## Introduction

- Interest in the influence of individual differences when investigating the progression of a quantity over time is ubiquitous across many research disciplines.
  - Consumer differences on product lifecycle
  - Patient factors on dose response curves
- The goal is to go beyond examining influences on the overall, average response pattern as differences among increasingly minute groups of patterns can provide additional insights.
- It may be desirable to model change at specific time points (e.g., time-varying treatments).
- Growth models allow us to shift focus to increasingly individual level analyses.
- Spline models allow a more appropriate fit and allow change to be modeled at points specified by the researcher.
- Therefore, we describe an extensible, hybrid statistical approach comprised of spline modeling and growth modeling which allows an examination of dynamic antecedent-outcome relationships while properly controlling for past effects.

Figure 1. A Basic Hypothetical Example of Additive Splines

## Model

$$Y_{ij} = \pi_{0j} + \pi_{1j}(TIME)_{ij} + \pi_{2j}D_{1j}(TIME - TIME_1)_{ij} + \pi_{3j}D_{2j}(TIME - TIME_2)_{ij} + r_{ij}$$

where  $r_{ij} \sim N(0, \sigma^2)$

and

$$\pi_{0j} = \beta_{00} + \beta_{01}(Z_{COVAR}) + u_{0j}$$

$$\pi_{1j} = \beta_{10} + \beta_{11}(Z_{COVAR}) + u_{1j}$$

$$\pi_{2j} = \beta_{20} + \beta_{21}(Z_{COVAR}) + u_{2j}$$

$$\pi_{3j} = \beta_{30} + \beta_{31}(Z_{COVAR}) + u_{3j}$$

where

$$\begin{pmatrix} u_{0j} \\ u_{1j} \\ u_{2j} \\ u_{3j} \end{pmatrix} \sim N \left( \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \end{pmatrix}, \begin{pmatrix} \tau_{00} & \tau_{01} & \tau_{02} & \tau_{03} \\ \tau_{10} & \tau_{11} & \tau_{12} & \tau_{13} \\ \tau_{20} & \tau_{21} & \tau_{22} & \tau_{23} \\ \tau_{30} & \tau_{31} & \tau_{32} & \tau_{33} \end{pmatrix} \right)$$

## Model Explanation

- Although there are many ways to code time in longitudinal models, time is coded here as 0, 1, 2, 3.
- The intercept estimates the value of the outcome variable, in this case performance (i.e., skill attainment), at occasion 0 (i.e., initial status).
- The slopes estimate rate of change in the outcome across occasions, in this case skill acquisition.
- $Y_{ij}$  is an individual's response at a given time point.
- $\pi_{0j}$  is an intercept coded as response at origin.
- $\pi_{1j}$  represents the initial spline and the underlying linear trend, conditional on the other splines, throughout the response period.
- $TIME_1$  and  $TIME_2$  variables are set times since the origin denoting spline starting points (e.g., knots).
- The  $D$  variables (i.e.,  $D_{1j}$  and  $D_{2j}$ ) are dummy variables equal to 0 when the amount of time from the origin, is less than  $TIME_1$  and  $TIME_2$  respectively, and equal to 1 when  $TIME$  is greater than  $i_1$  and  $i_2$  respectively.
- The remaining parameters ( $\pi_{2j}$  and  $\pi_{3j}$ ) become summative deviations to the underlying trend when enough time passes according to the  $D$  variables.
- Individually the splines represent response in a particular segment of time while controlling for past effects, but collectively they can capture the nature of the overall response trend. When applied to data with a decelerating logarithmic response pattern as in the current example, the resulting model is akin to that represented in Figure 1.

## Data Requirements

- This family of analyses focuses on examining influences on patterns.
- The simplest pattern is a line between two points.
- Therefore, the elemental child of this family consists of two linear trends and requires three longitudinal observations per subject.
- Of course, additional longitudinal observations are always desirable
- Therefore, this family of analyses is better suited for data sets containing an increased number of longitudinal observations, one or more covariates, and a response pattern at least nominally composed of segments (e.g., time-varying treatments, phases, states, or steps).

Table 1. Coding and Interpretation of Hypothetical Spline Variables

Variable	Measurement Occasion				Interpretation
	1	2	3	4	
Spline 1	0	1	2	3	Underlying linear change (e.g., base acquisition rate)
Spline 2	0	0	1	2	Linear deviation to the underlying linear change (e.g., change from base acquisition starting in second time period)
Spline 3	0	0	0	1	Deviation to the linear deviation to the underlying linear change (e.g., change in acquisition rate starting in the third time period)

## Example Data Set Background

- Extant skill acquisition theory posits that both the relative and absolute contributions of abilities to skill acquisition change through time.
- Previous tests of theory inadequately controlled for past acquisition.
- Participants were trained on a complex and dynamic computer-based task.
- Four performance observations are used to model skill acquisition using three additive, linear acquisition trends.
- The influence on each trend of a time-invariant, individual-level ability covariate (i.e., general mental ability), which was standardized to aide in model interpretation, is modeled.

Interpretation

- Random Effects
  - There appears to be significant variance between people in their initial skill attainment,  $\tau_{00} = 588,779$ ,  $z = 5.56$ ,  $p < .001$ , base skill acquisition,  $\tau_{11} = 297,471$ ,  $z = 5.42$ ,  $p < .001$ , linear deviation from base acquisition,  $\tau_{22} = 331,785$ ,  $z = 3.62$ ,  $p < .001$ , and final deviation from previously established acquisition,  $\tau_{33} = 51,734$ ,  $z = 19.82$ ,  $p < .001$ , which might all be predicted with additional covariates.
- Fixed Effects
  - The average individual has an initial skill attainment score of  $\beta_{00} = -1598.83$ ,  $t(129) = -19.93$ ,  $p < .001$ , and starts acquiring skill at a rate of  $\beta_{10} = 1606.33$ ,  $t(1173) = 27.82$ ,  $p < .001$ , per testing occasion. The average individual then experiences an acquisition deceleration of  $\beta_{20} = -1284.13$ ,  $t(1173) = -17.33$ ,  $p < .001$ , per testing occasion and then another deceleration of  $\beta_{30} = -76.35$ ,  $t(1173) = -1.87$ ,  $p < .10$ . With respect to the covariate, individuals who differ by a standard deviation in general mental ability have performance scores which differ by  $\beta_{01} = 402.17$ ,  $t(129) = 4.99$ ,  $p < .001$ , points on average and have initial skill acquisition rates which differ by  $\beta_{11} = 146.06$ ,  $t(1173) = 2.52$ ,  $p < .05$ , points on average. However, general mental ability appears to have little effect on later acquisition decelerations,  $\beta_{21} = -118.73$ ,  $t(1173) = -1.60$ ,  $p = .11$ , and  $\beta_{31} = -14.86$ ,  $t(1173) = -0.36$ ,  $p < .72$ .
