,m-1} + \left( \sum_{u=0}^{m-1} \Lambda_u \Psi_{m-1-u} \right) \Sigma_{ee} \left( \sum_{u=0}^{m-1} \Lambda_u \Psi_{m-1-u} \right)'
\]

### Relation of ARMA and State Space Forms

Every state space model has an ARMA representation, and conversely every ARMA model has a state space representation. This section discusses this equivalence. The following material is adapted from Akaike (1974), where there is a more complete discussion. Pham (1978) also contains a discussion of this material.

Suppose you are given the following ARMA model:

\[
\Phi(B)x_t = \Theta(B)e_t
\]

or, in more detail,

\[
x_t - \Phi_1 x_{t-1} - \cdots - \Phi_p x_{t-p} = e_t + \Theta_1 e_{t-1} + \cdots + \Theta_q e_{t-q}
\]  

where \( e_t \) is a sequence of independent multivariate normal random vectors with mean \( \theta \) and variance matrix \( \Sigma_{ee} \), \( B \) is the backshift operator (\( B x_t = x_{t-1} \)), \( \Phi(B) \) and \( \Theta(B) \) are matrix polynomials in \( B \), and \( x_t \) is the observed process.

If the roots of the determinantal equation \( |\Phi(B)| = 0 \) are outside the unit circle in the complex plane, the model can also be written as

\[
x_t = \Phi^{-1}(B)\Theta(B)e_t = \sum_{i=0}^{\infty} \Psi_i e_{t-i}
\]

The \( \Psi_i \) matrices are known as the impulse response matrices and can be computed as \( \Phi^{-1}(B)\Theta(B) \).

You can assume \( p > q \) since, if this is not initially true, you can add more terms \( \Phi_i \) that are identically 0 without changing the model.

To write this set of equations in a state space form, proceed as follows. Let \( x_{t+i|t} \) be the conditional expectation of \( x_{t+i} \) given \( x_w \) for \( w \leq t \). The following relations hold:

\[
x_{t+i|t} = \sum_{j=i}^{\infty} \Psi_j e_{t+i-j}
\]

\[
x_{t+i|t+1} = x_{t+i|t} + \Psi_{i-1} e_{t+1}
\]

However, from equation (1) you can derive the following relationship:

\[
x_{t+p|t} = \Phi_1 x_{t+p-1|t} + \cdots + \Phi_p x_t
\]

Hence, when \( i = p \), you can substitute for \( x_{t+p|t} \) in the right-hand side of equation (2) and close the system of equations.
This substitution results in the following model in the state space form:

\[
\begin{bmatrix}
  x_{t+1} \\
  x_{t+2} \\
  \vdots \\
  x_{t+p} \\
\end{bmatrix}
= 
\begin{bmatrix}
  0 & I & 0 & \cdots & 0 \\
  0 & 0 & I & \cdots & 0 \\
  \vdots & \vdots & \vdots & \ddots & \vdots \\
  \Phi_p & \Phi_{p-1} & \cdots & \Phi_1 \\
\end{bmatrix}
\begin{bmatrix}
  x_t \\
  x_{t+1} \mid t \\
  \vdots \\
  x_{t+p-1} \mid t \\
\end{bmatrix}
+ 
\begin{bmatrix}
  I \\
  \Psi_1 \\
  \vdots \\
  \Psi_{p-1} \\
\end{bmatrix}
\epsilon_{t+1}
\]

Note that the state vector \( z_t \) is composed of conditional expectations of \( x_t \) and the first \( r \) components of \( z_t \) are equal to \( x_t \).

The state space form can be cast into an ARMA form by solving the system of difference equations for the first \( r \) components.

When converting from an ARMA form to a state space form, you can generate a state vector larger than needed; that is, the state space model might not be a minimal representation. When going from a state space form to an ARMA form, you can have nontrivial common factors in the autoregressive and moving average operators that yield an ARMA model larger than necessary.

If the state space form used is not a minimal representation, some but not all components of \( x_{t+i\mid t} \) might be linearly dependent. This situation corresponds to \( [\Phi_p \Theta_{p-1}] \) being of less than full rank when \( \Phi(B) \) and \( \Theta(B) \) have no common nontrivial left factors. In this case, \( z_t \) consists of a subset of the possible components of \( [x_{t+i\mid t}] \quad i = 1, 2, \cdots, p - 1 \). However, once a component of \( x_{t+i\mid t} \) (for example, the \( j \)th one) is linearly dependent on the previous conditional expectations, then all subsequent \( j \)th components of \( x_{t+k\mid t} \) for \( k > i \) must also be linearly dependent. Note that in this case, equivalent but seemingly different structures can arise if the order of the components within \( x_t \) is changed.

---

**OUT= Data Set**

The forecasts are contained in the output data set specified by the OUT= option in the PROC STATESPACE statement. The OUT= data set contains the following variables:

- the BY variables
- the ID variable
- the VAR statement variables. These variables contain the actual values from the input data set.
- **FORi**, numeric variables that contain the forecasts. The variable FORi contains the forecasts for the \( i \)th variable in the VAR statement list. Forecasts are one-step-ahead predictions until the end of the data or until the observation specified by the BACK= option.
- **RESi**, numeric variables that contain the residual for the forecast of the \( i \)th variable in the VAR statement list. For forecast observations, the actual values are missing and the RESi variables contain missing values.
- **STDi**, numeric variables that contain the standard deviation for the forecast of the \( i \)th variable in the VAR statement list. The values of the STDi variables can be used to construct univariate confidence limits for the corresponding forecasts. However, such confidence limits do not take into account the covariance of the forecasts.
**OUTAR= Data Set**

The OUTAR= data set contains the estimates of the preliminary autoregressive models. The OUTAR= data set contains the following variables:

- **ORDER**, a numeric variable that contains the order $p$ of the autoregressive model that the observation represents.
- **AIC**, a numeric variable that contains the value of the information criterion $AIC_p$.
- **SIGFl$, numeric variables that contain the estimate of the innovation covariance matrices for the forward autoregressive models. The variable SIGFl contains the $l$th column of $\Sigma_p$ in the observations with ORDER=$p$.
- **SIGBl$, numeric variables that contain the estimate of the innovation covariance matrices for the backward autoregressive models. The variable SIGBl contains the $l$th column of $\Omega_p$ in the observations with ORDER=$p$.
- **FORk $$l$$, numeric variables that contain the estimates of the autoregressive parameter matrices for the forward models. The variable FORk $$l$$ contains the $l$th column of the lag $k$ autoregressive parameter matrix $\Phi^p_k$ in the observations with ORDER=$p$.
- **BACk $$l$$, numeric variables that contain the estimates of the autoregressive parameter matrices for the backward models. The variable BACk $$l$$ contains the $l$th column of the lag $k$ autoregressive parameter matrix $\Psi^p_k$ in the observations with ORDER=$p$.

The estimates for the order $p$ autoregressive model can be selected as those observations with ORDER=$p$. Within these observations, the $k,l$th element of $\Phi^p_k$ is given by the value of the FOR$i$ $$l$$ variable in the $k$th observation. The $k,l$th element of $\Psi^p_k$ is given by the value of BAC$i$ $$l$$ variable in the $k$th observation. The $k,l$th element of $\Sigma_p$ is given by SIGFl in the $k$th observation. The $k,l$th element of $\Omega_p$ is given by SIGBl in the $k$th observation.

Table 28.2 shows an example of the OUTAR= data set, with ARMAX=3 and $x_t$ of dimension 2. In Table 28.2, ($i, j$) indicate the $i,j$th element of the matrix.

The estimated autoregressive parameters can be used in the IML procedure to obtain autoregressive estimates of the spectral density function or forecasts based on the autoregressive models.

**OUTMODEL= Data Set**

The OUTMODEL= data set contains the estimates of the F and G matrices and their standard errors, the names of the components of the state vector, and the estimates of the innovation covariance matrix. The variables contained in the OUTMODEL= data set are as follows:

- **the BY variables**
- **STATEVEC**, a character variable that contains the name of the component of the state vector corresponding to the observation. The STATEVEC variable has the value STD for standard deviations observations, which contain the standard errors for the estimates given in the preceding observation.
- **F_**j, numeric variables that contain the columns of the F matrix. The variable F_ j contains the jth column of F. The number of F_ j variables is equal to the value of the DIMMAX= option. If the model is of smaller dimension, the extraneous variables are set to missing.
- **G_**j, numeric variables that contain the columns of the G matrix. The variable G_ j contains the jth column of G. The number of G_ j variables is equal to r, the dimension of x_t given by the number of variables in the VAR statement.
- **SIG_**j, numeric variables that contain the columns of the innovation covariance matrix. The variable SIG_ j contains the jth column of \( \Sigma_{ee} \). There are r variables SIG_ j.

Table 28.3 shows an example of the OUTMODEL= data set, with \( x_t = (x_t, y_t)' \), \( z_t = (x_t, y_t, x_{t+1}'y)' \), and DIMMAX=4. In Table 28.3, \( F_{i,j} \) and \( G_{i,j} \) are the i,jth elements of F and G respectively. Note that all elements for F_4 are missing because F is a 3 x 3 matrix.

Printed Output

The printed output produced by the STATESPACE procedure includes the following:

1. descriptive statistics, which include the number of observations used, the names of the variables, their means and standard deviations (Std), and the differencing operations used

2. the Akaike information criteria for the sequence of preliminary autoregressive models

3. if the PRINTOUT=LONG option is specified, the sample autocovariance matrices of the input series at various lags

4. if the PRINTOUT=LONG option is specified, the sample autocorrelation matrices of the input series

5. a schematic representation of the autocorrelation matrices, showing the significant autocorrelations

6. if the PRINTOUT=LONG option is specified, the partial autoregressive matrices. (These are $\Phi_p$ as described in the section “Preliminary Autoregressive Models” on page 2087.)

7. a schematic representation of the partial autocorrelation matrices, showing the significant partial autocorrelations

8. the Yule-Walker estimates of the autoregressive parameters for the autoregressive model with the minimum AIC

9. if the PRINTOUT=LONG option is specified, the autocovariance matrices of the residuals of the minimum AIC model. This is the sequence of estimated innovation variance matrices for the solutions of the Yule-Walker equations.

10. if the PRINTOUT=LONG option is specified, the autocorrelation matrices of the residuals of the minimum AIC model

11. If the CANCORR option is specified, the canonical correlations analysis for each potential state vector considered in the state vector selection process. This includes the potential state vector, the canonical correlations, the information criterion for the smallest canonical correlation, Bartlett’s $\chi^2$ statistic (“Chi Square”) for the smallest canonical correlation, and the degrees of freedom of Bartlett’s $\chi^2$.

12. the components of the chosen state vector

13. the preliminary estimate of the transition matrix, $F$, the input matrix, $G$, and the variance matrix for the innovations, $\Sigma_{ee}$

14. if the ITPRINT option is specified, the iteration history of the likelihood maximization. For each iteration, this shows the iteration number, the number of step halvings, the determinant of the innovation variance matrix, the damping factor Lambda, and the values of the parameters.

15. the state vector, printed again to aid interpretation of the following listing of $F$ and $G$

16. the final estimate of the transition matrix $F$
17. the final estimate of the input matrix $G$

18. the final estimate of the variance matrix for the innovations $\Sigma_{ee}$

19. a table that lists the estimates of the free parameters in $F$ and $G$ and their standard errors and $t$ statistics

20. if the COVB option is specified, the covariance matrix of the parameter estimates

21. if the COVB option is specified, the correlation matrix of the parameter estimates

22. if the PRINT option is specified, the forecasts and their standard errors

---

**ODS Table Names**

PROC STATESPACE assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

<table>

Example 28.1: Series J from Box and Jenkins

This example analyzes the gas furnace data (series J) from Box and Jenkins. (The data are not shown; see Box and Jenkins (1976) for the data.)

First, a model is selected and fit automatically using the following statements.

```latex
\begin{verbatim}
  title1 'Gas Furnace Data';
  title2 'Box & Jenkins Series J';
  title3 'Automatically Selected Model';

  proc statespace data=seriesj cancorr;
     var x y;
  run;
\end{verbatim}
```

The results for the automatically selected model are shown in Output 28.1.1.

**Output 28.1.1** Results for Automatically Selected Model

<table>
<thead>
<tr>
<th>Variable</th>
<th>Mean</th>
<th>Standard Error</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>

<td>1.072766</td>
</tr>
<tr>
<td>y</td>
<td>53.50912</td>
<td>3.202121</td>
</tr>
</tbody>
</table>

The statespace procedure is used to analyze time series data. In this example, the `proc statespace` statement is used to select an autoregressive model automatically. The output shows the estimated parameters and their standard errors. The results are consistent with the expected behavior of the gas furnace data, indicating that the model selected fits the data well.

</tbody>
</table>

The two series are believed to have a transfer function relation with the gas rate (variable X) as the input and the CO₂ concentration (variable Y) as the output. Since the parameter estimates shown in Output 28.1.1 support this kind of model, the model is reestimated with the feedback parameters restricted to 0. The following statements fit the transfer function (no feedback) model.

```
title3 'Transfer Function Model';
proc statespace data=seriesj printout=none;
   var x y;
   restrict f(3,2)=0 f(3,4)=0
       g(3,2)=0 g(4,1)=0 g(5,1)=0;
run;
```

The last two pages of the output are shown in Output 28.1.8.
