Overview: MDC Procedure

The MDC (multinomial discrete choice) procedure analyzes models in which the choice set consists of multiple alternatives. This procedure supports conditional logit, mixed logit, heteroscedastic extreme value, nested logit, and multinomial probit models. The MDC procedure uses the maximum likelihood (ML) or simulated maximum likelihood method for model estimation. The term multinomial logit is often used in the econometrics literature to refer to the conditional logit model of McFadden (1974). Here, the term conditional logit refers to McFadden’s conditional logit model, and the term multinomial logit refers to a model that differs slightly. Early applications of the multinomial logit model in the econometrics literature are provided by Schmidt and Strauss (1975); Theil (1969). The main difference between McFadden’s conditional logit model and the multinomial logit model is that the multinomial logit model makes the choice probabilities depend on the characteristics of the individuals only, whereas the conditional logit model considers the effects of choice attributes on choice probabilities as well.

Unordered multiple choices are observed in many settings in different areas of application. For example, choices of housing location, occupation, political party affiliation, type of automobile, and mode of transportation are all unordered multiple choices. Economics and psychology models often explain observed choices by using the random utility function. The utility of a specific choice can be interpreted as the relative pleasure or happiness that the decision maker derives from that choice with respect to other alternatives in a finite choice set. It is assumed that the individual chooses the alternative for which the associated utility is highest. However, the utilities are not known to the analyst with certainty and are therefore treated by the analyst as random variables. When the utility function contains a random component, the individual choice behavior becomes a probabilistic process.

The random utility function of individual \( i \) for choice \( j \) can be decomposed into deterministic and stochastic components

\[
U_{ij} = V_{ij} + \epsilon_{ij}
\]

where \( V_{ij} \) is a deterministic utility function, assumed to be linear in the explanatory variables, and \( \epsilon_{ij} \) is an unobserved random variable that captures the factors that affect utility that are not included in \( V_{ij} \). Different assumptions on the distribution of the errors, \( \epsilon_{ij} \), give rise to different classes of models.

The features of discrete choice models available in the MDC procedure are summarized in Table 23.1.
### Table 23.1 Summary of Models Supported by PROC MDC

<table>
<thead>
<tr>

</tr>
<tr>
<td>Multinomial probit</td>
<td>$U_{ij} = x'<em>{ij} \beta + \epsilon</em>{ij}$</td>
<td>MVN, correlated and nonidentical</td>
</tr>
</tbody>
</table>

IEV stands for type I extreme-value (or Gumbel) distribution with the probability density function and the cumulative distribution function of the random error given by $f(\epsilon_{ij}) = \exp(-\epsilon_{ij}) \exp(-\exp(-\epsilon_{ij}))$ and $F(\epsilon_{ij}) = \exp(-\exp(-\epsilon_{ij}))$. HEV stands for heteroscedastic extreme-value distribution with the probability density function and the cumulative distribution function of the random error given by $f(\epsilon_{ij}) = \frac{1}{\sigma_j} \exp\left(\frac{\epsilon_{ij}}{\sigma_j}\right) \exp[-\exp\left(-\frac{\epsilon_{ij}}{\sigma_j}\right)]$ and $F(\epsilon_{ij}) = \exp[-\exp\left(-\frac{\epsilon_{ij}}{\sigma_j}\right)]$, where $\theta_j$ is a scale parameter for the random component of the $j$th alternative. GEV stands for generalized extreme-value distribution. MVN represents multivariate normal distribution; and $\xi_{ij}$ is an error component. For more information about $\xi_{ij}$, see the section “Mixed Logit Model” on page 1382.

---

### Getting Started: MDC Procedure

#### Conditional Logit: Estimation and Prediction

The MDC procedure is similar in use to the other regression model procedures in the SAS System. However, the MDC procedure requires identification and choice variables. For example, consider a random utility function

$$U_{ij} = x_{1,ij} \beta_1 + x_{2,ij} \beta_2 + \epsilon_{ij} \quad j = 1, \ldots, 3$$

where the cumulative distribution function of the stochastic component is a Type I extreme value, $F(\epsilon_{ij}) = \exp(-\exp(-\epsilon_{ij}))$. You can estimate this conditional logit model with the following statements:

```sas
proc mdc;
   model decision = x1 x2 / type=clogit
       choice=(mode 1 2 3);
   id pid;
run;
```
Note that the MDC procedure, unlike other regression procedures, does not include the intercept term automatically. The dependent variable decision takes the value 1 when a specific alternative is chosen; otherwise, it takes the value 0. Each individual is allowed to choose one and only one of the possible alternatives. In other words, the variable decision takes the value 1 one time only for each individual. If each individual has three elements (1, 2, and 3) in the choice set, the NCHOICE=3 option can be specified instead of CHOICE=(mode 1 2 3).

Consider the following trinomial data from Daganzo (1979). The original data (origdata) contain travel time (ttime1–ttime3) and choice (choice) variables. The variables ttime1–ttime3 are the travel times for three different modes of transportation, and choice indicates which one of the three modes is chosen. The choice variable must have integer values.

```sas
data origdata;
  input ttime1 ttime2 ttime3 choice @@;
datalines;
12.578 10.671 18.335  2  11.513 20.582 27.838   1
10.651 15.537 17.418  1  8.359 15.675 21.05   1
... more lines ...
```

A new data set (newdata) is created because PROC MDC requires that each individual decision maker has one case for each alternative in his choice set. Note that the ID statement is required for all MDC models. In the following example, there are two public transportation modes, 1 and 2, and one private transportation mode, 3, and all individuals share the same choice set.

The first nine observations of the raw data set are shown in Figure 23.1.

The following statements transform the data according to MDC procedure requirements:

```sas
data newdata(keep=pid decision mode ttime);
  set origdata;
  array tvec{3} ttime1 - ttime3;
  retain pid 0;
  pid + 1;
  do i = 1 to 3;
    mode = i;
    ttime = tvec{i};
    decision = (choice = i);
    output;
  end;
run;
```

The first nine observations of the transformed data set are shown in Figure 23.2.

</tr>
</tbody>
</table>

The decision variable, decision, must have one nonzero value for each decision maker that corresponds to the actual choice. When the RANK option is specified, the decision variable must contain rank data. For more details, see the section “MODEL Statement” on page 1367. The following SAS statements estimate the conditional logit model by using maximum likelihood:

```sas
proc mdc data=newdata;
  model decision = ttime /
    type=clogit
    nchoice=3
    optmethod=qn
    covest=hess;
  id pid;
run;
```

The MDC procedure enables different individuals to have different choice sets. When all individuals have the same choice set, the NCHOICE= option can be used instead of the CHOICE= option. However, the NCHOICE= option is not allowed when a nested logit model is estimated. When the NCHOICE=number option is specified, the choices are generated as 1, . . . , number. For more flexible alternatives (for example, 1, 3, 6, 8), you need to use the CHOICE= option. The choice variable must have integer values.
The OPTMETHOD=QN option specifies the quasi-Newton optimization technique. The covariance matrix of
the parameter estimates is obtained from the Hessian matrix because COVEST=HESS is specified. You can
also specify COVEST=OP or COVEST=QML. For more information, see the section “MODEL Statement”
on page 1367.

The MDC procedure produces a summary of model estimation displayed in Figure 23.3. Since there are
multiple observations for each individual, the “Number of Cases” (150)—that is, the total number of choices
faced by all individuals—is larger than the number of individuals, “Number of Observations” (50).

The MDC procedure computes nine goodness-of-fit measures for the discrete choice model. Seven of them
are pseudo-R-square measures based on the null hypothesis that all coefficients except for an intercept term
are zero (Figure 23.5). McFadden’s likelihood ratio index (LRI) is the smallest in value. For more details,
see the section “Model Fit and Goodness-of-Fit Statistics” on page 1390.
Finally, the parameter estimate is displayed in Figure 23.6.

</tr>
</tbody>
</table>

The predicted choice probabilities are produced using the OUTPUT statement:

```r
output out=probdata pred=p;
```

The parameter estimates can be used to forecast the choice probability of individuals that are not in the input data set. To do so, you need to append to the input data set extra observations whose values of the dependent variable `decision` are missing, since these extra observations are not supposed to be used in the estimation stage. The identification variable `pid` must have values that are not used in the existing observations. The output data set, `probdata`, contains a new variable, `p`, in addition to input variables in the data set `extdata`.

The following statements forecast the choice probability of individuals that are not in the input data set:
data extra;
  input pid mode decision ttime;
datalines;
  51  1 .  5.0
  51  2 .  15.0
  51  3 .  14.0
;

data extdata;
  set newdata extra;
run;

proc mdc data=extdata;
  model decision = ttime /
    type=clogit
    covest=hess
    nchoice=3;
  id pid;
  output out=probdata pred=p;
run;

proc print data=probdata( where=( pid >= 49 ) );
  var mode decision p ttime;
  id pid;
run;

The last nine observations from the forecast data set (probdata ) are displayed in Figure 23.7. It is expected that the decision maker will choose mode “1” based on predicted probabilities for all modes.

**Figure 23.7 Out-of-Sample Mode Choice Forecast**

---

**Nested Logit Modeling**

A more general model can be specified using the nested logit model.

Consider, for example, the following random utility function:

\[ U_{ij} = x_{ij} \beta + \epsilon_{ij} \quad j = 1, \ldots, 3 \]
Suppose the set of all alternatives indexed by $j$ is partitioned into $K$ nests, $B_1, \ldots, B_K$. The nested logit model is obtained by assuming that the error term in the utility function has the GEV cumulative distribution function

$$\exp \left( -\sum_{k=1}^{K} \left( \sum_{j \in B_k} \exp\{-\epsilon_{ij} / \lambda_k\} \right)^{\lambda_k} \right)$$

where $\lambda_k$ is a measure of a degree of independence among the alternatives in nest $k$. When $\lambda_k = 1$ for all $k$, the model reduces to the standard logit model.

Since the public transportation modes, 1 and 2, tend to be correlated, these two choices can be grouped together. The decision tree displayed in Figure 23.8 is constructed.

**Figure 23.8** Decision Tree for Model Choice

![Decision Tree for Model Choice](image)

The two-level decision tree is specified in the NEST statement. The NCHOICE= option is not allowed for nested logit estimation. Instead, the CHOICE= option needs to be specified, as in the following statements:

```latex
/*-- nested logit estimation --*/
proc mdc data=newdata;
  model decision = ttime /
    type=nlogit
    choice=(mode 1 2 3)
    covest=hess;
  id pid;
  utility u(1,) = ttime;
  nest level(1) = (1 2 @ 1, 3 @ 2),
    level(2) = (1 2 @ 1);
run;
```

In Figure 23.9, estimates of the inclusive value parameters, INC_L2G1C1 and INC_L2G1C2, are indicative of a nested model structure. For more information about inclusive values, see the sections “Nested Logit” on page 1386 and “Decision Tree and Nested Logit” on page 1388.
The nested logit model is estimated with the restriction $\text{INC}_L2G1C1 = \text{INC}_L2G1C2$ by specifying the SAMESCALE option, as in the following statements:

```sas
/*-- nlogit with samescale option --*/
proc mdc data=newdata;
  model decision = ttime /
    type=nlogit
    choice=(mode 1 2 3)
    samescale
    covest=hess;
  id pid;
  utility u(1,) = ttime;
  nest level(1) = (1 2 @ 1, 3 @ 2),
    level(2) = (1 2 @ 1);
run;
```

The estimation result is displayed in Figure 23.10.

Figure 23.10 Nested Logit Estimates with One Dissimilarity Parameter

The nested logit model is equivalent to the conditional logit model if $\text{INC}_L2G1C1 = \text{INC}_L2G1C2 = 1$. You can verify this relationship by estimating a constrained nested logit model as shown in the following statements. (For more information about imposing linear restrictions on parameter estimates, see the section “RESTRICT Statement” on page 1376.)

```sas
/*-- constrained nested logit estimation --*/
proc mdc data=newdata;
  model decision = ttime /
    type=nlogit
    choice=(mode 1 2 3)
    covest=hess;
```

The nested logit model is equivalent to the conditional logit model if $\text{INC}_L2G1C1 = \text{INC}_L2G1C2 = 1$. You can verify this relationship by estimating a constrained nested logit model as shown in the following statements. (For more information about imposing linear restrictions on parameter estimates, see the section “RESTRICT Statement” on page 1376.)
id pid;
utility u(1,) = ttime;
nest level(1) = (1 2 @ 1, 3 @ 2),
level(2) = (1 2 @ 1);
restrict INC_L2G1C1 = 1, INC_L2G1C2 =1;
run;

The parameter estimates and the active linear constraints for the constrained nested logit model are displayed in Figure 23.11.

**Figure 23.11** Constrained Nested Logit Estimates

</tbody>
</table>

**Multivariate Normal Utility Function**

Consider the random utility function

\[ U_{ij} = t\text{time}_{ij}\beta + \epsilon_{ij}, \quad j = 1, 2, 3 \]

where

\[
\begin{pmatrix}
\epsilon_{i1} \\
\epsilon_{i2} \\
\epsilon_{i3}
\end{pmatrix}
\sim N\left(0, \begin{bmatrix}
1 & \rho_{21} & 0 \\
\rho_{21} & 1 & 0 \\
0 & 0 & 1
\end{bmatrix}\right)
\]

The correlation coefficient \(\rho_{21}\) between \(U_{i1}\) and \(U_{i2}\) represents commonly neglected attributes of public transportation modes, 1 and 2. The following SAS statements estimate this trinomial probit model:

```sas
/*-- homoscedastic mprobit --*/
proc mdc data=newdata;
   model decision = ttime /
      type=mprobit
      nchoice=3
      unitvariance=(1 2 3)
```
The UNITVARIANCE=(1 2 3) option specifies that the random component of utility for each of these choices has unit variance. If the UNITVARIANCE= option is specified, it needs to include at least two choices. The results of this constrained multinomial probit model estimation are displayed in Figure 23.12 and Figure 23.13. The test for ttime = 0 is rejected at the 1% significance level.

**HEV and Multinomial Probit: Heteroscedastic Utility Function**

When the stochastic components of utility are heteroscedastic and independent, you can model the data by using an HEV or a multinomial probit model. The HEV model assumes that the utility of alternative $j$ for each individual $i$ has heteroscedastic random components,

$$U_{ij} = V_{ij} + \epsilon_{ij}$$
where the cumulative distribution function of the Gumbel distributed $\epsilon_{ij}$ is

$$F(\epsilon_{ij}) = \exp(-\exp(-\epsilon_{ij}/\theta_j))$$

Note that the variance of $\epsilon_{ij}$ is $\frac{1}{\pi^2}\theta_j^2$. Therefore, the error variance is proportional to the square of the scale parameter $\theta_j$. For model identification, at least one of the scale parameters must be normalized to 1. The following SAS statements estimate an HEV model under a unit scale restriction for mode “1” ($\theta_1 = 1$):

```sas
/*-- hev with gauss-laguerre method --*/
proc mdc data=newdata;
    model decision = ttime /
        type=hev
        nchoice=3
        hev=(unitscale=1, integrate=laguerre)
        covest=hess;
    id pid;
run;
```

The results of computation are presented in Figure 23.14 and Figure 23.15.

The parameters SCALE2 and SCALE3 in the output correspond to the estimates of the scale parameters $\theta_2$ and $\theta_3$, respectively.
Chapter 23: The MDC Procedure

Note that the estimate of the HEV model is not always stable because computation of the log-likelihood function requires numerical integration. Bhat (1995) proposed the Gauss-Laguerre method. In general, the log-likelihood function value of HEV should be larger than that of conditional logit because HEV models include the conditional logit as a special case. However, in this example the reverse is true (–33.414 for the HEV model, which is less than –33.321 for the conditional logit model). (See Figure 23.14 and Figure 23.3.) This indicates that the Gauss-Laguerre approximation to the true probability is too coarse. You can see how well the Gauss-Laguerre method works by specifying a unit scale restriction for all modes, as in the following statements, since the HEV model with the unit variance for all modes reduces to the conditional logit model:

```sas
/*-- hev with gauss-laguerre and unit scale --*/
proc mdc data=newdata;
  model decision = ttime /
    type=hev
    nchoice=3
    hev=(unitscale=1 2 3, integrate=laguerre)
    covest=hess;
  id pid;
run;
```

Figure 23.16 shows that the `ttime` coefficient is not close to that of the conditional logit model.

**Figure 23.16** HEV Estimates with All Unit Scale Parameters

### The MDC Procedure

| Parameter Estimates | Standard Error | t Value | Pr > |t| |
|---------------------|----------------|---------|------|---|
| `ttime`             | 0.0438         | -6.68   | <.0001 |

There is another option of specifying the integration method. The INTEGRATE=HARDY option uses the adaptive Romberg-type integration method. The adaptive integration produces much more accurate probability and log-likelihood function values, but often it is not practical to use this method of analyzing the HEV model because it requires excessive CPU time. The following SAS statements produce the HEV estimates by using the adaptive Romberg-type integration method:

```sas
/*-- hev with adaptive integration --*/
proc mdc data=newdata;
  model decision = ttime /
    type=hev
    nchoice=3
    hev=(unitscale=1, integrate=hardy)
    covest=hess;
  id pid;
run;
```

The results are displayed in Figure 23.17 and Figure 23.18.
With the INTEGRATE=HARDY option, the log-likelihood function value of the HEV model, –33.026, is greater than that of the conditional logit model, –33.321. (See Figure 23.17 and Figure 23.3.)

When you impose unit scale restrictions on all choices, as in the following statements, the HEV model gives the same estimates as the conditional logit model. (See Figure 23.19 and Figure 23.6.)

```plaintext
/*-- hev with adaptive integration and unit scale --*/
proc mdc data=newdata;
   model decision = ttime /
       type=hev
       nchoice=3
       hev=(unitscale=1 2 3, integrate=hardy)
       covest=hess;
   id pid;
run;
```
For comparison, the following statements estimate a heteroscedastic multinomial probit model by imposing a zero restriction on the correlation parameter, $\rho_{31} = 0$. The MDC procedure requires normalization of at least two of the error variances in the multinomial probit model. Also, for identification, the correlation parameters associated with a unit normalized variance are restricted to be zero. When the UNITVARIANCE= option is specified, the zero restriction on correlation coefficients applies to the last choice of the list. In the following statements, the variances of the first and second choices are normalized. The UNITVARIANCE=(1 2) option imposes additional restrictions that $\rho_{32} = \rho_{21} = 0$. The default for the UNITVARIANCE= option is the last two choices (which would have been equivalent to UNITVARIANCE=(2 3) for this example). The result is presented in Figure 23.20.

The utility function can be defined as

$$U_{ij} = V_{ij} + \epsilon_{ij}$$

where

$$\epsilon_i \sim N\left(0, \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \sigma_i^2 \end{bmatrix} \right)$$

/*--- mprobit estimation ---*/
proc mdc data=newdata;
   model decision = ttime /
         type=mprobit
         nchoice=3
         unitvariance=(1 2)
         covest=hess;
   id pid;
   restrict RHO_31 = 0;
run;
Parameter Heterogeneity: Mixed Logit

One way of modeling unobserved heterogeneity across individuals in their sensitivity to observed exogenous variables is to use the mixed logit model with a random parameters or random coefficients specification. The probability of choosing alternative $j$ is written as

$$P_i(j) = \frac{\exp(x_i'\beta_j)}{\sum_{k=1}^{J} \exp(x_i'\beta_k)}$$

where $\beta$ is a vector of coefficients that varies across individuals and $x_{ij}$ is a vector of exogenous attributes.

Note that in the output the estimates of standard errors and correlations are denoted by STD$_i$ and RHO$_{ij}$, respectively. In this particular case the first two variances (STD$_1$ and STD$_2$) are normalized to one, and corresponding correlations (RHO$_{21}$ and RHO$_{32}$) are set to zero, so they are not listed among parameter estimates.

* Probability computed using beta distribution.
You can estimate the model with normally distributed random coefficients of `ttime` with the following SAS statements:

```sas
/*-- mixed logit estimation --*/
proc mdc data=newdata type=mixedlogit;
   model decision = ttime / nchoice=3
                  mixed=(normalparm=ttime);
   id pid;
run;
```

Let $\hat{\beta}^m$ and $\hat{\beta}^s$ be mean and scale parameters, respectively, for the random coefficient, $\beta$. The relevant utility function is

$$U_{ij} = ttime_{ij}\beta + \epsilon_{ij}$$

where $\beta = \beta^m + \beta^s \eta$ ($\beta^m$ and $\beta^s$ are fixed mean and scale parameters, respectively). The stochastic component, $\eta$, is assumed to be standard normal since the `NORMALPARM=` option is given. Alternatively, the `UNIFORMPARM=` or `LOGNORMALPARM=` option can be specified. The `LOGNORMALPARM=` option is useful when nonnegative parameters are being estimated. The `NORMALPARM=`, `UNIFORMPARM=`, and `LOGNORMALPARM=` variables must be included in the right-hand side of the `MODEL` statement. For more information, see the section “Mixed Logit Model” on page 1382. To estimate a mixed logit model by using the transportation mode choice data, the MDC procedure requires the `MIXED=` option for random components. Results of the mixed logit estimation are displayed in Figure 23.21.

Note that the parameter `ttime_M` corresponds to the constant mean parameter $\beta^m$ and the parameter `ttime_S` corresponds to the constant scale parameter $\beta^s$ of the random coefficient $\beta$. 
Syntax: MDC Procedure

The MDC procedure is controlled by the following statements:

```
PROC MDC options ;
   MDCDATA options ;
   BOUNDS bound1 < , bound2 . . . > ;
   BY variables ;
   CLASS variables ;
   ID variable ;
   MODEL dependent-variable = regressors / options ;
   NEST LEVEL(level-number) = ((choices)@choice, . . . , (choices)@choice)) ;
   NLOPTIONS options ;
   OUTPUT options ;
   RESTRICT restriction1 < , restriction2 . . . > ;
   TEST options ;
   UTILITY U() = variables, . . . , U() = variables ;
```

Functional Summary

Table 23.2 summarizes the statements and options used with the MDC procedure.

PROC MDC Statement

```
PROC MDC options;
```

The following options can be used in the PROC MDC statement:

- **DATA=SAS-data-set**
  specifies the input SAS data set. If the DATA= option is not specified, PROC MDC uses the most recently created SAS data set.

- **OUTEST=SAS-data-set**
  names the SAS data set that the parameter estimates are written to. For information about the contents of this data set, see the section “OUTEST= Data Set” on page 1392.

- **COVOUT**
  writes the covariance matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

In addition, any of the following MODEL statement options can be specified in the PROC MDC statement, which is equivalent to specifying the option for the MODEL statement: ALL, CONVERGE=, CORRB, COVB, COVEST=, HALTONSTART=, ITPRINT, MAXITER=, NOPRINT, NSIMUL=, OPTMETHOD=, RANDINIT, RANK, RESTART=, SAMESCALE, SEED=, SPSCALE, TYPE=, and UNITVARIANCE=.

BOUND Statement

```
BOUNDS bound1 <, bound2 . . . >;
```

The BOUNDS statement imposes simple boundary constraints on the parameter estimates. BOUNDS statement constraints refer to the parameters estimated by the MDC procedure. You can specify any number of BOUNDS statements.

Each `bound` is composed of parameters, constants, and inequality operators:

```
item operator item < operator item < operator item . . . > >;
```

Each `item` is a constant, parameter, or list of parameters. Parameters associated with a regressor variable are referred to by the name of the corresponding regressor variable. Each `operator` is `<`, `>`, `<=`, or `>=`. 
You can use both the BOUNDS statement and the RESTRICT statement to impose boundary constraints; however, the BOUNDS statement provides a simpler syntax for specifying these kinds of constraints. (See also the section “RESTRICT Statement” on page 1376.)

Lagrange multipliers are reported for all the active boundary constraints. In the displayed output, the Lagrange multiplier estimates are identified with the names Restrict1, Restrict2, and so on. The probability of the Lagrange multipliers is computed using a beta distribution (LaMotte 1994). Nonactive (nonbinding) bounds have no effect on the estimation results and are not noted in the output.

The following BOUNDS statement constrains the estimates of the coefficient of \( t \) to be negative and the coefficients of \( x_1 \) through \( x_{10} \) to be between zero and one. This example illustrates the use of parameter lists to specify boundary constraints.

```
bounds ttime < 0,
     0 < x1-x10 < 1;
```
VARLIST \((name1 = (\text{var1 var2} \ldots) \quad name2 = (\text{var1 var2} \ldots) \quad \ldots)\)
creates \(name\) variables from a multiple-variable list of choice alternatives in parentheses. The choice-specific dummy variables are created for the first set of multiple variables. At least one set of multiple variables must be specified. The order of \((\text{var1 var2} \ldots)\) in the VARLIST option determines the numbering of the alternative; that is, \(\text{var1}\) corresponds to alternative 1, \(\text{var2}\) corresponds to alternative 2, and so on.

SELECT=\((variable)\)
specifies a variable that contains choices for each individual. The SELECT= variable needs to be a character-type variable, with values that match variable names in the first VARLIST option: \(name1=(\text{var1 var2} \ldots)\).

ID=\((name)\)
creates a variable that identifies each individual.

ALT=\((name)\)
identifies selection alternatives for each individual.

DECVAR=\((name)\)
creates a 0/1 variable that indicates the choice made for each individual.

OUT=\(SAS\)-data-set
specifies a SAS data set to which modified data are output.

MODEL Statement

\[ \text{MODEL dependent-variable = regressors < / options > ;} \]

The MODEL statement specifies the dependent variable and independent regressor variables for the regression model. When the nested logit model is estimated, regressors in the UTILITY statement are used for estimation.

The following options can be used in the MODEL statement after a slash (/).

CHOICE=\(\text{variables}\)
CHOICE=\(\text{variable numbers}\)
specifies the variables that contain possible choices for each individual. Choice variables must have integer values. Multiple choice variables are allowed only for nested logit models and must be specified in order from the highest level to the lowest level. For example, CHOICE=\((upmode, mode)\) indicates that the nested logit model has two levels. The choices at the upper level are described by the upmode variable, and the choices at the lower level are described by the mode variable. If all possible alternatives are written with the variable name, the MDC procedure checks all values of the choice variable. CHOICE=\((X 1 2 3)\) implies that the value of \(X\) should be 1, 2, or 3. On the other hand, the CHOICE=\((X)\) considers all distinctive nonmissing values of \(X\) as elements of the choice set.

CONVERGE=number
specifies the convergence criterion. The CONVERGE= option is the same as the ABSGCONV= option in the NLOPTIONS statement. The ABSGCONV= option in the NLOPTIONS statement overrides the CONVERGE= option. The default value is 1E–5.
HALTONSTART=number
specifies the starting point of the Halton sequence. The specified number must be a positive integer.
The default is HALTONSTART=11.

HEV=( option-list )
specifies options that are used to estimate the HEV model. The HEV model with a unit scale for the
alternative 1 is estimated using the following SAS statement:

    model y = x1 x2 x3 / hev=(unitscale=1);

The following options can be used in the HEV= option. These options are listed within parentheses and separated by commas.

INTORDER=number
    specifies the number of summation terms for Gaussian quadrature integration. The default
    is INTORDER=40. The maximum order is limited to 45. This option applies only to the
    INTEGRATION=LAGUERRE method.

UNITSCALE=number-list
    specifies restrictions on scale parameters of stochastic utility components.

INTEGRATE=LAGUERRE | HARDY
    specifies the integration method. The INTEGRATE=HARDY option specifies an adaptive
    integration method, while the INTEGRATE=LAGUERRE option specifies the Gauss-Laguerre
    approximation method. The default is INTEGRATE=LAGUERRE.

MIXED=( option-list )
specifies options that are used for mixed logit estimation. The mixed logit model with normally
distributed random parameters is specified as follows:

    model y = x1 x2 x3 / mixed=(normalparm=x1);

The following options can be used in the MIXED= option. The options are listed within parentheses and separated by commas.

LOGNORMALPARM=variables
    specifies the variables whose random coefficients are lognormally distributed. LOGNORMALPARM= variables must be included on the right-hand side of the MODEL statement.

NORMALEC=variables
    specifies the error component variables whose coefficients have a normal distribution \( N(0, \sigma^2) \).

NORMALPARM=variables
    specifies the variables whose random coefficients are normally distributed. NORMALPARM= variables must be included on the right-hand side of the MODEL statement.

UNIFORMEC=variables
    specifies the error component variables whose coefficients have a uniform distribution \( U(-\sqrt{3}\sigma, \sqrt{3}\sigma) \).
UNIFORMPARM=variables
specifies the variables whose random coefficients are uniformly distributed. UNIFORMPARM=variables must be included on the right-hand side of the MODEL statement.

NCHOICE=number
specifies the number of choices for multinomial choice models when all individuals have the same choice set. When individuals have different number of choices, the NCHOICE= option is not allowed, and the CHOICE= option should be used. The NCHOICE= and CHOICE= options must not be used simultaneously, and the NCHOICE= option cannot be used for nested logit models.

NSIMUL=number
specifies the number of simulations when the mixed logit or multinomial probit model is estimated. The default is NSIMUL=100. In general, you need a smaller number of simulations with RANDNUM=HALTON than with RANDNUM=PSEUDO.

RANDNUM=value
specifies the type of the random number generator used for simulation. RANDNUM=HALTON is the default. The following option values are allowed:

PSEUDO specifies pseudo-random number generation.
HALTON specifies Halton sequence generation.

RANDINIT

RANDINIT=number
specifies that initial parameter values be perturbed by uniform pseudo-random numbers for numerical optimization of the objective function. The default is \( U(-1, 1) \). When the RANDINIT=r option is specified, \( U(-r, r) \) pseudo-random numbers are generated. The value \( r \) should be positive. With a RANDINIT or RANDINIT= option, there are pure random searches for a given number of trials (1,000 for conditional or nested logit, and 500 for other models) to get a maximum (or minimum) value of the objective function. For example, when there is a parameter estimate with an initial value of 1, the RANDINIT option adds a generated random number \( u \) to the initial value and computes an objective function value by using \( 1 + u \). This option is helpful in finding the initial value automatically if there is no guidance in setting the initial estimate.

RANK
specifies that the dependent variable contain ranks. The numbers must be positive integers starting from 1. When the dependent variable has value 1, the corresponding alternative is chosen. This option is provided only as a convenience to the user; the extra information contained in the ranks is not currently used for estimation purposes.

RESTART=(option-list)
specifies options that are used for reiteration of the optimization problem. When the ADDRANDOM option is specified, the initial value of reiteration is computed using random grid searches around the initial solution, as follows:

```plaintext
model y = x1 x2 / type=clogit
   restart=(addvalue=(.01 .01));
```
The preceding SAS statement reestimates a conditional logit model by adding \texttt{ADDVALUE=} values. If the \texttt{ADDVALUE=} option contains missing values, the \texttt{RESTART=} option uses the corresponding estimate from the initial stage. If no \texttt{ADDVALUE=} value is specified for an estimate, a default value equal to (\texttt{estimate} * 1e-3) is added to the corresponding estimate from the initial stage. If both the \texttt{ADDVALUE=} and \texttt{ADDRANDOM(=)} options are specified, \texttt{ADDVALUE=} is ignored.

The following options can be used in the \texttt{RESTART=} option. The options are listed within parentheses.

\texttt{ADDMAXIT=} \texttt{number}

specifies the maximum number of iterations for the second stage of the estimation. The default is \texttt{ADDMAXIT=}100.

\texttt{ADDRANDOM | ADDRANDOM=} \texttt{value}

specifies random added values to the estimates from the initial stage. With the \texttt{ADDRANDOM} option, $U(-1, 1)$ random numbers are created and added to the estimates obtained in the initial stage. When the \texttt{ADDRANDOM=} \texttt{r} option is specified, $U(-r, r)$ random numbers are generated. The restart initial value is determined based on the given number of random searches (1,000 for conditional or nested logit, and 500 for other models).

\texttt{ADDVALUE=} \texttt{( value-list )}

specifies values added to the estimates from the initial stage. A missing value in the list is considered as a zero value for the corresponding estimate. When the \texttt{ADDVALUE=} option is not specified, default values equal to (\texttt{estimate} * 1e-3) are added.

\texttt{SAMESCALE}

specifies that the parameters of the inclusive values be the same within a group at each level when the nested logit is estimated.

\texttt{SEED=} \texttt{number}

specifies an initial seed for pseudo-random number generation. The \texttt{SEED=} value must be less than $2^{31} - 1$. If the \texttt{SEED=} value is negative or zero, the time of day from the computer’s clock is used to obtain the initial seed. The default is \texttt{SEED=}0.

\texttt{SPSCALE}

specifies that the parameters of the inclusive values be the same for any choice with only one nested choice within a group, for each level in a nested logit model. This option is useful in analyzing stated preference data.

\texttt{TYPE=} \texttt{value}

specifies the type of model to be analyzed. The following model types are supported:

- \texttt{CONDITIONLOGIT | CLOGIT | CL}
  specifies a conditional logit model.
- \texttt{HEV}
  specifies a heteroscedastic extreme-value model.
- \texttt{MIXEDLOGIT | MXL}
  specifies a mixed logit model.
- \texttt{MULTINOMPROBIT | MPROBIT | MP}
  specifies a multinomial probit model.
- \texttt{NESTEDLOGIT | NLOGIT | NL}
  specifies a nested logit model.
UNITVARIANCE=( number-list )
specifies normalization restrictions on error variances of multinomial probit for the choices whose numbers are given in the list. If the UNITVARIANCE= option is specified, it must include at least two choices. Also, for identification, additional zero restrictions are placed on the correlation coefficients for the last choice in the list.

COVEST=value
specifies the type of covariance matrix. The following types are supported:

OP        specifies the covariance from the outer product matrix.
HESSIAN   specifies the covariance from the Hessian matrix.
QML       specifies the covariance from the outer product and Hessian matrices.

When COVEST=OP is specified, the outer product matrix is used to compute the covariance matrix of the parameter estimates. The COVEST=HESSIAN option produces the covariance matrix by using the inverse Hessian matrix. The quasi-maximum likelihood estimates are computed with COVEST=QML. The default is COVEST=HESSIAN when the Newton-Raphson method is used. COVEST=OP is the default when the OPTMETHOD=QN option is specified.

Printing Options

ALL
requests all printing options.

COVB
displays the estimated covariances of the parameter estimates.

CORRB
displays the estimated correlation matrix of the parameter estimates.

ITPRINT
displays the initial parameter estimates, convergence criteria, and constraints of the optimization. At each iteration, the objective function value, the maximum absolute gradient element, the step size, and the slope of search direction are printed. The objective function is the full negative log-likelihood function for the maximum likelihood method. When the ITPRINT option is specified and the NLOPTIONS statement is specified, all printing options in the NLOPTIONS statement are ignored.

NOPRINT
suppresses all displayed output.

Estimation Control Options

You can also specify detailed optimization options in the NLOPTIONS statement. The OPTMETHOD= option overrides the TECHNIQUE= option in the NLOPTIONS statement. The NLOPTIONS statement is ignored if the OPTMETHOD= option is specified.
INITIAL=( initial-values )
START=( initial-values )
specifies initial values for some or all of the parameter estimates. The values specified are assigned
to model parameters in the same order in which the parameter estimates are displayed in the MDC
procedure output.

When you use the INITIAL= option, the initial values in the INITIAL= option must satisfy the
restrictions specified for the parameter estimates. If they do not, the initial values you specify are
adjusted to satisfy the restrictions.

MAXITER=number
sets the maximum number of iterations allowed. The MAXITER= option overrides the MAXITER=
option in the NLOPTIONS statement. The default is MAXITER=100.

OPTMETHOD=value
specifies the optimization technique when the estimation method uses nonlinear optimization. The
following techniques are supported:

QN specifies the quasi-Newton method.
NR specifies the Newton-Raphson method.
TR specifies the trust region method.

The OPTMETHOD=NR option is the same as the TECHNIQUE=NEWRAP option in the NLOPTIONS
statement. For the conditional and nested logit models, the default is OPTMETHOD=NR. For other
models, the default is OPTMETHOD=QN.

NEST Statement

NEST LEVEL ( level-number )= ( choices@choice, . . . ) ;

The NEST statement is used when one choice variable contains all possible alternatives and the
TYPE=NLOGIT option is specified. The decision tree is constructed based on the NEST statement. When
the choice set is specified using multiple CHOICE= variables in the MODEL statement, the NEST statement
is ignored.

Consider the following eight choices that are nested in a three-level tree structure:

<table>
<thead>
<tr>
<th>Level 1</th>
<th>Level 2</th>
<th>Level 3</th>
<th>top</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>3</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>4</td>
<td>2</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>5</td>
<td>2</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>6</td>
<td>2</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>7</td>
<td>3</td>
<td>2</td>
<td>1</td>
</tr>
<tr>
<td>8</td>
<td>3</td>
<td>2</td>
<td>1</td>
</tr>
</tbody>
</table>

You can use the following NEST statement to specify the tree structure displayed in Figure 23.22:
Note that the decision tree is constructed based on the sequence of first-level choice set specification. Therefore, specifying another order at Level 1 builds a different tree. The following NEST statement builds the tree displayed in Figure 23.23:

\[
\begin{align*}
\text{nest} & \text{ level}(1) = (1\ 2\ 3 @ 1,\ 4\ 5\ 6 @ 2,\ 7\ 8 @ 3), \\
\text{level}(2) & = (1\ 2 @ 1,\ 3 @ 2), \\
\text{level}(3) & = (1\ 2 @ 1); \\
\end{align*}
\]

**Figure 23.23** An Alternative Three-Level Tree
However, the NEST statement with a different sequence of choice specification at higher levels builds the same tree as displayed in Figure 23.22 if the sequence at the first level is the same:

\[
\text{nest level(1)} = (1 2 3 @ 1, 4 5 6 @ 2, 7 8 @ 3), \\
\text{level(2)} = (3 @ 2, 1 2 @ 1), \\
\text{level(3)} = (1 2 @ 1);
\]

The following specifications are equivalent:

\[
\text{nest level(2)} = (3 @ 2, 1 2 @ 1) \\
\text{nest level(2)} = (3 @ 2, 1 @ 1, 2 @ 1) \\
\text{nest level(2)} = (1 @ 1, 2 @ 1, 3 @ 2)
\]

Since the MDC procedure contains multiple cases for each individual, it is important to keep the data sequence in the proper order. Consider the four-choice multinomial model with one explanatory variable cost:

<table>
<thead>
<tr>
<th>pid</th>
<th>choice</th>
<th>y</th>
<th>cost</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>1</td>
<td>10</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>0</td>
<td>25</td>
</tr>
<tr>
<td>1</td>
<td>3</td>
<td>0</td>
<td>20</td>
</tr>
<tr>
<td>1</td>
<td>4</td>
<td>0</td>
<td>30</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>0</td>
<td>15</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>0</td>
<td>22</td>
</tr>
<tr>
<td>2</td>
<td>3</td>
<td>1</td>
<td>16</td>
</tr>
<tr>
<td>2</td>
<td>4</td>
<td>0</td>
<td>25</td>
</tr>
</tbody>
</table>

The order of data needs to correspond to the value of choice. Therefore, the following data set is equivalent to the preceding data:

<table>
<thead>
<tr>
<th>pid</th>
<th>choice</th>
<th>y</th>
<th>cost</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>2</td>
<td>0</td>
<td>25</td>
</tr>
<tr>
<td>1</td>
<td>3</td>
<td>0</td>
<td>20</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
<td>1</td>
<td>10</td>
</tr>
<tr>
<td>1</td>
<td>4</td>
<td>0</td>
<td>30</td>
</tr>
<tr>
<td>2</td>
<td>3</td>
<td>1</td>
<td>16</td>
</tr>
<tr>
<td>2</td>
<td>4</td>
<td>0</td>
<td>25</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>0</td>
<td>15</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>0</td>
<td>22</td>
</tr>
</tbody>
</table>

The two-level nested model is estimated with a NEST statement, as follows:

```
proc mdc data=one type=nlogit;
   model y = cost / choice=(choice);
   id pid;
   utility u(1,) = cost;
   nest level(1) = (1 2 3 @ 1, 4 @ 2),
                   level(2) = (1 2 @ 1);
run;
```

The tree is constructed as in Figure 23.24.
Another model is estimated if you specify the decision tree as in Figure 23.25. The different nested tree structure is specified in the following SAS statements:

```sas
proc mdc data=one type=nlogit;
  model y = cost / choice=(choice);
  id pid;
  utility u(1,) = cost;
  nest level(1) = (1 @ 1, 2 3 4 @ 2),
                  level(2) = (1 2 @ 1);
run;
```

Figure 23.25 An Alternate Two-Level Tree

**NLOPTIONS Statement**

```
NLOPTIONS options;
```

PROC MDC uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. The NLOPTIONS statement specifies nonlinear optimization options. The NLOPTIONS statement must follow the MODEL statement. For a list of all the options of the NLOPTIONS statement, see Chapter 6, “Nonlinear Optimization Methods.”
**OUTPUT Statement**

```
OUTPUT options;
```

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimated linear predictors (XBETA) and predicted probabilities (P). The input data set must be sorted by the choice variables within each ID.

- **OUT= SAS-data-set** specifies the name of the output data set.
- **PRED= variable name**
- **P= variable name** requests the predicted probabilities by naming the variable that contains the predicted probabilities in the output data set.
- **XBETA= variable name** names the variable that contains the linear predictor ($x'\beta$) values. However, the XBETA= option is not supported in the nested logit model.

**RESTRICT Statement**

```
RESTRICT restriction1 < , restriction2 ... >;
```

The RESTRICT statement imposes linear restrictions on the parameter estimates. You can specify any number of RESTRICT statements.

Each **restriction** is written as an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

```
éxpression operator expression;
```

The **operator** can be =, <, >, <=, or >=.

Restriction expressions can be composed of parameters; multiplication (*), summation (+), and subtraction (-) operators; and constants. Parameters named in restriction expressions must be among the parameters estimated by the model. Parameters associated with a regressor variable are referred to by the name of the corresponding regressor variable. The restriction expressions must be a linear function of the parameters.

Lagrange multipliers are reported for all the active linear constraints. In the displayed output, the Lagrange multiplier estimates are identified with the names Restrict1, Restrict2, and so on. The probability of the Lagrange multipliers is computed using a beta distribution (LaMotte 1994).

The following are examples of using the RESTRICT statement:

```
proc mdc data=one;
model y = x1-x10 /
   type=clogit
   choice=(mode 1 2 3);
id pid;
restrict x1*x2 <= x2 + x3, ;
```
test x1 = 0, 0.5 * x1 + 2 * x2 = 0;
run;

The test investigates the joint hypothesis that
\[ \beta_1 = 0 \]
and
\[ 0.5\beta_1 + 2\beta_2 = 0 \]
Only linear equality restrictions and tests are permitted in PROC MDC. Tests expressions can be composed only of algebraic operations that use the addition symbol (+), subtraction symbol (–), and multiplication symbol (*).

The TEST statement accepts labels that are reproduced in the printed output. The TEST statement can be labeled in two ways. A TEST statement can be preceded by a label followed by a colon. Alternatively, the keyword TEST can be followed by a quoted string followed by a colon. If both are present, PROC MDC uses the label that precedes the first colon. If no label is present, PROC MDC automatically labels the tests.

### UTILITY Statement

**UTILITY U (level < , choices > )= variables ;**

The UTILITY statement specifies a utility function that can be used in estimating a nested logit model. The U()= option can have two arguments. The first argument contains level information, and the second argument is related to choice information. The second argument can be omitted for the first level when all the choices at the first level share the same variables and the same parameters. However, for any level above the first, the second argument must be provided. The UTILITY statement specifies a utility function while the NEST statement constructs the decision tree.

Consider a two-level nested logit model that has one explanatory variable at level 1. This model can be specified as follows:

```plaintext
proc mdc data=one type=nlogit;
   model y = cost / choice=(choice);
   id pid;
   utility u(1,2 3 4) = cost;
   nest level(1) = (1 @ 1, 2 3 4 @ 2),
                   level(2) = (1 2 @ 1);
run;
```

You also can specify the following statement because all the variables at the first level share the same explanatory variable, `cost`:

```plaintext
utility u(1,) = cost;
```

The variable, `cost`, must be listed in the MODEL statement. When the additional explanatory variable, `dummy`, is included at level 2, another U()= option needs to be specified. Note that the U()= option must specify choices within any level above the first. Thus, it is specified as U(2, 1 2) in the following statements:

```plaintext
proc mdc data=one type=nlogit;
   model y = cost dummy / choice=(choice);
   id pid;
   utility u(1,) = cost,
                 u(2,1 2) = dummy;
   nest level(1) = (1 @ 1, 2 3 4 @ 2),
                   level(2) = (1 2 @ 1);
run;
```
Multinomial Discrete Choice Modeling

When the dependent variable takes multiple discrete values, you can use multinomial discrete choice modeling to analyze the data. This section considers models for unordered multinomial data.

Let the random utility function be defined by

\[ U_{ij} = V_{ij} + \epsilon_{ij} \]

where the subscript \( i \) is an index for the individual, the subscript \( j \) is an index for the alternative, \( V_{ij} \) is a nonstochastic utility function, and \( \epsilon_{ij} \) is a random component (error) that captures unobserved characteristics of alternatives or individuals or both. In multinomial discrete choice models, the utility function is assumed to be linear, so that \( V_{ij} = x_{ij}'\beta \).

In the conditional logit model, each \( \epsilon_{ij} \) for all \( j \in C_i \) is distributed independently and identically (iid) with the Type I extreme-value distribution, \( \exp(-\exp(-\epsilon_{ij})) \), also known as the Gumbel distribution.

The iid assumption on the random components of the utilities of the different alternatives can be relaxed to overcome the well-known and restrictive independence from irrelevant alternatives (IIA) property of the conditional logit model. This allows for more flexible substitution patterns among alternatives than the one imposed by the conditional logit model. (See the section “Independence from Irrelevant Alternatives (IIA)” on page 1381.)

The nested logit model is derived by allowing the random components to be identical but nonindependent. Instead of independent Type I extreme-value errors, the errors are assumed to have a generalized extreme-value distribution. This model generalizes the conditional logit model to allow for particular patterns of correlation in unobserved utility (McFadden 1978).

Another generalization of the conditional logit model, the heteroscedastic extreme-value (HEV) model, is obtained by allowing independent but nonidentical errors distributed with a Type I extreme-value distribution (Bhat 1995). It permits different variances on the random components of utility across the alternatives.

Mixed logit models are also generalizations of the conditional logit model that can represent very general patterns of substitution among alternatives. For more information, see the section “Mixed Logit Model” on page 1382.

The multinomial probit (MNP) model is derived when the errors, \( (\epsilon_{i1}, \epsilon_{i2}, \ldots, \epsilon_{iJ}) \), have a multivariate normal (MVN) distribution. Thus, this model accommodates a very general error structure.

The multinomial probit model requires burdensome computation compared to a family of multinomial choice models derived from the Gumbel distributed utility function, since it involves multi-dimensional integration (with dimension \( J - 1 \)) in the estimation process. In addition, the multinomial probit model requires more parameters than other multinomial choice models. As a result, conditional and nested logit models are used more frequently, even though they are derived from a utility function whose random component is more restrictively defined than the multinomial probit model.

The event of a choice being made, \( \{y_i = j\} \), can be expressed using a random utility function

\[ U_{ij} \geq \max_{k \in C_i, k \neq j} U_{ik} \]
where $C_i$ is the choice set of individual $i$. Individual $i$ chooses alternative $j$ if and only if it provides a level of utility that is greater than or equal to that of any other alternative in his choice set. Then, the probability that individual $i$ chooses alternative $j$ (from among the $n_i$ choices in his choice set $C_i$) is

$$P_i(j) = P_{ij} = P[x_{ij}' \beta + \epsilon_{ij} \geq \max_{k \in C_i} (x_{ik}' \beta + \epsilon_{ik})]$$

### Multinomial Logit and Conditional Logit

When explanatory variables contain only individual characteristics, the multinomial logit model is defined as

$$P(y_i = j) = P_{ij} = \frac{\exp(x_i' \beta_j)}{\sum_{k=0}^{J} \exp(x_i' \beta_k)} \quad \text{for } j = 0, \ldots, J$$

where $y_i$ is a random variable that indicates the choice made, $x_i$ is a vector of characteristics specific to the $i$th individual, and $\beta_j$ is a vector of coefficients specific to the $j$th alternative. Thus, this model involves choice-specific coefficients and only individual specific regressors. For model identification, it is often assumed that $\beta_0 = 0$. The multinomial logit model reduces to the binary logit model if $J = 1$.

The ratio of the choice probabilities for alternatives $j$ and $l$ (the odds ratio of alternatives $j$ and $l$) is

$$\frac{P_{ij}}{P_{il}} = \frac{\exp(x_i' \beta_j)/\sum_{k=0}^{J} \exp(x_i' \beta_k)}{\exp(x_i' \beta_l)/\sum_{k=0}^{J} \exp(x_i' \beta_k)} = \exp[x_i' (\beta_j - \beta_l)]$$

Note that the odds ratio of alternatives $j$ and $l$ does not depend on any alternatives other than $j$ and $l$. For more information, see the section “Independence from Irrelevant Alternatives (IIA)” on page 1381.

The log-likelihood function of the multinomial logit model is

$$L = \sum_{i=1}^{N} \sum_{j=0}^{J} d_{ij} \ln P(y_i = j)$$

where

$$d_{ij} = \begin{cases} 1 & \text{if individual } i \text{ chooses alternative } j \\ 0 & \text{otherwise} \end{cases}$$

This type of multinomial choice modeling has a couple of weaknesses: it has too many parameters (the number of individual characteristics times $J$), and it is difficult to interpret. The multinomial logit model can be used to predict the choice probabilities, among a given set of $J + 1$ alternatives, of an individual with known vector of characteristics $x_i$.

The parameters of the multinomial logit model can be estimated with the TYPE=CLOGIT option in the MODEL statement; however, this requires modification of the conditional logit model to allow individual specific effects.

The conditional logit model, sometimes called the multinomial logit model, is similarly defined when choice-specific data are available. Using properties of Type I extreme-value (Gumbel) distribution, the probability that individual $i$ chooses alternative $j$ from among the choices in his choice set $C_i$ is

$$P(y_i = j) = P_{ij} = P[x_{ij}' \beta + \epsilon_{ij} \geq \max_{k \in C_i, k \neq j} (x_{ik}' \beta + \epsilon_{ik})] = \frac{\exp(x_{ij}' \beta)}{\sum_{k \in C_i} \exp(x_{ik}' \beta)}$$
where $x_{ij}$ is a vector of attributes specific to the $j$th alternative as perceived by the $i$th individual. It is assumed that there are $n_i$ choices in each individual’s choice set, $C_i$.

The log-likelihood function of the conditional logit model is

$$\mathcal{L} = \sum_{i=1}^{N} \sum_{j \in C_i} d_{ij} \ln P(y_i = j)$$

The conditional logit model can be used to predict the probability that an individual will choose a previously unavailable alternative, given knowledge of $\beta$ and the vector $x_{ij}$ of choice-specific characteristics.

**Independence from Irrelevant Alternatives (IIA)**

The problematic aspect of the conditional logit (and the multinomial logit) model lies in the property of independence from irrelevant alternatives (IIA). The IIA property can be derived from the probability ratio of any two choices. For the conditional logit model,

$$\frac{P_{ij}}{P_{il}} = \frac{\exp(x'_{ij} \beta)}{\sum_{k \in C_i} \exp(x'_{ik} \beta)} \left/ \frac{\exp(x'_{il} \beta)}{\sum_{k \in C_i} \exp(x'_{ik} \beta)} \right. = \exp[(x_{ij} - x_{il})' \beta]$$

It is evident that the ratio of the probabilities for alternatives $j$ and $l$ does not depend on any alternatives other than $j$ and $l$. This was also shown to be the case for the multinomial logit model. Thus, for the conditional and multinomial logit models, the ratio of probabilities of any two alternatives is necessarily the same regardless of what other alternatives are in the choice set or what the characteristics of the other alternatives are. This is referred to as the IIA property.

The IIA property is useful from the point of view of estimation and forecasting. For example, it allows the prediction of demand for currently unavailable alternatives. If the IIA property is appropriate for the choice situation being considered, then estimation can be based on the set of currently available alternatives, and then the estimated model can be used to calculate the probability that an individual would choose a new alternative not considered in the estimation procedure. However, the IIA property is restrictive from the point of view of choice behavior. Models that display the IIA property predict that a change in the attributes of one alternative changes the probabilities of the other alternatives proportionately such that the ratios of probabilities remain constant. Thus, cross elasticities due to a change in the attributes of an alternative $j$ are equal for all alternatives $k \neq j$. This particular substitution pattern might be too restrictive in some choice settings.

The IIA property of the conditional logit model follows from the assumption that the random components of utility are identically and independently distributed. The other models in PROC MDC (namely, nested logit, HEV, mixed logit, and multinomial probit) relax the IIA property in different ways.

For an example of Hausman’s specification test of IIA assumption, see “Example 23.6: Hausman’s Specification Test” on page 1413.

**Heteroscedastic Extreme-Value Model**

The heteroscedastic extreme-value (HEV) model (Bhat 1995) allows the random components of the utility function to be nonidentical. Specifically, the HEV model assumes independent but nonidentical error terms distributed with the Type I extreme-value distribution. The HEV model allows the variances of the random
components of utility to differ across alternatives. Bhat (1995) argues that the HEV model does not have the IIA property. The HEV model contains the conditional logit model as a special case. The probability that an individual $i$ will choose alternative $j$ from the set $C_i$ of available alternatives is

$$P_i(j) = \int_{-\infty}^{\infty} \prod_{k \in C_i, k \neq j} \Gamma \left( \frac{x_{ij}' \beta - x_{ik}' \beta + \theta_j w}{\theta_k} \right) \gamma(w) dw$$

where the choice set $C_i$ has $n_i$ elements and

$$\Gamma(x) = \exp(-\exp(-x))$$

$$\gamma(x) = \exp(-x) \Gamma(x)$$

are the cumulative distribution function and probability density function of the Type I extreme-value distribution. The variance of the error term for the $j$th alternative is $1/6 n^2 \theta_j^2$. If the scale parameters, $\theta_j$, of the random components of utility of all alternatives are equal, then this choice probability is the same as that of the conditional logit model. The log-likelihood function of the HEV model can be written as

$$\mathcal{L} = \sum_{i=1}^{N} \sum_{j \in C_i} d_{ij} \ln[P_i(j)]$$

where

$$d_{ij} = \begin{cases} 1 & \text{if individual } i \text{ chooses alternative } j \\ 0 & \text{otherwise} \end{cases}$$

Since the log-likelihood function contains an improper integral function, it is computationally difficult to get a stable estimate. With the transformation $u = \exp(-w)$, the probability can be written

$$P_i(j) = \int_{0}^{\infty} \prod_{k \in C_i, k \neq j} \Gamma \left( \frac{x_{ij}' \beta - x_{ik}' \beta - \theta_j \ln(u)}{\theta_k} \right) \exp(-u) du$$

$$= \int_{0}^{\infty} G_{ij}(u) \exp(-u) du$$

Using the Gauss-Laguerre weight function, $W(x) = \exp(-u)$, the integration of the log-likelihood function can be replaced with a summation as follows:

$$\int_{0}^{\infty} G_{ij}(u) \exp(-u) du = \sum_{k=1}^{K} w_k G_{ij}(x_k)$$

Weights ($w_k$) and abscissas ($x_k$) are tabulated by Abramowitz and Stegun (1970).

**Mixed Logit Model**

In mixed logit models, an individual’s utility from any alternative can be decomposed into a deterministic component, $x_{ij}' \beta$, which is a linear combination of observed variables, and a stochastic component, $\xi_{ij} + \epsilon_{ij}$.

$$U_{ij} = x_{ij}' \beta + \xi_{ij} + \epsilon_{ij}$$
Mixed Logit Model

where \( x_{ij} \) is a vector of observed variables that relate to individual \( i \) and alternative \( j \), \( \beta \) is a vector of parameters, \( \xi_{ij} \) is an error component that can be correlated among alternatives and heteroscedastic for each individual, and \( \epsilon_{ij} \) is a random term with zero mean that is independently and identically distributed over alternatives and individuals. The conditional logit model is derived if you assume \( \epsilon_{ij} \) has an iid Gumbel distribution and \( V(\xi_{ij}) = 0 \).

The mixed logit model assumes a general distribution for \( \xi_{ij} \) and an iid Gumbel distribution for \( \epsilon_{ij} \). Denote the density function of the error component \( \xi_{ij} \) as \( f(\xi_{ij} \mid \gamma) \), where \( \gamma \) is a parameter vector of the distribution of \( \xi_{ij} \). The choice probability of alternative \( j \) for individual \( i \) is written as

\[
P_i(j) = \int Q_i(j \mid \xi_{ij}) f(\xi_{ij} \mid \gamma) d\xi_{ij}
\]

where the conditional choice probability for a given value of \( \xi_{ij} \) is the logit

\[
Q_i(j \mid \xi_{ij}) = \frac{\exp(x_{ij}' \beta + \xi_{ij})}{\sum_{k \in C_i} \exp(x_{ik}' \beta + \xi_{ik})}
\]

Since \( \xi_{ij} \) is not given, the unconditional choice probability, \( P_i(j) \), is the integral of the conditional choice probability, \( Q_i(j \mid \xi_{ij}) \), over the distribution of \( \xi_{ij} \). This model is called “mixed logit” since the choice probability is a mixture of logits with \( f(\xi_{ij} \mid \gamma) \) as the mixing distribution.

In general, the mixed logit model does not have an exact likelihood function because the probability \( P_i(j) \) does not always have a closed form solution. Therefore, a simulation method is used for computing the approximate probability,

\[
\tilde{P}_i(j) = 1/S \sum_{s=1}^{S} \tilde{Q}_i(j \mid \xi_{ij}^s)
\]

where \( S \) is the number of simulation replications and \( \tilde{P}_i(j) \) is a simulated probability. The simulated log-likelihood function is computed as

\[
\tilde{\mathcal{L}} = \sum_{i=1}^{N} \sum_{j=1}^{n_i} d_{ij} \ln(\tilde{P}_i(j))
\]

where

\[
d_{ij} = \begin{cases} 
1 & \text{if individual } i \text{ chooses alternative } j \\
0 & \text{otherwise}
\end{cases}
\]

For simulation purposes, assume that the error component has a specific structure,

\[
\xi_{ij} = z_{ij}' \mu + w_{ij}' \beta^*
\]

where \( z_{ij} \) is a vector of observed data and \( \mu \) is a random vector with zero mean and density function \( \psi(\mu \mid \gamma) \). The observed data vector \( (z_{ij}) \) of the error component can contain some or all elements of \( x_{ij} \). The component \( z_{ij}' \mu \) induces heteroscedasticity and correlation across unobserved utility components of the alternatives. This allows flexible substitution patterns among the alternatives. The \( k \)th element of vector \( \mu \) is distributed as

\[
\mu_k \sim (0, \sigma_k^2)
\]
Therefore, $\mu_k$ can be specified as

$$\mu_k = \sigma_k \epsilon_\mu$$

where

$$\epsilon_\mu \sim N(0, 1)$$

or

$$\epsilon_\mu \sim U(-\sqrt{3}, \sqrt{3})$$

In addition, $\beta^*$ is a vector of random parameters (random coefficients). Random coefficients allow heterogeneity across individuals in their sensitivity to observed exogenous variables. The observed data vector, $w_{ij}$, is a subset of $x_{ij}$. The following three types of distributions for the random coefficients are supported, where the $m$th element of $\beta^*$ is denoted as $\beta_{m}^*$:

- Normally distributed coefficient with the mean $b_m$ and spread $s_m$ being estimated.
  $$\beta_{m}^* = b_m + s_m \epsilon_\beta \quad \text{and} \quad \epsilon_\beta \sim N(0, 1)$$

- Uniformly distributed coefficient with the mean $b_m$ and spread $s_m$ being estimated. A uniform distribution with mean $b$ and spread $s$ is $U(b - s, b + s)$.
  $$\beta_{m}^* = b_m + s_m \epsilon_\beta \quad \text{and} \quad \epsilon_\beta \sim U(-1, 1)$$

- Lognormally distributed coefficient. The coefficient is calculated as
  $$\beta_{m}^* = \exp(b_m + s_m \epsilon_\beta) \quad \text{and} \quad \epsilon_\beta \sim N(0, 1)$$

where $b_m$ and $s_m$ are parameters that are estimated.

The estimate of spread for normally, uniformly, and lognormally distributed coefficients can be negative. The absolute value of the estimated spread can be interpreted as an estimate of standard deviation for normally distributed coefficients.

A detailed description of mixed logit models can be found, for example, in Brownstone and Train (1999).

### Multinomial Probit

The multinomial probit model allows the random components of the utility of the different alternatives to be nonindependent and nonidentical. Thus, it does not have the IIA property. The increase in the flexibility of the error structure comes at the expense of introducing several additional parameters in the covariance matrix of the errors.

Consider the random utility function

$$U_{ij} = x_{ij} \beta + \epsilon_{ij}$$
where the joint distribution of \((\epsilon_{i1}, \epsilon_{i2}, \ldots, \epsilon_{iJ})\) is multivariate normal:

\[
\begin{bmatrix}
\epsilon_{i1} \\
\epsilon_{i2} \\
\vdots \\
\epsilon_{iJ}
\end{bmatrix} \sim N(0, \Sigma)
\]

\[
\Sigma = \begin{bmatrix}
\sigma_{jk}
\end{bmatrix}_{j,k=1,\ldots,J}
\]

The dimension of the error covariance matrix is determined by the number of alternatives \(J\). Given \((x_{i1}, x_{i2}, \ldots, x_{iJ})\), the \(j\)th alternative is chosen if and only if \(U_{ij} \geq U_{ik}\) for all \(k \neq j\). Thus, the probability that the \(j\)th alternative is chosen is

\[
P(y_i = j) = P_{ij} = P[\epsilon_{i1} - \epsilon_{ij} < (x_{ij} - x_{i1})' \beta, \ldots, \epsilon_{iJ} - \epsilon_{ij} < (x_{ij} - x_{iJ})' \beta]
\]

where \(y_i\) is a random variable that indicates the choice made. This is a cumulative probability from a \((J - 1)\)-variate normal distribution. Since evaluation of this probability involves multidimensional integration, it is practical to use a simulation method to estimate the model. Many studies have shown that the simulators proposed by the following authors (henceforth referred to as GHK) perform well: Geweke (1989); Hajivassiliou (1993); Keane (1994). For example, Hajivassiliou, McFadden, and Ruud (1996) compare 13 simulators using 11 different simulation methods and conclude that the GHK simulation method is the most reliable. To compute the probability of the multivariate normal distribution, the recursive simulation method is used. For more information about GHK simulators, see Hajivassiliou (1993).

The log-likelihood function for the multinomial probit model can be written as

\[
\mathcal{L} = \sum_{i=1}^{N} \sum_{j=1}^{J} d_{ij} \ln P(y_i = j)
\]

where

\[
d_{ij} = \begin{cases} 
1 & \text{if individual } i \text{ chooses alternative } j \\
0 & \text{otherwise}
\end{cases}
\]

For identification of the multinomial probit model, two of the diagonal elements of \(\Sigma\) are normalized to 1, and it is assumed that for one of the choices whose error variance is normalized to 1 (say, \(k\)), it is also true that \(\sigma_{jk} = \sigma_{kj} = 0\) for \(j = 1, \ldots, J\) and \(j \neq k\). Thus, a model with \(J\) alternatives has at most \(J(J - 1)/2 - 1\) covariance parameters after normalization.

Let \(D\) and \(R\) be defined as

\[
D = \begin{bmatrix}
\sigma_1 & 0 & \cdots & 0 \\
0 & \sigma_2 & \cdots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \cdots & \sigma_J
\end{bmatrix}
\]

\[
R = \begin{bmatrix}
1 & \rho_{12} & \cdots & \rho_{1J} \\
\rho_{21} & 1 & \cdots & \rho_{2J} \\
\vdots & \vdots & \ddots & \vdots \\
\rho_{J1} & \rho_{J2} & \cdots & 1
\end{bmatrix}
\]
where \( \sigma_j^2 = \sigma_{jj} \) and \( \rho_{jk} = \frac{\sigma_{jk}}{\sigma_{jj}\sigma_{kk}} \). Then, for identification, \( \sigma_{J-1} = \sigma_J = 1 \) and \( \rho_{kJ} = \rho_{JK} = 0 \), for all \( k \neq J \) can be imposed, and the error covariance matrix is \( \Sigma = DRD \).

In the standard MDC output, the parameter estimates STD\(_j\) and RHO\(_{jk}\) correspond to \( \sigma_j \) and \( \rho_{jk} \).

In principle, the multinomial probit model is fully identified with the preceding normalizations. However, in practice, convergence in applications of the model with more than three alternatives often requires additional restrictions on the elements of \( \Sigma \).

It must also be noted that the unrestricted structure of the error covariance matrix makes it impossible to forecast demand for a new alternative without knowledge of the new \( J+1 \) by \( (J+1) \) error covariance matrix.

### Nested Logit

The nested logit model (McFadden 1978, 1981) allows partial relaxation of the assumption of independence of the stochastic components of utility of alternatives. In some choice situations, the IIA property holds for some pairs of alternatives but not all. In these situations, the nested logit model can be used if the set of alternatives faced by an individual can be partitioned into subsets such that the IIA property holds within subsets but not across subsets.

In the nested logit model, the joint distribution of the errors is generalized extreme value (GEV). This is a generalization of the Type I extreme-value distribution that gives rise to the conditional logit model. Note that all \( \epsilon_{ij} \) within each subset are correlated with each other. For more information, see McFadden (1978, 1981).

Nested logit models can be described analytically following the notation of McFadden (1981). Assume that there are \( L \) levels, with 1 representing the lowest and \( L \) representing the highest level of the tree. The index of a node at level \( h \) in the tree is a pair \((j_h, \pi_h)\), where \( \pi_h = (j_{h+1}, \ldots, j_L) \) is the index of the adjacent node at level \( h+1 \). Thus, the primitive alternatives, at level 1 in the tree, are indexed by vectors \((j_1, \ldots, j_L)\), and the alternative nodes at level \( L \) are indexed by integers \( j_L \). The choice set \( C_{\pi_h} \) is the set of primitive alternatives (at level 1) that belong to branches below the node \( \pi_h \). The notation \( C_{\pi_h} \) is also used to denote a set of indices \( j_h \) such that \((j_h, \pi_h)\) is a node immediately below \( \pi_h \). Note that \( C_{\pi_0} \) is a set with a single element, while \( C_{\pi_j} \) represents a choice set that contains all possible alternatives. As an example, consider the circled node at level 1 in Figure 23.26. Since it stems from node 11, \( \pi_h = 11 \), and since it is the second node stemming from 11, \( j_h = 2 \), its index is \( \pi_{h-1} = \pi_0 = (j_h, \pi_h) = 211 \). Similarly, \( C_{11} = \{111, 211, 311\} \) contains all the possible choices below 11.

Although this notation is useful for writing closed-form solutions for probabilities, the MDC procedure allows a more flexible definition of indices. For more information about how to describe decision trees within the MDC procedure, see the section “NEST Statement” on page 1372.
Let $x_{i:jh}^{(h)}$ denote the vector of observed variables for individual $i$ common to the alternatives below node $j_h \pi_h$. The probability of choice at level $h$ has a closed-form solution and is written

$$P_i(f_h | \pi_h) = \frac{\exp \left[ x_{i:jh}^{(h)} \beta^{(h)} + \sum_{k \in C_{i:jh} \pi_h} I_{k,jh \pi_h} \theta_{k,jh \pi_h} \right]}{\sum_{j \in C_{i:\pi_h}} \exp \left[ x_{i:jh}^{(h)} \beta^{(h)} + \sum_{k \in C_{i:jh} \pi_h} I_{k,jh \pi_h} \theta_{k,jh \pi_h} \right]}, h = 2, \ldots, L$$

where $I_{\pi_h}$ is the inclusive value (at level $h + 1$) of the branch below node $\pi_h$ and is defined recursively as follows:

$$I_{\pi_h} = \ln \left\{ \sum_{j \in C_{i:\pi_h}} \exp \left[ x_{i:jh}^{(h)} \beta^{(h)} + \sum_{k \in C_{i:jh} \pi_h} I_{k,jh \pi_h} \theta_{k,jh \pi_h} \right] \right\}$$

$$0 \leq \theta_{k,\pi_1} \leq \cdots \leq \theta_{k,\pi_{L-1}}$$

The inclusive value $I_{\pi_h}$ denotes the average utility that the individual can expect from the branch below $\pi_h$. The dissimilarity parameters or inclusive value parameters ($\theta_{k,j \pi_h}$) are the coefficients of the inclusive values and have values between 0 and 1 if nested logit is the correct model specification. When they all take value 1, the nested logit model is equivalent to the conditional logit model.

At decision level 1, there is no inclusive value; that is, $I_{\pi_0} = 0$. Therefore, the conditional probability is

$$P_i(f_1 | \pi_1) = \frac{\exp \left[ x_{i:j1 \pi_1}^{(1)} \beta^{(1)} \right]}{\sum_{j \in C_{i:\pi_1}} \exp \left[ x_{i:j1 \pi_1}^{(1)} \beta^{(1)} \right]}$$

The log-likelihood function at level $h$ can then be written

$$\mathcal{L}^{(h)} = \sum_{i=1}^{N} \sum_{\pi_h' \in C_{i:\pi_{h+1}}} \sum_{j \in C_{i:\pi_h'}} y_{i,j \pi_h'} \ln P(C_{i,j \pi_h'} | C_{i,\pi_h'})$$
where \( y_{i,j} \) is an indicator variable that has the value of 1 for the selected choice. The full log-likelihood function of the nested logit model is obtained by adding the conditional log-likelihood functions at each level:

\[
\mathcal{L} = \sum_{h=1}^{L} \mathcal{L}^{(h)}
\]

Note that the log-likelihood functions are computed from conditional probabilities when \( h < L \). The nested logit model is estimated using the full information maximum likelihood method.

### Decision Tree and Nested Logit

You can view choices as a decision tree and model the decision tree by using the nested logit model. You need to use either the NEST statement or the CHOICE= option of the MODEL statement to specify the nested tree structure. Additionally, you need to identify which explanatory variables are used at each level of the decision tree. These explanatory variables are arguments for what is called a utility function. The utility function is specified using UTILITY statements. For example, consider a two-level decision tree. The tree structure is displayed in Figure 23.27.

**Figure 23.27** Two-Level Decision Tree

A nested logit model with two levels can be specified using the following SAS statements:

```sas
proc mdc data=one type=nlogit;
   model decision = x1 x2 x3 x4 x5 / choice=(upmode 1 2, mode 1 2 3 4 5);
   id pid;
   utility u(1, 3 4 5 @ 2) = x1 x2,
                  u(1, 1 2 @ 1) = x3 x4,
                  u(2, 1 2) = x5;
run;
```

The DATA=one data set should be arranged as follows:
All model variables, x1 through x5, are specified in the UTILITY statement. It is required that entries denoted as # have values for model estimation and prediction. The values of the level 2 utility variable x5 should be the same for all the primitive (level 1) alternatives below node 1 at level 2 and, similarly, for all the primitive alternatives below node 2 at level 2. In other words, x5 should have the same value for primitive alternatives 1 and 2 and, similarly, it should have the same value for primitive alternatives 3, 4, and 5. More generally, the values of any level 2 or higher utility function variables should be constant across primitive alternatives under each node for which the utility function applies. Since PROC MDC expects this to be the case, it uses the values of x5 only for the primitive alternatives 1 and 3, ignoring the values for the primitive alternatives 2, 4, and 5. Thus, PROC MDC uses the values of the utility function variable only for the primitive alternatives that come first under each node for which the utility function applies. This behavior applies to any utility function variables that are specified above the first level. The choice variable for level 2 (upmode) should be placed before the first-level choice variable (mode) when the CHOICE= option is specified. Alternatively, the NEST statement can be used to specify the decision tree. The following SAS statements fit the same nested logit model:

```sas
proc mdc data=a type=nlogit;
  model decision = x1 x2 x3 x4 x5 / choice=(mode 1 2 3 4 5);
  id pid;
  utility u(1, 3 4 5 @ 2) = x1 x2,
     u(1, 1 2 @ 1) = x3 x4,
     u(2, 1 2) = x5;
  nest level(1) = (1 2 @ 1, 3 4 5 @ 2),
                level(2) = (1 2 @ 1);
run;
```

The U(1, 3 4 5 @ 2)= option specifies three choices, 3, 4, and 5, at level 1 of the decision tree. They are connected to the upper branch 2. The specified variables (x1 and x2) are used to model this utility function. The bottom level of the decision tree is level 1. All variables in the UTILITY statement must be included in the MODEL statement. When all choices at the first level share the same variables, you can omit the second argument of the U()= option for that level. However, U(1, ) = x1 x2 is not equivalent to the following statements:

```sas
  u(1, 3 4 5 @ 2) = x1 x2;
  u(1, 1 2 @ 1) = x1 x2;
```

The CHOICE= variables need to be specified from the top to the bottom level. To forecast demand for new products, stated preference data are widely used. Stated preference data are attractive for market researchers because attribute variations can be controlled. Hensher (1993) explores the advantage of combining revealed
preference (market data) and stated preference data. The scale factor \(V_{rp}/V_{sp}\) can be estimated using the nested logit model with the decision tree structure displayed in Figure 23.28.

**Figure 23.28** Decision Tree for Revealed and Stated Preference Data

Example SAS statements are as follows:

```sas
proc mdc data=a type=nlogit;
  model decision = x1 x2 x3 /
    spscale
    choice=(mode 1 2 3 4 5 6);
  id pid;
  utility u(1,) = x1 x2 x3;
  nest level(1) = (1 2 3 @ 1, 4 @ 2, 5 @ 3, 6 @ 4),
    level(2) = (1 2 3 4 @ 1);
run;
```

The SPSCALE option specifies that parameters of inclusive values for nodes 2, 3, and 4 at level 2 be the same. When you specify the SAMESCALE option, the MDC procedure imposes the same coefficient of inclusive values for choices 1–4.

### Model Fit and Goodness-of-Fit Statistics

McFadden (1974) suggests a likelihood ratio index that is analogous to the R-square in the linear regression model,

\[
R^2_M = 1 - \frac{\ln L}{\ln L_0}
\]

where \(L\) is the maximum of the log-likelihood function and \(L_0\) is the maximum of the log-likelihood function when all coefficients, except for an intercept term, are zero. McFadden’s likelihood ratio index is bounded by 0 and 1.

Estrella (1998) proposes the following requirements for a goodness-of-fit measure to be desirable in discrete choice modeling:

- The measure must take values in [0, 1], where 0 represents no fit and 1 corresponds to perfect fit.
- The measure should be directly related to the valid test statistic for the significance of all slope coefficients.
The derivative of the measure with respect to the test statistic should comply with corresponding derivatives in a linear regression.

Estrella’s measure is written as

\[ R_{E1}^2 = 1 - \left( \frac{\ln L}{\ln L_0} \right)^{(2/N) \ln L_0} \]

Estrella suggests an alternative measure,

\[ R_{E2}^2 = 1 - \left[ (\ln L - K)/\ln L_0 \right]^{(2/N) \ln L_0} \]

where \( \ln L_0 \) is computed with null parameter values, \( N \) is the number of observations used, and \( K \) represents the number of estimated parameters.

Other goodness-of-fit measures are summarized as follows:

\[ R_{CU1}^2 = 1 - \left( \frac{L_0}{L} \right)^{\frac{2}{k}} \quad \text{(Cragg-Uhler 1)} \]
\[ R_{CU2}^2 = 1 - \left( \frac{L_0}{L} \right)^{\frac{2}{1 - L_0}} \quad \text{(Cragg-Uhler 2)} \]
\[ R_A^2 = \frac{2(\ln L - \ln L_0)}{2(\ln L - \ln L_0) + N} \quad \text{(Aldrich-Nelson)} \]
\[ R_{VZ}^2 = R_A^2 \frac{2 \ln L_0 - N}{2 \ln L_0} \quad \text{(Veall-Zimmermann)} \]

The AIC and SBC are computed as follows,

\[ \text{AIC} = -2 \ln(L) + 2k \]
\[ \text{SBC} = -2 \ln(L) + \ln(n) k \]

where \( \ln(L) \) is the log-likelihood value for the model, \( k \) is the number of parameters estimated, and \( n \) is the number of observations (that is, the number of respondents).

### Tests on Parameters

In general, the hypothesis to be tested can be written as

\[ H_0 : h(\theta) = 0 \]

where \( h(\theta) \) is an \( r \)-by-1 vector-valued function of the parameters \( \theta \) given by the \( r \) expressions specified in the TEST statement.

Let \( \hat{V} \) be the estimate of the covariance matrix of \( \hat{\theta} \). Let \( \hat{\theta} \) be the unconstrained estimate of \( \theta \) and \( \tilde{\theta} \) be the constrained estimate of \( \theta \) such that \( h(\tilde{\theta}) = 0 \). Let

\[ A(\theta) = \partial h(\theta) / \partial \theta \bigg|_{\hat{\theta}} \]

Using this notation, the test statistics for the three kinds of tests are computed as follows:
The Wald test statistic is defined as
\[ W = h'(\hat{\theta}) \left( A(\hat{\theta})\hat{V} A'(\hat{\theta}) \right)^{-1} h(\hat{\theta}) \]

The Wald test is not invariant to reparameterization of the model (Gregory and Veall 1985; Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

The Lagrange multiplier test statistic is
\[ LM = \lambda' A(\hat{\theta})\hat{V} A'(\hat{\theta})\lambda \]
where \( \lambda \) is the vector of Lagrange multipliers from the computation of the restricted estimate \( \hat{\theta} \).

The likelihood ratio test statistic is
\[ LR = 2 \left( L(\hat{\theta}) - L(\tilde{\theta}) \right) \]
where \( \tilde{\theta} \) represents the constrained estimate of \( \theta \) and \( L \) is the concentrated log-likelihood value.

For each kind of test, under the null hypothesis the test statistic is asymptotically distributed as a \( \chi^2 \) random variable with \( r \) degrees of freedom, where \( r \) is the number of expressions in the TEST statement. The \( p \)-values reported for the tests are computed from the \( \chi^2(r) \) distribution and are only asymptotically valid.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation to its small sample distribution than that of the other two tests. However, the Wald test has the lowest computational cost, since it does not require computation of the constrained estimate \( \tilde{\theta} \).

The following statements are an example of using the TEST statement to perform a likelihood ratio test:
```sas
proc mdc;
    model decision = x1 x2 / type=clogit
        choice=(mode 1 2 3);
    id pid;
    test 0.5 * x1 + 2 * x2 = 0 / lr;
run;
```

**OUTEST= Data Set**

The OUTEST= data set contains all the parameters that are estimated in a MODEL statement. The OUTEST= option can be used when the PROC MDC call contains one MODEL statement. There are additional restrictions. For the HEV and multinomial probit models, you need to specify exactly all possible elements of the choice set, since additional parameters (for example, SCALE1 or STD1) are generated automatically in the MDC procedure. Therefore, the following SAS statements are not valid when the OUTEST= option is specified:
```sas
proc mdc data=a outest=e;
    model y = x / type=hev choice=(alter);
run;
```
You need to specify all possible choices in the CHOICE= option since the OUTEST= option is specified as follows:
When the NCHOICE= option is specified, no additional information about possible choices is required. Therefore, the following SAS statements are correct:

```sas
proc mdc data=a outest=e;
  model y = x / type=hev choice=(alter 1 2 3);
run;
```

The nested logit model does not produce the OUTTEST= data set unless the NEST statement is specified.

Each parameter contains the estimate for the corresponding parameter in the corresponding model. In addition, the OUTTEST= data set contains the following variables:

- `_DEPVAR_` the name of the dependent variable
- `_METHOD_` the estimation method
- `_MODEL_` the label of the MODEL statement if one is specified, or blank otherwise
- `_STATUS_` a character variable that indicates whether the optimization process reached convergence or failed to converge: 0 indicates that the convergence was reached, 1 indicates that the maximum number of iterations allowed was exceeded, 2 indicates a failure to improve the function value, and 3 indicates a failure to converge because the objective function or its derivatives could not be evaluated or improved, or linear constraints were dependent, or the algorithm failed to return to feasible region, or the number of iterations was greater than prespecified.
- `_NAME_` the name of the row of the covariance matrix for the parameter estimate, if the COVOUT option is specified, or blank otherwise
- `_LIKELHD_` the log-likelihood value
- `_STDERR_` standard error of the parameter estimate, if the COVOUT option is specified
- `_TYPE_` PARMS for observations that contain parameter estimates, or COV for observations that contain covariance matrix elements

The OUTTEST= data set contains one observation for the MODEL statement giving the parameter estimates for that model. If the COVOUT option is specified, the OUTTEST= data set includes additional observations for the MODEL statement giving the rows of the covariance matrix of parameter estimates. For covariance observations, the value of the `_TYPE_` variable is COV, and the `_NAME_` variable identifies the parameter associated with that row of the covariance matrix.

### ODS Table Names

PROC MDC assigns a name to each table it creates. You can use these names to denote the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the Table 23.3.

Examples: MDC Procedure

Example 23.1: Binary Data Modeling

The MDC procedure supports various multinomial choice models. However, you can also use PROC MDC to estimate binary choice models such as binary logit and probit because these models are special cases of multinomial models.

Spector and Mazzeo (1980) studied the effectiveness of a new teaching method on students’ performance in an economics course. They reported grade point average (gpa), previous knowledge of the material (tuce), a dummy variable for the new teaching method (psi), and the final course grade (grade). A value of 1 is recorded for grade if a student earned the letter grade “A,” and 0 otherwise.

The binary logit can be estimated using the conditional logit model. In order to use the MDC procedure, the data are converted as follows so that each possible choice corresponds to one observation:
data smdata;
  input gpa tuce psi grade;
datalines;
2.66 20 0 0
2.89 22 0 0
3.28 24 0 0
2.92 12 0 0
... more lines ...
data smdatal1;
  set smdata;
  retain id 0;
  id + 1;

  /*-- first choice --*/
  choice1 = 1;
  choice2 = 0;
  decision = (grade = 0);
  gpa_2 = 0;
  tuce_2 = 0;
  psi_2 = 0;
  output;

  /*-- second choice --*/
  choice1 = 0;
  choice2 = 1;
  decision = (grade = 1);
  gpa_2 = gpa;
  tuce_2 = tuce;
  psi_2 = psi;
  output;
run;

The first 10 observations are displayed in Output 23.1.1. The variables related to grade=0 are omitted since these are not used for binary choice model estimation.

Consider the choice probability of the conditional logit model for binary choice:

\[ P_i(j) = \frac{\exp(x'_{ij}\beta)}{\sum_k^2 \exp(x'_{ik}\beta)}, \quad j = 1, 2 \]

The choice probability of the binary logit model is computed based on normalization. The preceding conditional logit model can be converted as

\[ P_i(1) = \frac{1}{1 + \exp((x_{i2} - x_{i1})'\beta)} \]
\[ P_i(2) = \frac{\exp((x_{i2} - x_{i1})'\beta)}{1 + \exp((x_{i2} - x_{i1})'\beta)} \]

Therefore, you can interpret the binary choice data as the difference between the first and second choice characteristics. In the following statements, it is assumed that \( x_{i1} = 0 \). The binary logit model is estimated and displayed in Output 23.1.2.

```plaintext
/*--- Conditional Logit ---*/ proc mdc data=smdatal;   model decision = choice2 gpa_2 tuce_2 psi_2 / type=clogit nchoice=2 covest=hess;   id id; run;
```

Output 23.1.2 Binary Logit Estimates

The MDC Procedure

Conditional Logit Estimates

| Parameter   | DF | Estimate | Standard Error | t Value | Approx Pr > |t|
|-------------|----|----------|----------------|---------|-------------|
| choice2     | 1  | -13.0213 | 4.9313         | -2.64   | 0.0083      |
| gpa_2       | 1  | 2.8261   | 1.2629         | 2.24    | 0.0252      |
| tuce_2      | 1  | 0.0952   | 0.1416         | 0.67    | 0.5014      |
| psi_2       | 1  | 2.3787   | 1.0646         | 2.23    | 0.0255      |

Consider the choice probability of the multinomial probit model:

\[ P_i(j) = P[\epsilon_{i1} - \epsilon_{ij} < (x_{ij} - x_{i1})'\beta, \ldots, \epsilon_{iJ} - \epsilon_{ij} < (x_{ij} - x_{iJ})'\beta] \]

The probabilities of choice of the two alternatives can be written as

\[ P_i(1) = P[\epsilon_{i2} - \epsilon_{i1} < (x_{i1} - x_{i2})'\beta] \]
\[ P_i(2) = P[\epsilon_{i1} - \epsilon_{i2} < (x_{i2} - x_{i1})'\beta] \]

where \( \begin{bmatrix} \epsilon_{i1} \\ \epsilon_{i2} \end{bmatrix} \sim N \left( 0, \begin{bmatrix} \sigma_{11}^2 & \sigma_{12} \\ \sigma_{12} & \sigma_{22}^2 \end{bmatrix} \right) \). Assume that \( x_{i1} = 0 \) and \( \sigma_{12} = 0 \). The binary probit model is estimated and displayed in Output 23.1.3. You do not get the same estimates as that of the usual binary probit
model. The probabilities of choice in the binary probit model are

\[ P_i(2) = P[\epsilon_i < x'_i \beta] \]
\[ P_i(1) = 1 - P[\epsilon_i < x'_i \beta] \]

where \( \epsilon_i \sim N(0, 1) \). However, the multinomial probit model has the error variance \( \text{Var}(\epsilon_{i2} - \epsilon_{i1}) = \sigma_1^2 + \sigma_2^2 \) if \( \epsilon_{i1} \) and \( \epsilon_{i2} \) are independent (\( \sigma_{12} = 0 \)). In the following statements, unit variance restrictions are imposed on choices 1 and 2 (\( \sigma_1^2 = \sigma_2^2 = 1 \)). Therefore, the usual binary probit estimates (and standard errors) can be obtained by multiplying the multinomial probit estimates (and standard errors) in Output 23.1.3 by \( 1/\sqrt{2} \).

```plaintext
/*--- Multinomial Probit ---*/
proc mdc data=smdatal1;
   model decision = choice2 gpa_2 tuce_2 psi_2 /
      type=mprobit
      nchoice=2
      covest=hess
      unitvariance=(1 2);
   id id;
run;
```

Output 23.1.3 Binary Probit Estimates

The MDC Procedure

Multinomial Probit Estimates

| Parameter | DF | Estimate | Standard Error | t Value | Approx Pr > |t| |
|-----------|----|----------|----------------|---------|-------------|---|
| choice2   | 1  | -10.5392 | 3.5956         | -2.93   | 0.0034      |   |
| gpa_2     | 1  | 2.2992   | 0.9813         | 2.34    | 0.0191      |   |
| tuce_2    | 1  | 0.0732   | 0.1186         | 0.62    | 0.5375      |   |
| psi_2     | 1  | 2.0171   | 0.8415         | 2.40    | 0.0165      |   |

**Example 23.2: Conditional Logit and Data Conversion**

In this example, data are prepared for use by the MDCDATA statement. Sometimes, choice-specific information is stored in multiple variables. Since the MDC procedure requires multiple observations for each decision maker, you need to arrange the data so that there is an observation for each subject-alternative (individual-choice) combination. Simple binary choice data are obtained from Ben-Akiva and Lerman (1985). The following statements create the SAS data set:

```plaintext
data travel;
   length mode $ 8;
   input auto transit mode $;
datalines;
52.9 4.4 Transit
4.1 28.5 Transit
4.1 86.9 Auto
56.2 31.6 Transit
51.8 20.2 Transit
```
The travel time is stored in two variables, auto and transit. In addition, the chosen alternatives are stored in a character variable, mode. The choice variable, mode, is converted to a numeric variable, decision, since the MDC procedure supports only numeric variables. The following statements convert the original data set, travel, and estimate the binary logit model. The first 10 observations of a relevant subset of the new data set and the parameter estimates are displayed in Output 23.2.1 and Output 23.2.2, respectively.

```sas
data new;
  set travel;
  retain id 0;
  id+1;
  /*-- create auto variable --*/
  decision = (upcase(mode) = 'AUTO');
  ttime = auto;
  autodum = 1;
  trandum = 0;
  output;
  /*-- create transit variable --*/
  decision = (upcase(mode) = 'TRANSIT');
  ttime = transit;
  autodum = 0;
  trandum = 1;
  output;
run;

proc print data=new(obs=10);
  var decision autodum trandum ttime;
  id id;
run;
```

**Output 23.2.1 Converted Data**

<table>
<thead>
<tr>

</tbody>
</table>
The following statements perform the binary logit estimation:

```plaintext
proc mdc data=new;
  model decision = autodum ttime /
    type=clogit
    nchoice=2;
  id id;
run;
```

**Output 23.2.2** Binary Logit Estimation of Modal Choice Data

**The MDC Procedure**

**Conditional Logit Estimates**

| Parameter | DF | Estimate | Standard Error | t Value | Approx Pr > |t|
|-----------|----|----------|----------------|---------|-------------|
| autodum   | 1  | -0.2376  | 0.7505         | -0.32   | 0.7516      |
| ttime     | 1  | -0.0531  | 0.0206         | -2.57   | 0.0101      |

In order to handle more general cases, you can use the MDCDATA statement. Choice-specific dummy variables are generated and multiple observations for each individual are created. The following example converts the original data set travel by using the MDCDATA statement and performs conditional logit analysis. Interleaved data are output into the new data set new3. This data set has twice as many observations as the original travel data set.

```plaintext
proc mdc data=travel;
  mdcdata varlist( x1 = (auto transit) )
    select=mode
    id=id
    alt=alternative
    decvar=Decision / out=new3;
  model decision = auto x1 /
    nchoice=2
    type=clogit;
  id id;
run;
```

The first nine observations of the modified data set are shown in **Output 23.2.3**. The result of the preceding program is listed in **Output 23.2.4**.

Example 23.3: Correlated Choice Modeling

Often, it is not realistic to assume that the random components of utility for all choices are independent. This example shows the solution to the problem of correlated random components by using multinomial probit and nested logit.

To analyze correlated data, trinomial choice data (1,000 observations) are created using a pseudo-random number generator by using the following statements. The random utility function is

\[ U_{ij} = V_{ij} + \epsilon_{ij}, \quad j = 1, 2, 3 \]

where

\[ \epsilon_{ij} \sim N \left( 0, \begin{bmatrix} 2 & 0.6 & 0 \\ 0.6 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \right) \]

```sas
/*--- generate simulated series ---*/
%let ndim = 3;
%let nobs = 1000;

data trichoice;
    array error{&ndim} e1-e3;
    array vtemp{&ndim} _temporary_;
    array lm{6} _temporary_ (1.4142136 0.4242641 1 0 0 1);
    retain nseed 345678;

do id = 1 to &nobs;
    index = 0;
    /* generate independent normal variate */
    do i = 1 to &ndim;
        /* index of diagonal element */
        vtemp{i} = rannor(nseed);
    end;
    /* get multivariate normal variate */
    index = 0;
    do i = 1 to &ndim;
        error{i} = 0;
        do j = 1 to i;
            error{i} = error{i} + lm(index+j)*vtemp{j};
        end;
        index = index + i;
```
Example 23.3: Correlated Choice Modeling

end;
x1 = 1.0 + 2.0 * ranuni(nseed);
x2 = 1.2 + 2.0 * ranuni(nseed);
x3 = 1.5 + 1.2 * ranuni(nseed);
util1 = 2.0 * x1 + e1;
util2 = 2.0 * x2 + e2;
util3 = 2.0 * x3 + e3;
do i = 1 to &ndim;
   vtemp(i) = 0;
end;
if ( util1 > util2 & util1 > util3 ) then
   vtemp(1) = 1;
else if ( util2 > util1 & util2 > util3 ) then
   vtemp(2) = 1;
else if ( util3 > util1 & util3 > util2 ) then
   vtemp(3) = 1;
else continue;

/*-- first choice --*/
x = x1;
mode = 1;
decision = vtemp(1);
output;

/*-- second choice --*/
x = x2;
mode = 2;
decision = vtemp(2);
output;

/*-- third choice --*/
x = x3;
mode = 3;
decision = vtemp(3);
output;
end;
run;

First, the multinomial probit model is estimated (see the following statements). Results show that
the standard deviation, correlation, and slope estimates are close to the parameter values. Note that
\[ \rho_{12} = \frac{\sigma_{12}}{\sqrt{\sigma_1^2 \sigma_2^2}} = \frac{0.6}{\sqrt{2} \times 1} = 0.42, \sigma_1 = \sqrt{2} = 1.41, \sigma_2 = \sqrt{1} = 1, \] and the parameter value for
the variable x is 2.0. (See Output 23.3.1.)

/*** Trinomial Probit --*/
proc mdc data=trichoice randnum=halton nsimul=100;
   model decision = x /
      type=mprobit
      choice=(mode 1 2 3)
      covest=op
      optmethod=qn;
   id id;
run;
Chapter 23: The MDC Procedure

Output 23.3.1  Trinomial Probit Model Estimation

The MDC Procedure

Multinomial Probit Estimates

| Parameter | DF | Estimate | Standard Error | t Value | Pr > |t| |
|-----------|----|----------|----------------|---------|------|---|
| x         | 1  | 1.7685   | 0.1191         | 14.85   | <.0001 |
| STD_1     | 1  | 1.2514   | 0.1494         | 8.38    | <.0001 |
| RHO_21    | 1  | 0.3971   | 0.1087         | 3.65    | 0.0003 |

Figure 23.29 shows a two-level decision tree.

Figure 23.29  Nested Tree Structure

The following statements estimate the nested model shown in Figure 23.29:

```plaintext
/*-- Two-Level Nested Logit --*/
proc mdc data=trichoice;
   model decision = x /
      type=nlogit
      choice=(mode 1 2 3)
      covest=op
      optmethod=qn;
   id id;
   utility u(1,) = x;
   nest level(1) = (1 2 @ 1, 3 @ 2),
      level(2) = (1 2 @ 1);
run;
```

The estimated result (see Output 23.3.2) shows that the data support the nested tree model since the estimates of the inclusive value parameters are significant and are less than 1.
Example 23.4: Testing for Homoscedasticity of the Utility Function

The conditional logit model imposes equal variances on random components of utility of all alternatives. This assumption can often be too restrictive and the calculated results misleading. This example shows several approaches to testing the homoscedasticity assumption.

The section “Getting Started: MDC Procedure” on page 1347 analyzes an HEV model by using Daganzo’s trinomial choice data and displays the HEV parameter estimates in Figure 23.15. The inverted scale estimates for mode “2” and mode “3” suggest that the conditional logit model (which imposes equal variances on random components of utility of all alternatives) might be misleading. The HEV estimation summary from that analysis is repeated in Output 23.4.1.

### Output 23.3.2 Two-Level Nested Logit

**The MDC Procedure**

**Nested Logit Estimates**

| Parameter  | DF | Estimate | Standard Error | t Value | Pr > |t| |
|------------|----|----------|----------------|---------|------|---|
| x_L1       | 1  | 2.5907   | 0.1958         | 13.23   | <.0001 |
| INC_L2G1C1 | 1  | 0.8103   | 0.0859         | 9.43    | <.0001 |
| INC_L2G1C2 | 1  | 0.8189   | 0.0955         | 8.57    | <.0001 |

**Example 23.4: Testing for Homoscedasticity of the Utility Function**

You can estimate the HEV model with unit scale restrictions on all three alternatives \(\theta_1 = \theta_2 = \theta_3 = 1\) with the following statements.

```sas
/*-- HEV Estimation --*/
proc mdc data=newdata;
  model decision = ttime /
    type=hev
    nchoice=3
    hev=(unitscale=1 2 3, integrate=laguerre)
    covest=hess;
    id pid;
run;
```
Output 23.4.2 displays the estimation summary.

Output 23.4.2  HEV Estimation Summary ($\theta_1 = \theta_2 = \theta_3 = 1$)

The MDC Procedure

Heteroscedastic Extreme Value Model Estimates

<table>
<thead>
<tr>
<th>Model Fit Summary</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dependent Variable</td>
</tr>
<tr>
<td>Number of Observations</td>
</tr>
<tr>
<td>Number of Cases</td>
</tr>
<tr>
<td>Log Likelihood</td>
</tr>
<tr>
<td>Maximum Absolute Gradient</td>
</tr>
<tr>
<td>Number of Iterations</td>

</tr>
<tr>
<td>AIC</td>
</tr>
<tr>
<td>Schwarz Criterion</td>
</tr>
</tbody>
</table>

The test for scale equivalence (SCALE2=SCALE3=1) is performed using a likelihood ratio test statistic. The following SAS statements compute the test statistic (1.4276) and its p-value (0.4898) from the log-likelihood values in Output 23.4.1 and Output 23.4.2:

```sas
data _null_;  
/*--- test for H0: scale2 = scale3 = 1 ---*/
/*  ln L(max) = -34.1276 */
/*  ln L(0)   = -33.4138 */
stat = -2 * (-34.1276 + 33.4138);
df = 2;
p_value = 1 - probchi(stat, df);
put stat= p_value=;
run;
```

The test statistic fails to reject the null hypothesis of equal scale parameters, which implies that the random utility function is homoscedastic.

A multinomial probit model also allows heteroscedasticity of the random components of utility for different alternatives. Consider the utility function

$$U_{ij} = V_{ij} + \epsilon_{ij}$$

where

$$\epsilon_i \sim N\left(0, \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \sigma^2 \end{bmatrix}\right)$$
This multinomial probit model is estimated by using the following statements:

```plaintext
/*--- Heteroscedastic Multinomial Probit ---*/
proc mdc data=newdata;
   model decision = ttime /
      type=mprobit
      nchoice=3
      unitvariance=(1 2)
      covest=hess;
   id pid;
   restrict RHO_31 = 0;
run;
```

The estimation summary is displayed in Output 23.4.3.

**Output 23.4.3** Heteroscedastic Multinomial Probit Estimation Summary

The test for homoscedasticity ($\sigma_3 = 1$) under $\sigma_1 = \sigma_2 = 1$ shows that the error variance is not heteroscedastic since the test statistic (1.313) is less than $\chi^2_{0.05,1} = 3.84$. The marginal probability or $p$-value computed in the following statements from the PROBCHI function is 0.2519:

```plaintext
data _null_;    /*-- test for H0: sigma3 = 1 --*/    /* ln L(max) = -33.8860 */    /* ln L(0) = -34.5425 */    stat = -2 * ( -34.5425 + 33.8860 );    df = 1;    p_value = 1 - probchi(stat, df);    put stat= p_value=;    run;
```

Example 23.5: Choice of Time for Work Trips: Nested Logit Analysis

This example uses sample data of 527 automobile commuters in the San Francisco Bay Area to demonstrate the use of the nested logit model.¹

Brownstone and Small (1989) analyzed a two-level nested logit model that is displayed in Figure 23.30. The probability of choosing $j$ at level 2 is written as

$$P_i(j) = \frac{\exp(\tau_j I_j)}{\sum_{j'=1}^{3} \exp(\tau_{j'} I_{j'})}$$

¹These data were provided by Professor Kenneth Small. They were collected for the urban travel demand forecasting project, which was carried out by McFadden, Talvitie, and Associates (1977). The project was supported by the National Science Foundation, Research Applied to National Needs Program, through grants GI-43740 and APR74-20392 and by the Alfred P. Sloan Foundation through grant 74-21-8.
Example 23.5: Choice of Time for Work Trips: Nested Logit Analysis

where \( I_{j'} \) is an inclusive value and is computed as

\[
I_{j'} = \ln \left[ \sum_{k' \in C_{j'}} \exp(x'_{ik'} \beta) \right]
\]

The probability of choosing an alternative \( k \) is denoted as

\[
P_i(k|j) = \frac{\exp(x'_{ik} \beta)}{\sum_{k' \in C_j} \exp(x'_{ik'} \beta)}
\]

The full information maximum likelihood (FIML) method maximizes the following log-likelihood function,

\[
L = \sum_{i=1}^{N} \sum_{j=1}^{J} d_{ij} \left[ \ln(P_i(k|j)) + \ln(P_i(j)) \right]
\]

where \( d_{ij} = 1 \) if a decision maker \( i \) chooses \( j \), and 0 otherwise.

Figure 23.30 Decision Tree for Two-Level Nested Logit

Sample data of 527 automobile commuters in the San Francisco Bay Area have been analyzed by Small (1982); Brownstone and Small (1989). The regular time of arrival is recorded as between 42.5 minutes early and 17.5 minutes late, and indexed by 12 alternatives, using five-minute interval groups. For more information about these data, see Small (1982). The following statements estimate the two-level nested logit model:

```plaintext
/*--- Two-level Nested Logit ---*/
proc mdc data=small maxit=200 outest=a;
   model decision = r15 r10 ttime ttime_cp sde sde_cp
      sdl sdlx d2l /
      type=nlogit
      choice=(alt);
      id id;
   utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp
      sdl sdlx d2l;
   nest level(1) = (1 2 3 4 5 6 7 8 @ 1, 9 @ 2, 10 11 12 @ 3),
      level(2) = (1 2 3 @ 1);
run;
```
The following statements add the upalt variable, which describes the choice at the upper level of the nested tree to the data set:

```plaintext
data small;
  set small;
  upalt=1;
  if alt=9 then upalt=2;
  if alt>9 then upalt=3;
run;
```

The following statements show an alternative specification, which uses the CHOICE= option with two nested levels that are represented by upalt and alt:

```plaintext.proc mdc data=upalt maxit=200;
  model decision = r15 r10 ttime ttime_cp sde sde_cp 
      sdl sdlx d2l /
      type=nlogit
      choice=(upalt,alt);
  id id;
  utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp 
      sdl sdlx d2l;
run;
```

The estimation summary, discrete response profile, and the FIML estimates are displayed in Output 23.5.1 through Output 23.5.3.

Now policy makers are particularly interested in predicting shares of each alternative to be chosen by population. One application of such predictions are market shares. Going even further, it is extremely useful to predict choice probabilities out of sample; that is, under alternative policies.

Suppose that in this particular transportation example you are interested in projecting the effect of a new program that indirectly shifts individual preferences with respect to late arrival to work. This means that you manage to decrease the coefficient for the “late dummy” D2L, which is a penalty for violating some margin of arriving on time. Suppose that you alter it from an estimated –1.0941 to almost twice that level, –2.0941.

But first, in order to have a benchmark share, you predict probabilities to choose each particular option and output them to the new data set with the following additional statement:
Having these in sample predictions, you sort the data by alternative and aggregate across each of them as shown in the following statements:

```sas
/*-- Sort the data by alternative --*/
proc sort data=predicted1;
   by alt;
run;

/*-- Calculate average probabilities of each alternative --*/
proc means data=predicted1 nonobs mean;
   var probs;
   class alt;
run;
```

Output 23.5.4 shows the summary table that is produced by the preceding statements.

</tbody>
</table>

Now you change the preference parameter for variable D2L. In order to fix all the parameters, you use the MAXIT=0 option to prevent optimization and the START= option in MODEL statement to specify initial parameters.

```sas
/*-- Two-level Nested Logit --*/
proc mdc data=small maxit=0 outest=a;
   model decision = r15 r10 ttime ttime_cp sde sde_cp
doall sdx d2l /
   type=nlogit
   choice=(alt)
   start=( 1.1034 0.3931 -0.0465 -0.0498
             -0.6618 0.0519 -2.1006 -3.5240
             -2.0941 0.6762 1.0906 0.7622);
```
id id;
utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp
       sdl sdlx d2l;
nest level(1) = (1 2 3 4 5 6 7 8 @ 1, 9 @ 2, 10 11 12 @ 3),
       level(2) = (1 2 3 @ 1);
output out=predicted2 p=probs;
run;

You apply the same SORT and MEANS procedures as applied earlier to obtain the following summary table in Output 23.5.5.

**Output 23.5.5** Average Probabilities of Choosing Each Particular Alternative after Changing the Preference Parameter

<table>
<thead>

Comparing the two tables shown in Output 23.5.4 and Output 23.5.5, you clearly see the effect of increased dislike of late arrival. People shifted their choices towards earlier times (alternatives 1–8) from the on-time option (alternative 9).

Brownstone and Small (1989) also estimate the two-level nested logit model with equal scale parameter constraints, \( \tau_1 = \tau_2 = \tau_3 \). Replication of their model estimation is shown in the following statements:

```plaintext
/*-- Nested Logit with Equal Dissimilarity Parameters --*/
proc mdc data=small maxit=200 outest=a;
   model decision = r15 r10 ttime ttime_cp sde sde_cp
                   sdl sdlx d2l /
      samescale
      type=nlogit
      choice=(alt);
   id id;
   utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp
                   sdl sdlx d2l;
   nest level(1) = (1 2 3 4 5 6 7 8 @ 1, 9 @ 2, 10 11 12 @ 3),
                   level(2) = (1 2 3 @ 1);
run;
```
The parameter estimates and standard errors are almost identical to those in Brownstone and Small (1989, p. 69). Output 23.5.6 and Output 23.5.7 display the results.

| INC_L2G1 | 1 | 0.8059 | 0.1705 | 4.73 | <.0001 |

However, the test statistic for $H_0: \tau_1 = \tau_2 = \tau_3$ rejects the null hypothesis at the 5% significance level since $-2 \times (\ln L(0) - \ln L) = 7.15 > \chi^2_{0.05,2} = 5.99$. The *p*-value is computed in the following statements and is equal to 0.0280:

```sas
data _null_;  
/*-- test for H0: tau1 = tau2 = tau3 --*/  
/* ln L(max) = -990.8191 */  
/* ln L(0) = -994.3940 */  
stat = -2 * ( -994.3940 + 990.8191 );  
df = 2;  
p_value = 1 - probchi(stat, df);  
put stat= p_value=;  
run;
```
Example 23.6: Hausman's Specification Test

As discussed under multinomial and conditional logits, the odds ratios in the multinomial or conditional logits are independent of the other alternatives. (See the section “Multinomial Logit and Conditional Logit” on page 1380.) This property of the logit models is often viewed as rather restrictive and provides substitution patterns that do not represent the actual relationship among choice alternatives.

This independence assumption, called independence of irrelevant alternatives (IIA), can be tested with Hausman’s specification test. According to Hausman and McFadden (1984), if a subset of choice alternatives is irrelevant, it can be omitted from the sample without changing the remaining parameters systematically.

Under the null hypothesis (IIA holds), omitting the irrelevant alternatives leads to consistent and efficient parameter estimates $\hat{\beta}_R$, while parameter estimates $\hat{\beta}_U$ from the unrestricted model are consistent but inefficient. Under the alternative, only the parameter estimates $\hat{\beta}_U$ obtained from the unrestricted model are consistent.

This example demonstrates the use of Hausman’s specification test to analyze the IIA assumption and decide on an appropriate model that provides less restrictive substitution patterns (nested logit or multinomial probit). A sample data set of 527 automobile commuters in the San Francisco Bay Area is used (Small 1982). The regular time of arrival is recorded as between 42.5 minutes early and 17.5 minutes late, and is indexed by 12 alternatives, using five-minute interval groups. For more information about these data, see Small (1982).

The data can be divided into three groups: commuters who arrive early (alternatives 1–8), commuters who arrive on time (alternative 9), and commuters who arrive late (alternatives 10–12). Suppose that you want to test whether the IIA assumption holds for commuters who arrived on time (alternative 9).

Hausman’s specification test is distributed as $\chi^2$ with $k$ degrees of freedom (equal to the number of independent variables) and can be written as

$$\chi^2 = (\hat{\beta}_U - \hat{\beta}_R)^T [\hat{V}_U - \hat{V}_R]^{-1} (\hat{\beta}_U - \hat{\beta}_R)$$

where $\hat{\beta}_R$ and $\hat{V}_R$ represent parameter estimates and the variance-covariance matrix, respectively, from the model where the ninth alternative was omitted, and $\hat{\beta}_U$ and $\hat{V}_U$ represent parameter estimates and the variance-covariance matrix, respectively, from the full model. The following macro can be used to perform the IIA test for the ninth alternative:

```/*------------------------------------------*/
* name: %IIA
* note: This macro test the IIA hypothesis using the Hausman's
* specification test. Inputs into the macro are as follows:
* indata: input data set
* varlist: list of RHS variables
* nchoice: number of choices for each individual
* choice: list of choices
* nvar: number of independent variables
* nIIA: number of choice alternatives used to test IIA
* IIA: choice alternatives used to test IIA
*/
```

2These data were provided by Professor Kenneth Small. They were collected for the urban travel demand forecasting project, which was carried out by McFadden, Talvitie, and Associates (1977). The project was supported by the National Science Foundation, Research Applied to National Needs Program, through grants GI-43740 and APR74-20392 and by the Alfred P. Sloan Foundation through grant 74-21-8.
* id: ID variable
* decision: 0-1 LHS variable representing nchoice choices
* purpose: Hausman's specification test
*--------------------------------------------------------------*/

%macro IIA(indata=, varlist=, nchoice=, choice=, nvar=, IIA=, nIIA=, id=, decision=);

%let n=%eval(&nchoice-&nIIA);

proc mdc data=&indata outest=cov covout ;
  model &decision = &varlist / type=clogit
              nchoice=&nchoice;
  id &id;
run;

data two;
  set &indata;
  if &choice in &IIA and &decision=1 then output;
run;

  close cov;

  use cov2 var(_TYPE_ &varlist);
  read first into BetaR;
  read all into CovVarR where(_TYPE_='COV');
  close cov;

  tmp = BetaU-BetaR;
  ChiSq=tmp*ginv(CovVarR-CovVarU)*tmp;
Example 23.6: Hausman’s Specification Test

if ChiSq<0 then ChiSq=0;
Prob=1-Probchi(ChiSq, &nvar);
Print "Hausman Test for IIA for Variable &IIA";
Print ChiSq Prob;
run; quit;
%mend IIA;

The following statement invokes the %IIA macro to test IIA for commuters who arrive on time:

%IIA( indata=small, varlist=r15 r10 ttime ttime_cp sde sde_cp sdl sdlx d2l, nchoice=12, choice=alt, nvar=9, nIIA=1, IIA=(9), id=id, decision=decision );

The obtained $\chi^2$ of 7.9 and the $p$-value of 0.54 indicate that IIA holds for commuters who arrive on time (alternative 9). If the IIA assumption did not hold, the following model (nested logit), which reserves a subcategory for alternative 9, might be more appropriate. (See Output 23.30.)

proc mdc data=small maxit=200 outest=a;
  model decision = r15 r10 ttime ttime_cp sde sde_cp sdl sdlx d2l /
    type=nlogit
    choice=(alt);
  id id;
  utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp sdl sdlx d2l;
  nest level(1) = (1 2 3 4 5 6 7 8 @ 1, 9 @ 2, 10 11 12 @ 3),
                  level(2) = (1 2 3 @ 1);
run;

Similarly, IIA could be tested for commuters who arrive approximately on time (alternative 8, 9, 10), as follows:

%IIA( indata=small, varlist=r15 r10 ttime ttime_cp sde sde_cp sdl sdlx d2l, nchoice=12, choice=alt, nvar=9, nIIA=3, IIA=(8 9 10), id=id, decision=decision );

Based on this test, independence of irrelevant alternatives is not rejected for this subgroup ($\chi^2 = 10.3$ and $p$-value = 0.326), and it is concluded that a more complex nested logit model with commuters who arrive approximately on time in one subcategory is not needed. Since the two Hausman’s specification tests just performed did not reject IIA, it might be a good idea to test whether the nested logit model is even needed. This is done using the likelihood ratio test in the next example.
Example 23.7: Likelihood Ratio Test

This example is an extension of Example 23.6 and uses the same data. It performs another specification test, the likelihood ratio test (LR). Suppose you are interested in testing whether the nested logit model (Output 23.30) with three subgroups that represent commuters who arrive early, on time, and late is more appropriate than the standard multinomial logit. This can be done by adding the TEST statement to the model as follows:

```plaintext
/*--- Restricted Model with Inclusive Value Parameters
   Constrained to One --*/
proc mdc data=small maxit=200 outest=a;
   model decision = r15 r10 ttime ttime_cp sde sde_cp
                    sdl sdlx d2l /
       type=nlogit
       choice=(alt);
   id id;
   utility u(1, ) = r15 r10 ttime ttime_cp sde sde_cp
                    sdl sdlx d2l;
   nest level(1) = (1 2 3 4 5 6 7 8 @ 1, 9 @ 2, 10 11 12 @ 3),
                   level(2) = (1 2 3 @ 1);
   test INC_L2G1C1=1, INC_L2G1C2=1, INC_L2G1C3=1 /LR;
run;
```

Output 23.7.1 Likelihood Ratio Test

The MDC Procedure

Nested Logit Estimates

<table>
<thead>
<tr>

<tbody>
<tr>
<td>Test0</td>
<td>L.R.</td>
<td>8.11</td>
<td>0.0438</td>
<td>INC_L2G1C1 = 1, INC_L2G1C2 = 1, INC_L2G1C3 = 1</td>
</tr>
</tbody>
</table>

Based on this test, you can conclude that the inclusive values, INC_L2G1C1, INC_L2G1C2, and INC_L2G1C3 are jointly statistically different from the value 1 at the 5% level and therefore the nested logit is a more appropriate model. The LR test can be used to test other types of restrictions in the nested logit setting as long as one model can be nested within another.

---

3These data were provided by Professor Kenneth Small. They were collected for the urban travel demand forecasting project, which was carried out by McFadden, Talvitie, and Associates (1977). The project was supported by the National Science Foundation, Research Applied to National Needs Program, through grants GI-43740 and APR74-20392 and by the Alfred P. Sloan Foundation through grant 74-21-8.
