Let r be the number of unique instruments times the number of equations. The value r represents the number of orthogonality conditions imposed by the GMM method. Under the assumptions of the GMM method, $r - p$ linearly independent combinations of the orthogonality should be close to zero. The GMM estimates are computed by setting these combinations to zero. When r exceeds the number of parameters to be estimated, the `OBJECTIVE*N`, reported at the end of the estimation, is an asymptotically valid statistic to test the null hypothesis that the overidentifying restrictions of the model are valid. The `OBJECTIVE*N` is distributed as a chi-square with $r - p$ degrees of freedom (Hansen 1982, p. 1049). When the GMM method is selected, the value of the overidentifying restrictions test statistic, also known as Hansen’s J test statistic, and its associated number of degrees of freedom are reported together with the probability under the null hypothesis.

Iterated Generalized Method of Moments (ITGMM)

Iterated generalized method of moments is similar to the iterated versions of 2SLS, SUR, and 3SLS. The variance matrix for GMM estimation is reestimated at each iteration with the parameters determined by the

GMM estimation. The iteration terminates when the variance matrix for the equation errors change less than the CONVERGE= value. Iterated generalized method of moments is selected by the ITGMM option on the FIT statement. For some indication of the small sample properties of ITGMM, see Ferson and Foerster (1993).

Simulated Method of Moments (SMM)

The SMM method uses simulation techniques in model inference and estimation. It is appropriate for estimating models in which integrals appear in the objective function, and these integrals can be approximated by simulation. There might be various reasons for integrals to appear in an objective function (for example, transformation of a latent model into an observable model, missing data, random coefficients, heterogeneity, and so on).

This simulation method can be used with all the estimation methods except full information maximum likelihood (FIML) in PROC MODEL. SMM, also known as simulated generalized method of moments (SGMM), is the default estimation method because of its nice properties.

Estimation Details

A general nonlinear model can be described as

$$\epsilon_t = \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})$$

where $\mathbf{q} \in R^g$ is a real vector valued function of $\mathbf{y}_t \in R^g$, $\mathbf{x}_t \in R^l$, $\boldsymbol{\theta} \in R^p$; g is the number of equations; l is the number of exogenous variables (lagged endogenous variables are considered exogenous here); p is the number of parameters; and t ranges from 1 to n . ϵ_t is an unobservable disturbance vector with the following properties:

$$\begin{aligned} E(\epsilon_t) &= 0 \\ E(\epsilon_t \epsilon_t') &= \Sigma \end{aligned}$$

In many cases, it is not possible to write $\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})$ in a closed form. Instead \mathbf{q} is expressed as an integral of a function \mathbf{f} ; that is,

$$\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) = \int \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}, \mathbf{u}_t) dP(\mathbf{u})$$

where $\mathbf{f} \in R^g$ is a real vector valued function of $\mathbf{y}_t \in R^g$, $\mathbf{x}_t \in R^l$, $\boldsymbol{\theta} \in R^p$, and $\mathbf{u}_t \in R^m$, m is the number of stochastic variables with a known distribution $P(\mathbf{u})$. Since the distribution of \mathbf{u} is completely known, it is possible to simulate artificial draws from this distribution. Using such independent draws \mathbf{u}_{ht} , $h = 1, \dots, H$, and the strong law of large numbers, \mathbf{q} can be approximated by

$$\frac{1}{H} \sum_{h=1}^H \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}, \mathbf{u}_{ht}).$$

Simulated Generalized Method of Moments (SGMM)

Generalized method of moments (GMM) is widely used to obtain efficient estimates for general model systems. When the moment conditions are not readily available in closed forms but can be approximated by simulation, simulated generalized method of moments (SGMM) can be used. The SGMM estimators have the nice property of being asymptotically consistent and normally distributed even if the number of draws H is fixed (see McFadden 1989; Pakes and Pollard 1989).

Consider the nonlinear model

$$\begin{aligned}\epsilon_t &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) = \frac{1}{H} \sum_{h=1}^H \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \theta, \mathbf{u}_{ht}) \\ \mathbf{z}_t &= \mathbf{Z}(\mathbf{x}_t)\end{aligned}$$

where $\mathbf{z}_t \in R^k$ is a vector of k instruments and ϵ_t is an unobservable disturbance vector that can be serially correlated and nonstationary. In the case of no instrumental variables, \mathbf{z}_t is 1. $\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)$ is the vector of moment conditions, and it is approximated by simulation.

In general, theory suggests the following orthogonality condition

$$E(\epsilon_t \otimes \mathbf{z}_t) = 0$$

which states that the expected crossproducts of the unobservable disturbances, ϵ_t , and functions of the observable variables are set to 0. The sample means of the crossproducts are

$$\begin{aligned}\mathbf{m}_n &= \frac{1}{n} \sum_{t=1}^n \mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \theta) \\ \mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \theta) &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \otimes \mathbf{z}_t\end{aligned}$$

where $\mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \theta) \in R^{gk}$. The case where $gk > p$, where p is the number of parameters, is considered here. An estimate of the true parameter vector θ^0 is the value of $\hat{\theta}$ that minimizes

$$S(\theta, V) = [n\mathbf{m}_n(\theta)]' \mathbf{V}^{-1} [n\mathbf{m}_n(\theta)] / n$$

where

$$\mathbf{V} = \text{Cov}(\mathbf{m}(\theta^0), \mathbf{m}(\theta^0)').$$

The steps for SGMM are as follows:

1. Start with a positive definite $\hat{\mathbf{V}}$ matrix. This $\hat{\mathbf{V}}$ matrix can be estimated from a consistent estimator of θ . If $\hat{\theta}$ is a consistent estimator, then \mathbf{u}_t for $t = 1, \dots, n$ can be simulated H' number of times. A consistent estimator of \mathbf{V} is obtained as

$$\hat{\mathbf{V}} = \frac{1}{n} \sum_{t=1}^n \left[\frac{1}{H'} \sum_{h=1}^{H'} \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \hat{\theta}, \mathbf{u}_{ht}) \otimes \mathbf{z}_t \right] \left[\frac{1}{H'} \sum_{h=1}^{H'} \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \hat{\theta}, \mathbf{u}_{ht}) \otimes \mathbf{z}_t \right]'$$

H' must be large so that this is an consistent estimator of \mathbf{V} .

2. Simulate H number of \mathbf{u}_t for $t = 1, \dots, n$. As shown by Gourieroux and Monfort (1993), the number of simulations H does not need to be very large. For $H = 10$, the SGMM estimator achieves 90% of the efficiency of the corresponding GMM estimator. Find $\hat{\theta}$ that minimizes the quadratic product of the moment conditions again with the weight matrix being $\hat{\mathbf{V}}^{-1}$.

$$\min_{\theta} [n\mathbf{m}_n(\theta)]' \hat{\mathbf{V}}^{-1} [n\mathbf{m}_n(\theta)] / n$$

3. The covariance matrix of $\sqrt{n}\theta$ is given as (Gourieroux and Monfort 1993)

$$\Sigma_1^{-1} \mathbf{D} \hat{\mathbf{V}}^{-1} \mathbf{V}(\hat{\theta}) \hat{\mathbf{V}}^{-1} \mathbf{D}' \Sigma_1^{-1} + \frac{1}{H} \Sigma_1^{-1} \mathbf{D} \hat{\mathbf{V}}^{-1} E[\mathbf{z} \otimes \text{Var}(\mathbf{f}|\mathbf{x}) \otimes \mathbf{z}] \hat{\mathbf{V}}^{-1} \mathbf{D}' \Sigma_1^{-1}$$

where $\Sigma_1 = \mathbf{D} \hat{\mathbf{V}}^{-1} \mathbf{D}$, \mathbf{D} is the matrix of partial derivatives of the residuals with respect to the parameters, $\mathbf{V}(\hat{\theta})$ is the covariance of moments from estimated parameters $\hat{\theta}$, and $\text{Var}(\mathbf{f}|\mathbf{x})$ is the covariance of moments for each observation from simulation. The first term is the variance-covariance matrix of the exact GMM estimator, and the second term accounts for the variation contributed by simulating the moments.

Implementation in PROC MODEL

In PROC MODEL, if the user specifies the GMM and NDRAW options in the FIT statement, PROC MODEL first fits the model by using N2SLS and computes $\hat{\mathbf{V}}$ by using the estimates from N2SLS and H' simulation. If NO2SLS is specified in the FIT statement, $\hat{\mathbf{V}}$ is read from VDATA= data set. If the user does not provide a $\hat{\mathbf{V}}$ matrix, the initial starting value of θ is used as the estimator for computing the $\hat{\mathbf{V}}$ matrix in step 1. If ITGMM option is specified instead of GMM, then PROC MODEL iterates from step 1 to step 3 until the \mathbf{V} matrix converges.

The consistency of the parameter estimates is not affected by the variance correction shown in the second term in step 3. The correction on the variance of parameter estimates is not computed by default. To add the adjustment, use ADJSMMV option on the FIT statement. This correction is of the order of $\frac{1}{H}$ and is small even for moderate H .

The following example illustrates how to use SMM to estimate a simple regression model. Suppose the model is

$$y = a + bx + u, u \sim iid N(0, s^2).$$

First, consider the problem in a GMM context. The first two moments of y are easily derived:

$$\begin{aligned} E(y) &= a + bx \\ E(y^2) &= (a + bx)^2 + s^2 \end{aligned}$$

Rewrite the moment conditions in the form similar to the discussion above:

$$\begin{aligned} \epsilon_{1t} &= y_t - (a + bx_t) \\ \epsilon_{2t} &= y_t^2 - (a + bx_t)^2 - s^2 \end{aligned}$$

Then you can estimate this model by using GMM with following statements:

```

proc model data=a;
  parms a b s;
  instrument x;
  eq.m1 = y-(a+b*x);
  eq.m2 = y*y - (a+b*x)**2 - s*s;
  bound s > 0;
  fit m1 m2 / gmm;
run;

```

Now suppose you do not have the closed form for the moment conditions. Instead you can simulate the moment conditions by generating H number of simulated samples based on the parameters. Then the simulated moment conditions are

$$\epsilon_{1t} = \frac{1}{H} \sum_{h=1}^H \{y_t - (a + bx_t + su_{t,h})\}$$

$$\epsilon_{2t} = \frac{1}{H} \sum_{h=1}^H \{y_t^2 - (a + bx_t + su_{t,h})^2\}$$

This model can be estimated by using SGMM with the following statements:

```

proc model data=_tmpdata;
  parms a b s;
  instrument x;
  ysim = (a+b*x) + s * rannor( 98711 );
  eq.m1 = y-ysim;
  eq.m2 = y*y - ysim*ysim;
  bound s > 0;
  fit m1 m2 / gmm ndraw=10;
run;

```

You can use the following MOMENT statement instead of specifying the two moment equations above:

```

moment ysim=(1, 2);

```

In cases where you require a large number of moment equations, using the MOMENT statement to specify them is more efficient.

Note that the NDRAW= option tells PROC MODEL that this is a simulation-based estimation. Thus, the random number function RANNOR returns random numbers in estimation process. During the simulation, 10 draws of $m1$ and $m2$ are generated for each observation, and the averages enter the objective functions just as the equations specified previously.

Other Estimation Methods

The simulation method can be used not only with GMM and ITGMM, but also with OLS, ITOLS, SUR, ITSUR, N2SLS, IT2SLS, N3SLS, and IT3SLS. These simulation-based methods are similar to the corresponding methods in PROC MODEL; the only difference is that the objective functions include the average of the H simulations.

Full Information Maximum Likelihood Estimation (FIML)

A different approach to the simultaneous equation bias problem is the full information maximum likelihood (FIML) estimation method (Amemiya 1977).

Compared to the instrumental variables methods (2SLS and 3SLS), the FIML method has these advantages and disadvantages:

- FIML does not require instrumental variables.
- FIML requires that the model include the full equation system, with as many equations as there are endogenous variables. With 2SLS or 3SLS, you can estimate some of the equations without specifying the complete system.
- FIML assumes that the equations errors have a multivariate normal distribution. If the errors are not normally distributed, the FIML method might produce poor results. 2SLS and 3SLS do not assume a specific distribution for the errors.
- The FIML method is computationally expensive.

The full information maximum likelihood estimators of θ and σ are the $\hat{\theta}$ and $\hat{\sigma}$ that minimize the negative log-likelihood function:

$$\begin{aligned} \mathbf{l}_n(\theta, \sigma) = & \frac{ng}{2} \ln(2\pi) - \sum_{t=1}^n \ln \left(\left| \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)}{\partial \mathbf{y}'_t} \right| \right) + \frac{n}{2} \ln(|\Sigma(\sigma)|) \\ & + \frac{1}{2} \text{tr} \left(\Sigma(\sigma)^{-1} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \mathbf{q}'(\mathbf{y}_t, \mathbf{x}_t, \theta) \right) \end{aligned}$$

The option FIML requests full information maximum likelihood estimation. If the errors are distributed normally, FIML produces efficient estimators of the parameters. If instrumental variables are not provided, the starting values for the estimation are obtained from a SUR estimation. If instrumental variables are provided, then the starting values are obtained from a 3SLS estimation. The log-likelihood value and the l_2 norm of the gradient of the negative log-likelihood function are shown in the estimation summary.

FIML Details

To compute the minimum of $\mathbf{l}_n(\theta, \sigma)$, this function is *concentrated* using the relation

$$\Sigma(\theta) = \frac{1}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \mathbf{q}'(\mathbf{y}_t, \mathbf{x}_t, \theta)$$

This results in the concentrated negative log-likelihood function discussed in Davidson and MacKinnon (1993):

$$\mathbf{l}_n(\theta) = \frac{ng}{2} (1 + \ln(2\pi)) - \sum_{t=1}^n \ln \left| \frac{\partial}{\partial \mathbf{y}'_t} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \right| + \frac{n}{2} \ln |\Sigma(\theta)|$$

The gradient of the negative log-likelihood function is

$$\begin{aligned}\frac{\partial}{\partial \theta_i} \mathbf{l}_n(\boldsymbol{\theta}) &= \sum_{t=1}^n \nabla_i(t) \\ \nabla_i(t) &= -\text{tr} \left(\left(\frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{\partial \mathbf{y}'_t} \right)^{-1} \frac{\partial^2 \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{\partial \mathbf{y}'_t \partial \theta_i} \right) \\ &+ \frac{1}{2} \text{tr} \left(\boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \frac{\partial \boldsymbol{\Sigma}(\boldsymbol{\theta})}{\partial \theta_i} \right. \\ &\quad \left. [I - \boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'] \right) \\ &+ \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}') \boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{\partial \theta_i}\end{aligned}$$

where

$$\frac{\partial \boldsymbol{\Sigma}(\boldsymbol{\theta})}{\partial \theta_i} = \frac{2}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \theta_i}$$

The estimator of the variance-covariance of $\hat{\boldsymbol{\theta}}$ (COVB) for FIML can be selected with the COVBEST= option with the following arguments:

CROSS selects the crossproducts estimator of the covariance matrix (Gallant 1987, p. 473):

$$C = \left(\frac{1}{n} \sum_{t=1}^n \nabla(t) \nabla'(t) \right)^{-1}$$

where $\nabla(t) = [\nabla_1(t), \nabla_2(t), \dots, \nabla_p(t)]'$. This is the default.

GLS selects the generalized least squares estimator of the covariance matrix. This is computed as (Dagenais 1978)

$$C = [\hat{\mathbf{Z}}'(\boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \otimes I) \hat{\mathbf{Z}}]^{-1}$$

where $\hat{\mathbf{Z}} = (\hat{Z}_1, \hat{Z}_2, \dots, \hat{Z}_p)$ is $ng \times p$ and each \hat{Z}_i column vector is obtained from stacking the columns of

$$\mathbf{U} \frac{1}{n} \sum_{t=1}^n \left(\frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \mathbf{y}} \right)^{-1} \frac{\partial^2 \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \mathbf{y}'_n \partial \theta_i} - Q_i$$

\mathbf{U} is an $n \times g$ matrix of residuals and q_i is an $n \times g$ matrix $\frac{\partial \mathbf{Q}}{\partial \theta_i}$.

FDA selects the inverse of concentrated likelihood Hessian as an estimator of the covariance matrix. The Hessian is computed numerically, so for a large problem this is computationally expensive.

The HESSIAN= option controls which approximation to the Hessian is used in the minimization procedure. Alternate approximations are used to improve convergence and execution time. The choices are as follows:

CROSS	The crossproducts approximation is used.
GLS	The generalized least squares approximation is used (default).
FDA	The Hessian is computed numerically by finite differences.

HESSIAN=GLS has better convergence properties in general, but COVBEST=CROSS produces the most pessimistic standard error bounds. When the HESSIAN= option is used, the default estimator of the variance-covariance of $\hat{\theta}$ is the inverse of the Hessian selected.

Multivariate t Distribution Estimation

The multivariate t distribution is specified by using the ERRORMODEL statement with the T option. Other method specifications (FIML and OLS, for example) are ignored when the ERRORMODEL statement is used for a distribution other than normal.

The probability density function for the multivariate t distribution is

$$P_q = \frac{\Gamma(\frac{df+m}{2})}{(\pi * df)^{\frac{m}{2}} * \Gamma(\frac{df}{2}) |\Sigma(\sigma)|^{\frac{1}{2}}} * \left(1 + \frac{\mathbf{q}'(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \Sigma(\sigma)^{-1} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{df} \right)^{-\frac{df+m}{2}}$$

where m is the number of equations and df is the degrees of freedom.

The maximum likelihood estimators of θ and σ are the $\hat{\theta}$ and $\hat{\sigma}$ that minimize the negative log-likelihood function:

$$\begin{aligned} \ln(\boldsymbol{\theta}, \sigma) = & - \sum_{t=1}^n \ln \left(\frac{\Gamma(\frac{df+m}{2})}{(\pi * df)^{\frac{m}{2}} * \Gamma(\frac{df}{2})} * \left(1 + \frac{q'_t \Sigma^{-1} q_t}{df} \right)^{-\frac{df+m}{2}} \right) \\ & + \frac{n}{2} * \ln(|\Sigma|) - \sum_{t=1}^n \ln \left(\left| \frac{\partial q_t}{\partial \mathbf{y}'_t} \right| \right) \end{aligned}$$

The ERRORMODEL statement is used to request the t distribution maximum likelihood estimation. An OLS estimation is done to obtain initial parameter estimates and MSE.var estimates. Use NOOLS to turn off this initial estimation. If the errors are distributed normally, t distribution estimation produces results similar to FIML.

The multivariate model has a single shared degrees-of-freedom parameter, which is estimated. The degrees-of-freedom parameter can also be set to a fixed value. The log-likelihood value and the l_2 norm of the gradient of the negative log-likelihood function are shown in the estimation summary.

t Distribution Details

Since a variance term is explicitly specified by using the ERRORMODEL statement, $\Sigma(\theta)$ is estimated as a correlation matrix and $\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})$ is normalized by the variance. The gradient of the negative log-likelihood

function with respect to the degrees of freedom is

$$\begin{aligned} \frac{\partial l_n}{\partial df} &= \frac{nm}{2df} - \frac{n}{2} \frac{\Gamma'(\frac{df+m}{2})}{\Gamma(\frac{df+m}{2})} + \frac{n}{2} \frac{\Gamma'(\frac{df}{2})}{\Gamma(\frac{df}{2})} + \\ &\quad 0.5 \log(1 + \frac{\mathbf{q}'\Sigma^{-1}\mathbf{q}}{df}) - \frac{0.5(df+m)}{(1 + \frac{\mathbf{q}'\Sigma^{-1}\mathbf{q}}{df})} \frac{\mathbf{q}'\Sigma^{-1}\mathbf{q}}{df^2} \end{aligned}$$

The gradient of the negative log-likelihood function with respect to the parameters is

$$\frac{\partial l_n}{\partial \theta_i} = \frac{0.5(df+m)}{(1 + \mathbf{q}'\Sigma^{-1}\mathbf{q}/df)} \left[\frac{(2 \mathbf{q}'\Sigma^{-1} \frac{\partial \mathbf{q}}{\partial \theta_i})}{df} + \mathbf{q}'\Sigma^{-1} \frac{\partial \Sigma}{\partial \theta_i} \Sigma^{-1} \mathbf{q} \right] - \frac{n}{2} \text{trace}(\Sigma^{-1} \frac{\partial \Sigma}{\partial \theta_i})$$

where

$$\frac{\partial \Sigma(\theta)}{\partial \theta_i} = \frac{2}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)'}{\partial \theta_i}$$

and

$$\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) = \frac{\epsilon(\theta)}{\sqrt{h(\theta)}} \in R^{m \times n}$$

The estimator of the variance-covariance of $\hat{\theta}$ (COVB) for the t distribution is the inverse of the likelihood Hessian. The gradient is computed analytically, and the Hessian is computed numerically.

Empirical Distribution Estimation and Simulation

The following SAS statements fit a model that uses least squares as the likelihood function, but represent the distribution of the residuals with an empirical cumulative distribution function (CDF). The plot of the empirical probability distribution is shown in [Figure 19.22](#).

```
data t; /* Sum of two normals */
  format date monyy.;
  do t = 0 to 9.9 by 0.1;
    date = intnx( 'month', '1jun90'd, (t*10)-1 );
    y = 0.1 * (rannor(123)-10) +
        .5 * (rannor(123)+10);
    output;
  end;
run;

ods select Model.Likelihood.ResidSummary
           Model.Likelihood.ParameterEstimates;

proc model data=t time=t itprint;
  dependent y;
```

```

parm a 5;

y = a;
obj = resid.y * resid.y;
errormodel y ~ general( obj )
cdf=(empirical=(tails=( normal percent=10)));

solve y / data=t(where=(date='1aug98'd))
      residdata=r sdata=s
      random=200 seed=6789 out=monte ;

run;

proc kde data=monte;
  univar y / plots=density;
run;

```

Figure 19.22 Empirical PDF Plot

For simulation, if the CDF for the model is not built in to the procedure, you can use the `CDF=EMPIRICAL()` option. This uses the sorted residual data to create an empirical CDF. For computing the inverse CDF, the program needs to know how to handle the tails. For continuous data, the tail distribution is generally poorly determined. To counter this, the `PERCENT=` option specifies the percentage of the observations to use in constructing each tail. The default for the `PERCENT=` option is 10.

A normal distribution or a t distribution is used to extrapolate the tails to infinity. The standard errors for this extrapolation are obtained from the data so that the empirical CDF is continuous.

Properties of the Estimates

All of the methods are consistent. Small sample properties might not be good for nonlinear models. The tests and standard errors reported are based on the convergence of the distribution of the estimates to a normal distribution in large samples.

These nonlinear estimation methods reduce to the corresponding linear systems regression methods if the model is linear. If this is the case, PROC MODEL produces the same estimates as PROC SYSLIN.

Except for GMM, the estimation methods assume that the equation errors for each observation are identically and independently distributed with a 0 mean vector and positive definite covariance matrix Σ consistently estimated by S . For FIML, the errors need to be normally distributed. There are no other assumptions concerning the distribution of the errors for the other estimation methods.

The consistency of the parameter estimates relies on the assumption that the S matrix is a consistent estimate of Σ . These standard error estimates are asymptotically valid, but for nonlinear models they might not be reliable for small samples.

The S matrix used for the calculation of the covariance of the parameter estimates is the best estimate available for the estimation method selected. For S -iterated methods, this is the most recent estimation of Σ . For OLS and 2SLS, an estimate of the S matrix is computed from OLS or 2SLS residuals and used for the calculation of the covariance matrix. For a complete list of the S matrix used for the calculation of the covariance of the parameter estimates, see [Table 19.2](#).

Missing Values

An observation is excluded from the estimation if any variable used for FIT tasks is missing, if the weight for the observation is not greater than 0 when weights are used, or if a DELETE statement is executed by the model program. Variables used for FIT tasks include the equation errors for each equation, the instruments, if any, and the derivatives of the equation errors with respect to the parameters estimated. Note that variables can become missing as a result of computational errors or calculations with missing values.

The number of usable observations can change when different parameter values are used; some parameter values can be invalid and cause execution errors for some observations. PROC MODEL keeps track of the number of usable and missing observations at each pass through the data, and if the number of missing observations counted during a pass exceeds the number that was obtained using the previous parameter vector, the pass is terminated and the new parameter vector is considered infeasible. PROC MODEL never takes a step that produces more missing observations than the current estimate does.

The values used to compute the Durbin-Watson, R^2 , and other statistics of fit are from the observations used in calculating the objective function and do not include any observation for which any needed variable was missing (residuals, derivatives, and instruments).

Details on the Covariance of Equation Errors

There are several \mathbf{S} matrices that can be involved in the various estimation methods and in forming the estimate of the covariance of parameter estimates. These \mathbf{S} matrices are estimates of $\mathbf{\Sigma}$, the true covariance of the equation errors. Apart from the choice of instrumental or noninstrumental methods, many of the methods provided by PROC MODEL differ in the way the various \mathbf{S} matrices are formed and used.

All of the estimation methods result in a final estimate of $\mathbf{\Sigma}$, which is included in the output if the COVS option is specified. The final \mathbf{S} matrix of each method provides the initial \mathbf{S} matrix for any subsequent estimation.

This estimate of the covariance of equation errors is defined as

$$\mathbf{S} = \mathbf{D}(\mathbf{R}'\mathbf{R})\mathbf{D}$$

where $\mathbf{R} = (\mathbf{r}_1, \dots, \mathbf{r}_g)$ is composed of the equation residuals computed from the current parameter estimates in an $n \times g$ matrix and \mathbf{D} is a diagonal matrix that depends on the VARDEF= option.

For VARDEF=N, the diagonal elements of \mathbf{D} are $1/\sqrt{n}$, where n is the number of nonmissing observations. For VARDEF=WGT, n is replaced with the sum of the weights. For VARDEF=WDF, n is replaced with the sum of the weights minus the model degrees of freedom. For the default VARDEF=DF, the i th diagonal element of \mathbf{D} is $1/\sqrt{n - df_i}$, where df_i is the degrees of freedom (number of parameters) for the i th equation. Binkley and Nelson (1984) show the importance of using a degrees-of-freedom correction in estimating $\mathbf{\Sigma}$. Their results indicate that the DF method produces more accurate confidence intervals for N3SLS parameter estimates in the linear case than the alternative approach they tested. VARDEF=N is always used for the computation of the FIML estimates.

For the fixed \mathbf{S} methods, the OUTSUSED= option writes the \mathbf{S} matrix used in the estimation to a data set. This \mathbf{S} matrix is either the estimate of the covariance of equation errors matrix from the preceding estimation, or a prior $\mathbf{\Sigma}$ estimate read in from a data set when the SDATA= option is specified. For the diagonal \mathbf{S} methods, all of the off-diagonal elements of the \mathbf{S} matrix are set to 0 for the estimation of the parameters and for the OUTSUSED= data set, but the output data set produced by the OUTS= option contains the off-diagonal elements. For the OLS and N2SLS methods, there is no previous estimate of the covariance of equation errors matrix, and the option OUTSUSED= saves an identity matrix unless a prior $\mathbf{\Sigma}$ estimate is supplied by the SDATA= option. For FIML, the OUTSUSED= data set contains the \mathbf{S} matrix computed with VARDEF=N. The OUTS= data set contains the \mathbf{S} matrix computed with the selected VARDEF= option. Both versions of the \mathbf{S} matrix appear in the printed output for FIML.

If the COVS option is used, the method is not \mathbf{S} -iterated, \mathbf{S} is not an identity, and the OUTSUSED= matrix is included in the printed output.

For the methods that iterate the covariance of equation errors matrix, the \mathbf{S} matrix is iteratively re-estimated from the residuals produced by the current parameter estimates. This \mathbf{S} matrix estimate iteratively replaces the previous estimate until both the parameter estimates and the estimate of the covariance of equation errors matrix converge. The final OUTS= matrix and OUTSUSED= matrix are thus identical for the \mathbf{S} -iterated methods.

Nested Iterations

By default, for **S**-iterated methods, the **S** matrix is held constant until the parameters converge once. Then the **S** matrix is reestimated. One iteration of the parameter estimation algorithm is performed, and the **S** matrix is again reestimated. This latter process is repeated until convergence of both the parameters and the **S** matrix. Since the objective of the minimization depends on the **S** matrix, this has the effect of chasing a moving target.

When the NESTIT option is specified, iterations are performed to convergence for the structural parameters with a fixed **S** matrix. The **S** matrix is then reestimated, the parameter iterations are repeated to convergence, and so on until both the parameters and the **S** matrix converge. This has the effect of fixing the objective function for the inner parameter iterations. It is more reliable, but usually more expensive, to nest the iterations.

R-Square Statistic

For unrestricted linear models with an intercept successfully estimated by OLS, R^2 is always between 0 and 1. However, nonlinear models do not necessarily encompass the dependent mean as a special case and can produce negative R^2 statistics. Negative R^2 statistics can also be produced even for linear models when an estimation method other than OLS is used and no intercept term is in the model.

R^2 is defined for normalized equations as

$$R^2 = 1 - \frac{SSE}{SSA - \bar{y}^2 \times n}$$

where SSA is the sum of the squares of the actual y 's and \bar{y} are the actual means. R^2 cannot be computed for models in general form because of the need for an actual Y .

Minimization Methods

PROC MODEL currently supports two methods for minimizing the objective function. These methods are described in the following sections.

GAUSS

The Gauss-Newton parameter-change vector for a system with g equations, n nonmissing observations, and p unknown parameters is

$$\Delta = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{r}$$

where Δ is the change vector, \mathbf{X} is the stacked $ng \times p$ Jacobian matrix of partial derivatives of the residuals with respect to the parameters, and \mathbf{r} is an $ng \times 1$ vector of the stacked residuals. The components of \mathbf{X} and \mathbf{r} are weighted by the \mathbf{S}^{-1} matrix. When instrumental methods are used, \mathbf{X} and \mathbf{r} are the projections of the Jacobian matrix and residuals vector in the instruments space and not the Jacobian and residuals themselves.

In the preceding formula, \mathbf{S} and \mathbf{W} are suppressed. If instrumental variables are used, then the change vector becomes:

$$\Delta = (\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X})^{-1} \mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{r}$$

This vector is computed at the end of each iteration. The objective function is then computed at the changed parameter values at the start of the next iteration. If the objective function is not improved by the change, the Δ vector is reduced by one-half and the objective function is reevaluated. The change vector will be halved up to MAXSUBITER= times until the objective function is improved. If the objective function cannot be improved after MAXSUBITER= times, the procedure switches to the MARQUARDT method described in the next section to further improve the objective function.

For FIML, the $\mathbf{X}'\mathbf{X}$ matrix is substituted with one of three choices for approximations to the Hessian. See the section “Full Information Maximum Likelihood Estimation (FIML)” on page 1099 in this chapter.

MARQUARDT

The Marquardt-Levenberg parameter change vector is

$$\Delta = (\mathbf{X}'\mathbf{X} + \lambda \text{diag}(\mathbf{X}'\mathbf{X}))^{-1} \mathbf{X}'\mathbf{r}$$

where Δ is the change vector, and \mathbf{X} and \mathbf{r} are the same as for the Gauss-Newton method, described in the preceding section. Before the iterations start, λ is set to a small value (1E–6). At each iteration, the objective function is evaluated at the parameters changed by Δ . If the objective function is not improved, λ is increased to 10λ and the step is tried again. λ can be increased up to MAXSUBITER= times to a maximum of 1E15 (whichever comes first) until the objective function is improved. For the start of the next iteration, λ is reduced to $\max(\lambda/10, 1\text{E}–10)$.

Convergence Criteria

There are a number of measures that could be used as convergence or stopping criteria. PROC MODEL computes five convergence measures labeled R, S, PPC, RPC, and OBJECT.

When an estimation technique that iterates estimates of Σ is used (that is, IT3SLS), two convergence criteria are used. The termination values can be specified with the CONVERGE=(p,s) option in the FIT statement. If the second value, s , is not specified, it defaults to p . The criterion labeled S (described later in the section) controls the convergence of the \mathbf{S} matrix. When S is less than s , the \mathbf{S} matrix has converged. The criterion labeled R is compared to the p -value to test convergence of the parameters.

The R convergence measure cannot be computed accurately in the special case of singular residuals (when all the residuals are close to 0) or in the case of a 0 objective value. When either the trace of the \mathbf{S} matrix computed from the current residuals (trace(S)) or the objective value is less than the value of the SINGULAR= option, convergence is assumed.

The various convergence measures are explained in the following:

R is the primary convergence measure for the parameters. It measures the degree to which the residuals are orthogonal to the Jacobian columns, and it approaches 0 as the gradient of the objective function becomes small. R is defined as the square root of

$$\frac{(r'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X}(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})r)}{(r'(\mathbf{S}^{-1} \otimes \mathbf{W})r)}$$

where \mathbf{X} is the Jacobian matrix and \mathbf{r} is the residuals vector. R is similar to the relative offset orthogonality convergence criterion proposed by Bates and Watts (1981).

In the univariate case, the R measure has several equivalent interpretations:

- the cosine of the angle between the residuals vector and the column space of the Jacobian matrix. When this cosine is 0, the residuals are orthogonal to the partial derivatives of the predicted values with respect to the parameters, and the gradient of the objective function is 0.
- the square root of the R^2 for the current linear pseudo-model in the residuals
- a norm of the gradient of the objective function, where the norming matrix is proportional to the current estimate of the covariance of the parameter estimates. Thus, using R, convergence is judged when the gradient becomes small in this norm.
- the prospective relative change in the objective function value expected from the next GAUSS step, assuming that the current linearization of the model is a good local approximation.

In the multivariate case, R is somewhat more complicated but is designed to go to 0 as the gradient of the objective becomes small and can still be given the previous interpretations for the aggregation of the equations weighted by \mathbf{S}^{-1} .

PPC is the prospective parameter change measure. PPC measures the maximum relative change in the parameters implied by the parameter-change vector computed for the next iteration. At the k th iteration, PPC is the maximum over the parameters

$$\frac{|\theta_i^{k+1} - \theta_i^k|}{|\theta_i^k| + 10^{-6}}$$

where θ_i^k is the current value of the i th parameter and θ_i^{k+1} is the prospective value of this parameter after adding the change vector computed for the next iteration. The parameter with the maximum prospective relative change is printed with the value of PPC, unless the PPC is nearly 0.

RPC is the retrospective parameter change measure. RPC measures the maximum relative change in the parameters from the previous iteration. At the k th iteration, RPC is the maximum over i of

$$\frac{|\theta_i^k - \theta_i^{k-1}|}{|\theta_i^{k-1}| + 10^{-6}}$$

where θ_i^k is the current value of the i th parameter and θ_i^{k-1} is the previous value of this parameter. The name of the parameter with the maximum retrospective relative change is printed with the value of RPC, unless the RPC is nearly 0.

OBJECT measures the relative change in the objective function value between iterations:

$$\frac{|O^k - O^{k-1}|}{|O^{k-1}| + 10^{-6}}$$

where O^{k-1} is the value of the objective function (O^k) from the previous iteration.

S measures the relative change in the **S** matrix. S is computed as the maximum over i, j of

$$\frac{|S_{ij}^k - S_{ij}^{k-1}|}{|S_{ij}^{k-1}| + 10^{-6}}$$

where S^{k-1} is the previous **S** matrix. The S measure is relevant only for estimation methods that iterate the **S** matrix.

An example of the convergence criteria output is shown in [Figure 19.23](#).

Figure 19.23 Convergence Criteria Output

Final Convergence Criteria	
R	0.000737
PPC (b)	0.003943
RPC (b)	0.00968
Object	4.784E-6
Trace (S)	0.533325
Objective Value	0.522214

The Trace(S) is the trace (the sum of the diagonal elements) of the **S** matrix computed from the current residuals. This row is labeled MSE if there is only one equation.

Troubleshooting Convergence Problems

As with any nonlinear estimation routine, there is no guarantee that the estimation will be successful for a given model and data. If the equations are linear with respect to the parameters, the parameter estimates always converge in one iteration. The methods that iterate the **S** matrix must iterate further for the **S** matrix to converge. Nonlinear models might not necessarily converge.

Convergence can be expected only with fully identified parameters, adequate data, and starting values sufficiently close to solution estimates.

Convergence and the rate of convergence might depend primarily on the choice of starting values for the estimates. This does not mean that a great deal of effort should be invested in choosing starting values. First, try the default values. If the estimation fails with these starting values, examine the model and data and rerun the estimation using reasonable starting values. It is usually not necessary that the starting values be very good, just that they not be very bad; choose values that seem plausible for the model and data.

An Example of Requiring Starting Values

Suppose you want to regress a variable Y on a variable X , assuming that the variables are related by the following nonlinear equation:

$$y = a + bx^c + \epsilon$$

In this equation, Y is linearly related to a power transformation of X . The unknown parameters are a , b , and c . ϵ is an unobserved random error. The following SAS statements generate simulated data. In this simulation, $a = 10$, $b = 2$, and the use of the SQRT function corresponds to $c = .5$.

```
data test;
  do i = 1 to 20;
    x = 5 * ranuni(1234);
    y = 10 + 2 * sqrt(x) + .5 * rannor(1234);
    output;
  end;
run;
```

The following statements specify the model and give descriptive labels to the model parameters. Then the FIT statement attempts to estimate a , b , and c by using the default starting value 0.0001.

```
proc model data=test;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y;
run;
```

PROC MODEL prints model summary and estimation problem summary reports and then prints the output shown in Figure 19.24.

Figure 19.24 Diagnostics for Convergence Failure

The MODEL Procedure									
OLS Estimation									
ERROR: The parameter estimates failed to converge for OLS after 100 iterations using CONVERGE=0.001 as the convergence criteria.									
The MODEL Procedure									
OLS Estimation									
	Iteration	N	Obs	R	Objective	Subit	a	b	c
OLS	100	20	0.9627	3.9678	2	137.3822	-126.533	-0.00213	
Gauss Method Parameter Change Vector									
	a	b	c						
	-69369.08	69368.01	-1.16						

By using the default starting values, PROC MODEL is unable to take even the first step in iterating to the solution. The change in the parameters that the Gauss-Newton method computes is very extreme and makes the objective values worse instead of better. Even when this step is shortened by a factor of a million, the objective function is still worse, and PROC MODEL is unable to estimate the model parameters.

The problem is caused by the starting value of C. Using the default starting value $C=0.0001$, the first iteration attempts to compute better values of A and B by what is, in effect, a linear regression of Y on the 10,000th root of X, which is almost the same as the constant 1. Thus the matrix that is inverted to compute the changes is nearly singular and affects the accuracy of the computed parameter changes.

This is also illustrated by the next part of the output, which displays collinearity diagnostics for the crossproducts matrix of the partial derivatives with respect to the parameters, shown in [Figure 19.25](#).

Figure 19.25 Collinearity Diagnostics

Collinearity Diagnostics					
Number	Eigenvalue	Condition Number	-----Proportion of Variation-----		
			a	b	c
1	2.376793	1.0000	0.0000	0.0000	0.0000
2	0.623207	1.9529	0.0000	0.0000	0.0000
3	1.68475E-12	1187758	1.0000	1.0000	1.0000

This output shows that the matrix is singular and that the partials of A, B, and C with respect to the residual are collinear at the point (0.0001, 0.0001, 0.0001) in the parameter space. See the section “[Linear Dependencies](#)” on page 1119 for a full explanation of the collinearity diagnostics.

The MODEL procedure next prints the note shown in [Figure 19.26](#), which suggests that you try different starting values.

Figure 19.26 Estimation Failure Note

NOTE: The parameter estimation is abandoned. Check your model and data. If the model is correct and the input data are appropriate, try rerunning the parameter estimation using different starting values for the parameter estimates.

PROC MODEL continues as if the parameter estimates had converged.

PROC MODEL then produces the usual printout of results for the nonconverged parameter values. The estimation summary is shown in [Figure 19.27](#). The heading includes the reminder “(Not Converged)”.

Figure 19.27 Nonconverged Estimation Summary

The nonconverged estimation results are shown in Figure 19.28.

Figure 19.28 Nonconverged Results

The MODEL Procedure							
Nonlinear OLS Summary of Residual Errors (Not Converged)							
Equation	DF Model	DF Error	SSE	MSE	Root MSE	R-Square	Adj R-Sq
y	3	17	79.3551	4.6679	2.1605	-1.6812	-1.9966

Note that the R^2 statistic is negative. An $R^2 < 0$ results when the residual mean squared error for the model is larger than the variance of the dependent variable. Negative R^2 statistics might be produced when either the parameter estimates fail to converge correctly, as in this case, or when the correctly estimated model fits the data very poorly.

Controlling Starting Values

To fit the preceding model you must specify a better starting value for C. Avoid starting values of C that are either very large or close to 0. For starting values of A and B, you can specify values, use the default, or have PROC MODEL fit starting values for them conditional on the starting value for C.

Starting values are specified with the START= option of the FIT statement or in a PARMS statement. In PROC MODEL, you have several options to specify starting values for the parameters to be estimated.

When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. When no starting values for the parameter estimates are specified with BY group processing, the default start value 0.0001 is used for each by group. Again, when no starting values are specified, and a model with a FIT statement is stored by the OUTMODEL=*outmodel-filename* option in a previous step, the *outmodel-filename* can be invoked in a subsequent PROC MODEL step by using the MODEL=*outmodel-filename* option with multiple estimation methods in the second step. In such a case, the parameter estimates from the *outmodel-filename* are used directly as starting values for OLS, and OLS results from the second step provide starting values for the subsequent estimation method such as 2SLS or SUR, provided that NOOLS is not specified.

For example, the following statements estimate the model parameters by using the starting values A=0.0001, B=0.0001, and C=5.

```
proc model data=test;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y start=(c=5);
run;
```

Using these starting values, the estimates converge in 16 iterations. The results are shown in [Figure 19.29](#). Note that since the START= option explicitly declares parameters, the parameter C is placed first in the table.

Figure 19.29 Converged Results

The MODEL Procedure							
Nonlinear OLS Summary of Residual Errors							
Equation	DF Model	DF Error	SSE	MSE	Root MSE	R-Square	Adj R-Sq
y	3	17	5.7359	0.3374	0.5809	0.8062	0.7834
Nonlinear OLS Parameter Estimates							
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t	Label		
c	0.327079	0.2892	1.13	0.2738	Power Transformation Parameter		
a	8.384311	3.3775	2.48	0.0238	Intercept		
b	3.505391	3.4858	1.01	0.3287	Coefficient of Transformed X		

Using the STARTITER Option

PROC MODEL can compute starting values for some parameters conditional on starting values you specify for the other parameters. You supply starting values for some parameters and specify the STARTITER option on the FIT statement.

For example, the following statements set C to 1 and compute starting values for A and B by estimating these parameters conditional on the fixed value of C. With C=1, this is equivalent to computing A and B by linear regression on X. A PARMS statement is used to declare the parameters in alphabetical order. The ITPRINT option is used to print the parameter values at each iteration.

```
proc model data=test;
  parms a b c;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y start=(c=1) / startiter itprint;
run;
```

With better starting values, the estimates converge in only eight iterations. Counting the iteration required to compute the starting values for A and B, this is seven fewer than the 16 iterations required without the STARTITER option. The iteration history listing is shown in [Figure 19.30](#).

Figure 19.30 ITPRINT Listing

The MODEL Procedure									
OLS Estimation									
	Iteration	N	Obs	R	Objective	Subit	a	b	c
GRID	0	20	0.9989		162.9	0	0.00010	0.00010	1.00000

OLS	6	20	0.0612		0.2879	0	8.51825	3.36746	0.33201
OLS	7	20	0.0022		0.2868	0	8.39485	3.49449	0.32776
OLS	8	20	0.0001		0.2868	0	8.38467	3.50502	0.32711

NOTE: At OLS Iteration 8 CONVERGE=0.001 Criteria Met.

The results produced in this case are almost the same as the results shown in [Figure 19.29](#), except that the PARMS statement causes the parameter estimates table to be ordered A, B, C instead of C, A, B. They are not exactly the same because the different starting values caused the iterations to converge at a slightly different place. This effect is controlled by changing the convergence criterion with the CONVERGE= option.

By default, the STARTITER option performs one iteration to find starting values for the parameters that are not given values. In this case, the model is linear in A and B, so only one iteration is needed. If A or B were nonlinear, you could specify more than one “starting values” iteration by specifying a number for the STARTITER= option.

Finding Starting Values by Grid Search

PROC MODEL can try various combinations of parameter values and use the combination that produces the smallest objective function value as starting values. (For OLS the objective function is the residual mean square.) This is known as a preliminary *grid search*. You can combine the STARTITER option with a grid search.

For example, the following statements try five different starting values for C: 1, 0.7, 0.5, 0.3, and 0. For each value of C, values for A and B are estimated. The combination of A, B, and C values that produce the smallest residual mean square is then used to start the iterative process.

```
proc model data=test;
  parms a b c;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y start=(c=1 .7 .5 .3 0) / startiter itprint;
run;
```

The iteration history listing is shown in [Figure 19.31](#). Using the best starting values found by the grid search, the OLS estimation only requires two iterations. However, since the grid search required nine iterations, the total iterations in this case is 11.

Figure 19.31 ITPRINT Listing

Figure 19.31 *continued*

	Iteration	N	Obs	R	Objective	Subit	N	a	b	c
OLS	0	20	0.0189	0.2869	0	8.04397	3.85767	0.30000		
OLS	1	20	0.0158	0.2869	0	8.35023	3.54145	0.32233		
OLS	2	20	0.0006	0.2868	0	8.37468	3.51540	0.32622		

NOTE: At OLS Iteration 2 CONVERGE=0.001 Criteria Met.

Because no initial values for A or B were provided in the PARAMETERS statement or were read in with a PARMSDATA= or ESTDATA= option, A and B were given the default value of 0.0001 for the first iteration. At the second grid point, C=5, the values of A and B obtained from the previous iterations are used for the initial iteration. If initial values are provided for parameters, the parameters start at those initial values at each grid point.

Guessing Starting Values from the Logic of the Model

Example 19.1, which uses a logistic growth curve model of the U.S. population, illustrates the need for reasonable starting values. This model can be written

$$pop = \frac{a}{1 + \exp(b - c(t - 1790))}$$

where t is time in years. The model is estimated by using decennial census data of the U.S. population in millions. If this simple but highly nonlinear model is estimated by using the default starting values, the estimation fails to converge.

To find reasonable starting values, first consider the meaning of a and c . Taking the limit as time increases, a is the limiting or maximum possible population. So, as a starting value for a , several times the most recent population known can be used—for example, one billion (1000 million).

Dividing the time derivative by the function to find the growth rate and taking the limit as t moves into the past, you can determine that c is the initial growth rate. You can examine the data and compute an estimate of the growth rate for the first few decades, or you can pick a number that sounds like a plausible population growth rate figure, such as 2%.

To find a starting value for b , let t equal the base year used, 1790, which causes c to drop out of the formula for that year, and then solve for the value of b that is consistent with the known population in 1790 and with the starting value of a . This yields $b = \ln(a/3.9 - 1)$ or about 5.5, where a is 1000 and 3.9 is roughly the population for 1790 given in the data. The estimates converge using these starting values.

Convergence Problems

When estimating nonlinear models, you might encounter some of the following convergence problems.

Unable to Improve

The optimization algorithm might be unable to find a step that improves the objective function. If this happens in the Gauss-Newton method, the step size is halved to find a change vector for which the objective improves. In the Marquardt method, λ is increased to find a change vector for which the objective improves. If, after MAXSUBITER= step-size halvings or increases in λ , the change vector still does not produce a better objective value, the iterations are stopped and an error message is printed.

Failure of the algorithm to improve the objective value can be caused by a CONVERGE= value that is too small. Look at the convergence measures reported at the point of failure. If the estimates appear to be approximately converged, you can accept the NOT CONVERGED results reported, or you can try rerunning the FIT task with a larger CONVERGE= value.

If the procedure fails to converge because it is unable to find a change vector that improves the objective value, check your model and data to ensure that all parameters are identified and data values are reasonably scaled. Then, rerun the model with different starting values. Also, consider using the Marquardt method if the Gauss-Newton method fails; the Gauss-Newton method can get into trouble if the Jacobian matrix is nearly singular or ill-conditioned. Keep in mind that a nonlinear model may be well-identified and well-conditioned for parameter values close to the solution values but unidentified or numerically ill-conditioned for other parameter values. The choice of starting values can make a big difference.

Nonconvergence

The estimates might diverge into areas where the program overflows or the estimates might go into areas where function values are illegal or too badly scaled for accurate calculation. The estimation might also take steps that are too small or that make only marginal improvement in the objective function and thus fail to converge within the iteration limit.

When the estimates fail to converge, collinearity diagnostics for the Jacobian crossproducts matrix are printed if there are 20 or fewer parameters estimated. See the section “[Linear Dependencies](#)” on page 1119 for an explanation of these diagnostics.

Inadequate Convergence Criterion

If convergence is obtained, the resulting estimates approximate only a minimum point of the objective function. The statistical validity of the results is based on the exact minimization of the objective function, and for nonlinear models the quality of the results depends on the accuracy of the approximation of the minimum. This is controlled by the convergence criterion used.

There are many nonlinear functions for which the objective function is quite flat in a large region around the minimum point so that many quite different parameter vectors might satisfy a weak convergence criterion. By using different starting values, different convergence criteria, or different minimization methods, you can produce very different estimates for such models.

You can guard against this by running the estimation with different starting values and different convergence criteria and checking that the estimates produced are essentially the same. If they are not, use a smaller CONVERGE= value.

Local Minimum

You might have converged to a local minimum rather than a global one. This problem is difficult to detect because the procedure appears to have succeeded. You can guard against this by running the estimation with different starting values or with a different minimization technique. The `START=` option can be used to automatically perform a grid search to aid in the search for a global minimum.

Discontinuities

The computational methods assume that the model is a continuous and smooth function of the parameters. If this is not the case, the methods might not work.

If the model equations or their derivatives contain discontinuities, the estimation usually succeeds, provided that the final parameter estimates lie in a continuous interval and that the iterations do not produce parameter values at points of discontinuity or parameter values that try to cross asymptotes.

One common case of discontinuities causing estimation failure is that of an asymptotic discontinuity between the final estimates and the initial values. For example, consider the following model, which is basically linear but is written with one parameter in reciprocal form:

$$y = a + b * x1 + x2 / c;$$

By placing the parameter `C` in the denominator, a singularity is introduced into the parameter space at `C=0`. This is not necessarily a problem, but if the correct estimate of `C` is negative while the starting value is positive (or vice versa), the asymptotic discontinuity at 0 will lie between the estimate and the starting value. This means that the iterations have to pass through the singularity to get to the correct estimates. The situation is shown in [Figure 19.32](#).

Figure 19.32 Asymptotic Discontinuity

Because of the incorrect sign of the starting value, the C estimate goes off towards positive infinity in a vain effort to get past the asymptote and onto the correct arm of the hyperbola. As the computer is required to work with ever closer approximations to infinity, the numerical calculations break down and an “objective function was not improved” convergence failure message is printed. At this point, the iterations terminate with an extremely large positive value for C . When the sign of the starting value for C is changed, the estimates converge quickly to the correct values.

Linear Dependencies

In some cases, the Jacobian matrix might not be of full rank; parameters might not be fully identified for the current parameter values with the current data. When linear dependencies occur among the derivatives of the model, some parameters appear with a standard error of 0 and with the word **BIASED** printed in place of the t statistic. When this happens, collinearity diagnostics for the Jacobian crossproducts matrix are printed if the **DETAILS** option is specified and there are twenty or fewer parameters estimated. Collinearity diagnostics are also printed out automatically when a minimization method fails, or when the **COLLIN** option is specified.

For each parameter, the proportion of the variance of the estimate accounted for by each *principal component* is printed. The principal components are constructed from the eigenvalues and eigenvectors of the correlation matrix (scaled covariance matrix). When collinearity exists, a principal component is associated with proportion of the variance of more than one parameter. The numbers reported are proportions so they remain between 0 and 1. If two or more parameters have large proportion values associated with the same

principal component, then two problems can occur: the computation of the parameter estimates are slow or nonconvergent; and the parameter estimates have inflated variances (Belsley, Kuh, and Welsch 1980, p. 105–117).

For example, the following cubic model is fit to a quadratic data set:

```
proc model data=test3;
  exogenous x1;
  parms b1 a1 c1 ;
  y1 = a1 * x1 + b1 * x1 * x1 + c1 * x1 * x1 *x1;
  fit y1 / collin;
run;
```

The collinearity diagnostics are shown in Figure 19.33.

Figure 19.33 Collinearity Diagnostics

The MODEL Procedure					
Collinearity Diagnostics					
Number	Eigenvalue	Condition Number	-----Proportion of Variation-----		
			b1	a1	c1
1	2.942920	1.0000	0.0001	0.0004	0.0002
2	0.056638	7.2084	0.0001	0.0357	0.0148
3	0.000442	81.5801	0.9999	0.9639	0.9850

Notice that the proportions associated with the smallest eigenvalue are almost 1. For this model, removing any of the parameters decreases the variances of the remaining parameters.

In many models, the collinearity might not be clear cut. Collinearity is not necessarily something you remove. A model might need to be reformulated to remove the redundant parameterization, or the limitations on the estimability of the model can be accepted. The GINV=G4 option can be helpful to avoid problems with convergence for models containing collinearities.

Collinearity diagnostics are also useful when an estimation does not converge. The diagnostics provide insight into the numerical problems and can suggest which parameters need better starting values. These diagnostics are based on the approach of Belsley, Kuh, and Welsch (1980).

Iteration History

The options ITPRINT, ITDETAILS, XPX, I, and ITALL specify a detailed listing of each iteration of the minimization process.

ITPRINT Option

The ITPRINT information is selected whenever any iteration information is requested.

The following information is displayed for each iteration:

N	is the number of usable observations.
Objective	is the corrected objective function value.
Trace(S)	is the trace of the S matrix.
subit	is the number of subiterations required to find a λ or a damping factor that reduces the objective function.
R	is the R convergence measure.

The estimates for the parameters at each iteration are also printed.

ITDETAILS Option

The additional values printed for the ITDETAILS option are:

Theta	is the angle in degrees between Δ , the parameter change vector, and the negative gradient of the objective function.
Phi	is the directional derivative of the objective function in the Δ direction scaled by the objective function.
Stepsize	is the value of the damping factor used to reduce Δ if the Gauss-Newton method is used.
Lambda	is the value of λ if the Marquardt method is used.
Rank(XPX)	is the rank of the X'X matrix (output if the projected Jacobian crossproducts matrix is singular).

The definitions of PPC and R are explained in the section “[Convergence Criteria](#)” on page 1107. When the values of PPC are large, the parameter associated with the criteria is displayed in parentheses after the value.

XPX and I Options

The XPX and the I options select the printing of the augmented **X'X** matrix and the augmented **X'X** matrix after a *sweep* operation (Goodnight 1979) has been performed on it. An example of the output from the following statements is shown in [Figure 19.34](#).

```
proc model data=test2;
  y1 = a1 * x2 * x2 - exp( d1*x1);
  y2 = a2 * x1 * x1 + b2 * exp( d2*x2);
  fit y1 y2 / itall XPX I ;
run;
```

Figure 19.34 XPX and I Options Output

The MODEL Procedure						
OLS Estimation						
Cross Products for System At OLS Iteration 0						
	a1	d1	a2	b2	d2	Residual
a1	1839468	-33818.35	0.0	0.00	0.000000	3879959
d1	-33818	1276.45	0.0	0.00	0.000000	-76928
a2	0	0.00	42925.0	1275.15	0.154739	470686
b2	0	0.00	1275.2	50.01	0.003867	16055
d2	0	0.00	0.2	0.00	0.000064	2
Residual	3879959	-76928.14	470686.3	16055.07	2.329718	24576144
XPX Inverse for System At OLS Iteration 0						
	a1	d1	a2	b2	d2	Residual
a1	0.000001	0.000028	0.000000	0.0000	0.00	2
d1	0.000028	0.001527	0.000000	0.0000	0.00	-9
a2	0.000000	0.000000	0.000097	-0.0025	-0.08	6
b2	0.000000	0.000000	-0.002455	0.0825	0.95	172
d2	0.000000	0.000000	-0.084915	0.9476	15746.71	11931
Residual	1.952150	-8.546875	5.823969	171.6234	11930.89	10819902

The first matrix, labeled “Cross Products,” for OLS estimation is

$$\begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{r} \\ \mathbf{r}'\mathbf{X} & \mathbf{r}'\mathbf{r} \end{bmatrix}$$

The column labeled Residual in the output is the vector $\mathbf{X}'\mathbf{r}$, which is the gradient of the objective function. The diagonal scalar value $\mathbf{r}'\mathbf{r}$ is the objective function uncorrected for degrees of freedom. The second matrix, labeled “XPX Inverse,” is created through a sweep operation on the augmented $\mathbf{X}'\mathbf{X}$ matrix to get:

$$\begin{bmatrix} (\mathbf{X}'\mathbf{X})^{-1} & (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{r} \\ (\mathbf{X}'\mathbf{r})'(\mathbf{X}'\mathbf{X})^{-1} & \mathbf{r}'\mathbf{r} - (\mathbf{X}'\mathbf{r})'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{r} \end{bmatrix}$$

Note that the residual column is the change vector used to update the parameter estimates at each iteration. The corner scalar element is used to compute the R convergence criteria.

ITALL Option

The ITALL option, in addition to causing the output of all of the preceding options, outputs the \mathbf{S} matrix, the inverse of the \mathbf{S} matrix, the CROSS matrix, and the swept CROSS matrix. An example of a portion of the CROSS matrix for the preceding example is shown in [Figure 19.35](#).

Computer Resource Requirements

If you are estimating large systems, you need to be aware of how PROC MODEL uses computer resources (such as memory and the CPU) so they can be used most efficiently.

Saving Time with Large Data Sets

If your input data set has many observations, the FIT statement performs a large number of model program executions. A pass through the data is made at least once for each iteration and the model program is executed once for each observation in each pass. If you refine the starting estimates by using a smaller data set, the final estimation with the full data set might require fewer iterations.

For example, you could use

```
proc model;
  /* Model goes here */
  fit / data=a(obs=25);
  fit / data=a;
```

where OBS=25 selects the first 25 observations in A. The second FIT statement produces the final estimates using the full data set and starting values from the first run.

Fitting the Model in Sections to Save Space and Time

If you have a very large model (with several hundred parameters, for example), the procedure uses considerable space and time. You might be able to save resources by breaking the estimation process into several steps and estimating the parameters in subsets.

You can use the FIT statement to select for estimation only the parameters for selected equations. Do not break the estimation into too many small steps; the total computer time required is minimized by compromising between the number of FIT statements that are executed and the size of the crossproducts matrices that must be processed.

When the parameters are estimated for selected equations, the entire model program must be executed even though only a part of the model program might be needed to compute the residuals for the equations selected for estimation. If the model itself can be broken into sections for estimation (and later combined for simulation and forecasting), then more resources can be saved.

For example, to estimate the following four equation model in two steps, you could use

```
proc model data=a outmodel=part1;
  parms a0-a2 b0-b2 c0-c3 d0-d3;
  y1 = a0 + a1*y2 + a2*x1;
  y2 = b0 + b1*y1 + b2*x2;
  y3 = c0 + c1*y1 + c2*y4 + c3*x3;
  y4 = d0 + d1*y1 + d2*y3 + d3*x4;
  fit y1 y2;
  fit y3 y4;
  fit y1 y2 y3 y4;
run;
```

You should try estimating the model in pieces to save time only if there are more than 14 parameters; the preceding example takes more time, not less, and the difference in memory required is trivial.

Memory Requirements for Parameter Estimation

PROC MODEL is a large program, and it requires much memory. Memory is also required for the SAS System, various data areas, the model program and associated tables and data vectors, and a few crossproducts matrices. For most models, the memory required for PROC MODEL itself is much larger than that required for the model program, and the memory required for the model program is larger than that required for the crossproducts matrices.

The number of bytes needed for two crossproducts matrices, four **S** matrices, and three parameter covariance matrices is

$$8 \times (2 + k + m + g)^2 + 16 \times g^2 + 12 \times (p + 1)^2$$

plus lower-order terms, where m is the number of unique nonzero derivatives of each residual with respect to each parameter, g is the number of equations, k is the number of instruments, and p is the number of parameters. This formula is for the memory required for 3SLS. If you are using OLS, a reasonable estimate of the memory required for large problems (greater than 100 parameters) is to divide the value obtained from the formula in half.

Consider the following model program.

```
proc model data=test2 details;
  exogenous x1 x2;
  parms b1 100 a1 a2 b2 2.5 c2 55;
  y1 = a1 * y2 + b1 * x1 * x1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2;
  fit y1 y2 / n3sls memoryuse;
  inst b1 b2 c2 x1 ;
run;
```

The DETAILS option prints the storage requirements information shown in Figure 19.36.

Figure 19.36 Storage Requirements Information

The MODEL Procedure	
Storage Requirements for this Problem	
Order of XPX Matrix	6
Order of S Matrix	2
Order of Cross Matrix	13
Total Nonzero Derivatives	5
Distinct Variable Derivatives	5
Size of Cross matrix	728

The matrix $\mathbf{X}'\mathbf{X}$ augmented by the residual vector is called the XPX matrix in the output, and it has the size $m + 1$. The order of the \mathbf{S} matrix, 2 for this example, is the value of g . The CROSS matrix is made up of the k unique instruments, a constant column that represents the intercept terms, followed by the m unique Jacobian variables plus a constant column that represents the parameters with constant derivatives, followed by the g residuals.

The size of two CROSS matrices in bytes is

$$8 \times (2 + k + m + g)^2 + 2 + k + m + g$$

Note that the CROSS matrix is symmetric, so only the diagonal and the upper triangular part of the matrix is stored. For examples of the CROSS and XPX matrices see the section “[Iteration History](#)” on page 1120.

The MEMORYUSE Option

The MEMORYUSE option in the FIT, SOLVE, MODEL, or RESET statement can be used to request a comprehensive memory usage summary.

Figure 19.37 shows an example of the output produced by the MEMORYUSE option.

Figure 19.37 MEMORYUSE Option Output for FIT Task

Memory Usage Summary (in bytes)	
Symbols	15652
Strings	2593
Lists	2412
Arrays	2112
Statements	2448
Opcodes	1840
Parsing	6180
Executable	12716
Block option	0
Cross reference	0
Flow analysis	336
Derivatives	28640
Data vector	368
Cross matrix	1480
X'X matrix	590
S matrix	144
GMM memory	0
Jacobian	0
Work vectors	702
Overhead	14110

Total	92323

Definitions of the memory components follow:

symbols	memory used to store information about variables in the model
strings	memory used to store the variable names and labels
lists	space used to hold lists of variables
arrays	memory used by ARRAY statements
statements	memory used for the list of programming statements in the model
opcodes	memory used to store the code compiled to evaluate the expression in the model program
parsing	memory used in parsing the SAS statements
executable	the compiled model program size
block option	memory used by the BLOCK option
cross ref.	memory used by the XREF option
flow analysis	memory used to compute the interdependencies of the variables
derivatives	memory used to compute and store the analytical derivatives
data vector	memory used for the program data vector
cross matrix	memory used for one or more copies of the CROSS matrix
X'X matrix	memory used for one or more copies of the X'X matrix
S matrix	memory used for the covariance matrix
GMM memory	additional memory used for the GMM and ITGMM methods
Jacobian	memory used for the Jacobian matrix for SOLVE and FIML
work vectors	memory used for miscellaneous work vectors
overhead	other miscellaneous memory

Testing for Normality

The NORMAL option in the FIT statement performs multivariate and univariate tests of normality.

The three multivariate tests provided are Mardia's skewness test and kurtosis test (Mardia 1970) and the Henze-Zirkler $T_{n,\beta}$ test (Henze and Zirkler 1990). The two univariate tests provided are the Shapiro-Wilk W test and the Kolmogorov-Smirnov test. (For details on the univariate tests, refer to "Goodness-of-Fit Tests" section in "The UNIVARIATE Procedure" chapter in the *Base SAS Procedures Guide*.) The null hypothesis for all these tests is that the residuals are normally distributed.

For a random sample X_1, \dots, X_n , $X_i \in \mathbb{R}^d$, where d is the dimension of X_i and n is the number of observations, a measure of multivariate skewness is

$$b_{1,d} = \frac{1}{n^2} \sum_{i=1}^n \sum_{j=1}^n [(X_i - \mu)' \mathbf{S}^{-1} (X_j - \mu)]^3$$

where \mathbf{S} is the sample covariance matrix of \mathbf{X} . For weighted regression, both \mathbf{S} and $(X_i - \mu)$ are computed by using the weights supplied by the WEIGHT statement or the _WEIGHT_ variable.

Mardia showed that under the null hypothesis $\frac{n}{6}b_{1,d}$ is asymptotically distributed as $\chi^2(d(d+1)(d+2)/6)$. For small samples, Mardia's skewness test statistic is calculated with a small sample correction formula, given by $\frac{nk}{6}b_{1,d}$ where the correction factor k is given by $k = (d+1)(n+1)(n+3)/n(((n+1)(d+1))-6)$. Mardia's skewness test statistic in PROC MODEL uses this small sample corrected formula.

A measure of multivariate kurtosis is given by

$$b_{2,d} = \frac{1}{n} \sum_{i=1}^n [(X_i - \mu)' \mathbf{S}^{-1} (X_i - \mu)]^2$$

Mardia showed that under the null hypothesis, $b_{2,d}$ is asymptotically normally distributed with mean $d(d+2)$ and variance $8d(d+2)/n$.

The Henze-Zirkler test is based on a nonnegative functional $D(.,.)$ that measures the distance between two distribution functions and has the property that

$$D(\mathbf{N}_d(0, I_d), Q) = 0$$

if and only if

$$Q = \mathbf{N}_d(0, I_d)$$

where $\mathbf{N}_d(\mu, \Sigma_d)$ is a d -dimensional normal distribution.

The distance measure $D(.,.)$ can be written as

$$D_\beta(P, Q) = \int_{\mathbb{R}^d} |\hat{P}(t) - \hat{Q}(t)|^2 \varphi_\beta(t) dt$$

where $\hat{P}(t)$ and $\hat{Q}(t)$ are the Fourier transforms of P and Q , and $\varphi_\beta(t)$ is a weight or a kernel function. The density of the normal distribution $\mathbf{N}_d(0, \beta^2 I_d)$ is used as $\varphi_\beta(t)$

$$\varphi_\beta(t) = (2\pi\beta^2)^{-\frac{d}{2}} \exp\left(\frac{-|t|^2}{2\beta^2}\right), t \in \mathbb{R}^d$$

where $|t| = (t' t)^{0.5}$.

The parameter β depends on n as

$$\beta_d(n) = \frac{1}{\sqrt{2}} \left(\frac{2d+1}{4} \right)^{1/(d+4)} n^{1/(d+4)}$$

The test statistic computed is called $T_\beta(d)$ and is approximately distributed as a lognormal. The lognormal distribution is used to compute the null hypothesis probability.

$$T_\beta(d) = \frac{1}{n^2} \sum_{j=1}^n \sum_{k=1}^n \exp\left(-\frac{\beta^2}{2} |Y_j - Y_k|^2\right) - 2(1 + \beta^2)^{-d/2} \frac{1}{n} \sum_{j=1}^n \exp\left(-\frac{\beta^2}{2(1 + \beta^2)} |Y_j|^2\right) + (1 + 2\beta^2)^{-d/2}$$

where

$$|Y_j - Y_k|^2 = (X_j - X_k)' \mathbf{S}^{-1} (X_j - X_k)$$

$$|Y_j|^2 = (X_j - \bar{X})' \mathbf{S}^{-1} (X_j - \bar{X})$$

Monte Carlo simulations suggest that $T_\beta(d)$ has good power against distributions with heavy tails.

The Shapiro-Wilk W test is computed only when the number of observations (n) is less than 2000 while computation of the Kolmogorov-Smirnov test statistic requires at least 2000 observations.

The following is an example of the output produced by the NORMAL option.

```
proc model data=test2;
  y1 = a1 * x2 * x2 - exp( d1*x1);
  y2 = a2 * x1 * x1 + b2 * exp( d2*x2);
  fit y1 y2 / normal ;
run;
```

Figure 19.38 Normality Test Output

The MODEL Procedure			
Normality Test			
Equation	Test Statistic	Value	Prob
y1	Shapiro-Wilk W	0.37	<.0001
y2	Shapiro-Wilk W	0.84	<.0001
System	Mardia Skewness	286.4	<.0001
	Mardia Kurtosis	31.28	<.0001
	Henze-Zirkler T	7.09	<.0001

Heteroscedasticity

One of the key assumptions of regression is that the variance of the errors is constant across observations. If the errors have constant variance, the errors are called *homoscedastic*. Typically, residuals are plotted to assess this assumption. Standard estimation methods are inefficient when the errors are *heteroscedastic* or have nonconstant variance.

Heteroscedasticity Tests

The MODEL procedure provides two tests for heteroscedasticity of the errors: White's test and the modified Breusch-Pagan test.

Both White's test and the Breusch-Pagan are based on the residuals of the fitted model. For systems of equations, these tests are computed separately for the residuals of each equation.

The residuals of an estimation are used to investigate the heteroscedasticity of the true disturbances.

The WHITE option tests the null hypothesis

$$H_0 : \sigma_i^2 = \sigma^2 \text{ for all } i$$

White's test is general because it makes no assumptions about the form of the heteroscedasticity (White 1980). Because of its generality, White's test might identify specification errors other than heteroscedasticity (Thursby 1982). Thus, White's test might be significant when the errors are homoscedastic but the model is misspecified in other ways.

White's test is equivalent to obtaining the error sum of squares for the regression of squared residuals on a constant and all the unique variables in $\mathbf{J} \otimes \mathbf{J}$, where the matrix \mathbf{J} is composed of the partial derivatives of the equation residual with respect to the estimated parameters. White's test statistic W is computed as follows:

$$W = nR^2$$

where R^2 is the correlation coefficient obtained from the above regression. The statistic is asymptotically distributed as chi-squared with $P-1$ degrees of freedom, where P is the number of regressors in the regression, including the constant and n is the total number of observations. In the example given below, the regressors are constant, income, income*income, income*income*income, and income*income*income*income. income*income occurs twice and one is dropped. Hence, $P=5$ with degrees of freedom, $P-1=4$.

Note that White's test in the MODEL procedure is different than White's test in the REG procedure requested by the SPEC option. The SPEC option produces the test from Theorem 2 on page 823 of White (1980). The WHITE option, on the other hand, produces the statistic discussed in Greene (1993).

The null hypothesis for the modified Breusch-Pagan test is homoscedasticity. The alternate hypothesis is that the error variance varies with a set of regressors, which are listed in the BREUSCH= option.

Define the matrix \mathbf{Z} to be composed of the values of the variables listed in the BREUSCH= option, such that $z_{i,j}$ is the value of the j th variable in the BREUSCH= option for the i th observation. The null hypothesis of the Breusch-Pagan test is

$$\sigma_i^2 = \sigma^2(\alpha_0 + \boldsymbol{\alpha}' \mathbf{z}_i) \qquad H_0 : \boldsymbol{\alpha} = \mathbf{0}$$

where σ_i^2 is the error variance for the i th observation and α_0 and α are regression coefficients.

The test statistic for the Breusch-Pagan test is

$$bp = \frac{1}{v} (\mathbf{u} - \bar{u}\mathbf{i})' \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \mathbf{Z}' (\mathbf{u} - \bar{u}\mathbf{i})$$

where $\mathbf{u} = (e_1^2, e_2^2, \dots, e_n^2)$, \mathbf{i} is a $n \times 1$ vector of ones, and

$$v = \frac{1}{n} \sum_{i=1}^n (e_i^2 - \frac{\mathbf{e}'\mathbf{e}}{n})^2$$

This is a modified version of the Breusch-Pagan test, which is less sensitive to the assumption of normality than the original test (Greene 1993, p. 395).

The statements in the following example produce the output in Figure 19.39:

```
proc model data=schools;
    parms const inc inc2;

    exp = const + inc * income + inc2 * income * income;
    incsq = income * income;

    fit exp / white breusch=(1 income incsq);
run;
```

Figure 19.39 Output for Heteroscedasticity Tests

The MODEL Procedure					
Heteroscedasticity Test					
Equation	Test	Statistic	DF	Pr > ChiSq	Variables
exp	White's Test	21.16	4	0.0003	Cross of all vars
	Breusch-Pagan	15.83	2	0.0004	1, income, incsq

Correcting for Heteroscedasticity

There are two methods for improving the efficiency of the parameter estimation in the presence of heteroscedastic errors. If the error variance relationships are known, weighted regression can be used or an error model can be estimated. For details about error model estimation, see the section “[Error Covariance Structure Specification](#)” on page 1140. If the error variance relationship is unknown, GMM estimation can be used.

Weighted Regression

The WEIGHT statement can be used to correct for the heteroscedasticity. Consider the following model, which has a heteroscedastic error term:

$$y_t = 250(e^{-0.2t} - e^{-0.8t}) + \sqrt{(9/t)}\epsilon_t$$

The data for this model is generated with the following SAS statements.

```
data test;
  do t=1 to 25;
    y = 250 * (exp( -0.2 * t ) - exp( -0.8 * t )) +
      sqrt( 9 / t ) * rannor(1);
    output;
  end;
run;
```

If this model is estimated with OLS, as shown in the following statements, the estimates shown in [Figure 19.40](#) are obtained for the parameters.

```
proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  fit y;
run;
```

Figure 19.40 Unweighted OLS Estimates

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
b1	0.200977	0.00101	198.60	<.0001
b2	0.826236	0.00853	96.82	<.0001

If both sides of the model equation are multiplied by \sqrt{t} , the model has a homoscedastic error term. This multiplication or weighting is done through the WEIGHT statement. The WEIGHT statement variable operates on the squared residuals as

$$\epsilon'_t \epsilon_t = \text{weight} \times \mathbf{q}'_t \mathbf{q}_t$$

so that the WEIGHT statement variable represents the square of the model multiplier. The following PROC MODEL statements corrects the heteroscedasticity with a WEIGHT statement:

```
proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  fit y;
  weight t;
run;
```

Note that the WEIGHT statement follows the FIT statement. The weighted estimates are shown in [Figure 19.41](#).

Figure 19.41 Weighted OLS Estimates

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
b1	0.200503	0.000844	237.53	<.0001
b2	0.816701	0.0139	58.71	<.0001

The weighted OLS estimates are identical to the output produced by the following PROC MODEL example:

```
proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  _weight_ = t;
  fit y;
run;
```

If the WEIGHT statement is used in conjunction with the `_WEIGHT_` variable, the two values are multiplied together to obtain the weight used.

The WEIGHT statement and the `_WEIGHT_` variable operate on all the residuals in a system of equations. If a subset of the equations needs to be weighted, the residuals for each equation can be modified through the `RESID.` variable for each equation. The following example demonstrates the use of the `RESID.` variable to make a homoscedastic error term:

```
proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  resid.y = resid.y * sqrt(t);
  fit y;
run;
```

These statements produce estimates of the parameters and standard errors that are identical to the weighted OLS estimates. The reassignment of the `RESID.Y` variable must be done after `Y` is assigned; otherwise it would have no effect. Also, note that the residual (`RESID.Y`) is multiplied by \sqrt{t} . Here the multiplier is acting on the residual before it is squared.

GMM Estimation

If the form of the heteroscedasticity is unknown, generalized method of moments estimation (GMM) can be used. The following PROC MODEL statements use GMM to estimate the example model used in the preceding section:

```

proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  fit y / gmm;
  instruments b1 b2;
run;

```

GMM is an instrumental method, so instrument variables must be provided.

GMM estimation generates estimates for the parameters shown in Figure 19.42.

Figure 19.42 GMM Estimation for Heteroscedasticity

The MODEL Procedure				
Nonlinear GMM Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
b1	0.200487	0.000800	250.69	<.0001
b2	0.822148	0.0148	55.39	<.0001

Heteroscedasticity-Consistent Covariance Matrix Estimation

Homoscedasticity is required for ordinary least squares regression estimates to be efficient. A nonconstant error variance, heteroscedasticity, causes the OLS estimates to be inefficient, and the usual OLS covariance matrix, $\hat{\Sigma}$, is generally invalid:

$$\hat{\Sigma} = \sigma^2(\mathbf{X}'\mathbf{X})^{-1}$$

When the variance of the errors of a classical linear model

$$Y = \mathbf{X}\beta + \epsilon$$

is not constant across observations (heteroscedastic), so that $\sigma_i^2 \neq \sigma_j^2$ for some $j > 1$, the OLS estimator

$$\hat{\beta}_{OLS} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'Y$$

is unbiased but it is inefficient. Models that take into account the changing variance can make more efficient use of the data. When the variances, σ_i^2 , are known, generalized least squares (GLS) can be used and the estimator

$$\hat{\beta}_{GLS} = (\mathbf{X}'\mathbf{\Omega}\mathbf{X})^{-1}\mathbf{X}'\mathbf{\Omega}^{-1}Y$$

where

$$\mathbf{\Omega} = \begin{bmatrix} \sigma_1^2 & 0 & 0 & 0 \\ 0 & \sigma_2^2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \sigma_T^2 \end{bmatrix}$$

is unbiased and efficient. However, GLS is unavailable when the variances, σ_t^2 , are unknown.

To solve this problem White (1980) proposed a heteroscedastic consistent-covariance matrix estimator (HC-CME)

$$\hat{\Sigma} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\hat{\Omega}\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}$$

that is consistent as well as unbiased, where

$$\hat{\Omega}_0 = \begin{bmatrix} \epsilon_1^2 & 0 & 0 & 0 \\ 0 & \epsilon_2^2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \epsilon_T^2 \end{bmatrix}$$

and $\epsilon_t = Y_t - \mathbf{X}_t\beta_{OLS}$.

This estimator is considered somewhat unreliable in finite samples. Therefore, Davidson and MacKinnon (1993) propose three different modifications to estimating $\hat{\Omega}$. The first solution is to simply multiply ϵ_t^2 by $\frac{n}{n-df}$, where n is the number of observations and df is the number of explanatory variables, so that

$$\hat{\Omega}_1 = \begin{bmatrix} \frac{n}{n-df} \epsilon_1^2 & 0 & 0 & 0 \\ 0 & \frac{n}{n-df} \epsilon_2^2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \frac{n}{n-df} \epsilon_n^2 \end{bmatrix}$$

The second solution is to define

$$\hat{\Omega}_2 = \begin{bmatrix} \frac{\epsilon_1^2}{1-\hat{h}_1} & 0 & 0 & 0 \\ 0 & \frac{\epsilon_2^2}{1-\hat{h}_2} & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \frac{\epsilon_n^2}{1-\hat{h}_n} \end{bmatrix}$$

where $\hat{h}_t = \mathbf{X}_t(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}_t'$.

The third solution, called the “jackknife,” is to define

$$\hat{\Omega}_3 = \begin{bmatrix} \frac{\epsilon_1^2}{(1-\hat{h}_1)^2} & 0 & 0 & 0 \\ 0 & \frac{\epsilon_2^2}{(1-\hat{h}_2)^2} & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \frac{\epsilon_n^2}{(1-\hat{h}_n)^2} \end{bmatrix}$$

MacKinnon and White (1985) investigated these three modified HCCMEs, including the original HCCME, based on finite-sample performance of pseudo- t statistics. The original HCCME performed the worst. The first modification performed better. The second modification performed even better than the first, and the third modification performed the best. They concluded that the original HCCME should never be used in finite sample estimation, and that the second and third modifications should be used over the first modification if the diagonals of $\hat{\Omega}$ are available.

Seemingly Unrelated Regression HCCME

Extending the discussion to systems of g equations, the HCCME for SUR estimation is

$$(\tilde{\mathbf{X}}'\tilde{\mathbf{X}})^{-1}\tilde{\mathbf{X}}'\hat{\mathbf{\Omega}}\tilde{\mathbf{X}}(\tilde{\mathbf{X}}'\tilde{\mathbf{X}})^{-1}$$

where $\tilde{\mathbf{X}}$ is a $ng \times k$ matrix with the first g rows representing the first observation, the next g rows representing the second observation, and so on. $\hat{\mathbf{\Omega}}$ is now a $ng \times ng$ block diagonal matrix with typical block $g \times g$

$$\hat{\mathbf{\Omega}}_i = \begin{bmatrix} \psi_{1,i} & \psi_{1,i} & \psi_{1,i} & \psi_{2,i} & \cdots & \psi_{1,i} & \psi_{g,i} \\ \psi_{2,i} & \psi_{1,i} & \psi_{2,i} & \psi_{2,i} & \cdots & \psi_{2,i} & \psi_{g,i} \\ \vdots & & \vdots & & \vdots & & \vdots \\ \psi_{g,i} & \psi_{1,i} & \psi_{g,i} & \psi_{2,i} & \cdots & \psi_{g,i} & \psi_{g,i} \end{bmatrix}$$

where

$$\psi_{j,i} = \epsilon_{j,i} \quad HC_0$$

or

$$\psi_{j,i} = \sqrt{\frac{n}{n-df}} \epsilon_{j,i} \quad HC_1$$

or

$$\psi_{j,i} = \epsilon_{j,i} / \sqrt{1 - \hat{h}_i} \quad HC_2$$

or

$$\psi_{j,i} = \epsilon_{j,i} / (1 - \hat{h}_i) \quad HC_3$$

Two- and Three-Stage Least Squares HCCME

For two- and three-stage least squares, the HCCME for a g equation system is

$$\text{Cov} F(\hat{\mathbf{\Omega}}) \text{Cov}$$

where

$$\text{Cov} = \left(\frac{1}{n} \mathbf{X}'(\mathbf{I} \otimes \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}')\mathbf{X} \right)^{-1}$$

is the normal covariance matrix without the \mathbf{S} matrix and

$$F(\mathbf{\Omega}) = \frac{1}{n} \sum_i^g \sum_j^g \mathbf{X}_i' \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \mathbf{Z}' \hat{\mathbf{\Omega}}_{ij} \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \mathbf{Z}' \mathbf{X}_j$$

where \mathbf{X}_j is a $n \times p$ matrix with the j th equations regressors in the appropriate columns and zeros everywhere else.

$$\hat{\Omega}_{ij} = \begin{bmatrix} \psi_{i,1}\psi_{j,1} & 0 & 0 & 0 \\ 0 & \psi_{i,2}\psi_{j,2} & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \psi_{i,n}\psi_{j,n} \end{bmatrix}$$

For 2SLS $\hat{\Omega}_{ij} = 0$ when $i \neq j$. The ϵ_t used in $\hat{\Omega}$ is computed by using the parameter estimates obtained from the instrumental variables estimation.

The leverage value for the i th equation used in the HCCME=2 and HCCME=3 methods is computed as conditional on the first stage as

$$h_{ti} = \mathbf{Z}_t(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{X}_i(\mathbf{X}'(\mathbf{I} \otimes \mathbf{Z}(\mathbf{Z}' * \mathbf{Z})^{-1}\mathbf{Z}')\mathbf{X})^{-1}\mathbf{X}_i'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}_t'$$

for 2SLS and

$$h_{ti} = \mathbf{Z}_t(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{X}_i(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{Z}(\mathbf{Z}' * \mathbf{Z})^{-1}\mathbf{Z}')\mathbf{X})^{-1}\mathbf{X}_i'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}_t'/\mathbf{S}_{ii}$$

for 3SLS.

Testing for Autocorrelation

The GODFREY= option in the FIT statement produces the Godfrey Lagrange multiplier test for serially correlated residuals for each equation (Godfrey 1978a and 1978b). n is the maximum autoregressive order, and specifies that Godfrey's tests be computed for lags 1 through n . The default number of lags is four.

The tests are performed separately for each equation estimated by the FIT statement. When a nonlinear model is estimated, the test is computed by using a linearized model.

The following is an example of the output produced by the GODFREY=3 option:

Figure 19.43 Autocorrelation Test Output

Godfrey Test Output			
The MODEL Procedure			
Godfrey's Serial Correlation Test			
Equation	Alternative	LM	Pr > LM
y	1	6.63	0.0100
	2	6.89	0.0319
	3	6.96	0.0732

The three variations of the test reported by the GODFREY=3 option are designed to have power against different alternative hypothesis. Thus, if the residuals in fact have only first-order autocorrelation, the lag

1 test has the most power for rejecting the null hypothesis of uncorrelated residuals. If the residuals have second- but not higher-order autocorrelation, the lag 2 test might be more likely to reject; the same is true for third-order autocorrelation and the lag 3 test.

The null hypothesis of Godfrey's tests is that the equation residuals are white noise. However, if the equation includes autoregressive error model of order p ($AR(p)$), then the lag i test, when considered in terms of the structural error, is for the null hypothesis that the structural errors are from an $AR(p)$ process versus the alternative hypothesis that the errors are from an $AR(p + i)$ process.

The alternative $ARMA(p, i)$ process is locally equivalent to the alternative $AR(p + i)$ process with respect to the null model $AR(p)$. Thus, the GODFREY= option results are also a test of $AR(p)$ errors against the alternative hypothesis of $ARMA(p, i)$ errors. See Godfrey (1978a and 1978b) for more detailed information.

Transformation of Error Terms

In PROC MODEL you can control the form of the error term. By default, the error term is assumed to be additive. This section demonstrates how to specify nonadditive error terms and discusses the effects of these transformations.

Models with Nonadditive Errors

The estimation methods used by PROC MODEL assume that the error terms of the equations are independently and identically distributed with zero means and finite variances. Furthermore, the methods assume that the *RESID.name* equation variable for normalized form equations or the *EQ.name* equation variable for general form equations contains an estimate of the error term of the true stochastic model whose parameters are being estimated. Details on *RESID.name* and *EQ.name* equation variables are in the section “[Equation Translations](#)” on page 1232.

To illustrate these points, consider the common loglinear model

$$y = \alpha x^\beta \quad (1)$$

$$\ln y = a + b \ln(x) \quad (2)$$

where $a = \log(\alpha)$ and $b = \beta$. Equation (2) is called the *log form* of the equation in contrast to equation (1), which is called the *level form* of the equation. Using the SYSLIN procedure, you can estimate equation (2) by specifying

```
proc syslin data=in;
  model logy=logx;
run;
```

where LOGY and LOGX are the logs of Y and X computed in a preceding DATA step. The resulting values for INTERCEPT and LOGX correspond to a and b in equation (2).

Using the MODEL procedure, you can try to estimate the parameters in the level form (and avoid the DATA step) by specifying

```
proc model data=in;
  parms alpha beta;
  y = alpha * x ** beta;
  fit y;
run;
```

where ALPHA and BETA are the parameters in equation (1).

Unfortunately, at least one of the preceding is wrong; an ambiguity results because equations (1) and (2) contain no explicit error term. The SYSLIN and MODEL procedures both deal with additive errors; the residual used (the estimate of the error term in the equation) is the difference between the predicted and actual values (of LOGY for PROC SYSLIN and of Y for PROC MODEL in this example). If you perform the regressions discussed previously, PROC SYSLIN estimates equation (3) while PROC MODEL estimates equation (4).

$$\ln y = a + b \ln(x) + \epsilon \quad (3)$$

$$y = \alpha x^\beta + \xi \quad (4)$$

These are different statistical models. Equation (3) is the log form of equation (5)

$y = \alpha x^\beta \mu$ (5) where $\mu = e^\epsilon$. Equation (4), on the other hand, cannot be linearized because the error term ξ (different from μ) is additive in the level form.

You must decide whether your model is equation (4) or (5). If the model is equation (4), you should use PROC MODEL. If you linearize equation (1) without considering the error term and apply SYSLIN to MODEL LOGY=LOGX, the results will be wrong. On the other hand, if your model is equation (5) (in practice it usually is), and you want to use PROC MODEL to estimate the parameters in the *level* form, you must do something to account for the multiplicative error.

PROC MODEL estimates parameters by minimizing an objective function. The objective function is computed using either the RESID.-prefixed equation variable or the EQ.-prefixed equation variable. You must make sure that these prefixed equation variables are assigned an appropriate error term. If the model has additive errors that satisfy the assumptions, nothing needs to be done. In the case of equation (5), the error is nonadditive and the equation is in normalized form, so you must alter the value of RESID.Y.

The following assigns a valid estimate of μ to RESID.Y:

```
y = alpha * x ** beta;
resid.y = actual.y / pred.y;
```

However, $\mu = e^\epsilon$, and therefore μ , cannot have a mean of zero, and you cannot consistently estimate α and β by minimizing the sum of squares of an estimate of μ . Instead, you use $\epsilon = \ln \mu$.

```
proc model data=in;
  parms alpha beta;
  y = alpha * x ** beta;
  resid.y = log( actual.y / pred.y );
  fit y;
run;
```

If the model was expressed in general form, this transformation becomes

```
proc model data=in;
  parms alpha beta;
  EQ.trans = log( y / (alpha * x ** beta));
  fit trans;
run;
```

Both examples produce estimates of α and β of the level form that match the estimates of a and b of the log form. That is, $\text{ALPHA} = \exp(\text{INTERCEPT})$ and $\text{BETA} = \text{LOGX}$, where INTERCEPT and LOGX are the PROC SYSLIN parameter estimates from the MODEL $\text{LOGY} = \text{LOGX}$. The standard error reported for ALPHA is different from that for the INTERCEPT in the log form.

The preceding example is not intended to suggest that loglinear models should be estimated in level form but, rather, to make the following points:

- Nonlinear transformations of equations involve the error term of the equation, and this should be taken into account when transforming models.
- The RESID.-prefixed and the EQ.-prefixed equation variables for models estimated by the MODEL procedure must represent additive errors with zero means.
- You can use assignments to RESID.-prefixed and EQ.-prefixed equation variables to transform error terms.
- Some models do not have additive errors or zero means, and many such models can be estimated using the MODEL procedure. The preceding approach applies not only to multiplicative models but to any model that can be manipulated to isolate the error term.

Predicted Values of Transformed Models

Nonadditive or transformed errors affect the distribution of the predicted values, as well as the estimates. For the preceding loglinear example, the MODEL procedure produces consistent parameter estimates. However, the predicted values for Y computed by PROC MODEL are not unbiased estimates of the expected values of Y, although they do estimate the conditional median Y values.

In general, the predicted values produced for a model with nonadditive errors are not unbiased estimates of the conditional means of the endogenous value. If the model can be transformed to a model with additive errors by using a *monotonic* transformation, the predicted values estimate the conditional medians of the endogenous variable.

For transformed models in which the biasing factor is known, you can use programming statements to correct for the bias in the predicted values as estimates of the endogenous means. In the preceding log-linear case, the predicted values are biased by the factor $\exp(\sigma^2/2)$. You can produce approximately unbiased predicted values in this case by writing the model as

```
proc model data=in;
  parms alpha beta;
```

```

y=alpha * x ** beta;
resid.y = log( actual.y / pred.y );
fit y;
run;

```

See Miller (1984) for a discussion of bias factors for predicted values of transformed models.

Note that models with transformed errors are not appropriate for Monte Carlo simulation that uses the `SDATA=` option. PROC MODEL computes the `OUTS=` matrix from the transformed `RESID.-`prefixed equation variables, while it uses the `SDATA=` matrix to generate multivariate normal errors, which are added to the predicted values. This method of computing errors is inconsistent when the equation variables have been transformed.

Error Covariance Structure Specification

One of the key assumptions of regression is that the variance of the errors is constant across observations. Correcting for heteroscedasticity improves the efficiency of the estimates.

Consider the following general form for models:

$$\begin{aligned}
 \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) &= \boldsymbol{\varepsilon}_t \\
 \boldsymbol{\varepsilon}_t &= H_t * \boldsymbol{\epsilon}_t \\
 H_t &= \begin{bmatrix} \sqrt{h_{t,1}} & 0 & \dots & 0 \\ 0 & \sqrt{h_{t,2}} & \dots & 0 \\ & & \ddots & \\ 0 & 0 & \dots & \sqrt{h_{t,g}} \end{bmatrix} \\
 \mathbf{h}_t &= \mathbf{g}(\mathbf{y}_t, \mathbf{x}_t, \phi)
 \end{aligned}$$

where $\boldsymbol{\epsilon}_t \sim N(0, \Sigma)$.

For models that are homoscedastic,

$$h_t = 1$$

If you have a model that is heteroscedastic with known form, you can improve the efficiency of the estimates by performing a weighted regression. The weight variable, using this notation, would be $1/\sqrt{h_t}$.

If the errors for a model are heteroscedastic and the functional form of the variance is known, the model for the variance can be estimated along with the regression function.

To specify a functional form for the variance, assign the function to an `H.var` variable where `var` is the equation variable. For example, if you want to estimate the scale parameter for the variance of a simple regression model

$$y = a * x + b$$

you can specify

```
proc model data=s;
  y = a * x + b;
  h.y = sigma**2;
fit y;
```

Consider the same model with the following functional form for the variance:

$$h_t = \sigma^2 * x^{2*\alpha}$$

This would be written as

```
proc model data=s;
  y = a * x + b;
  h.y = sigma**2 * x**(2*alpha);
fit y;
```

There are three ways to model the variance in the MODEL procedure: feasible generalized least squares, generalized method of moments, and full information maximum likelihood.

Feasible GLS

A simple approach to estimating a variance function is to estimate the mean parameters θ by using some auxiliary method, such as OLS, and then use the residuals of that estimation to estimate the parameters ϕ of the variance function. This scheme is called *feasible GLS*. It is possible to use the residuals from an auxiliary method for the purpose of estimating ϕ because in many cases the residuals consistently estimate the error terms.

For all estimation methods except GMM and FIML, using the H.var syntax specifies that feasible GLS is used in the estimation. For feasible GLS, the mean function is estimated by the usual method. The variance function is then estimated using pseudo-likelihood (PL) function of the generated residuals. The objective function for the PL estimation is

$$p_n(\sigma, \theta) = \sum_{i=1}^n \left(\frac{(y_i - f(x_i, \hat{\beta}))^2}{\sigma^2 h(z_i, \theta)} + \log[\sigma^2 h(z_i, \theta)] \right)$$

Once the variance function has been estimated, the mean function is reestimated by using the variance function as weights. If an S-iterated method is selected, this process is repeated until convergence (iterated feasible GLS).

Note that feasible GLS does not yield consistent estimates when one of the following is true:

- The variance is unbounded.
- There is too much serial dependence in the errors (the dependence does not fade with time).
- There is a combination of serial dependence and lag dependent variables.

The first two cases are unusual, but the third is much more common. Whether iterated feasible GLS avoids consistency problems with the last case is an unanswered research question. For more information see Davidson and MacKinnon (1993, pp. 298–301) or Gallant (1987, pp. 124–125) and Amemiya (1985, pp. 202–203).

One limitation is that parameters cannot be shared between the mean equation and the variance equation. This implies that certain GARCH models, cross-equation restrictions of parameters, or testing of combinations of parameters in the mean and variance component are not allowed.

Generalized Method of Moments

In GMM, normally the first moment of the mean function is used in the objective function.

$$\begin{aligned} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) &= \epsilon_t \\ \mathbf{E}(\epsilon_t) &= 0 \end{aligned}$$

To add the second moment conditions to the estimation, add the equation

$$\mathbf{E}(\epsilon_t * \epsilon_t - h_t) = 0$$

to the model. For example, if you want to estimate σ for linear example above, you can write

```
proc model data=s;
  y = a * x + b;
  eq.two = resid.y**2 - sigma**2;
fit y two/ gmm;
instruments x;
run;
```

This is a popular way to estimate a continuous-time interest rate processes (see Chan et al. 1992). The H.var syntax automatically generates this system of equations.

To further take advantage of the information obtained about the variance, the moment equations can be modified to

$$\begin{aligned} \mathbf{E}(\epsilon_t / \sqrt{h_t}) &= 0 \\ \mathbf{E}(\epsilon_t * \epsilon_t - h_t) &= 0 \end{aligned}$$

For the above example, this can be written as

```
proc model data=s;
  y = a * x + b;
  eq.two = resid.y**2 - sigma**2;
  resid.y = resid.y / sigma;
fit y two/ gmm;
instruments x;
run;
```

Note that, if the error model is misspecified in this form of the GMM model, the parameter estimates might be inconsistent.

Full Information Maximum Likelihood

For FIML estimation of variance functions, the concentrated likelihood below is used as the objective function. That is, the mean function is coupled with the variance function and the system is solved simultaneously.

$$l_n(\phi) = \frac{ng}{2}(1 + \ln(2\pi)) - \sum_{t=1}^n \ln \left(\left| \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)}{\partial \mathbf{y}_t} \right| \right) \\ + \frac{1}{2} \sum_{t=1}^n \sum_{i=1}^g (\ln(h_{t,i}) + \mathbf{q}_i(\mathbf{y}_t, \mathbf{x}_t, \theta)^2 / h_{t,i})$$

where g is the number of equations in the system.

The HESSIAN=GLS option is not available for FIML estimation that involves variance functions. The matrix used when HESSIAN=CROSS is specified is a crossproducts matrix that has been enhanced by the dual quasi-Newton approximation.

Examples

You can specify a GARCH(1,1) model as follows:

```
proc model data=modloc.usd_jpy;

    /* Mean model -----*/
    jpyret = intercept ;

    /* Variance model -----*/
    h.jpyret = arch0
              + arch1 * xlag( resid.jpyret ** 2, mse.jpyret )
              + garch1 * xlag(h.jpyret, mse.jpyret) ;

    bounds arch0 arch1 garch1 >= 0;

    fit jpyret / method=marquardt fiml;
run;
```

Note that the BOUNDS statement is used to ensure that the parameters are positive, a requirement for GARCH models.

EGARCH models are used because there are no restrictions on the parameters. You can specify a EGARCH(1,1) model as follows:

```

proc model data=sasuser.usd_dem ;

    /* Mean model -----*/
    demret = intercept ;

    /* Variance model -----*/
    if ( _OBS_ =1 ) then
        h.demret = exp( earch0 + egarch1 * log(mse.demret) );
    else
        h.demret = exp( earch0 + earch1 * zlag( g)
                        + egarch1 * log(zlag(h.demret))) ;
        g = - theta * nresid.demret + abs( nresid.demret ) - sqrt(2/3.1415);

fit demret / method=marquardt fiml maxiter=100 converge=1.0e-6;
run;

```

Ordinary Differential Equations

Ordinary differential equations (ODEs) are also called *initial value problems* because a time zero value for each first-order differential equation is needed. The following is an example of a first-order system of ODEs:

$$\begin{aligned}
 y' &= -0.1y + 2.5z^2 \\
 z' &= -z \\
 y_0 &= 0 \\
 z_0 &= 1
 \end{aligned}$$

Note that you must provide an initial value for each ODE.

As a reminder, any n -order differential equation can be modeled as a system of first-order differential equations. For example, consider the differential equations

$$\begin{aligned}
 y'' &= by' + cy \\
 y_0 &= 0 \\
 y'_0 &= 1
 \end{aligned}$$

which can be written as the system of differential equations

$$\begin{aligned}
 y' &= z \\
 z' &= by' + cy \\
 y_0 &= 0 \\
 z_0 &= 1
 \end{aligned}$$

This differential system can be simulated as follows:

```
data t;
  time=0; output;
  time=1; output;
  time=2; output;
run;

proc model data=t ;
  dependent y 0 z 1;
  parm b -2 c -4;

  dert.y = z;
  dert.z = b * dert.y + c * y;

  solve y z / dynamic solveprint;
run;
```

The preceding statements produce the output shown in Figure 19.44. These statements produce additional output, which is not shown.

Figure 19.44 Simulation Results for Differential System

The MODEL Procedure							
Simultaneous Simulation							
Observation	1	Missing	2	CC	-1.000000

		y				z	
		0.000000				1.000000	
Observation	2	Iterations	0	CC	0.000000	ERROR.y	0.000000
Solution Values							
		y				z	
		0.2096398				-.2687053	
Observation	3	Iterations	0	CC	9.464802	ERROR.y	-0.234405
Solution Values							
		y				z	
		-.0247649				-.1035929	

The differential variables are distinguished by the derivative with respect to time (DERT.) prefix. Once you define the DERT. variable, you can use it on the right-hand side of another equation. The differential equations must be expressed in normal form; implicit differential equations are not allowed, and other terms on the left-hand side are not allowed.

The TIME variable is the *implied with respect to* variable for all DERT. variables. The TIME variable is also the only variable that must be in the input data set.

You can provide initial values for the differential equations in the data set, in the declaration statement (as in the previous example), or in statements in the program. Using the previous example, you can specify the initial values as

```
proc model data=t ;
    dependent y z ;
    parm b -2 c -4;

    if ( time=0 ) then
        do;
            y=0;
            z=1;
        end;
    else
        do;
            dert.y = z;
            dert.z = b * dert.y + c * y;
        end;
    end;

    solve y z / dynamic solveprint;
run;
```

If you do not provide an initial value, 0 is used.

DYNAMIC and STATIC Simulation

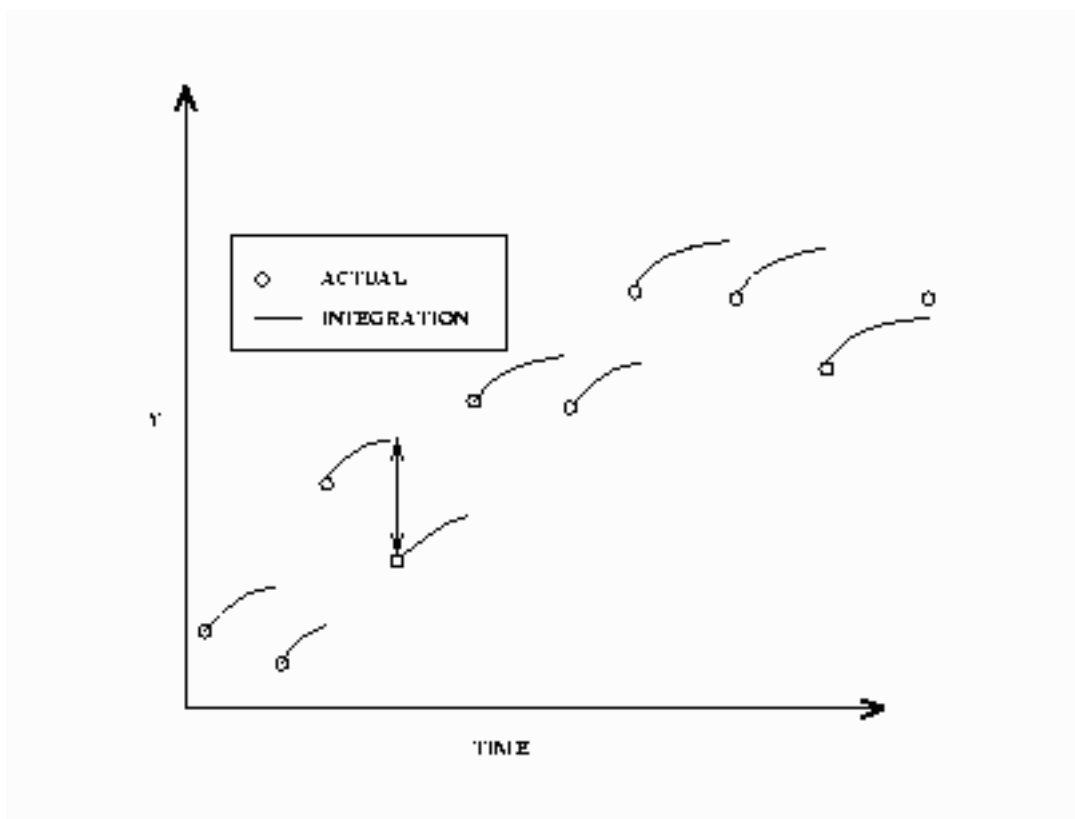

Note that, in the previous example, the DYNAMIC option is specified in the SOLVE statement. The DYNAMIC and STATIC options work the same for differential equations as they do for dynamic systems. In the differential equation case, the DYNAMIC option makes the initial value needed at each observation the computed value from the previous iteration. For a static simulation, the data set must contain values for the integrated variables. For example, if DERT.Y and DERT.Z are the differential variables, you must include Y and Z in the input data set in order to do a static simulation of the model.

If the simulation is dynamic, the initial values for the differential equations are obtained from the data set, if they are available. If the variable is not in the data set, you can specify the initial value in a declaration statement. If you do not specify an initial value, the value of 0.0 is used.

A dynamic solution is obtained by solving one initial value problem for all the data. A graph of a simple dynamic simulation is shown in [Figure 19.45](#). If the time variable for the current observation is less than the time variable for the previous observation, the integration is restarted from this point. This allows for multiple samples in one data file.

Figure 19.45 Dynamic Solution

In a static solution, $n-1$ initial value problems are solved using the first $n-1$ data values as initial values. The equations are integrated using the i th data value as an initial value to the $i+1$ data value. [Figure 19.46](#) displays a static simulation of noisy data from a simple differential equation. The static solution does not propagate errors in initial values as the dynamic solution does.

Figure 19.46 Static Solution

For estimation, the DYNAMIC and STATIC options in the FIT statement perform the same functions as they do in the SOLVE statement. Components of differential systems that have missing values or are not in the data set are simulated dynamically. For example, often in multiple compartment kinetic models, only one compartment is monitored. The differential equations that describe the unmonitored compartments are simulated dynamically.

For estimation, it is important to have accurate initial values for ODEs that are not in the data set. If an accurate initial value is not known, the initial value can be made an unknown parameter and estimated. This allows for errors in the initial values but increases the number of parameters to estimate by the number of equations.

Estimation of Differential Equations

Consider the kinetic model for the accumulation of mercury (Hg) in mosquito fish (Matis, Miller, and Allen 1991, p. 177). The model for this process is the one-compartment constant infusion model shown in Figure 19.47.

Figure 19.47 One-Compartment Constant Infusion Model

The differential equation that models this process is

$$\begin{aligned}\frac{dconc}{dt} &= k_u - k_e conc \\ conc_0 &= 0\end{aligned}$$

The analytical solution to the model is

$$conc = (k_u/k_e)(1 - \exp(-k_e t))$$

The data for the model are

```
data fish;
  input day conc;
datalines;
0.0    0.0
1.0    0.15
2.0    0.2
3.0    0.26
4.0    0.32
6.0    0.33
;
```

To fit this model in differential form, use the following statements:

```
proc model data=fish;
  parm ku ke;

  dert.conc = ku - ke * conc;

  fit conc / time=day;
run;
```

The results from this estimation are shown in [Figure 19.48](#).

Figure 19.48 Static Estimation Results for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.180159	0.0312	5.78	0.0044
ke	0.524661	0.1181	4.44	0.0113

To perform a dynamic estimation of the differential equation, add the DYNAMIC option to the FIT statement.

```
proc model data=fish;
  parm ku .3 ke .3;

  dert.conc = ku - ke * conc;

  fit conc / time = day dynamic;
run;
```

The equation DERT.CONC is integrated from $conc(0) = 0$. The results from this estimation are shown in Figure 19.49.

Figure 19.49 Dynamic Estimation Results for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.167109	0.0170	9.84	0.0006
ke	0.469033	0.0731	6.42	0.0030

To perform a dynamic estimation of the differential equation and estimate the initial value, use the following statements:

```
proc model data=fish;
  parm ku .3 ke .3 conc0 0;

  dert.conc = ku - ke * conc;

  fit conc initial=(conc = conc0) / time = day dynamic;
run;
```

The INITIAL= option in the FIT statement is used to associate the initial value of a differential equation with a parameter. The results from this estimation are shown in Figure 19.50.

Figure 19.50 Dynamic Estimation with Initial Value for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.164408	0.0230	7.14	0.0057
ke	0.45949	0.0943	4.87	0.0165
conc0	0.003798	0.0174	0.22	0.8414

Finally, to estimate the fish model by using the analytical solution, use the following statements:

```
proc model data=fish;
  parm ku .3 ke .3;

  conc = (ku/ ke)*( 1 -exp(-ke * day));

  fit conc;
run;
```

The results from this estimation are shown in [Figure 19.51](#).

Figure 19.51 Analytical Estimation Results for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.167109	0.0170	9.84	0.0006
ke	0.469033	0.0731	6.42	0.0030

A comparison of the results among the four estimations reveals that the two dynamic estimations and the analytical estimation give nearly identical results (identical to the default precision). The two dynamic estimations are identical because the estimated initial value (0.00013071) is very close to the initial value used in the first dynamic estimation (0). Note also that the static model did not require an initial guess for the parameter values. Static estimation, in general, is more forgiving of bad initial values.

The form of the estimation that is preferred depends mostly on the model and data. If a very accurate initial value is known, then a dynamic estimation makes sense. If, additionally, the model can be written analytically, then the analytical estimation is computationally simpler. If only an approximate initial value is known and not modeled as an unknown parameter, the static estimation is less sensitive to errors in the initial value.

The form of the error in the model is also an important factor in choosing the form of the estimation. If the error term is additive and independent of previous error, then the dynamic mode is appropriate. If, on the

other hand, the errors are cumulative, a static estimation is more appropriate. See the section “[Monte Carlo Simulation](#)” on page 1197 for an example.

Auxiliary Equations

Auxiliary equations can be used with differential equations. These are equations that need to be satisfied with the differential equations at each point between each data value. They are automatically added to the system, so you do not need to specify them in the SOLVE or FIT statement.

Consider the following example.

The Michaelis-Menten equations describe the kinetics of an enzyme-catalyzed reaction. The enzyme is E, and S is called the *substrate*. The enzyme first reacts with the substrate to form the enzyme-substrate complex ES, which then breaks down in a second step to form enzyme and products P.

The reaction rates are described by the following system of differential equations:

$$\frac{d[ES]}{dt} = k_1([E] - [ES])[S] - k_2[ES] - k_3[ES]$$

$$\frac{d[S]}{dt} = -k_1([E] - [ES])[S] + k_2[ES]$$

$$[E] = [E]_{tot} - [ES]$$

The first equation describes the rate of formation of ES from E + S. The rate of formation of ES from E + P is very small and can be ignored. The enzyme is in either the complexed or the uncomplexed form. So if the total $([E]_{tot})$ concentration of enzyme and the amount bound to the substrate is known, $[E]$ can be obtained by conservation.

In this example, the conservation equation is an auxiliary equation and is coupled with the differential equations for integration.

Time Variable

You must provide a time variable in the data set. The name of the time variable defaults to TIME. You can use other variables as the time variable by specifying the TIME= option in the FIT or SOLVE statement. The time intervals need not be evenly spaced. If the time variable for the current observation is less than the time variable for the previous observation, the integration is restarted.

Differential Equations and Goal Seeking

Consider the following differential equation

$$y' = a * x$$

and the data set

```

data t2;
  y=0; time=0; output;
  y=2; time=1; output;
  y=3; time=2; output;
run;

```

The problem is to find values for X that satisfy the differential equation and the data in the data set. Problems of this kind are sometimes referred to as *goal-seeking problems* because they require you to search for values of X that satisfy the goal of Y .

This problem is solved with the following statements:

```

proc model data=t2;
  independent x 0;
  dependent y;
  parm a 5;
  dert.y = a * x;
  solve x / out=goaldata;
run;

proc print data=goaldata;
run;

```

The output from the PROC PRINT statement is shown in [Figure 19.52](#).

Figure 19.52 Dynamic Solution

Obs	_TYPE_	_MODE_	_ERRORS_	x	y	time
1	PREDICT	SIMULATE	0	0.0	0	0
2	PREDICT	SIMULATE	0	0.8	2	1
3	PREDICT	SIMULATE	0	-0.4	3	2

Note that an initial value of 0 is provided for the X variable because it is undetermined at $\text{TIME} = 0$.

In the preceding goal-seeking example, X is treated as a linear function between each set of data points (see [Figure 19.53](#)).

Figure 19.53 Form of X Used for Integration in Goal Seeking

If you integrate $y' = ax$ manually, you have

$$\begin{aligned}
 x(t) &= \frac{t_f - t}{t_f - t_o} x_o + \frac{t - t_o}{t_f - t_o} x_f \\
 y_f - y_o &= \int_{t_o}^{t_f} ax(t) dt \\
 &= a \frac{1}{t_f - t_o} (t(t_f x_o - t_o x_f) + \frac{1}{2} t^2 (x_f - x_o)) \Big|_{t_o}^{t_f}
 \end{aligned}$$

For observation 2, this reduces to

$$\begin{aligned}
 y_f - y_o &= \frac{1}{2} a * x_f \\
 2 &= 2.5 * x_f
 \end{aligned}$$

So $x = 0.8$ for this observation.

Goal seeking for the TIME variable is not allowed.

Restrictions and Bounds on Parameters

Using the BOUNDS and RESTRICT statements, PROC MODEL can compute optimal estimates subject to equality or inequality constraints on the parameter estimates.

Equality restrictions can be written as a vector function:

$$\mathbf{h}(\theta) = 0$$

Inequality restrictions are either active or inactive. When an inequality restriction is active, it is treated as an equality restriction. All inactive inequality restrictions can be written as a vector function:

$$F(\theta) \geq 0$$

Strict inequalities, such as $(f(\theta) > 0)$, are transformed into inequalities as $f(\theta) \times (1 - \epsilon) - \epsilon \geq 0$, where the tolerance ϵ is controlled by the EPSILON= option in the FIT statement and defaults to 10^{-8} . The i th inequality restriction becomes active if $F_i < 0$ and remains active until its Lagrange multiplier becomes negative. Lagrange multipliers are computed for all the nonredundant equality restrictions and all the active inequality restrictions.

For the following, assume the vector $\mathbf{h}(\theta)$ contains all the current active restrictions. The constraint matrix \mathbf{A} is

$$\mathbf{A}(\hat{\theta}) = \frac{\partial \mathbf{h}(\hat{\theta})}{\partial \hat{\theta}}$$

The covariance matrix for the restricted parameter estimates is computed as

$$\mathbf{Z}(\mathbf{Z}'\mathbf{H}\mathbf{Z})^{-1}\mathbf{Z}'$$

where \mathbf{H} is Hessian or approximation to the Hessian of the objective function $((\mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{X})$ for OLS), and \mathbf{Z} is the last $(np - nc)$ columns of \mathbf{Q} . \mathbf{Q} is from an LQ factorization of the constraint matrix, nc is the number of active constraints, and np is the number of parameters. See Gill, Murray, and Wright (1981) for more details on LQ factorization. The covariance column in Table 19.2 summarizes the Hessian approximation used for each estimation method.

The covariance matrix for the Lagrange multipliers is computed as

$$(\mathbf{A}\mathbf{H}^{-1}\mathbf{A}')^{-1}$$

The p -value reported for a restriction is computed from a beta distribution rather than a t distribution because the numerator and the denominator of the t ratio for an estimated Lagrange multiplier are not independent.

The Lagrange multipliers for the active restrictions are printed with the parameter estimates. The Lagrange multiplier estimates are computed using the relationship

$$\mathbf{A}'\lambda = \mathbf{g}$$

where the dimensions of the constraint matrix \mathbf{A} are the number of constraints by the number of parameters, λ is the vector of Lagrange multipliers, and \mathbf{g} is the gradient of the objective function at the final estimates.

The final gradient includes the effects of the estimated \mathbf{S} matrix. For example, for OLS the final gradient would be:

$$\mathbf{g} = \mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{r}$$

where \mathbf{r} is the residual vector. Note that when nonlinear restrictions are imposed, the convergence measure R might have values greater than one for some iterations.

Tests on Parameters

In general, the hypothesis tested can be written as

$$H_0 : \mathbf{h}(\theta) = 0$$

where $\mathbf{h}(\theta)$ is a vector-valued function of the parameters θ given by the r expressions specified on the TEST statement.

Let $\hat{\mathbf{V}}$ be the estimate of the covariance matrix of $\hat{\theta}$. Let $\hat{\theta}$ be the unconstrained estimate of θ and $\tilde{\theta}$ be the constrained estimate of θ such that $h(\tilde{\theta}) = 0$. Let

$$\mathbf{A}(\theta) = \partial h(\theta) / \partial \theta \big|_{\hat{\theta}}$$

Let r be the dimension of $h(\theta)$ and n be the number of observations. Using this notation, the test statistics for the three kinds of tests are computed as follows.

The Wald test statistic is defined as

$$W = h'(\hat{\theta}) \left(\mathbf{A}(\hat{\theta}) \hat{\mathbf{V}} \mathbf{A}'(\hat{\theta}) \right)^{-1} h(\hat{\theta})$$

The Wald test is not invariant to reparameterization of the model (Gregory and Veall 1985; Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

The Lagrange multiplier test statistic is

$$R = \lambda' \mathbf{A}(\tilde{\theta}) \tilde{\mathbf{V}} \mathbf{A}'(\tilde{\theta}) \lambda$$

where λ is the vector of Lagrange multipliers from the computation of the restricted estimate $\tilde{\theta}$.

The Lagrange multiplier test statistic is equivalent to Rao's efficient score test statistic:

$$R = (\partial L(\tilde{\theta}) / \partial \theta)' \tilde{\mathbf{V}} (\partial L(\tilde{\theta}) / \partial \theta)$$

where L is the log-likelihood function for the estimation method used. For SUR, 3SLS, GMM, and iterated versions of these methods, the likelihood function is computed as

$$L = \text{Objective} \times Nobs / 2$$

For OLS and 2SLS, the Lagrange multiplier test statistic is computed as:

$$R = [(\partial \hat{S}(\tilde{\theta}) / \partial \theta)' \tilde{\mathbf{V}} (\partial \hat{S}(\tilde{\theta}) / \partial \theta)] / \hat{S}(\tilde{\theta})$$

where $\hat{S}(\tilde{\theta})$ is the corresponding objective function value at the constrained estimate.

The likelihood ratio test statistic is

$$T = 2 \left(L(\hat{\theta}) - L(\tilde{\theta}) \right)$$

where $\tilde{\theta}$ represents the constrained estimate of θ and L is the concentrated log-likelihood value.

For OLS and 2SLS, the likelihood ratio test statistic is computed as:

$$T = (n - nparms) \times (\hat{S}(\tilde{\theta}) - \hat{S}(\hat{\theta})) / \hat{S}(\hat{\theta})$$

This test statistic is an approximation from

$$T = n \times \log \left(1 + \frac{rF}{n - nparms} \right)$$

when the value of $rF/(n - nparms)$ is small (Greene 2004, p. 421).

The likelihood ratio test is not appropriate for models with nonstationary serially correlated errors (Gallant 1987, p. 139). The likelihood ratio test should not be used for dynamic systems, for systems with lagged dependent variables, or with the FIML estimation method unless certain conditions are met (see Gallant 1987, p. 479).

For each kind of test, under the null hypothesis the test statistic is asymptotically distributed as a χ^2 random variable with r degrees of freedom, where r is the number of expressions in the TEST statement. The p -values reported for the tests are computed from the $\chi^2(r)$ distribution and are only asymptotically valid. When both RESTRICT and TEST statements are used in a PROC MODEL step, test statistics are computed by taking into account the constraints imposed by the RESTRICT statement.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation to its small sample distribution than the other two tests. However, the Wald test has the least computational cost, since it does not require computation of the constrained estimate $\tilde{\theta}$.

The following is an example of using the TEST statement to perform a likelihood ratio test for a compound hypothesis.

```
test a*exp(-k) = 1-k, d = 0 , / 1r;
```

It is important to keep in mind that although individual t tests for each parameter are printed by default into the parameter estimates table, they are only asymptotically valid for nonlinear models. You should be cautious in drawing any inferences from these t tests for small samples.

Hausman Specification Test

Hausman's specification test, or m -statistic, can be used to test hypotheses in terms of bias or inconsistency of an estimator. This test was also proposed by Wu (1973). Hausman's m -statistic is as follows.

Given two estimators, $\hat{\beta}_0$ and $\hat{\beta}_1$, where under the null hypothesis both estimators are consistent but only $\hat{\beta}_0$ is asymptotically efficient and under the alternative hypothesis only $\hat{\beta}_1$ is consistent, the m -statistic is

$$m = \hat{q}'(\hat{\mathbf{V}}_1 - \hat{\mathbf{V}}_0)^{-1}\hat{q}$$

where $\hat{\mathbf{V}}_1$ and $\hat{\mathbf{V}}_0$ represent consistent estimates of the asymptotic covariance matrices of $\hat{\beta}_1$ and $\hat{\beta}_0$ respectively, and

$$q = \hat{\beta}_1 - \hat{\beta}_0$$

The m -statistic is then distributed χ^2 with k degrees of freedom, where k is the rank of the matrix $(\hat{\mathbf{V}}_1 - \hat{\mathbf{V}}_0)$. A generalized inverse is used, as recommended by Hausman and Taylor (1982).

In the MODEL procedure, Hausman's m -statistic can be used to determine if it is necessary to use an instrumental variables method rather than a more efficient OLS estimation. Hausman's m -statistic can also be used to compare 2SLS with 3SLS for a class of estimators for which 3SLS is asymptotically efficient (similarly for OLS and SUR).

Hausman's m -statistic can also be used, in principle, to test the null hypothesis of normality when comparing 3SLS to FIML. Because of the poor performance of this form of the test, it is not offered in the MODEL procedure. See Fair (1984, pp. 246–247) for a discussion of why Hausman's test fails for common econometric models.

To perform a Hausman's specification test, specify the HAUSMAN option in the FIT statement. The selected estimation methods are compared using Hausman's m -statistic.

In the following example, Hausman's test is used to check the presence of measurement error. Under H_0 of no measurement error, OLS is efficient, while under H_1 , 2SLS is consistent. In the following code, OLS and 2SLS are used to estimate the model, and Hausman's test is requested.

```
proc model data=one out=fiml2;
    endogenous y1 y2;

    y1 = py2 * y2 + px1 * x1 + interrc;
    y2 = py1* y1 + pz1 * z1 + d2;

    fit y1 y2 / ols 2sls hausman;
    instruments x1 z1;
run;
```

The output specified by the HAUSMAN option produces the results shown in Figure 19.54.

Figure 19.54 Hausman's Specification Test Results

The MODEL Procedure				
Hausman's Specification Test Results				
Efficient under H0	Consistent under H1	DF	Statistic	Pr > ChiSq
OLS	2SLS	6	13.86	0.0313

Figure 19.54 indicates that 2SLS is preferred over OLS at 5% level of significance. In this case, the null hypothesis of no measurement error is rejected. Hence, the instrumental variable estimator is required for this example due to the presence of measurement error.

Chow Tests

The Chow test is used to test for break points or structural changes in a model. The problem is posed as a partitioning of the data into two parts of size n_1 and n_2 . The null hypothesis to be tested is

$$H_0 : \beta_1 = \beta_2 = \beta$$

where β_1 is estimated by using the first part of the data and β_2 is estimated by using the second part.

The test is performed as follows (see Davidson and MacKinnon 1993, p. 380).

1. The p parameters of the model are estimated.
2. A second linear regression is performed on the residuals, \hat{u} , from the nonlinear estimation in step one.

$$\hat{u} = \hat{\mathbf{X}}b + \text{residuals}$$

where $\hat{\mathbf{X}}$ is Jacobian columns that are evaluated at the parameter estimates. If the estimation is an instrumental variables estimation with matrix of instruments \mathbf{W} , then the following regression is performed:

$$\hat{u} = \mathbf{P}_W \hat{\mathbf{X}}b + \text{residuals}$$

where \mathbf{P}_W is the projection matrix.

3. The restricted SSE (RSSE) from this regression is obtained. An SSE for each subsample is then obtained by using the same linear regression.
4. The F statistic is then

$$f = \frac{(RSSE - SSE_1 - SSE_2)/p}{(SSE_1 + SSE_2)/(n - 2p)}$$

This test has p and $n - 2p$ degrees of freedom.

Chow's test is not applicable if $\min(n_1, n_2) < p$, since one of the two subsamples does not contain enough data to estimate β . In this instance, the *predictive Chow test* can be used. The predictive Chow test is defined as

$$f = \frac{(RSSE - SSE_1) \times (n_1 - p)}{SSE_1 \times n_2}$$

where $n_1 > p$. This test can be derived from the Chow test by noting that the $SSE_2 = 0$ when $n_2 \leq p$ and by adjusting the degrees of freedom appropriately.

You can select the Chow test and the predictive Chow test by specifying the `CHOW=arg` and the `PCHOW=arg` options in the FIT statement, where *arg* is either the number of observations in the first sample or a parenthesized list of first sample sizes. If the size of the one of the two groups in which the sample is partitioned is less than the number of parameters, then a predictive Chow test is automatically used. These tests statistics are not produced for GMM and FIML estimations.

The following is an example of the use of the Chow test.

```

data exp;
  x=0;
  do time=1 to 100;
    if time=50 then x=1;
    y = 35 * exp( 0.01 * time ) + rannor( 123 ) + x * 5;
    output;
  end;
run;

proc model data=exp;
  parm zo 35 b;
  dert.z = b * z;
  y=z;
  fit y init=(z=zo) / chow =(40 50 60) pchow=90;
run;

```

The data set introduces an artificial structural change into the model (the structural change effects the intercept parameter). The output from the requested Chow tests are shown in [Figure 19.55](#).

Chow	60	2	96	26.43	<.0001
Predictive Chow	90	11	87	1.86	0.0566

Profile Likelihood Confidence Intervals

Wald-based and likelihood-ratio-based confidence intervals are available in the MODEL procedure for computing a confidence interval on an estimated parameter. A confidence interval on a parameter θ can be constructed by inverting a Wald-based or a likelihood-ratio-based test.

The approximate $100(1 - \alpha) \%$ Wald confidence interval for a parameter θ is

$$\hat{\theta} \pm z_{1-\alpha/2} \hat{\sigma}$$

where z_p is the 100 p th percentile of the standard normal distribution, $\hat{\theta}$ is the maximum likelihood estimate of θ , and $\hat{\sigma}$ is the standard error estimate of $\hat{\theta}$.

A likelihood-ratio-based confidence interval is derived from the χ^2 distribution of the generalized likelihood

ratio test. The approximate $1 - \alpha$ confidence interval for a parameter θ is

$$\theta : 2[l(\hat{\theta}) - l(\theta)] \leq q_{1,1-\alpha} = 2l^*$$

where $q_{1,1-\alpha}$ is the $(1 - \alpha)$ quantile of the χ^2 with one degree of freedom, and $l(\theta)$ is the log likelihood as a function of one parameter. The endpoints of a confidence interval are the zeros of the function $l(\theta) - l^*$. Computing a likelihood-ratio-based confidence interval is an iterative process. This process must be performed twice for each parameter, so the computational cost is considerable. Using a modified form of the algorithm recommended by Venzon and Moolgavkar (1988), you can determine that the cost of each endpoint computation is approximately the cost of estimating the original system.

To request confidence intervals on estimated parameters, specify the PRL= option in the FIT statement. By default, the PRL option produces 95% likelihood ratio confidence limits. The coverage of the confidence interval is controlled by the ALPHA= option in the FIT statement.

The following is an example of the use of the confidence interval options.

```
data exp;
  do time = 1 to 20;
    y = 35 * exp( 0.01 * time ) + 5*rannor( 123 );
  output;
  end;
run;

proc model data=exp;
  parm zo 35 b;
  dert.z = b * z;
  y=z;
  fit y init=(z=zo) / prl=both;
  test zo = 40.475437 ,/ lr;
run;
```

The output from the requested confidence intervals and the TEST statement are shown in [Figure 19.56](#)

Figure 19.56 Confidence Interval Estimation

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
zo	36.58933	1.9471	18.79	<.0001
b	0.006497	0.00464	1.40	0.1780
Test Results				
Test	Type	Statistic	Pr > ChiSq	Label
Test0	L.R.	3.81	0.0509	zo = 40.475437

Figure 19.56 continued

Parameter Wald			
95% Confidence Intervals			
Parameter	Value	Lower	Upper
zo	36.5893	32.7730	40.4056
b	0.00650	-0.00259	0.0156

Parameter Likelihood Ratio			
95% Confidence Intervals			
Parameter	Value	Lower	Upper
zo	36.5893	32.8381	40.4921
b	0.00650	-0.00264	0.0157

In this example the parameter value used in the likelihood ratio test, $z_o = 40.475437$, is close to the upper bound computed for the likelihood ratio confidence interval, $z_o \leq 40.4921$. This coincidence is not germane to the analysis however, since the likelihood ratio test is a test of the null hypothesis $H_0 : z_o = 40.475437$ and the confidence interval can be viewed as a test of the null hypothesis $H_0 : 32.8381 \leq z_o \leq 40.4921$.

Choice of Instruments

Several of the estimation methods supported by PROC MODEL are instrumental variables methods. There is no standard method for choosing instruments for nonlinear regression. Few econometric textbooks discuss the selection of instruments for nonlinear models. See Bowden and Turkington (1984, pp. 180–182) for more information.

The purpose of the instrumental projection is to purge the regressors of their correlation with the residual. For nonlinear systems, the regressors are the partials of the residuals with respect to the parameters.

Possible instrumental variables include the following:

- any variable in the model that is independent of the errors
- lags of variables in the system
- derivatives with respect to the parameters, if the derivatives are independent of the errors
- low-degree polynomials in the exogenous variables
- variables from the data set or functions of variables from the data set

Selected instruments must not have any of the following characteristics:

- depend on any variable endogenous with respect to the equations estimated
- depend on any of the parameters estimated
- be lags of endogenous variables if there is serial correlation of the errors

If the preceding rules are satisfied and there are enough observations to support the number of instruments used, the results should be consistent and the efficiency loss held to a minimum.

You need at least as many instruments as the maximum number of parameters in any equation, or some of the parameters cannot be estimated. Note that *number of instruments* means linearly independent instruments. If you add an instrument that is a linear combination of other instruments, it has no effect and does not increase the effective number of instruments.

You can, however, use too many instruments. In order to get the benefit of instrumental variables, you must have more observations than instruments. Thus, there is a trade-off; the instrumental variables technique completely eliminates the simultaneous equation bias only in large samples. In finite samples, the larger the excess of observations over instruments, the more the bias is reduced. Adding more instruments might improve the efficiency, but after some point efficiency declines as the excess of observations over instruments becomes smaller and the bias grows.

The instruments used in an estimation are printed out at the beginning of the estimation. For example, the following statements produce the instruments list shown in Figure 19.57.

```
proc model data=test2;
  exogenous x1 x2;
  parms b1 a1 a2 b2 2.5 c2 55;
  y1 = a1 * y2 + b1 * exp(x1);
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2;
  fit y1 y2 / n2s1s;
  inst b1 b2 c2 x1 ;
run;
```

Figure 19.57 Instruments Used Message

<p style="text-align: center;">The MODEL Procedure</p> <p style="text-align: center;">The 2 Equations to Estimate</p> <p style="text-align: center;">y1 = F(b1, a1(y2)) y2 = F(a2(y1), b2, c2)</p> <p style="text-align: center;">Instruments 1 x1 @y1/@b1 @y2/@b2 @y2/@c2</p>

This states that an intercept term, the exogenous variable X1, and the partial derivatives of the equations with respect to B1, B2, and C2, were used as instruments for the estimation.

Examples

Suppose that Y1 and Y2 are endogenous variables, that X1 and X2 are exogenous variables, and that A, B, C, D, E, F, and G are parameters. Consider the following model:

```
y1 = a + b * x1 + c * y2 + d * lag(y1);
y2 = e + f * x2 + g * y1;
fit y1 y2;
instruments exclude=(c g);
```

The INSTRUMENTS statement produces X1, X2, LAG(Y1), and an intercept as instruments.

In order to estimate the Y1 equation by itself, it is necessary to include X2 explicitly in the instruments since F, in this case, is not included in the following estimation:

```
y1 = a + b * x1 + c * y2 + d * lag(y1);
y2 = e + f * x2 + g * y1;
fit y1;
instruments x2 exclude=(c);
```

This produces the same instruments as before. You can list the parameter associated with the lagged variable as an instrument instead of using the EXCLUDE= option. Thus, the following is equivalent to the previous example:

```
y1 = a + b * x1 + c * y2 + d * lag(y1);
y2 = e + f * x2 + g * y1;
fit y1;
instruments x1 x2 d;
```

For an example of declaring instruments when estimating a model involving identities, consider Klein's Model I:

```
proc model data=klien;
  endogenous c p w i x wsum k y;
  exogenous wp g t year;
  parms c0-c3 i0-i3 w0-w3;
  a: c = c0 + c1 * p + c2 * lag(p) + c3 * wsum;
  b: i = i0 + i1 * p + i2 * lag(p) + i3 * lag(k);
  c: w = w0 + w1 * x + w2 * lag(x) + w3 * year;
  x = c + i + g;
  y = c + i + g-t;
  p = x-w-t;
  k = lag(k) + i;
  wsum = w + wp;
run;
```

The three equations to estimate are identified by the labels A, B, and C. The parameters associated with the predetermined terms are C2, I2, I3, W2, and W3 (and the intercepts, which are automatically added to the instruments). In addition, the system includes five identities that contain the predetermined variables G, T, LAG(K), and WP. Thus, the INSTRUMENTS statement can be written as

```
lagk = lag(k);
instruments c2 i2 i3 w2 w3 g t wp lagk;
```

where LAGK is a program variable used to hold LAG(K). However, this is more complicated than it needs to be. Except for LAG(K), all the predetermined terms in the identities are exogenous variables, and LAG(K) is already included as the coefficient of I3. There are also more parameters for predetermined terms than for endogenous terms, so you might prefer to use the EXCLUDE= option. Thus, you can specify the same instruments list with the simpler statement

```
instruments _exog_ exclude=(c1 c3 i1 w1);
```

To illustrate the use of polynomial terms as instrumental variables, consider the following model:

$$y_1 = a + b * \exp(c * x_1) + d * \log(x_2) + e * \exp(f * y_2);$$

The parameters are A, B, C, D, E, and F, and the right-hand-side variables are X1, X2, and Y2. Assume that X1 and X2 are exogenous (independent of the error), while Y2 is endogenous. The equation for Y2 is not specified, but assume that it includes the variables X1, X3, and Y1, with X3 exogenous, so the exogenous variables of the full system are X1, X2, and X3. Using as instruments quadratic terms in the exogenous variables, the model is specified to PROC MODEL as follows:

```
proc model;
  parms a b c d e f;
  y1 = a + b * exp( c * x1 ) + d * log( x2 ) + e * exp( f * y2 );
  instruments inst1-inst9;
  inst1 = x1; inst2 = x2; inst3 = x3;
  inst4 = x1 * x1; inst5 = x1 * x2; inst6 = x1 * x3;
  inst7 = x2 * x2; inst8 = x2 * x3; inst9 = x3 * x3;
  fit y1 / 2s1s;
run;
```

It is not clear what degree polynomial should be used. There is no way to know how good the approximation is for any degree chosen, although the first-stage R^2 s might help the assessment.

First-Stage R-Squares

When the FSRSQ option is used on the FIT statement, the MODEL procedure prints a column of first-stage R^2 (FSRSQ) statistics along with the parameter estimates. The FSRSQ measures the fraction of the variation of the derivative column associated with the parameter that remains after projection through the instruments.

Ideally, the FSRSQ should be very close to 1.00 for exogenous derivatives. If the FSRSQ is small for an endogenous derivative, it is unclear whether this reflects a poor choice of instruments or a large influence of the errors in the endogenous right-hand-side variables. When the FSRSQ for one or more parameters is small, the standard errors of the parameter estimates are likely to be large.

Note that you can make all the FSRSQs larger (or 1.00) by including more instruments, because of the disadvantage discussed previously. The FSRSQ statistics reported are unadjusted R^2 s and do not include a degrees-of-freedom correction.

Autoregressive Moving-Average Error Processes

Autoregressive moving-average error processes (ARMA errors) and other models that involve lags of error terms can be estimated by using FIT statements and simulated or forecast by using SOLVE statements.

ARMA models for the error process are often used for models with autocorrelated residuals. The %AR macro can be used to specify models with autoregressive error processes. The %MA macro can be used to specify models with moving-average error processes.

Autoregressive Errors

A model with first-order autoregressive errors, AR(1), has the form

$$y_t = f(x_t, \theta) + \mu_t$$

$$\mu_t = \phi \mu_{t-1} + \epsilon_t$$

while an AR(2) error process has the form

$$\mu_t = \phi_1 \mu_{t-1} + \phi_2 \mu_{t-2} + \epsilon_t$$

and so forth for higher-order processes. Note that the ϵ_t 's are independent and identically distributed and have an expected value of 0.

An example of a model with an AR(2) component is

$$y = \alpha + \beta x_1 + \mu_t$$

$$\mu_t = \phi_1 \mu_{t-1} + \phi_2 \mu_{t-2} + \epsilon_t$$

You would write this model as

```
proc model data=in;
  parms a b p1 p2;
  y = a + b * x1 + p1 * zlag1(y - (a + b * x1)) +
      p2 * zlag2(y - (a + b * x1));
  fit y;
run;
```

or equivalently using the %AR macro as

```
proc model data=in;
  parms a b;
  y = a + b * x1;
  %ar( y, 2 );
  fit y;
run;
```

Moving-Average Models

A model with first-order moving-average errors, MA(1), has the form

$$y_t = f(x_t) + \mu_t$$

$$\mu_t = \epsilon_t - \theta_1 \epsilon_{t-1}$$

where ϵ_t is identically and independently distributed with mean zero. An MA(2) error process has the form

$$\mu_t = \epsilon_t - \theta_1\epsilon_{t-1} - \theta_2\epsilon_{t-2}$$

and so forth for higher-order processes.

For example, you can write a simple linear regression model with MA(2) moving-average errors as

```
proc model data=inma2;
  parms a b ma1 ma2;
  y = a + b * x + ma1 * zlag1( resid.y ) +
      ma2 * zlag2( resid.y );
  fit;
run;
```

where MA1 and MA2 are the moving-average parameters.

Note that RESID.Y is automatically defined by PROC MODEL as

```
pred.y = a + b * x + ma1 * zlag1( resid.y ) +
      ma2 * zlag2( resid.y );
resid.y = pred.y - actual.y;
```

Note that RESID.Y is negative of ϵ_t .

The ZLAG function must be used for MA models to truncate the recursion of the lags. This ensures that the lagged errors start at zero in the lag-priming phase and do not propagate missing values when lag-priming period variables are missing, and it ensures that the future errors are zero rather than missing during simulation or forecasting. For details about the lag functions, see the section “[Lag Logic](#)” on page 1237.

This model written using the %MA macro is as follows:

```
proc model data=inma2;
  parms a b;
  y = a + b * x;
  %ma(y, 2);
  fit;
run;
```

General Form for ARMA Models

The general ARMA(p, q) process has the following form

$$\mu_t = \phi_1\mu_{t-1} + \dots + \phi_p\mu_{t-p} + \epsilon_t - \theta_1\epsilon_{t-1} - \dots - \theta_q\epsilon_{t-q}$$

An ARMA(p, q) model can be specified as follows:

```

yhat = ... compute structural predicted value here ... ;
yarma = ar1 * zlag1( y - yhat ) + ... /* ar part */
        + ar(p) * zlag(p)( y - yhat )
        + ma1 * zlag1( resid.y ) + ... /* ma part */
        + ma(q) * zlag(q)( resid.y );
y = yhat + yarma;

```

where AR_i and MA_j represent the autoregressive and moving-average parameters for the various lags. You can use any names you want for these variables, and there are many equivalent ways that the specification could be written.

Vector ARMA processes can also be estimated with PROC MODEL. For example, a two-variable AR(1) process for the errors of the two endogenous variables Y1 and Y2 can be specified as follows:

```

y1hat = ... compute structural predicted value here ... ;

y1      = y1hat + ar1_1 * zlag1( y1 - y1hat ) /* ar part y1,y1 */
          + ar1_2 * zlag1( y2 - y2hat ); /* ar part y1,y2 */

y21hat = ... compute structural predicted value here ... ;

y2      = y2hat + ar2_2 * zlag1( y2 - y2hat ) /* ar part y2,y2 */
          + ar2_1 * zlag1( y1 - y1hat ); /* ar part y2,y1 */

```

Convergence Problems with ARMA Models

ARMA models can be difficult to estimate. If the parameter estimates are not within the appropriate range, a moving-average model's residual terms grow exponentially. The calculated residuals for later observations can be very large or can overflow. This can happen either because improper starting values were used or because the iterations moved away from reasonable values.

Care should be used in choosing starting values for ARMA parameters. Starting values of 0.001 for ARMA parameters usually work if the model fits the data well and the problem is well-conditioned. Note that an MA model can often be approximated by a high-order AR model, and vice versa. This can result in high collinearity in mixed ARMA models, which in turn can cause serious ill-conditioning in the calculations and instability of the parameter estimates.

If you have convergence problems while estimating a model with ARMA error processes, try to estimate in steps. First, use a FIT statement to estimate only the structural parameters with the ARMA parameters held to zero (or to reasonable prior estimates if available). Next, use another FIT statement to estimate the ARMA parameters only, using the structural parameter values from the first run. Since the values of the structural parameters are likely to be close to their final estimates, the ARMA parameter estimates might now converge. Finally, use another FIT statement to produce simultaneous estimates of all the parameters. Since the initial values of the parameters are now likely to be quite close to their final joint estimates, the estimates should converge quickly if the model is appropriate for the data.

AR Initial Conditions

The initial lags of the error terms of $AR(p)$ models can be modeled in different ways. The autoregressive error startup methods supported by SAS/ETS procedures are the following:

CLS	conditional least squares (ARIMA and MODEL procedures)
ULS	unconditional least squares (AUTOREG, ARIMA, and MODEL procedures)
ML	maximum likelihood (AUTOREG, ARIMA, and MODEL procedures)
YW	Yule-Walker (AUTOREG procedure only)
HL	Hildreth-Lu, which deletes the first p observations (MODEL procedure only)

See Chapter 8, “[The AUTOREG Procedure](#),” for an explanation and discussion of the merits of various $AR(p)$ startup methods.

The CLS, ULS, ML, and HL initializations can be performed by PROC MODEL. For $AR(1)$ errors, these initializations can be produced as shown in [Table 19.3](#). These methods are equivalent in large samples.

Table 19.3 Initializations Performed by PROC MODEL: $AR(1)$ ERRORS

Method	Formula
conditional least squares	$Y = YHAT + AR1 * ZLAG1(Y - YHAT);$
unconditional least squares	$Y = YHAT + AR1 * ZLAG1(Y - YHAT);$ IF _OBS_=1 THEN $RESID.Y = SQRT(1 - AR1**2) * RESID.Y;$
maximum likelihood	$Y = YHAT + AR1 * ZLAG1(Y - YHAT);$ $W = (1 - AR1**2)**(-1/(2 * _NUSED_));$ IF _OBS_=1 THEN $W = W * SQRT(1 - AR1**2);$ $RESID.Y = W * RESID.Y;$
Hildreth-Lu	$Y = YHAT + AR1 * LAG1(Y - YHAT);$

MA Initial Conditions

The initial lags of the error terms of $MA(q)$ models can also be modeled in different ways. The following moving-average error start-up paradigms are supported by the ARIMA and MODEL procedures:

ULS	unconditional least squares
CLS	conditional least squares
ML	maximum likelihood

The conditional least squares method of estimating moving-average error terms is not optimal because it ignores the start-up problem. This reduces the efficiency of the estimates, although they remain unbiased.

The initial lagged residuals, extending before the start of the data, are assumed to be 0, their unconditional expected value. This introduces a difference between these residuals and the generalized least squares residuals for the moving-average covariance, which, unlike the autoregressive model, persists through the data set. Usually this difference converges quickly to 0, but for nearly noninvertible moving-average processes the convergence is quite slow. To minimize this problem, you should have plenty of data, and the moving-average parameter estimates should be well within the invertible range.

This problem can be corrected at the expense of writing a more complex program. Unconditional least squares estimates for the MA(1) process can be produced by specifying the model as follows:

```
yhat = ... compute structural predicted value here ... ;
if _obs_ = 1 then do;
  h = sqrt( 1 + ma1 ** 2 );
  y = yhat;
  resid.y = ( y - yhat ) / h;
end;
else do;
  g = ma1 / zlag1( h );
  h = sqrt( 1 + ma1 ** 2 - g ** 2 );
  y = yhat + g * zlag1( resid.y );
  resid.y = ( ( y - yhat ) - g * zlag1( resid.y ) ) / h;
end;
```

Moving-average errors can be difficult to estimate. You should consider using an $AR(p)$ approximation to the moving-average process. A moving-average process can usually be well-approximated by an autoregressive process if the data have not been smoothed or differenced.

The %AR Macro

The SAS macro %AR generates programming statements for PROC MODEL for autoregressive models. The %AR macro is part of SAS/ETS software, and no special options need to be set to use the macro. The autoregressive process can be applied to the structural equation errors or to the endogenous series themselves.

The %AR macro can be used for the following types of autoregression:

- univariate autoregression
- unrestricted vector autoregression
- restricted vector autoregression

Univariate Autoregression

To model the error term of an equation as an autoregressive process, use the following statement after the equation:

```
%ar( varname, nlags )
```

For example, suppose that Y is a linear function of X_1 , X_2 , and an AR(2) error. You would write this model as follows:

```
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 2 )
  fit y / list;
run;
```

The calls to %AR must come *after* all of the equations that the process applies to.

The preceding macro invocation, %AR(y,2), produces the statements shown in the LIST output in Figure 19.58.

Figure 19.58 LIST Option Output for an AR(2) Model

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	2260:4	PRED.y = a + b * x1 + c * x2;
1	2260:4	RESID.y = PRED.y - ACTUAL.y;
1	2260:4	ERROR.y = PRED.y - y;
2	2261:14	_PRED__y = PRED.y;
3	2261:15	_OLD_PRED.y = PRED.y + y_11
		* ZLAG1(y - _PRED__y) + y_12
		* ZLAG2(y - _PRED__y);
3	2261:15	PRED.y = _OLD_PRED.y;
3	2261:15	RESID.y = PRED.y - ACTUAL.y;
3	2261:15	ERROR.y = PRED.y - y;

The _PRED__ prefixed variables are temporary program variables used so that the lags of the residuals are the correct residuals and not the ones redefined by this equation. Note that this is equivalent to the statements explicitly written in the section “General Form for ARMA Models” on page 1167.

You can also restrict the autoregressive parameters to zero at selected lags. For example, if you wanted autoregressive parameters at lags 1, 12, and 13, you can use the following statements:

```
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 13, , 1 12 13 )
  fit y / list;
run;
```

These statements generate the output shown in Figure 19.59.

Figure 19.59 LIST Option Output for an AR Model with Lags at 1, 12, and 13

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	2269:4	PRED.y = a + b * x1 + c * x2;
1	2269:4	RESID.y = PRED.y - ACTUAL.y;
1	2269:4	ERROR.y = PRED.y - y;
2	2270:14	_PRED__y = PRED.y;
3	2270:15	_OLD_PRED.y = PRED.y + y_l1 * ZLAG1(y - _PRED__y) + y_l12 * ZLAG12(y - _PRED__y) + y_l13 * ZLAG13(y - _PRED__y);
3	2270:15	PRED.y = _OLD_PRED.y;
3	2270:15	RESID.y = PRED.y - ACTUAL.y;
3	2270:15	ERROR.y = PRED.y - y;

There are variations on the conditional least squares method, depending on whether observations at the start of the series are used to “warm up” the AR process. By default, the %AR conditional least squares method uses all the observations and assumes zeros for the initial lags of autoregressive terms. By using the M= option, you can request that %AR use the unconditional least squares (ULS) or maximum-likelihood (ML) method instead. For example,

```
proc model data=in;
  y = a + b * x1 + c * x2;
  %ar( y, 2, m=uls )
  fit y;
run;
```

Discussions of these methods is provided in the section “AR Initial Conditions” on page 1169.

By using the M=CLS*n* option, you can request that the first *n* observations be used to compute estimates of the initial autoregressive lags. In this case, the analysis starts with observation *n* + 1. For example:

```
proc model data=in;
  y = a + b * x1 + c * x2;
  %ar( y, 2, m=cls2 )
  fit y;
run;
```

You can use the %AR macro to apply an autoregressive model to the endogenous variable, instead of to the error term, by using the TYPE=V option. For example, if you want to add the five past lags of Y to the equation in the previous example, you could use %AR to generate the parameters and lags by using the following statements:

```
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 5, type=v )
  fit y / list;
run;
```

The preceding statements generate the output shown in Figure 19.60.

Figure 19.60 LIST Option Output for an AR model of Y

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	2292:4	PRED.y = a + b * x1 + c * x2;
1	2292:4	RESID.y = PRED.y - ACTUAL.y;
1	2292:4	ERROR.y = PRED.y - y;
2	2293:15	_OLD_PRED.y = PRED.y + y_l1 * ZLAG1(y) + y_l2 * ZLAG2(y) + y_l3 * ZLAG3(y) + y_l4 * ZLAG4(y) + y_l5 * ZLAG5(y);
2	2293:15	PRED.y = _OLD_PRED.y;
2	2293:15	RESID.y = PRED.y - ACTUAL.y;
2	2293:15	ERROR.y = PRED.y - y;

This model predicts Y as a linear combination of X1, X2, an intercept, and the values of Y in the most recent five periods.

Unrestricted Vector Autoregression

To model the error terms of a set of equations as a vector autoregressive process, use the following form of the %AR macro after the equations:

```
%ar( process_name, nlags, variable_list )
```

The *process_name* value is any name that you supply for %AR to use in making names for the autoregressive parameters. You can use the %AR macro to model several different AR processes for different sets of equations by using different process names for each set. The process name ensures that the variable names used are unique. Use a short *process_name* value for the process if parameter estimates are to be written to an output data set. The %AR macro tries to construct parameter names less than or equal to eight characters, but this is limited by the length of *process_name*, which is used as a prefix for the AR parameter names.

The *variable_list* value is the list of endogenous variables for the equations.

For example, suppose that errors for equations Y1, Y2, and Y3 are generated by a second-order vector autoregressive process. You can use the following statements:

```
proc model data=in;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 2, y1 y2 y3 )
  fit y1 y2 y3;
run;
```

which generate the following for Y1 and similar code for Y2 and Y3:

```
y1 = pred.y1 + name1_1_1*zlag1(y1-name_y1) +
      name1_1_2*zlag1(y2-name_y2) +
      name1_1_3*zlag1(y3-name_y3) +
      name2_1_1*zlag2(y1-name_y1) +
      name2_1_2*zlag2(y2-name_y2) +
      name2_1_3*zlag2(y3-name_y3) ;
```

Only the conditional least squares (M=CLS or M=CLSn) method can be used for vector processes.

You can also use the same form with restrictions that the coefficient matrix be 0 at selected lags. For example, the following statements apply a third-order vector process to the equation errors with all the coefficients at lag 2 restricted to 0 and with the coefficients at lags 1 and 3 unrestricted:

```
proc model data=in;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 3, y1 y2 y3, 1 3 )
  fit y1 y2 y3;
```

You can model the three series Y1–Y3 as a vector autoregressive process in the variables instead of in the errors by using the TYPE=V option. If you want to model Y1–Y3 as a function of past values of Y1–Y3 and some exogenous variables or constants, you can use %AR to generate the statements for the lag terms. Write an equation for each variable for the nonautoregressive part of the model, and then call %AR with the TYPE=V option. For example,

```
proc model data=in;
  parms a1-a3 b1-b3;
  y1 = a1 + b1 * x;
  y2 = a2 + b2 * x;
  y3 = a3 + b3 * x;
  %ar( name, 2, y1 y2 y3, type=v )
  fit y1 y2 y3;
run;
```

The nonautoregressive part of the model can be a function of exogenous variables, or it can be intercept parameters. If there are no exogenous components to the vector autoregression model, including no intercepts, then assign zero to each of the variables. There must be an assignment to each of the variables before %AR is called.

```
proc model data=in;
  y1=0;
  y2=0;
  y3=0;
  %ar( name, 2, y1 y2 y3, type=v )
  fit y1 y2 y3;
run;
```

This example models the vector $Y=(Y1 \ Y2 \ Y3)'$ as a linear function only of its value in the previous two periods and a white noise error vector. The model has $18=(3 \times 3 + 3 \times 3)$ parameters.

Syntax of the %AR Macro

There are two cases of the syntax of the %AR macro. When restrictions on a vector AR process are not needed, the syntax of the %AR macro has the general form

%AR (*name* , *nlag* < ,*endolist* < , *laglist* > > < ,*M=method* > < ,*TYPE=V* >) ;

where

<i>name</i>	specifies a prefix for %AR to use in constructing names of variables needed to define the AR process. If the <i>endolist</i> is not specified, the endogenous list defaults to <i>name</i> , which must be the name of the equation to which the AR error process is to be applied. The <i>name</i> value cannot exceed 32 characters.
<i>nlag</i>	is the order of the AR process.
<i>endolist</i>	specifies the list of equations to which the AR process is to be applied. If more than one name is given, an unrestricted vector process is created with the structural residuals of all the equations included as regressors in each of the equations. If not specified, <i>endolist</i> defaults to <i>name</i> .
<i>laglist</i>	specifies the list of lags at which the AR terms are to be added. The coefficients of the terms at lags not listed are set to 0. All of the listed lags must be less than or equal to <i>nlag</i> , and there must be no duplicates. If not specified, the <i>laglist</i> defaults to all lags 1 through <i>nlag</i> .
<i>M=method</i>	specifies the estimation method to implement. Valid values of <i>M=</i> are CLS (conditional least squares estimates), ULS (unconditional least squares estimates), and ML (maximum likelihood estimates). <i>M=CLS</i> is the default. Only <i>M=CLS</i> is allowed when more than one equation is specified. The ULS and ML methods are not supported for vector AR models by %AR.
<i>TYPE=V</i>	specifies that the AR process is to be applied to the endogenous variables themselves instead of to the structural residuals of the equations.

Restricted Vector Autoregression

You can control which parameters are included in the process, restricting to 0 those parameters that you do not include. First, use %AR with the DEFER option to declare the variable list and define the dimension of the process. Then, use additional %AR calls to generate terms for selected equations with selected variables at selected lags. For example,

```
proc model data=d;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 2, y1 y2 y3, defer )
```

```

%ar( name, y1, y1 y2 )
%ar( name, y2 y3, , 1 )
fit y1 y2 y3;
run;

```

The error equations produced are as follows:

```

y1 = pred.y1 + name1_1_1*zlag1(y1-name_y1) +
      name1_1_2*zlag1(y2-name_y2) + name2_1_1*zlag2(y1-name_y1) +
      name2_1_2*zlag2(y2-name_y2) ;
y2 = pred.y2 + name1_2_1*zlag1(y1-name_y1) +
      name1_2_2*zlag1(y2-name_y2) + name1_2_3*zlag1(y3-name_y3) ;
y3 = pred.y3 + name1_3_1*zlag1(y1-name_y1) +
      name1_3_2*zlag1(y2-name_y2) + name1_3_3*zlag1(y3-name_y3) ;

```

This model states that the errors for Y1 depend on the errors of both Y1 and Y2 (but not Y3) at both lags 1 and 2, and that the errors for Y2 and Y3 depend on the previous errors for all three variables, but only at lag 1.

%AR Macro Syntax for Restricted Vector AR

An alternative use of %AR is allowed to impose restrictions on a vector AR process by calling %AR several times to specify different AR terms and lags for different equations.

The first call has the general form

```
%AR( name, nlag, endolist , DEFER ) ;
```

where

<i>name</i>	specifies a prefix for %AR to use in constructing names of variables needed to define the vector AR process.
<i>nlag</i>	specifies the order of the AR process.
<i>endolist</i>	specifies the list of equations to which the AR process is to be applied.
DEFER	specifies that %AR is not to generate the AR process but is to wait for further information specified in later %AR calls for the same <i>name</i> value.

The subsequent calls have the general form

```
%AR( name, eqlist, varlist, laglist, TYPE= )
```

where

name is the same as in the first call.

<i>eqlist</i>	specifies the list of equations to which the specifications in this %AR call are to be applied. Only names specified in the <i>endolist</i> value of the first call for the <i>name</i> value can appear in the list of equations in <i>eqlist</i> .
<i>varlist</i>	specifies the list of equations whose lagged structural residuals are to be included as regressors in the equations in <i>eqlist</i> . Only names in the <i>endolist</i> of the first call for the <i>name</i> value can appear in <i>varlist</i> . If not specified, <i>varlist</i> defaults to <i>endolist</i> .
<i>laglist</i>	specifies the list of lags at which the AR terms are to be added. The coefficients of the terms at lags not listed are set to 0. All of the listed lags must be less than or equal to the value of <i>nlag</i> , and there must be no duplicates. If not specified, <i>laglist</i> defaults to all lags 1 through <i>nlag</i> .

The %MA Macro

The SAS macro %MA generates programming statements for PROC MODEL for moving-average models. The %MA macro is part of SAS/ETS software, and no special options are needed to use the macro. The moving-average error process can be applied to the structural equation errors. The syntax of the %MA macro is the same as the %AR macro except there is no TYPE= argument.

When you are using the %MA and %AR macros combined, the %MA macro must follow the %AR macro. The following SAS/IML statements produce an ARMA(1, (1 3)) error process and save it in the data set MADAT2.

```
proc iml;
  phi = { 1 .2 };
  theta = { 1 .3 0 .5 };
  y = armasim( phi, theta, 0, .1, 200, 32565 );
  create madat2 from y[colname='y'];
  append from y;
quit;
```

The following PROC MODEL statements are used to estimate the parameters of this model by using maximum likelihood error structure:

```
title 'Maximum Likelihood ARMA(1, (1 3))';
proc model data=madat2;
  y=0;
  %ar( y, 1, , M=m1 )
  %ma( y, 3, , 1 3, M=m1 ) /* %MA always after %AR */
  fit y;
run;
title;
```

The estimates of the parameters produced by this run are shown in [Figure 19.61](#).

Figure 19.61 Estimates from an ARMA(1, (1 3)) Process

Maximum Likelihood ARMA(1, (1 3))							
The MODEL Procedure							
Nonlinear OLS Summary of Residual Errors							
Equation	DF Model	DF Error	SSE	MSE	Root MSE	R-Square	Adj R-Sq
y	3	197	2.6383	0.0134	0.1157	-0.0067	-0.0169
RESID.y		197	1.9957	0.0101	0.1007		
Nonlinear OLS Parameter Estimates							
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t	Label		
y_l1	-0.10067	0.1187	-0.85	0.3973	AR(y) y lag1 parameter		
y_m1	-0.1934	0.0939	-2.06	0.0408	MA(y) y lag1 parameter		
y_m3	-0.59384	0.0601	-9.88	<.0001	MA(y) y lag3 parameter		

Syntax of the %MA Macro

There are two cases of the syntax for the %MA macro. When restrictions on a vector MA process are not needed, the syntax of the %MA macro has the general form

```
%MA ( name , nlag < , endolist < , laglist >> < , M= method > ) ;
```

where

- | | |
|-----------------|---|
| <i>name</i> | specifies a prefix for %MA to use in constructing names of variables needed to define the MA process and is the default <i>endolist</i> . |
| <i>nlag</i> | is the order of the MA process. |
| <i>endolist</i> | specifies the equations to which the MA process is to be applied. If more than one name is given, CLS estimation is used for the vector process. |
| <i>laglist</i> | specifies the lags at which the MA terms are to be added. All of the listed lags must be less than or equal to <i>nlag</i> , and there must be no duplicates. If not specified, the <i>laglist</i> defaults to all lags 1 through <i>nlag</i> . |
| <i>M=method</i> | specifies the estimation method to implement. Valid values of M= are CLS (conditional least squares estimates), ULS (unconditional least squares estimates), and ML (maximum likelihood estimates). M=CLS is the default. Only M=CLS is allowed when more than one equation is specified in the <i>endolist</i> . |

%MA Macro Syntax for Restricted Vector Moving-Average

An alternative use of %MA is allowed to impose restrictions on a vector MA process by calling %MA several times to specify different MA terms and lags for different equations.

The first call has the general form

```
%MA( name , nlag , endolist , DEFER ) ;
```

where

<i>name</i>	specifies a prefix for %MA to use in constructing names of variables needed to define the vector MA process.
<i>nlag</i>	specifies the order of the MA process.
<i>endolist</i>	specifies the list of equations to which the MA process is to be applied.
DEFER	specifies that %MA is not to generate the MA process but is to wait for further information specified in later %MA calls for the same <i>name</i> value.

The subsequent calls have the general form

```
%MA( name, eqlist, varlist, laglist )
```

where

<i>name</i>	is the same as in the first call.
<i>eqlist</i>	specifies the list of equations to which the specifications in this %MA call are to be applied.
<i>varlist</i>	specifies the list of equations whose lagged structural residuals are to be included as regressors in the equations in <i>eqlist</i> .
<i>laglist</i>	specifies the list of lags at which the MA terms are to be added.

Distributed Lag Models and the %PDL Macro

In the following example, the variable y is modeled as a linear function of x , the first lag of x , the second lag of x , and so forth:

$$y_t = a + b_0 x_t + b_1 x_{t-1} + b_2 x_{t-2} + b_3 x_{t-3} + \dots + b_n x_{t-n}$$

Models of this sort can introduce a great many parameters for the lags, and there may not be enough data to compute accurate independent estimates for them all. Often, the number of parameters is reduced by assuming that the lag coefficients follow some pattern. One common assumption is that the lag coefficients follow a polynomial in the lag length

$$b_i = \sum_{j=0}^d \alpha_j (i)^j$$

where d is the degree of the polynomial used. Models of this kind are called *Almon lag models*, *polynomial distributed lag models*, or *PDLs* for short. For example, Figure 19.62 shows the lag distribution that can be modeled with a low-order polynomial. Endpoint restrictions can be imposed on a PDL to require that the lag coefficients be 0 at the 0th lag, or at the final lag, or at both.

Figure 19.62 Polynomial Distributed Lags

For linear single-equation models, SAS/ETS software includes the PDLREG procedure for estimating PDL models. See Chapter 21, “[The PDLREG Procedure](#),” for a more detailed discussion of polynomial distributed lags and an explanation of endpoint restrictions.

Polynomial and other distributed lag models can be estimated and simulated or forecast with PROC MODEL. For polynomial distributed lags, the %PDL macro can generate the needed programming statements automatically.

The %PDL Macro

The SAS macro %PDL generates the programming statements to compute the lag coefficients of polynomial distributed lag models and to apply them to the lags of variables or expressions.

To use the %PDL macro in a model program, you first call it to declare the lag distribution; later, you call it again to apply the PDL to a variable or expression. The first call generates a PARMS statement for the polynomial parameters and assignment statements to compute the lag coefficients. The second call generates an expression that applies the lag coefficients to the lags of the specified variable or expression. A PDL can be declared only once, but it can be used any number of times (that is, the second call can be repeated).

The initial declaratory call has the general form

%PDL (*pdlname*, *nlags*, *degree* , *R=code* , *OUTEST=dataset*) ;

where *pdlname* is a name (up to 32 characters) that you give to identify the PDL, *nlags* is the lag length, and *degree* is the degree of the polynomial for the distribution. The *R=code* is optional for endpoint restrictions. The value of *code* can be FIRST (for upper), LAST (for lower), or BOTH (for both upper and lower endpoints). See Chapter 21, “[The PDLREG Procedure](#),” for a discussion of endpoint restrictions. The option *OUTEST=dataset* creates a data set that contains the estimates of the parameters and their covariance matrix.

The later calls to apply the PDL have the general form

%PDL(*pdlname*, *expression*)

where *pdlname* is the name of the PDL and *expression* is the variable or expression to which the PDL is to be applied. The *pdlname* given must be the same as the name used to declare the PDL.

The following statements produce the output in [Figure 19.63](#):

```
proc model data=in list;
  parms int pz;
  %pdl(xpdl,5,2);
  y = int + pz * z + %pdl(xpdl,x);
  %ar(y,2,M=ULS);
  id i;
fit y / out=model1 outresid converge=1e-6;
run;
```

Figure 19.63 %PDL Macro Estimates

The MODEL Procedure					
Nonlinear OLS Estimates					
Term	Estimate	Approx Std Err	t Value	Approx Pr > t	Label
XPDL_L0	1.568788	0.0935	16.77	<.0001	PDL(XPDL,5,2) coefficient for lag0
XPDL_L1	0.564917	0.0328	17.22	<.0001	PDL(XPDL,5,2) coefficient for lag1
XPDL_L2	-0.05063	0.0593	-0.85	0.4155	PDL(XPDL,5,2) coefficient for lag2
XPDL_L3	-0.27785	0.0517	-5.37	0.0004	PDL(XPDL,5,2) coefficient for lag3
XPDL_L4	-0.11675	0.0368	-3.17	0.0113	PDL(XPDL,5,2) coefficient for lag4
XPDL_L5	0.43267	0.1362	3.18	0.0113	PDL(XPDL,5,2) coefficient for lag5

This second example models two variables, Y1 and Y2, and uses two PDLs:

```

proc model data=in;
  parms int1 int2;
  %pdl( logxpdl, 5, 3 )
  %pdl( zpdl, 6, 4 )
  y1 = int1 + %pdl( logxpdl, log(x) ) + %pdl( zpdl, z );
  y2 = int2 + %pdl( zpdl, z );
  fit y1 y2;
run;

```

A (5,3) PDL of the log of X is used in the equation for Y1. A (6,4) PDL of Z is used in the equations for both Y1 and Y2. Since the same ZPDL is used in both equations, the lag coefficients for Z are the same for the Y1 and Y2 equations, and the polynomial parameters for ZPDL are shared by the two equations. See [Example 19.5](#) for a complete example and comparison with PDLREG.

Input Data Sets

DATA= Input Data Set

For FIT tasks, the DATA= option specifies which input data set to use in estimating parameters. Variables in the model program are looked up in the DATA= data set and, if found, their attributes (type, length, label, and format) are set to be the same as those in the DATA= data set (if not defined otherwise within PROC MODEL).

ESTDATA= Input Data Set

The ESTDATA= option specifies an input data set that contains an observation that gives values for some or all of the model parameters. The data set can also contain observations that give the rows of a covariance matrix for the parameters.

Parameter values read from the ESTDATA= data set provide initial starting values for parameters estimated. Observations that provide covariance values, if any are present in the ESTDATA= data set, are ignored.

The ESTDATA= data set is usually created by the OUTEST= option in a previous FIT statement. You can also create an ESTDATA= data set with a SAS DATA step program. The data set must contain a numeric variable for each parameter to be given a value or covariance column. The name of the variable in the ESTDATA= data set must match the name of the parameter in the model. Parameters with names longer than 32 characters cannot be set from an ESTDATA= data set. The data set must also contain a character variable _NAME_ of length 32. _NAME_ has a blank value for the observation that gives values to the parameters. _NAME_ contains the name of a parameter for observations that define rows of the covariance matrix.

More than one set of parameter estimates and covariances can be stored in the ESTDATA= data set if the observations for the different estimates are identified by the variable _TYPE_. _TYPE_ must be a character variable of length 8. The TYPE= option is used to select for input the part of the ESTDATA= data set for which the _TYPE_ value matches the value of the TYPE= option.

In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used.

The following SAS statements generate the ESTDATA= data set shown in Figure 19.64. The second FIT statement uses the TYPE= option to select the estimates from the GMM estimation as starting values for the FIML estimation.

```
/* Generate test data */
data gmm2;
  do t=1 to 50;
    x1 = sqrt(t) ;
    x2 = rannor(10) * 10;
    y1 = -.002 * x2 * x2 - .05 / x2 - 0.001 * x1 * x1;
    y2 = 0.002* y1 + 2 * x2 * x2 + 50 / x2 + 5 * rannor(1);
    y1 = y1 + 5 * rannor(1);
    z1 = 1; z2 = x1 * x1; z3 = x2 * x2; z4 = 1.0/x2;
  output;
  end;
run;

proc model data=gmm2 ;
  exogenous x1 x2;
  parms a1 a2 b1 2.5 b2 c2 55 d1;
  inst b1 b2 c2 x1 x2;
  y1 = a1 * y2 + b1 * x1 * x1 + d1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;

  fit y1 y2 / 3sls gmm kernel=(qs,1,0.2) outest=gmmest;

  fit y1 y2 / fiml type=gmm estdata=gmmest;
run;

proc print data=gmmest;
run;
```

Figure 19.64 ESTDATA= Data Set

		—		S		—

2	GMM	0	Converged	50	-.001772196	-1.02345	0.014025	1.99726	49.8648	-0.87573	

MISSING=PAIRWISE | DELETE

When missing values are encountered for any one of the equations in a system of equations, the default action is to drop that observation for all of the equations. The new MISSING=PAIRWISE option in the FIT statement provides a different method of handling missing values that avoids losing data for nonmissing equations for the observation. This is especially useful for SUR estimation on equations with unequal numbers of observations.

The option MISSING=PAIRWISE specifies that missing values are tracked on an equation-by-equation basis. The MISSING=DELETE option specifies that the entire observation is omitted from the analysis when any equation has a missing predicted or actual value for the equation. The default is MISSING=DELETE.

When you specify the MISSING=PAIRWISE option, the **S** matrix is computed as

$$\mathbf{S} = \mathbf{D}(\mathbf{R}'\mathbf{R})\mathbf{D}$$

where **D** is a diagonal matrix that depends on the VARDEF= option, the matrix **R** is $(\mathbf{r}_1, \dots, \mathbf{r}_g)$, and \mathbf{r}_i is the vector of residuals for the i th equation with r_{ij} replaced with zero when r_{ij} is missing.

For MISSING=PAIRWISE, the calculation of the diagonal element $d_{i,i}$ of **D** is based on n_i , the number of nonmissing observations for the i th equation, instead of on n . Similarly, for VARDEF=WGT or WDF, the calculation is based on the sum of the weights for the nonmissing observations for the i th equation instead of on the sum of the weights for all observations. See the description of the VARDEF= option for the definition of **D**.

The degrees-of-freedom correction for a shared parameter is computed by using the average number of observations used in its estimation.

The MISSING=PAIRWISE option is not valid for the GMM and FIML estimation methods.

For the instrumental variables estimation methods (2SLS, 3SLS), when an instrument is missing for an observation, that observation is dropped for all equations, regardless of the MISSING= option.

PARMSDATA= Input Data Set

The option PARMSDATA= reads values for all parameters whose names match the names of variables in the PARMSDATA= data set. Values for any or all of the parameters in the model can be reset by using the PARMSDATA= option. The PARMSDATA= option goes in the PROC MODEL statement, and the data set is read before any FIT or SOLVE statements are executed.

In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used. Together, the OUTPARMS= and PARMSDATA= options enable you to change part of a model and recompile the new model program without the need to reestimate equations that were not changed.

Suppose you have a large model with parameters estimated and you now want to replace one equation, Y , with a new specification. Although the model program must be recompiled with the new equation, you don't need to reestimate all the equations, just the one that changed.

Using the OUTPARMS= and PARMSDATA= options, you could do the following:

```
proc model model=oldmod outparms=temp; run;
proc model outmodel=newmod parmsdata=temp data=in;
    ... include new model definition with changed y eq. here ...
fit y;
run;
```

The model file NEWMOD then contains the new model and its estimated parameters plus the old models with their original parameter values.

SDATA= Input Data Set

The SDATA= option allows a cross-equation covariance matrix to be input from a data set. The **S** matrix read from the SDATA= data set, specified in the FIT statement, is used to define the objective function for the OLS, N2SLS, SUR, and N3SLS estimation methods and is used as the initial **S** for the methods that iterate the **S** matrix.

Most often, the SDATA= data set has been created by the OUTS= or OUTSUSED= option in a previous FIT statement. The OUTS= and OUTSUSED= data sets from a FIT statement can be read back in by a FIT statement in the same PROC MODEL step.

You can create an input SDATA= data set by using the DATA step. PROC MODEL expects to find a character variable `_NAME_` in the SDATA= data set as well as variables for the equations in the estimation or solution. For each observation with a `_NAME_` value that matches the name of an equation, PROC MODEL fills the corresponding row of the **S** matrix with the values of the names of equations found in the data set. If a row or column is omitted from the data set, a 1 is placed on the diagonal for the row or column. Missing values are ignored, and since the **S** matrix is symmetric, you can include only a triangular part of the **S** matrix in the SDATA= data set with the omitted part indicated by missing values. If the SDATA= data set contains multiple observations with the same `_NAME_`, the last values supplied for the `_NAME_` are used. The structure of the expected data set is further described in the section “[OUTS= Data Set](#)” on page 1189.

Use the TYPE= option in the PROC MODEL or FIT statement to specify the type of estimation method used to produce the **S** matrix you want to input.

The following SAS statements are used to generate an **S** matrix from a GMM and a 3SLS estimation and to store that estimate in the data set GMMS:

```
proc model data=gmm2 ;
    exogenous x1 x2;
    parms a1 a2 b1 2.5 b2 c2 55 d1;
    inst b1 b2 c2 x1 x2;
    y1 = a1 * y2 + b1 * x1 * x1 + d1;
    y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;

    fit y1 y2 / 3s1s gmm kernel=(qs,1,0.2)
                outest=gmmest outs=gmmns;
run;
```

```
proc print data=gmmms;
run;
```

The data set GMMS is shown in Figure 19.65.

Figure 19.65 SDATA= Data Set

Obs	_NAME_	_TYPE_	_NUSED_	y1	y2
1	y1	3SLS	50	27.1032	38.1599
2	y2	3SLS	50	38.1599	74.6253
3	y1	GMM	50	27.6248	32.2811
4	y2	GMM	50	32.2811	58.8387

VDATA= Input data set

The VDATA= option enables a variance matrix for GMM estimation to be input from a data set. When the VDATA= option is used in the PROC MODEL or FIT statement, the matrix that is input is used to define the objective function and is used as the initial **V** for the methods that iterate the **V** matrix.

Normally the VDATA= matrix is created from the OUTV= option in a previous FIT statement. Alternately an input VDATA= data set can be created by using the DATA step. Each row and column of the **V** matrix is associated with an equation and an instrument. The position of each element in the **V** matrix can then be indicated by an equation name and an instrument name for the row of the element and an equation name and an instrument name for the column. Each observation in the VDATA= data set is an element in the **V** matrix. The row and column of the element are indicated by four variables (EQ_ROW, INST_ROW, EQ_COL, and INST_COL) that contain the equation name or instrument name. The variable name for an element is VALUE. Missing values are set to 0. Because the variance matrix is symmetric, only a triangular part of the matrix needs to be input.

The following SAS statements are used to generate a **V** matrix estimation from GMM and to store that estimate in the data set GMMV:

```
proc model data=gmm2;
  exogenous x1 x2;
  parms a1 a2 b2 b1 2.5 c2 55 d1;
  inst b1 b2 c2 x1 x2;
  y1 = a1 * y2 + b1 * x1 * x1 + d1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;

  fit y1 y2 / gmm outv=gmmv;
run;
proc print data=gmmv (obs=15);
run;
```

The data set GMM2 was generated by the example in the preceding ESTDATA= section. The **V** matrix stored in GMMV is selected for use in an additional GMM estimation by the following FIT statement:

```
fit y1 y2 / gmm vdata=gmmv;
run;
```

A partial listing of the GMMV data set is shown in Figure 19.66. There are a total of 78 observations in this data set. The **V** matrix is 12 by 12 for this example.

Figure 19.66 The First 15 Observations in the VDATA= Data Set

Obs	_TYPE_	EQ_ROW	EQ_COL	INST_ROW	INST_COL	VALUE

Output Data Sets

OUT= Data Set

For normalized form equations, the OUT= data set specified in the FIT statement contains residuals, actuals, and predicted values of the dependent variables computed from the parameter estimates. For general form equations, actual values of the endogenous variables are copied for the residual and predicted values.

The variables in the data set are as follows:

- BY variables
- RANGE variable
- ID variables
- _ESTYPE_, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, ITSUR, IT2SLS, IT3SLS, GMM, ITGMM, or FIML
- _TYPE_, a character variable of length 8 that identifies the type of observation: RESIDUAL, PREDICT, or ACTUAL
- _WEIGHT_, the weight of the observation in the estimation. The _WEIGHT_ value is 0 if the observation was not used. It is equal to the product of the _WEIGHT_ model program variable and the variable named in the WEIGHT statement, if any, or 1 if weights were not used.
- the WEIGHT statement variable if used

- the model variables. The dependent variables for the normalized form equations in the estimation contain residuals, actuals, or predicted values, depending on the `_TYPE_` variable, whereas the model variables that are not associated with estimated equations always contain actual values from the input data set.
- any other variables named in the `OUTVARS` statement. These can be program variables computed by the model program, `CONTROL` variables, parameters, or special variables in the model program.

The following SAS statements are used to generate and print an `OUT=` data set:

```
proc model data=gmm2;
  exogenous x1 x2;
  parms a1 a2 b1 b2 2.5 c2 55 d1;
  inst b1 b2 c2 x1 x2;
  y1 = a1 * y2 + b1 * x1 * x1 + d1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;

  fit y1 y2 / 3sls gmm out=resid outall ;
run;
proc print data=resid(obs=20);
run;
```

The data set `GMM2` was generated by the example in the preceding `ESTDATA=` section above. A partial listing of the `RESID` data set is shown in [Figure 19.67](#).

OUTEST= Data Set

The OUTEST= data set contains parameter estimates and, if requested, estimates of the covariance of the parameter estimates.

The variables in the data set are as follows:

- BY variables
- `_NAME_`, a character variable of length 32, blank for observations that contain parameter estimates or a parameter name for observations that contain covariances
- `_TYPE_`, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, ITSUR, IT2SLS, IT3SLS, GMM, ITGMM, or FIML
- `_STATUS_`, variable that gives the convergence status of estimation. `_STATUS_` = 0 when convergence criteria are met, = 1 when estimation converges with a note, = 2 when estimation converges with a warning, and = 3 when estimation fails to converge
- `_NUSED_`, the number of observations used in estimation
- the parameters estimated

If the COVOUT option is specified, an additional observation is written for each row of the estimate of the covariance matrix of parameter estimates, with the `_NAME_` values that contain the parameter names for the rows. Parameter names longer than 32 characters are truncated.

OUTPARMS= Data Set

The option OUTPARMS= writes all the parameter estimates to an output data set. This output data set contains one observation and is similar to the OUTEST= data set, but it contains all the parameters, is not associated with any FIT task, and contains no covariances. The OUTPARMS= option is used in the PROC MODEL statement, and the data set is written at the end, after any FIT or SOLVE steps have been performed.

OUTS= Data Set

The OUTS= SAS data set contains the estimate of the covariance matrix of the residuals across equations. This matrix is formed from the residuals that are computed by using the parameter estimates.

The variables in the OUTS= data set are as follows:

- BY variables
- `_NAME_`, a character variable that contains the name of the equation
- `_TYPE_`, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, ITSUR, IT2SLS, IT3SLS, GMM, ITGMM, or FIML

- variables with the names of the equations in the estimation

Each observation contains a row of the covariance matrix. The data set is suitable for use with the `SDATA=` option in a subsequent `FIT` or `SOLVE` statement. (See the section “[Tests on Parameters](#)” on page 1156 in this chapter for an example of the `SDATA=` option.)

OUTSUSED= Data Set

The `OUTSUSED=` SAS data set contains the covariance matrix of the residuals across equations that is used to define the objective function. The form of the `OUTSUSED=` data set is the same as that for the `OUTS=` data set.

Note that `OUTSUSED=` is the same as `OUTS=` for the estimation methods that iterate the **S** matrix (ITOLS, IT2SLS, ITSUR, and IT3SLS). If the `SDATA=` option is specified in the `FIT` statement, `OUTSUSED=` is the same as the `SDATA=` matrix read in for the methods that do not iterate the **S** matrix (OLS, SUR, N2SLS, and N3SLS).

OUTV= Data Set

The `OUTV=` data set contains the estimate of the variance matrix, **V**. This matrix is formed from the instruments and the residuals that are computed by using the final parameter estimates obtained from the estimation method chosen.

An estimate of **V** obtained from 2SLS is used in GMM estimation. Hence if you input the dataset obtained from the `OUTV` statement in 2SLS into the `VDATA` statement while fitting GMM, you get the same result by fitting GMM directly without specifying the `VDATA` option.

ODS Table Names

PROC MODEL assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 19.4 ODS Tables Produced in PROC MODEL

ODS Table Name	Description	Option
ODS Tables Created by the FIT Statement		
AugGMMCovariance	Crossproducts matrix	GMM ITALL
ChowTest	Structural change test	CHOW=
CollinDiagnostics	Collinearity diagnostics	
ConfInterval	Profile likelihood confidence intervals	PRL=
ConvCrit	Convergence criteria for estimation	default

Table 19.4 (continued)

ODS Table Name	Description	Option
ConvergenceStatus	Convergence status	default
CorrB	Correlations of parameters	COVB/CORRB
CorrResiduals	Correlations of residuals	CORRS/COVS
CovB	Covariance of parameters	COVB/CORRB
CovResiduals	Covariance of residuals	CORRS/COVS
Crossproducts	Crossproducts matrix	ITALL/ITPRINT
DatasetOptions	Data sets used	default
DetResidCov	Determinant of the residuals	DETAILS
DWTest	Durbin Watson test	DW=
Equations	Listing of equations to estimate	default
EstSummaryMiss	Model summary statistics for PAIRWISE	MISSING=
EstSummaryStats	Objective, objective * N	default
FirstLagrMultEst	First order Lagrange Multiplier estimates	GMM ITALL
GMMCovariance	Crossproducts matrix	GMM DETAILS
GMMTestStats	GMM test statistics	GMM
Godfrey	Godfrey's serial correlation test	GF=
HausmanTest	Hausman's test table	HAUSMAN
HeteroTest	Heteroscedasticity test tables	BREUSCH/PAGEN
InvXPXMat	X'X inverse for system	I
IterInfo	Iteration printing	ITALL/ITPRINT
LagLength	Model lag length	default
MinSummary	Number of parameters, estimation kind	default
ModSummary	Listing of all categorized variables	default
ModVars	Listing of model variables and parameters	default
NormalityTest	Normality test table	NORMAL
ObsSummary	Identifies observations with errors	default
ObsUsed	Observations read, used, and missing.	default
ParameterEstimates	Parameter estimates	default
ParmChange	Parameter change vector	ITALL
ResidSummary	Summary of the SSE, MSE for the equations	default
SecondLagrMultEst	Second order Lagrange Multiplier estimates	GMM ITALL
SizeInfo	Storage requirement for estimation	DETAILS
TermEstimates	Nonlinear OLS and ITOLS Estimates	OLS/ITOLS
TestResults	Test statement table	
WgtVar	The name of the weight variable

SortAdjacencyMatrix	Sorted adjacency graph	GRAPH
TransitiveClosure	Transitive closure graph	GRAPH

The AugGMMCovariance table is the **V** matrix augmented with the moment vector at iteration zero, produced when the ITALL option is used with the GMM option. If the **V** matrix to be used in GMM is read in by the VDATA option, then AugGMMCovariance would be the same matrix augmented with the moment vectors. The GMMCovariance ODS output is produced only when you read in a covariance matrix to be used in the GMM method. This table is produced by using DETAILS option with the GMM option.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#)” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the MODEL procedure.

ODS Graph Names

PROC MODEL assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when you use ODS. The names are listed in [Table 19.5](#).

To request these graphs, ODS Graphics must be enabled.

Table 19.5 ODS Graphics Produced by PROC MODEL

ODS Graph Name	Plot Description
ACFPlot	Autocorrelation of residuals
ActualByPredicted	Predicted versus actual plot
CooksD	Cook’s D plot
DiagnosticsPanel	Panel of all plots
IACFPlot	Inverse autocorrelation of residuals
QQPlot	Q-Q plot of residuals
PACFPlot	Partial autocorrelation of residuals
ResidualHistogram	Histogram of the residuals
StudentResidualPlot	Studentized residual plot

Details: Simulation by the MODEL Procedure

The *solution*, given the vector \mathbf{k} , of the following nonlinear system of equations is the vector \mathbf{u} that satisfies this equation:

$$\mathbf{q}(\mathbf{u}, \mathbf{k}, \boldsymbol{\theta}) = 0$$

A *simulation* is a set of solutions \mathbf{u}_t for a specific sequence of vectors \mathbf{k}_t .

Model simulation can be performed to do the following:

- check how well the model predicts the actual values over the historical period
- investigate the sensitivity of the solution to changes in the input values or parameters
- examine the dynamic characteristics of the model
- check the stability of the simultaneous solution

- estimate the statistical distribution of the predicted values of the nonlinear model using Monte Carlo methods

By combining the various solution modes with different input data sets, model simulation can answer many different questions about the model. This section presents details of model simulation and solution.

Solution Modes

The following solution modes are commonly used:

- The *dynamic simultaneous forecast* mode is used for forecasting with the model. Collect the historical data on the model variables, the future assumptions of the exogenous variables, and any prior information on the future endogenous values, and combine them in a SAS data set. Use the FORECAST option in the SOLVE statement.
- The *dynamic simultaneous simulation* mode is often called *ex post simulation*, *historical simulation*, or *ex post forecasting*. Use the DYNAMIC option. This mode is the default.
- The *static simultaneous simulation* mode can be used to examine the within-period performance of the model without the complications of previous period errors. Use the STATIC option.
- The *NAHEAD=n dynamic simultaneous simulation* mode can be used to see how well *n*-period-ahead forecasting would have performed over the historical period. Use the NAHEAD=*n* option.

The different solution modes are explained in detail in the following sections.

Dynamic and Static Simulations

In model simulation, either solved values or actual values from the data set can be used to supply lagged values of an endogenous variable. A *dynamic* solution refers to a solution obtained by using only solved values for the lagged values. Dynamic mode is used both for forecasting and for simulating the dynamic properties of the model.

A *static* solution refers to a solution obtained by using the actual values when available for the lagged endogenous values. Static mode is used to simulate the behavior of the model without the complication of previous period errors. Dynamic simulation is the default.

If you want to use static values for lags only for the first *n* observations, and dynamic values thereafter, specify the START=*n* option. For example, if you want a dynamic simulation to start after observation twenty-four, specify START=24 on the SOLVE statement. If the model being simulated had a value lagged for four time periods, then this value would start using dynamic values when the simulation reached observation number 28.

***n*-Period-Ahead Forecasting**

Suppose you want to regularly forecast 12 months ahead and produce a new forecast each month as more data becomes available. *n*-period-ahead forecasting allows you to test how well you would have done over time if you had been using your model to forecast one year ahead.

To see how well a model predicts *n* time periods in the future, perform an *n*-period-ahead forecast on real data and compare the forecast values with the actual values.

n-period-ahead forecasting refers to using dynamic values for the lagged endogenous variables only for lags 1 through *n*–1. For example, one-period-ahead forecasting, specified by the NAHEAD=1 option in the SOLVE statement, is the same as if a static solution had been requested. Specifying NAHEAD=2 produces a solution that uses dynamic values for lag one and static, actual, values for longer lags.

The following example is a two-year-ahead dynamic simulation. The output is shown in [Figure 19.68](#).

```
data yearly;
  input year x1 x2 x3 y1 y2 y3;
  datalines;
84 4 9 0 7 4 5
85 5 6 1 1 27 4
86 3 8 2 5 8 2
87 2 10 3 0 10 10
88 4 7 6 20 60 40
89 5 4 8 40 40 40
90 3 2 10 50 60 60
91 2 5 11 40 50 60
;
run;

proc model data=yearly outmodel=yearlyModel;
  endogenous y1 y2 y3;
  exogenous x1 x2 x3;

  y1 = 2 + 3*x1 - 2*x2 + 4*x3;
  y2 = 4 + lag2( y3 ) + 2*y1 + x1;
  y3 = lag3( y1 ) + y2 - x2;

  solve y1 y2 y3 / nahead=2 out=c;
run;

proc print data=c;
run;
```

Figure 19.68 NAHEAD Summary Report

The C data set is shown in [Figure 19.69](#):

Figure 19.69 C Data Set

Obs	_TYPE_	_MODE_	_LAG_	_ERRORS_	y1	y2	y3	x1	x2	x3
1	PREDICT	SIMULATE	0	0	0	10	7	2	10	3
2	PREDICT	SIMULATE	1	0	24	58	52	4	7	6
3	PREDICT	SIMULATE	1	0	41	101	102	5	4	8
4	PREDICT	SIMULATE	1	0	47	141	139	3	2	10
5	PREDICT	SIMULATE	1	0	42	130	145	2	5	11

The preceding two-year-ahead simulation can be emulated without using the NAHEAD= option by the following PROC MODEL statements:

```
proc model data=yearly model=yearlyModel;
  range year = 87 to 88;
  solve y1 y2 y3 / dynamic solveprint;
run;

  range year = 88 to 89;
  solve y1 y2 y3 / dynamic solveprint;
run;

  range year = 89 to 90;
  solve y1 y2 y3 / dynamic solveprint;
run;

  range year = 90 to 91;
  solve y1 y2 y3 / dynamic solveprint;
```

The totals shown under “Observations Processed” in Figure 19.68 are equal to the sum of the four individual runs.

Simulation and Forecasting

You can perform a simulation of your model or use the model to produce forecasts. *Simulation* refers to the determination of the endogenous or dependent variables as a function of the input values of the other variables, even when actual data for some of the solution variables are available in the input data set. The simulation mode is useful for verifying the fit of the model parameters. Simulation is selected by the SIMULATE option in the SOLVE statement. Simulation mode is the default.

In forecast mode, PROC MODEL solves only for those endogenous variables that are missing in the data set. The actual value of an endogenous variable is used as the solution value whenever nonmissing data for it is available in the input data set. Forecasting is selected by the FORECAST option in the SOLVE statement.

For example, an econometric forecasting model can contain an equation to predict future tax rates, but tax rates are usually set in advance by law. Thus, for the first year or so of the forecast, the predicted tax rate should really be exogenous. Or, you might want to use a prior forecast of a certain variable from a short-run forecasting model to provide the predicted values for the earlier periods of a longer-range forecast of a long-run model. A common situation in forecasting is when historical data needed to fill the initial lags of a dynamic model are available for some of the variables but have not yet been obtained for others. In this case, the forecast must start in the past to supply the missing initial lags. Clearly, you should use the actual data that are available for the lags. In all the preceding cases, the forecast should be produced by running the model in the FORECAST mode; simulating the model over the future periods would not be appropriate.

Monte Carlo Simulation

The accuracy of the forecasts produced by PROC MODEL depends on four sources of error (Pindyck and Rubinfeld 1981, 405–406):

- The system of equations contains an implicit random error term ϵ

$$\mathbf{g}(\mathbf{y}, \mathbf{x}, \hat{\boldsymbol{\theta}}) = \boldsymbol{\epsilon}$$

where \mathbf{y} , \mathbf{x} , \mathbf{g} , $\hat{\boldsymbol{\theta}}$, and $\boldsymbol{\epsilon}$ are vector valued.

- The estimated values of the parameters, $\hat{\boldsymbol{\theta}}$, are themselves random variables.
- The exogenous variables might have been forecast themselves and therefore might contain errors.
- The system of equations might be incorrectly specified; the model only approximates the process modeled.

The RANDOM= option is used to request Monte Carlo (or stochastic) simulations to generate confidence intervals for errors that arise from the first two sources. The Monte Carlo simulations can be performed with $\boldsymbol{\epsilon}$, $\boldsymbol{\theta}$, or both vectors represented as random variables. The SEED= option is used to control the random

number generator for the simulations. SEED=0 forces the random number generator to use the system clock as its seed value.

In Monte Carlo simulations, repeated simulations are performed on the model for random perturbations of the parameters and the additive error term. The random perturbations follow a multivariate normal distribution with expected value of 0 and covariance described by a covariance matrix of the parameter estimates in the case of θ , or a covariance matrix of the equation residuals for the case of ϵ . PROC MODEL can generate both covariance matrices or you can provide them.

The ESTDATA= option specifies a data set that contains an estimate of the covariance matrix of the parameter estimates to use for computing perturbations of the parameters. The ESTDATA= data set is usually created by the FIT statement with the OUTEST= and OUTCOV options. When the ESTDATA= option is specified, the matrix read from the ESTDATA= data set is used to compute vectors of random shocks or perturbations for the parameters. These random perturbations are computed at the start of each repetition of the solution and added to the parameter values. The perturbed parameters are fixed throughout the solution range. If the covariance matrix of the parameter estimates is not provided, the parameters are not perturbed.

The SDATA= option specifies a data set that contains the covariance matrix of the residuals to use for computing perturbations of the equations. The SDATA= data set is usually created by the FIT statement with the OUTS= option. When SDATA= is specified, the matrix read from the SDATA= data set is used to compute vectors of random shocks or perturbations for the equations. These random perturbations are computed at each observation. The simultaneous solution satisfies the model equations plus the random shocks. That is, the solution is not a perturbation of a simultaneous solution of the structural equations; rather, it is a simultaneous solution of the stochastic equations by using the simulated errors. If the SDATA= option is not specified, the random shocks are not used.

The different random solutions are identified by the _REP_ variable in the OUT= data set. An unperturbed solution with _REP_=0 is also computed when the RANDOM= option is used. RANDOM= n produces $n + 1$ solution observations for each input observation in the solution range. If the RANDOM= option is not specified, the SDATA= and ESTDATA= options are ignored, and no Monte Carlo simulation is performed.

PROC MODEL does not have an automatic way of modeling the exogenous variables as random variables for Monte Carlo simulation. If the exogenous variables have been forecast, the error bounds for these variables should be included in the error bounds generated for the endogenous variables. If the models for the exogenous variables are included in PROC MODEL, then the error bounds created from a Monte Carlo simulation contain the uncertainty due to the exogenous variables.

Alternatively, if the distribution of the exogenous variables is known, the built-in random number generator functions can be used to perturb these variables appropriately for the Monte Carlo simulation. For example, if you know the forecast of an exogenous variable, X, has a standard error of 5.2 and the error is normally distributed, then the following statements can be used to generate random values for X:

```
x_new = x + 5.2 * rannor(456);
```

During a Monte Carlo simulation, the random number generator functions produce one value at each observation. It is important to use a different seed value for all the random number generator functions in the model program; otherwise, the perturbations will be correlated. For the unperturbed solution, _REP_=0, the random number generator functions return 0.

PROC UNIVARIATE can be used to create confidence intervals for the simulation (see the Monte Carlo simulation example in the section “[Getting Started: MODEL Procedure](#)” on page 1029).

Multivariate t Distribution Simulation

To perform a Monte Carlo analysis of models that have residuals distributed as a multivariate t , use the ERRORMODEL statement with either the $\sim t(\text{variance}, df)$ option or with the CDF= $t(\text{variance}, df)$ option. The CDF= option specifies the distribution that is used for simulation so that the estimation can be done for one set of distributional assumptions and the simulation for another.

The following is an example of estimating and simulating a system of equations with t distributed errors by using the ERRORMODEL statement.

```
/* generate simulation data set */
data five;
  set xfrate end=last;
  if last then do;
    todate = date +5;
    do date = date to todate;
      output;
    end;
  end;
run;
```

The preceding DATA step generates the data set to request a five-days-ahead forecast. The following statements estimate and forecast the three forward-rate models of the following form.

$$\begin{aligned} rate_t &= rate_{t-1} + \mu * rate_{t-1} + v \\ v &= \sigma * rate_{t-1} * \epsilon \\ \epsilon &\sim N(0, 1) \end{aligned}$$

```
title "Daily Multivariate Geometric Brownian Motion Model "
      "of D-Mark/USDollar Forward Rates";
```

```
proc model data=xfrate;

  parms df 15;          /* Give initial value to df */

  demusd1m = lag(demusd1m) + mu1m * lag(demusd1m);
  var_demusd1m = sigma1m ** 2 * lag(demusd1m **2);
  demusd3m = lag(demusd3m) + mu3m * lag(demusd3m);
  var_demusd3m = sigma3m ** 2 * lag(demusd3m ** 2);
  demusd6m = lag(demusd6m) + mu6m * lag(demusd6m);
  var_demusd6m = sigma6m ** 2 * lag(demusd6m ** 2);

  /* Specify the error distribution */
  errormodel demusd1m demusd3m demusd6m
    ~ t( var_demusd1m var_demusd3m var_demusd6m, df );
```

```

        /* output normalized S matrix */
        fit demusd1m demusd3m demusd6m / outsn=s;
run;

        /* forecast five days in advance */
        solve demusd1m demusd3m demusd6m /
            data=five sdata=s random=1500 out=monte;
        id date;
run;

        /* select out the last date ---*/
        data monte; set monte;
        if date = '10dec95'd then output;
run;

title "Distribution of demusd1m Five Days Ahead";
proc univariate data=monte noprint;
    var demusd1m;
    histogram demusd1m /
        normal(noprint color=red)
        kernel(noprint color=blue) cfill=ligr;
run;

```

The Monte Carlo simulation specified in the preceding example draws from a multivariate t distribution with constant degrees of freedom and forecasted variance, and it computes future states of DEMUSD1M, DEMUSD3M, and DEMUSD6M. The OUTSN= option in the FIT statement is used to specify the data set for the normalized Σ matrix. That is, the Σ matrix is created by crossing the normally distributed residuals. The normally distributed residuals are created from the t distributed residuals by using the normal inverse CDF and the t CDF. This matrix is a correlation matrix.

The distribution of DEMUSD1M on the fifth day is shown in the [Figure 19.70](#). The two curves overlaid on the graph are a kernel density estimation and a normal distribution fit to the results.

Figure 19.70 Distribution of DEMUSD1M

Alternate Distribution Simulation

As an alternate to the normal distribution, the `ERRORMODEL` statement can be used in a simulation to specify other distributions. The distributions available for simulation are Cauchy, chi-squared, F , Poisson, t , and uniform. An empirical distribution can also be used if the residuals are specified by using the `RESIDDATA=` option in the `SOLVE` statement.

Except for the t distribution, all of these alternate distributions are univariate but can be used together in a multivariate simulation. The `ERRORMODEL` statement applies to solved for equations only. That is, the normal form or general form equation referred to by the `ERRORMODEL` statement must be one of the equations you have selected in the `SOLVE` statement.

In the following example, two Poisson distributed variables are used to simulate the calls that arrive at and leave a call center.

```
data s;      /* Covariance between arriving and leaving */
  arriving = 1; leaving = 0.7; _name_ = "arriving";
```

```

    output;
    arriving = 0.7; leaving = 1.0; _name_ = "leaving";
    output;
run;

data calls;
    date = '20mar2001'd;
    output;
run;

```

The first DATA step generates a data set that contains a covariance matrix for the ARRIVING and LEAVING variables. The covariance is

$$\begin{vmatrix} 1 & .7 \\ .7 & 1 \end{vmatrix}$$

The following statements create the number of waiting clients data:

```

proc model data=calls;
    arriving = 0;
    errormodel arriving ~ poisson( 10 );
    leaving = 4;
    errormodel leaving ~ poisson( 11 );

    waiting = arriving - leaving;
    if waiting < 0 then waiting=0;
    outvars waiting;

    solve arriving leaving / random=500 sdata=s out=sim;
run;

title "Distribution of Clients Waiting";
proc univariate data=sim noprint;
    var waiting ;
    histogram waiting / cfill=ligr;
run;

```

The distribution of number of waiting clients is shown in [Figure 19.71](#).

Figure 19.71 Distribution of Number of Clients Waiting

Mixtures of Distributions—Copulas

The theory of copulas is what enables the MODEL procedure to combine and simulate multivariate distributions with different marginals. This section provides a brief overview of copulas.

Modeling a system of variables accurately is a difficult task. The underlying, ideal, distributional assumptions for each variable are usually different from each other. An individual variable might be best modeled as a t distribution or as a Poisson process. The correlation of the various variables are very important to estimate as well. A joint estimation of a set of variables would make it possible to estimate a correlation structure but would restrict the modeling to single, simple multivariate distribution (for example, the normal). Even with a simple multivariate distribution, the joint estimation would be computationally difficult and would have to deal with issues of missing data.

By using the MODEL procedure ERRORMODEL statement, you can combine and simulate from models of different distributions. The covariance matrix for the combined model is constructed by using the copula induced by the multivariate normal distribution. A copula is a function that couples joint distributions to their marginal distributions.

By default, the copula used in the MODEL procedure is based on the multivariate normal. This particular multivariate normal has zero mean and covariance matrix \mathbf{R} . The user provides \mathbf{R} , which can be created by using the following steps:

1. Each model is estimated separately and their residuals are saved.
2. The residuals for each model are converted to a normal distribution by using their CDFs, $F_i(\cdot)$, using the relationship $\Phi^{-1}(F(\epsilon_{it}))$.
3. These normal residuals are crossed to create a covariance matrix \mathbf{R} .

If the model of interest can be estimated jointly, such as multivariate T, then the OUTSN= option can be used to generate the correct covariance matrix.

A draw from this mixture of distributions is created by using the following steps that are performed automatically by the MODEL procedure.

1. Independent $N(0, 1)$ variables are generated.
2. These variables are transformed to a correlated set by using the covariance matrix \mathbf{R} .
3. These correlated normals are transformed to a uniform by using $\Phi(\cdot)$.
4. $F^{-1}(\cdot)$ is used to compute the final sample value.

Alternate Copulas

The Gaussian, t , and the normal mixture copula are available in the MODEL procedure. These copulas support asymmetric parameters and can use alternate estimation methods for creating the base covariance matrix.

The normal (Gaussian) copula is the default. A draw from a Gaussian copula is obtained from

$$\mathbf{x} = \mathbf{A}\mathbf{z}$$

where $\mathbf{z} \in R^d$ is a vector of independent random normal(0, 1) draws, $\mathbf{A} \in R^{d \times d}$ is the square root of the covariance matrix, \mathbf{R} . For the normal mixture and t copula, a draw is created as

$$\mathbf{x} = w\boldsymbol{\gamma} + \sqrt{w}\mathbf{A}\mathbf{z}$$

where w is a scalar random variable and $\boldsymbol{\gamma} \in R^d$ is a vector of asymmetry parameters. $\boldsymbol{\gamma}$ is specified in the SDATA= data set. If $W \sim \text{inverse gamma}(df/2, df/2)$, then \mathbf{x} is multivariate t or skewed t if $\boldsymbol{\gamma}$ is provided. When NORMALMIX is specified, w is distributed as a step function with each of the n positive variances, $v_1 \dots v_n$, having probability $p_1 \dots p_n$.

The covariance matrix $\mathbf{R} = \mathbf{A}'\mathbf{A}$ is specified with the SDATA= option. The vector of asymmetry parameters, $\boldsymbol{\gamma}$, defaults to zero or is specified in the SDATA= data set with _TYPE_=ASYM. The ASYM option specifies that the nonzero asymmetry vector, $\boldsymbol{\gamma}$, is to be used.

The actual draw for an individual variable, y_i , depends on the marginal distribution of the variable, \tilde{F} , and the chosen copula F as

$$y_i = \tilde{F}_i^{-1}(F(x_i))$$

Asymmetrical Copula Example

In this example, an asymmetrical t copula is used to correlate two uniform distributions. The asymmetrical parameter is varied over a range of values to demonstrate its effect. The resulting graphs is produced by using ODS graphics.

```
data histdata;
  do asym = -1.3 to 1.1 by .3;
    date='01aug2007'd;
    y = .5;
    z = .5;
    output;
  end;
run ;

/* Add the asymmetric parameter to cov mat */
data asym;
  do asym = -1.3 to 1.1 by .3;
    y = asym;
    z = 0;
    _name_ = "      ";
    _type_ = "asym";
    output;
    y = 1;
    z = .65;
    _name_ = "y";
    _type_ = "cov";
    output;
    y = .65;
    z = 1;
    _name_ = "z";
    _type_ = "cov";
    output;
  end;
run;

proc model out=sim(where=( _REP_ > 0 )) data=histdata sdata=asym;
  y = 0;
  errormodel y ~ Uniform(0,1);

  z = 0;
  errormodel z ~ Uniform(0,1);

  solve y z / random=500 seed=12345 copula=(t(5) asym );
  by asym;
run;
```

To produce a panel plot of this joint distribution, use the following SAS/GRAPH statements.

```
ods graphics on / height=800 width=800;
proc template;
  define statgraph myplot.panel;
    BeginGraph;
```

```

entrytitle halign=left halign=center
      textattrs=GRAPHTITLETEXT "t Copula with a Range of Asymmetry";

layout datapanel classvars=(asym) / rows=3 columns=3
      order=rowmajor height=1024 width=1420
      rowaxisopts=(griddisplay=on label=' ')
      columnaxisopts=(griddisplay=on label=' ');
      layout prototype;
      scatterplot x=z y=y ;
      endlayout;
endlayout;
EndGraph;
end;
run;

proc sgrender data=sim template='myplot.panel';
run;

```

Figure 19.72 *t* Copula with Asymmetry

Quasi-Random Number Generators

Traditionally high-discrepancy pseudo-random number generators are used to generate innovations in Monte Carlo simulations. Loosely translated, a high-discrepancy pseudo-random number generator is one in which there is very little correlation between the current number generated and the past numbers generated. This property is ideal if indeed independence of the innovations is required. If, on the other hand, the efficient spanning of a multidimensional space is desired, a low discrepancy, quasi-random number generator can be used. A quasi-random number generator produces numbers that have no random component.

A simple one-dimensional quasi-random sequence is the van der Corput sequence. Given a prime number r ($r \geq 2$), any integer has a unique representation in terms of base r . A number in the interval $[0,1)$ can be created by inverting the representation base power by base power. For example, consider $r=3$ and $n=1$, 1 in base 3 is

$$1_{10} = 1 \cdot 3^0 = 1_3$$

When the powers of 3 are inverted,

$$\phi(1) = \frac{1}{3}$$

Also, 11 in base 3 is

$$11_{10} = 1 \cdot 3^2 + 2 \cdot 3^0 = 10_3$$

When the powers of 3 are inverted,

$$\phi(11) = \frac{1}{9} + 2 \cdot \frac{1}{3} = \frac{7}{9}$$

The first 10 numbers in this sequence $\phi(1) \dots \phi(10)$ are provided below

$$0, \frac{1}{3}, \frac{2}{3}, \frac{1}{9}, \frac{4}{9}, \frac{7}{9}, \frac{2}{9}, \frac{5}{9}, \frac{8}{9}, \frac{1}{27}$$

As the sequence proceeds, it fills in the gaps in a uniform fashion.

Several authors have expanded this idea to many dimensions. Two versions supported by the MODEL procedure are the Sobol sequence (QUASI=SOBOL) and the Faure sequence (QUASI=FAURE). The Sobol sequence is based on binary numbers and is generally computationally faster than the Faure sequence. The Faure sequence uses the dimensionality of the problem to determine the number base to use to generate the sequence. The Faure sequence has better distributional properties than the Sobol sequence for dimensions greater than 8.

As an example of the difference between a pseudo-random number and a quasi-random number, consider simulating a bivariate normal with 100 draws.

Figure 19.73 Kernel Density of a Bivariate Normal produced by 100 Faure-Random Draws

Figure 19.74 Kernel Density of a Bivariate Normal produced by 100 Pseudo-Random Draws

Solution Mode Output

The following SAS statements dynamically forecast the solution to a nonlinear equation:

```
proc model data=sashelp.citimon;
  parameters a 0.010708 b -0.478849 c 0.929304;
  lhur = 1/(a * ip) + b + c * lag(lhur);
  solve lhur / out=sim forecast dynamic;
run;
```

The first page of output produced by the SOLVE step is shown in [Figure 19.75](#). This is the summary description of the model. The error message states that the simulation was aborted at observation 144 because of missing input values.

Figure 19.75 Solve Step Summary Output

```

                                The MODEL Procedure

                                Model Summary

                                Model Variables      1

                                Dynamic Single-Equation Forecast

                                --- Listing of Program Data Vector ---
_N_:      144      ACTUAL.LHUR:      .      ERROR.LHUR:      .
IP:      .      LHUR:      7.10000      PRED.LHUR:      .
a:      0.01071      b:      -0.47885      c:      0.92930

NOTE: Simulation aborted.

```

From the program data vector, you can see the variable IP is missing for observation 144. LHUR could not be computed, so the simulation aborted.

The solution summary table is shown in [Figure 19.77](#).

Figure 19.77 Solution Summary Report

The MODEL Procedure	
Dynamic Single-Equation Forecast	
Data Set Options	
DATA=	SASHELP.CITIMON
OUT=	SIM
Solution Summary	
Variables Solved	1
Forecast Lag Length	1
Solution Method	NEWTON
CONVERGE=	1E-8
Maximum CC	0
Maximum Iterations	1
Total Iterations	143
Average Iterations	1
Observations Processed	
Read	145
Lagged	1
Solved	143
First	2
Last	145
Failed	1
Variables Solved For	LHUR

This solution summary table includes the names of the input data set and the output data set followed by a description of the model. The table also indicates that the solution method defaulted to Newton's method. The remaining output is defined as follows.

Maximum CC	is the maximum convergence value accepted by the Newton procedure. This number is always less than the value for the CONVERGE= option.
Maximum Iterations	is the maximum number of Newton iterations performed at each observation and each replication of Monte Carlo simulations.
Total Iterations	is the sum of the number of iterations required for each observation and each Monte Carlo simulation.
Average Iterations	is the average number of Newton iterations required to solve the system at each step.
Solved	is the number of observations used times the number of random replications selected plus one, for Monte Carlo simulations. The one additional simulation is the original unperturbed solution. For simulations that do not involve Monte Carlo, this number is the number of observations used.

Summary Statistics

The STATS and THEIL options are used to select goodness-of-fit statistics. Actual values must be provided in the input data set for these statistics to be printed. When the RANDOM= option is specified, the statistics do not include the unperturbed (_REP_=0) solution.

STATS Option Output

The following statements show the addition of the STATS and THEIL options to the model in the previous section:

```
proc model data=sashelp.citimon;
  parameters a 0.010708 b -0.478849 c 0.929304;
  lhur= 1/(a * ip) + b + c * lag(lhur) ;
  solve lhur / out=sim dynamic stats theil;
  range date to '01nov91'd;
run;
```

The STATS output in Figure 19.78 and the THEIL output in Figure 19.79 are generated.

Figure 19.78 STATS Output

The MODEL Procedure							
Dynamic Single-Equation Simulation							
Solution Range DATE = FEB1980 To NOV1991							
Descriptive Statistics

Statistics of fit							
Variable	R-Square		Label				
LHUR	0.7049		UNEMPLOYMENT RATE: ALL WORKERS, 16 YEARS				

The number of observations (Nobs), the number of observations with both predicted and actual values nonmissing (N), and the mean and standard deviation of the actual and predicted values of the determined variables are printed first. The next set of columns in the output are defined as follows:

Mean Error	$\frac{1}{N} \sum_{j=1}^N (\hat{y}_j - y_j)$
Mean % Error	$\frac{100}{N} \sum_{j=1}^N (\hat{y}_j - y_j)/y_j$
Mean Abs Error	$\frac{1}{N} \sum_{j=1}^N \hat{y}_j - y_j $
Mean Abs % Error	$\frac{100}{N} \sum_{j=1}^N (\hat{y}_j - y_j)/y_j $
RMS Error	$\sqrt{\frac{1}{N} \sum_{j=1}^N (\hat{y}_j - y_j)^2}$
RMS % Error	$100 \sqrt{\frac{1}{N} \sum_{j=1}^N ((\hat{y}_j - y_j)/y_j)^2}$
R-square	$1 - SSE/CSSA$
SSE	$\sum_{j=1}^N (\hat{y}_j - y_j)^2$
SSA	$\sum_{j=1}^N (y_j)^2$
CSSA	$SSA - \left(\sum_{j=1}^N y_j\right)^2$
\hat{y}	predicted value
y	actual value

When the RANDOM= option is specified, the statistics do not include the unperturbed (_REP_=0) solution.

THEIL Option Output

The THEIL option specifies that Theil forecast error statistics be computed for the actual and predicted values and for the relative changes from lagged values. Mathematically, the quantities are

$$\hat{y}c = (\hat{y} - lag(y))/lag(y)$$

$$yc = (y - lag(y))/lag(y)$$

where $\hat{y}c$ is the relative change for the predicted value and yc is the relative change for the actual value.

Figure 19.79 THEIL Output

Theil Forecast Error Statistics								
Variable	N	MSE	Corr (R)	MSE Decomposition Proportions				
				Bias (UM)	Reg (UR)	Dist (UD)	Var (US)	Covar (UC)

Variable	Inequality Coef			U	Label			
	U1							
LHUR		4.1226	0.8348		UNEMPLOYMENT RATE: ALL WORKERS, 16 YEARS			

The columns have the following meaning:

Corr (R) is the correlation coefficient, ρ , between the actual and predicted values.

$$\rho = \frac{\text{cov}(y, \hat{y})}{\sigma_a \sigma_p}$$

where σ_p and σ_a are the standard deviations of the predicted and actual values.

Bias (UM) is an indication of systematic error and measures the extent to which the average values of the actual and predicted deviate from each other.

$$\frac{(E(y) - E(\hat{y}))^2}{\frac{1}{N} \sum_{t=1}^N (y_t - \hat{y}_t)^2}$$

Reg (UR) is defined as $(\sigma_p - \rho * \sigma_a)^2 / \text{MSE}$. Consider the regression

$$y = \alpha + \beta \hat{y}$$

If $\hat{\beta} = 1$, UR will equal zero.

Dist (UD) is defined as $(1 - \rho^2)\sigma_a\sigma_a/MSE$ and represents the variance of the residuals obtained by regressing yc on $\hat{y}c$.

Var (US) is the variance proportion. US indicates the ability of the model to replicate the degree of variability in the endogenous variable.

$$US = \frac{(\sigma_p - \sigma_a)^2}{MSE}$$

Covar (UC) represents the remaining error after deviations from average values and average variabilities have been accounted for.

$$UC = \frac{2(1 - \rho)\sigma_p\sigma_a}{MSE}$$

U1 is a statistic that measures the accuracy of a forecast defined as follows:

$$U1 = \frac{\sqrt{MSE}}{\sqrt{\frac{1}{N} \sum_{t=1}^N (y_t)^2}}$$

U is the Theil's inequality coefficient defined as follows:

$$U = \frac{\sqrt{MSE}}{\sqrt{\frac{1}{N} \sum_{t=1}^N (y_t)^2} + \sqrt{\frac{1}{N} \sum_{t=1}^N (\hat{y}_t)^2}}$$

MSE is the mean square error. In the case of the relative change Theil statistics, the MSE is computed as follows:

$$MSE = \frac{1}{N} \sum_{t=1}^N (\hat{y}c_t - yc_t)^2$$

More information about these statistics can be found in the references Maddala (1977, 344–347) and Pindyck and Rubinfeld (1981, 364–365).

Goal Seeking: Solving for Right-Hand-Side Variables

The process of computing input values that are needed to produce target results is often called *goal seeking*. To compute a goal-seeking solution, use a SOLVE statement that lists the variables you want to solve for and provide a data set that contains values for the remaining variables.

Consider the following demand model for packaged rice

$$\text{quantity demanded} = \alpha_1 + \alpha_2 \text{price}^{2/3} + \alpha_3 \text{income}$$

where *price* is the price of the package and *income* is disposable personal income. The only variable the company has control over is the price it charges for rice. This model is estimated by using the following simulated data and PROC MODEL statements:

```

data demand;
  do t=1 to 40;
    price = (rannor(10) +5) * 10;
    income = 8000 * t ** (1/8);
    demand = 7200 - 1054 * price ** (2/3) +
              7 * income + 100 * rannor(1);
    output;
  end;
run;

data goal;
  demand = 85000;
  income = 12686;
run;

```

The goal is to find the price the company would have to charge to meet a sales target of 85,000 units. To do this, a data set is created with a DEMAND variable set to 85000 and with an INCOME variable set to 12686, the last income value.

The desired price is then determined by using the following PROC MODEL statements:

```

proc model data=demand
  outmodel=demandModel;
  demand = a1 - a2 * price ** (2/3) + a3 * income;
  fit demand / outest=demest;
  solve price / estdata=demest data=goal solveprint;
run;

```

The SOLVEPRINT option prints the solution values, number of iterations, and final residuals at each observation. The SOLVEPRINT output from this solve is shown in Figure 19.80.

Figure 19.80 Goal Seeking, SOLVEPRINT Output

The MODEL Procedure							
Single-Equation Simulation							
Observation	1	Iterations	6	CC	0.000000	ERROR.demand	0.000000
Solution Values							
price							
33.59016							

The output indicates that it took six Newton iterations to determine the PRICE of 33.5902, which makes the DEMAND value within 16E-11 of the goal of 85,000 units.

Consider a more ambitious goal of 100,000 units. The output shown in Figure 19.81 indicates that the sales target of 100,000 units is not attainable according to this model.

```

data goal;
    demand = 100000;
    income = 12686;
run;

proc model model=demandModel;
    solve price / estdata=demest data=goal solveprint;
run;

```

Figure 19.81 Goal Seeking, Convergence Failure

                                The MODEL Procedure
                                Single-Equation Simulation

ERROR: Could not reduce norm of residuals in 10 subiterations.
ERROR: The solution failed because 1 equations are missing or have extreme
       values for observation 1 at NEWTON iteration 1.

      Observation      1      Iteration      1      CC      -1.000000
                        Missing      1

                                The MODEL Procedure
                                Single-Equation Simulation

                                --- Listing of Program Data Vector ---
_N_:                12  ACTUAL.demand:    100000  ERROR.demand:      .
PRED.demand:        .  a1:                7126.437997  a2:                1040.841492
a3:                 6.992694  demand:        100000  income:                12686
price:              -0.000172
@PRED.demand/@pri:      .

```

The program data vector with the error note indicates that even after 10 subiterations, the norm of the residuals could not be reduced. The sales target of 100,000 units are unattainable with the given model. You might need to reformulate your model or collect more data to more accurately reflect the market response.

Numerical Solution Methods

If the SINGLE option is not used, PROC MODEL computes values that simultaneously satisfy the model equations for the variables named in the SOLVE statement. PROC MODEL provides three iterative methods, Newton, Jacobi, and Seidel, for computing a simultaneous solution of the system of nonlinear equations.

Single-Equation Solution

For normalized form equation systems, the solution either can simultaneously satisfy all the equations or can be computed for each equation separately, by using the actual values of the solution variables in the current period to compute each predicted value. By default, PROC MODEL computes a simultaneous solution. The SINGLE option in the SOLVE statement selects single-equation solutions.

Single-equation simulations are often made to produce residuals (which estimate the random terms of the stochastic equations) rather than the predicted values themselves. If the input data and range are the same as that used for parameter estimation, a static single-equation simulation reproduces the residuals of the estimation.

Newton's Method

The NEWTON option in the SOLVE statement requests Newton's method to simultaneously solve the equations for each observation. Newton's method is the default solution method. Newton's method is an iterative scheme that uses the derivatives of the equations with respect to the solution variables, \mathbf{J} , to compute a change vector as

$$\Delta \mathbf{y}^i = \mathbf{J}^{-1} \mathbf{q}(\mathbf{y}^i, \mathbf{x}, \boldsymbol{\theta})$$

PROC MODEL builds and solves \mathbf{J} by using efficient sparse matrix techniques. The solution variables \mathbf{y}^i at the i th iteration are then updated as

$$\mathbf{y}^{i+1} = \mathbf{y}^i + d \times \Delta \mathbf{y}^i$$

where d is a damping factor between 0 and 1 chosen iteratively so that

$$\|\mathbf{q}(\mathbf{y}^{i+1}, \mathbf{x}, \boldsymbol{\theta})\| < \|\mathbf{q}(\mathbf{y}^i, \mathbf{x}, \boldsymbol{\theta})\|$$

The number of subiterations allowed for finding a suitable d is controlled by the MAXSUBITER= option. The number of iterations of Newton's method allowed for each observation is controlled by MAXITER= option. See Ortega and Rheinbolt (1970) for more details.

Jacobi Method

The JACOBI option in the SOLVE statement selects a matrix-free alternative to Newton's method. This method is the traditional nonlinear Jacobi method found in the literature. The Jacobi method as implemented in PROC MODEL substitutes predicted values for the endogenous variables and iterates until a fixed point is reached. Then necessary derivatives are computed only for the diagonal elements of the jacobian, \mathbf{J} .

If the normalized form equation is

$$\mathbf{y} = \mathbf{f}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})$$

the Jacobi iteration has the form

$$\mathbf{y}^{i+1} = \mathbf{f}(\mathbf{y}^i, \mathbf{x}, \boldsymbol{\theta})$$

Seidel Method

The Seidel method is an order-dependent alternative to the Jacobi method. The Seidel method is selected by the SEIDEL option in the SOLVE statement. The Seidel method is like the Jacobi method except that in the Seidel method the model is further edited to substitute the predicted values into the solution variables immediately after they are computed. Seidel thus differs from the other methods in that the values of the solution variables are not fixed within an iteration. With the other methods, the order of the equations in the model program makes no difference, but the Seidel method might work much differently when the equations are specified in a different sequence. Note that this fixed point method is the traditional nonlinear Seidel method found in the literature.

The iteration has the form

$$\mathbf{y}_j^{i+1} = \mathbf{f}(\hat{\mathbf{y}}^i, \mathbf{x}, \boldsymbol{\theta})$$

where \mathbf{y}_j^{i+1} is the j th equation variable at the i th iteration and

$$\hat{\mathbf{y}}^i = (y_1^{i+1}, y_2^{i+1}, y_3^{i+1}, \dots, y_{j-1}^{i+1}, y_j^i, y_{j+1}^i, \dots, y_g^i)'$$

If the model is recursive, and if the equations are in recursive order, the Seidel method converges at once. If the model is block-recursive, the Seidel method might converge faster if the equations are grouped by block and the blocks are placed in block-recursive order. The BLOCK option can be used to determine the block-recursive form.

Jacobi and Seidel Methods with General Form Equations

Jacobi and Seidel solution methods support general form equations.

There are two cases where derivatives are (automatically) computed. The first case is for equations with the solution variable on the right-hand side and on the left-hand side of the equation

$$y^i = f(\mathbf{x}, y^i)$$

In this case the derivative of `ERROR.y` with respect to y is computed, and the new y approximation is computed as

$$y^{i+1} = y^i - \frac{f(\mathbf{x}, y^i) - y^i}{\partial(f(\mathbf{x}, y^i) - y^i)/\partial y}$$

The second case is a system of equations that contains one or more `EQ.var` equations. In this case, a heuristic algorithm is used to make the assignment of a unique solution variable to each general form equation. Use the DETAILS option in the SOLVE statement to print a listing of the assigned variables.

Once the assignment is made, the new y approximation is computed as

$$y^{i+1} = y^i - \frac{f(\mathbf{x}, \mathbf{y}^i) - y^i}{\partial(f(\mathbf{x}, \mathbf{y}^i) - y^i)/\partial y}$$

If k is the number of general form equations, then k derivatives are required.

The convergence properties of the Jacobi and Seidel solution methods remain significantly poorer than the default Newton's method.

Comparison of Methods

Newton's method is the default and should work better than the others for most small- to medium-sized models. The Seidel method is always faster than the Jacobi for recursive models with equations in recursive order. For very large models and some highly nonlinear smaller models, the Jacobi or Seidel methods can sometimes be faster. Newton's method uses more memory than the Jacobi or Seidel methods.

Both the Newton's method and the Jacobi method are order-invariant in the sense that the order in which equations are specified in the model program has no effect on the operation of the iterative solution process. In order-invariant methods, the values of the solution variables are fixed for the entire execution of the model program. Assignments to model variables are automatically changed to assignments to corresponding equation variables. Only after the model program has completed execution are the results used to compute the new solution values for the next iteration.

Troubleshooting Problems

In solving a simultaneous nonlinear dynamic model you might encounter some of the following problems.

Missing Values

For SOLVE tasks, there can be no missing parameter values. Missing right-hand-side variables result in missing left-hand-side variables for that observation.

Unstable Solutions

A solution might exist but be unstable. An unstable system can cause the Jacobi and Seidel methods to diverge.

Explosive Dynamic Systems

A model might have well-behaved solutions at each observation but be dynamically unstable. The solution might oscillate wildly or grow rapidly with time.

Propagation of Errors

During the solution process, solution variables can take on values that cause computational errors. For example, a solution variable that appears in a LOG function might be positive at the solution but might be given a negative value during one of the iterations. When computational errors occur, missing values are generated and propagated, and the solution process might collapse.

Convergence Problems

The following items can cause convergence problems:

- There are illegal function values (for example $\sqrt{-1}$).

- There are local minima in the model equation.
- No solution exists.
- Multiple solutions exist.
- Initial values are too far from the solution.
- The CONVERGE= value is too small.

When PROC MODEL fails to find a solution to the system, the current iteration information and the program data vector are printed. The simulation halts if actual values are not available for the simulation to proceed. Consider the following program, which produces the output shown in Figure 19.82:

```
data test1;
  do t=1 to 50;
    x1 = sqrt(t) ;
    y = .;
    output;
  end;

proc model data=test1;
  exogenous x1 ;
  control a1 -1 b1 -29 c1 -4 ;
  y = a1 * sqrt(y) + b1 * x1 * x1 + c1 * lag(x1);
  solve y / out=sim forecast dynamic ;
run;
```

Figure 19.82 SOLVE Convergence Problems

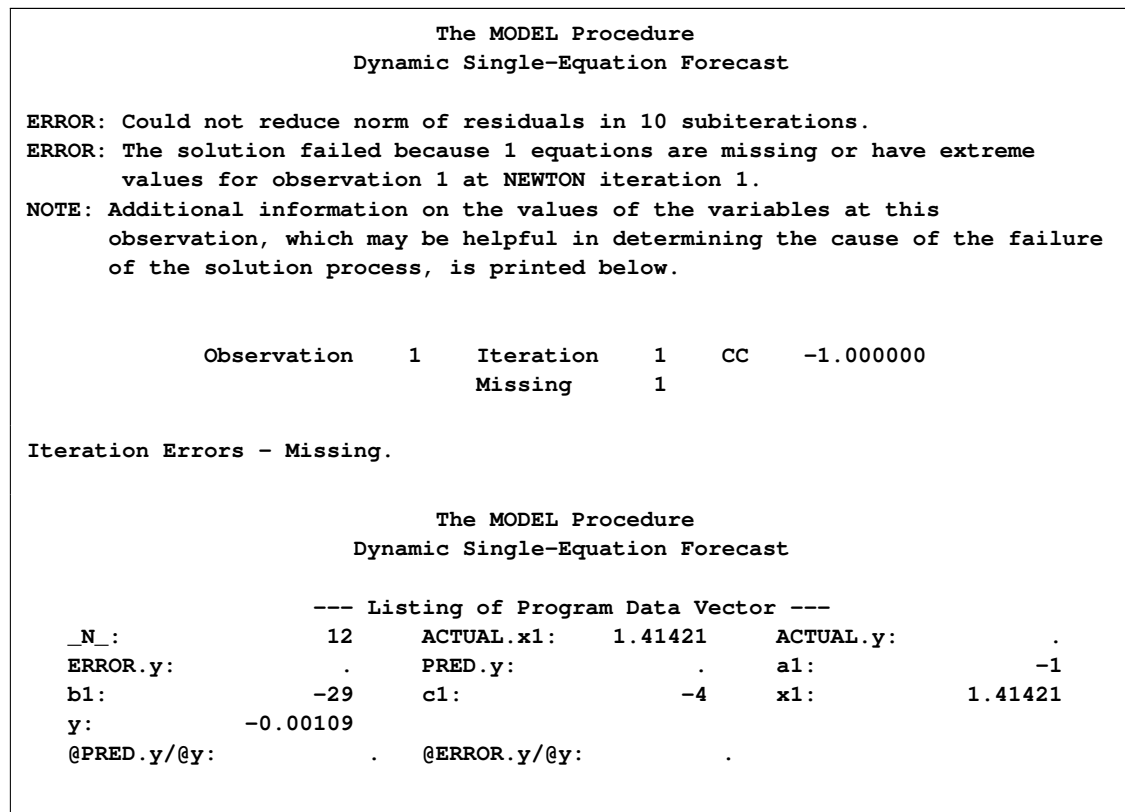

Figure 19.82 *continued*

NOTE: Check for missing input data or uninitialized lags.
 (Note that the LAG and DIF functions return missing values for the initial lag starting observations. This is a change from the 1982 and earlier versions of SAS/ETS which returned zero for uninitialized lags.)
 NOTE: Simulation aborted.

At the first observation, a solution to the following equation is attempted:

$$y = -\sqrt{y} - 62$$

There is no solution to this problem. The iterative solution process got as close as it could to making Y negative while still being able to evaluate the model. This problem can be avoided in this case by altering the equation.

In other models, the problem of missing values can be avoided by either altering the data set to provide better starting values for the solution variables or by altering the equations.

You should be aware that, in general, a nonlinear system can have any number of solutions and the solution found might not be the one that you want. When multiple solutions exist, the solution that is found is usually determined by the starting values for the iterations. If the value from the input data set for a solution variable is missing, the starting value for it is taken from the solution of the last period (if nonmissing) or else the solution estimate is started at 0.

Iteration Output

The iteration output, produced by the ITPRINT option, is useful in determining the cause of a convergence problem. The ITPRINT option forces the printing of the solution approximation and equation errors at each iteration for each observation. A portion of the ITPRINT output from the following statements is shown in Figure 19.83.

```
proc model data=test1;
  exogenous x1 ;
  control a1 -1 b1 -29 c1 -4 ;
  y = a1 * sqrt(abs(y)) + b1 * x1 * x1 + c1 * lag(x1);
  solve y / out=sim forecast dynamic itprint;
run;
```

For each iteration, the equation with the largest error is listed in parentheses after the Newton convergence criteria measure. From this output you can determine which equation or equations in the system are not converging well.

Numerical Integration

The differential equation system is numerically integrated to obtain a solution for the derivative variables at each data point. The integration is performed by evaluating the provided model at multiple points between each data point. The integration method used is a variable order, variable step-size backward difference scheme; for more detailed information, see Aiken (1985) and Byrne and Hindmarsh (1975). The step size or time step is chosen to satisfy a *local truncation error* requirement. The term *truncation error* comes from the fact that the integration scheme uses a truncated series expansion of the integrated function to do the

integration. Because the series is truncated, the integration scheme is within the truncation error of the true value.

To further improve the accuracy of the integration, the total integration time is broken up into small intervals (time steps or step sizes), and the integration scheme is applied to those intervals. The integration at each time step uses the values computed at the previous time step so that the truncation error tends to accumulate. It is usually not possible to estimate the global error with much precision. The best that can be done is to monitor and to control the local truncation error, which is the truncation error committed at each time step relative to

$$d = \max_{0 \leq t \leq T} (\|y(t)\|_{\infty}, 1)$$

where $y(t)$ is the integrated variable. Furthermore, the $y(t)$ s are dynamically scaled to within two orders of magnitude of one to keep the error monitoring well-behaved.

The local truncation error requirement defaults to 1.0E–9. You can specify the LTEBOUND= option to modify that requirement. The LTEBOUND= option is a relative measure of accuracy, so a value smaller than 1.0E–10 is usually not practical. A larger bound increases the speed of the simulation and estimation but decreases the accuracy of the results. If the LTEBOUND= option is set too small, the integrator is not able to take time steps small enough to satisfy the local truncation error requirement and still have enough machine precision to compute the results. Since the integrations are scaled to within 1.0E–2 of one, the simulated values should be correct to at least seven decimal places.

There is a default minimum time step of 1.0E–14. This minimum time step is controlled by the MINTIMESTEP= option and the machine epsilon. If the minimum time step is smaller than the machine epsilon times the final time value, the minimum time step is increased automatically.

For the points between each observation in the data set, the values for nonintegrated variables in the data set are obtained from a linear interpolation from the two closest points. Lagged variables can be used with integrations, but their values are discrete and are not interpolated between points. Lagging, therefore, can then be used to input step functions into the integration.

The derivatives necessary for estimation (the gradient with respect to the parameters) and goal seeking (the Jacobian) are computed by numerically integrating analytical derivatives. The accuracy of the derivatives is controlled by the same integration techniques mentioned previously.

Limitations

There are limitations to the types of differential equations that can be solved or estimated. One type is an explosive differential equation (finite escape velocity) for which the following differential equation is an example:

$$y' = a \times y, a > 0$$

If this differential equation is integrated too far in time, y exceeds the maximum value allowed on the computer, and the integration terminates.

Likewise, differential systems that are singular cannot be solved or estimated in general. For example, consider the following differential system:

$$\begin{aligned}x' &= -y' + 2x + 4y + \exp(t) \\ y' &= -x' + y + \exp(4t)\end{aligned}$$

This system has an analytical solution, but an accurate numerical solution is very difficult to obtain. The reason is that y' and x' cannot be isolated on the left-hand side of the equation. If the equation is modified slightly to

$$\begin{aligned}x' &= -y' + 2x + 4y + \exp(t) \\ y' &= x' + y + \exp(4t)\end{aligned}$$

the system is nonsingular, but the integration process could still fail or be extremely slow. If the MODEL procedure encounters either system, a warning message is issued.

This system can be rewritten as the following recursive system, which can be estimated and simulated successfully with the MODEL procedure:

$$\begin{aligned}x' &= 0.5y + 0.5\exp(4t) + x + 1.5y - 0.5\exp(t) \\ y' &= x' + y + \exp(4t)\end{aligned}$$

Petzold (1982) mentions a class of differential algebraic equations that, when integrated numerically, could produce incorrect or misleading results. An example of such a system is

$$\begin{aligned}y_2'(t) &= y_1(t) + g_1(t) \\ 0 &= y_2(t) + g_2(t)\end{aligned}$$

The analytical solution to this system depends on g and its derivatives at the current time only and not on its initial value or past history. You should avoid systems of this and other similar forms mentioned in Petzold (1982).

SOLVE Data Sets

SDATA= Input Data Set

The SDATA= option reads a cross-equation covariance matrix from a data set. The covariance matrix read from the SDATA= data set specified in the SOLVE statement is used to generate random equation errors when the RANDOM= option specifies Monte Carlo simulation.

Typically, the `SDATA=` data set is created by the `OUTS=` option in a previous `FIT` statement. (The `OUTS=` data set from a `FIT` statement can be read back in by a `SOLVE` statement in the same `PROC MODEL` step.)

You can create an input `SDATA=` data set by using the `DATA` step. `PROC MODEL` expects to find a character variable `_NAME_` in the `SDATA=` data set as well as variables for the equations in the estimation or solution. For each observation with a `_NAME_` value that matches the name of an equation, `PROC MODEL` fills the corresponding row of the **S** matrix with the values of the names of equations found in the data set. If a row or column is omitted from the data set, an identity matrix row or column is assumed. Missing values are ignored. Since the **S** matrix is symmetric, you can include only a triangular part of the **S** matrix in the `SDATA=` data set with the omitted part indicated by missing values. If the `SDATA=` data set contains multiple observations with the same `_NAME_`, the last values supplied for the `_NAME_` variable are used. The section “[OUTS= Data Set](#)” on page 1189 contains more details on the format of this data set.

Use the `TYPE=` option to specify the type of estimation method used to produce the **S** matrix you want to input.

ESTDATA= Input Data Set

The `ESTDATA=` option specifies an input data set that contains an observation with values for some or all of the model parameters. It can also contain observations with the rows of a covariance matrix for the parameters.

When the `ESTDATA=` option is used, parameter values are set from the first observation. If the `RANDOM=` option is used and the `ESTDATA=` data set contains a covariance matrix, the covariance matrix of the parameter estimates is read and used to generate pseudo-random shocks to the model parameters for Monte Carlo simulation. These random perturbations have a multivariate normal distribution with the covariance matrix read from the `ESTDATA=` data set.

The `ESTDATA=` data set is usually created by the `OUTEST=` option in a `FIT` statement. The `OUTEST=` data set contains the parameter estimates produced by the `FIT` statement and also contains the estimated covariance of the parameter estimates if the `OUTCOV` option is used. This `OUTEST=` data set can be read in by the `ESTDATA=` option in a `SOLVE` statement.

You can also create an `ESTDATA=` data set with a SAS `DATA` step program. The data set must contain a numeric variable for each parameter to be given a value or covariance column. The name of the variable in the `ESTDATA=` data set must match the name of the parameter in the model. Parameters with names longer than 32 characters cannot be set from an `ESTDATA=` data set. The data set must also contain a character variable `_NAME_` of length 32. `_NAME_` has a blank value for the observation that gives values to the parameters. `_NAME_` contains the name of a parameter for observations that define rows of the covariance matrix.

More than one set of parameter estimates and covariances can be stored in the `ESTDATA=` data set if the observations for the different estimates are identified by the variable `_TYPE_`. `_TYPE_` must be a character variable of length eight. The `TYPE=` option is used to select for input the part of the `ESTDATA=` data set for which the value of the `_TYPE_` variable matches the value of the `TYPE=` option.

OUT= Data Set

The OUT= data set contains solution values, residual values, and actual values of the solution variables.

The OUT= data set contains the following variables:

- BY variables
- RANGE variable
- ID variables
- `_TYPE_`, a character variable of length eight that identifies the type of observation. The `_TYPE_` variable can be PREDICT, RESIDUAL, ACTUAL, or ERROR.
- `_MODE_`, a character variable of length eight that identifies the solution mode. `_MODE_` takes the value FORECAST or SIMULATE.
- if lags are used, a numeric variable, `_LAG_`, that contains the number of dynamic lags that contribute to the solution. The value of `_LAG_` is always zero for STATIC mode solutions. `_LAG_` is set to a missing value for lag-starting observations.
- if the RANDOM= option is used, `_REP_`, a numeric variable that contains the replication number. For example, if RANDOM=10, each input observation results in eleven output observations with `_REP_` values 0 through 10. The observations with `_REP_`=0 are from the unperturbed solution. (The random-number generator functions are suppressed, and the parameter and endogenous perturbations are zero when `_REP_`=0.)
- `_ERRORS_`, a numeric variable that contains the number of errors that occurred during the execution of the program for the last iteration for the observation. If the solution failed to converge, this is counted as one error, and the `_ERRORS_` variable is made negative.
- solution and other variables. The solution variables contain solution or predicted values for `_TYPE_`=PREDICT observations, residuals for `_TYPE_`=RESIDUAL observations, or actual values for `_TYPE_`=ACTUAL observations. The other model variables, and any other variables read from the input data set, are always actual values from the input data set.
- any other variables named in the OUTVARS statement. These can be program variables computed by the model program, CONTROL variables, parameters, or special variables in the model program. Compound variable names longer than 32 characters are truncated in the OUT= data set.

By default, only the predicted values are written to the OUT= data set. The OUTRESID, OUTACTUAL, and OUTERROR options are used to add the residual, actual, and ERROR. values, respectively, to the data set.

For examples of the OUT= data set, see [Example 19.6](#).

DATA= Input Data Set

The input data set should contain all of the exogenous variables and should supply nonmissing values for them for each period to be solved.

Solution variables can be supplied in the input data set and are used as follows:

- to supply initial lags. For example, if the lag length of the model is three, three observations are read in to feed the lags before any solutions are computed.
- to evaluate the goodness of fit. Goodness-of-fit measures are computed based on the difference between the solved values and the actual values supplied from the data set.
- to supply starting values for the iterative solution. If the value from the input data set for a solution variable is missing, the starting value for it is taken from the solution of the last period (if nonmissing) or else the solution estimate is started at zero.
- for STATIC mode solutions, actual values from the data set are used by the lagging functions for the solution variables.
- for FORECAST mode solutions, actual values from the data set are used as the solution values when nonmissing.

Programming Language Overview: MODEL Procedure

Variables in the Model Program

Variable names are alphanumeric but must start with a letter. The length is limited to 32 characters.

PROC MODEL uses several classes of variables, and different variable classes are treated differently. The variable class is controlled by *declaration statements*: the VAR, ENDOGENOUS, and EXOGENOUS statements for model variables, the PARAMETERS statement for parameters, and the CONTROL statement for control class variables. These declaration statements have several valid abbreviations. Various *internal variables* are also made available to the model program to allow communication between the model program and the procedure. RANGE, ID, and BY variables are also available to the model program. Those variables not declared as any of the preceding classes are *program variables*.

Some classes of variables can be lagged; that is, their value at each observation is remembered, and previous values can be referred to by the lagging functions. Other classes have only a single value and are not affected by lagging functions. For example, parameters have only one value and are not affected by lagging functions; therefore, if P is a parameter, $DIF_n(P)$ is always 0, and $LAG_n(P)$ is always the same as P for all values of n .

The different variable classes and their roles in the model are described in the following.

Model Variables

Model variables are declared by VAR, ENDOGENOUS, or EXOGENOUS statements, or by FIT and SOLVE statements. The model variables are the variables that the model is intended to explain or predict.

PROC MODEL enables you to use expressions on the left-hand side of the equal sign to define model equations. For example, a log-linear model for Y can be written as

$$\log(y) = a + b * x;$$

Previously, only a variable name was allowed on the left-hand side of the equal sign.

The text on the left-hand side of the equation serves as the equation name used to identify the equation in printed output, in the OUT= data sets, and in FIT or SOLVE statements. To refer to equations specified by using left-hand side expressions (in the FIT statement, for example), place the left-hand side expression in quotes. For example, the following statements fit a log-linear model to the dependent variable Y:

```
proc model data=in;
  log( y ) = a + b * x;
  fit "log(y)";
run;
```

The estimation and simulation is performed by transforming the models into general form equations. No actual or predicted value is available for general form equations, so no R^2 or adjusted R^2 is computed.

Equation Variables

An equation variable is one of several special variables used by PROC MODEL to control the evaluation of model equations. An equation variable name consists of one of the prefixes EQ, RESID, ERROR, PRED, or ACTUAL, followed by a period and the name of a model equation.

Equation variable names can appear in parts of the PROC MODEL printed output, and they can be used in the model program. For example, RESID-prefixed variables can be used in LAG functions to define equations with moving-average error terms. See the section “[Autoregressive Moving-Average Error Processes](#)” on page 1165 for details.

The meaning of these prefixes is detailed in the section “[Equation Translations](#)” on page 1232.

Parameters

Parameters are variables that have the same value for each observation. Parameters can be given values or can be estimated by fitting the model to data. During the SOLVE stage, parameters are treated as constants. If no estimation is performed, the SOLVE stage uses the initial value provided in the ESTDATA= data set, the MODEL= file, or in the PARAMETER statement, as the value of the parameter.

The PARAMETERS statement declares the parameters of the model. Parameters are not lagged, and they cannot be changed by the model program.

Control Variables

Control variables supply constant values to the model program that can be used to control the model in various ways. The CONTROL statement declares control variables and specifies their values. A control variable is like a parameter except that it has a fixed value and is not estimated from the data.

Control variables are not reinitialized before each pass through the data and can thus be used to retain values between passes. You can use control variables to vary the program logic. Control variables are not affected by lagging functions.

For example, if you have two versions of an equation for a variable Y, you could put both versions in the model and, by using a CONTROL statement to select one of them, produce two different solutions to explore the effect the choice of equation has on the model, as shown in the following statements:

```
select (case);
  when (1) y = ...first version of equation... ;
  when (2) y = ...second version of equation... ;
end;

control case 1;
solve / out=case1;
run;

control case 2;
solve / out=case2;
run;
```

RANGE, ID, and BY Variables

The RANGE statement controls the range of observations in the input data set that is processed by PROC MODEL. The ID statement lists variables in the input data set that are used to identify observations in the printout and in the output data set. The BY statement can be used to make PROC MODEL perform a separate analysis for each BY group. The variable in the RANGE statement, the ID variables, and the BY variables are available for the model program to examine, but their values should not be changed by the program. The BY variables are not affected by lagging functions.

Internal Variables

You can use several internal variables in the model program to communicate with the procedure. For example, if you want PROC MODEL to list the values of all the variables when more than 10 iterations are performed and the procedure is past the 20th observation, you can write

```
if _obs_ > 20 then if _iter_ > 10 then _list_ = 1;
```

Internal variables are not affected by lagging functions, and they cannot be changed by the model program except as noted. The following internal variables are available. The variables are all numeric except where noted.

<code>_ERRORS_</code>	is a flag that is set to 0 at the start of program execution and is set to a nonzero value whenever an error occurs. The program can also set the <code>_ERRORS_</code> variable.
<code>_ITER_</code>	is the iteration number. For FIT tasks, the value of <code>_ITER_</code> is negative for preliminary grid-search passes. The iterative phase of the estimation starts with iteration 0. After the estimates have converged, a final pass is made to collect statistics with <code>_ITER_</code> set to a missing value. Note that at least one pass, and perhaps several subiteration passes as well, is made for each iteration. For SOLVE tasks, <code>_ITER_</code> counts the iterations used to compute the simultaneous solution of the system.
<code>_LAG_</code>	is the number of dynamic lags that contribute to the solution at the current observation. <code>_LAG_</code> is always 0 for FIT tasks and for STATIC solutions. <code>_LAG_</code> is set to a missing value during the lag starting phase.
<code>_LIST_</code>	is a list flag that is set to 0 at the start of program execution. The program can set <code>_LIST_</code> to a nonzero value to request a listing of the values of all the variables in the program after the program has finished executing.
<code>_METHOD_</code>	is the solution method in use for SOLVE tasks. <code>_METHOD_</code> is set to a blank value for FIT tasks. <code>_METHOD_</code> is a character-valued variable. Values are NEWTON, JACOBI, SIEDEL, or ONEPASS.
<code>_MODE_</code>	takes the value ESTIMATE for FIT tasks and the value SIMULATE or FORECAST for SOLVE tasks. <code>_MODE_</code> is a character-valued variable.
<code>_NMISS_</code>	is the number of missing or otherwise unusable observations during the model estimation. For FIT tasks, <code>_NMISS_</code> is initially set to 0; at the start of each iteration, <code>_NMISS_</code> is set to the number of unusable observations for the previous iteration. For SOLVE tasks, <code>_NMISS_</code> is set to a missing value.
<code>_NUSED_</code>	is the number of nonmissing observations used in the estimation. For FIT tasks, PROC MODEL initially sets <code>_NUSED_</code> to the number of parameters; at the start of each iteration, <code>_NUSED_</code> is reset to the number of observations used in the previous iteration. For SOLVE tasks, <code>_NUSED_</code> is set to a missing value.
<code>_OBS_</code>	counts the observations being processed. <code>_OBS_</code> is negative or 0 for observations in the lag starting phase.
<code>_REP_</code>	is the replication number for Monte Carlo simulation when the RANDOM= option is specified in the SOLVE statement. <code>_REP_</code> is 0 when the RANDOM= option is not used and for FIT tasks. When <code>_REP_=0</code> , the random-number generator functions always return 0.
<code>_WEIGHT_</code>	is the weight of the observation. For FIT tasks, <code>_WEIGHT_</code> provides a weight for the observation in the estimation. <code>_WEIGHT_</code> is initialized to 1.0 at the start of execution for FIT tasks. For SOLVE tasks, <code>_WEIGHT_</code> is ignored.

Program Variables

Variables not in any of the other classes are called program variables. Program variables are used to hold intermediate results of calculations. Program variables are reinitialized to missing values before each observation is processed. Program variables can be lagged. The RETAIN statement can be used to give program variables initial values and enable them to keep their values between observations.

Character Variables

PROC MODEL supports both numeric and character variables. Character variables are not involved in the model specification but can be used to label observations, to write debugging messages, or for documentation purposes. All variables are numeric unless they are the following.

- character variables in a DATA= SAS data set
- program variables assigned a character value
- declared to be character by a LENGTH or ATTRIB statement

Equation Translations

Equations written in normalized form are always automatically converted to general form equations. For example, when a normalized form equation such as

$$y = a + b \cdot x;$$

is encountered, it is translated into the equations

```
PRED.y = a + b*x;
RESID.y = PRED.y - ACTUAL.y;
ERROR.y = PRED.y - y;
```

If the same system is expressed as the following general form equation, then this equation is used unchanged.

$$EQ.y = y - (a + b \cdot x);$$

This makes it easy to solve for arbitrary variables and to modify the error terms for autoregressive or moving average models.

Use the LIST option to see how this transformation is performed. For example, the following statements produce the listing shown in [Figure 19.84](#).

```
proc model data=line list;
  y = a1 + b1*x1 + c1*x2;
  fit y;
run;
```

Figure 19.84 LIST Output

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	3997:4	PRED.y = a1 + b1 * x1 + c1 * x2;
1	3997:4	RESID.y = PRED.y - ACTUAL.y;
1	3997:4	ERROR.y = PRED.y - y;

PRED.Y is the predicted value of Y, and ACTUAL.Y is the value of Y in the data set. The predicted value minus the actual value, RESID.Y, is then the error term, ϵ , for the original Y equation. Note that the residuals obtained from the OUTRESID option in the OUT=dataset for both the FIT and SOLVE statements are defined as *actual – predicted*, the negative of RESID.Y. See the section “[Syntax: MODEL Procedure](#)” on page 1042 for details. ACTUAL.Y and Y have the same value for parameter estimation. For solve tasks, ACTUAL.Y is still the value of Y in the data set but Y becomes the solved value; the value that satisfies $\text{PRED.Y} - Y = 0$.

The following are the equation variable definitions.

- EQ.** The value of an EQ.-prefixed equation variable (normally used to define a general form equation) represents the failure of the equation to hold. When the EQ.name variable is 0, the name equation is satisfied.
- RESID.** The RESID.name variables represent the stochastic parts of the equations and are used to define the objective function for the estimation process. A RESID.-prefixed equation variable is like an EQ.-prefixed variable but makes it possible to use or transform the stochastic part of the equation. The RESID. equation is used in place of the ERROR. equation for model solutions if it has been reassigned or used in the equation.
- ERROR.** An ERROR.name variable is like an EQ.-prefixed variable, except that it is used only for model solution and does not affect parameter estimation.
- PRED.** For a normalized form equation (specified by assignment to a model variable), the PRED.name equation variable holds the predicted value, where name is the name of both the model variable and the corresponding equation. (PRED.-prefixed variables are not created for general form equations.)
- ACTUAL.** For a normalized form equation (specified by assignment to a model variable), the ACTUAL.name equation variable holds the value of the name model variable read from the input data set.
- DERT.** The DERT.name variable defines a differential equation. Once defined, it might be used on the right-hand side of another equation.
- H.** The H.name variable specifies the functional form for the variance of the named equation.
- GMM_H.** This is created for H.vars and is the moment equation for the variance for GMM. This variable is used only for GMM.

GMM_H.name = RESID.name2 - H.name;**

MSE. The `MSE.y` variable contains the value of the mean squared error for `y` at each iteration. An `MSE.` variable is created for each dependent/endogenous variable in the model. These variables can be used to specify the missing lagged values in the estimation and simulation of GARCH type models.

```
demret = intercept ;
h.demret = arch0 +
            arch1 * xlag( resid.demret ** 2, mse.demret) +
            garch1 * xlag(h.demret, mse.demret) ;
```

NRESID. This is created for `H.vars` and is the normalized residual of the variable `<name>`. The formula is

```
NRESID.name = RESID.name / sqrt(H.name) ;
```

The three equation variable prefixes, `RESID.`, `ERROR.`, and `EQ.` allow for control over the objective function for the `FIT`, the `SOLVE`, or both the `FIT` and the `SOLVE` stages. For `FIT` tasks, `PROC MODEL` looks first for a `RESID.name` variable for each equation. If defined, the `RESID.`-prefixed equation variable is used to define the objective function for the parameter estimation process. Otherwise, `PROC MODEL` looks for an `EQ.`-prefixed variable for the equation and uses it instead.

For `SOLVE` tasks, `PROC MODEL` looks first for an `ERROR.name` variable for each equation. If defined, the `ERROR.`-prefixed equation variable is used for the solution process. Otherwise, `PROC MODEL` looks for an `EQ.`-prefixed variable for the equation and uses it instead. To solve the simultaneous equation system, `PROC MODEL` computes values of the solution variables (the model variables being solved for) that make all of the `ERROR.name` and `EQ.name` variables close to 0.

Derivatives

Nonlinear modeling techniques require the calculation of derivatives of certain variables with respect to other variables. The `MODEL` procedure includes an analytic differentiator that determines the model derivatives and generates program code to compute these derivatives. When parameters are estimated, the `MODEL` procedure takes the derivatives of the equation with respect to the parameters. When the model is solved, Newton's method requires the derivatives of the equations with respect to the variables solved for.

`PROC MODEL` uses exact mathematical formulas for derivatives of non-user-defined functions. For other functions, numerical derivatives are computed and used.

The differentiator differentiates the entire model program, including the conditional logic and flow of control statements. Delayed definitions, as when the `LAG` of a program variable is referred to before the variable is assigned a value, are also differentiated correctly.

The differentiator includes optimization features that produce efficient code for the calculation of derivatives. However, when flow of control statements such as `GOTO` statements are used, the optimization process is impeded, and less efficient code for derivatives might be produced. Optimization is also reduced by conditional statements, iterative `DO` loops, and multiple assignments to the same variable.

The table of derivatives is printed with the LISTDER option. The code generated for the computation of the derivatives is printed with the LISTCODE option.

Derivative Variables

When the differentiator needs to generate code to evaluate the expression for the derivative of a variable, the result is stored in a special derivative variable. Derivative variables are not created when the derivative expression reduces to a previously computed result, a variable, or a constant. The names of derivative variables, which might sometimes appear in the printed output, have the form *@obj/@wrt*, where *obj* is the variable whose derivative is being taken and *wrt* is the variable that the differentiation is with respect to. For example, the derivative variable for the derivative of *Y* with respect to *X* is named *@Y/@X*.

The derivative variables can be accessed or used as part of the model program using the GETDER() function.

GETDER(*x*, *a*) the derivative of *x* with respect to *a*.

GETDER(*x*, *a*, *b*) the second derivative of *x* with respect to *a* and *b*.

The main purpose of the GETDER() function is for surfacing the derivatives so they can be stored in a data set for further processing. Only derivatives that are implied by the problem are available to the GETDER() function. When derivatives are requested that aren't already created, a missing value will be returned. The derivative of the GETDER() function is always zero so the results of the GETDER() function shouldn't be used in any of the equations in the FIT or the SOLVE statement.

The following example adds the gradient of the PRED.y value with respect to the parameters to the OUT= data set.

```
proc model data=line ;
  y = a1 + b1**2 *x1 + c1*x2;
  Dy_a1 = getder(PRED.y, a1);
  Dy_b1 = getder(PRED.y, b1);
  Dy_c1 = getder(PRED.y, c1);
  outvars Dy_a1 Dy_b1 Dy_c1;
  fit y / out=grad;
run;
```

Mathematical Functions

The following is a brief summary of SAS functions that are useful for defining models. Additional functions and details are in *SAS Language: Reference*. Information about creating new functions can be found in *SAS/BASE Software: Procedure Reference*, Chapter 18, "The FCMP Procedure."

ABS(<i>x</i>)	the absolute value of <i>x</i>
ARCOS(<i>x</i>)	the arccosine in radians of <i>x</i> ; <i>x</i> should be between -1 and 1 .
ARSIN(<i>x</i>)	the arcsine in radians of <i>x</i> ; <i>x</i> should be between -1 and 1 .
ATAN(<i>x</i>)	the arctangent in radians of <i>x</i>

<code>COS(<i>x</i>)</code>	the cosine of <i>x</i> ; <i>x</i> is in radians.
<code>COSH(<i>x</i>)</code>	the hyperbolic cosine of <i>x</i>
<code>EXP(<i>x</i>)</code>	e^x
<code>LOG(<i>x</i>)</code>	the natural logarithm of <i>x</i>
<code>LOG10(<i>x</i>)</code>	the log base ten of <i>x</i>
<code>LOG2(<i>x</i>)</code>	the log base two of <i>x</i>
<code>SIN(<i>x</i>)</code>	the sine of <i>x</i> ; <i>x</i> is in radians.
<code>SINH(<i>x</i>)</code>	the hyperbolic sine of <i>x</i>
<code>SQRT(<i>x</i>)</code>	the square root of <i>x</i>
<code>TAN(<i>x</i>)</code>	the tangent of <i>x</i> ; <i>x</i> is in radians and is not an odd multiple of $\pi/2$.
<code>TANH(<i>x</i>)</code>	the hyperbolic tangent of <i>x</i>

Random-Number Functions

The MODEL procedure provides several functions for generating random numbers for Monte Carlo simulation. These functions use the same generators as the corresponding SAS DATA step functions.

The following random number functions are supported: RANBIN, RANCAU, RAND, RANEXP, RANGAM, RANNOR, RANPOI, RANTBL, RANTRI, and RANUNI. For more information, refer to *SAS Language: Reference*.

Each reference to a random number function sets up a separate pseudo-random sequence. Note that this means that two calls to the same random function with the same seed produce identical results. This is different from the behavior of the random number functions used in the SAS DATA step. For example, the following statements produce identical values for X and Y, but Z is from an independent pseudo-random sequence:

```
x=rannor(123);
y=rannor(123);
z=rannor(567);
q=rand('BETA', 1, 12 );
```

For FIT tasks, all random number functions always return 0. For SOLVE tasks, when Monte Carlo simulation is requested, a random number function computes a new random number on the first iteration for an observation (if it is executed on that iteration) and returns that same value for all later iterations of that observation. When Monte Carlo simulation is not requested, random number functions always return 0.

Functions across Time

PROC MODEL provides four types of special built-in functions that refer to the values of variables and expressions in previous time periods. These functions have the following forms where *n* represents the

number of periods, x is any expression, and the argument i is a variable or expression that gives the lag length ($0 \leq i \leq n$). If the index value i is omitted, the maximum lag length n is used.

$LAGn (< i, > x)$ returns the i th lag of x , where n is the maximum lag;

$DIFn (x)$ is the difference of x at lag n

$ZLAGn (< i, > x)$ returns the i th lag of x , where n is the maximum lag, with missing lags replaced with zero

$XLAGn (x, y)$ returns the n th lag of x if x is nonmissing, or y if x is missing

$ZDIFn (x)$ is the difference with lag length truncated and missing values converted to zero; x is the variable or expression to compute the moving average of

$MOVAVGn (x)$ is the moving average if X_t denotes the observation at time point t , to ensure compatibility with the number n of observations used to calculate the moving average $MOVAVGn$, the following definition is used:

$$MOVAVGn(X_t) = \frac{X_t + X_{t-1} + X_{t-2} + \dots + X_{t-n+1}}{n}$$

The moving average calculation for SAS 9.1 and earlier releases is as follows:

$$MOVAVGn(X_t) = \frac{X_t + X_{t-1} + X_{t-2} + \dots + X_{t-n}}{n + 1}$$

Missing values of x are omitted in computing the average.

If you do not specify n , the number of periods is assumed to be one. For example, $LAG(X)$ is the same as $LAG1(X)$. No more than four digits can be used with a lagging function; that is, $LAG9999$ is the greatest LAG function, $ZDIF9999$ is the greatest ZDIF function, and so on.

The LAG functions get values from previous observations and make them available to the program. For example, $LAG(X)$ returns the value of the variable X as it was computed in the execution of the program for the preceding observation. The expression $LAG2(X+2*Y)$ returns the value of the expression $X+2*Y$, computed by using the values of the variables X and Y that were computed by the execution of the program for the observation two periods ago.

The DIF functions return the difference between the current value of a variable or expression and the value of its LAG. For example, $DIF2(X)$ is a short way of writing $X-LAG2(X)$, and $DIF15(SQRT(2*Z))$ is a short way of writing $SQRT(2*Z)-LAG15(SQRT(2*Z))$.

The ZLAG and ZDIF functions are like the LAG and DIF functions, but they are not counted in the determination of the program lag length, and they replace missing values with 0s. The ZLAG function returns the lagged value if the lagged value is nonmissing, or 0 if the lagged value is missing. The ZDIF function returns the differenced value if the differenced value is nonmissing, or 0 if the value of the differenced value is missing. The ZLAG function is especially useful for models with ARMA error processes. See the next section for details.

Lag Logic

The LAG and DIF lagging functions in the MODEL procedure are different from the queuing functions with the same names in the DATA step. Lags are determined by the final values that are set for the program

variables by the execution of the model program for the observation. This can have upsetting consequences for programs that take lags of program variables that are given different values at various places in the program, as shown in the following statements:

```
temp = x + w;
t    = lag( temp );
temp = q - r;
s    = lag( temp );
```

The expression LAG(TEMP) always refers to LAG(Q–R), never to LAG(X+W), since Q–R is the final value assigned to the variable TEMP by the model program. If LAG(X+W) is wanted for T, it should be computed as T=LAG(X+W) and not T=LAG(TEMP), as in the preceding example.

Care should also be exercised in using the DIF functions with program variables that might be reassigned later in the program. For example, the program

```
temp = x ;
s    = dif( temp );
temp = 3 * y;
```

computes values for S equivalent to

```
s = x - lag( 3 * y );
```

Note that in the preceding examples, TEMP is a program variable, *not* a model variable. If it were a model variable, the assignments to it would be changed to assignments to a corresponding equation variable.

Note that whereas LAG1(LAG1(X)) is the same as LAG2(X), DIF1(DIF1(X)) is *not* the same as DIF2(X). The DIF2 function is the difference between the current period value at the point in the program where the function is executed and the final value at the end of execution two periods ago; DIF2 is not the second difference. In contrast, DIF1(DIF1(X)) is equal to DIF1(X)-LAG1(DIF1(X)), which equals X–2*LAG1(X)+LAG2(X), which is the second difference of X.

More information about the differences between PROC MODEL and the DATA step LAG and DIF functions is found in Chapter 3, “[Working with Time Series Data](#).”

Lag Lengths

The lag length of the model program is the number of lags needed for any relevant equation. The program lag length controls the number of observations used to initialize the lags.

PROC MODEL keeps track of the use of lags in the model program and automatically determines the lag length of each equation and of the model as a whole. PROC MODEL sets the program lag length to the maximum number of lags needed to compute any equation to be estimated, solved, or needed to compute any instrument variable used.

In determining the lag length, the ZLAG and ZDIF functions are treated as always having a lag length of 0. For example, if Y is computed as

```
y = lag2( x + zdif3( temp ) );
```

then Y has a lag length of 2 (regardless of how TEMP is defined). If Y is computed as

```
y = zlag2( x + dif3( temp ) );
```

then Y has a lag length of 0.

This is so that ARMA errors can be specified without causing the loss of additional observations to the lag starting phase and so that recursive lag specifications, such as moving-average error terms, can be used. Recursive lags are not permitted unless the ZLAG or ZDIF functions are used to truncate the lag length. For example, the following statement produces an error message:

```
t = a + b * lag( t );
```

The program variable T depends recursively on its own lag, and the lag length of T is therefore undefined.

In the following equation RESID.Y depends on the predicted value for the Y equation but the predicted value for the Y equation depends on the LAG of RESID.Y, and thus, the predicted value for the Y equation depends recursively on its own lag.

```
y = yhat + ma * lag( resid.y );
```

The lag length is infinite, and PROC MODEL prints an error message and stops. Since this kind of specification is allowed, the recursion must be truncated at some point. The ZLAG and ZDIF functions do this.

The following equation is valid and results in a lag length for the Y equation equal to the lag length of YHAT:

```
y = yhat + ma * zlag( resid.y );
```

Initially, the lags of RESID.Y are missing, and the ZLAG function replaces the missing residuals with 0s, their unconditional expected values.

The ZLAG0 function can be used to zero out the lag length of an expression. ZLAG0(*x*) returns the current period value of the expression *x*, if nonmissing, or else returns 0, and prevents the lag length of *x* from contributing to the lag length of the current statement.

Initializing Lags

At the start of each pass through the data set or BY group, the lag variables are set to missing values and an initialization is performed to fill the lags. During this phase, observations are read from the data set, and the model variables are given values from the data. If necessary, the model is executed to assign values

to program variables that are used in lagging functions. The results for variables used in lag functions are saved. These observations are not included in the estimation or solution.

If, during the execution of the program for the lag starting phase, a lag function refers to lags that are missing, the lag function returns missing. Execution errors that occur while starting the lags are not reported unless requested. The modeling system automatically determines whether the program needs to be executed during the lag starting phase.

If *L* is the maximum lag length of any equation being fit or solved, then the first *L* observations are used to prime the lags. If a *BY* statement is used, the first *L* observations in the *BY* group are used to prime the lags. If a *RANGE* statement is used, the first *L* observations prior to the first observation requested in the *RANGE* statement are used to prime the lags. Therefore, there should be at least *L* observations in the data set.

Initial values for the lags of model variables can also be supplied in *VAR*, *ENDOGENOUS*, and *EXOGENOUS* statements. This feature provides initial lags of solution variables for dynamic solution when initial values for the solution variable are not available in the input data set. For example, the statement

```
var x 2 3 y 4 5 z 1;
```

feeds the initial lags exactly like these values in an input data set:

Lag	X	Y	Z
2	3	5	.
1	2	4	1

If initial values for lags are available in the input data set and initial lag values are also given in a declaration statement, the values in the *VAR*, *ENDOGENOUS*, or *EXOGENOUS* statements take priority.

The *RANGE* statement is used to control the range of observations in the input data set that are processed by PROC MODEL. In the following statement, '01jan1924' specifies the starting period of the range, and '01dec1943' specifies the ending period:

```
range date = '01jan1924'd to '01dec1943'd;
```

The observations in the data set immediately prior to the start of the range are used to initialize the lags.

Language Differences

For the most part, PROC MODEL programming statements work the same as they do in the DATA step as documented in *SAS Language: Reference*. However, there are several differences that should be noted.

DO Statement Differences

The DO statement in PROC MODEL does not allow a character index variable. Thus, the following DO statement is not valid in PROC MODEL, although it is supported in the DATA step:

```
do i = 'A', 'B', 'C'; /* invalid PROC MODEL code */
```

IF Statement Differences

The IF statement in PROC MODEL does not allow a character-valued condition. For example, the following IF statement is not supported by PROC MODEL:

```
if 'this' then statement;
```

Comparisons of character values are supported in IF statements, so the following IF statement is acceptable:

```
if 'this' < 'that' then statement;
```

PROC MODEL allows for embedded conditionals in expressions. For example the following two statements are equivalent:

```
flag = if time = 1 or time = 2 then conc+30/5 + dose*time
      else if time > 5 then (0=1) else (patient * flag);
```

```
if time = 1 or time = 2 then flag= conc+30/5 + dose*time;
else if time > 5 then flag=(0=1); else flag=patient*flag;
```

Note that the ELSE operator involves only the first object or token after it so that the following assignments are not equivalent:

```
total = if sum > 0 then sum else sum + reserve;
total = if sum > 0 then sum else (sum + reserve);
```

The first assignment makes TOTAL always equal to SUM plus RESERVE.

PUT Statement Differences

The PUT statement, mostly used in PROC MODEL for program debugging, supports only some of the features of the DATA step PUT statement. It also has some new features that the DATA step PUT statement does not support.

The PROC MODEL PUT statement does not support line pointers, factored lists, iteration factors, overprinting, the `_INFILE_` option, or the colon (:) format modifier.

The PROC MODEL PUT statement does support expressions, but an expression must be enclosed in parentheses. For example, the following statement prints the square root of x:

```
put (sqrt(x));
```

Subscripted array names must be enclosed in parentheses. For example, the following statement prints the *i*th element of the array A:

```
put (a i);
```

However, the following statement is an error:

```
put a i;
```

The PROC MODEL PUT statement supports the print item `_PDV_` to print a formatted listing of all the variables in the program. For example, the following statement prints a much more readable listing of the variables than does the `_ALL_` print item:

```
put _pdv_;
```

To print all the elements of the array A, use the following statement:

```
put a;
```

To print all the elements of A with each value labeled by the name of the element variable, use the following statement:

```
put a=;
```

ABORT Statement Difference

In the MODEL procedure, the ABORT statement does not allow any arguments.

SELECT/WHEN/OTHERWISE Statement Differences

The WHEN and OTHERWISE statements allow more than one target statement. That is, DO groups are not necessary for multiple statement WHENs. For example in PROC MODEL, the following syntax is valid:

```
select;
  when (exp1)
    stmt1;
    stmt2;
  when (exp2)
    stmt3;
    stmt4;
end;
```

The ARRAY Statement

ARRAY *arrayname* < {*dimensions*} > < \$ [*length*] > < *variables and constants* > ; ;

The ARRAY statement is used to associate a name with a list of variables and constants. The array name can then be used with subscripts in the model program to refer to the items in the list.

In PROC MODEL, the ARRAY statement does not support all the features of the DATA step ARRAY statement. Implicit indexing cannot be used; all array references must have explicit subscript expressions. Only exact array dimensions are allowed; lower-bound specifications are not supported. A maximum of six dimensions is allowed.

On the other hand, the ARRAY statement supported by PROC MODEL does allow both variables and constants to be used as array elements. You cannot make assignments to constant array elements. Both dimension specification and the list of elements are optional, but at least one must be supplied. When the list of elements is not given or fewer elements than the size of the array are listed, array variables are created by suffixing element numbers to the array name to complete the element list.

The following are valid PROC MODEL array statements:

```
array x[120];           /* array X of length 120           */
array q[2,2];           /* Two dimensional array Q           */
array b[4] va vb vc vd; /* B[2] = VB, B[4] = VD             */
array x x1-x30;         /* array X of length 30, X[7] = X7   */
array a[5] (1 2 3 4 5); /* array A initialized to 1,2,3,4,5 */
```

RETAIN Statement

RETAIN *variables initial-values* ;

The RETAIN statement causes a program variable to hold its value from a previous observation until the variable is reassigned. The RETAIN statement can be used to initialize program variables.

The RETAIN statement does not work for model variables, parameters, or control variables because the values of these variables are under the control of PROC MODEL and not programming statements. Use the PARS and CONTROL statements to initialize parameters and control variables. Use the VAR, ENDOGENOUS, or EXOGENOUS statement to initialize model variables.

Storing Programs in Model Files

Models can be saved in and recalled from SAS catalog files as well as XML-based data sets. SAS catalogs are special files that can store many kinds of data structures as separate units in one SAS file. Each separate unit is called an entry, and each entry has an entry type that identifies its structure to the SAS system. Starting with SAS 9.2, model files are being stored as SAS data sets instead of being stored as members of a SAS catalog as in earlier releases. This makes MODEL files more readily extendable in the future and enables Java-based applications to read the MODEL files directly. You can choose between the two formats by specifying a global CMPMODEL option in an OPTIONS statement. Details are given below.

In general, to save a model, use the `OUTMODEL=name` option in the `PROC MODEL` statement, where *name* is specified as *libref.catalog.entry*, *libref.entry*, or *entry* for catalog entry and, starting with SAS 9.2, *libref.datasetname* or *datasetname* for XML-based SAS datasets. The *libref*, *catalog*, *datasetnames* and *entry* names must be valid SAS names no more than 32 characters long. The *catalog* name is restricted to seven characters on the CMS operating system. If not given, the *catalog* name defaults to `MODELS`, and the *libref* defaults to `WORK`. The entry type is always `MODEL`. Thus, `OUTMODEL=X` writes the model to the file `WORK.MODELS.X.MODEL` in the SAS catalog or creates a `WORK.X` XML-based dataset in the `WORK` library depending on the format chosen by using the `CMPMODEL=` option. By default, both these formats are chosen.

The `CMPMODEL=` option can be used in an `OPTIONS` statement to modify the behavior when reading and writing `MODEL` files. The values allowed are `CMPMODEL= BOTH | XML | CATALOG`. For example, the following statements restore the previous behavior:

```
options cmpmodel=catalog;
```

The `CMPMODEL=` option defaults to `BOTH` in SAS 9.2 and is intended for transitional use. If `CMPMODEL=BOTH`, the `MODEL` procedure writes both formats; when loading model files `PROC MODEL` attempts to load the XML version first and the `CATALOG` version second (if the XML version is not found). If `CMPMODEL=XML`, the `MODEL` procedure reads and writes only the XML format. If `CMPMODEL=CATALOG`, only the catalog format is used.

The `MODEL=` option is used to read in a model. A list of model files can be specified in the `MODEL=` option, and a range of names with numeric suffixes can be given, as in `MODEL=(MODEL1–MODEL10)`. When more than one model file is given, the list must be placed in parentheses, as in `MODEL=(A B C)`, except in case of a single name. If more than one model file is specified, the files are combined in the order listed in the `MODEL=` option.

The `MODEL` procedure continues to read and write catalog `MODEL` files, and model files created by previous releases of SAS/ETS continue to work, so you should experience no direct impact from this change.

When the `MODEL=` option is specified in the `PROC MODEL` statement and model definition statements are also given later in the `PROC MODEL` step, the model files are read in first, in the order listed, and the model program specified in the `PROC MODEL` step is appended after the model program read from the `MODEL=` files. The class assigned to a variable, when multiple model files are used, is the last declaration of that variable. For example, if `Y1` was declared endogenous in the model file `M1` and exogenous in the model file `M2`, the following statement causes `Y1` to be declared exogenous.

```
proc model model=(m1 m2);
```

The `INCLUDE` statement can be used to append model code to the current model code. In contrast, when the `MODEL=` option is used in the `RESET` statement, the current model is deleted before the new model is read.

By default, no model file is output if the `PROC MODEL` step performs any `FIT` or `SOLVE` tasks, or if the `MODEL=` option or the `NOSTORE` option is used. However, to ensure compatibility with previous versions of SAS/ETS software, when the `PROC MODEL` step does nothing but compile the model program, no input model file is read, and the `NOSTORE` option is not used, a model file is written. This model file is the default

input file for a later PROC SYSLIN or PROC SIMLIN step. The default output model filename in this case is WORK.MODELS._MODEL_.MODEL.

If FIT statements are used to estimate model parameters, the parameter estimates written to the output model file are the estimates from the last estimation performed for each parameter.

Macro Return Codes (SYSINFO)

PROC MODEL stores a return code in the automatic macro variable SYSINFO upon completion of the PROC MODEL step. In the event any FIT or SOLVE task fails to converge during the completion of a PROC MODEL step the value 1 is stored in the SYSINFO macro variable. Any subsequent SAS step will reset the value of SYSINFO.

Diagnostics and Debugging

PROC MODEL provides several features to aid in finding errors in the model program. These debugging features are not usually needed; most models can be developed without them.

The example model program that follows is used in the following sections to illustrate the diagnostic and debugging capabilities. This example is the estimation of a segmented model.

```

/*--- Diagnostics and Debugging ---*/

  else                  /* Plateau part of model */
    y = a + b*x0 + c*x0*x0;

  fit y;
run;

```

Program Listing

The LIST option produces a listing of the model program. The statements are printed one per line with the original line number and column position of the statement.

The program listing from the example program is shown in [Figure 19.85](#).

Figure 19.85 LIST Output for Segmented Model

QUADRATIC MODEL WITH PLATEAU		
The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	4043:4	x0 = (-0.5 * b) / c;
2	4044:4	if x < x0 then
3	4045:7	PRED.y = a + b * x + c * x * x;
3	4045:7	RESID.y = PRED.y - ACTUAL.y;
3	4045:7	ERROR.y = PRED.y - y;
4	4046:4	else
5	4047:7	PRED.y = a + b * x0 + c * x0 * x0;
5	4047:7	RESID.y = PRED.y - ACTUAL.y;
5	4047:7	ERROR.y = PRED.y - y;

The LIST option also shows the model translations that PROC MODEL performs. LIST output is useful for understanding the code generated by the %AR and the %MA macros.

Cross-Reference

The XREF option produces a cross-reference listing of the variables in the model program. The XREF listing is usually used in conjunction with the LIST option. The XREF listing does not include derivative (@-prefixed) variables. The XREF listing does not include generated assignments to equation variables, PRED., RESID., and ERROR.-prefixed variables, unless the DETAILS option is used.

The cross-reference from the example program is shown in [Figure 19.86](#).

Compiler Listing

The LISTCODE option lists the model code and derivatives tables produced by the compiler. This listing is useful only for debugging and should not normally be needed.

LISTCODE prints the operator and operands of each operation generated by the compiler for each model program statement. Many of the operands are temporary variables generated by the compiler and given names such as #temp1. When derivatives are taken, the code listing includes the operations generated for the derivatives calculations. The derivatives tables are also listed.

A LISTCODE option prints the transformed equations from the example shown in [Figure 19.87](#) and [Figure 19.88](#).

Analyzing the Structure of Large Models

PROC MODEL provides several features to aid in analyzing the structure of the model program. These features summarize properties of the model in various forms.

The following Klein's model program is used to introduce the LISTDEP, BLOCK, and GRAPH options.

```

proc model out=m data=klein listdep graph block;
  endogenous c p w i x wsum k y;
  exogenous wp g t year;
  parms c0-c3 i0-i3 w0-w3;
  a: c = c0 + c1 * p + c2 * lag(p) + c3 * wsum;
  b: i = i0 + i1 * p + i2 * lag(p) + i3 * lag(k);
  c: w = w0 + w1 * x + w2 * lag(x) + w3 * year;
  x = c + i + g;
  y = c + i + g-t;
  p = x-w-t;
  k = lag(k) + i;
  wsum = w + wp;
  id year;
run;

```

Dependency List

The LISTDEP option produces a dependency list for each variable in the model program. For each variable, a list of variables that depend on it and a list of variables it depends on is given. The dependency list produced by the example program is shown in [Figure 19.89](#).

BLOCK Listing

The BLOCK option prints an analysis of the program variables based on the assignments in the model program. The output produced by the example is shown in [Figure 19.90](#).

Figure 19.90 The BLOCK Output for Klein's Model

```

                                The MODEL Procedure
                                Model Structure Analysis
                                (Based on Assignments to Endogenous Model Variables)

                                Exogenous Variables      wp g t year
                                Endogenous Variables     c p w i x wsum k y

                                Block Structure of the System

                                Block 1      c p w i x wsum

                                Dependency Structure of the System

                                Block 1      Depends On All_Exogenous
                                k           Depends On Block 1 All_Exogenous
                                y           Depends On Block 1 All_Exogenous

```

One use for the block output is to put a model in recursive form. Simulations of the model can be done with the SEIDEL method, which is efficient if the model is recursive and if the equations are in recursive order. By examining the block output, you can determine how to reorder the model equations for the most efficient simulation.

Adjacency Graph

The GRAPH option displays the same information as the BLOCK option with the addition of an adjacency graph. An X in a column in an adjacency graph indicates that the variable associated with the row depends on the variable associated with the column. The output produced by the example is shown in [Figure 19.91](#).

The first and last graphs are straightforward. The middle graph represents the dependencies of the nonexogenous variables after transitive closure has been performed (that is, A depends on B, and B depends on C, so A depends on C). The preceding transitive closure matrix indicates that K and Y do not directly or indirectly depend on each other.

Examples: MODEL Procedure

Example 19.1: OLS Single Nonlinear Equation

This example illustrates the use of the MODEL procedure for nonlinear ordinary least squares (OLS) regression. The model is a logistic growth curve for the population of the United States. The data is the population in millions recorded at ten-year intervals starting in 1790 and ending in 2000. For an explanation of the starting values given by the START= option, see the section “[Troubleshooting Convergence Problems](#)” on page 1109. Portions of the output from the following statements are shown in [Output 19.1.1](#) through [Output 19.1.3](#).

```

title 'Logistic Growth Curve Model of U.S. Population';

c	0.022703	0.00107	21.22	<.0001	Initial Growth Rate	

The adjusted R^2 value indicates the model fits the data well. There are only 21 observations and the model is nonlinear, so significance tests on the parameters are only approximate. The significance tests and associated approximate probabilities indicate that all the parameters are significantly different from 0.

The FIT statement included the options OUT=RESID and OUTRESID so that the residuals from the estimation are saved to the data set RESID. The residuals are plotted to check for heteroscedasticity by using PROC SGPLOT as follows.

```

title2 "Residuals Plot";
proc sgplot data=resid;
  refline 0;
  scatter x=year y=pop / markerattrs=(symbol=circlefilled);
  xaxis values=(1780 to 2000 by 20);
run;

```

The plot is shown in [Output 19.1.4](#).

Output 19.1.4 Residual for Population Model (Actual–Predicted)

The residuals do not appear to be independent, and the model could be modified to explain the remaining nonrandom errors.

Example 19.2: A Consumer Demand Model

This example shows the estimation of a system of nonlinear consumer demand equations based on the translog functional form by using seemingly unrelated regression (SUR). Expenditure shares and corresponding normalized prices are given for three goods.

Since the shares add up to one, the system is singular; therefore, one equation is omitted from the estimation process. The choice of which equation to omit is arbitrary. The nonlinear system is first estimated in unrestricted form by the following statements:

```

title1 'Consumer Demand--Translog Functional Form';
title2 'Asymmetric Model';

proc model data=tlog1;
  endogenous share1 share2;
  parms a1 a2 b11 b12 b13 b21 b22 b23 b31 b32 b33;

  bm1 = b11 + b21 + b31;
  bm2 = b12 + b22 + b32;
  bm3 = b13 + b23 + b33;
  lp1 = log(p1);
  lp2 = log(p2);
  lp3 = log(p3);
  share1 = ( a1 + b11 * lp1 + b12 * lp2 + b13 * lp3 ) /
            ( -1 + bm1 * lp1 + bm2 * lp2 + bm3 * lp3 );
  share2 = ( a2 + b21 * lp1 + b22 * lp2 + b23 * lp3 ) /
            ( -1 + bm1 * lp1 + bm2 * lp2 + bm3 * lp3 );

  fit share1 share2
    start=( a1 -.14 a2 -.45 b11 .03 b12 .47 b22 .98 b31 .20
            b32 1.11 b33 .71 ) / outsused=smatrix sur;
run;

```

A portion of the printed output produced by this example is shown in [Output 19.2.1](#) through [Output 19.2.3](#).

```

Hypothesis testing requires that the **S** matrix from the unrestricted model be imposed on the restricted model, as explained in the section “[Tests on Parameters](#)” on page 1156. The **S** matrix saved in the data set **SMATRIX** is requested by the **SDATA=** option.

A chi-square test is used to see if the hypothesis of symmetry is accepted or rejected. $(Oc - Ou)$ has a chi-square distribution asymptotically, where Oc is the constrained **OBJECTIVE*N** and Ou is the unconstrained **OBJECTIVE*N**. The degrees of freedom is equal to the difference in the number of free parameters in the two models.

In this example, O_u is 76.9697 and O_c is 78.4097, resulting in a difference of 1.44 with 3 degrees of freedom. You can obtain the probability value by using the following statements:

```
data _null_;
  /* probchi( reduced-full, n-restrictions )*/
  p = 1-probchi( 1.44, 3 );
  put p=;
run;
```

The output from this DATA step run is $p = 0.6961858724$. With this p -value you cannot reject the hypothesis of symmetry. This test is asymptotically valid.

Example 19.3: Vector AR(1) Estimation

This example shows the estimation of a two-variable vector AR(1) error process for the Grunfeld model (Grunfeld and Griliches 1960) by using the %AR macro. First, the full model is estimated. Second, the model is estimated with the restriction that the errors are univariate AR(1) instead of a vector process. The following statements produce [Output 19.3.1](#) through [Output 19.3.5](#).

```
data grunfeld;
  input year gei gef gec whi whf whc;
  label gei = 'Gross Investment GE'
        gec = 'Capital Stock Lagged GE'
        gef = 'Value of Outstanding Shares GE Lagged'
        whi = 'Gross Investment WH'
        whc = 'Capital Stock Lagged WH'
        whf = 'Value of Outstanding Shares Lagged WH';
datalines;

proc model outmodel=grunmod;
  var gei whi gef gec whf whc;
  parms ge_int ge_f ge_c wh_int wh_f wh_c;
  label ge_int = 'GE Intercept'
        ge_f   = 'GE Lagged Share Value Coef'
        ge_c   = 'GE Lagged Capital Stock Coef'
        wh_int = 'WH Intercept'
        wh_f   = 'WH Lagged Share Value Coef'
        wh_c   = 'WH Lagged Capital Stock Coef';
  gei = ge_int + ge_f * gef + ge_c * gec;
  whi = wh_int + wh_f * whf + wh_c * whc;
run;
```

The preceding PROC MODEL step defines the structural model and stores it in the model file named GRUNMOD.

The following PROC MODEL step reads in the model, adds the vector autoregressive terms using %AR, and requests SUR estimation by using the FIT statement.

```
title2 'With Unrestricted Vector AR(1) Error Process';

proc model data=grunfeld model=grunmod;
  %ar( ar, 1, gei whi )
  fit gei whi / sur;
run;
```

The final PROC MODEL step estimates the restricted model, as shown in the following statements:

```
title2 'With restricted AR(1) Error Process';

proc model data=grunfeld model=grunmod;
  %ar( gei, 1 )
  %ar( whi, 1)
  fit gei whi / sur;
run;
```

Number of Residuals				20			

The model stored in [Example 19.3](#) is read in by using the MODEL= option and the moving-average terms are added using the %MA macro.

The MA(1) model using maximum likelihood is estimated by using the following statements:

```

title2 'MA(1) Error Process Using Maximum Likelihood ';

proc model data=grunfeld model=grunmod;
  %ma(gei,1, m=ml);
  %ma(whi,1, m=ml);
  fit whi gei;
run;

```

For comparison, the model is estimated by using PROC ARIMA as follows:

```

title2 'PROC ARIMA Using Maximum Likelihood ';

proc arima data=grunfeld;
  identify var=whi cross=(whf whc) noprint;
  estimate q=1 input=(whf whc) method=ml;
run;

```

PROC ARIMA does not estimate systems, so only one equation is evaluated.

The estimation results are shown in [Output 19.4.3](#) and [Output 19.4.4](#). The small differences in the parameter values between PROC MODEL and PROC ARIMA can be eliminated by tightening the convergence criteria for both procedures.

Example 19.5: Polynomial Distributed Lags by Using %PDL

This example shows the use of the %PDL macro for polynomial distributed lag models. Simulated data is generated so that Y is a linear function of six lags of X, with the lag coefficients following a quadratic polynomial. The model is estimated by using a fourth-degree polynomial, both with and without endpoint constraints. The example uses simulated data generated from the following model:

$$y_t = 10 + \sum_{z=0}^6 f(z)x_{t-z} + \epsilon$$

$$f(z) = -5z^2 + 1.5z$$

The LIST option prints the model statements added by the %PDL macro. The following statements generate simulated data as shown:

```

/*-----*/
/*  Generate Simulated Data for a Linear Model with a PDL on X  */
/*      y = 10 + x(6,2) + e                                     */
/*      pdl(x) = -5.*(lg)**2 + 1.5*(lg) + 0.                    */
/*-----*/
data pdl;
  pdl2=-5.; pdl1=1.5; pdl0=0;
  array zz(i) z0-z6;
  do i=1 to 7;
    z=i-1;
    zz=pdl2*z**2 + pdl1*z + pdl0;
  end;
  do n=-11 to 30;
    x =10*ranuni(1234567)-5;
    pdl=z0*x + z1*x11 + z2*x12 + z3*x13 + z4*x14 + z5*x15 + z6*x16;
    e =10*rannor(1234567);
    y =10+pdl+e;
    if n>=1 then output;
    x16=x15; x15=x14; x14=x13; x13=x12; x12=x11; x11=x;
  end;
run;

title1 'Polynomial Distributed Lag Example';
title3 'Estimation of PDL(6,4) Model-- No Endpoint Restrictions';

```

```

proc model data=pdl;
  parms int;                                /* declare the intercept parameter */
  %pdl( xpdL, 6, 4 )                        /* declare the lag distribution */
  y = int + %pdl( xpdL, x );                /* define the model equation */
  fit y / list;                             /* estimate the parameters */
run;

```

The LIST output for the model without endpoint restrictions is shown in [Output 19.5.1](#). The first seven statements in the generated program are the polynomial expressions for lag parameters XPDL_L0 through XPDL_L6. The estimated parameters are INT, XPDL_0, XPDL_1, XPDL_2, XPDL_3, and XPDL_4.

XPDL_3	-9.3535	1.7602	-5.31	<.0001	parameter for (L)**2		
XPDL_4	1.032421	0.1471	7.02	<.0001	PDL(XPDL, 6, 4)		
					parameter for (L)**3		
					PDL(XPDL, 6, 4)		
					parameter for (L)**4		

Note that XPDL_0 and XPDL_1 are not shown in the estimate summary. They were used to satisfy the endpoint restrictions analytically by the generated %PDL macro code. Their values can be determined by back substitution.

To estimate the PDL model with one or more of the polynomial terms dropped, specify the largest degree of the polynomial desired with the %PDL macro and use the DROP= option in the FIT statement to remove the unwanted terms. The dropped parameters should be set to 0. The following PROC MODEL statements demonstrate estimation with a PDL of degree 2 without the 0th order term.

```

title3 'Estimation of PDL(6,2) Model-- With XPDL_0 Dropped';

proc model data=pd1 list;
  parms int;                               /* declare the intercept parameter */
  %pdl( xpdl, 6, 2 )                       /* declare the lag distribution */
  y = int + %pdl( xpdl, x );               /* define the model equation */
  xpdl_0 =0;
  fit y drop=xpdl_0;                       /* estimate the parameters */
run;

```

The results from this estimation are shown in [Output 19.5.4](#).

Output 19.5.4 PROC MODEL Results That Specify %PDL(XPDL, 6, 2)

Example 19.6: General Form Equations

Data for this example are generated. General form equations are estimated and forecast by using PROC MODEL. The system is a basic supply and demand model.

The following statements specify the form of the model:

```

title1 "General Form Equations for Supply-Demand Model";

proc model outmodel=model;
  var price quantity income unitcost;
  parms d0-d2 s0-s2;
  eq.demand=d0+d1*price+d2*income-quantity;
  eq.supply=s0+s1*price+s2*unitcost-quantity;
run;

```

Three data sets are used in this example. The first data set, HISTORY, is used to estimate the parameters of the model. The ASSUME data set is used to produce a forecast of PRICE and QUANTITY. Notice that the ASSUME data set does not need to contain the variables PRICE and QUANTITY. The HISTORY data set is shown as follows:

```

data history;
  input year income unitcost price quantity;
datalines;
1976      2221.87      3.31220      0.17903      266.714

```

```

1977      2254.77      3.61647      0.06757      276.049
... more lines ...

```

The ASSUME data set is shown as follows:

```

data assume;
  input year income unitcost;
datalines;
1986      2571.87      2.31220

Example 19.7: Spring and Damper Continuous System

This model simulates the mechanical behavior of a spring and damper system shown in Figure 19.92.

Figure 19.92 Spring and Damper System Model

A mass is hung from a spring with spring constant K . The motion is slowed by a damper with damper constant C . The damping force is proportional to the velocity, while the spring force is proportional to the displacement.

This is actually a continuous system; however, the behavior can be approximated by a discrete time model. We approximate the differential equation

$$\frac{\partial \text{disp}}{\partial \text{time}} = \text{velocity}$$

with the difference equation

$$\frac{\Delta \text{disp}}{\Delta \text{time}} = \text{velocity}$$

This is rewritten as

$$\frac{\text{disp} - \text{LAG}(\text{disp})}{dt} = \text{velocity}$$

where dt is the time step used. In PROC MODEL, this is expressed with the program statement

```
disp = lag(disp) + vel * dt;
```

or

```
dert.disp = vel;
```

The first statement is simply a computing formula for Euler's approximation for the integral

$$\text{disp} = \int \text{velocity} dt$$

If the time step is small enough with respect to the changes in the system, the approximation is good. Although PROC MODEL does not have the variable step-size and error-monitoring features of simulators designed for continuous systems, the procedure is a good tool to use for less challenging continuous models.

The second form instructs the MODEL procedure to do the integration for you.

This model is unusual because there are no exogenous variables, and endogenous data are not needed. Although you still need a SAS data set to count the simulation periods, no actual data are brought in.

Since the variables DISP and VEL are lagged, initial values specified in the VAR statement determine the starting state of the system. The mass, time step, spring constant, and damper constant are declared and initialized by a CONTROL statement as shown in the following statements:

```
title1 'Simulation of Spring-Mass-Damper System';

/*- Data to drive the simulation time periods ---*/
data one;
  do n=1 to 100;
    output;
  end;
run;

proc model data=one outmodel=spring;
  var      force -200  disp  10  vel  0  accel -20  time 0;
  control  mass   9.2  c    1.5  dt   .1  k      20;
  force = -k * disp -c * vel;
  disp  = lag(disp) + vel * dt;
  vel   = lag(vel) + accel * dt;
```

```

    accel = force / mass;
    time = lag(time) + dt;
run;

```

The displacement scale is zeroed at the point where the force of gravity is offset, so the acceleration of the gravity constant is omitted from the force equation. The control variable C and K represent the damper and the spring constants respectively.

The model is simulated three times, and the simulation results are written to output data sets. The first run uses the original initial conditions specified in the VAR statement. In the second run, the initial displacement is doubled; the results show that the period of the motion is unaffected by the amplitude. In the third run, the DERT. syntax is used to do the integration. Notice that the path of the displacement is close to the old path, indicating that the original time step is short enough to yield an accurate solution. These simulations are performed by the following statements:

```

proc model data=one model=spring;
    title2 "Simulation of the model for the base case";
    control run '1';
    solve / out=a;
run;

    title2 "Simulation of the model with twice the initial displacement";
    control run '2';
    var disp 20;
    solve / out=b;
run;

data two;
    do time = 0 to 10 by .2; output;end;
run;

title2 "Simulation of the model using the dert. syntax";
proc model data=two;
    var      force -200  disp  10  vel  0  accel -20  time 0;
    control  mass   9.2  c    1.5  dt   .1  k      20;
    control run '3' ;
    force = -k * disp -c * vel;
    dert.disp = vel ;
    dert.vel   = accel;
    accel = force / mass;
    solve / out=c;
    id time ;
run;

```

The output SAS data sets that contain the solution results are merged and the displacement time paths for the three simulations are plotted. The three runs are identified on the plot as 1, 2, and 3. The following statements produce [Output 19.7.1](#) through [Output 19.7.5](#).

```

data p;
    set a b c;
run;

title2 'Overlay Plot of All Three Simulations';

```

```
proc sgplot data=p;
  series x=time y=disp / group=run lineattrs=(pattern=1);
  xaxis values=(0 to 10 by 1);
  yaxis values=(-20 to 20 by 10);
run;
```

Output 19.7.5 Overlay Plot of Three Simulations**Example 19.8: Nonlinear FIML Estimation**

The data and model for this example were obtained from Bard (1974, p.133–138). The example is a two-equation econometric model used by Bodkin and Klein to fit U.S production data for the years 1909–1949. The model is the following:

$$g_1 = c_1 10^{c_2 z_4} (c_5 z_1^{-c_4} + (1 - c_5) z_2^{-c_4})^{-c_3/c_4} - z_3 = 0$$

$$g_2 = [c_5 / (1 - c_5)] (z_1 / z_2)^{(-1 - c_4)} - z_5 = 0$$

where z_1 is capital input, z_2 is labor input, z_3 is real output, z_4 is time in years with 1929 as year zero, and z_5 is the ratio of price of capital services to wage scale. The c_i 's are the unknown parameters. z_1 and z_2 are considered endogenous variables. A FIML estimation is performed by using the following statements:

```
data bodkin;
  input z1 z2 z3 z4 z5;
```

```

datalines;
1.33135 0.64629 0.4026 -20 0.24447
1.39235 0.66302 0.4084 -19 0.23454

... more lines ...

title1 "Nonlinear FIML Estimation";

proc model data=bodkin;
  parms c1-c5;
  endogenous z1 z2;
  exogenous z3 z4 z5;

  eq.g1 = c1 * 10 ** (c2 * z4) * (c5*z1**(-c4)+
    (1-c5)*z2**(-c4))**(-c3/c4) - z3;
  eq.g2 = (c5/(1-c5))*(z1/z2)**(-1-c4) -z5;

  fit g1 g2 / fiml ;
run;

```

When FIML estimation is selected, the log likelihood of the system is output as the objective value. The results of the estimation are shown in [Output 19.8.1](#).

Example 19.9: Circuit Estimation

Consider the nonlinear circuit shown in Figure 19.93.

Figure 19.93 Nonlinear Resistor Capacitor Circuit

The theory of electric circuits is governed by Kirchhoff's laws: the sum of the currents flowing to a node is zero, and the net voltage drop around a closed loop is zero. In addition to Kirchhoff's laws, there are relationships between the current I through each element and the voltage drop V across the elements. For the circuit in Figure 19.93, the relationships are

$$C \frac{dV}{dt} = I$$

for the capacitor and

$$V = (R_1 + R_2(1 - \exp(-V)))I$$

for the nonlinear resistor. The following differential equation describes the current at node 2 as a function of time and voltage for this circuit:

$$C \frac{dV_2}{dt} - \frac{V_1 - V_2}{R_1 + R_2(1 - \exp(-V))} = 0$$

This equation can be written in the form

$$\frac{dV_2}{dt} = \frac{V_1 - V_2}{(R_1 + R_2(1 - \exp(-V)))C}$$

Consider the following data.

```
data circ;
  input v2 v1 time@@;
datalines;
```

```

;

```

You can estimate the parameters in the preceding equation by using the following SAS statements:

```

title1 'Circuit Model Estimation Example';

proc model data=circ mintimestep=1.0e-23;
  parm R2 2000 R1 4000 C 5.0e-13;
  dert.v2 = (v1-v2)/((r1 + r2*(1-exp( -(v1-v2)))) * C);
  fit v2;
run;

```

The results of the estimation are shown in [Output 19.9.1](#).

Output 19.9.1 Circuit Estimation

Circuit Model Estimation Example				
The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
R2	3002.471	1517.1	<-----	Biased
R1	4984.842	1466.8	<-----	Biased
C	5E-13	0	<-----	Biased
NOTE: The model was singular. Some estimates are marked 'Biased'.				

In this case, the model equation is such that there is linear dependency that causes biased results and inflated variances. The Jacobian matrix is singular or nearly singular, but eliminating one of the parameters is not a solution in this case.

Example 19.10: Systems of Differential Equations

The following is a simplified reaction scheme for the competitive inhibitors with recombinant human renin (Morelock et al. 1995).

Figure 19.94 Competitive Inhibition of Recombinant Human Renin

In Figure 19.94, E =enzyme, D =probe, and I =inhibitor.

The differential equations that describe this reaction scheme are as follows:

$$\frac{dD}{dt} = k1r*ED - k1f*E*D$$

$$\frac{dED}{dt} = k1f*E*D - k1r*ED$$

$$\frac{dE}{dt} = k1r*ED - k1f*E*D + k2r*EI - k2f*E*I$$

$$\frac{dEI}{dt} = k2f*E*I - k2r*EI$$

$$\frac{dI}{dt} = k2r*EI - k2f*E*I$$

For this system, the initial values for the concentrations are derived from equilibrium considerations (as a function of parameters) or are provided as known values.

The experiment used to collect the data was carried out in two ways; preincubation (type='disassoc') and no preincubation (type='assoc'). The data also contain repeated measurements. The data contain values for fluorescence F , which is a function of concentration. Since there are no direct data for the concentrations, all the differential equations are simulated dynamically.

The SAS statements used to fit this model are as follows:

```

title1 'Systems of Differential Equations Example';

proc sort data=fit;
    by type time;
run;

Example 19.11: Monte Carlo Simulation

This example illustrates how the form of the error in a ODE model affects the results from a static and dynamic estimation. The differential equation studied is

$$\frac{dy}{dt} = a - ay$$

The analytical solution to this differential equation is

$$y = 1 - \exp(-at)$$

The first data set contains errors that are strictly additive and independent. The data for this estimation are generated by the following DATA step:

```
data drive1;
  a = 0.5;
  do iter=1 to 100;
    do time = 0 to 50;
      y = 1 - exp(-a*time) + 0.1 *rannor(123);
      output;
    end;
  end;
run;
```

The second data set contains errors that are cumulative in form.

```
data drive2;
  a = 0.5;
  yp = 1.0 + 0.01 *rannor(123);
  do iter=1 to 100;
    do time = 0 to 50;
      y = 1 - exp(-a)*(1 - yp);
      yp = y + 0.01 *rannor(123);
      output;
    end;
  end;
run;
```

The following statements perform the 100 static estimations for each data set:

```

title1 'Monte Carlo Simulation of ODE';

proc model data=drive1 noprint;
  parm a 0.5;
  dert.y = a - a * y;
  fit y / outest=est;
  by iter;
run;

```

Similar statements are used to produce 100 dynamic estimations with a fixed and an unknown initial value. The first value in the data set is used to simulate an error in the initial value. The following PROC UNIVARIATE statements process the estimations:

```

proc univariate data=est noprint;
  var a;
  output out=monte mean=mean p5=p5 p95=p95;
run;

proc print data=monte;
run;

```

The results of these estimations are summarized in [Table 19.6](#).

Table 19.6 Monte Carlo Summary, A=0.5

Estimation Type	Additive Error			Cumulative Error		
	mean	p95	p5	mean	p95	p5
static	0.77885	1.03524	0.54733	0.57863	1.16112	0.31334
dynamic fixed	0.48785	0.63273	0.37644	3.8546E24	8.88E10	-51.9249
dynamic unknown	0.48518	0.62452	0.36754	641704.51	1940.42	-25.6054

For this example model, it is evident that the static estimation is the least sensitive to misspecification.

Example 19.12: Cauchy Distribution Estimation

In this example a nonlinear model is estimated by using the Cauchy distribution. Then a simulation is done for one observation in the data.

The following DATA step creates the data for the model.

```

/* Generate a Cauchy distributed Y */
data c;
  format date monyy.;
  call streaminit(156789);
  do t=0 to 20 by 0.1;
    date=intnx('month', '01jun90'd, (t*10)-1);
    x=rand('normal');

```

```

        e=rand('cauchy') + 10 ;
        y=exp(4*x)+e;
        output;
    end;
run;

```

The model to be estimated is

$$y = e^{-a x} + \epsilon$$

$$\epsilon \sim \text{Cauchy}(nc)$$

That is, the residuals of the model are distributed as a Cauchy distribution with noncentrality parameter nc .

The log likelihood for the Cauchy distribution is

$$like = -\log(1 + (x - nc)^2 * \pi)$$

The following SAS statements specify the model and the log-likelihood function.

```

title1 'Cauchy Distribution';

proc model data=c ;
    dependent y;
    parm a -2 nc 4;
    y=exp(-a*x);

    /* Likelihood function for the residuals */
    obj = log(1+(-resid.y-nc)**2 * 3.1415926);

    errormodel y ~ general(obj) cdf=cauchy(nc);

    fit y / outsn=s1 method=marquardt;
    solve y / sdata=s1 data=c(obs=1) random=1000
            seed=256789 out=out1;
run;

title 'Distribution of Y';
proc sgplot data=out1;
    histogram y;
run;

```

The FIT statement uses the OUTSN= option to output the Σ matrix for residuals from the normal distribution. The Σ matrix is 1×1 and has value 1.0 because it is a correlation matrix. The OUTS= matrix is the scalar 2989.0. Because the distribution is univariate (no covariances), the OUTS= option would produce the same simulation results. The simulation is performed by using the SOLVE statement.

The distribution of y is shown in the following output.

Output 19.12.1 Distribution of Y**Example 19.13: Switching Regression Example**

Take the usual linear regression problem

$$y = \mathbf{X}\beta + u$$

where Y denotes the n column vector of the dependent variable, \mathbf{X} denotes the $(n \times k)$ matrix of independent variables, β denotes the k column vector of coefficients to be estimated, n denotes the number of observations ($i = 1, 2, \dots, n$), and k denotes the number of independent variables.

You can take this basic equation and split it into two regimes, where the i th observation on y is generated by one regime or the other:

$$y_i = \sum_{j=1}^k \beta_{1j} X_{ji} + u_{1i} = x_i' \beta_1 + u_{1i}$$

$$y_i = \sum_{j=1}^k \beta_{2j} X_{ji} + u_{2i} = x_i' \beta_2 + u_{2i}$$

where x_{hi} and x_{hj} are the i th and j th observations, respectively, on x_h . The errors, u_{1i} and u_{2i} , are assumed to be distributed normally and independently with mean zero and constant variance. The variance for the first regime is σ_1^2 , and the variance for the second regime is σ_2^2 . If $\sigma_1^2 \neq \sigma_2^2$ and $\beta_1 \neq \beta_2$, the regression system given previously is thought to be switching between the two regimes.

The problem is to estimate β_1 , β_2 , σ_1 , and σ_2 without knowing *a priori* which of the n values of the dependent variable, y , was generated by which regime. If it is known *a priori* which observations belong to which regime, a simple Chow test can be used to test $\sigma_1^2 = \sigma_2^2$ and $\beta_1 = \beta_2$.

Using Goldfeld and Quandt's D-method for switching regression, you can solve this problem. Assume that observations exist on some exogenous variables z_{1i} , z_{2i} , ..., z_{pi} , where z determines whether the i th observation is generated from one equation or the other. The equations are given as follows:

$$y_i = x_i' \beta_1 + u_{1i} \quad \text{if } \sum_{j=1}^p \pi_j z_{ji} \leq 0$$

$$y_i = x_i' \beta_2 + u_{2i} \quad \text{if } \sum_{j=1}^p \pi_j z_{ji} > 0$$

where π_j are unknown coefficients to be estimated. Define $d(z_i)$ as a continuous approximation to a step function. Replacing the unit step function with a continuous approximation by using the cumulative normal integral enables a more practical method that produces consistent estimates.

$$d(z_i) = \frac{1}{\sqrt{2\pi}\sigma} \int_{-\infty}^{\sum \pi_j z_{ji}} \exp\left[-\frac{1}{2} \frac{\xi^2}{\sigma^2}\right] d\xi$$

D is the n dimensional diagonal matrix consisting of $d(z_i)$:

$$\mathbf{D} = \begin{bmatrix} d(z_1) & 0 & 0 & 0 \\ 0 & d(z_2) & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & d(z_n) \end{bmatrix}$$

The parameters to estimate are now the k β_1 's, the k β_2 's, σ_1^2 , σ_2^2 , p π 's, and the σ introduced in the $d(z_i)$ equation. The σ can be considered as given *a priori*, or it can be estimated, in which case, the estimated magnitude provides an estimate of the success in discriminating between the two regimes (Goldfeld and Quandt 1976). Given the preceding equations, the model can be written as:

$$Y = (\mathbf{I} - \mathbf{D}) \mathbf{X} \beta_1 + \mathbf{D} \mathbf{X} \beta_2 + W$$

where $W = (\mathbf{I} - \mathbf{D})U_1 + \mathbf{D}U_2$, and W is a vector of unobservable and heteroscedastic error terms. The covariance matrix of W is denoted by $\mathbf{\Omega}$, where $\mathbf{\Omega} = (\mathbf{I} - \mathbf{D})^2\sigma_1^2 + \mathbf{D}^2\sigma_2^2$. The maximum likelihood parameter estimates maximize the following log-likelihood function.

$$\begin{aligned} \log L = & -\frac{n}{2} \log 2\pi - \frac{1}{2} \log |\mathbf{\Omega}| - \\ & \frac{1}{2} * [Y - (\mathbf{I} - \mathbf{D})\mathbf{X}\beta_1 - \mathbf{D}\mathbf{X}\beta_2]' \mathbf{\Omega}^{-1} [Y - (\mathbf{I} - \mathbf{D})\mathbf{X}\beta_1 - \mathbf{D}\mathbf{X}\beta_2] \end{aligned}$$

As an example, you now can use this switching regression likelihood to develop a model of housing starts as a function of changes in mortgage interest rates. The data for this example are from the U.S. Census Bureau and cover the period from January 1973 to March 1999. The hypothesis is that there are different coefficients on your model based on whether the interest rates are going up or down.

So the model for z_i is

$$z_i = p * (\text{rate}_i - \text{rate}_{i-1})$$

where rate_i is the mortgage interest rate at time i and p is a scale parameter to be estimated.

The regression model is

$$\begin{aligned} \text{starts}_i &= \text{intercept}_1 + \text{ar1} * \text{starts}_{i-1} + \text{djf1} * \text{decjanfeb} & z_i < 0 \\ \text{starts}_i &= \text{intercept}_2 + \text{ar2} * \text{starts}_{i-1} + \text{djf2} * \text{decjanfeb} & z_i \geq 0 \end{aligned}$$

where starts_i is the number of housing starts at month i and decjanfeb is a dummy variable that indicates that the current month is one of December, January, or February.

This model is written by using the following SAS statements:

```

title1 'Switching Regression Example';

proc model data=switch;
  parms sig1=10 sig2=10 int1 b11 b13 int2 b21 b23 p;
  bounds 0.0001 < sig1 sig2;

  decjanfeb = ( month(date) = 12 | month(date) <= 2 );

  a = p*dif(rate);          /* Upper bound of integral */
  d = probnorm(a);         /* Normal CDF as an approx of switch */

                                /* Regime 1 */
  y1 = int1 + zlag(starts)*b11 + decjanfeb *b13 ;
                                /* Regime 2 */
  y2 = int2 + zlag(starts)*b21 + decjanfeb *b23 ;
                                /* Composite regression equation */
  starts = (1 - d)*y1 + d*y2;

                                /* Resulting log-likelihood function */
  logL = (1/2)*( (log(2*3.1415)) +
    log( (sig1**2)*((1-d)**2)+(sig2**2)*(d**2) )

```

```

      + (resid.starts*( 1/( (sig1**2)*((1-d)**2)+
        (sig2**2)*(d**2) ) ) *resid.starts) ) ;

errormodel starts ~ general(logL);

fit starts / method=marquardt converge=1.0e-5;

/* Test for significant differences in the parms */
test int1 = int2 ,/ lm;
test b11 = b21 ,/ lm;
test b13 = b23 ,/ lm;
test sig1 = sig2 ,/ lm;

run;

```

Four TEST statements are added to test the hypothesis that the parameters are the same in both regimes. The parameter estimates and ANOVA table from this run are shown in [Output 19.13.1](#).

Output 19.13.1 Parameter Estimates from the Switching Regression

Switching Regression Example						
The MODEL Procedure

Example 19.14: Simulating from a Mixture of Distributions

This example illustrates how to perform a multivariate simulation by using models that have different error distributions. Three models are used. The first model has t distributed errors. The second model is a GARCH(1,1) model with normally distributed errors. The third model has a noncentral Cauchy distribution.

The following SAS statements generate the data for this example. The t and the CAUCHY data sets use a common seed so that those two series are correlated.

```

/* set distribution parameters */
%let df = 7.5;
%let sig1 = .5;
%let var2 = 2.5;

data t;
  format date monyy.;
  do date='1jun2001'd to '1nov2002'd;
    /* t-distribution with df,sig1 */
    t = .05 * date + 5000 + &sig1*tinv(ranuni(1234),&df);
    output;
  end;
run;

data normal;
  format date monyy.;
  le = &var2;
  lv = &var2;
  do date='1jun2001'd to '1nov2002'd;
    /* Normal with GARCH error structure */
    v = 0.0001 + 0.2 * le**2 + .75 * lv;
    e = sqrt(v) * rannor(12345);
    normal = 25 + e;
    le = e;
    lv = v;
    output;
  end;
run;

data cauchy;

```

```

format date monyy.;
PI = 3.1415926;
do date='1jun2001'd to '1nov2002'd;
    cauchy = -4 + tan((ranuni(1234) - 0.5) * PI);
    output;
end;
run;

```

Since the multivariate joint likelihood is unknown, the models must be estimated separately. The residuals for each model are saved by using the OUT= option. Also, each model is saved by using the OUTMODEL= option. The ID statement is used to provide a variable in the residual data set to merge by. The XLAG function is used to model the GARCH(1,1) process. The XLAG function returns the lag of the first argument if it is nonmissing, otherwise it returns the second argument.

```

title1 't-distributed Errors Example';

proc model data=t outmod=tModel;
    parms df 10 vt 4;
    t = a * date + c;
    errormodel t ~ t( vt, df );
    fit t / out=tresid;
    id date;
run;

title1 'GARCH-distributed Errors Example';

proc model data=normal outmodel=normalModel;
    normal = b0 ;
    h.normal = arch0 + arch1 * xlag(resid.normal **2 , mse.normal)
                + GARCH1 * xlag(h.normal, mse.normal);

    fit normal /fiml out=nresid;
    id date;
run;

title1 'Cauchy-distributed Errors Example';

proc model data=cauchy outmod=cauchyModel;
    parms nc = 1;
    /* nc is noncentrality parm to Cauchy dist */
    cauchy = nc;
    obj = log(1+resid.cauchy**2 * 3.1415926);
    errormodel cauchy ~ general(obj) cdf=cauchy(nc);

    fit cauchy / out=cresid;
    id date;
run;

```

The simulation requires a covariance matrix created from normal residuals. The following DATA step statements use the inverse CDFs of the t and Cauchy distributions to convert the residuals to the normal distribution. The CORR procedure is used to create a correlation matrix that uses the converted residuals.

```

/* Merge and normalize the 3 residual data sets */
data c; merge tresid nresid cresid; by date;
    t = probit(cdf("T", t/sqrt(0.2789), 16.58 ));
    cauchy = probit(cdf("CAUCHY", cauchy, -4.0623));
run;

proc corr data=c out=s;
    var t normal cauchy;
run;

```

Now the models can be simulated together by using the MODEL procedure SOLVE statement. The data set created by the CORR procedure is used as the correlation matrix.

```

title1 'Simulating Equations with Different Error Distributions';

/* Create one observation driver data set */
data sim; merge t normal cauchy; by date;
data sim; set sim(firstobs = 519 );

proc model data=sim model=( tModel normalModel cauchyModel );
    errormodel t ~ t( vt, df );
    errormodel cauchy ~ cauchy(nc);
    solve t cauchy normal / random=2000 seed=1962 out=monte
        sdata=s(where=(_type_="CORR"));
run;

```

An estimation of the joint density of the t and Cauchy distribution is created by using the KDE procedure. Bounds are placed on the Cauchy dimension because of its fat tail behavior. The joint PDF is shown in [Output 19.14.1](#).

```

title "T and Cauchy Distribution";

proc kde data=monte;
    univar t          / out=t_dens;
    univar cauchy     / out=cauchy_dens;
    bivar t cauchy    / out=density
                    plots=all;
run;

```

Example 19.15: Simulated Method of Moments—Simple Linear Regression

This example illustrates how to use SMM to estimate a simple linear regression model for the following process:

$$y = a + bx + \epsilon, \epsilon \sim iid N(0, s^2)$$

In the following SAS statements, *ysim* is simulated, and the first moment and the second moment of *ysim* are compared with those of the observed endogenous variable *y*.

```
title "Simple regression model";

data regdata;
  do i=1 to 500;
    x = rannor( 1013 );
```

```

        y = 2 + 1.5 * x + 1.5 * rannor( 1013 );
        output;
    end;
run;

proc model data=regdata;
    parms a b s;
    instrument x;

    ysim = (a+b*x) + s * rannor( 8003 );
    y = ysim;
    eq.ysq = y*y - ysim*ysim;

    fit y ysq / gmm ndraw;
    bound s > 0;
run;

```

Alternatively, the MOMENT statement can be used to specify the moments using the following syntax:

```

proc model data=regdata;
    parms a b s;
    instrument x;

    ysim = (a+b*x) + s * rannor( 8003 );
    y = ysim;
    moment y = (2);

    fit y / gmm ndraw;
    bound s > 0;
run;

```

The output of the MODEL procedure is shown in [Output 19.15.1](#):

Example 19.16: Simulated Method of Moments—AR(1) Process

This example illustrates how to use SMM to estimate an AR(1) regression model for the following process:

$$\begin{aligned}
 y_t &= a + bx_t + u_t \\
 u_t &= \alpha u_{t-1} + \epsilon_t \\
 \epsilon_t &\sim iid N(0, s^2)
 \end{aligned}$$

In the following SAS statements, *ysim* is simulated by using this model, and the endogenous variable *y* is set to be equal to *ysim*. The **MOMENT** statement creates two more moments for the estimation. One is the second moment, and the other is the first-order autocovariance. The **NPRESS=10** option instructs **PROC MODEL** to run the simulation 10 times before *ysim* is compared to the first observation of *y*. Because the initial **zlag(u)** is zero, the first *ysim* is $a + b * x + s * \text{rannor}(8003)$. Without the **NPRESS** option, this *ysim* is matched with the first observation of *y*. With **NPRESS**, this *ysim* and the next nine *ysim* are thrown away, and the moment match starts with the eleventh *ysim* with the first observation of *y*. This way, the initial values do not exert a large influence on the simulated endogenous variables.

Example 19.17: Simulated Method of Moments—Stochastic Volatility Model

This example illustrates how to use SMM to estimate a stochastic volatility model as in Andersen and Sorensen (1996):

$$\begin{aligned}y_t &= \sigma_t z_t \\ \log(\sigma_t^2) &= a + b \log(\sigma_{t-1}^2) + s u_t \\ (z_t, u_t) &\sim iid N(0, I_2)\end{aligned}$$

This model is widely used in modeling the return process of stock prices and foreign exchange rates. This is called the stochastic volatility model because the volatility is stochastic as the random variable u_t appears in the volatility equation. The following SAS statements use three moments: absolute value, the second-order moment, and absolute value of the first-order autoregressive moment. Note the ADJSMMV option in the FIT statement to request the SMM covariance adjustment for the parameter estimates. Although these moments have closed form solution as shown by Andersen and Sorensen (1996), the simulation approach significantly simplifies the moment conditions.

Example 19.19: EMM Estimation of a Stochastic Volatility Model

The efficient method of moments (EMM), introduced by Bansal et al. (1993 and 1995) and Gallant and Tauchen (2001), can be considered a variant of SMM. The idea is to match the efficiency of the maximum likelihood (ML) estimation with the flexibility of the SMM procedure. ML itself can be interpreted as a method of moments procedure, where the *score vector*, the vector of derivatives of the log-likelihood function with respect to the parameters, provides the exactly identifying moment conditions. EMM employs an auxiliary (or pseudo) model that closely matches the true model. The score vector of the auxiliary model provides the moment conditions in the SMM step.

This example uses the SMM feature of PROC MODEL to estimate the simple stochastic volatility (SV) model of [Example 19.17](#) with the EMM method.

Suppose that your data are the time series $\{y_1, y_2, \dots, y_n\}$, and the model that you want to estimate, or the structural model, is characterized by the vector of parameters θ . For the SV model, θ is given by (a, b, s) .

The first step of the EMM method is to fit the data with an auxiliary model (or score generator) that has transition density $f(y_t|Y_{t-1}, \eta)$, parametrized by the pseudo parameter η , where $Y_{t-1} = \{y_{t-1}, \dots, y_1\}$. The auxiliary model must approximate the true data-generating process as closely as possible and be such that ML estimation is feasible.

The only identification requirement is that the dimension of the pseudo parameter η be greater than or equal to that of the structural parameter θ .

Andersen, Chung, and Sorensen (1999) showed that the GARCH(1,1) is an appropriate auxiliary model that leads to a good performance of the EMM estimator for the SV model.

The analytical expression for the GARCH(1,1) model with mean zero is

$$\begin{aligned} y_t &= \sigma_t z_t \\ \sigma_t^2 &= \omega + \alpha y_{t-1} + \beta \sigma_{t-1}^2 \end{aligned}$$

The pseudo parameter vector η is given by (ω, α, β) .

One advantage of such a class of models is that the conditional density of y_t is Gaussian—that is,

$$f(y_t|Y_{t-1}, \eta) \propto \frac{1}{\sigma_t} \exp\left(-\frac{y_t^2}{2\sigma_t^2}\right)$$

Therefore the score vector can easily be computed analytically.

The AUTOREG procedure provides the ML estimates, $\hat{\eta}_n$. The output is stored in the garchout data set, while the estimates are stored in the garchest data set.

```

title1 'Efficient Method of Moments for Stochastic Volatility Model';

/* estimate GARCH(1,1) model */
proc autoreg data=svdata(keep=y)
    outest=garchest
    noprint covout;
    model y = / noint garch=(q=1,p=1);
    output out=garchout cev=gsigmasq r=resid;
run;

```

If the pseudo model is close enough to the structural model, in a suitable sense, Gallant and Long (1997) showed that a consistent estimator of the asymptotic covariance matrix of the sample pseudo-score vector can be obtained from the formula

$$\hat{V}_n = \frac{1}{n} \sum_{t=1}^n s_f(Y_t, \hat{\eta}_n) s_f(Y_t, \hat{\eta}_n)'$$

where $s_f(Y_t, \hat{\eta}_n) = (\partial/\partial \eta_n) \log f(y_t|Y_{t-1}, \hat{\eta}_n)$ denotes the score function of the auxiliary model computed at the ML estimates.

The ML estimates of the GARCH(1,1) model are used in the following SAS statements to compute the variance-covariance matrix \hat{V}_n .

```

/* compute the V matrix */
data vvalues;
    set garchout(keep=y gsigmasq resid);

    /* compute scores of GARCH model */
    score_1 = (-1 + y**2/gsigmasq)/ gsigmasq;
    score_2 = (-1 + y**2/gsigmasq)*lag(gsigmasq) / gsigmasq;
    score_3 = (-1 + y**2/gsigmasq)*lag(y**2) / gsigmasq;

    array score{*} score_1-score_3;
    array v_t{*} v_t_1-v_t_6;
    array v{*} v_1-v_6;

    /* compute external product of score vector */
    do i=1 to 3;
        do j=i to 3;
            v_t{j*(j-1)/2 + i} = score{i}*score{j};
        end;
    end;

    /* average them over t */
    do s=1 to 6;
        v{s}+ v_t{s}/&nobs;
    end;
run;

```

The $\hat{\mathbf{V}}$ matrix must be formatted to be used with the VDATA= option of the MODEL procedure. See the section “VDATA= Input data set” on page 1186 for more information about the VDATA= data set.

```
/* Create a VDATA dataset acceptable to PROC MODEL */

/* Transpose the last obs in the dataset */
proc transpose data=vvalues(firstobs=&nobs keep=v_1-v_6)
    out=tempv;
run;

/* Add eq and inst labels */
data vhat;
    set tempv(drop=_name_);
    value = coll;
    drop coll;
    input _type_ $ eq_row $ eq_col $ inst_row $ inst_col $; *$;
    datalines;
        gmm m1 m1 1 1 /* intcpt is the only inst we use */
        gmm m1 m2 1 1
        gmm m2 m2 1 1
        gmm m1 m3 1 1
        gmm m2 m3 1 1
        gmm m3 m3 1 1
    ;
```

The last step of the EMM procedure is to estimate θ by using SMM, where the moment conditions are given by the scores of the auxiliary model.

Given a fixed value of the parameter vector θ and an arbitrarily large T , one can simulate a series $\{\hat{y}_1(\theta), \hat{y}_2(\theta), \dots, \hat{y}_T(\theta)\}$ from the structural model. The EMM estimator is the value $\hat{\theta}_n$ that minimizes the quantity

$$m_T(\theta, \hat{\eta}_n)' \hat{\mathbf{V}}_n^{-1} m_T(\theta, \hat{\eta}_n)$$

where

$$m_T(\theta, \hat{\eta}_n) = \frac{1}{T} \sum_{k=1}^T s_f(\hat{Y}_k(\theta), \hat{\eta}_n)$$

is the sample moment condition evaluated at the fixed estimated pseudo parameter $\hat{\eta}_n$. Note that the target function depends on the parameter θ only through the simulated series \hat{y}_k .

The following statements generate a data set that contains $T = 20,000$ replicates of the estimated pseudo parameter $\hat{\eta}_n$ and that is then input to the MODEL procedure. The EMM estimates are found by using the SMM option of the FIT statement. The $\hat{\mathbf{V}}_n$ matrix computed above serves as weighting matrix by using the VDATA= option, and the scores of the GARCH(1,1) auxiliary model evaluated at the ML estimates are the moment conditions in the GMM step.

Since the number of structural parameters to estimate (3) is equal to the number of moment equations (3) times the number of instruments (1), the model is exactly identified and the objective function has value zero at the minimum.

For simplicity, the starting values are set to the true values of the parameters.

```

/* USE SMM TO FIND EMM ESTIMATES */

/* Generate dataset of length T */

Overview: PANEL Procedure

The PANEL procedure analyzes a class of linear econometric models that commonly arise when time series and cross-sectional data are combined. This type of pooled data on time series cross-sectional bases is often referred to as panel data. Typical examples of panel data include observations in time on households, countries, firms, trade, and so on. For example, in the case of survey data on household income, the panel is created by repeatedly surveying the same households in different time periods (years).

The panel data models can be grouped into several categories depending on the structure of the error term. The error structures and the corresponding methods that the PANEL procedure uses to analyze data are as follows:

- one-way and two-way models
- fixed-effects and random-effects models
- autoregressive models
- moving-average models

If the specification is dependent only on the cross section to which the observation belongs, such a model is referred to as a one-way model. A specification that depends on both the cross section and the time period to which the observation belongs is called a two-way model.

Apart from the possible one-way or two-way nature of the effect, the other dimension of difference between the possible specifications is the nature of the cross-sectional or time-series effect. The models are referred to as fixed-effects models if the effects are nonrandom and as random-effects models otherwise.

If the effects are fixed, the models are essentially regression models with dummy variables that correspond to the specified effects. For fixed-effects models, ordinary least squares (OLS) estimation is the best linear unbiased estimator. Random-effects models use a two-stage approach. In the first stage, variance components are calculated by using methods described by Fuller and Battese, Wansbeek and Kapteyn, Wallace and Hussain, or Nerlove. In the second stage, variance components are used to standardize the data, and ordinary least squares(OLS) regression is performed.

There are two types of models in the PANEL procedure that accommodate an autoregressive structure. The Parks method is used to estimate a first-order autoregressive model with contemporaneous correlation. The dynamic panel estimator is used to estimate an autoregressive model with lagged dependent variable.

The Da Silva method is used to estimate mixed variance-component moving-average error process. The regression parameters are estimated by using a two-step generalized least squares(GLS)-type estimator.

The new PANEL procedure enhances the features that were implemented in the TSCSREG procedure. The following list shows the most important additions.

- New estimation methods include between estimators, pooled estimators, and dynamic panel estimators that use the generalized method of moments (GMM). The variance components for random-effects models can be calculated for both balanced and unbalanced panels by using the methods described by Fuller and Battese, Wansbeek and Kapteyn, Wallace and Hussain, or Nerlove.
- The CLASS statement creates classification variables that are used in the analysis.
- The TEST statement includes new options for Wald, Lagrange multiplier, and the likelihood ratio tests.
- The new RESTRICT statement specifies linear restrictions on the parameters.
- The FLATDATA statement enables the data to be in a compressed form.
- Several methods that produce heteroscedasticity-consistent covariance matrices (HCCME) are added because the presence of heteroscedasticity can result in inefficient and biased estimates of the variance covariance matrix in the OLS framework.
- The LAG statement can generate a large number of missing values, depending on lag order. Typically, it is difficult to create lagged variables in the panel setting. If lagged variables are created in a DATA step, several programming steps that include loops are often needed. By including the LAG statement, the PANEL procedure makes the creation of lagged values easy. The missing values can be replaced with zeros, overall mean, time mean, or cross section mean by using the LAG, ZLAG, XLAG, SLAG, and CLAG statements.
- The OUTPUT statement enables you to output data and estimates that can be used in other analyses.

Getting Started: PANEL Procedure

This section demonstrates the use of the PANEL procedure.

Specifying the Input Data

The PANEL procedure is similar to other regression procedures in SAS. Suppose you want to regress the variable *Y* on regressors *X1* and *X2*. Cross sections are identified by the variable *STATE*, and time periods are identified by the variable *DATE*. The input data set used by PROC PANEL must be sorted by cross section and by time within each cross section. Therefore, the first step in PROC PANEL is to make sure that the input data set is sorted. The following statements sort the data set *A* appropriately:

```
proc sort data=a;
    by state date;
run;
```

The next step is to invoke the PANEL procedure and specify the cross section and time series variables in an ID statement. The following statements shows the correct syntax:

```
proc panel data=a;
    id state date;
    model y = x1 x2;
run;
```

Alternatively, PROC PANEL has the capability to read “flat” data. Say that you are using the data set *A*, which has observations on states. Specifically, the data are composed of observations on *Y*, *X1*, and *X2*. Unlike the previous case, the data is not recorded with a PROC PANEL structure. Instead, you have all of a state’s information on a single row. You have variables to denote the name of the state (say *state*). The time observations for the *Y* variable are recorded horizontally. So the variable *Y_1* is the first period’s time observation, *Y_10* is the tenth period’s observation for some state. The same holds for the other variables. You have variables *X1_1* to *X1_10*, *X2_1* to *X2_10*, and *X3_1* to *X3_10* for others. With such data, PROC PANEL could be called by using the following syntax:

```
proc panel data=a;
    flatdata indid = state base = (Y X1 X2) tsname = t;
    id state t;
    model Y = X1 X2;
run;
```

See “[FLATDATA Statement](#)” on page 1348 and [Example 20.2](#) for more information about the use of the FLATDATA statement.

Specifying the Regression Model

The MODEL statement in PROC PANEL is specified like the MODEL statement in other SAS regression procedures: the dependent variable is listed first, followed by an equal sign, followed by the list of regressor variables, as shown in the following statements:

```
proc panel data=a;
    id state date;
    model y = x1 x2;
run;
```

The major advantage of using PROC PANEL is that you can incorporate a model for the structure of the random errors. It is important to consider what kind of error structure model is appropriate for your data and to specify the corresponding option in the MODEL statement.

The error structure options supported by the PANEL procedure are FIXONE, FIXONETIME, FIXTWO, RANONE, RANTWO, PARKS, DASILVA, GMM and ITGMM(iterated GMM). See the section “[Details: PANEL Procedure](#)” on page 1358 for more information about these methods and the error structures they assume. The following statements fit a Fuller-Battese one-way random-effects model.

```
proc panel data=a;
    id state date;
    model y = x1 x2 / ranone vcomp=fb;
run;
```

You can specify more than one error structure option in the MODEL statement; the analysis is repeated using each specified method. You can use any number of MODEL statements to estimate different regression models or estimate the same model by using different options. See [Example 20.1](#) for more information.

In order to aid in model specification within this class of models, the procedure provides two specification test statistics. The first is an F statistic that tests the null hypothesis that the fixed-effects parameters are all zero. The second is a Hausman m statistic that provides information about the appropriateness of the random-effects specification. The m statistic is based on the idea that, under the null hypothesis of no correlation between the effects variables and the regressors, OLS and GLS are consistent, but OLS is inefficient. Hence, a test can be based on the result that the covariance of an efficient estimator with its difference from an inefficient estimator is zero. Rejection of the null hypothesis might suggest that the fixed-effects model is more appropriate.

The procedure also provides the Buse R square measure. This number is interpreted as a measure of the proportion of the transformed sum of squares of the dependent variable that is attributable to the influence of the independent variables. In the case of OLS estimation, the Buse R square measure is equivalent to the usual R square measure.

Unbalanced Data

In the case of fixed-effects models, random-effects models, between estimators, and dynamic panel estimators, the PANEL procedure can process data with different numbers of time series observations across different cross sections. The Parks and Da Silva methods cannot be used with unbalanced data. The missing time series observations are recognized by the absence of time series ID variable values in some of the cross sections in the input data set. Moreover, if an observation with a particular time series ID value and cross-sectional ID value is present in the input data set, but one or more of the model variables are missing, that time series point is treated as missing for that cross section.

Introductory Example

The following statements use the cost function data from Greene (1990) to estimate the variance components model. The variable PRODUCTION is the log of output in millions of kilowatt-hours, and COST is the log of cost in millions of dollars. Refer to Greene (1990) for details.

```
data greene;
  input firm year production cost @@;
datalines;
  1 1955    5.36598    1.14867    1 1960    6.03787    1.45185
  1 1965    6.37673    1.52257    1 1970    6.93245    1.76627
  2 1955    6.54535    1.35041    2 1960    6.69827    1.71109
  2 1965    7.40245    2.09519    2 1970    7.82644    2.39480
... more lines ...
```

You decide to fit the following model to the data:

$$C_{it} = \text{Intercept} + \beta P_{it} + v_i + e_t + \epsilon_{it} \quad i = 1, \dots, N; \quad t = 1, \dots, T$$

where C_{it} and P_{it} represent the cost and production, and v_i , e_t and ϵ_{it} are the cross-sectional, time series, and error variance components.

If you assume that the time and cross-sectional effects are random, you are left with four possible estimators for the variance components. You choose Fuller-Battese.

The following statements fit this model.

```
proc sort data=greene;
  by firm year;
run;

proc panel data=greene;
  model cost = production / rantwo vcomp = fb;
  id firm year;
run;
```

The PANEL procedure output is shown in Figure 20.1. A model description is printed first, which reports the estimation method used and the number of cross sections and time periods. The variance components estimates are printed next. Finally, the table of regression parameter estimates shows the estimates, standard errors, and t tests.

Figure 20.1 The Variance Components Estimates

The PANEL Procedure					
Fuller and Battese Variance Components (RanTwo)					
Dependent Variable: cost					
Model Description					
Estimation Method			RanTwo		
Number of Cross Sections			6		
Time Series Length			4

production	1	0.746596	0.0762	9.80	<.0001

Syntax: PANEL Procedure

The following statements are used with the PANEL procedure.

```

PROC PANEL options ;
  BY variables ;
  CLASS options ;
  FLATDATA options ;
  ID cross-section-id time-series-id ;
  INSTRUMENTS options ;
  LAG options ;
  MODEL dependent = regressors < / options > ;
  RESTRICT equation1 < , equation2 . . . > ;
  TEST equation1 < , equation2 . . . > ;

```

Functional Summary

The statements and options used with the PANEL procedure are summarized in the following table.

Description	Statement	Option
Data Set Options		
Includes correlations in the OUTEST= data set	PANEL	CORROUT
Includes covariances in the OUTEST= data set	PANEL	COVOUT
Specifies the input data set	PANEL	DATA=
Specifies variables to keep but not transform	FLATDATA	KEEP=
Specifies the output data set for CLASS STATEMENT	CLASS	OUT =
Specifies the output data set	FLATDATA	OUT =
Specifies the name of an output SAS data set	OUTPUT	OUT=
Writes parameter estimates to an output data set	PANEL	OUTEST=
Writes the transformed series to an output data set	PANEL	OUTTRANS=
Requests that the procedure produce graphics via the Output Delivery System	PANEL	PLOTS=
Declaring the Role of Variables		
Specifies BY-group processing	BY	
Specifies the classification variables	CLASS	
Transfers the data into uncompressed form	FLATDATA	
Specifies the cross section and time ID variables	ID	

Description	Statement	Option
Declares instrumental variables	INSTRUMENTS	
Lag Generation		
Specifies output data set for lags where missing values are replaced with the cross section mean	CLAG	OUT=
Specifies output data set for lags with missing values included	LAG	OUT=
Specifies output data set for lags where missing values are replaced with the time period mean	SLAG	OUT=
Specifies output data set for lags where missing values are replaced with overall mean	XLAG	OUT=
Specifies output data set for lags where missing values are replaced with zero	ZLAG	OUT=
Printing Control Options		
Prints correlations of the estimates	MODEL	CORRB
Prints covariances of the estimates	MODEL	COVB
Suppresses printed output	MODEL	NOPRINT
Requests that the procedure produce graphics via the Output Delivery System	MODEL	PLOTS=
Performs tests of linear hypotheses	TEST	
Model Estimation Options		
Requests the Breusch-Pagan test for one-way random effects	MODEL	BP
Requests the Breusch-Pagan test for two-way random effects	MODEL	BP2
Specifies the between-groups model	MODEL	BTWNG
Specifies the between-time-periods model	MODEL	BTWNT
Requests the clustered HCCME estimator for the variance-covariance matrix	MODEL	CLUSTER
Specifies the Da Silva method	MODEL	DASILVA
Specifies the one-way fixed-effects model	MODEL	FIXONE
Specifies the one-way fixed-effects model with respect to time	MODEL	FIXONETIME
Specifies the two-way fixed-effects model	MODEL	FIXTWO
Specifies the Moore-Penrose generalized inverse	MODEL	GINV = G4
Specifies the dynamic panel estimator model	MODEL	GMM
Requests the HCCME estimator for the variance-covariance matrix	MODEL	HCCME=
Specifies the order of the moving average error process for Da Silva method	MODEL	M=
Suppresses the intercept term	MODEL	NOINT
Specifies the Parks method	MODEL	PARKS

Description	Statement	Option
Prints the Φ matrix for Parks method	MODEL	PHI
Specifies the pooled model	MODEL	POOLED
Specifies the one-way random-effects model	MODEL	RANONE
Specifies the two-way random-effects model	MODEL	RANTWO
Prints autocorrelation coefficients for Parks method	MODEL	RHO
Controls the check for singularity	MODEL	SINGULAR=
Specifies the method for the variance components estimator	MODEL	VCOMP=
Specifies linear equality restrictions on the parameters	RESTRICT	
Specifies the TEST statement	TEST	WALD, LM, LR

PROC PANEL Statement

PROC PANEL *options* ;

The following options can be specified on the PROC PANEL statement.

DATA=SAS-data-set

names the input data set. The input data set must be sorted by cross section and by time period within cross section. If you omit the DATA= option, the most recently created SAS data set is used.

OUTEST=SAS-data-set

names an output data set to contain the parameter estimates. When the OUTEST= option is not specified, the OUTEST= data set is not created. See the section “[The OUTEST= Data Set](#)” on page 1397 for details about the structure of the OUTEST= data set.

OUTTRANS=SAS-data-set

names an output data set to contain the transformed series for further analysis and computation of models with time observations greater than two. See the section “[The OUTTRANS= Data Set](#)” on page 1398 for details about the structure of the OUTTRANS= data set.

OUTCOV

COVOUT

writes the standard errors and covariance matrix of the parameter estimates to the OUTEST= data set. See the section “[The OUTEST= Data Set](#)” on page 1397 for details.

OUTCORR

CORROUT

writes the correlation matrix of the parameter estimates to the OUTEST= data set. See the section “[The OUTEST= Data Set](#)” on page 1397 for details.

PLOTS < (*global-plot-options* < (**NCROSS**=*value*) >) > < = (*specific-plot-options*) >

selects plots to be produced via the Output Delivery System. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#)” (*SAS/STAT User’s Guide*). The *global-plot-options* apply to all relevant plots generated by the PANEL procedure.

Global Plot Options

The following *global-plot-options* are supported:

ONLY	suppresses the default plots. Only the plots specifically requested are produced.
UNPACKPANEL UNPACK	breaks a graphic that is otherwise paneled into individual component plots.
NCROSS= <i>value</i>	specifies the number of cross sections to be combined into one time series plot.

Specific Plot Options

The following *specific-plot-options* are supported:

ACTSURFACE	produces a surface plot of actual values.
ALL	produces all appropriate plots.
FITPLOT	plots the predicted and actual values.
NONE	suppresses all plots.
PREDSURFACE	produces a surface plot of predicted values.
QQ	produces a QQ plot of residuals.
RESIDSTACK RESSTACK	produces a stacked plot of residuals.
RESIDSURFACE	produces a surface plot of residual values.
RESIDUAL RES	plots the residuals.
RESIDUALHISTOGRAM RESIDHISTOGRAM	plots the histogram of residuals.

For more details, see the section “[ODS Graphics](#)” on page 1396.

In addition, any of the following MODEL statement options can be specified in the PROC PANEL statement: CORRB, COVB, FIXONE, FIXONETIME, FIXTWO, BTWNG, BTWNT, POOLED, RANONE, RANTWO, FULLER, PARKS, DASILVA, NOINT, NOPRINT, M=, PHI, RHO, VCOMP=, and SINGULAR=. When specified in the PROC PANEL statement, these options are equivalent to specifying the options for every MODEL statement. See the section “[MODEL Statement](#)” on page 1352 for a complete description of each of these options.

BY Statement

BY *variables* ;

A BY statement can be used with PROC PANEL to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the input data set must be sorted by the BY variables as well as by cross section and time period within the BY groups.

The following statements show an example:

```
proc sort data=a;
    by byvar1 byvar2 csid tsid;
run;

proc panel data=a;
    by byvar1 byvar2;
    id csid tsid;
    ...
run;
```

CLASS Statement

CLASS *variables* </ out= SAS-data-set> ;

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric.

In PROC PANEL, the CLASS statement enables you to output class variables to a data set that contains a copy of the original data.

FLATDATA Statement

FLATDATA *options* </ out= SAS-data-set> ;

The following options must be specified in the FLATDATA statement:

BASE=(*variable, variable, ..., variable*)

specifies the variables that are to be transformed into a proper PROC PANEL format. All variables to be transformed must be named according to the convention: *basename_timeperiod*. You supply just the *basename*, and the procedure extracts the appropriate variables to transform. If some year's data are missing for a variable, then PROC PANEL detects this and fills in with missing values.

INDID=*variable*

names the variable in the input data set that uniquely identifies each individual. The INDID variable can be a character or numeric variable.

KEEP=(*variable, variable, . . . , variable*)

specifies the variables that are to be copied without any transformation. These variables remain constant with respect to time when the data are converted to PROC PANEL format. This is an optional item.

TSNAME=*name*

specifies a name for the generated time identifier. The name must satisfy the requirements for the name of a SAS variable. The name can be quoted, but it must not be the name of a variable in the input data set.

The following options can be specified on the FLATDATA statement after the slash (/):

OUT =*SAS-data-set*

saves the converted flat data set to a PROC PANEL formatted data set.

ID Statement

ID *cross-section-id time-series-id* ;

The ID statement is used to specify variables in the input data set that identify the cross section and time period for each observation.

When an ID statement is used, the PANEL procedure verifies that the input data set is sorted by the cross section ID variable and by the time series ID variable within each cross section. The PANEL procedure also verifies that the time series ID values are the same for all cross sections.

To make sure the input data set is correctly sorted, use PROC SORT to sort the input data set with a BY statement with the variables listed exactly as they are listed in the ID statement, as shown in the following statements:

```
proc sort data=a;
    by csid tsid;
run;

proc panel data=a;
    id csid tsid;
    ... etc. ...
run;
```

INSTRUMENT Statement

INSTRUMENTS *options* ;

The INSTRUMENTS statement denotes which variables are used in the moment condition equations of the dynamic panel estimator. The following options can be used with the INSTRUMENTS statement.

CONSTANT

includes an intercept (column of ones) as an uncorrelated exogenous instrument.

DEPVAR

specifies that a dependent variable be used at an appropriate lag as an instrument.

CORRELATED=(*variable, variable, ..., variable*)

specifies a list of variables correlated with the error term. These variables are not used in forming moment conditions from level equations.

EXOGENOUS=(*variable, variable, ..., variable*)

specifies a list of variables that are not correlated with the error term.

PREDETERMINED=(*variable, variable, ..., variable*)

specifies a list of variables whose future realizations can be correlated with the error term but whose present and past realizations are not.

If a variable listed in the EXOGENOUS list is not included in the CORRELATED list, then it is considered to be uncorrelated to the error term. For example, in the following statements, the exogenous instruments are Z1, Z2 and X1. Z1 is an instrument that is correlated to the individual fixed effects.

```
proc panel data=a;
  inst exogenous=(Z1 Z2 X1)
    correlated = (Z1) constant depvar;
  model Y = X1 X2 X3 / gmm;
run;
```

For a detailed discussion of the model set up and the use of the INSTRUMENTS statement, see “[Dynamic Panel Estimator](#)” on page 1380.

Note that for each MODEL statement, one INSTRUMENT statement is required. In other words, if there are two models to be estimated by using GMM within one PANEL procedure, then there should be two INSTRUMENT statements. For example,

```
proc panel data=test;
  inst depvar pred=(x1 x2) exog=(x3 x4 x5) correlated=(x3 x4 x5);
  model y = y_1 x1 x2 / gmm maxband=6 nolevels ginv=g4 artest=5;
  inst pred=(x2 x4) exog=(x3 x5) correlated=(x3 x4);
  model y = y_1 x2 / gmm maxband=6 nolevels ginv=g4 artest=5;
  id cs ts;
run;
```

LAG, ZLAG, XLAG, SLAG or CLAG Statement

LAG *var*₁(*lag*₁ *lag*₂ ... *lag*_T), ..., *var*_N(*lag*₁ *lag*₂ ... *lag*_T) < /OUT= SAS-data-set > ;

Generally, creating lags of variables in a panel setting is a tedious process in which you must generate many DATA STEP statements. The PANEL procedure now enables you to generate lags of any series without jumping across any individual's boundary. The lag statement is a data set generation tool. Using the data created by a LAG statement requires a subsequent PROC PANEL call. There can be more than one LAG statement in each call to PROC PANEL.

The LAG statement tends to generate many missing values in the data. This can be problematic, because the number of usable observations diminishes with the lag length. Therefore, PROC PANEL offers alternatives to the LAG statement. The OUT= option must be specified on the LAG statement. The output data set includes all variables in the input set, plus the lags that are denoted with the convention originalvar_lag. The following statements can be used instead of LAG with otherwise identical syntax:

CLAG

replaces missing values with the cross section mean for that variable in that cross section. Note that missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

SLAG

replaces missing values with the time mean for that variable in that time period. Note that missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

XLAG

replaces missing values with the overall mean for that variable. Note that missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

ZLAG

replaces missing values with zero for that variable. Note that missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

Assume that data set A has been sorted by cross section and time period within cross section (or FLATDATA has been specified), and the variables are Y, X1, X2 and X3. You desire the lags 1 and 3 of the X1 variable; lag 3, 6, and 9 of X2; and lag 2 of variable X3. The following PROC PANEL statements generate a series with those characteristics.

```
proc panel data=A;
  id i t;
  lag X1(1 3) X2(3 6 9) X3(2) / out=A_lag;
run;
```

If you want a zeroing instead of missing values, then you specify the following:

```
proc panel data=A;
```

```

id i t;
zlag x1(1 3) x2(3 6 9) x3(2) / out=A_zlag;
run;

```

Similarly, you can specify XLAG to replace with overall means, SLAG to replace with time means, and CLAG to replace with cross section means.

MODEL Statement

MODEL *response = regressors* </ options > ;

The MODEL statement specifies the regression model and the error structure assumed for the regression residuals. The response variable on the left side of the equal sign is regressed on the independent variables listed after the equal sign. Any number of MODEL statements can be used. For each model statement, only one response variable can be specified on the left side of the equal sign.

The error structure is specified by the FULLER, PARKS, DASILVA, FIXONE, FIXONETIME, FIXTWO, RANONE, RANTWO, GMM, and ITGMM options. More than one of these options can be used, in which case the analysis is repeated for each error structure model specified.

Models can be given labels. Model labels are used in the printed output to identify the results for different models. If no label is specified, the response variable name is used as the label for the model. The model label is specified as follows:

label : MODEL ...;

The following options can be specified in the MODEL statement after a slash (/).

ARTEST=integer

specifies the maximum order of the test for the presence of AR effects in the residual in the dynamic panel model. The acceptable range of values for this option is 1 to $t - 3$.

ATOL=number

specifies the convergence criterion for iterated GMM when convergence of the method is determined by convergence in the weighting matrix. The convergence criterion must be positive. The default option is the BTOL= option unless the ATOL= option is specified. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

BANDOPT=TRAILING | CENTERED | LEADING

specifies which observations are included in the instrument list when the MAXBAND= option is specified. This option should be used only for exogenous instruments. BANDOPT=TRAILING is the default. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

BP

requests the Breusch-Pagan one-way test for random effects.

BP2

requests the Breusch-Pagan two-way test for random effects.

BTOL=number

specifies the convergence criterion for iterated GMM when convergence of the method is determined by convergence in the parameter matrix. The convergence criterion must be positive. The default is BTOL=1E-8. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

BTWNG

specifies that a between-groups model be estimated.

BTWNT

specifies that a between-time-periods model be estimated.

CLUSTER

specifies the cluster correction for the variance-covariance matrix. The cluster correction can be requested with HCCME=0, 1, 2 or 3.

CORRB**CORR**

prints the matrix of estimated correlations between the parameter estimates.

COVB**VAR**

prints the matrix of estimated covariances between the parameter estimates.

DASILVA

specifies that the model be estimated by using the Da Silva method, which assumes a mixed variance-component moving average model for the error structure. See the section “[Da Silva Method \(Variance-Component Moving Average Model\)](#)” on page 1378 for details.

FIXONE

specifies that a one-way fixed-effects model be estimated with the one-way model corresponding to cross-sectional effects only.

FIXONETIME

specifies that a one-way fixed-effects model be estimated with the one-way model corresponding to time effects only.

FIXTWO

specifies that a two-way fixed-effects model be estimated.

GINV= G2 | G4

specifies what type of generalized inverse to use. The default is a G2 inverse. The G4 inverse is generally more desirable except that it is a more numerically intensive methodology.

GMM

specifies that the model be estimated by using the dynamic panel estimator method, which allows for autoregressive processes. This is the single-step model. Note that with this option one INSTRUMENT statement is required for each MODEL statement. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

HCCME=number

specifies the type of HCCME variance-covariance matrix requested. The expected range of values is NO or 0 to 4. The default is NO, no correction. See the section “[Heteroscedasticity-Corrected Covariance Matrices](#)” on page 1389 for details.

ITGMM

specifies that the model be estimated by using the dynamic panel estimator method, but that PROC PANEL keep updating the weighting matrix until either the parameter vector converges or the weighting matrix converges. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

ITPRINT

prints out the iteration history of the parameter and transformed sum of error squared.

M=number

specifies the order of the moving-average process in the Da Silva method. The value of the M=option must be less than $T - 1$. The default is M=1.

MAXBAND=integer

specifies the maximum number of time periods (per instrumental variable) that are allowed into the moment condition. The acceptable range of values for this option is 1 to $T - 1$. If BANDOPT=LEADING or CENTERED, then the default value of MAXBAND is 2. If BANDOPT=TRAILING, then the default value of MAXBAND is 1. If no BANDOPT option is specified such as when no exogenous instruments are used, then the default value of MAXBAND is 1. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

MAXITER=integer

specifies the maximum number of iterations allowed for the iterated GMM option. The default value is MAXITER=200. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

NODIFFS

specifies that the dynamic panel model be estimated without moment conditions from the difference equations. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

NOESTIM

limits the estimation of a FIXONE, FIXONETIME, RANONE model to the generation of the transformed series. This option is intended for use with an OUTTRANS= data set.

NOINT

suppresses the intercept parameter from the model.

NOLEVELS

specifies that the dynamic panel model be estimated without moment conditions from the level equations. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

NOPRINT

suppresses the normal printed output.

PARKS

specifies that the model be estimated by using the Parks method, which assumes a first-order autoregressive model for the error structure. See the section “[Parks Method \(Autoregressive Model\)](#)” on page 1376 for details.

PHI

prints the Φ matrix of estimated covariances of the observations for the Parks method. The PHI option is relevant only when the PARKS option is used. See the section “[Parks Method \(Autoregressive Model\)](#)” on page 1376 for details.

POOLED

specifies that a pooled (OLS) model be estimated.

RANONE

specifies that a one-way random-effects model be estimated.

RANTWO

specifies that a two-way random-effects model be estimated.

RHO

prints the estimated autocorrelation coefficients for the Parks method.

ROBUST

specifies that the robust weighting matrix be used in the calculation of the variance-covariance matrix of the single-step dynamic panel estimator. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

SINGULAR=number

specifies a singularity criterion for the inversion of the matrix. The default depends on the precision of the computer system.

TIME

specifies that the model be estimated by using the dynamic panel estimator method, but that PROC PANEL includes time dummy variables to model any time effects present in the data. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

TWOSTEP

specifies that the model be estimated by using the dynamic panel estimator method, but that two steps be used in the estimation. An initial first step is used to form an estimator for the weighting matrix used in the second step. See the section “[Dynamic Panel Estimator](#)” on page 1380 for details.

VCOMP=FB | NL | WH | WK

specifies the type of variance component estimate to use. The default is VCOMP=FB for balanced data and VCOMP=WK for unbalanced data. See the section “[The One-Way Random-Effects Model](#)” on page 1368 and “[The Two-Way Random-Effects Model](#)” on page 1371 for details.

OUTPUT Statement

OUTPUT *OUT=SAS-data-set* < = options ... > ;

The OUTPUT statement creates an output SAS data set as specified by the following options:

OUT=SAS-data-set

names the output SAS data set to contain the predicted and transformed values. If the OUT= option is not specified, the new data set is named according to the DATA*n* convention.

PREDICTED=name**P=name**

writes the predicted values to the output data set.

RESIDUAL=name**R=name**

writes the residuals from the predicted values based on both the structural and time series parts of the model to the output data set.

RESTRICT Statement

RESTRICT < "string"> equation < ,equation2... > ;

The RESTRICT statement specifies linear equality restrictions on the parameters in the previous model statement. There can be as many unique restrictions as the number of parameters in the preceding model statement. Multiple RESTRICT statements are understood as joint restrictions on a model's parameters. Restrictions on the intercept are obtained by the use of the keyword INTERCEPT.

Currently, only linear equality restrictions are permitted in PROC PANEL. Tests and restriction expressions can only be composed of algebraic operations that involve the addition symbol (+), subtraction symbol (−), and multiplication symbol (*).

The RESTRICT statement accepts labels that are produced in the printed output. RESTRICT statement can be labeled in two ways. A RESTRICT statement can be preceded by a label followed by a colon. This is illustrated in **rest1** in the example below. Alternatively, the keyword RESTRICT can be followed by a quoted string.

The following statements illustrate the use of the RESTRICT statement:

```
proc panel;
  model y = x1 x2 x3;
  restrict x1 = 0, x2 * .5 + 2 * x3 = 0;
  rest1: restrict x2 = 0, x3 = 0;
  restrict "rest2" intercept=1;
run;
```

Note that a restrict statement cannot include a division sign in its formulation.

TEST Statement

TEST < "string"> equation < ,equation2... > < / options > ;

The TEST statement performs Wald, Lagrange multiplier and likelihood ratio tests of linear hypotheses about the regression parameters in the preceding MODEL statement. Each equation specifies a linear hypothesis to be tested. All hypotheses in one TEST statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. The keyword INTERCEPT refers to the coefficient of the intercept.

The following options can be specified on the TEST statement after the slash (/):

ALL

specifies Wald, Lagrange multiplier and likelihood ratio tests.

WALD

specifies the WALD test.

LM

specifies the Lagrange multiplier test.

LR

specifies the likelihood ratio test.

The Wald test is performed by default.

The following statements illustrate the use of the TEST statement:

```
proc panel;
  id csid tsid;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0;
  test_int: test intercept = 0, x3 = 0;
run;
```

The first test investigates the joint hypothesis that

$$\beta_1 = 0$$

and

$$.5\beta_2 + 2\beta_3 = 0$$

Currently, only linear equality restrictions and tests are permitted in PROC PANEL. Tests and restriction expressions can be composed only of algebraic operations that involve the addition symbol (+), subtraction symbol (−), and multiplication symbol (*).

The TEST statement accepts labels that are produced in the printed output. The TEST statement can be labeled in two ways. A TEST statement can be preceded by a label followed by a colon. Alternatively, the keyword TEST can be followed by a quoted string. If both are presented, PROC PANEL uses the quoted string. In the event no label is present, PROC PANEL automatically labels the tests. If both a TEST and a RESTRICT statement are specified, the test is run with restrictions applied.

Note that for the DaSilva method, only the WALD test is available.

Details: PANEL Procedure

Missing Values

Any observation in the input data set with a missing value for one or more of the regressors is ignored by PROC PANEL and is not used in the model fit.

If there are observations in the input data set with missing dependent variable values but with nonmissing regressors, PROC PANEL can compute predicted values and store them in an output data set by using the OUTPUT statement. Note that the presence of such observations with missing dependent variable values does not affect the model fit because these observations are excluded from the calculation.

If either some regressors or the dependent variable values are missing, the model is estimated as unbalanced where the number of time series observations across different cross sections does not have to be equal. The Parks and Da Silva methods cannot be used with unbalanced data.

Computational Resources

The more parameters there are to be estimated, the more memory and time are required to estimate the model. Also affecting these resources are the estimation method chosen and the method to calculate variance components. If the model has p parameters including the intercept, there are at least $p + [p * (p + 1)]/2$ numbers being held in the memory.

If the Arellano and Bond GMM approach is used, the amount of memory grows proportionately to the number of instruments in the INSTRUMENT statement. If the ITGMM (iterated GMM) option is selected, the computation time also depends on the convergence criteria selected and the maximum number of iterations allowed.

Restricted Estimates

A consequence of estimating a linear model with a restriction is that the error degrees of freedom increase by the number of restrictions. PROC PANEL produces the Lagrange multiplier associated with each restriction.

Say that you are interested in linear regression in which there are r restrictions. A linear restriction implies the following set of equations that relate the regression coefficients:

$$\begin{aligned}
 R_{1,1}\beta_1 + R_{1,2}\beta_2 + \cdots + R_{1,p}\beta_p &= q_1 \\
 R_{2,1}\beta_1 + R_{2,2}\beta_2 + \cdots + R_{2,p}\beta_p &= q_2 \\
 &\dots\dots\dots \\
 R_{r,1}\beta_1 + R_{r,2}\beta_2 + \cdots + R_{r,p}\beta_p &= q_r
 \end{aligned}$$

To economize on notation, you can represent the restriction structure in the following matrix notation $\mathbf{R}\boldsymbol{\beta} = \mathbf{q}$. The restricted $\boldsymbol{\beta}$ estimator is given by:

$$\boldsymbol{\beta}^* = \boldsymbol{\beta} - (\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1} (\mathbf{R}\boldsymbol{\beta} - \mathbf{q})$$

The Lagrange multipliers are given as:

$$\boldsymbol{\lambda}_* = \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1} (\mathbf{R}\boldsymbol{\beta} - \mathbf{q})$$

The standard errors of the Lagrange Multipliers are calculated from the following relationship:

$$\text{Var}(\boldsymbol{\lambda}_*) = \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1} \mathbf{R} \text{Var}(\boldsymbol{\beta}) \mathbf{R}' \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1}$$

A significant Lagrange multiplier implies that you can reject the null hypothesis that the restrictions are not binding.

Note that in the special case of the fixed-effects models, the NOINT option and RESTRICT INTERCEPT=0 option give different estimates. This is not an error; it reflects two perspectives on the same issue. In the FIXONE case, the intercept is the last cross section's fixed effect (or the last time affecting the case of FIXONETIME). Specifying the NOINT option removes the intercept, but allows the last effect in. The NOINT command simply reclassifies the effects. The dummy variables become true cross section effects. If you specify the NOINT option with the FIXTWO option, the restriction is imposed that the last time effect is zero. A RESTRICT INTERCEPT=0 statement suppresses the estimation of the last effect in the FIXONE and FIXONETIME case. A RESTRICT INTERCEPT=0 has similar effects on the FIXTWO estimator. In general, restricting the intercept to zero is not recommended because OLS loses its unbiased nature.

Notation

The following notation represents the usual panel structure, with the specification of u_{it} dependent on the particular model:

$$y_{it} = \sum_{k=1}^K x_{itk} \beta_k + u_{it} \quad i = 1, \dots, N; t = 1, \dots, T_i$$

The total number of observations $M = \sum_{i=1}^N T_i$. For the balanced data case, $T_i = T$ for all i . The $M \times M$ covariance matrix of u_{it} is denoted by \mathbf{V} . Let \mathbf{X} and \mathbf{y} be the independent and dependent variables arranged by cross section and by time within each cross section. Let \mathbf{X}_s be the X matrix without the intercept. All other notation is specific to each section.

The One-Way Fixed-Effects Model

The specification for the one-way fixed-effects model is

$$u_{it} = \gamma_i + \epsilon_{it}$$

where the γ_i s are nonrandom parameters to be estimated.

Let $\mathbf{Q}_0 = \text{diag}(\mathbf{E}_{T_i})$, with $\bar{\mathbf{J}}_{T_i} = \mathbf{J}_{T_i}/T_i$ and $\mathbf{E}_{T_i} = \mathbf{I}_{T_i} - \bar{\mathbf{J}}_{T_i}$, where \mathbf{J}_{T_i} is a matrix of T_i ones.

The matrix \mathbf{Q}_0 represents the within transformation. In the one-way model, the within transformation is the conversion of the raw data to deviations from a cross section's mean. The vector $\tilde{\mathbf{x}}_{it}$ is a row of the general matrix \mathbf{X}_s , where the subscripted s implies the constant (column of ones) is missing.

Let $\tilde{\mathbf{X}}_s = \mathbf{Q}_0\mathbf{X}_s$ and $\tilde{\mathbf{y}} = \mathbf{Q}_0\mathbf{y}$. The estimator of the slope coefficients is given by

$$\tilde{\beta}_s = (\tilde{\mathbf{X}}_s'\tilde{\mathbf{X}}_s)^{-1}\tilde{\mathbf{X}}_s'\tilde{\mathbf{y}}$$

Once the slope estimates are in hand, the estimation of an intercept or the cross-sectional fixed effects is handled as follows. First, you obtain the cross-sectional effects:

$$\gamma_i = \bar{y}_i - \tilde{\beta}_s\bar{x}_i \quad \text{for } i = 1 \dots N$$

If the NOINT option is specified, then the dummy variables' coefficients are set equal to the fixed effects. If an intercept is desired, then the i th dummy variable is obtained from the following expression:

$$D_i = \gamma_i - \gamma_N \quad \text{for } i = 1 \dots N - 1$$

The intercept is the N th fixed effect γ_N .

The within model sum of squared errors is:

$$\text{SSE} = \sum_{i=1}^N \sum_{t=1}^{T_i} (y_{it} - \gamma_i - \mathbf{X}_s\tilde{\beta}_s)^2$$

The estimated error variance can be written:

$$\hat{\sigma}_\epsilon^2 = \text{SSE}/(M - N - (K - 1))$$

Alternatively, an equivalent way to express the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}'\mathbf{Q}_0\tilde{\mathbf{u}}/(M - N - (K - 1))$$

where the residuals $\tilde{\mathbf{u}}$ are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M\mathbf{j}_M'/M)(\mathbf{y} - \mathbf{X}_s\tilde{\beta}_s)$ if there is an intercept and by $\tilde{\mathbf{u}} = (\mathbf{y} - \mathbf{X}_s\tilde{\beta}_s)$ if there is not. The drawback is that the formula changes (but the results do not) with the inclusion of a constant.

The variance covariance matrix of $\tilde{\beta}_s$ is given by:

$$\text{Var}[\tilde{\beta}_s] = \hat{\sigma}_\epsilon^2(\tilde{\mathbf{X}}_s'\tilde{\mathbf{X}}_s)^{-1}$$

The covariance of the dummy variables and the dummy variables with the $\tilde{\beta}_s$ is dependent on whether the intercept is included in the model.

- *no intercept:*

$$\text{Var}[\gamma_i] = \text{Var}[D_i] = \frac{\hat{\sigma}_\epsilon^2}{T_i} + \tilde{\mathbf{x}}_i'\text{Var}[\tilde{\beta}_s]\tilde{\mathbf{x}}_i$$

$$\text{Cov}[\gamma_i, \gamma_j] = \text{Cov}[D_i, D_j] = \tilde{\mathbf{x}}_i'\text{Var}[\tilde{\beta}_s]\tilde{\mathbf{x}}_j$$

$$\text{Cov}[\gamma_i, \tilde{\beta}_s] = \text{Cov}[D_i, \tilde{\beta}_s] = -\tilde{\mathbf{x}}_i'\text{Var}[\tilde{\beta}_s]$$

- *intercept*:

$$\text{Var}[D_i] = \frac{\hat{\sigma}_\epsilon^2}{T_i} + (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})' \text{Var}[\tilde{\beta}_s] (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})$$

$$\text{Cov}[D_i, D_j] = \frac{\hat{\sigma}_\epsilon^2}{T_i} + (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})' \text{Var}[\tilde{\beta}_s] (\bar{\mathbf{x}}_j - \bar{\mathbf{x}}_{N\cdot})$$

$$\text{Var}[\text{Intercept}] = \text{Var}[\gamma_N] = \frac{\hat{\sigma}_\epsilon^2}{T_N} + \bar{\mathbf{x}}_N' \text{Var}[\tilde{\beta}_s] \bar{\mathbf{x}}_N$$

$$\text{Cov}[D_i, \tilde{\beta}_s] = -(\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})' \text{Var}[\tilde{\beta}_s]$$

$$\text{Cov}[\text{Intercept}, D_i] = -\frac{\hat{\sigma}_\epsilon^2}{T_i} + \bar{\mathbf{x}}_N' \text{Var}[\tilde{\beta}_s] (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})$$

$$\text{Cov}[\text{Intercept}, \tilde{\beta}_s] = -\bar{\mathbf{x}}_N' \text{Var}[\tilde{\beta}_s]$$

Alternatively, the model option `FIXONETIME` estimates a one-way model where the heterogeneity comes from time effects. This option is analogous to re-sorting the data by time and then by cross section and running a `FIXONE` model. The advantage of using the `FIXONETIME` option is that sorting is avoided and the model remains labeled correctly.

The Two-Way Fixed-Effects Model

The specification for the two-way fixed-effects model is

$$u_{it} = \gamma_i + \alpha_t + \epsilon_{it}$$

where the γ_i s and α_t s are nonrandom parameters to be estimated.

If you do not specify the `NOINT` option, which suppresses the intercept, the estimates for the fixed effects are reported under the restriction that $\gamma_N = 0$ and $\alpha_T = 0$. If you specify the `NOINT` option to suppress the intercept, only the restriction $\alpha_T = 0$ is imposed.

Balanced Panels

Assume that the data are balanced (for example, all cross sections have T observations). Then you can write the following:

$$\tilde{y}_{it} = y_{it} - \bar{y}_i - \bar{y}_{\cdot t} + \bar{\bar{y}}$$

$$\tilde{\mathbf{x}}_{it} = \mathbf{x}_{it} - \bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{\cdot t} + \bar{\bar{\mathbf{x}}}$$

where the symbols:

y_{it} and \mathbf{x}_{it} are the dependent variable (a scalar) and the explanatory variables (a vector whose columns are the explanatory variables not including a constant), respectively

$\bar{y}_{i\cdot}$ and $\bar{\mathbf{x}}_{i\cdot}$ are cross section means

$\bar{y}_{\cdot t}$ and $\bar{\mathbf{x}}_{\cdot t}$ are time means

$\bar{\bar{y}}$ and $\bar{\bar{\mathbf{x}}}$ are the overall means

The two-way fixed-effects model is simply a regression of \tilde{y}_{it} on $\tilde{\mathbf{x}}_{it}$. Therefore, the two-way β is given by:

$$\tilde{\beta}_s = (\tilde{\mathbf{X}}' \tilde{\mathbf{X}})^{-1} \tilde{\mathbf{X}}' \tilde{\mathbf{y}}$$

The calculations of cross section dummy variables, time dummy variables, and intercepts follow in a fashion similar to that used in the one-way model.

First, you obtain the net cross-sectional and time effects. Denote the cross-sectional effects by γ and the time effects by α . These effects are calculated from the following relations:

$$\hat{\gamma}_i = (\bar{y}_{i\cdot} - \bar{\bar{y}}) - \tilde{\beta}_s (\bar{\mathbf{x}}_{i\cdot} - \bar{\bar{\mathbf{x}}})$$

$$\hat{\alpha}_t = (\bar{y}_{\cdot t} - \bar{\bar{y}}) - \tilde{\beta}_s (\bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}})$$

Denote the cross-sectional dummy variables and time dummy variables with the superscript C and T. Under the NOINT option the following equations give the dummy variables:

$$D_i^C = \hat{\gamma}_i + \hat{\alpha}_T$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

When an intercept is specified, the equations for dummy variables and intercept are:

$$D_i^C = \hat{\gamma}_i - \hat{\gamma}_N$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

$$\text{Intercept} = \hat{\gamma}_N + \hat{\alpha}_T$$

The sum of squared errors is:

$$\text{SSE} = \sum_{i=1}^N \sum_{t=1}^{T_i} (y_{it} - \gamma_i - \alpha_t - \mathbf{X}_s \tilde{\beta}_s)^2$$

The estimated error variance is:

$$\hat{\sigma}_\epsilon^2 = \text{SSE} / (M - N - T - (K - 1))$$

With or without a constant, the variance covariance matrix of $\tilde{\beta}_s$ is given by:

$$\text{Var}[\tilde{\beta}_s] = \hat{\sigma}_\epsilon^2 (\tilde{\mathbf{X}}_s' \tilde{\mathbf{X}}_s)^{-1}$$

Variance Covariance of Dummy Variables with No Intercept

The variances and covariances of the dummy variables are given with the NOINT specification as follows:

$$\begin{aligned}\text{Var}\left(D_i^C\right) &= \hat{\sigma}_\epsilon^2 \left(\frac{1}{T} + \frac{1}{N} - \frac{1}{NT} \right) \\ &+ \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)' \text{Var}\left[\tilde{\beta}_s\right] \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)\end{aligned}$$

$$\text{Var}\left(D_i^T\right) = \frac{2\hat{\sigma}_\epsilon^2}{N} + \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var}\left[\tilde{\beta}_s\right] \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)$$

$$\begin{aligned}\text{Cov}\left(D_i^C, D_j^C\right) &= \hat{\sigma}_\epsilon^2 \left(\frac{1}{N} - \frac{1}{NT} \right) \\ &+ \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)' \text{Var}\left[\tilde{\beta}_s\right] \left(\bar{\mathbf{x}}_{j\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)\end{aligned}$$

$$\text{Cov}\left(D_i^T, D_u^T\right) = \frac{\hat{\sigma}_\epsilon^2}{N} + \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var}\left[\tilde{\beta}_s\right] \left(\bar{\mathbf{x}}_{\cdot u} - \bar{\mathbf{x}}_{\cdot T} \right)$$

$$\text{Cov}\left(D_i^C, D_i^T\right) = -\frac{\hat{\sigma}_\epsilon^2}{N} + \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)' \text{Var}\left[\tilde{\beta}_s\right] \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)$$

$$\text{Cov}\left(D_i^C, \beta\right) = -\left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)' \text{Var}\left[\tilde{\beta}_s\right]$$

$$\text{Cov}\left(D_i^T, \beta\right) = -\left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var}\left[\tilde{\beta}_s\right]$$

Variance Covariance of Dummy Variables with Intercept

The variances and covariances of the dummy variables are given when the intercept is included as follows:

$$\begin{aligned}
 \text{Var} \left(D_i^C \right) &= \frac{\hat{\sigma}_\epsilon^2}{T} + (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot}) \\
 \text{Var} \left(D_t^T \right) &= \frac{2\hat{\sigma}_\epsilon^2}{N} + (\bar{\mathbf{x}}_t - \bar{\mathbf{x}}_{\cdot T})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_t - \bar{\mathbf{x}}_{\cdot T}) \\
 \text{Var} (\text{Intercept}) &= \hat{\sigma}_\epsilon^2 \left(\frac{1}{T} + \frac{1}{N} - \frac{1}{NT} \right) + (\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}}) \\
 \text{Cov} \left(D_i^C, D_j^C \right) &= \frac{\hat{\sigma}_\epsilon^2}{T} + (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{j\cdot} - \bar{\mathbf{x}}_{N\cdot}) \\
 \text{Cov} \left(D_t^T, D_u^T \right) &= (\bar{\mathbf{x}}_t - \bar{\mathbf{x}}_{\cdot T})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_u - \bar{\mathbf{x}}_{\cdot T}) \\
 \text{Cov} \left(D_i^C, \text{Intercept} \right) &= - \left(\frac{\hat{\sigma}_\epsilon^2}{T} \right) + (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot})' \text{Var} \left(\tilde{\beta}_s \right) (\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}}) \\
 \text{Cov} \left(D_t^T, \text{Intercept} \right) &= - \left(\frac{\hat{\sigma}_\epsilon^2}{N} \right) + (\bar{\mathbf{x}}_t - \bar{\mathbf{x}}_{\cdot T})' \text{Var} \left[\tilde{\beta}_s \right] (\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}}) \\
 \text{Cov} \left(D_i^C, \tilde{\beta} \right) &= - (\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot})' \text{Var} \left[\tilde{\beta}_s \right] \\
 \text{Cov} \left(D_t^T, \tilde{\beta} \right) &= - (\bar{\mathbf{x}}_t - \bar{\mathbf{x}}_{\cdot T})' \text{Var} \left[\tilde{\beta}_s \right] \\
 \text{Cov} \left(\text{Intercept}, \tilde{\beta} \right) &= - (\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}})' \text{Var} \left[\tilde{\beta}_s \right]
 \end{aligned}$$

Unbalanced Panels

Let \mathbf{X}_* and \mathbf{y}_* be the independent and dependent variables arranged by time and by cross section within each time period. (Note that the input data set used by the PANEL procedure must be sorted by cross section and then by time within each cross section.) Let M_t be the number of cross sections observed in year t and let $\sum_t M_t = M$. Let \mathbf{D}_t be the $M_t \times N$ matrix obtained from the $N \times N$ identity matrix from which rows that correspond to cross sections not observed at time t have been omitted. Consider

$$\mathbf{Z} = (\mathbf{Z}_1, \mathbf{Z}_2)$$

where $\mathbf{Z}_1 = (\mathbf{D}'_1, \mathbf{D}'_2, \dots, \mathbf{D}'_T)'$ and $\mathbf{Z}_2 = \text{diag}(\mathbf{D}_1 \mathbf{j}_N, \mathbf{D}_2 \mathbf{j}_N, \dots, \mathbf{D}_T \mathbf{j}_N)$. The matrix \mathbf{Z} gives the dummy variable structure for the two-way model.

Let

$$\Delta_N = \mathbf{Z}'_1 \mathbf{Z}_1$$

$$\Delta_T = \mathbf{Z}'_2 \mathbf{Z}_2$$

$$\mathbf{A} = \mathbf{Z}'_2 \mathbf{Z}_1$$

$$\bar{\mathbf{Z}} = \mathbf{Z}_2 - \mathbf{Z}_1 \Delta_N^{-1} \mathbf{A}'$$

$$\mathbf{Q} = \Delta_T - \mathbf{A} \Delta_N^{-1} \mathbf{A}'$$

$$\mathbf{P} = (\mathbf{I}_M - \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1) - \bar{\mathbf{Z}} \mathbf{Q}^{-1} \bar{\mathbf{Z}}'$$

The estimate of the regression slope coefficients is given by

$$\tilde{\beta}_s = (\mathbf{X}_{*s}' \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}_{*s}' \mathbf{P} \mathbf{y}_*$$

where \mathbf{X}_{*s} is the \mathbf{X}_* matrix without the vector of 1s.

The estimator of the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{P} \tilde{\mathbf{u}} / (M - T - N + 1 - (K - 1))$$

where the residuals are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M \mathbf{j}_M' / M)(\mathbf{y}_* - \mathbf{X}_{*s} \tilde{\beta}_s)$ if there is an intercept in the model and by $\tilde{\mathbf{u}} = \mathbf{y}_* - \mathbf{X}_{*s} \tilde{\beta}_s$ if there is no intercept.

The actual implementation is quite different from the theory. The PANEL procedure transforms all series using the \mathbf{P} matrix.

$$\bar{\mathbf{v}} = \mathbf{P} \mathbf{v}$$

The variable being transformed is v , which could be \mathbf{y} or any column of \mathbf{X} . After the data are properly transformed, OLS is run on the resulting series.

Given $\tilde{\beta}_s$, the next step is estimating the cross-sectional and time effects. Given that $\boldsymbol{\gamma}$ is the column vector of cross-sectional effects and $\boldsymbol{\alpha}$ is the column vector of time effects,

$$\tilde{\boldsymbol{\alpha}} = \mathbf{Q}^{-1} \bar{\mathbf{Z}}' \mathbf{y} - \mathbf{Q}^{-1} \bar{\mathbf{Z}}' \mathbf{X}_s \tilde{\beta}_s$$

$$\tilde{\boldsymbol{\gamma}} = (\Theta_1 + \Theta_2 - \Theta_3) \mathbf{y} - (\Theta_1 + \Theta_2 - \Theta_3) \mathbf{X}_s \tilde{\beta}_s$$

$$\Theta_1 = \Delta_N^{-1} \mathbf{Z}_1'$$

$$\Theta_2 = \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{Z}_2'$$

$$\Theta_3 = \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1} \mathbf{Z}_1'$$

Given the cross-sectional and time effects, the next step is to derive the associated dummy variables. Using the NOINT option, the following equations give the dummy variables:

$$D_i^C = \hat{\gamma}_i + \hat{\alpha}_T$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

When an intercept is desired, the equations for dummy variables and intercept are:

$$D_i^C = \hat{\gamma}_i - \hat{\gamma}_N$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

$$\text{Intercept} = \hat{\gamma}_N + \hat{\alpha}_T$$

The calculation of the variance-covariance matrix is as follows:

$$\begin{aligned} \text{Var}[\hat{\boldsymbol{\gamma}}] &= \hat{\sigma}_\epsilon^2 (\Delta_N^{-1} - \Sigma_1 + \Sigma_2) \\ &+ (\Theta_1 + \Theta_2 - \Theta_3) \text{Var}[\tilde{\beta}_s] (\Theta_1 + \Theta_2 - \Theta_3)' \end{aligned}$$

where

$$\Sigma_1 = \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1}$$

$$\Sigma_2 = \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \Delta_T \mathbf{Q}^{-1} \mathbf{A} \Delta_N$$

$$\text{Var}[\hat{\alpha}] = \hat{\sigma}_\epsilon^2 \left(\mathbf{Q}^{-1} \bar{\mathbf{Z}}' \bar{\mathbf{Z}} \mathbf{Q}^{-1} \right) + \left(\mathbf{Q}^{-1} \bar{\mathbf{Z}}' \mathbf{X}_s \right) \text{Var}[\tilde{\beta}_s] \left(\mathbf{X}_s' \bar{\mathbf{Z}} \mathbf{Q}^{-1} \right)$$

$$\begin{aligned} \text{Cov}[\hat{\alpha}, \hat{\gamma}'] &= \hat{\sigma}_\epsilon^2 \Delta_N^{-1} \left[\mathbf{A}' \mathbf{Q}^{-1} \Delta_T - \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1} \mathbf{A}' \right] \mathbf{Q}^{-1} \\ &+ (\Theta_1 + \Theta_2 - \Theta_3) \text{Var}[\tilde{\beta}_s] \left(\mathbf{X}_s' \bar{\mathbf{Z}} \mathbf{Q}^{-1} \right) \end{aligned}$$

$$\text{Cov}[\hat{\gamma}, \tilde{\beta}] = (\Theta_1 + \Theta_2 - \Theta_3) \text{Var}[\tilde{\beta}_s]$$

$$\text{Cov}[\hat{\alpha}, \tilde{\beta}] = \left(\mathbf{Q}^{-1} \bar{\mathbf{Z}}' \mathbf{X}_s \right) \text{Var}[\tilde{\beta}_s]$$

Now you work out the variance covariance estimates for the dummy variables.

Variance Covariance of Dummy variables with No Intercept

The variances and covariances of the dummy variables are given under the NOINT selection as follows:

$$\text{Cov}(D_i^C, D_j^C) = \text{Cov}(\hat{\gamma}_i, \hat{\gamma}_j) + \text{Cov}(\hat{\gamma}_i, \hat{\alpha}_T) + \text{Cov}(\hat{\gamma}_j, \hat{\alpha}_T) + \text{Var}(\hat{\alpha}_T)$$

$$\text{Cov}(D_t^T, D_u^T) = \text{Cov}(\hat{\alpha}_t, \hat{\alpha}_u) - \text{Cov}(\hat{\alpha}_t, \hat{\alpha}_T) - \text{Cov}(\hat{\alpha}_u, \hat{\alpha}_T) + \text{Var}(\hat{\alpha}_T)$$

$$\text{Cov}(D_i^C, D_t^T) = \text{Cov}(\hat{\gamma}_i, \hat{\alpha}_t) + \text{Cov}(\hat{\gamma}_i, \hat{\alpha}_T) - \text{Cov}(\hat{\gamma}_i, \hat{\alpha}_T) - \text{Var}(\hat{\alpha}_T)$$

$$\text{Cov}(D_i^C, \tilde{\beta}) = -\text{Cov}(\hat{\gamma}_i, \tilde{\beta}) - \text{Cov}(\hat{\alpha}_T, \tilde{\beta})$$

$$\text{Cov}(D_t^T, \tilde{\beta}) = -\text{Cov}(\hat{\alpha}_t, \tilde{\beta}) + \text{Cov}(\hat{\alpha}_T, \tilde{\beta})$$

Variance Covariance of Dummy variables with Intercept

The variances and covariances of the dummy variables are given as follows when the intercept is included:

$$\begin{aligned}
 \text{Cov} \left(D_i^C, D_j^C \right) &= \text{Cov} \left(\hat{\gamma}_i, \hat{\gamma}_j \right) - \text{Cov} \left(\hat{\gamma}_i, \hat{\gamma}_N \right) - \text{Cov} \left(\hat{\gamma}_j, \hat{\gamma}_N \right) + \text{Var} \left(\hat{\gamma}_N \right) \\
 \text{Cov} \left(D_t^T, D_u^T \right) &= \text{Cov} \left(\hat{\alpha}_t, \hat{\alpha}_u \right) - \text{Cov} \left(\hat{\alpha}_t, \hat{\alpha}_T \right) - \text{Cov} \left(\hat{\alpha}_u, \hat{\alpha}_T \right) + \text{Var} \left(\hat{\alpha}_T \right) \\
 \text{Cov} \left(D_i^C, D_t^T \right) &= \text{Cov} \left(\hat{\gamma}_i, \hat{\alpha}_t \right) - \text{Cov} \left(\hat{\gamma}_i, \hat{\alpha}_T \right) - \text{Cov} \left(\hat{\gamma}_N, \hat{\alpha}_t \right) + \text{Cov} \left(\hat{\gamma}_N, \hat{\alpha}_T \right) \\
 \text{Cov} \left(D_i^C, \text{Intercept} \right) &= \text{Cov} \left(\hat{\gamma}_i, \hat{\gamma}_N \right) + \text{Cov} \left(\hat{\gamma}_i, \hat{\alpha}_T \right) - \text{Cov} \left(\hat{\gamma}_j, \hat{\alpha}_T \right) - \text{Var} \left(\hat{\gamma}_N \right) \\
 \text{Cov} \left(D_t^T, \text{Intercept} \right) &= \text{Cov} \left(\hat{\alpha}_t, \hat{\alpha}_T \right) + \text{Cov} \left(\hat{\alpha}_t, \hat{\gamma}_N \right) - \text{Cov} \left(\hat{\alpha}_T, \hat{\alpha}_N \right) - \text{Var} \left(\hat{\alpha}_T \right) \\
 \text{Cov} \left(D_i^C, \tilde{\beta} \right) &= -\text{Cov} \left(\hat{\gamma}_i, \tilde{\beta} \right) - \text{Cov} \left(\hat{\gamma}_N, \tilde{\beta} \right) \\
 \text{Cov} \left(D_t^T, \tilde{\beta} \right) &= -\text{Cov} \left(\hat{\alpha}_t, \tilde{\beta} \right) + \text{Cov} \left(\hat{\alpha}_T, \tilde{\beta} \right) \\
 \text{Cov} \left(\text{Intercept}, \tilde{\beta}_f \right) &= -\text{Cov} \left(\hat{\alpha}_T, \tilde{\beta} \right) - \text{Cov} \left(\hat{\gamma}_N, \tilde{\beta} \right)
 \end{aligned}$$

Between Estimators

The between groups estimator is the regression of the cross section means of \mathbf{y} on the cross section means of $\tilde{\mathbf{X}}_s$. In other words, you fit the following regression:

$$\bar{y}_{i\cdot} = \bar{\mathbf{x}}_{i\cdot} \beta^{BG} + \eta_i$$

The between time periods estimator is the regression of the time means of \mathbf{y} on the time means of $\tilde{\mathbf{X}}_s$. In other words, you fit the following regression:

$$\bar{y}_{\cdot t} = \bar{\mathbf{x}}_{\cdot t} \beta^{BT} + \zeta_t$$

In either case, the error is assumed to be normally distributed with mean zero and a constant variance.

Pooled Estimator

PROC PANEL allows you to pool time series cross-sectional data and run regressions on the data. Pooling is admissible if there are no fixed effects or random effects present in the data. This feature is included to aid in analysis and comparison across model types and to give you access to HCCME standard errors and other panel diagnostics. In general, this model type should not be used with time series cross-sectional data.

The One-Way Random-Effects Model

The specification for the one-way random-effects model is

$$u_{it} = v_i + \epsilon_{it}$$

Let $\mathbf{Z}_0 = \text{diag}(\mathbf{J}_{T_i})$, $\mathbf{P}_0 = \text{diag}(\bar{\mathbf{J}}_{T_i})$, and $\mathbf{Q}_0 = \text{diag}(\mathbf{E}_{T_i})$, with $\bar{\mathbf{J}}_{T_i} = \mathbf{J}_{T_i}/T_i$ and $\mathbf{E}_{T_i} = \mathbf{I}_{T_i} - \bar{\mathbf{J}}_{T_i}$. Define $\tilde{\mathbf{X}}_s = \mathbf{Q}_0\mathbf{X}_s$ and $\tilde{\mathbf{y}} = \mathbf{Q}_0\mathbf{y}$ and \mathbf{J} as a vector of ones T_i long.

In the one-way model, estimation proceeds in a two-step fashion. First, you obtain estimates of the variance of the σ_ϵ^2 and σ_v^2 . There are multiple ways to derive these estimates; PROC PANEL provides four options. All four options are valid for balanced or unbalanced panels. Once these estimates are in hand, they are used to form a weighting factor θ , and estimation proceeds via OLS on partial deviations from group means.

PROC PANEL gives the following options for variance component estimators.

Fuller and Battese's Method

The Fuller and Battese method for estimating variance components can be obtained with the option VCOMP = FB and the option RANONE. The variance components are given by the following equations (see Baltagi and Chang (1994) and Fuller and Battese (1974) for the approach in the two-way model). Let

$$R(v) = \mathbf{y}'\mathbf{Z}_0(\mathbf{Z}_0'\mathbf{Z}_0)^{-1}\mathbf{Z}_0'\mathbf{y}$$

$$R(\beta|v) = ((\tilde{\mathbf{X}}_s'\tilde{\mathbf{X}}_s)^{-1}\tilde{\mathbf{X}}_s'\tilde{\mathbf{y}})'(\tilde{\mathbf{X}}_s'\tilde{\mathbf{y}})$$

$$R(\beta) = (\mathbf{X}_s'\mathbf{y})'(\mathbf{X}_s'\mathbf{X}_s)^{-1}\mathbf{X}_s'\mathbf{y}$$

$$R(v|\beta) = R(\beta|v) + R(v) - R(\beta)$$

The estimator of the error variance is given by

$$\hat{\sigma}_\epsilon^2 = (\mathbf{y}'\mathbf{y} - R(\beta|v) - R(v))/(M - N - (K - 1))$$

If the NOINT option is specified, the estimator is

$$\hat{\sigma}_\epsilon^2 = (\mathbf{y}'\mathbf{y} - R(\beta|v) - R(v))/(M - N - K)$$

The estimator of the cross-sectional variance component is given by

$$\hat{\sigma}_v^2 = (R(v|\beta) - (N - 1)\hat{\sigma}_\epsilon^2)/(M - \text{tr}(\mathbf{Z}_0'\mathbf{X}_s(\mathbf{X}_s'\mathbf{X}_s)^{-1}\mathbf{X}_s'\mathbf{Z}_0))$$

Note that the error variance is the variance of the residual of the within estimator.

According to Baltagi and Chang (1994), the Fuller and Battese method is appropriate to apply to both balanced and unbalanced data. The Fuller and Battese method is the default for estimation of one-way random-effects models with balanced panels. However, the Fuller and Battese method does not always obtain nonnegative estimates for the cross section (or group) variance. In the case of a negative estimate, a warning is printed and the estimate is set to zero.

Wansbeek and Kapteyn's Method

The Wansbeek and Kapteyn method for estimating variance components can be obtained by setting VCOMP = WK (together with the option RANONE). The estimation of the one-way unbalanced data model is performed by using a specialization (Baltagi and Chang 1994) of the approach used by Wansbeek and Kapteyn (1989) for unbalanced two-way models. The Wansbeek and Kapteyn method is the default for unbalanced data. If just RANONE is specified, without the VCOMP= option, PROC PANEL estimates the variance component under Wansbeek and Kapteyn's method.

The estimation of the variance components is performed by using a quadratic unbiased estimation (QUE) method. This involves focusing on quadratic forms of the centered residuals, equating their expected values to the realized quadratic forms, and solving for the variance components.

Let

$$q_1 = \tilde{\mathbf{u}}' \mathbf{Q}_0 \tilde{\mathbf{u}}$$

$$q_2 = \tilde{\mathbf{u}}' \mathbf{P}_0 \tilde{\mathbf{u}}$$

where the residuals $\tilde{\mathbf{u}}$ are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M \mathbf{j}'_M / M)(\mathbf{y} - \mathbf{X}_s (\tilde{\mathbf{X}}'_s \tilde{\mathbf{X}}_s)^{-1} \tilde{\mathbf{X}}'_s \tilde{\mathbf{y}})$ if there is an intercept and by $\tilde{\mathbf{u}} = \mathbf{y} - \mathbf{X}_s (\tilde{\mathbf{X}}'_s \tilde{\mathbf{X}}_s)^{-1} \tilde{\mathbf{X}}'_s \tilde{\mathbf{y}}$ if there is not. A vector of M ones is represented by \mathbf{j} .

Consider the expected values

$$E(q_1) = (M - N - (K - 1))\sigma_\epsilon^2$$

$$E(q_2) = (N - 1 + \text{tr}[(\mathbf{X}'_s \mathbf{Q}_0 \mathbf{X}_s)^{-1} \mathbf{X}'_s \mathbf{P}_0 \mathbf{X}_s] - \text{tr}[(\mathbf{X}'_s \mathbf{Q}_0 \mathbf{X}_s)^{-1} \mathbf{X}'_s \bar{\mathbf{J}}_M \mathbf{X}_s])\sigma_\epsilon^2 \\ [M - (\sum_i T_i^2 / M)]\sigma_v^2$$

where $\hat{\sigma}_\epsilon^2$ and $\hat{\sigma}_v^2$ are obtained by equating the quadratic forms to their expected values.

The estimator of the error variance is the residual variance of the within estimate. The Wansbeek and Kapteyn method can also generate negative variance components estimates.

Wallace and Hussain's Method

The Wallace and Hussain method for estimating variance components can be obtained by setting VCOMP = WH (together with the option RANONE). Wallace-Hussain estimates start from OLS residuals on a data that are assumed to exhibit groupwise heteroscedasticity. As in the Wansbeek and Kapteyn method, you start with

$$q_1 = \tilde{\mathbf{u}}'_{OLS} \mathbf{Q}_0 \tilde{\mathbf{u}}_{OLS}$$

$$q_2 = \tilde{\mathbf{u}}'_{OLS} \mathbf{P}_0 \tilde{\mathbf{u}}_{OLS}$$

However, instead of using the 'true' errors, you substitute the OLS residuals. You solve the system

$$E(\hat{q}_1) = E(\hat{\mathbf{u}}'_{OLS} \mathbf{Q}_0 \hat{\mathbf{u}}_{OLS}) = \delta_{11} \hat{\sigma}_v^2 + \delta_{12} \hat{\sigma}_\epsilon^2$$

$$E(\hat{q}_2) = E(\hat{\mathbf{u}}'_{OLS} \mathbf{P}_0 \hat{\mathbf{u}}_{OLS}) = \delta_{21} \hat{\sigma}_v^2 + \delta_{22} \hat{\sigma}_\epsilon^2$$

The constants $\delta_{11}, \delta_{12}, \delta_{21}, \delta_{22}$ are given by

$$\delta_{11} = \text{tr} \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{Z}_0\mathbf{Z}_0'\mathbf{X} \right) - \text{tr} \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{P}_0\mathbf{X} \left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{Z}_0\mathbf{Z}_0'\mathbf{X} \right)$$

$$\delta_{12} = M - N - K + \text{tr} \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{P}_0\mathbf{X} \right)$$

$$\delta_{21} = M - 2tr \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{Z}_0\mathbf{Z}_0'\mathbf{X} \right) + \text{tr} \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{P}_0\mathbf{X} \right)$$

$$\delta_{22} = N - \text{tr} \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{P}_0\mathbf{X} \right)$$

where $\text{tr}()$ is the trace operator on a square matrix.

Solving this system produces the variance components. This method is applicable to balanced and unbalanced panels. However, there is no guarantee of positive variance components. Any negative values are fixed equal to zero.

Nerlove's Method

The Nerlove method for estimating variance components can be obtained by setting `VCOMP = NL`. The Nerlove method (see Baltagi 1995, page 17) is assured to give estimates of the variance components that are always positive. Furthermore, it is simple in contrast to the previous estimators.

If γ_i is the i th fixed effect, Nerlove's method uses the variance of the fixed effects as the estimate of $\hat{\sigma}_v^2$. You have $\hat{\sigma}_v^2 = \sum_{i=1}^N \frac{(\gamma_i - \bar{\gamma})^2}{N-1}$, where $\bar{\gamma}$ is the mean fixed effect. The estimate of σ_ϵ^2 is simply the residual sum of squares of the one-way fixed-effects regression divided by the number of observations.

With the variance components in hand, from any method, the next task is to estimate the regression model of interest. For each individual, you form a weight (θ_i) as follows:

$$\theta_i = 1 - \sigma_\epsilon / w_i$$

$$w_i^2 = T_i \sigma_v^2 + \sigma_\epsilon^2$$

where T_i is the i th cross section's time observations.

Taking the θ_i , you form the partial deviations,

$$\tilde{y}_{it} = y_{it} - \theta_i \bar{y}_i$$

$$\tilde{x}_{it} = x_{it} - \theta_i \bar{x}_i$$

where \bar{y}_i and \bar{x}_i are cross section means of the dependent variable and independent variables (including the constant if any), respectively.

The random-effects β is then the result of simple OLS on the transformed data.

The Two-Way Random-Effects Model

The specification for the two-way random-effects model is

$$u_{it} = v_i + e_t + \epsilon_{it}$$

As in the one-way random-effects model, the PANEL procedure provides four options for variance component estimators. Unlike the one-way random-effects model, unbalanced panels present some special concerns.

Let \mathbf{X}_* and \mathbf{y}_* be the independent and dependent variables arranged by time and by cross section within each time period. (Note that the input data set used by the PANEL procedure must be sorted by cross section and then by time within each cross section.) Let M_t be the number of cross sections observed in time t and $\sum_t M_t = M$. Let \mathbf{D}_t be the $M_t \times N$ matrix obtained from the $N \times N$ identity matrix from which rows that correspond to cross sections not observed at time t have been omitted. Consider

$$\mathbf{Z} = (\mathbf{Z}_1, \mathbf{Z}_2)$$

where $\mathbf{Z}_1 = (\mathbf{D}'_1, \mathbf{D}'_2, \dots, \mathbf{D}'_T)'$ and $\mathbf{Z}_2 = \text{diag}(\mathbf{D}_1 \mathbf{j}_N, \mathbf{D}_2 \mathbf{j}_N, \dots, \mathbf{D}_T \mathbf{j}_N)$.

The matrix \mathbf{Z} gives the dummy variable structure for the two-way model.

For notational ease, let

$$\Delta_N = \mathbf{Z}'_1 \mathbf{Z}_1, \Delta_T = \mathbf{Z}'_2 \mathbf{Z}_2, \mathbf{A} = \mathbf{Z}'_2 \mathbf{Z}_1$$

$$\bar{\mathbf{Z}} = \mathbf{Z}_2 - \mathbf{Z}_1 \Delta_N^{-1} \mathbf{A}'$$

$$\bar{\Delta}_1 = \mathbf{I}_M - \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1$$

$$\bar{\Delta}_2 = \mathbf{I}_M - \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}'_2$$

$$\mathbf{Q} = \Delta_T - \mathbf{A} \Delta_N^{-1} \mathbf{A}'$$

$$\mathbf{P} = (\mathbf{I}_M - \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1) - \bar{\mathbf{Z}} \mathbf{Q}^{-1} \bar{\mathbf{Z}}'$$

Fuller and Battese's Method

The Fuller and Battese method for estimating variance components can be obtained by setting VCOMP = FB (with the option RANTWO). FB is the default method for a RANTWO model with balanced panel. If RANTWO is requested without specifying the VCOMP= option, PROC PANEL proceeds under the Fuller and Battese method.

Following the discussion in Baltagi, et. al. (2002), the Fuller and Battese method forms the estimates as follows.

The estimator of the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{P} \tilde{\mathbf{u}} / (M - T - N + 1 - (K - 1))$$

where \mathbf{P} is the Wansbeek and Kapteyn within estimator for unbalanced (or balanced) panel in a two-way setting.

The estimator of the error variance is the same as that in the Wansbeek and Kapteyn method.

Consider the expected values

$$\begin{aligned}
 E(q_N) &= \sigma_\epsilon^2 [M - T - K + 1] \\
 &+ \sigma_v^2 \left[M - T - \text{tr} \left(\mathbf{X}'_s \bar{\Delta}_2 \mathbf{Z}_1 \mathbf{Z}'_1 \bar{\Delta}_2 \mathbf{X}_s (\mathbf{X}'_s \bar{\Delta}_2 \mathbf{X}_s)^{-1} \right) \right] \\
 E(q_T) &= \sigma_\epsilon^2 [M - N - K + 1] \\
 &+ \sigma_e^2 \left[M - N - \text{tr} \left(\mathbf{X}'_s \bar{\Delta}_1 \mathbf{Z}_2 \mathbf{Z}'_2 \bar{\Delta}_1 \mathbf{X}_s (\mathbf{X}'_s \bar{\Delta}_1 \mathbf{X}_s)^{-1} \right) \right]
 \end{aligned}$$

Just as in the one-way case, there is always the possibility that the (estimated) variance components will be negative. In such a case, the negative components are fixed to equal zero. After substituting the group sum of the within residuals for (q_N) , the time sums of the within residuals for (q_T) , and $\hat{\sigma}_\epsilon^2$, the two equations are solved for $\hat{\sigma}_v^2$ and $\hat{\sigma}_e^2$.

Wansbeek and Kapteyn's Method

The Wansbeek and Kapteyn method for estimating variance components can be obtained by setting VCOMP = WK. The following methodology, outlined in Wansbeek and Kapteyn (1989) is used to handle both balanced and unbalanced data. The Wansbeek and Kapteyn method is the default for a RANTWO model with unbalanced panel. If RANTWO is requested without specifying the VCOMP= option, PROC PANEL proceeds under the Wansbeek and Kapteyn method if the panel is unbalanced.

The estimator of the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{P} \tilde{\mathbf{u}} / (M - T - N + 1 - (K - 1))$$

where the $\tilde{\mathbf{u}}$ are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M \mathbf{j}'_M / M)(\mathbf{y}_* - \mathbf{X}_{*s}(\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{P} \mathbf{y}_*)$ if there is an intercept and by $\tilde{\mathbf{u}} = (\mathbf{y}_* - \mathbf{X}_{*s}(\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{P} \mathbf{y}_*)$ if there is not.

The estimation of the variance components is performed by using a quadratic unbiased estimation (QUE) method that involves computing on quadratic forms of the residuals $\tilde{\mathbf{u}}$, equating their expected values to the realized quadratic forms, and solving for the variance components.

Let

$$q_N = \tilde{\mathbf{u}}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}'_2 \tilde{\mathbf{u}}$$

$$q_T = \tilde{\mathbf{u}}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1 \tilde{\mathbf{u}}$$

The expected values are

$$E(q_N) = (T + k_N - (1 + k_0))\sigma^2 + (T - \frac{\lambda_1}{M})\sigma_v^2 + (M - \frac{\lambda_2}{M})\sigma_e^2$$

$$\begin{aligned}
 E(q_T) &= (N + k_T - (1 + k_0))\sigma^2 \\
 &+ (M - \frac{\lambda_1}{M})\sigma_v^2 + (N - \frac{\lambda_2}{M})\sigma_e^2
 \end{aligned}$$

where

$$\begin{aligned}
 k_0 &= \mathbf{j}'_M \mathbf{X}_{*s} (\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{j}_M / M \\
 k_N &= \text{tr}((\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}'_2 \mathbf{X}_{*s}) \\
 k_T &= \text{tr}((\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1 \mathbf{X}_{*s}) \\
 \lambda_1 &= \mathbf{j}'_M \mathbf{Z}_1 \mathbf{Z}'_1 \mathbf{j}_M \\
 \lambda_2 &= \mathbf{j}'_M \mathbf{Z}_2 \mathbf{Z}'_2 \mathbf{j}_M
 \end{aligned}$$

The quadratic unbiased estimators for σ_v^2 and σ_e^2 are obtained by equating the expected values to the quadratic forms and solving for the two unknowns.

When the NOINT option is specified, the variance component equations change slightly. In particular, the following is true (Wansbeek and Kapteyn 1989):

$$\begin{aligned}
 E(q_N) &= (T + k_N)\sigma^2 + T\sigma_v^2 + M\sigma_e^2 \\
 E(q_T) &= (N + k_T)\sigma^2 + M\sigma_v^2 + N\sigma_e^2
 \end{aligned}$$

Wallace and Hussain's Method

The Wallace and Hussain method for estimating variance components can be obtained by setting VCOMP = WH. Wallace and Hussain's method is by far the most computationally intensive. It uses the OLS residuals to estimate the variance components. In other words, the Wallace and Hussain method assumes that the following holds:

$$\begin{aligned}
 q_\epsilon &= \tilde{\mathbf{u}}'_{OLS} \mathbf{P} \tilde{\mathbf{u}}_{OLS} \\
 q_N &= \tilde{\mathbf{u}}'_{OLS} \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}'_2 \tilde{\mathbf{u}}_{OLS} \\
 q_T &= \tilde{\mathbf{u}}'_{OLS} \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1 \tilde{\mathbf{u}}_{OLS}
 \end{aligned}$$

Taking expectations yields

$$\begin{aligned}
 E(q_\epsilon) &= E(\tilde{\mathbf{u}}'_{OLS} \mathbf{P} \tilde{\mathbf{u}}_{OLS}) = \delta_{11}\sigma_\epsilon^2 + \delta_{12}\sigma_v^2 + \delta_{13}\sigma_e^2 \\
 E(q_N) &= E(\tilde{\mathbf{u}}'_{OLS} \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}'_2 \tilde{\mathbf{u}}_{OLS}) = \delta_{21}\sigma_\epsilon^2 + \delta_{22}\sigma_v^2 + \delta_{23}\sigma_e^2 \\
 E(q_T) &= E(\tilde{\mathbf{u}}'_{OLS} \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1 \tilde{\mathbf{u}}_{OLS}) = \delta_{31}\sigma_\epsilon^2 + \delta_{32}\sigma_v^2 + \delta_{33}\sigma_e^2
 \end{aligned}$$

where the δ_{js} constants are defined by

$$\begin{aligned}
 \delta_{11} &= M - N - T + 1 - \text{tr}\left(\mathbf{X}' \mathbf{P} \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1}\right) \\
 \delta_{12} &= \text{tr}\left(\mathbf{X}' \mathbf{Z}_1 \mathbf{Z}'_1 \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \left(\mathbf{X}' \mathbf{P} \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1}\right)\right)
 \end{aligned}$$

$$\delta_{13} = \text{tr} \left(\mathbf{X}' \mathbf{Z}_2 \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \left(\mathbf{X}' \mathbf{P} \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \right)$$

$$\delta_{21} = T - \text{tr} \left(\mathbf{X}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right)$$

$$\begin{aligned} \delta_{22} &= T - 2\text{tr} \left(\mathbf{X}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \mathbf{Z}_1 \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \\ &+ \text{tr} \left(\mathbf{X}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \mathbf{X}' \mathbf{Z}_1 \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \end{aligned}$$

$$\begin{aligned} \delta_{23} &= T - 2\text{tr} \left(\mathbf{X}' \mathbf{Z}_2 \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \\ &+ \text{tr} \left(\mathbf{X}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \mathbf{X}' \mathbf{Z}_2 \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \end{aligned}$$

$$\delta_{31} = N - \text{tr} \left(\mathbf{X}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right)$$

$$\begin{aligned} \delta_{32} &= M - 2\text{tr} \left(\mathbf{X}' \mathbf{Z}_1 \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \\ &+ \text{tr} \left(\mathbf{X}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \mathbf{X}' \mathbf{Z}_1 \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \end{aligned}$$

$$\begin{aligned} \delta_{33} &= N - 2\text{tr} \left(\mathbf{X}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \mathbf{Z}_2 \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \\ &+ \text{tr} \left(\mathbf{X}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \mathbf{X}' \mathbf{Z}_2 \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \end{aligned}$$

The PANEL procedure solves this system for the estimates $\hat{\sigma}_\epsilon$, $\hat{\sigma}_v$, and $\hat{\sigma}_e$. Some of the estimated variance components can be negative. Negative components are set to zero and estimation proceeds.

Nerlove's Method

The Nerlove method for estimating variance components can be obtained with by setting VCOMP = NL.

The estimator of the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{P} \tilde{\mathbf{u}} / M$$

The variance components for cross section and time effects are:

$$\hat{\sigma}_v^2 = \sum_{i=1}^N \frac{(\gamma_i - \bar{\gamma})^2}{N-1} \text{ where } \gamma_i \text{ is the } i\text{th cross section effect}$$

and

$$\hat{\sigma}_e^2 = \sum_{i=1}^T \frac{(\alpha_i - \bar{\alpha})^2}{T-1} \text{ where } \alpha_i \text{ is the } i\text{th time effect}$$

With the estimates of the variance components in hand, you can proceed to the final estimation. If the panel is balanced, partial mean deviations are used:

$$\tilde{y}_{it} = y_{it} - \theta_1 \bar{y}_{i\cdot} - \theta_2 \bar{y}_{\cdot t} + \theta_3 \bar{y}_{\cdot\cdot}$$

$$\tilde{x}_{it} = x_{it} - \theta_1 \bar{x}_{i\cdot} - \theta_2 \bar{x}_{\cdot t} + \theta_3 \bar{x}_{\cdot\cdot}$$

The θ estimates are obtained from

$$\theta_1 = 1 - \frac{\sigma_\epsilon}{\sqrt{T\sigma_v^2 + \sigma_\epsilon^2}}$$

$$\theta_2 = 1 - \frac{\sigma_\epsilon}{\sqrt{N\sigma_e^2 + \sigma_\epsilon^2}}$$

$$\theta_3 = \theta_1 + \theta_2 + \frac{\sigma_\epsilon}{\sqrt{T\sigma_v^2 + N\sigma_e^2 + \sigma_\epsilon^2}} - 1;$$

With these partial deviations, PROC PANEL uses OLS on the transformed series (including an intercept if so desired).

The case of an unbalanced panel is somewhat trickier. You could naively substitute the variance components in the equation below:

$$\Omega = \sigma_\epsilon^2 \mathbf{I}_M + \sigma_v^2 \mathbf{Z}_1 \mathbf{Z}_1' + \sigma_e^2 \mathbf{Z}_2 \mathbf{Z}_2'$$

After inverting the expression for Ω , it is possible to do GLS on the data (even if the panel is unbalanced). However, the inversion of Ω is no small matter because the dimension is at least $\frac{M(M+1)}{2}$.

Wansbeek and Kapteyn show that the inverse of Ω can be written as

$$\sigma_\epsilon^2 \Omega^{-1} = \mathbf{V} - \mathbf{V} \mathbf{Z}_2 \tilde{\mathbf{P}}^{-1} \mathbf{Z}_2' \mathbf{V}$$

with the following:

$$\begin{aligned} \mathbf{V} &= \mathbf{I}_M - \mathbf{Z}_1 \tilde{\Delta}_N^{-1} \mathbf{Z}_1' \\ \tilde{\mathbf{P}} &= \tilde{\Delta}_T - \mathbf{A} \tilde{\Delta}_N^{-1} \mathbf{A}' \\ \tilde{\Delta}_N &= \Delta_N + \left(\frac{\sigma_\epsilon^2}{\sigma_v^2} \right) \mathbf{I}_N \\ \tilde{\Delta}_T &= \Delta_T + \left(\frac{\sigma_\epsilon^2}{\sigma_e^2} \right) \mathbf{I}_T \end{aligned}$$

Computationally, this is a much less intensive approach.

By using the inverse of the variance-covariance matrix of the error, it becomes possible to complete GLS on the unbalanced panel.

Parks Method (Autoregressive Model)

Parks (1967) considered the first-order autoregressive model in which the random errors u_{it} , $i = 1, 2, \dots, N$, and $t = 1, 2, \dots, T$ have the structure

$$\begin{aligned} E(u_{it}^2) &= \sigma_{ii}(\text{heteroscedasticity}) \\ E(u_{it}u_{jt}) &= \sigma_{ij}(\text{contemporaneously correlated}) \\ u_{it} &= \rho_i u_{i,t-1} + \epsilon_{it}(\text{autoregression}) \end{aligned}$$

where

$$\begin{aligned} E(\epsilon_{it}) &= 0 \\ E(u_{i,t-1}\epsilon_{jt}) &= 0 \\ E(\epsilon_{it}\epsilon_{jt}) &= \phi_{ij} \\ E(\epsilon_{it}\epsilon_{js}) &= 0(s \neq t) \\ E(u_{i0}) &= 0 \\ E(u_{i0}u_{j0}) &= \sigma_{ij} = \phi_{ij}/(1 - \rho_i\rho_j) \end{aligned}$$

The model assumed is first-order autoregressive with contemporaneous correlation between cross sections. In this model, the covariance matrix for the vector of random errors \mathbf{u} can be expressed as

$$E(\mathbf{u}\mathbf{u}') = \mathbf{V} = \begin{bmatrix} \sigma_{11}P_{11} & \sigma_{12}P_{12} & \dots & \sigma_{1N}P_{1N} \\ \sigma_{21}P_{21} & \sigma_{22}P_{22} & \dots & \sigma_{2N}P_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{N1}P_{N1} & \sigma_{N2}P_{N2} & \dots & \sigma_{NN}P_{NN} \end{bmatrix}$$

where

$$P_{ij} = \begin{bmatrix} 1 & \rho_j & \rho_j^2 & \dots & \rho_j^{T-1} \\ \rho_i & 1 & \rho_j & \dots & \rho_j^{T-2} \\ \rho_i^2 & \rho_i & 1 & \dots & \rho_j^{T-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \rho_i^{T-1} & \rho_i^{T-2} & \rho_i^{T-3} & \dots & 1 \end{bmatrix}$$

The matrix \mathbf{V} is estimated by a two-stage procedure, and $\boldsymbol{\beta}$ is then estimated by generalized least squares. The first step in estimating \mathbf{V} involves the use of ordinary least squares to estimate $\boldsymbol{\beta}$ and obtain the fitted residuals, as follows:

$$\hat{\mathbf{u}} = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{OLS}$$

A consistent estimator of the first-order autoregressive parameter is then obtained in the usual manner, as follows:

$$\hat{\rho}_i = \left(\sum_{t=2}^T \hat{u}_{it} \hat{u}_{i,t-1} \right) / \left(\sum_{t=2}^T \hat{u}_{i,t-1}^2 \right) \quad i = 1, 2, \dots, N$$

Finally, the autoregressive characteristic of the data is removed (asymptotically) by the usual transformation of taking weighted differences. That is, for $i = 1, 2, \dots, N$,

$$y_{i1} \sqrt{1 - \hat{\rho}_i^2} = \sum_{k=1}^p X_{i1k} \beta_k \sqrt{1 - \hat{\rho}_i^2} + u_{i1} \sqrt{1 - \hat{\rho}_i^2}$$

$$y_{it} - \hat{\rho}_i y_{i,t-1} = \sum_{k=1}^p (X_{itk} - \hat{\rho}_i X_{i,t-1,k}) \beta_k + u_{it} - \hat{\rho}_i u_{i,t-1} \quad t = 2, \dots, T$$

which is written

$$y_{it}^* = \sum_{k=1}^p X_{itk}^* \beta_k + u_{it}^* \quad i = 1, 2, \dots, N; \quad t = 1, 2, \dots, T$$

Notice that the transformed model has not lost any observations (Seely and Zyskind 1971).

The second step in estimating the covariance matrix \mathbf{V} is applying ordinary least squares to the preceding transformed model, obtaining

$$\hat{\mathbf{u}}^* = \mathbf{y}^* - \mathbf{X}^* \hat{\boldsymbol{\beta}}_{OLS}^*$$

from which the consistent estimator of σ_{ij} is calculated as follows:

$$s_{ij} = \frac{\hat{\phi}_{ij}}{(1 - \hat{\rho}_i \hat{\rho}_j)}$$

where

$$\hat{\phi}_{ij} = \frac{1}{(T - p)} \sum_{t=1}^T \hat{u}_{it}^* \hat{u}_{jt}^*$$

Estimated generalized least squares (EGLS) then proceeds in the usual manner,

$$\hat{\boldsymbol{\beta}}_P = (\mathbf{X}' \hat{\mathbf{V}}^{-1} \mathbf{X})^{-1} \mathbf{X}' \hat{\mathbf{V}}^{-1} \mathbf{y}$$

where $\hat{\mathbf{V}}$ is the derived consistent estimator of \mathbf{V} . For computational purposes, $\hat{\boldsymbol{\beta}}_P$ is obtained directly from the transformed model,

$$\hat{\boldsymbol{\beta}}_P = (\mathbf{X}^{*'} (\hat{\Phi}^{-1} \otimes I_T) \mathbf{X}^*)^{-1} \mathbf{X}^{*'} (\hat{\Phi}^{-1} \otimes I_T) \mathbf{y}^*$$

where $\hat{\Phi} = [\hat{\phi}_{ij}]_{i,j=1,\dots,N}$.

The preceding procedure is equivalent to Zellner's two-stage methodology applied to the transformed model (Zellner 1962).

Parks demonstrates that this estimator is consistent and asymptotically, normally distributed with

$$\text{Var}(\hat{\boldsymbol{\beta}}_P) = (\mathbf{X}' \mathbf{V}^{-1} \mathbf{X})^{-1}$$

Standard Corrections

For the PARKS option, the first-order autocorrelation coefficient must be estimated for each cross section. Let ρ be the $N \times 1$ vector of true parameters and $R = (r_1, \dots, r_N)'$ be the corresponding vector of estimates. Then, to ensure that only range-preserving estimates are used in PROC PANEL, the following modification for R is made:

$$r_i = \begin{cases} r_i & \text{if } |r_i| < 1 \\ \max(.95, r_{\max}) & \text{if } r_i \geq 1 \\ \min(-.95, r_{\min}) & \text{if } r_i \leq -1 \end{cases}$$

where

$$r_{\max} = \begin{cases} 0 & \text{if } r_i < 0 \text{ or } r_i \geq 1 \quad \forall i \\ \max_j [r_j : 0 \leq r_j < 1] & \text{otherwise} \end{cases}$$

and

$$r_{\min} = \begin{cases} 0 & \text{if } r_i > 0 \text{ or } r_i \leq -1 \quad \forall i \\ \max_j [r_j : -1 < r_j \leq 0] & \text{otherwise} \end{cases}$$

Whenever this correction is made, a warning message is printed.

Da Silva Method (Variance-Component Moving Average Model)

The Da Silva method assumes that the observed value of the dependent variable at the t th time point on the i th cross-sectional unit can be expressed as

$$y_{it} = \mathbf{x}_{it}'\beta + a_i + b_t + e_{it} \quad i = 1, \dots, N; t = 1, \dots, T$$

where

$\mathbf{x}_{it}' = (x_{it1}, \dots, x_{itp})$ is a vector of explanatory variables for the t th time point and i th cross-sectional unit

$\beta = (\beta_1, \dots, \beta_p)'$ is the vector of parameters

a_i is a time-invariant, cross-sectional unit effect

b_t is a cross-sectionally invariant time effect

e_{it} is a residual effect unaccounted for by the explanatory variables and the specific time and cross-sectional unit effects

Since the observations are arranged first by cross sections, then by time periods within cross sections, these equations can be written in matrix notation as

$$\mathbf{y} = \mathbf{X}\beta + \mathbf{u}$$

where

$$\begin{aligned}\mathbf{u} &= (\mathbf{a} \otimes \mathbf{1}_T) + (\mathbf{1}_N \otimes \mathbf{b}) + \mathbf{e} \\ \mathbf{y} &= (y_{11}, \dots, y_{1T}, y_{21}, \dots, y_{NT})' \\ \mathbf{X} &= (\mathbf{x}_{11}, \dots, \mathbf{x}_{1T}, \mathbf{x}_{21}, \dots, \mathbf{x}_{NT})' \\ \mathbf{a} &= (a_1 \dots a_N)' \\ \mathbf{b} &= (b_1 \dots b_T)' \\ \mathbf{e} &= (e_{11}, \dots, e_{1T}, e_{21}, \dots, e_{NT})'\end{aligned}$$

Here $\mathbf{1}_N$ is an $N \times 1$ vector with all elements equal to 1, and \otimes denotes the Kronecker product.

The following conditions are assumed:

1. \mathbf{x}_{it} is a sequence of nonstochastic, known $p \times 1$ vectors in \Re^p whose elements are uniformly bounded in \Re^p . The matrix \mathbf{X} has a full column rank p .
2. $\boldsymbol{\beta}$ is a $p \times 1$ constant vector of unknown parameters.
3. \mathbf{a} is a vector of uncorrelated random variables such that $E(a_i) = 0$ and $\text{var}(a_i) = \sigma_a^2$, $\sigma_a^2 > 0, i = 1, \dots, N$.
4. \mathbf{b} is a vector of uncorrelated random variables such that $E(b_t) = 0$ and $\text{var}(b_t) = \sigma_b^2$ where $\sigma_b^2 > 0$ and $t = 1, \dots, T$.
5. $\mathbf{e}_i = (e_{i1}, \dots, e_{iT})'$ is a sample of a realization of a finite moving-average time series of order $m < T - 1$ for each i ; hence,

$$e_{it} = \alpha_0 \epsilon_t + \alpha_1 \epsilon_{t-1} + \dots + \alpha_m \epsilon_{t-m} \quad t = 1, \dots, T; i = 1, \dots, N$$

where $\alpha_0, \alpha_1, \dots, \alpha_m$ are unknown constants such that $\alpha_0 \neq 0$ and $\alpha_m \neq 0$, and $\{\epsilon_j\}_{j=-\infty}^{j=\infty}$ is a white noise process—that is, a sequence of uncorrelated random variables with $E(\epsilon_t) = 0$, $E(\epsilon_t^2) = \sigma_\epsilon^2$, and $\sigma_\epsilon^2 > 0$.

6. The sets of random variables $\{a_i\}_{i=1}^N$, $\{b_t\}_{t=1}^T$, and $\{e_{it}\}_{t=1}^T$ for $i = 1, \dots, N$ are mutually uncorrelated.
7. The random terms have normal distributions $a_i \sim N(0, \sigma_a^2)$, $b_t \sim N(0, \sigma_b^2)$, and $\epsilon_{t-k} \sim N(0, \sigma_\epsilon^2)$, for $i = 1, \dots, N$; $t = 1, \dots, T$; and $k = 1, \dots, m$.

If assumptions 1–6 are satisfied, then

$$E(\mathbf{y}) = \mathbf{X}\boldsymbol{\beta}$$

and

$$\text{var}(\mathbf{y}) = \sigma_a^2(I_N \otimes J_T) + \sigma_b^2(J_N \otimes I_T) + (I_N \otimes \Psi_T)$$

where Ψ_T is a $T \times T$ matrix with elements ψ_{ts} as follows:

$$\text{Cov}(e_{it}e_{is}) = \begin{cases} \psi(|t-s|) & \text{if } |t-s| \leq m \\ 0 & \text{if } |t-s| > m \end{cases}$$

where $\psi(k) = \sigma_\epsilon^2 \sum_{j=0}^{m-k} \alpha_j \alpha_{j+k}$ for $k = |t-s|$. For the definition of I_N , I_T , J_N , and J_T , see the section “[Fuller and Battese’s Method](#)” on page 1368.

The covariance matrix, denoted by \mathbf{V} , can be written in the form

$$\mathbf{V} = \sigma_a^2(I_N \otimes J_T) + \sigma_b^2(J_N \otimes I_T) + \sum_{k=0}^m \psi(k)(I_N \otimes \Psi_T^{(k)})$$

where $\Psi_T^{(0)} = I_T$, and, for $k=1, \dots, m$, $\Psi_T^{(k)}$ is a band matrix whose k th off-diagonal elements are 1’s and all other elements are 0’s.

Thus, the covariance matrix of the vector of observations \mathbf{y} has the form

$$\text{Var}(\mathbf{y}) = \sum_{k=1}^{m+3} v_k V_k$$

where

$$\begin{aligned} v_1 &= \sigma_a^2 \\ v_2 &= \sigma_b^2 \\ v_k &= \psi(k-3) \quad k = 3, \dots, m+3 \\ V_1 &= I_N \otimes J_T \\ V_2 &= J_N \otimes I_T \\ V_k &= I_N \otimes \Psi_T^{(k-3)} \quad k = 3, \dots, m+3 \end{aligned}$$

The estimator of β is a two-step GLS-type estimator—that is, GLS with the unknown covariance matrix replaced by a suitable estimator of \mathbf{V} . It is obtained by substituting Seely estimates for the scalar multiples v_k , $k = 1, 2, \dots, m+3$.

Seely (1969) presents a general theory of unbiased estimation when the choice of estimators is restricted to finite dimensional vector spaces, with a special emphasis on quadratic estimation of functions of the form $\sum_{i=1}^n \delta_i v_i$.

The parameters v_i ($i = 1, \dots, n$) are associated with a linear model $E(\mathbf{y}) = \mathbf{X}\beta$ with covariance matrix $\sum_{i=1}^n v_i V_i$ where V_i ($i = 1, \dots, n$) are real symmetric matrices. The method is also discussed by Seely (1970a, 1970b) and Seely and Zyskind (1971). Seely and Soong (1971) consider the MINQUE principle, using an approach along the lines of Seely (1969).

Dynamic Panel Estimator

For an example on dynamic panel estimation using GMM option, see “[Example 20.6: The Cigarette Sales Data: Dynamic Panel Estimation with GMM](#)” on page 1418.

Consider the case of the following general model:

$$y_{it} = \sum_{l=1}^{maxlag} \phi_l y_{i(t-l)} + \sum_{k=1}^K \beta_k x_{itk} + \gamma_i + \alpha_t + \epsilon_{it}$$

The x variables can include ones that are correlated or uncorrelated to the individual effects, predetermined, or strictly exogenous. The γ and α are cross-sectional and time series fixed effects, respectively. Arellano and Bond (1991) show that it is possible to define conditions that should result in a consistent estimator.

Consider the simple case of an autoregression in a panel setting (with only individual effects):

$$y_{it} = \phi y_{i(t-1)} + \gamma_i + \epsilon_{it}$$

Differencing the preceding relationship results in:

$$\Delta y_{it} = \phi \Delta y_{i(t-1)} + v_{it}$$

where $v_{it} = \epsilon_{it} - \epsilon_{it-1}$.

Obviously, y is not exogenous. However, Arellano and Bond (1991) show that it is still useful as an instrument, if properly lagged.

For $t = 2$ (assuming the first observation corresponds to time period 1) you have,

$$\Delta y_{i2} = \phi \Delta y_{i1} + v_{i2}$$

Using y_{i1} as an instrument is not a good idea since $\text{Cov}(\epsilon_{i1}, v_{i2}) \neq 0$. Therefore, since it is not possible to form a moment restriction, you discard this observation.

For $t = 3$ you have,

$$\Delta y_{i3} = \phi \Delta y_{i2} + v_{i3}$$

Clearly, you have every reason to suspect that $\text{Cov}(\epsilon_{i1}, v_{i3}) = 0$. This condition forms one restriction.

For $t = 4$, both $\text{Cov}(\epsilon_{i1}, v_{i4}) = 0$ and $\text{Cov}(\epsilon_{i2}, v_{i4}) = 0$ must hold.

Proceeding in that fashion, you have the following matrix of instruments,

$$\mathbf{Z}_i = \begin{pmatrix} y_{i1} & 0 & 0 & \cdots & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & y_{i1} & y_{i2} & 0 & \cdots & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & y_{i1} & y_{i2} & y_{i3} & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & & & & \vdots & & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & y_{i1} & \cdots & y_{i(T-2)} \end{pmatrix}$$

Using the instrument matrix, you form the weighting matrix \mathbf{A}_N as

$$\mathbf{A}_N = \left(\frac{1}{N} \sum_i^N \mathbf{Z}_i' \mathbf{H}_i \mathbf{Z}_i \right)^{-1}$$

The initial weighting matrix is

$$\mathbf{H}_i = \begin{pmatrix} 2 & -1 & 0 & \cdots & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & \cdots & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 & \cdots & 0 & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & & & & \vdots & & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 2 & -1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 2 \end{pmatrix}$$

Note that the maximum size of the \mathbf{H}_i matrix is $T-2$. The origins of the initial weighting matrix are the expected error covariances. Notice that on the diagonals,

$$E(v_{it}v_{it}) = E(\epsilon_{it}^2 - 2\epsilon_{it}\epsilon_{i(t-1)} + \epsilon_{i(t-1)}^2) = 2\sigma_\epsilon^2$$

and off diagonals,

$$E(v_{it}v_{i(t-1)}) = E(\epsilon_{it}\epsilon_{i(t-1)} - \epsilon_{it}\epsilon_{i(t-2)} - \epsilon_{i(t-1)}\epsilon_{i(t-1)} + \epsilon_{i(t-1)}\epsilon_{i(t-2)}) = -\sigma_\epsilon^2$$

If you let the vector of lagged differences (in the series y_{it}) be denoted as Δy_{i-} and the dependent variable as Δy_i , then the optimal GMM estimator is

$$\phi = \left[\left(\sum_i \Delta y_{i-}' \mathbf{Z}_i \right) A_N \left(\sum_i \mathbf{Z}_i' \Delta y_{i-} \right) \right]^{-1} \left(\sum_i \Delta y_{i-}' \mathbf{Z}_i \right) A_N \left(\sum_i \mathbf{Z}_i' \Delta y_i \right)$$

Using the estimate, $\hat{\phi}$, you can obtain estimates of the errors, $\hat{\epsilon}$, or the differences, \hat{v} . From the errors, the variance is calculated as,

$$\sigma^2 = \frac{\hat{\epsilon}'\hat{\epsilon}}{M-1}$$

where $M = \sum_{i=1}^N T_i$ is the total number of observations.

Furthermore, you can calculate the variance of the parameter as,

$$\sigma^2 \left[\left(\sum_i \Delta y_{i-}' \mathbf{Z}_i \right) A_N \left(\sum_i \mathbf{Z}_i' \Delta y_{i-} \right) \right]^{-1}$$

Alternatively, you can view the initial estimate of the ϕ as a first step. That is, by using $\hat{\phi}$, you can improve the estimate of the weight matrix, A_N .

Instead of imposing the structure of the weighting, you form the \mathbf{H}_i matrix through the following:

$$\mathbf{H}_i = \hat{v}_i \hat{v}_i'$$

You then complete the calculation as previously shown. The PROC PANEL option TWOSTEP specifies this estimation.

The case of multiple right-hand-side variables illustrates more clearly the power of Arellano and Bond (1991) and Arellano and Bover (1995).

Considering the general case you have:

$$y_{it} = \sum_{l=1}^{maxlag} \phi_l y_{i(t-l)} + \mathbf{X}_i + \gamma_i + \alpha_t + \epsilon_{it}$$

It is clear that lags of the dependent variable are both not exogenous and correlated to the fixed effects. However, the independent variables can fall into one of several categories. An independent variable can be correlated and exogenous, uncorrelated and exogenous, correlated and predetermined, and uncorrelated and predetermined. The category in which an independent variable is found influences when or whether it becomes a suitable instrument. Note, however, that neither PROC PANEL nor Arellano and Bond require that a regressor be an instrument or that an instrument be a regressor.

First, consider the question of exogenous or endogenous. An exogenous variable is not correlated with the error term in the model at all. Therefore, all observations (on the exogenous variable) become valid instruments at all time periods. If the model has only one instrument and it happens to be exogenous, then the optimal instrument matrix looks like,

$$\mathbf{Z}_i = \begin{pmatrix} x_{i1} \cdots x_{iT} & 0 & 0 & 0 & 0 \\ 0 & x_{i1} \cdots x_{iT} & 0 & 0 & 0 \\ 0 & 0 & x_{i1} \cdots x_{iTS} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & x_{i1} \cdots x_{iTS} \end{pmatrix}$$

The situation for the predetermined variables becomes a little more difficult. A predetermined variable is one whose future realizations can be correlated to current shocks in the dependent variable. With such an understanding, it is admissible to allow all current and lagged realizations as instruments. In other words you have,

$$\mathbf{Z}_i = \begin{pmatrix} x_{i1} & 0 & 0 & 0 & 0 \\ 0 & x_{i1}x_{i2} & 0 & 0 & 0 \\ 0 & 0 & x_{i1} \cdots x_{i3} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & x_{i1} \cdots x_{i(TS-2)} \end{pmatrix}$$

When the data contain a mix of endogenous, exogenous, and predetermined variables, the instrument matrix is formed by combining the three. The third observation would have one observation on the dependent variable as an instrument, three observations on the predetermined variables as instruments, and all observations on the exogenous variables.

There is yet another set of moment restrictions that can be employed. An uncorrelated variable means that the variable's level is not affected by the individual specific effect. You write the general model presented above as:

$$y_{it} = \sum_{l=1}^{maxlag} \phi_l y_{i(t-l)} + \sum_{k=1}^K \beta_k x_{itk} + \alpha_t + \mu_{it}$$

where $\mu_{it} = \gamma_i + \epsilon_{it}$.

Since the variables are uncorrelated with γ and uncorrelated with the error, you can perform a system estimation with the difference and level equations. That is, the uncorrelated variables imply moment restrictions on the level equation. If you denote the new instrument matrix with the full complement of instruments available by a $*$ and both x^p and x^e are uncorrelated, then you have:

$$\mathbf{Z}_i^* = \begin{pmatrix} \mathbf{Z}_i & 0 & 0 & 0 & 0 \\ 0 & x_{i1}^p & x_{i1}^e & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & x_{iTS}^p & x_{iTS}^e \end{pmatrix}$$

The formation of the initial weighting matrix becomes somewhat problematic. If you denote the new weighting matrix with a $*$, then you can write the following:

$$\mathbf{A}_N^* = \left(\frac{1}{N} \sum_i \mathbf{Z}_i^{*'} \mathbf{H}_i^* \mathbf{Z}_i^* \right)^{-1}$$

where

$$\mathbf{H}_i^* = \begin{pmatrix} \mathbf{H}_i & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{pmatrix}$$

To finish, you write out the two equations (or two stages) that are estimated.

$$\Delta y_{it} = \boldsymbol{\beta}^* \Delta \mathbf{S}_i + \alpha_t - \alpha_{t-1} + v_{it} \qquad y_{it} = \boldsymbol{\beta}^* \mathbf{S}_i + \gamma_i + \alpha_t + \epsilon_{it}$$

where \mathbf{S}_i is the matrix of all explanatory variables, lagged endogenous, exogenous, and predetermined.

Let \mathbf{y}_{it}^* be given by

$$\mathbf{y}_{it}^* = \begin{pmatrix} \Delta y_{it} \\ y_{it} \end{pmatrix} \quad \boldsymbol{\beta}^* = \begin{pmatrix} \boldsymbol{\phi} & \boldsymbol{\beta} \end{pmatrix} \quad \mathbf{S}_i^* = \begin{pmatrix} \Delta \mathbf{S}_i \\ \mathbf{S}_i \end{pmatrix}$$

Using the information above,

$$\boldsymbol{\beta}^* = \left[\left(\sum_i \mathbf{S}_i^{*'} \mathbf{Z}_i^* \right) \mathbf{A}_N^* \left(\sum_i \mathbf{Z}_i^{*'} \mathbf{S}_i \right) \right]^{-1} \left(\sum_i \mathbf{S}_i^{*'} \mathbf{Z}_i^* \right) \mathbf{A}_N^* \left(\sum_i \mathbf{Z}_i^{*'} \mathbf{y}_i^* \right)$$

If the TWOSTEP or ITGMM option is not requested, estimation terminates here. If it terminates, you can obtain the following information.

Variance of the error term comes from the second stage equation—that is,

$$\sigma^2 = \frac{\hat{\epsilon}' \hat{\epsilon}}{M - p}$$

where p is the number of regressors.

The variance covariance matrix can be obtained from

$$\left[\left(\sum_i \mathbf{S}_i^{*'} \mathbf{Z}_i^* \right) A_N^* \left(\sum_i \mathbf{Z}_i^{*'} \mathbf{S}_i^* \right) \right]^{-1} \sigma^2$$

Alternatively, a robust estimate of the variance covariance matrix can be obtained by specifying the ROBUST option. Without further reestimation of the model, the \mathbf{H}_i^* matrix is recalculated as follows:

$$\mathbf{H}_{i,2}^* = \begin{pmatrix} \mathbf{v}\mathbf{v}' & 0 \\ 0 & \boldsymbol{\epsilon}\boldsymbol{\epsilon}' \end{pmatrix}$$

And the weighting matrix becomes

$$A_{N,2}^* = \left(\frac{1}{N} \sum_i \mathbf{Z}_i^{*'} \mathbf{H}_{i,2}^* \mathbf{Z}_i^* \right)^{-1}$$

Using the information above, you construct the robust variance covariance matrix from the following:

Let \mathbf{G} denote a temporary matrix.

$$\mathbf{G} = \left[\left(\sum_i \mathbf{S}_i^{*'} \mathbf{Z}_i^* \right) A_N^* \left(\sum_i \mathbf{Z}_i^{*'} \mathbf{S}_{*i} \right) \right]^{-1} \left(\sum_i \mathbf{S}_i^{*'} \mathbf{Z}_i^* \right) A_N^*$$

The robust variance covariance estimate of $\boldsymbol{\beta}^*$ is:

$$\mathbf{V}^{robust}(\boldsymbol{\beta}^*) = \mathbf{G} A_{N,2}^{*-1} \mathbf{G}'$$

Alternatively, the new weighting matrix can be used to form an updated estimate of the regression parameters. This results when the TWOSTEP option is requested. In short,

$$\boldsymbol{\beta}^* = \left[\left(\sum_i \mathbf{S}_i^{*'} \mathbf{Z}_i^* \right) A_{N,2}^* \left(\sum_i \mathbf{Z}_i^{*'} \mathbf{S}_i^* \right) \right]^{-1} \left(\sum_i \mathbf{S}_i^{*'} \mathbf{Z}_i^* \right) A_{N,2}^* \left(\sum_i \mathbf{Z}_i^{*'} \mathbf{S}_i^* \right)$$

The variance covariance estimate of the two step $\boldsymbol{\beta}^*$ becomes

$$\mathbf{V}(\boldsymbol{\beta}^*) = \left[\left(\sum_i \mathbf{S}_i^{*'} \mathbf{Z}_i^* \right) A_{N,2}^* \left(\sum_i \mathbf{Z}_i^{*'} \mathbf{S}_i^* \right) \right]^{-1}$$

As a final note, it is possible to iterate more than twice by specifying the ITGMM option. Such a multiple iteration should result in a more stable estimate of the variance covariance estimate. PROC PANEL allows two convergence criteria. Convergence can occur in the parameter estimates or in the weighting matrices. Iterate until

$$\max_{i,j \leq \dim(A_{N,k})} \frac{|A_{N,k+1}^*(i,j) - A_{N,k}^*(i,j)|}{|A_{N,k}^*(i,j)|} \leq \text{ATOL}$$

or

$$\max_{i \leq \dim(\beta_k^*)} \frac{|\beta_{k+1}^*(i) - \beta_k^*(i)|}{|\beta_k^*(i)|} \leq \text{BTOL}$$

where ATOL is the tolerance for convergence in the weighting matrix and BTOL is the tolerance for convergence in the parameter estimate matrix. The default convergence criteria is $\text{BTOL} = 1\text{E-}8$ for PROC PANEL.

Specification Testing For Dynamic Panel

Specification tests under the GMM in PROC PANEL follow Arellano and Bond (1991) very generally. The first test available is a Sargan/Hansen test of over-identification. The test for a one-step estimation is constructed as

$$\left(\sum_i \eta_i' \mathbf{Z}_i^* \right) A_N^* \left(\sum_i \mathbf{Z}_i^{*'} \eta_i \right) \sigma^2$$

where η_i is the stacked error term (of the differenced equation and level equation).

When the robust weighting matrix is used, the test statistic is computed as

$$\left(\sum_i \eta_i' \mathbf{Z}_i^* \right) A_{N,2}^* \left(\sum_i \mathbf{Z}_i^{*'} \eta_i \right)$$

This definition of the Sargan test is used for all iterated estimations. The Sargan test is distributed as a χ^2 with degrees of freedom equal to the number of moment conditions minus the number of parameters.

In addition to the Sargan test, PROC PANEL tests for autocorrelation in the residuals. These tests are distributed as standard normal. PROC PANEL tests the hypothesis that the autocorrelation of the l th lag is significant.

Define ω_l as the lag of the differenced error, with zero padding for the missing values generated. Symbolically,

$$\omega_l = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ v_1 \\ \vdots \\ v_{TS-2-l} \end{pmatrix}$$

You define the constant k_0 as

$$k_0(l) = \sum_i \omega_{l,i}' v_i$$

You next define the constant k_1 as

$$k_1(l) = \sum_i \omega_{l,i}' \mathbf{H}_i \omega_{l,i}$$

Note that the choice of \mathbf{H}_i is dependent on the stage of estimation. If the estimation is first stage, then you would use the matrix with twos along the main diagonal, and minus ones along the primary subdiagonals. In a robust estimation or multi-step estimation, this matrix would be formed from the outer product of the residuals (from the previous step).

Define the constant k_2 as

$$k_2(l) = -2 \left(\sum_i \omega'_{l,i} \Delta \mathbf{S}_i \right) \mathbf{G} \left(\sum_i \Delta \mathbf{S}'_i \mathbf{Z}_i \right) A_{N,k} \left(\sum_i \mathbf{Z}'_i \mathbf{H}_i \omega_{l,i} \right)$$

The matrix \mathbf{G} is defined as

$$\mathbf{G} = \left[\left(\sum_i \Delta \mathbf{S}^{*'}_i \mathbf{Z}^*_i \right) A^*_{N,k} \left(\sum_i \mathbf{Z}^{*'}_i \Delta \mathbf{S}^*_i \right) \right]^{-1}$$

The constant k_3 is defined as

$$k_3(l) = \left(\sum_i \omega'_{l,i} \Delta \mathbf{S}_i \right) V(\beta^*) \left(\sum_i \Delta \mathbf{S}'_i \omega_{l,i} \right)$$

Using the four quantities, the test for autoregressive structure in the differenced residual is

$$m(l) = \frac{k_0(l)}{\sqrt{k_1(l) + k_2(l) + k_3(l)}}$$

The m statistic is distributed as a normal random variable with mean zero and standard deviation of one.

Instrument Choice

Arellano and Bond's technique is a very useful method for dealing with any autoregressive characteristics in the data. However, there is one caveat to consider. Too many instruments bias the estimator to the within estimate. Furthermore, many instruments make this technique not scalable. The weighting matrix becomes very large, so every operation that involves it becomes more computationally intensive. The PANEL procedure enables you to specify a bandwidth for instrument selection. For example, specifying MAXBAND=10 means that at most there will be ten time observations for each variable that enters as an instrument. The default is to follow the Arellano-Bond methodology.

In specifying a maximum bandwidth, you can also specify the selection of the time observations. There are three possibilities: leading, trailing (default), and centered. The exact consequence of choosing any of those possibilities depends on the variable type (correlated, exogenous, or predetermined) and the time period of the current observation.

If the MAXBAND option is specified, then the following is true under any selection criterion (let t be the time subscript for the current observation). The first observation for the endogenous variable (as instrument) is $\max(t - \text{MAXBAND}, 1)$ and the last instrument is $t - 2$. The first observation for a predetermined variable is $\max(t - \text{MAXBAND}, 1)$ and the last is $t - 1$. The first and last observation for an exogenous variable is given in the following list:

- *Trailing*: If $t < \text{MAXBAND}$, then the first instrument is for the first time period and the last observation is MAXBAND. Otherwise, if $t \geq \text{MAXBAND}$, then the first observation is $t - \text{MAXBAND} + 1$

and the last instrument to enter is t .

- *Centered*: If $t \leq \frac{\text{MAXBAND}}{2}$, then the first observation is the first time period and the last observation is MAXBAND. If $t > T - \frac{\text{MAXBAND}}{2}$, then the first instrument included is $T - \text{MAXBAND} + 1$ and the last observation is T . If $\frac{\text{MAXBAND}}{2} < t \leq T - \frac{\text{MAXBAND}}{2}$, then the first included instrument is $t - \frac{\text{MAXBAND}}{2} + 1$ and the last observation is $t + \frac{\text{MAXBAND}}{2}$. If the MAXBAND value is an odd number, the procedure decrements by one.
- *Leading* : If $t > T - \text{MAXBAND}$, then the first instrument corresponds to time period $T - \text{MAXBAND} + 1$ and the last observation is T . Otherwise, if $t \leq T - \text{MAXBAND}$, then the first observation is t and the last observation is $t + \text{MAXBAND} + 1$.

The PANEL procedure enables you to include dummy variables to deal with the presence of time effects that are not captured by including the lagged dependent variable. The dummy variables directly affect the level equations. However, this implies that the difference of the dummy variable for time period t and $t - 1$ enters the difference equation. The first usable observation occurs at $t = 3$. If the level equation is not used in the estimation, then there is no way to identify the dummy variables. Selecting the TIME option gives the same result as that which would be obtained by creating dummy variables in the data set and using those in the regression.

The PANEL procedure gives you several options when it comes to missing values and unbalanced panel. By default, any time period for which there are missing values is skipped. The corresponding rows and columns of **H** matrices are zeroed, and the calculation is continued. Alternatively, you can elect to replace missing values and missing observations with zeros (ZERO), the overall mean of the series (OAM), the cross-sectional mean (CSM), or the time series mean (TSM).

Linear Hypothesis Testing

For a linear hypothesis of the form $\mathbf{R}\beta = \mathbf{r}$ where \mathbf{R} is $J \times K$ and \mathbf{r} is $J \times 1$, the F -statistic with $J, M - K$ degrees of freedom is computed as

$$(\mathbf{R}\hat{\beta} - \mathbf{r})' [\mathbf{R}\hat{\mathbf{V}}\mathbf{R}']^{-1} (\mathbf{R}\hat{\beta} - \mathbf{r})$$

However, it is also possible to write the F statistic as

$$F = \frac{(\hat{\mathbf{u}}_*' \hat{\mathbf{u}}_* - \hat{\mathbf{u}}' \hat{\mathbf{u}}) / J}{\hat{\mathbf{u}}' \hat{\mathbf{u}} / (M - K)}$$

where

- $\hat{\mathbf{u}}_*$ is the residual vector from the restricted regression
- $\hat{\mathbf{u}}$ is the residual vector from the unrestricted regression
- J is the number of restrictions

- $(M - K)$ are the degrees of freedom, M is the number of observations, and K is the number of parameters in the model

The Wald, likelihood ratio (LR) and Lagrange multiplier (LM) tests are all related to the F test. You use this relationship of the F test to the likelihood ratio and Lagrange multiplier tests. The Wald test is calculated from its definition.

The Wald test statistic is:

$$W = (\mathbf{R}\beta - \mathbf{r})' [\mathbf{R}\hat{\mathbf{V}}\mathbf{R}]^{-1} (\mathbf{R}\beta - \mathbf{r})$$

The advantage of calculating Wald in this manner is that it enables you to substitute a heteroscedasticity-corrected covariance matrix for the matrix \mathbf{V} . PROC PANEL makes such a substitution if you request the HCCME option in the MODEL statement.

The likelihood ratio is:

$$LR = M \ln \left[1 + \frac{1}{M - K} JF \right]$$

The Lagrange multiplier test statistic is:

$$LM = M \left[\frac{JF}{M - K + JF} \right]$$

where JF represents the number of restrictions multiplied by the result of the F test.

Note that only the Wald is changed when the HCCME option is selected. The LR and LM tests are unchanged.

The distribution of these test statistics is the χ^2 with degrees of freedom equal to the number of restrictions imposed (J). The three tests are asymptotically equivalent, but they have differing small sample properties. Greene (2000, p. 392) and Davidson and MacKinnon (1993, pg. 456-458) discuss the small sample properties of these statistics.

Heteroscedasticity-Corrected Covariance Matrices

The HCCME= option in the MODEL statement selects the type of heteroscedasticity-consistent covariance matrix. In the presence of heteroscedasticity, the covariance matrix has a complicated structure which can result in inefficiencies in the OLS estimates and biased estimates of the variance covariance matrix. Consider the simple linear model:

$$\mathbf{y} = \mathbf{X}\beta + \epsilon$$

This discussion parallels the discussion in Davidson and MacKinnon, 1993, pg. 548–562. The assumptions that make the linear regression best linear unbiased estimator (BLUE) are $E(\epsilon) = 0$ and $E(\epsilon\epsilon') = \Omega$, where Ω has the simple structure $\sigma^2\mathbf{I}$. Heteroscedasticity results in a general covariance structure, so that it is not possible to simplify Ω . The result is the following:

$$\tilde{\beta} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'(\mathbf{X}\beta + \epsilon) = \beta + (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\epsilon$$

As long as the following is true, then you are assured that the OLS estimate is consistent and unbiased:

$$\text{plim}_{n \rightarrow \infty} \left(\frac{1}{n} \mathbf{X}' \boldsymbol{\epsilon} \right) = 0$$

If the regressors are nonrandom, then it is possible to write the variance of the estimated $\boldsymbol{\beta}$ as the following:

$$\text{Var}(\boldsymbol{\beta} - \tilde{\boldsymbol{\beta}}) = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}' \Omega \mathbf{X} (\mathbf{X}'\mathbf{X})^{-1}$$

The effect of structure in the variance-covariance matrix can be ameliorated by using generalized least squares (GLS), provided that Ω^{-1} can be calculated. Using Ω^{-1} , you premultiply both sides of the regression equation,

$$L^{-1}\mathbf{y} = L^{-1}\mathbf{X}_c + L^{-1}\boldsymbol{\epsilon}$$

where L denotes the Cholesky root of Ω . (that is, $\Omega = LL'$ with L lower triangular).

The resulting GLS $\boldsymbol{\beta}$ is

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \mathbf{X}'\Omega^{-1}\mathbf{y}$$

Using the GLS $\boldsymbol{\beta}$, you can write

$$\begin{aligned} \hat{\boldsymbol{\beta}} &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \mathbf{X}'\Omega^{-1}\mathbf{y} \\ &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \mathbf{X}'(\Omega^{-1}\mathbf{X}_c + \Omega^{-1}\boldsymbol{\epsilon}) \\ &= \boldsymbol{\beta} + (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \mathbf{X}'\Omega^{-1}\boldsymbol{\epsilon} \end{aligned}$$

The resulting variance expression for the GLS estimator is

$$\begin{aligned} \text{Var}(\boldsymbol{\beta} - \hat{\boldsymbol{\beta}}) &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \mathbf{X}'\Omega^{-1}\boldsymbol{\epsilon}\boldsymbol{\epsilon}'\Omega^{-1}\mathbf{X}(\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \\ &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \mathbf{X}'\Omega^{-1}\Omega\Omega^{-1}\mathbf{X}(\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \\ &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \end{aligned}$$

The difference in variance between the OLS estimator and the GLS estimator can be written as

$$(\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}' \Omega \mathbf{X} (\mathbf{X}'\mathbf{X})^{-1} - (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}$$

By the Gauss-Markov theorem, the difference matrix must be positive definite under most circumstances (zero if OLS and GLS are the same, when the usual classical regression assumptions are met). Thus, OLS is not efficient under a general error structure. It is crucial to realize that OLS does not produce biased results. It would suffice if you had a method for estimating a consistent covariance matrix and you used the OLS $\boldsymbol{\beta}$. Estimation of the Ω matrix is certainly not simple. The matrix is square and has M^2 elements; unless some sort of structure is assumed, it becomes an impossible problem to solve. However, the heteroscedasticity can have quite a general structure. White (1980) shows that it is not necessary to have a consistent estimate of Ω . On the contrary, it suffices to calculate an estimate of the middle expression. That is, you need an estimate of:

$$\Lambda = \mathbf{X}'\Omega\mathbf{X}$$

This matrix, Λ , is easier to estimate because its dimension is K . PROC PANEL provides the following classical HCCME estimators for Λ :

The matrix is approximated by:

- HCCME=N0:

$$\sigma^2 \mathbf{X}'\mathbf{X}$$

This is the simple OLS estimator. If you do not specify the HCCME= option, PROC PANEL defaults to this estimator.

- HCCME=0:

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}'$$

where N is the number of cross sections and T_i is the number of observations in i th cross section. The \mathbf{x}_{it}' is from the t th observation in the i th cross section, constituting the $(\sum_{j=1}^{i-1} T_j + t)$ th row of the matrix \mathbf{X} . If the CLUSTER option is specified, one extra term is added to the preceding equation so that the estimator of matrix Λ is

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}' + 2 \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \hat{\epsilon}_{it} \hat{\epsilon}_{is} \mathbf{x}_{it} \mathbf{x}_{is}'$$

- HCCME=1:

$$\frac{M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}'$$

where M is the total number of observations, $\sum_{j=1}^N T_j$, and K is the number of parameters. With the CLUSTER option, the estimator becomes

$$\frac{M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}' + \frac{2M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \hat{\epsilon}_{it} \hat{\epsilon}_{is} \mathbf{x}_{it} \mathbf{x}_{is}'$$

- HCCME=2:

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{1 - \hat{h}_{it}} \mathbf{x}_{it} \mathbf{x}_{it}'$$

The \hat{h}_{it} term is the $(\sum_{j=1}^{i-1} T_j + t)$ th diagonal element of the hat matrix. The expression for \hat{h}_{it} is $\mathbf{x}_{it}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_{it}$. The hat matrix attempts to adjust the estimates for the presence of influence or leverage points. With the CLUSTER option, the estimator becomes

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{1 - \hat{h}_{it}} \mathbf{x}_{it} \mathbf{x}_{it}' + 2 \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \frac{\hat{\epsilon}_{it}}{\sqrt{1 - \hat{h}_{it}}} \frac{\hat{\epsilon}_{is}}{\sqrt{1 - \hat{h}_{is}}} \mathbf{x}_{it} \mathbf{x}_{is}'$$

- HCCME=3:

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{(1 - \hat{h}_{it})^2} \mathbf{x}_{it} \mathbf{x}_{it}'$$

With the CLUSTER option, the estimator becomes

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{(1 - \hat{h}_{it})^2} \mathbf{x}_{it} \mathbf{x}_{it}' + 2 \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \frac{\hat{\epsilon}_{it}}{1 - \hat{h}_{it}} \frac{\hat{\epsilon}_{is}}{1 - \hat{h}_{is}} \mathbf{x}_{it} \mathbf{x}_{is}'$$

- HCCME=4: PROC PANEL includes this option for the calculation of the Arellano (1987) version of the White (1980) HCCME in the panel setting. Arellano's insight is that there are N covariance matrices in a panel, and each matrix corresponds to a cross section. Forming the White HCCME for each panel, you need to take only the average of those N estimators that yield Arellano. The details of the estimation follow. First, you arrange the data such that the first cross section occupies the first T_i observations. You treat the panels as separate regressions with the form:

$$\mathbf{y}_i = \alpha_i \mathbf{i} + \mathbf{X}_{is} \tilde{\boldsymbol{\beta}} + \boldsymbol{\epsilon}_i$$

The parameter estimates $\tilde{\boldsymbol{\beta}}$ and α_i are the result of least squares dummy variables (LSDV) or within estimator regressions, and \mathbf{i} is a vector of ones of length T_i . The estimate of the i th cross section's $\mathbf{X}'\Omega\mathbf{X}$ matrix (where the s subscript indicates that no constant column has been suppressed to avoid confusion) is $\mathbf{X}'_i\Omega\mathbf{X}_i$. The estimate for the whole sample is:

$$\mathbf{X}'_s\Omega\mathbf{X}_s = \sum_{i=1}^N \mathbf{X}'_i\Omega\mathbf{X}_i$$

The Arellano standard error is in fact a White-Newey-West estimator with constant and equal weight on each component. In the between estimators, selecting HCCME=4 returns the HCCME=0 result since there is no 'other' variable to group by.

In their discussion, Davidson and MacKinnon (1993, pg. 554) argue that HCCME=1 should always be preferred to HCCME=0. Although HCCME=3 is generally preferred to 2 and 2 is preferred to 1, the calculation of HCCME=1 is as simple as the calculation of HCCME=0. Therefore, it is clear that HCCME=1 is preferred when the calculation of the hat matrix is too tedious.

All HCCME estimators have well-defined asymptotic properties. The small sample properties are not well-known, and care must be exercised when sample sizes are small.

The HCCME estimator of $\text{Var}(\boldsymbol{\beta})$ is used to drive the covariance matrices for the fixed effects and the Lagrange multiplier standard errors. Robust estimates of the variance-covariance matrix for $\boldsymbol{\beta}$ imply robust variance-covariance matrices for all other parameters.

R Square

The conventional R-square measure is inappropriate for all models that the PANEL procedure estimates by using GLS because a number outside the $[0,1]$ range might be produced. Hence, a generalization of the R square measure is reported. The following goodness-of-fit measure (Buse 1973) is reported:

$$R^2 = 1 - \frac{\hat{\mathbf{u}}' \hat{\mathbf{V}}^{-1} \hat{\mathbf{u}}}{\mathbf{y}' \mathbf{D}' \hat{\mathbf{V}}^{-1} \mathbf{D} \mathbf{y}}$$

where $\hat{\mathbf{u}}$ are the residuals of the transformed model, $\hat{\mathbf{u}} = \mathbf{y} - \mathbf{X}(\mathbf{X}' \hat{\mathbf{V}}^{-1} \mathbf{X})^{-1} \mathbf{X}' \hat{\mathbf{V}}^{-1} \mathbf{y}$,

and $\mathbf{D} = \mathbf{I}_M - \mathbf{j}_M \mathbf{j}_M' \left(\frac{\hat{\mathbf{V}}^{-1}}{\mathbf{j}_M' \hat{\mathbf{V}}^{-1} \mathbf{j}_M} \right)$.

This is a measure of the proportion of the transformed sum of squares of the dependent variable that is attributable to the influence of the independent variables.

If there is no intercept in the model, the corresponding measure (Theil 1961) is

$$R^2 = 1 - \frac{\hat{\mathbf{u}}' \hat{\mathbf{V}}^{-1} \hat{\mathbf{u}}}{\mathbf{y}' \hat{\mathbf{V}}^{-1} \mathbf{y}}$$

However, the fixed-effects models are somewhat different. In the case of a fixed-effects model, the choice of including or excluding an intercept becomes merely a choice of classification. Suppressing the intercept in the FIXONE or FIXONETIME case merely changes the name of the intercept to a fixed effect. It makes no sense to redefine the R-square measure since nothing material changes in the model. Similarly, for the FIXTWO model there is no reason to change the R-square measure. In the case of the FIXONE, FIXONETIME, and FIXTWO models, the R square is defined as the Theil (1961) R square as shown in the preceding equation. This makes intuitive sense since you are regressing a transformed (demeaned) series on transformed regressors, excluding a constant. In other words, you are looking at 1 minus the sum of squared errors divided by the sum of squares of the (transformed) dependent variable.

In the case of OLS estimation, both of the R-square formulas given here reduce to the usual R-square formula.

Specification Tests

The PANEL procedure outputs the results of one specification test for fixed effects and two specification tests for random effects.

For fixed effects, let β_f be the n dimensional vector of fixed-effects parameters. The specification test reported is the conventional F statistic for the hypothesis $\beta_f = \mathbf{0}$. The F statistic with $n, M - K$ degrees of freedom is computed as

$$\hat{\beta}_f' \hat{\mathbf{S}}_f^{-1} \hat{\beta}_f / n$$

where $\hat{\mathbf{S}}_f$ is the estimated covariance matrix of the fixed-effects parameters.

Hausman's (1978) specification test or m statistic can be used to test hypotheses in terms of bias or inconsistency of an estimator. This test was also proposed by Wu (1973) and further extended in Hausman and Taylor (1982). Hausman's m statistic is as follows.

Consider two estimators, $\hat{\beta}_a$ and $\hat{\beta}_b$, which under the null hypothesis are both consistent, but only $\hat{\beta}_a$ is asymptotically efficient. Under the alternative hypothesis, only $\hat{\beta}_b$ is consistent. The m statistic is

$$m = (\hat{\beta}_b - \hat{\beta}_a)' (\hat{\mathbf{S}}_b - \hat{\mathbf{S}}_a)^{-1} (\hat{\beta}_b - \hat{\beta}_a)$$

where $\hat{\mathbf{S}}_b$ and $\hat{\mathbf{S}}_a$ are consistent estimates of the asymptotic covariance matrices of $\hat{\beta}_b$ and $\hat{\beta}_a$. Then m is distributed χ^2 with k degrees of freedom, where k is the dimension of $\hat{\beta}_a$ and $\hat{\beta}_b$.

In the random-effects specification, the null hypothesis of no correlation between effects and regressors implies that the OLS estimates of the slope parameters are consistent and inefficient but the GLS estimates of the slope parameters are consistent and efficient. This facilitates a Hausman specification test. The reported χ^2 statistic has degrees of freedom equal to the number of slope parameters. If the null hypothesis holds, the random-effects specification should be used.

Breusch and Pagan (1980) lay out a Lagrange multiplier test for random effects based on the simple OLS (pooled) estimator. If \hat{u}_{it} is the it th residual from the OLS regression, then the Breusch-Pagan (BP) test for one-way random effects is

$$BP = \frac{NT}{2(T-1)} \left[\frac{\sum_{i=1}^N \left[\sum_{t=1}^T \hat{u}_{it} \right]^2}{\sum_{i=1}^N \sum_{t=1}^T \hat{u}_{it}^2} - 1 \right]^2$$

The BP test generalizes to the case of a two-way random-effects model (Greene 2000, page 589). Specifically,

$$\begin{aligned} BP2 = & \frac{NT}{2(T-1)} \left[\frac{\sum_{i=1}^n \left[\sum_{t=1}^T \hat{u}_{it} \right]^2}{\sum_{i=1}^N \sum_{t=1}^T \hat{u}_{it}^2} - 1 \right]^2 \\ & + \frac{NT}{2(N-1)} \left[\frac{\sum_{t=1}^T \left[\sum_{i=1}^N \hat{u}_{it} \right]^2}{\sum_{i=1}^N \sum_{t=1}^T \hat{u}_{it}^2} - 1 \right]^2 \end{aligned}$$

is distributed as a χ^2 statistic with two degrees of freedom. Since the BP2 test generalizes (nests the BP test) the test for random effects, the absence of random effects (nonrejection of the null of no random effects) in the BP2 is a fairly clear indication that there will probably not be any one-way effects either. In both cases (BP and BP2), the residuals are obtained from a pooled regression. There is very little extra cost in selecting both the BP and BP2 test. Notice that in the case of just groupwise heteroscedasticity, the BP2 test approaches BP. In the case of time based heteroscedasticity, the BP2 test reduces to a BP test of time effects. In the case of unbalanced panels, neither the BP nor BP2 statistics are valid.

Finally, you should be aware that the BP option generates different results depending on whether the estimation is FIXONE or FIXONETIME. Specifically, under the FIXONE estimation technique, the BP tests for cross-sectional random effects. Under the FIXONETIME estimation, the BP tests for time random effects.

While the Hausman statistic is automatically generated, you request Breusch-Pagan via the BP or BP2 option (see Baltagi 1995 for details).

Troubleshooting

Some guidelines need to be followed when you use PROC PANEL for analysis. For each cross section, PROC PANEL requires at least two time series observations with nonmissing values for all model variables. There should be at least two cross sections for each time point in the data. If these two conditions are not met, then an error message is printed in the log stating that there is only one cross section or time series observation and further computations will be terminated. You have to give adequate data for an estimation method to produce results, and you should check the log for any data related errors.

If the number of cross sections is greater than the number of time series observations per cross section, PROC PANEL while using PARKS method produces an error message stating that the phi matrix is singular.

This is analogous to seemingly unrelated regression with fewer observations than equations in the model. To avoid the problem, reduce the number of cross sections.

Your data set could have multiple observations for each time ID within a particular cross section. However, PROC PANEL is applicable only in cases where you have only a single observation for each time ID within each cross section. In such a case, after you have sorted the data, an error warning specifying that the data has not been sorted in ascending sequence with respect to time series ID appears in the log.

The cause of the error is due to multiple observations for each time ID for a given cross section. PROC PANEL allows only one observation for each time ID within each cross section.

The following data set shown in [Figure 20.2](#) illustrates the preceding instance with the correct representation.

Figure 20.2 Single Observation for Each Time Series

Obs	firm	year	production	cost
1	1	1955	5.36598	1.14867
2	1	1960	6.03787	1.45185
3	1	1965	6.37673	1.52257
4	1	1970	6.93245	1.76627
5	2	1955	6.54535	1.35041
6	2	1960	6.69827	1.71109
7	2	1965	7.40245	2.09519
8	2	1970	7.82644	2.39480

In this case, you can observe that there are no multiple observations with respect to a given time series ID within a cross section. This is the correct representation of a data set where PROC PANEL is applicable.

If for state ID 1 you have two observations for the year=1955, then PROC PANEL produces the following error message:

“The data set is not sorted in ascending sequence with respect to time series ID. The current time period has year=1955 and the previous time period has year=1955 in cross section firm=1.”

A data set similar to the previous example with multiple observations for the YEAR=1955 is shown in [Figure 20.3](#); this data set results in an error message due to multiple observations while using PROC PANEL.

Figure 20.3 Multiple Observations for Each Time Series

Obs	firm	year	production	cost
1	1	1955	5.36598	1.14867
2	1	1955	6.37673	1.52257
3	1	1960	6.03787	1.45185
4	1	1970	6.93245	1.76627
5	2	1955	6.54535	1.35041
6	2	1960	6.69827	1.71109
7	2	1965	7.40245	2.09519
8	2	1970	7.82644	2.39480

In order to use PROC PANEL, you need to aggregate the data so that you have unique time ID values within

each cross section. One possible way to do this is to run a PROC MEANS on the input data set and compute the mean of all the variables by FIRM and YEAR, and then use the output data set.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#)” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the PANEL procedure. The table below lists the graph names, the plot descriptions, and the options used.

Table 20.2 ODS Graphics Produced by PROC PANEL

ODS Graph Name	Plot Description	Plots=Option
DiagnosticsPanel	All applicable plots listed below	
ResidualPlot	Plot of the residuals	RESIDUAL, RESID
FitPlot	Predicted versus actual plot	FITPLOT
QQPlot	Plot of the quantiles of the residuals	QQ
ResidSurfacePlot	Surface plot of the residuals	RESIDSURFACE
PredSurfacePlot	Surface plot of the predicted values	PREDSURFACE
ActSurfacePlot	Surface plot of the actual values	ACTSURFACE
ResidStackPlot	Stack plot of the residuals	RESIDSTACK, RESSTACK
ResidHistogram	Plot of the histogram of residuals	RESIDUALHISTOGRAM, RESIDHISTOGRAM

The OUTPUT OUT= Data Set

PROC PANEL writes the initial data of the estimated model, predicted values, and residuals to an output data set when the OUTPUT OUT= statement is specified. The OUT= data set contains the following variables:

<code>_MODEL_</code>	is a character variable that contains the label for the MODEL statement if a label is specified.
<code>_METHOD_</code>	is a character variable that identifies the estimation method.
<code>_MODLNO_</code>	is the number of the model estimated.
<code>_ACTUAL_</code>	contains the value of the dependent variable.

<code>_WEIGHT_</code>	contains the weighing variable.
<code>_CSID_</code>	is the value of the cross section ID.
<code>_TSID_</code>	is the value of the time period in the dynamic model.
regressors	are the values of regressor variables specified in the MODEL statement.
<i>name</i>	if <code>PRED= name1</code> and/or <code>RESIDUAL= name2</code> options are specified, then <i>name1</i> and <i>name2</i> are the columns of predicted values of dependent variable and residuals of the regression, respectively.

The OUTEST= Data Set

PROC PANEL writes the parameter estimates to an output data set when the OUTEST= option is specified. The OUTEST= data set contains the following variables:

<code>_MODEL_</code>	is a character variable that contains the label for the MODEL statement if a label is specified.
<code>_METHOD_</code>	is a character variable that identifies the estimation method.
<code>_TYPE_</code>	is a character variable that identifies the type of observation. Values of the <code>_TYPE_</code> variable are CORR, COVB, CSPARMS, STD, and the type of model estimated. The CORR observation contains correlations of the parameter estimates, the COVB observation contains covariances of the parameter estimates, the CSPARMS observation contains cross-sectional parameter estimates, the STD observation indicates the row of standard deviations of the corresponding coefficients, and the type of model estimated observation contains the parameter estimates.
<code>_NAME_</code>	is a character variable that contains the name of a regressor variable for COVB and CORR observations and is left blank for other observations. The <code>_NAME_</code> variable is used in conjunction with the <code>_TYPE_</code> values COVB and CORR to identify rows of the correlation or covariance matrix.
<code>_DEPVAR_</code>	is a character variable that contains the name of the response variable.
<code>_MSE_</code>	is the mean square error of the transformed model.
<code>_CSID_</code>	is the value of the cross section ID for CSPARMS observations. The <code>_CSID_</code> variable is used with the <code>_TYPE_</code> value CSPARMS to identify the cross section for the first-order autoregressive parameter estimate contained in the observation. The <code>_CSID_</code> variable is missing for observations with other <code>_TYPE_</code> values. (Currently, only the <code>_A_1</code> variable contains values for CSPARMS observations.)
<code>_VARCS_</code>	is the variance component estimate due to cross sections. The <code>_VARCS_</code> variable is included in the OUTEST= data set when either the FULLER or DASILVA option is specified.
<code>_VARTS_</code>	is the variance component estimate due to time series. The <code>_VARTS_</code> variable is included in the OUTEST= data set when either the FULLER or DASILVA option is specified.
<code>_VARERR_</code>	is the variance component estimate due to error. The <code>_VARERR_</code> variable is included in the OUTEST= data set when the FULLER option is specified.

<code>_A_1</code>	is the first-order autoregressive parameter estimate. The <code>_A_1</code> variable is included in the <code>OUTEST=</code> data set when the <code>PARKS</code> option is specified. The values of <code>_A_1</code> are cross-sectional parameters, meaning that they are estimated for each cross section separately. The <code>_A_1</code> variable has a value only for <code>_TYPE_=CSPARMS</code> observations. The cross section to which the estimate belongs is indicated by the <code>_CSID_</code> variable.
Intercept	is the intercept parameter estimate. (Intercept is missing for models when the <code>NOINT</code> option is specified.)
regressors	are the regressor variables specified in the <code>MODEL</code> statement. The regressor variables in the <code>OUTEST=</code> data set contain the corresponding parameter estimates for the model identified by <code>_MODEL_</code> for <code>_TYPE_=PARMS</code> observations, and the corresponding covariance or correlation matrix elements for <code>_TYPE_=COVB</code> and <code>_TYPE_=CORRB</code> observations. The response variable contains the value -1 for the <code>_TYPE_=PARMS</code> observation for its model.

The OUTTRANS= Data Set

PROC PANEL writes the transformed series to an output data set. That is, if the user selects `FIXONE`, `FIXONETIME`, or `RANONE` and supplies the `OUTTRANS =` option, the transformed dependent variable and independent variables are written out to a SAS data set; other variables in the input data set are copied unchanged.

Say that your data set contains variables `y`, `x1`, `x2`, `x3`, and `z2`. The following statements result in a SAS data set:

```
proc panel data=datain outtrans=dataout;
  id cs ts;
  model y = x1 x2 x3 / fixone;
run;
```

First, `z2` is copied over. Then `_Int`, `x1`, `x2`, `y`, and `x3`, are replaced with their mean deviates (from cross sections). Furthermore, two new variables are created.

<code>_MODELL_</code>	is the model's label (if it exists).
<code>_METHOD_</code>	is the model's transformation type. In the <code>FIXONE</code> case, this is <code>_FIXONE_</code> or <code>_FIXONETIME_</code> . If the model <code>RANONE</code> model is selected, the <code>_METHOD_</code> variable is either <code>_Ran1FB_</code> , <code>_Ran1WK_</code> , <code>_Ran1WH_</code> , or <code>_Ran1NL_</code> , depending on the variance component estimators chosen.

Printed Output

For each `MODEL` statement, the printed output from PROC PANEL includes the following:

- a model description, which gives the estimation method used, the model statement label if specified, the number of cross sections and the number of observations in each cross section, and the order of moving average error process for the DASILVA option. For fixed-effects model analysis, an F test for the absence of fixed effects is produced, and for random-effects model analysis, a Hausman test is used for the appropriateness of the random-effects specification.
- the estimates of the underlying error structure parameters
- the regression parameter estimates and analysis. For each regressor, this includes the name of the regressor, the degrees of freedom, the parameter estimate, the standard error of the estimate, a t statistic for testing whether the estimate is significantly different from 0, and the significance probability of the t statistic.

Optionally, PROC PANEL prints the following:

- the covariance and correlation of the resulting regression parameter estimates for each model and assumed error structure
- the $\hat{\Phi}$ matrix that is the estimated contemporaneous covariance matrix for the PARKS option

ODS Table Names

PROC PANEL assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 20.3.

Table 20.3 ODS Tables Produced in PROC PANEL

ODS Table Name	Description	Option
ODS Tables Created by the MODEL Statement		
ModelDescription	Model description	Default
FitStatistics	Fit statistics	Default
FixedEffectsTest	F test for no fixed effects	FIXONE, FIXTWO, FIXONETIME

Example: PANEL Procedure

Example 20.1: Analyzing Demand for Liquid Assets

In this example, the demand equations for liquid assets are estimated. The demand function for the demand deposits is estimated under three error structures while demand equations for time deposits and savings and loan (S&L) association shares are calculated using the Parks method. The data for seven states (CA, DC, FL, IL, NY, TX, and WA) are selected out of 49 states. See Feige (1964) for data description. All variables were transformed via natural logarithm. The data set A is shown below.

```
data a;
  length state $ 2;
  input state $ year d t s y rd rt rs;
  label d = 'Per Capita Demand Deposits'
        t = 'Per Capita Time Deposits'
        s = 'Per Capita S & L Association Shares'
        y = 'Permanent Per Capita Personal Income'
        rd = 'Service Charge on Demand Deposits'
        rt = 'Interest on Time Deposits'
        rs = 'Interest on S & L Association Shares';
datalines;
CA  1949  6.2785  6.1924  4.4998  7.2056 -1.0700  0.1080  1.0664
CA  1950  6.4019  6.2106  4.6821  7.2889 -1.0106  0.1501  1.0767
CA  1951  6.5058  6.2729  4.8598  7.3827 -1.0024  0.4008  1.1291
CA  1952  6.4785  6.2729  5.0039  7.4000 -0.9970  0.4492  1.1227
CA  1953  6.4118  6.2538  5.1761  7.4200 -0.8916  0.4662  1.2110
... more lines ...
```

As shown in the following statements, the SORT procedure is used to sort the data into the required time series cross-sectional format; then PROC PANEL analyzes the data.

```
proc sort data=a;
    by state year;
run;

proc panel data=a;
    model d = y rd rt rs / fuller parks dasilva m=7;
    model t = y rd rt rs / parks;
    model s = y rd rt rs / parks;
    id state year;
run;
```

The income elasticities for liquid assets are greater than 1 except for the demand deposit income elasticity (0.692757) estimated by the Da Silva method. In [Output 20.1.1](#), [Output 20.1.2](#), and [Output 20.1.3](#), the coefficient estimates (−0.29094, −0.43591, and −0.27736) of demand deposits (RD) imply that demand deposits increase significantly as the service charge is reduced. The price elasticities (0.227152 and 0.408066) for time deposits (RT) and S&L association shares (RS) have the expected sign. Thus an increase in the interest rate on time deposits or S&L shares will increase the demand for the corresponding liquid asset. Demand deposits and S&L shares appear to be substitutes (see [Output 20.1.2](#), [Output 20.1.3](#), and [Output 20.1.5](#)). Time deposits are also substitutes for S&L shares in the time deposit demand equation (see [Output 20.1.4](#)), while these liquid assets are independent of each other in [Output 20.1.5](#) (insignificant coefficient estimate of RT, −0.02705). Demand deposits and time deposits appear to be weak complements in [Output 20.1.3](#) and [Output 20.1.4](#), while the cross elasticities between demand deposits and time deposits are not significant in [Output 20.1.2](#) and [Output 20.1.5](#).

Example 20.2: The Airline Cost Data: Fixtwo Model

The Christenson Associates airline data are a frequently cited data set (see Greene 2000). The data measure costs, prices of inputs, and utilization rates for six airlines over the time span 1970–1984. This example analyzes the log transformations of the cost, price and quantity, and the raw (not logged) capacity utilization measure. You speculate the following model:

$$\ln(TC_{it}) = \alpha_N + \gamma_T + (\alpha_i - \alpha_N) + (\gamma_t - \gamma_T) + \beta_1 \ln(Q_{it}) + \beta_2 \ln(PF_{it}) + \beta_3 LF_{it} + \epsilon_{it}$$

where the α are the pure cross-sectional effects and γ are the time effects. The actual model speculated is highly nonlinear in the original variables. It would look like the following:

$$TC_{it} = \exp(\alpha_i + \gamma_t + \beta_3 LF_{it} + \epsilon_{it}) Q_{it}^{\beta_1} PF_{it}^{\beta_2}$$

The data and preliminary SAS statements are:

```
data airline;
  input  Obs I T C Q PF LF;
  label obs = "Observation number";
  label I  = "Firm Number (CSID)";
  label T  = "Time period (TSID)";
  label Q  = "Output in revenue passenger miles (index)";
  label C  = "Total cost, in thousands";
  label PF = "Fuel price";
  label LF = "Load Factor (utilization index)";
datalines;

... more lines ...
```

```
data airline;
  set airline;
  lC = log(C);
  lQ = log(Q);
  lPF = log(PF);
  label lC = "Log transformation of costs";
  label lQ = "Log transformation of quantity";
  label lPF = "Log transformation of price of fuel";
run;
```

The following statements fit the model.

```
proc panel data=airline;
  id i t;
  model lC = lQ lPF LF / fixtwo;
run;
```

First, you see the model's description in [Output 20.2.1](#). The model is a two-way fixed-effects model. There are six cross sections and fifteen time observations.

Output 20.2.1 The Airline Cost Data—Model Description

The PANEL Procedure	
Fixed Two Way Estimates	
Dependent Variable: lC Log transformation of costs	
Model Description	
Estimation Method	FixTwo
Number of Cross Sections	6
Time Series Length	15

The R square and degrees of freedom can be seen in [Table 20.2.2](#). On the whole, you see a large R square, so there is a reasonable fit. The degrees of freedom of the estimate are 90 minus 14 time dummy variables minus 5 cross section dummy variables and 4 regressors.

Output 20.2.2 The Airline Cost Data—Fit Statistics

Fit Statistics			
SSE	0.1768	DFE	67
MSE	0.0026	Root MSE	0.0514
R-Square	0.9984		

The F test for fixed effects is shown in [Table 20.2.3](#). Testing the hypothesis that there are no fixed effects, you easily reject the null of poolability. There are group effects, or time effects, or both. The test is highly significant. OLS would not give reasonable results.

Output 20.2.3 The Airline Cost Data—Test for Fixed Effects

F Test for No Fixed Effects			
Num DF	Den DF	F Value	Pr > F
19	67	23.10	<.0001

Looking at the parameters, you see a more complicated pattern. Most of the cross-sectional effects are highly significant (with the exception of CS2). This means that the cross sections are significantly different from the sixth cross section. Many of the time effects show significance, but this is not uniform. It looks like the significance might be driven by a large 16th period effect, since the first six time effects are negative and of similar magnitude. The time dummy variables taper off in size and lose significance from time period 12 onward. There are many causes to which you could attribute this decay of time effects. The time period of the data spans the OPEC oil embargoes and the dissolution of the Civil Aeronautics Board (CAB). These two forces are two possible reasons to observe the decay and parameter instability. As for the regression parameters, you see that quantity affects cost positively, and the price of fuel has a positive effect, but load factors negatively affect the costs of the airlines in this sample. The somewhat disturbing result is that the fuel cost is not significant. If the time effects are proxies for the effect of the oil embargoes, then an insignificant fuel cost parameter would make some sense. If the dummy variables proxy for the dissolution of the CAB, then the effect of load factors is also not being precisely estimated.

ODS Graphics Plots

ODS graphics plots can be obtained to graphically analyze the results. The following statements show how to generate the plots. If the PLOTS=ALL option is specified, all available plots are produced in two panels. For a complete list of options, see the section “ODS Graphics” on page 1396.

```
proc panel data=airline;
  id i t;
  model lC = lQ lPF LF / fixtwo plots = all;
run;
```

The preceding statements result in plots shown in [Output 20.2.5](#) and [Output 20.2.6](#).

Output 20.2.5 Diagnostic Panel 1

Output 20.2.6 Diagnostic Panel 2

The UNPACK and ONLY options produce individual detail images of paneled plots. The graph shown in [Output 20.2.7](#) shows a detail plot of residuals by cross section. The packed version always puts all cross sections on one plot while the unpacked one shows the cross sections in groups of ten to avoid loss of detail.

```
proc panel data=airline;
  id i t;
  model lc = lq lpf lf / fixtwo plots(unpack only) = residsurface;
run;
```

Output 20.2.7 Surface Plot of the Residual

Example 20.3: The Airline Cost Data: Further Analysis

Using the same data as in [Example 20.2](#), you further investigate the ‘true’ effect of fuel prices. Specifically, you run the FixOne model, ignoring time effects. You specify the following statements in PROC PANEL to run this model:

```
proc panel data=airline;
  id i t;
  model lC = lQ lPF LF / fixone;
run;
```

The preceding statements result in [Output 20.3.1](#). The fit seems to have deteriorated somewhat. The SSE rises from 0.1768 to 0.2926.

Output 20.3.1 The Airline Cost Data—Fit Statistics

The PANEL Procedure			
Fixed One Way Estimates			
Dependent Variable: lC Log transformation of costs			
Fit Statistics			
SSE	0.2926	DFE	81
MSE	0.0036	Root MSE	0.0601
R-Square	0.9974		

You still reject poolability based on the F test in [Output 20.3.2](#) at all accepted levels of significance.

Output 20.3.2 The Airline Cost Data—Test for Fixed Effects

F Test for No Fixed Effects			
Num DF	Den DF	F Value	Pr > F
5	81	57.74	<.0001

The parameters change somewhat dramatically as shown in [Output 20.3.3](#). The effect of fuel costs comes in very strong and significant. The load factor's coefficient increases, although not as dramatically. This suggests that the fixed time effects might be proxies for both the oil shocks and deregulation.

Output 20.3.3 The Airline Cost Data—Parameter Estimates

Example 20.4: The Airline Cost Data: Random-Effects Models

This example continues to use the Christenson Associates airline data, which measures costs, prices of inputs, and utilization rates for six airlines over the time span 1970–1984. There are six cross sections and fifteen time observations. Here, you examine the different estimates generated from the one-way random-effects and two-way random-effects models, by using four different methods to estimate the variance components: Fuller and Battese, Wansbeek and Kapteyn, Wallace and Hussain, and Nerlove.

The data for this example is created by the PROC PANEL statements shown in [Example 20.2](#). The PROC PANEL statements necessary to generate the estimates are as follows:

```
proc panel data=airline outest=estimates;
  id I T;
  RANONE:   model lC = lQ lPF lF / ranone vcomp=fb;
  RANONEwk: model lC = lQ lPF lF / ranone vcomp=wk;
  RANONEwh: model lC = lQ lPF lF / ranone vcomp=wh;
  RANONEnl: model lC = lQ lPF lF / ranone vcomp=nl;
  RANTWO:   model lC = lQ lPF lF / rantwo vcomp=fb;
  RANTWOwk: model lC = lQ lPF lF / rantwo vcomp=wk;
  RANTWOwh: model lC = lQ lPF lF / rantwo vcomp=wh;
  RANTWOnl: model lC = lQ lPF lF / rantwo vcomp=nl;
  POOLED:   model lC = lQ lPF lF / pooled;
  BTWNG:    model lC = lQ lPF lF / btwng;
  BTWNT:    model lC = lQ lPF lF / btwnt;
run;

data table;
  set estimates;
  VarCS = round(_VARCS_, .00001);
  VarTS = round(_VARTS_, .00001);
  VarErr = round(_VARERR_, .00001);
  Int = round(Intercept, .0001);
  lQ2 = round(lQ, .0001);
  lPF2 = round(lPF, .0001);
  lF2 = round(lF, .0001);
  if _n_ >= 9 then do;
    VarCS = . ;
    VarTS = . ;
  end;
  keep _MODEL_ _METHOD_ VarCS VarTS VarErr Int lQ2 lPF2 lF2;
run;
```

The parameter estimates and variance components for both models are reported in [Output 20.4.1](#) and [Output 20.4.2](#).

Output 20.4.1 Parameter Estimates

In the random-effects model, individual constant terms are viewed as randomly distributed across cross-sectional units and not as parametric shifts of the regression function, as in the fixed-effects model. This is appropriate when the sampled cross-sectional units are drawn from a large population. Clearly, in this example, the six airlines are a sample of all the airlines in the industry and not an exhaustive, or nearly exhaustive, list.

There are four ways of computing the variance components in the one-way random-effects model. The method by Fuller and Battese (1974) (FB), uses a “fitting of constants” methods to estimate them. The Wansbeek and Kapteyn (1989) (WK) method uses the true disturbances, while the Wallace and Hussain (WH) method uses ordinary least squares residuals.

Looking at the estimates of the variance components for cross section and error in [Output 20.4.2](#), you see that equal variance components for error are computed for both FB and WK, while WH and NL are nearly

equal.

All four techniques produce different variance components for cross sections. These estimates are then used to estimate the values of the parameters in [Output 20.4.1](#). All the parameters appear to have similar and equally plausible estimates. Both the index for output in revenue passenger miles (IQ) and fuel price (IPF) have small, positive effects on total costs, which you would expect. The load factor (LF) has a somewhat larger and negative effect on total costs, suggesting that as utilization increases, costs decrease.

As in the one-way random-effects model, the variance components for error produced by the FB and WK methods are equal. However, in this case, the WH and NL methods produce variance estimates that are dissimilar. The estimates of the variance component for cross sections are all different, but in a close range. The same cannot be said for the variance component for time series. As varied as each of the variance estimates may be, they produce parameter estimates that are similar and plausible. As with the one-way effects model, the index for output (IQ) and fuel price (IPF) are small and positive. The load factor (LF) estimates are all negative and, with the exception of the estimate produced by the WH method, somewhat smaller than the estimates produced in the one-way model. During the time the data were collected, the Civil Aeronautics Board dissolved, so it is possible that the dummy variables are proxies for this dissolution. This would lead to the decay of time effects and an imprecise estimation of the effects of the load factors, even though the estimates are statistically significant.

The pooled estimates give you something to compare the random-effects estimates against. You see that signs and magnitudes of output and fuel price are similar but that the magnitude of the load factor coefficient is somewhat larger under pooling. Since the model appears to have both cross-sectional and time series effects, the pooled model should not be used.

Finally, you examine the between groups estimators. For the between groups estimate, you are looking at each airline's data averaged across time. You see in [Output 20.4.1](#) that the between groups parameter estimates are radically different from all other parameter estimates. This could indicate that the time component is not being appropriately handled with this technique. For the between times estimate, you are looking at the average across all airlines in each time period. In this case, the parameter estimates are of the same sign and closer in magnitude to the previously computed estimates. Both the output and load factor effects appear to have more bearing on total costs.

Example 20.5: Using the FLATDATA Statement

Sometimes the data can be found in compressed form, where each line consists of all observations for the dependent and independent variables for the cross section. To illustrate, suppose you have a data set with 20 cross sections where each cross section consists of observations for six time periods. Each time period has values for dependent and independent variables $Y_1 \dots Y_6$ and $X_1 \dots X_6$. The *cs* and *num* variables represent other character and numeric variables that are constant across each cross section.

The observations for first five cross sections along with other variables are shown in [Output 20.5.1](#). In this example, *i* represents the cross section. The time period is identified by the subscript on the *Y* and *X* variables; it ranges from 1 to 6.

Output 20.5.1 Compressed Data Set

Obs	i	cs	num	X_1	X_2	X_3	X_4	X_5

Example 20.6: The Cigarette Sales Data: Dynamic Panel Estimation with GMM

In this example, a dynamic panel demand model for cigarette sales is estimated. It illustrates the application of the method described in the section “[Dynamic Panel Estimator](#)” on page 1380. The data are a panel from 46 American states over the period 1963–92. See Baltagi and Levin (1992) and Baltagi (1995) for data description. All variables were transformed by taking the natural logarithm. The data set CIGAR is shown in the following statements.

```
data cigar;
  input state year price pop pop_16 cpi ndi sales pimin;
  label
    state = 'State abbreviation'
    year  = 'YEAR'
    price = 'Price per pack of cigarettes'
    pop   = 'Population'
    pop_16 = 'Population above the age of 16'
    cpi   = 'Consumer price index with (1983=100)'
    ndi   = 'Per capita disposable income'
    sales = 'Cigarette sales in packs per capita'
    pimin = 'Minimum price in adjoining states per pack of cigarettes';
  datalines;
1 63 28.6 3383 2236.5 30.6 1558.3045298 93.9 26.1

1 65 29.8 3486 2327.5 31.5 1809.8418752 98.5 28.9
1 66 31.5 3524 2369.7 32.4 1915.1603572 96.4 29.5
1 67 31.6 3533 2393.7 33.4 2023.5463678 95.5 29.6
1 68 35.6 3522 2405.2 34.8 2202.4855362 88.4 32
1 69 36.6 3531 2411.9 36.7 2377.3346665 90.1 32.8
1 70 39.6 3444 2394.6 38.8 2591.0391591 89.8 34.3
1 71 42.7 3481 2443.5 40.5 2785.3159706 95.4 35.8

... more lines ...
```

The following statements sort the data by STATE and YEAR variables.

```
proc sort data=cigar;
  by state year;
run;
```

Next, logarithms of the variables required for regression estimation are calculated, as shown in the following statements:

```
data cigar;
  set cigar;
  lsales = log(sales);
  lprice = log(price);
  lndi   = log(ndi);
  lpimin = log(pimin);
  label lprice = 'Log price per pack of cigarettes';
```

```

label lndi = 'Log per capita disposable income';
label lsales = 'Log cigarette sales in packs per capita';
label lpimin = 'Log minimum price in adjoining states
               per pack of cigarettes';

run;

```

The following statements create the CIGAR_LAG data set with lagged variable for each cross section.

```

proc panel data=cigar;
  id state year;
  clag lsales(1) / out=cigar_lag;
run;

data cigar_lag;
  set cigar_lag;
  label lsales_1 = 'Lagged log cigarette sales in packs per capita';
run;

```

Finally, the model is estimated by a two step GMM method. Five lags (MAXBAND=5) of the dependent variable are used as instruments. NOLEVELS options is specified to avoid use of level equations, as shown in the following statements:

```

proc panel data=cigar_lag;
  inst depvar;
  model lsales = lsales_1 lprice lndi lpimin
    / gmm nolevels twostep maxband=5 noint;
  id state year;
run;

```

Overview: PDLREG Procedure

The PDLREG procedure estimates regression models for time series data in which the effects of some of the regressor variables are distributed across time. The distributed lag model assumes that the effect of an input variable X on an output Y is distributed over time. If you change the value of X at time t , Y will experience some immediate effect at time t , and it will also experience a delayed effect at times $t + 1$, $t + 2$, and so on up to time $t + p$ for some limit p .

The regression model supported by PROC PDLREG can include any number of regressors with distribution lags and any number of covariates. (Simple regressors without lag distributions are called covariates.) For example, the two-regressor model with a distributed lag effect for one regressor is written

$$y_t = \alpha + \sum_{i=0}^p \beta_i x_{t-i} + \gamma z_t + u_t$$

Here, x_t is the regressor with a distributed lag effect, z_t is a simple covariate, and u_t is an error term.

The distribution of the lagged effects is modeled by Almon lag polynomials. The coefficients b_i of the lagged values of the regressor are assumed to lie on a polynomial curve. That is,

$$b_i = \alpha_0^* + \sum_{j=1}^d \alpha_j^* i^j$$

where $d(\leq p)$ is the degree of the polynomial. For the numerically efficient estimation, the PDLREG procedure uses *orthogonal polynomials*. The preceding equation can be transformed into orthogonal polynomials:

$$b_i = \alpha_0 + \sum_{j=1}^d \alpha_j f_j(i)$$

where $f_j(i)$ is a polynomial of degree j in the lag length i , and α_j is a coefficient estimated from the data.

The PDLREG procedure supports endpoint restrictions for the polynomial. That is, you can constrain the estimated polynomial lag distribution curve so that $b_{-1} = 0$ or $b_{p+1} = 0$, or both. You can also impose linear restrictions on the parameter estimates for the covariates.

You can specify a minimum degree and a maximum degree for the lag distribution polynomial, and the procedure fits polynomials for all degrees in the specified range. (However, if distributed lags are specified for more than one regressor, you can specify a range of degrees for only one of them.)

The PDLREG procedure can also test for autocorrelated residuals and perform autocorrelated error correction by using the autoregressive error model. You can specify any order autoregressive error model and can specify several different estimation methods for the autoregressive model, including exact maximum likelihood.

The PDLREG procedure computes generalized Durbin-Watson statistics to test for autocorrelated residuals. For models with lagged dependent variables, the procedure can produce Durbin h and Durbin t statistics. You can request significance level p -values for the Durbin-Watson, Durbin h , and Durbin t statistics. See Chapter 8, “[The AUTOREG Procedure](#),” for details about these statistics.

The PDLREG procedure assumes that the input observations form a time series. Thus, the PDLREG procedure should be used only for ordered and equally spaced time series data.

Getting Started: PDLREG Procedure

Use the MODEL statement to specify the regression model. The PDLREG procedure’s MODEL statement is written like MODEL statements in other SAS regression procedures, except that a regressor can be followed by a lag distribution specification enclosed in parentheses.

For example, the following MODEL statement regresses Y on X and Z and specifies a distributed lag for X:

```
model y = x(4,2) z;
```

The notation X(4,2) specifies that the model includes X and 4 lags of X, with the coefficients of X and its lags constrained to follow a second-degree (quadratic) polynomial. Thus, the regression model specified by this MODEL statement is

$$y_t = a + b_0x_t + b_1x_{t-1} + b_2x_{t-2} + b_3x_{t-3} + b_4x_{t-4} + cz_t + u_t$$

$$b_i = \alpha_0 + \alpha_1 f_1(i) + \alpha_2 f_2(i)$$

where $f_1(i)$ is a polynomial of degree 1 in i and $f_2(i)$ is a polynomial of degree 2 in i .

Lag distribution specifications are enclosed in parentheses and follow the name of the regressor variable. The general form of the lag distribution specification is

regressor-name (length, degree, minimum-degree, end-constraint)

where

<i>length</i>	is the length of the lag distribution—that is, the number of lags of the regressor to use.
<i>degree</i>	is the degree of the distribution polynomial.
<i>minimum-degree</i>	is an optional minimum degree for the distribution polynomial.
<i>end-constraint</i>	is an optional endpoint restriction specification, which can have the value FIRST, LAST, or BOTH.

If the *minimum-degree* option is specified, the PDLREG procedure estimates models for all degrees between *minimum-degree* and *degree*.

Introductory Example

The following statements generate simulated data for variables Y and X. Y depends on the first three lags of X, with coefficients .25, .5, and .25. Thus, the effect of changes of X on Y takes effect 25% after one period, 75% after two periods, and 100% after three periods.

```
data test;
  x11 = 0; x12 = 0; x13 = 0;
  do t = -3 to 100;
    x = ranuni(1234);
    y = 10 + .25 * x11 + .5 * x12 + .25 * x13
        + .1 * rannor(1234);
    if t > 0 then output;
    x13 = x12; x12 = x11; x11 = x;
  end;
run;
```

The following statements use the PDLREG procedure to regress Y on a distributed lag of X . The length of the lag distribution is 4, and the degree of the distribution polynomial is specified as 3.

```
proc pdlreg data=test;
    model y = x( 4, 3 );
run;
```

The PDLREG procedure first prints a table of statistics for the residuals of the model, as shown in [Figure 21.1](#). See Chapter 8, “[The AUTOREG Procedure](#),” for an explanation of these statistics.

Figure 21.1 Residual Statistics

The PDLREG Procedure			
Dependent Variable		y	
Ordinary Least Squares Estimates			
SSE	0.86604442	DFE	91
MSE	0.00952	Root MSE	0.09755
SBC	-156.72612	AIC	-169.54786
MAE	0.07761107	AICC	-168.88119
MAPE	0.73971576	HQC	-164.3651
Durbin-Watson	1.9920	Regress R-Square	0.7711
		Total R-Square	0.7711

The PDLREG procedure next prints a table of parameter estimates, standard errors, and t tests, as shown in [Figure 21.2](#).

Figure 21.2 Parameter Estimates

Parameter Estimates					
Variable	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	10.0030	0.0431	231.87	<.0001
x**0	1	0.4406	0.0378	11.66	<.0001
x**1	1	0.0113	0.0336	0.34	0.7377
x**2	1	-0.4108	0.0322	-12.75	<.0001
x**3	1	0.0331	0.0392	0.84	0.4007

The table in [Figure 21.2](#) shows the model intercept and the estimated parameters of the lag distribution polynomial. The parameter labeled $X^{**}0$ is the constant term, α_0 , of the distribution polynomial. $X^{**}1$ is the linear coefficient, α_1 ; $X^{**}2$ is the quadratic coefficient, α_2 ; and $X^{**}3$ is the cubic coefficient, α_3 .

The parameter estimates for the distribution polynomial are not of interest in themselves. Since the PDLREG procedure does not print the orthogonal polynomial basis that it constructs to represent the distribution polynomial, these coefficient values cannot be interpreted.

However, because these estimates are for an orthogonal basis, you can use these results to test the degree of the polynomial. For example, this table shows that the X^{**3} estimate is not significant; the p -value for its t ratio is 0.4007, while the X^{**2} estimate is highly significant ($p < .0001$). This indicates that a second-degree polynomial might be more appropriate for this data set.

The PDLREG procedure next prints the lag distribution coefficients and a graphical display of these coefficients, as shown in [Figure 21.3](#).

Figure 21.3 Coefficients and Graph of Estimated Lag Distribution

x(2)	0.416661	0.0239	17.45	<.0001
x(3)	0.289482	0.0315	9.20	<.0001
x(4)	-0.004926	0.0365	-0.13	0.8929
Estimate of Lag Distribution				
Variable	-0.04			0.4167
x(0)	***			
x(1)		*****		
x(2)		*****		
x(3)		*****		
x(4)				

The lag distribution coefficients are the coefficients of the lagged values of X in the regression model. These coefficients lie on the polynomial curve defined by the parameters shown in [Figure 21.2](#). Note that the estimated values for $X(1)$, $X(2)$, and $X(3)$ are highly significant, while $X(0)$ and $X(4)$ are not significantly different from 0. These estimates are reasonably close to the true values used to generate the simulated data.

The graphical display of the lag distribution coefficients plots the estimated lag distribution polynomial reported in [Figure 21.2](#). The roughly quadratic shape of this plot is another indication that a third-degree distribution curve is not needed for this data set.

Syntax: PDLREG Procedure

The following statements can be used with the PDLREG procedure:

```

PROC PDLREG option ;
  BY variables ;
  MODEL dependents = effects / options ;
  OUTPUT OUT= SAS-data-set keyword = variables ;
  RESTRICT restrictions ;

```

Functional Summary

The statements and options used with the PDLREG procedure are summarized in the following table.

PROC PDLREG Statement

PROC PDLREG *option* ;

The PROC PDLREG statement has the following option:

DATA= *SAS-data-set*

specifies the name of the SAS data set containing the input data. If you do not specify the DATA= option, the most recently created SAS data set is used.

In addition, you can place any of the following MODEL statement options in the PROC PDLREG statement, which is equivalent to specifying the option for every MODEL statement: ALL, COEF, CONVERGE=, CORRB, COVB, DW=, DWPROB, GINV, ITPRINT, MAXITER=, METHOD=, NOINT, NOPRINT, and PARTIAL.

BY Statement

BY *variables* ;

A BY statement can be used with PROC PDLREG to obtain separate analyses on observations in groups defined by the BY variables.

MODEL Statement

MODEL *dependent = effects / options* ;

The MODEL statement specifies the regression model. The keyword MODEL is followed by the dependent variable name, an equal sign, and a list of independent effects. Only one MODEL statement is allowed.

Every variable in the model must be a numeric variable in the input data set. Specify an independent effect with a variable name optionally followed by a polynomial lag distribution specification.

Specifying Independent Effects

The general form of an effect is

variable (*length*, *degree*, *minimum-degree*, *constraint*)

The term in parentheses following the variable name specifies a polynomial distributed lag (PDL) for the variable. The PDL specification is as follows:

<i>length</i>	specifies the number of lags of the variable to include in the lag distribution.
<i>degree</i>	specifies the maximum degree of the distribution polynomial. If not specified, the degree defaults to the lag length.
<i>minimum-degree</i>	specifies the minimum degree of the polynomial. By default <i>minimum-degree</i> is the same as <i>degree</i> .
<i>constraint</i>	specifies endpoint restrictions on the polynomial. The value of <i>constraint</i> can be FIRST, LAST, or BOTH. If a value is not specified, there are no endpoint restrictions.

If you do not specify the *degree* or *minimum-degree* parameter, but you do specify endpoint restrictions, you must use commas to show which parameter, *degree* or *minimum-degree*, is left out.

MODEL Statement Options

The following options can appear in the MODEL statement after a slash (/).

ALL

prints all the matrices computed during the analysis of the model.

COEF

prints the transformation coefficients for the first p observations. These coefficients are formed from a scalar multiplied by the inverse of the Cholesky root of the Toeplitz matrix of autocovariances.

CORRB

prints the matrix of estimated correlations between the parameter estimates.

COVB

prints the matrix of estimated covariances between the parameter estimates.

DW= j

prints the generalized Durbin-Watson statistics up to the order of j . The default is DW=1. When you specify the LAGDEP or LAGDEP=*name* option, the Durbin-Watson statistic is not printed unless you specify the DW= option.

DWPROB

prints the marginal probability of the Durbin-Watson statistic.

CONVERGE= *value*

sets the convergence criterion. If the maximum absolute value of the change in the autoregressive parameter estimates between iterations is less than this amount, then convergence is assumed. The default is CONVERGE=.001.

GINV

prints the inverse of the Toeplitz matrix of autocovariances for the Yule-Walker solution.

I

prints $(\mathbf{X}'\mathbf{X})^{-1}$, the inverse of the crossproducts matrix for the model; or, if restrictions are specified, it prints $(\mathbf{X}'\mathbf{X})^{-1}$ adjusted for the restrictions.

ITPRINT

prints information on each iteration.

LAGDEP**LAGDV**

prints the t statistic for testing residual autocorrelation when regressors contain lagged dependent variables.

LAGDEP= *name***LAGDV= *name***

prints the Durbin h statistic for testing the presence of first-order autocorrelation when regressors contain the lagged dependent variable whose name is specified as LAGDEP=*name*. When the h statistic cannot be computed, the asymptotically equivalent t statistic is given.

MAXITER= *number*

sets the maximum number of iterations allowed. The default is MAXITER=50.

METHOD= *value*

specifies the type of estimates for the autoregressive component. The values of the METHOD= option are as follows:

METHOD=ML	specifies the maximum likelihood method.
METHOD=ULS	specifies unconditional least squares.
METHOD=YW	specifies the Yule-Walker method.
METHOD=ITYW	specifies iterative Yule-Walker estimates.

The default is METHOD=ML if you specified the LAGDEP or LAGDEP= option; otherwise, METHOD=YW is the default.

NLAG= *m***NLAG=** (*number-list*)

specifies the order of the autoregressive process or the subset of autoregressive lags to be fit. If you do not specify the NLAG= option, PROC PDLREG does not fit an autoregressive model.

NOINT

suppresses the intercept parameter from the model.

NOPRINT

suppresses the printed output.

PARTIAL

prints partial autocorrelations if the NLAG= option is specified.

STB

prints standardized parameter estimates. Sometimes known as a standard partial regression coefficient, a *standardized parameter estimate* is a parameter estimate multiplied by the standard deviation of the associated regressor and divided by the standard deviation of the regressed variable.

XPX

prints the crossproducts matrix, $\mathbf{X}'\mathbf{X}$, used for the model. \mathbf{X} refers to the transformed matrix of regressors for the regression.

OUTPUT Statement

OUTPUT *OUT= SAS-data-set keyword= option ... ;*

The OUTPUT statement creates an output SAS data set with variables as specified by the following keyword options. See the section “Predicted Values” in Chapter 8, “[The AUTOREG Procedure](#),” for a description of the associated computations for these options.

ALPHACLI= *number*

sets the confidence limit size for the estimates of future values of the current realization of the response time series to *number*, where *number* is less than one and greater than zero. The resulting confidence

interval has 1-*number* confidence. The default value for *number* is 0.05, corresponding to a 95% confidence interval.

ALPHACL= *number*

sets the confidence limit size for the estimates of the structural or regression part of the model to *number*, where *number* is less than one and greater than zero. The resulting confidence interval has 1-*number* confidence. The default value for *number* is 0.05, corresponding to a 95% confidence interval.

OUT= *SAS-data-set*

names the output data.

The following specifications are of the form *KEYWORD=names*, where *KEYWORD=* specifies the statistic to include in the output data set and *names* gives names to the variables that contain the statistics.

CONSTANT= *variable*

writes the transformed intercept to the output data set.

LCL= *name*

requests that the lower confidence limit for the predicted value (specified in the *PREDICTED=* option) be added to the output data set under the name given.

LCLM= *name*

requests that the lower confidence limit for the structural predicted value (specified in the *PREDICTEDM=* option) be added to the output data set under the name given.

PREDICTED= *name*

P= *name*

stores the predicted values in the output data set under the name given.

PREDICTEDM= *name*

PM= *name*

stores the structural predicted values in the output data set under the name given. These values are formed from only the structural part of the model.

RESIDUAL= *name*

R= *name*

stores the residuals from the predicted values based on both the structural and time series parts of the model in the output data set under the name given.

RESIDUALM= *name*

RM= *name*

requests that the residuals from the structural prediction be given.

TRANSFORM= *variables*

requests that the specified variables from the input data set be transformed by the autoregressive model and put in the output data set. If you need to reproduce the data suitable for reestimation, you must also transform an intercept variable. To do this, transform a variable that only takes the value 1 or use the *CONSTANT=* option.

UCL= *name*

stores the upper confidence limit for the predicted value (specified in the PREDICTED= option) in the output data set under the name given.

UCLM= *name*

stores the upper confidence limit for the structural predicted value (specified in the PREDICTEDM= option) in the output data set under the name given.

For example, the SAS statements

```
proc pdlreg data=a;
  model y=x1 x2;
  output out=b p=yhat r=resid;
run;
```

create an output data set named B. In addition to the input data set variables, the data set B contains the variable YHAT, whose values are predicted values of the dependent variable Y, and RESID, whose values are the residual values of Y.

RESTRICT Statement

RESTRICT *equation* , . . . , *equation* ;

The RESTRICT statement places restrictions on the parameter estimates for covariates in the preceding MODEL statement. A parameter produced by a distributed lag cannot be restricted with the RESTRICT statement.

Each restriction is written as a linear equation. If you specify more than one restriction in a RESTRICT statement, the restrictions are separated by commas.

You can refer to parameters by the name of the corresponding regressor variable. Each name used in the equation must be a regressor in the preceding MODEL statement. Use the keyword INTERCEPT to refer to the intercept parameter in the model.

RESTRICT statements can be given labels. You can use labels to distinguish results for different restrictions in the printed output. Labels are specified as follows:

label : **RESTRICT** . . .

The following is an example of the use of the RESTRICT statement, in which the coefficients of the regressors X1 and X2 are required to sum to 1:

```
proc pdlreg data=a;
  model y = x1 x2;
  restrict x1 + x2 = 1;
run;
```

Parameter names can be multiplied by constants. When no equal sign appears, the linear combination is set equal to 0. Note that the parameters associated with the variables are restricted, not the variables themselves. Here are some examples of valid RESTRICT statements:

```
restrict x1 + x2 = 1;
restrict x1 + x2 - 1;
restrict 2 * x1 = x2 + x3 , intercept + x4 = 0;
restrict x1 = x2 = x3 = 1;
restrict 2 * x1 - x2;
```

Restricted parameter estimates are computed by introducing a Lagrangian parameter λ for each restriction (Pringle and Rayner 1971). The estimates of these Lagrangian parameters are printed in the parameter estimates table. If a restriction cannot be applied, its parameter value and degrees of freedom are listed as 0.

The Lagrangian parameter, λ , measures the sensitivity of the SSE to the restriction. If the restriction is changed by a small amount ϵ , the SSE is changed by $2\lambda\epsilon$.

The t ratio tests the significance of the restrictions. If λ is zero, the restricted estimates are the same as the unrestricted ones.

You can specify any number of restrictions in a RESTRICT statement, and you can use any number of RESTRICT statements. The estimates are computed subject to all restrictions specified. However, restrictions should be consistent and not redundant.

Details: PDLREG Procedure

Missing Values

The PDLREG procedure skips any observations at the beginning of the data set that have missing values. The procedure uses all observations with nonmissing values for all the independent and dependent variables such that the lag distribution has sufficient nonmissing lagged independent variables.

Polynomial Distributed Lag Estimation

The simple finite distributed lag model is expressed in the form

$$y_t = \alpha + \sum_{i=0}^p \beta_i x_{t-i} + \epsilon_t$$

When the lag length (p) is long, severe multicollinearity can occur. Use the Almon or *polynomial distributed lag* model to avoid this problem, since the relatively low-degree d ($\leq p$) polynomials can capture the true lag distribution. The lag coefficient can be written in the Almon polynomial lag

$$\beta_i = \alpha_0^* + \sum_{j=1}^d \alpha_j^* i^j$$

Emerson (1968) proposed an efficient method of constructing orthogonal polynomials from the preceding polynomial equation as

$$\beta_i = \alpha_0 + \sum_{j=1}^d \alpha_j f_j(i)$$

where $f_j(i)$ is a polynomial of degree j in the lag length i . The polynomials $f_j(i)$ are chosen so that they are orthogonal:

$$\sum_{i=1}^n w_i f_j(i) f_k(i) = \begin{cases} 1 & \text{if } j = k \\ 0 & \text{if } j \neq k \end{cases}$$

where w_i is the weighting factor, and $n = p + 1$. PROC PDLREG uses the equal weights ($w_i = 1$) for all i . To construct the orthogonal polynomials, the following recursive relation is used:

$$f_j(i) = (A_j i + B_j) f_{j-1}(i) - C_j f_{j-2}(i) \quad j = 1, \dots, d$$

The constants A_j , B_j , and C_j are determined as follows:

$$\begin{aligned} A_j &= \left\{ \sum_{i=1}^n w_i i^2 f_{j-1}^2(i) - \left(\sum_{i=1}^n w_i i f_{j-1}^2(i) \right)^2 \right. \\ &\quad \left. - \left(\sum_{i=1}^n w_i i f_{j-1}(i) f_{j-2}(i) \right)^2 \right\}^{-1/2} \\ B_j &= -A_j \sum_{i=1}^n w_i i f_{j-1}^2(i) \\ C_j &= A_j \sum_{i=1}^n w_i i f_{j-1}(i) f_{j-2}(i) \end{aligned}$$

where $f_{-1}(i) = 0$ and $f_0(i) = 1/\sqrt{\sum_{i=1}^n w_i}$.

PROC PDLREG estimates the orthogonal polynomial coefficients, $\alpha_0, \dots, \alpha_d$, to compute the coefficient estimate of each independent variable (X) with distributed lags. For example, if an independent variable is specified as X(9,3), a third-degree polynomial is used to specify the distributed lag coefficients. The third-degree polynomial is fit as a constant term, a linear term, a quadratic term, and a cubic term. The four terms are constructed to be orthogonal. In the output produced by the PDLREG procedure for this case, parameter estimates with names X**0, X**1, X**2, and X**3 correspond to $\hat{\alpha}_0, \hat{\alpha}_1, \hat{\alpha}_2$, and $\hat{\alpha}_3$, respectively. A test using the t statistic and the approximate p -value (“Approx Pr > | t |”) associated with X**3 can determine whether a second-degree polynomial rather than a third-degree polynomial is appropriate. The estimates of the 10 lag coefficients associated with the specification X(9,3) are labeled X(0), X(1), X(2), X(3), X(4), X(5), X(6), X(7), X(8), and X(9).

Autoregressive Error Model Estimation

The PDLREG procedure uses the same autoregressive error model estimation methods as the AUTOREG procedure. These two procedures share the same computational resources for computing estimates. See Chapter 8, “[The AUTOREG Procedure](#),” for details about estimation methods for autoregressive error models.

OUT= Data Set

The OUT= data set produced by the PDLREG procedure’s OUTPUT statement is similar in form to the OUT= data set produced by the AUTOREG procedure. See Chapter 8, “[The AUTOREG Procedure](#),” for details on the OUT= data set.

Printed Output

The PDLREG procedure prints the following items:

1. the name of the dependent variable
2. the ordinary least squares (OLS) estimates
3. the estimates of autocorrelations and of the autocovariance, and if line size permits, a graph of the autocorrelation at each lag. The autocorrelation for lag 0 is 1. These items are printed if you specify the NLAG= option.
4. the partial autocorrelations if the PARTIAL and NLAG= options are specified. The first partial autocorrelation is the autocorrelation for lag 1.

5. the preliminary mean square error, which results from solving the Yule-Walker equations if you specify the NLAG= option
6. the estimates of the autoregressive parameters, their standard errors, and the ratios of estimates to standard errors (t) if you specify the NLAG= option
7. the statistics of fit for the final model if you specify the NLAG= option. These include the error sum of squares (SSE), the degrees of freedom for error (DFE), the mean square error (MSE), the root mean square error (Root MSE), the mean absolute error (MAE), the mean absolute percentage error (MAPE), the Schwarz information criterion (SBC), the Akaike's information criterion (AIC), Akaike's information criterion corrected (AICC), the regression R^2 (Regress R-Square), the total R^2 (Total R-Square), and the Durbin-Watson statistic (Durbin-Watson). See Chapter 8, “[The AUTOREG Procedure](#),” for details of the regression R^2 and the total R^2 .
8. the parameter estimates for the structural model (B), a standard error estimate, the ratio of estimate to standard error (t), and an approximation to the significance probability for the parameter being 0 (“Approx Pr > $|t|$ ”)
9. a plot of the lag distribution (estimate of lag distribution)
10. the covariance matrix of the parameter estimates if the COVB option is specified

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#)” (*SAS/STAT User's Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

PROC PDLREG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 21.2 ODS Tables Produced in PROC PDLREG

ODS Table Name	Description	Option
ODS Tables Created by the MODEL Statement		
ARParameterEstimates	Estimates of autoregressive parameters	NLAG=
CholeskyFactor	Cholesky root of gamma	NLAG= and ALL
Coefficients	Coefficients for first NLAG observations	NLAG= and (COEF or ALL)
ConvergenceStatus	Convergence status table	default

Table 21.2 *continued*

ODS Table Name	Description	Option
CorrB	Correlation of parameter estimates	CORRB
CorrGraph	Estimates of autocorrelations	NLAG=
CovB	Covariance of parameter estimates	COVB
DependenceEquations	Linear dependence equation	
Dependent	Dependent variable	default
DWTest	Durbin-Watson statistics	DW=
DWTestProb	Durbin-Watson statistics and p -values	DW= DWPROB
ExpAutocorr	Expected autocorrelations	{NLAG= and (COEF or ALL)} or {NLAG=($l_1 \dots l_m$) where $l_m > m$ }
FitSummary	Summary of regression	default
GammaInverse	Gamma inverse	NLAG= and (GINV or ALL)
IterHistory	Iteration history	ITPRINT
LagDist	Lag distribution	default
ParameterEstimates	Parameter estimates	default
ParameterEstimatesGivenAR	Parameter estimates assuming AR parameters are given	NLAG=
PartialAutoCorr	Partial autocorrelation	PARTIAL
PreMSE	Preliminary MSE	NLAG=
XPXIMatrix	$(\mathbf{X}'\mathbf{X})^{-1}$ matrix	XPX
XPXMatrix	$\mathbf{X}'\mathbf{X}$ matrix	XPX
YWIterSSE	Yule-Walker iteration sum of squared error	METHOD=ITYW
ODS Tables Created by the RESTRICT Statement		
Restrict	Restriction table	default

Examples: PDLREG Procedure

Example 21.1: Industrial Conference Board Data

In this example, a second-degree Almon polynomial lag model is fit to a model with a five-period lag, and dummy variables are used for quarter effects. The PDL model is estimated using capital appropriations data series for the period 1952 to 1967. The estimation model is written

$$CE_t = a_0 + b_1 Q1_t + b_2 Q2_t + b_3 Q3_t \\ + c_0 CA_t + c_1 CA_{t-1} + \dots + c_5 CA_{t-5}$$

where CE represents capital expenditures and CA represents capital appropriations.

Example 21.2: Money Demand Model

This example estimates the demand for money by using the following dynamic specification:

$$m_t = a_0 + b_0 m_{t-1} + \sum_{i=0}^5 c_i y_{t-i} + \sum_{i=0}^2 d_i r_{t-i} + \sum_{i=0}^3 f_i p_{t-i} + u_t$$

where

m_t = log of real money stock (M1)

y_t = log of real GNP

r_t = interest rate (commercial paper rate)

p_t = inflation rate

c_i, d_i , and f_i ($i > 0$) are coefficients for the lagged variables

The following DATA step reads the data and transforms the real money and real GNP variables using the natural logarithm. Refer to Balke and Gordon (1986) for a description of the data.

```
data a;
  input m1 gnp gdf r @@;
  m    = log( 100 * m1 / gdf );
  lagm = lag( m );
  y     = log( gnp );
  p     = log( gdf / lag( gdf ) );
  date = intnx( 'qtr', '1jan1968'd, _n_-1 );
  format date yyqc6.;
  label m      = 'Real Money Stock (M1)'
        lagm   = 'Lagged Real Money Stock'
        y      = 'Real GNP'
        r      = 'Commercial Paper Rate'
        p      = 'Inflation Rate';
datalines;

... more lines ...
```

Output 21.2.1 shows a partial list of the data set.

Output 21.2.1 Partial List of the Data Set A

Overview: QLIM Procedure

The QLIM (qualitative and limited dependent variable model) procedure analyzes univariate and multivariate limited dependent variable models in which dependent variables take discrete values or dependent variables are observed only in a limited range of values. These models include logit, probit, tobit, selection, and multivariate models. The multivariate model can contain discrete choice and limited endogenous variables in addition to continuous endogenous variables.

The QLIM procedure supports the following models:

- linear regression model with heteroscedasticity
- Box-Cox regression with heteroscedasticity
- probit with heteroscedasticity
- logit with heteroscedasticity
- tobit (censored and truncated) with heteroscedasticity
- bivariate probit
- bivariate tobit
- sample selection and switching regression models
- multivariate limited dependent variables
- stochastic frontier production and cost models

In the linear regression models with heteroscedasticity, the assumption that error variance is constant across observations is relaxed. The QLIM procedure allows for a number of different linear and nonlinear variance specifications. Another way to make the linear model more appropriate to fit the data and reduce skewness is to apply Box-Cox transformation. If the nature of data is such that the dependent variable is discrete and it takes only two possible values, OLS estimates are inconsistent. The QLIM procedure offers probit and logit models to overcome these estimation problems. Assumptions about the error variance can also be relaxed in order to estimate probit or logit with heteroscedasticity.

The QLIM procedure also offers a class of models in which the dependent variable is censored or truncated from below or above or both. When a continuous dependent variable is observed only within a certain range and values outside this range are not available, the QLIM procedure offers a class of models that adjust for truncation. In some cases, the dependent variable is continuous only in a certain range and all values outside this range are reported as being on its boundary. For example, if it is not possible to observe negative values, the value of the dependent variable is reported as equal to zero. Because the data are censored, ordinary least squares (OLS) results are inconsistent, and it cannot be guaranteed that the predicted values from the model fall in the appropriate region.

Most of the models in the QLIM procedure can be extended to accommodate bivariate and multivariate scenarios. The assumption that one variable is observed only if another variable takes on certain values lead to the introduction of sample selection models. If the dependent variables are mutually exclusive and observed only for certain ranges of the selection variable, the sample selection can be extended to include cases of switching regression. Stochastic frontier production and cost models allow for random shocks of the production or cost. They include a systematic positive component in the error term that adjusts for technological or cost inefficiency.

The QLIM procedure uses maximum likelihood methods. Initial starting values for the nonlinear optimizations are typically calculated by OLS.

Getting Started: QLIM Procedure

The QLIM procedure is similar in use to the other regression or simultaneous equations model procedures in the SAS System. For example, the following statements are used to estimate a binary choice model by using the probit probability function:

```
proc qlim data=a;
  model y = x1;
  endogenous y ~ discrete;
run;
```

The response variable, *y*, is numeric and has discrete values. PROC QLIM enables the user to specify the type of endogenous variables in the ENDOGENOUS statement. The binary probit model can be also specified as follows:

```
model y = x1 / discrete;
```

When multiple endogenous variables are specified in the QLIM procedure, these equations are estimated as a system. Multiple endogenous variables can be specified with one MODEL statement in the QLIM procedure when these models have the same exogenous variables:

```
model y1 y2 = x1 x2 / discrete;
```

The preceding specification is equivalent to the following statements:

```
proc qlim data=a;
  model y1 = x1 x2;
  model y2 = x1 x2;
  endogenous y1 y2 ~ discrete;
run;
```

Some equations in multivariate models can be continuous while other equations can be discrete. A bivariate model with a discrete and a continuous equation is specified as follows:

```
proc qlim data=a;
  model y1 = x1 x2;
  model y2 = x3 x4;
  endogenous y1 ~ discrete;
run;
```

The standard tobit model is estimated by specifying the endogenous variable to be truncated or censored. The limits of the dependent variable can be specified with the CENSORED or TRUNCATED option in the ENDOGENOUS or MODEL statement when the data are limited by specific values or variables. For example, the two-limit censored model requires two variables that contain the lower (bottom) and upper (top) bound:

```
proc qlim data=a;
  model y = x1 x2 x3;
  endogenous y ~ censored(lb=bottom ub=top);
run;
```

The bounds can be numbers if they are fixed for all observations in the data set. For example, the standard tobit model can be specified as follows:

```
proc qlim data=a;
  model y = x1 x2 x3;
  endogenous y ~ censored(lb=0);
run;
```

Introductory Example: Binary Probit and Logit Models

The following example illustrates the use of PROC QLIM. The data were originally published by Mroz (1987) and downloaded from Wooldridge (2002). This data set is based on a sample of 753 married white women. The dependent variable is a discrete variable of labor force participation (`lnlf`). Explanatory variables are the number of children ages 5 or younger (`kidslt6`), the number of children ages 6 to 18 (`kidsge6`), the woman's age (`age`), the woman's years of schooling (`educ`), wife's labor experience (`exper`), square of experience (`expersq`), and the family income excluding the wife's wage (`nwifeinc`). The program (with data values omitted) is as follows:

```

/*-- Binary Probit --*/
proc qlim data=mroz;
  model inlf = nwifeinc educ exper expersq
            age kidslt6 kidsge6 / discrete;
run;

```

Results of this analysis are shown in the following four figures. In the first table, shown in [Figure 22.1](#), PROC QLIM provides frequency information about each choice. In this example, 428 women participate in the labor force ($\text{inlf} = 1$).

Figure 22.1 Choice Frequency Summary

Binary Data		
The QLIM Procedure		
Discrete Response Profile of inlf		
Index	Value	Total Frequency
1	0	325
2	1	428

The second table is the estimation summary table shown in [Figure 22.2](#). Included are the number of dependent variables, names of dependent variables, the number of observations, the log-likelihood function value, the maximum absolute gradient, the number of iterations, AIC, and Schwarz criterion.

Figure 22.2 Fit Summary Table of Binary Probit

Model Fit Summary	
Number of Endogenous Variables	1
Endogenous Variable	inlf
Number of Observations	753
Log Likelihood	-401.30219
Maximum Absolute Gradient	0.0000669
Number of Iterations	15
Optimization Method	Quasi-Newton
AIC	818.60439
Schwarz Criterion	855.59691

Goodness-of-fit measures are displayed in [Figure 22.3](#). All measures except McKelvey-Zavoina's definition are based on the log-likelihood function value. The likelihood ratio test statistic has chi-square distribution conditional on the null hypothesis that all slope coefficients are zero. In this example, the likelihood ratio statistic is used to test the hypothesis that $\text{kidslt6} = \text{kidge6} = \text{age} = \text{educ} = \text{exper} = \text{expersq} = \text{nwifeinc} = 0$.

Figure 22.3 Goodness of Fit

Goodness-of-Fit Measures		
Measure	Value	Formula
Likelihood Ratio (R)	227.14	$2 * (\text{LogL} - \text{LogL0})$
Upper Bound of R (U)	1029.7	$- 2 * \text{LogL0}$
Aldrich-Nelson	0.2317	$R / (R+N)$
Cragg-Uhler 1	0.2604	$1 - \exp(-R/N)$
Cragg-Uhler 2	0.3494	$(1 - \exp(-R/N)) / (1 - \exp(-U/N))$
Estrella	0.2888	$1 - (1 - R/U)^{(U/N)}$
Adjusted Estrella	0.2693	$1 - ((\text{LogL} - K) / \text{LogL0})^{(-2/N * \text{LogL0})}$
McFadden's LRI	0.2206	R / U
Veall-Zimmermann	0.4012	$(R * (U+N)) / (U * (R+N))$
McKelvey-Zavoina	0.4025	
N = # of observations, K = # of regressors		

Finally, the parameter estimates and standard errors are shown in [Figure 22.4](#).

Figure 22.4 Parameter Estimates of Binary Probit

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.270077	0.508590	0.53	0.5954
nwifeinc	1	-0.012024	0.004840	-2.48	0.0130
educ	1	0.130905	0.025255	5.18	<.0001
exper	1	0.123348	0.018720	6.59	<.0001
expersq	1	-0.001887	0.000600	-3.14	0.0017
age	1	-0.052853	0.008477	-6.24	<.0001
kidslt6	1	-0.868329	0.118519	-7.33	<.0001
kidsge6	1	0.036005	0.043477	0.83	0.4076

When the error term has a logistic distribution, the binary logit model is estimated. To specify a logistic distribution, add D=LOGIT option as follows:

```

/*-- Binary Logit --*/
proc qlim data=mroz;
  model inlf = nwifeinc educ exper expersq
              age kidslt6 kidsge6 / discrete(d=logit);
run;

```

The estimated parameters are shown in [Figure 22.5](#).

Figure 22.5 Parameter Estimates of Binary Logit

Binary Data					
The QLIM Procedure					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.425452	0.860365	0.49	0.6210
nwifeinc	1	-0.021345	0.008421	-2.53	0.0113
educ	1	0.221170	0.043441	5.09	<.0001
exper	1	0.205870	0.032070	6.42	<.0001
expersq	1	-0.003154	0.001017	-3.10	0.0019
age	1	-0.088024	0.014572	-6.04	<.0001
kidslt6	1	-1.443354	0.203575	-7.09	<.0001
kidsge6	1	0.060112	0.074791	0.80	0.4215

The heteroscedastic logit model can be estimated using the HETERO statement. If the variance of the logit model is a function of the family income level excluding wife's income (nwifeinc), the variance can be specified as

$$\text{Var}(\epsilon_i) = \sigma^2 \exp(\gamma * \text{nwifeinc}_i)$$

where σ^2 is normalized to 1 because the dependent variable is discrete. The following SAS statements estimate the heteroscedastic logit model:

```

/*-- Binary Logit with Heteroscedasticity --*/
proc qlim data=mroz;
  model inlf = nwifeinc educ exper expersq
              age kidslt6 kidsge6 / discrete(d=logit);
  hetero inlf ~ nwifeinc / noconst;
run;

```

The parameter estimate, γ , of the heteroscedasticity variable is listed as _H.nwifeinc; see Figure 22.6.

Figure 22.6 Parameter Estimates of Binary Logit with Heteroscedasticity

_H.nwifeinc	1	0.013280	0.013606	0.98	0.3291

Syntax: QLIM Procedure

The QLIM procedure is controlled by the following statements:

```

PROC QLIM options ;
BOUNDS bound1 < , bound2 ... > ;
BY variables ;
CLASS variables ;
FREQ variable ;
ENDOGENOUS variables ~ options ;
HETERO dependent variables ~ exogenous variables / options ;
INIT initvalue1 < , initvalue2 ... > ;
MODEL dependent variables = regressors / options ;
NLOPTIONS options ;
OUTPUT options ;
RESTRICT restriction1 < , restriction2 ... > ;
TEST options ;
WEIGHT variable ;

```

At least one MODEL statement is required. If more than one MODEL statement is used, the QLIM procedure estimates a system of models. If a FREQ or WEIGHT statement is specified more than once, the variable specified in the first instance is used. Main effects and higher-order terms can be specified in the MODEL statement, as in the GLM procedure and PROBIT procedure in SAS/STAT. If a CLASS statement is used, it must precede the MODEL statement.

Functional Summary

Table 22.1 summarizes the statements and options used with the QLIM procedure.

Table 22.1 QLIM Functional Summary

Description	Statement	Option
Data Set Options		
Specifies the input data set	QLIM	DATA=
Writes parameter estimates to an output data set	QLIM	OUTEST=
Writes predictions to an output data set	OUTPUT	OUT=
Declaring the Role of Variables		
Specifies BY-group processing	BY	
Specifies classification variables	CLASS	
Specifies a frequency variable	FREQ	
Specifies a weight variable	WEIGHT	NONNORMALIZE
Printing Control Options		
Requests all printing options	QLIM	PRINTALL
Prints correlation matrix of the estimates	QLIM	CORRB
Prints covariance matrix of the estimates	QLIM	COVB
Prints a summary iteration listing	QLIM	ITPRINT
Suppresses the normal printed output	QLIM	NOPRINT
Options to Control the Optimization Process		
Specifies the optimization method	QLIM	METHOD=
Specifies the optimization options	NLOPTIONS	see Chapter 6, “Non-linear Optimization Methods,”
Sets initial values for parameters	INIT	
Specifies upper and lower bounds for the parameter estimates	BOUNDS	
Specifies linear restrictions on the parameter estimates	RESTRICT	
Model Estimation Options		
Specifies options specific to Box-Cox transformation	MODEL	BOXCOX()
Suppresses the intercept parameter	MODEL	NOINT
Specifies a seed for pseudo-random number generation	QLIM	SEED=
Specifies number of draws for Monte Carlo integration	QLIM	NDRAW=
Specifies method to calculate parameter covariance	QLIM	COVEST=
Endogenous Variable Options

Requests the Lagrange multiplier test	TEST	LM
Requests the likelihood ratio test	TEST	LR

PROC QLIM Statement

PROC QLIM *options* ;

The following options can be used in the PROC QLIM statement.

Data Set Options

DATA=SAS-data-set

specifies the input SAS data set. If the DATA= option is not specified, PROC QLIM uses the most recently created SAS data set.

Output Data Set Options

OUTEST=SAS-data-set

writes the parameter estimates to an output data set.

COVOUT

writes the covariance matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

CORROUT

writes the correlation matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

Printing Options

NOPRINT

suppresses the normal printed output but does not suppress error listings. If NOPRINT option is set, then any other print option is turned off.

PRINTALL

turns on all the printing-control options. The options set by PRINTALL are COVB and CORRB.

CORRB

prints the correlation matrix of the parameter estimates.

COVB

prints the covariance matrix of the parameter estimates.

ITPRINT

prints the initial parameter estimates, convergence criteria, and all constraints of the optimization. At each iteration, objective function value, step size, maximum gradient, and slope of search direction are printed as well.

Model Estimation Options

COVEST=covariance-option

specifies the method to calculate the covariance matrix of parameter estimates. The supported covariance types are as follows:

OP specifies the covariance from the outer product matrix.

HESSIAN	specifies the covariance from the inverse Hessian matrix.
QML	specifies the covariance from the outer product and Hessian matrices (the quasi-maximum likelihood estimates).

The default is COVEST=HESSIAN.

NDRAW=value

specifies the number of draws for Monte Carlo integration.

SEED=value

specifies a seed for pseudo-random number generation in Monte Carlo integration.

Options to Control the Optimization Process

PROC QLIM uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. All the NLO options are available from the NLOPTIONS statement. For details, see Chapter 6, “[Nonlinear Optimization Methods](#).”

METHOD=value

specifies the optimization method. If this option is specified, it overwrites the TECH= option in NLOPTIONS statement. Valid values are as follows:

CONGRA	performs a conjugate-gradient optimization
DBLDOG	performs a version of double-dogleg optimization
NMSIMP	performs a Nelder-Mead simplex optimization
NEWRAP	performs a Newton-Raphson optimization combining a line-search algorithm with ridging
NRRIDG	performs a Newton-Raphson optimization with ridging
QUANEW	performs a quasi-Newton optimization
TRUREG	performs a trust region optimization

The default method is METHOD=QUANEW.

BOUNDS Statement

BOUNDS *bound1* < , *bound2* ... > ;

The BOUNDS statement imposes simple boundary constraints on the parameter estimates. BOUNDS statement constraints refer to the parameters estimated by the QLIM procedure. Any number of BOUNDS statements can be specified.

Each *bound* is composed of parameters and constants and inequality operators. Parameters associated with regressor variables are referred to by the names of the corresponding regressor variables:

item operator item < operator item < operator item ... > >

Each *item* is a constant, the name of a parameter, or a list of parameter names. See the section “[Naming of Parameters](#)” on page 1491 for more details on how parameters are named in the QLIM procedure. Each *operator* is '<', '>', '<=', or '>='.

Both the BOUNDS statement and the RESTRICT statement can be used to impose boundary constraints; however, the BOUNDS statement provides a simpler syntax for specifying these kinds of constraints. See the “[RESTRICT Statement](#)” on page 1468 for more information.

The following BOUNDS statement constrains the estimates of the parameters associated with the variable *ttime* and the variables *x1* through *x10* to be between zero and one. This example illustrates the use of parameter lists to specify boundary constraints.

```
bounds 0 < ttime x1-x10 < 1;
```

The following BOUNDS statement constrains the estimates of the correlation (*_RHO*) and sigma (*_SIGMA*) in the bivariate model:

```
bounds _rho >= 0, _sigma.y1 > 1, _sigma.y2 < 5;
```

BY Statement

BY *variables* ;

A BY statement can be used with PROC QLIM to obtain separate analyses on observations in groups defined by the BY variables.

CLASS Statement

CLASS *variables* ;

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric.

Class levels are determined from the formatted values of the CLASS variables. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in *SAS Language Reference: Dictionary* for details.

ENDOGENOUS Statement

ENDOGENOUS *variables ~ options* ;

The ENDOGENOUS statement specifies the type of dependent variables that appear on the left-hand side of the equation. Endogenous variables listed refer to the dependent variables that appear on the left-hand side of the equation. Currently, no right-hand side endogeneity is handled in PROC QLIM. All variables appearing on the right-hand side of the equation are treated as exogenous.

Discrete Variable Options

DISCRETE <(*discrete-options*)>

specifies that the endogenous variables in this statement are discrete. Valid *discrete-options* are as follows:

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sorting order for the levels of the discrete variables specified in the ENDOGENOUS statement. This ordering determines which parameters in the model correspond to each level in the data. The following table shows how PROC QLIM interprets values of the ORDER= option.

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	Formatted value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, ORDER=FORMATTED. For the values FORMATTED and INTERNAL, the sort order is machine dependent. For more information about sorting order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide*.

DISTRIBUTION=*distribution-type*

DIST=*distribution-type*

D=*distribution-type*

specifies the cumulative distribution function used to model the response probabilities. Valid values for *distribution-type* are as follows:

NORMAL the normal distribution for the probit model
 LOGISTIC the logistic distribution for the logit model

By default, DISTRIBUTION=NORMAL.

If a multivariate model is specified, logistic distribution is not allowed. Only normal distribution is supported.

Censored Variable Options

CENSORED <(*censored-options*)>

specifies that the endogenous variables in this statement be censored. Valid *censored-options* are as follows:

LB=*value or variable*

LOWERBOUND=*value or variable*

specifies the lower bound of the censored variables. If *value* is missing or the value in *variable* is missing, no lower bound is set. By default, no lower bound is set.

UB=*value or variable*

UPPERBOUND=*value or variable*

specifies the upper bound of the censored variables. If *value* is missing or the value in *variable* is missing, no upper bound is set. By default, no upper bound is set.

Truncated Variable Options

TRUNCATED <(*truncated-options*)>

specifies that the endogenous variables in this statement be truncated. Valid *truncated-options* are as follows:

LB=*value or variable*

LOWERBOUND=*value or variable*

specifies the lower bound of the truncated variables. If *value* is missing or the value in *variable* is missing, no lower bound is set. By default, no lower bound is set.

UB=*value or variable*

UPPERBOUND=*value or variable*

specifies the upper bound of the truncated variables. If *value* is missing or the value in *variable* is missing, no upper bound is set. By default, no upper bound is set.

Stochastic Frontier Variable Options

FRONTIER <(*frontier-options*)>

specifies that the endogenous variable in this statement follow a production or cost frontier. Valid *frontier-options* are as follows:

TYPE=

HALF specifies half-normal model.

EXPONENTIAL specifies exponential model.

TRUNCATED specifies truncated normal model.

PRODUCTION

specifies that the model estimated be a production function.

COST

specifies that the model estimated be a cost function.

If neither PRODUCTION nor COST option is specified, production function is estimated by default.

Selection Options

SELECT (*select-option*)

specifies selection criteria for sample selection model. *Select-option* specifies the condition for the endogenous variable to be selected. It is written as a variable name, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a number:

variable operator number

The *variable* is the endogenous variable that the selection is based on. The *operator* can be =, <, >, <=, or >=. Multiple *select-options* can be combined with the logic operators: AND, OR. The following example illustrates the use of the SELECT option:

```
endogenous y1 ~ select (z=0);
endogenous y2 ~ select (z=1 or z=2);
```

The SELECT option can be used together with the DISCRETE, CENSORED, or TRUNCATED option. For example:

```
endogenous y1 ~ select (z=0) discrete;
endogenous y2 ~ select (z=1) censored (lb=0);
endogenous y3 ~ select (z=1 or z=2) truncated (ub=10);
```

For more details about selection models with censoring or truncation, see the section “[Selection Models](#)” on page 1483.

FREQ Statement

FREQ *variable* ;

The FREQ statement identifies a variable that contains the frequency of occurrence of each observation. PROC QLIM treats each observation as if it appears n times, where n is the value of the FREQ variable for the observation. If it is not an integer, the frequency value is truncated to an integer. If the frequency value is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not specified, each observation is assigned a frequency of 1. If you specify more than one FREQ statement, then the first FREQ statement is used.

HETERO Statement

HETERO *dependent variables* ~ *exogenous variables* </ options > ;

The HETERO statement specifies variables that are related to the heteroscedasticity of the residuals and the way these variables are used to model the error variance. The heteroscedastic regression model supported

by PROC QLIM is

$$y_i = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$\epsilon_i \sim N(0, \sigma_i^2)$$

See the section “[Heteroscedasticity](#)” on page 1480 for more details on the specification of functional forms.

LINK=value

The functional form can be specified using the LINK= option. The following option values are allowed:

EXP specifies the exponential link function

$$\sigma_i^2 = \sigma^2(1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma}))$$

LINEAR specifies the linear link function

$$\sigma_i^2 = \sigma^2(1 + \mathbf{z}_i' \boldsymbol{\gamma})$$

When the LINK= option is not specified, the exponential link function is specified by default.

NOCONST

specifies that there be no constant in the linear or exponential heteroscedasticity model.

$$\sigma_i^2 = \sigma^2(\mathbf{z}_i' \boldsymbol{\gamma})$$

$$\sigma_i^2 = \sigma^2 \exp(\mathbf{z}_i' \boldsymbol{\gamma})$$

SQUARE

estimates the model by using the square of linear heteroscedasticity function. For example, you can specify the following heteroscedasticity function:

$$\sigma_i^2 = \sigma^2(1 + (\mathbf{z}_i' \boldsymbol{\gamma})^2)$$

```
model y = x1 x2 / discrete;
hetero y ~ z1 / link=linear square;
```

The option SQUARE does not apply to exponential heteroscedasticity function because the square of an exponential function of $\mathbf{z}_i' \boldsymbol{\gamma}$ is the same as the exponential of $2\mathbf{z}_i' \boldsymbol{\gamma}$. Hence the only difference is that all $\boldsymbol{\gamma}$ estimates are divided by two.

INIT Statement

```
INIT initvalue1 < , initvalue2 ... > ;
```

The INIT statement is used to set initial values for parameters in the optimization. Any number of INIT statements can be specified.

Each *initvalue* is written as a parameter or parameter list, followed by an optional equality operator (=), followed by a number:

parameter <=> **number**

MODEL Statement

MODEL *dependent* = *regressors* < / *options* > ;

The MODEL statement specifies the dependent variable and independent regressor variables for the regression model.

The following options can be used in the MODEL statement after a slash (/).

LIMIT1=*value*

specifies the restriction of the threshold value of the first category when the ordinal probit or logit model is estimated. LIMIT1=ZERO is the default option. When LIMIT1=VARYING is specified, the threshold value is estimated.

NOINT

suppresses the intercept parameter.

Endogenous Variable Options

The endogenous variable options are the same as the options specified in the ENDOGENOUS statement. If an endogenous variable has an endogenous option specified in both the MODEL statement and the ENDOGENOUS statement, the option in the ENDOGENOUS statement is used.

BOXCOX Estimation Options

BOXCOX (*option-list*)

specifies options that are used for Box-Cox regression or regressor transformation. For example, the Box-Cox regression is specified as

```
model y = x1 x2 / boxcox(y=lambda,x1 x2)
```

PROC QLIM estimates the following Box-Cox regression model:

$$y_i^{(\lambda)} = \beta_0 + \beta_1 x_{1i}^{(\lambda_1)} + \beta_2 x_{2i}^{(\lambda_2)} + \epsilon_i$$

The *option-list* takes the form *variable-list* < = *varname* > separated by ','. The *variable-list* specifies that the list of variables have the same Box-Cox transformation; *varname* specifies the name of this Box-Cox coefficient. If *varname* is not specified, the coefficient is called *_Lambdai*, where *i* increments sequentially.

NLOPTIONS Statement

NLOPTIONS *< options >* ;

PROC QLIM uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. For a list of all the options of the NLOPTIONS statement, see Chapter 6, “[Nonlinear Optimization Methods](#).”

OUTPUT Statement

OUTPUT *< OUT=SAS-data-set >* *< output-options >* ;

The OUTPUT statement creates a new SAS data set containing all variables in the input data set and, optionally, the estimates of $\mathbf{x}'\boldsymbol{\beta}$, predicted value, residual, marginal effects, probability, standard deviation of the error, expected value, conditional expected value, technical efficiency measures, and inverse Mills ratio. When the response values are missing for the observation, all output estimates except residual are still computed as long as none of the explanatory variables is missing. This enables you to compute these statistics for prediction. You can specify only one OUTPUT statement.

Details on the specifications in the OUTPUT statement are as follows:

CONDITIONAL

outputs estimates of conditional expected values of continuous endogenous variables.

ERRSTD

outputs estimates of σ_j , the standard deviation of the error term.

EXPECTED

outputs estimates of expected values of continuous endogenous variables.

MARGINAL

outputs marginal effects.

MILLS

outputs estimates of inverse Mills ratios of censored or truncated continuous, binary discrete, and selection endogenous variables.

OUT=SAS-data-set

names the output data set.

PREDICTED

outputs estimates of predicted endogenous variables.

PROB

outputs estimates of probability of discrete endogenous variables taking the current observed responses.

PROBALL

outputs estimates of probability of discrete endogenous variables for all possible responses.

RESIDUAL

outputs estimates of residuals of continuous endogenous variables.

XBETA

outputs estimates of $\mathbf{x}'\boldsymbol{\beta}$.

TE1

outputs estimates of technical efficiency for each producer in the stochastic frontier model suggested by Battese and Coelli (1988).

TE2

outputs estimates of technical efficiency for each producer in the stochastic frontier model suggested by Jondrow et al. (1982).

RESTRICT Statement

RESTRICT *restriction1* <, *restriction2* ... > ;

The RESTRICT statement is used to impose linear restrictions on the parameter estimates. Any number of RESTRICT statements can be specified, but the number of restrictions imposed is limited by the number of regressors.

Each *restriction* is written as an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

expression operator expression

The *operator* can be =, <, >, <=, or >=. The operator and second expression are optional.

Restriction expressions can be composed of parameter names, multiplication (*), addition (+) and subtraction (−) operators, and constants. Parameters named in restriction expressions must be among the parameters estimated by the model. Parameters associated with a regressor variable are referred to by the name of the corresponding regressor variable. The restriction expressions must be a linear function of the parameters.

The following is an example of the use of the RESTRICT statement:

```
proc qlim data=one;
  model y = x1-x10 / discrete;
  restrict x1*x2 <= x2 + x3;
run;
```

The RESTRICT statement can also be used to impose cross-equation restrictions in multivariate models. The following RESTRICT statement imposes an equality restriction on coefficients of x_1 in equation y_1 and x_1 in equation y_2 :

```
proc qlim data=one;
  model y1 = x1-x10;
  model y2 = x1-x4;
  endogenous y1 y2 ~ discrete;
  restrict y1.x1=y2.x1;
run;
```

TEST Statement

<'label':> TEST <'string':> equation [,equation...]/ options ;

The TEST statement performs Wald, Lagrange multiplier, and likelihood ratio tests of linear hypotheses about the regression parameters in the preceding MODEL statement. Each equation specifies a linear hypothesis to be tested. All hypotheses in one TEST statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. The keyword INTERCEPT refers to the coefficient of the intercept.

The following options can be specified in the TEST statement after the slash (/):

ALL

requests Wald, Lagrange multiplier, and likelihood ratio tests.

WALD

requests the Wald test.

LM

requests the Lagrange multiplier test.

LR

requests the likelihood ratio test.

The following illustrates the use of the TEST statement:

```
proc qlim;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0;
  test _int: test intercept = 0, x3 = 0;
run;
```

The first test investigates the joint hypothesis that

$$\beta_1 = 0$$

and

$$0.5\beta_2 + 2\beta_3 = 0$$

In case there is more than one MODEL statement in one QLIM procedure, then TEST statement is capable of testing cross equation restrictions. Each parameter reference should be preceded by the name of the dependent variable of the particular model and the dot sign. For example,

```
proc qlim;
  model y1 = x1 x2 x3;
  model y2 = x3 x5 x6;
  test y1.x1 + y2.x6 = 1;
run;
```

This cross equation test investigates the null hypothesis that

$$\beta_{1,1} + \beta_{2,3} = 1$$

in the system of equations

$$\begin{aligned} y_{1,i} &= \alpha_1 + \beta_{1,1}x_{1,i} + \beta_{1,2}x_{2,i} + \beta_{1,3}x_{3,i} \\ y_{2,i} &= \alpha_2 + \beta_{2,1}x_{3,i} + \beta_{2,2}x_{5,i} + \beta_{2,3}x_{6,i}. \end{aligned}$$

Only linear equality restrictions and tests are permitted in PROC QLIM. Tests expressions can be composed only of algebraic operations involving the addition symbol (+), subtraction symbol (-), and multiplication symbol (*).

The TEST statement accepts labels that are reproduced in the printed output. TEST statement can be labeled in two ways. A TEST statement can be preceded by a label followed by a colon. Alternatively, the keyword TEST can be followed by a quoted string. If both are present, PROC QLIM uses the label preceding the colon. In the event no label is present, PROC QLIM automatically labels the tests.

WEIGHT Statement

WEIGHT *variable* </ option> ;

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters. The log likelihood for each observation is multiplied by the corresponding weight variable value.

If the weight of an observation is nonpositive, that observation is not used in the estimation.

The following option can be added to the WEIGHT statement after a slash (/).

NONNORMALIZE

specifies that the weights are required to be used as is. When this option is not specified, the weights are normalized so that they add up to the actual sample size. Weights w_i are normalized by multiplying them by $\frac{n}{\sum_{i=1}^n w_i}$, where n is the sample size.

Details: QLIM Procedure

Ordinal Discrete Choice Modeling

Binary Probit and Logit Model

The binary choice model is

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

where value of the latent dependent variable, y_i^* , is observed only as follows:

$$\begin{aligned} y_i &= 1 \quad \text{if } y_i^* > 0 \\ &= 0 \quad \text{otherwise} \end{aligned}$$

The disturbance, ϵ_i , of the probit model has standard normal distribution with the distribution function (CDF)

$$\Phi(x) = \int_{-\infty}^x \frac{1}{\sqrt{2\pi}} \exp(-t^2/2) dt$$

The disturbance of the logit model has standard logistic distribution with the CDF

$$\Lambda(x) = \frac{\exp(x)}{1 + \exp(x)} = \frac{1}{1 + \exp(-x)}$$

The binary discrete choice model has the following probability that the event $\{y_i = 1\}$ occurs:

$$P(y_i = 1) = F(\mathbf{x}_i' \boldsymbol{\beta}) = \begin{cases} \Phi(\mathbf{x}_i' \boldsymbol{\beta}) & \text{(probit)} \\ \Lambda(\mathbf{x}_i' \boldsymbol{\beta}) & \text{(logit)} \end{cases}$$

The log-likelihood function is

$$\ell = \sum_{i=1}^N \{y_i \log[F(\mathbf{x}_i' \boldsymbol{\beta})] + (1 - y_i) \log[1 - F(\mathbf{x}_i' \boldsymbol{\beta})]\}$$

where the CDF $F(x)$ is defined as $\Phi(x)$ for the probit model while $F(x) = \Lambda(x)$ for logit. The first order derivative of the logit model are

$$\frac{\partial \ell}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N (y_i - \Lambda(\mathbf{x}_i' \boldsymbol{\beta})) \mathbf{x}_i$$

The probit model has more complicated derivatives

$$\frac{\partial \ell}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N \left[\frac{(2y_i - 1) \phi(\mathbf{x}_i' \boldsymbol{\beta})}{\Phi(\mathbf{x}_i' \boldsymbol{\beta})} \right] \mathbf{x}_i = \sum_{i=1}^N r_i \mathbf{x}_i$$

where

$$r_i = \frac{(2y_i - 1)\phi(\mathbf{x}'_i\boldsymbol{\beta})}{\Phi(\mathbf{x}'_i\boldsymbol{\beta})}$$

Note that the logit maximum likelihood estimates are $\frac{\pi}{\sqrt{3}}$ times greater than probit maximum likelihood estimates, since the probit parameter estimates, $\boldsymbol{\beta}$, are standardized, and the error term with logistic distribution has a variance of $\frac{\pi^2}{3}$.

Ordinal Probit/Logit

When the dependent variable is observed in sequence with M categories, binary discrete choice modeling is not appropriate for data analysis. McKelvey and Zavoina (1975) proposed the ordinal (or ordered) probit model.

Consider the following regression equation:

$$y_i^* = \mathbf{x}'_i\boldsymbol{\beta} + \epsilon_i$$

where error disturbances, ϵ_i , have the distribution function F . The unobserved continuous random variable, y_i^* , is identified as M categories. Suppose there are $M + 1$ real numbers, μ_0, \dots, μ_M , where $\mu_0 = -\infty$, $\mu_1 = 0$, $\mu_M = \infty$, and $\mu_0 \leq \mu_1 \leq \dots \leq \mu_M$. Define

$$R_{i,j} = \mu_j - \mathbf{x}'_i\boldsymbol{\beta}$$

The probability that the unobserved dependent variable is contained in the j th category can be written as

$$P[\mu_{j-1} < y_i^* \leq \mu_j] = F(R_{i,j}) - F(R_{i,j-1})$$

The log-likelihood function is

$$\ell = \sum_{i=1}^N \sum_{j=1}^M d_{ij} \log [F(R_{i,j}) - F(R_{i,j-1})]$$

where

$$d_{ij} = \begin{cases} 1 & \text{if } \mu_{j-1} < y_i \leq \mu_j \\ 0 & \text{otherwise} \end{cases}$$

The first derivatives are written as

$$\begin{aligned} \frac{\partial \ell}{\partial \boldsymbol{\beta}} &= \sum_{i=1}^N \sum_{j=1}^M d_{ij} \left[\frac{f(R_{i,j-1}) - f(R_{i,j})}{F(R_{i,j}) - F(R_{i,j-1})} \mathbf{x}_i \right] \\ \frac{\partial \ell}{\partial \mu_k} &= \sum_{i=1}^N \sum_{j=1}^M d_{ij} \left[\frac{\delta_{j,k} f(R_{i,j}) - \delta_{j-1,k} f(R_{i,j-1})}{F(R_{i,j}) - F(R_{i,j-1})} \right] \end{aligned}$$

where $f(x) = \frac{dF(x)}{dx}$ and $\delta_{j,k} = 1$ if $j = k$. When the ordinal probit is estimated, it is assumed that $F(R_{i,j}) = \Phi(R_{i,j})$. The ordinal logit model is estimated if $F(R_{i,j}) = \Lambda(R_{i,j})$. The first threshold

parameter, μ_1 , is estimated when the LIMIT1=VARYING option is specified. By default (LIMIT1=ZERO), so that $M - 2$ threshold parameters (μ_2, \dots, μ_{M-1}) are estimated.

The ordered probit models are analyzed by Aitchison and Silvey (1957), and Cox (1970) discussed ordered response data by using the logit model. They defined the probability that y_i^* belongs to j th category as

$$P[\mu_{j-1} < y_i \leq \mu_j] = F(\mu_j + \mathbf{x}_i' \boldsymbol{\theta}) - F(\mu_{j-1} + \mathbf{x}_i' \boldsymbol{\theta})$$

where $\mu_0 = -\infty$ and $\mu_M = \infty$. Therefore, the ordered response model analyzed by Aitchison and Silvey can be estimated if the LIMIT1=VARYING option is specified. Note that $\boldsymbol{\theta} = -\boldsymbol{\beta}$.

Goodness-of-Fit Measures

The goodness-of-fit measures discussed in this section apply only to discrete dependent variable models.

McFadden (1974) suggested a likelihood ratio index that is analogous to the R^2 in the linear regression model:

$$R_M^2 = 1 - \frac{\ln L}{\ln L_0}$$

where L is the value of the maximum likelihood function and L_0 is a likelihood function when regression coefficients except an intercept term are zero. It can be shown that L_0 can be written as

$$L_0 = \sum_{j=1}^M N_j \ln\left(\frac{N_j}{N}\right)$$

where N_j is the number of responses in category j .

Estrella (1998) proposes the following requirements for a goodness-of-fit measure to be desirable in discrete choice modeling:

- The measure must take values in $[0, 1]$, where 0 represents no fit and 1 corresponds to perfect fit.
- The measure should be directly related to the valid test statistic for significance of all slope coefficients.
- The derivative of the measure with respect to the test statistic should comply with corresponding derivatives in a linear regression.

Estrella's (1998) measure is written

$$R_{E1}^2 = 1 - \left(\frac{\ln L}{\ln L_0} \right)^{-\frac{2}{N} \ln L_0}$$

An alternative measure suggested by Estrella (1998) is

$$R_{E2}^2 = 1 - [(\ln L - K) / \ln L_0]^{-\frac{2}{N} \ln L_0}$$

where $\ln L_0$ is computed with null slope parameter values, N is the number observations used, and K represents the number of estimated parameters.

Other goodness-of-fit measures are summarized as follows:

$$R_{CU1}^2 = 1 - \left(\frac{L_0}{L} \right)^{\frac{2}{N}} \quad (\text{Cragg} - \text{Uhler1})$$

$$R_{CU2}^2 = \frac{1 - (L_0/L)^{\frac{2}{N}}}{1 - L_0^{\frac{2}{N}}} \quad (\text{Cragg} - \text{Uhler2})$$

$$R_A^2 = \frac{2(\ln L - \ln L_0)}{2(\ln L - \ln L_0) + N} \quad (\text{Aldrich} - \text{Nelson})$$

$$R_{VZ}^2 = R_A^2 \frac{2 \ln L_0 - N}{2 \ln L_0} \quad (\text{Veall} - \text{Zimmermann})$$

$$R_{MZ}^2 = \frac{\sum_{i=1}^N (\hat{y}_i - \bar{\hat{y}})^2}{N + \sum_{i=1}^N (\hat{y}_i - \bar{\hat{y}})^2} \quad (\text{McKelvey} - \text{Zavoina})$$

where $\hat{y}_i = \mathbf{x}_i' \hat{\boldsymbol{\beta}}$ and $\bar{\hat{y}} = \sum_{i=1}^N \hat{y}_i / N$.

Limited Dependent Variable Models

Censored Regression Models

When the dependent variable is censored, values in a certain range are all transformed to a single value. For example, the standard tobit model can be defined as

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$y_i = \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases}$$

where $\epsilon_i \sim iidN(0, \sigma^2)$. The log-likelihood function of the standard censored regression model is

$$\ell = \sum_{i \in \{y_i=0\}} \ln[1 - \Phi(\mathbf{x}_i' \boldsymbol{\beta} / \sigma)] + \sum_{i \in \{y_i>0\}} \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) / \sigma \right]$$

where $\Phi(\cdot)$ is the cumulative density function of the standard normal distribution and $\phi(\cdot)$ is the probability density function of the standard normal distribution.

The tobit model can be generalized to handle observation-by-observation censoring. The censored model on both of the lower and upper limits can be defined as

$$y_i = \begin{cases} R_i & \text{if } y_i^* \geq R_i \\ y_i^* & \text{if } L_i < y_i^* < R_i \\ L_i & \text{if } y_i^* \leq L_i \end{cases}$$

The log-likelihood function can be written as

$$\begin{aligned} \ell = & \sum_{i \in \{L_i < y_i < R_i\}} \ln \left[\phi \left(\frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) / \sigma \right] + \sum_{i \in \{y_i = R_i\}} \ln \left[\Phi \left(-\frac{R_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) \right] + \\ & \sum_{i \in \{y_i = L_i\}} \ln \left[\Phi \left(\frac{L_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) \right] \end{aligned}$$

Log-likelihood functions of the lower- or upper-limit censored model are easily derived from the two-limit censored model. The log-likelihood function of the lower-limit censored model is

$$\ell = \sum_{i \in \{y_i > L_i\}} \ln \left[\phi \left(\frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) / \sigma \right] + \sum_{i \in \{y_i = L_i\}} \ln \left[\Phi \left(\frac{L_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) \right]$$

The log-likelihood function of the upper-limit censored model is

$$\ell = \sum_{i \in \{y_i < R_i\}} \ln \left[\phi \left(\frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) / \sigma \right] + \sum_{i \in \{y_i = R_i\}} \ln \left[1 - \Phi \left(\frac{R_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) \right]$$

Types of Tobit Models

Amemiya (1984) classified Tobit models into five types based on characteristics of the likelihood function. For notational convenience, let P denote a distribution or density function, y_{ji}^* is assumed to be normally distributed with mean $\mathbf{x}'_{ji} \boldsymbol{\beta}_j$ and variance σ_j^2 .

Type 1 Tobit

The Type 1 Tobit model was already discussed in the preceding section.

$$\begin{aligned} y_{1i}^* &= \mathbf{x}'_{1i} \boldsymbol{\beta}_1 + u_{1i} \\ y_{1i} &= y_{1i}^* \quad \text{if } y_{1i}^* > 0 \\ &= 0 \quad \text{if } y_{1i}^* \leq 0 \end{aligned}$$

The likelihood function is characterized as $P(y_1 < 0)P(y_1)$.

Type 2 Tobit

The Type 2 Tobit model is defined as

$$\begin{aligned}
 y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + u_{1i} \\
 y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + u_{2i} \\
 y_{1i} &= 1 \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{2i} &= y_{2i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0
 \end{aligned}$$

where $(u_{1i}, u_{2i}) \sim N(0, \Sigma)$. The likelihood function is described as $P(y_1 < 0)P(y_1 > 0, y_2)$.

Type 3 Tobit

The Type 3 Tobit model is different from the Type 2 Tobit in that y_{1i}^* of the Type 3 Tobit is observed when $y_{1i}^* > 0$.

$$\begin{aligned}
 y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + u_{1i} \\
 y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + u_{2i} \\
 y_{1i} &= y_{1i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{2i} &= y_{2i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0
 \end{aligned}$$

where $(u_{1i}, u_{2i})' \sim iidN(0, \Sigma)$.

The likelihood function is characterized as $P(y_1 < 0)P(y_1, y_2)$.

Type 4 Tobit

The Type 4 Tobit model consists of three equations:

$$\begin{aligned}
 y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + u_{1i} \\
 y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + u_{2i} \\
 y_{3i}^* &= \mathbf{x}_{3i}'\boldsymbol{\beta}_3 + u_{3i} \\
 y_{1i} &= y_{1i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{2i} &= y_{2i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{3i} &= y_{3i}^* \quad \text{if } y_{1i}^* \leq 0 \\
 &= 0 \quad \text{if } y_{1i}^* > 0
 \end{aligned}$$

where $(u_{1i}, u_{2i}, u_{3i})' \sim iidN(0, \Sigma)$. The likelihood function of the Type 4 Tobit model is characterized as $P(y_1 < 0, y_3)P(y_1, y_2)$.

Type 5 Tobit

The Type 5 Tobit model is defined as follows:

$$\begin{aligned}
 y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + u_{1i} \\
 y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + u_{2i} \\
 y_{3i}^* &= \mathbf{x}_{3i}'\boldsymbol{\beta}_3 + u_{3i} \\
 y_{1i} &= 1 \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{2i} &= y_{2i}^* \quad \text{if } y_{1i}^* > 0 \\
 &= 0 \quad \text{if } y_{1i}^* \leq 0 \\
 y_{3i} &= y_{3i}^* \quad \text{if } y_{1i}^* \leq 0 \\
 &= 0 \quad \text{if } y_{1i}^* > 0
 \end{aligned}$$

where $(u_{1i}, u_{2i}, u_{3i})'$ are from *iid* trivariate normal distribution. The likelihood function of the Type 5 Tobit model is characterized as $P(y_1 < 0, y_3)P(y_1 > 0, y_2)$.

Code examples for these models can be found in “[Example 22.6: Types of Tobit Models](#)” on page 1503.

Truncated Regression Models

In a truncated model, the observed sample is a subset of the population where the dependent variable falls in a certain range. For example, when neither a dependent variable nor exogenous variables are observed for $y_i^* \leq 0$, the truncated regression model can be specified.

$$\ell = \sum_{i \in \{y_i > 0\}} \left\{ -\ln \Phi(\mathbf{x}_i'\boldsymbol{\beta}/\sigma) + \ln \left[\frac{\phi((y_i - \mathbf{x}_i'\boldsymbol{\beta})/\sigma)}{\sigma} \right] \right\}$$

Two-limit truncation model is defined as

$$y_i = y_i^* \text{ if } L_i < y_i^* < R_i$$

The log-likelihood function of the two-limit truncated regression model is

$$\ell = \sum_{i=1}^N \left\{ \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right)/\sigma \right] - \ln \left[\Phi\left(\frac{R_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right) - \Phi\left(\frac{L_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right) \right] \right\}$$

The log-likelihood functions of the lower- and upper-limit truncation model are

$$\begin{aligned}
 \ell &= \sum_{i=1}^N \left\{ \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right)/\sigma \right] - \ln \left[1 - \Phi\left(\frac{L_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right) \right] \right\} \quad (\text{lower}) \\
 \ell &= \sum_{i=1}^N \left\{ \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right)/\sigma \right] - \ln \left[\Phi\left(\frac{R_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right) \right] \right\} \quad (\text{upper})
 \end{aligned}$$

Stochastic Frontier Production and Cost Models

Stochastic frontier production models were first developed by Aigner, Lovell, and Schmidt (1977) and Meeusen and van den Broeck (1977). Specification of these models allow for random shocks of the production or cost but also include a term for technological or cost inefficiency. Assuming that the production function takes a log-linear Cobb-Douglas form, the stochastic frontier production model can be written as

$$\ln(y_i) = \beta_0 + \sum_n \beta_n \ln(x_{ni}) + \epsilon_i$$

where $\epsilon_i = v_i - u_i$. The v_i term represents the stochastic error component and u_i is the nonnegative, technology inefficiency error component. The v_i error component is assumed to be distributed iid normal and independently from u_i . If $u_i > 0$, the error term, ϵ_i , is negatively skewed and represents technology inefficiency. If $u_i < 0$, the error term ϵ_i is positively skewed and represents cost inefficiency. PROC QLIM models the u_i error component as a half normal, exponential, or truncated normal distribution.

The Normal-Half Normal Model

In case of the normal-half normal model, v_i is iid $N(0, \sigma_v^2)$, u_i is iid $N^+(0, \sigma_u^2)$ with v_i and u_i independent of each other. Given the independence of error terms, the joint density of v and u can be written as

$$f(u, v) = \frac{2}{2\pi\sigma_u\sigma_v} \exp \left\{ -\frac{u^2}{2\sigma_u^2} - \frac{v^2}{2\sigma_v^2} \right\}$$

Substituting $v = \epsilon + u$ into the preceding equation gives

$$f(u, \epsilon) = \frac{2}{2\pi\sigma_u\sigma_v} \exp \left\{ -\frac{u^2}{2\sigma_u^2} - \frac{(\epsilon + u)^2}{2\sigma_v^2} \right\}$$

Integrating u out to obtain the marginal density function of ϵ results in the following form:

$$\begin{aligned} f(\epsilon) &= \int_0^\infty f(u, \epsilon) du \\ &= \frac{2}{\sqrt{2\pi}\sigma} \left[1 - \phi \left(\frac{\epsilon\lambda}{\sigma} \right) \right] \exp \left\{ -\frac{\epsilon^2}{2\sigma^2} \right\} \\ &= \frac{2}{\sigma} \phi \left(\frac{\epsilon}{\sigma} \right) \Phi \left(-\frac{\epsilon\lambda}{\sigma} \right) \end{aligned}$$

where $\lambda = \sigma_u/\sigma_v$ and $\sigma = \sqrt{\sigma_u^2 + \sigma_v^2}$.

In the case of a stochastic frontier cost model, $v = \epsilon - u$ and

$$f(\epsilon) = \frac{2}{\sigma} \phi \left(\frac{\epsilon}{\sigma} \right) \Phi \left(\frac{\epsilon\lambda}{\sigma} \right)$$

The log-likelihood function for the production model with N producers is written as

$$\ln L = \text{constant} - N \ln \sigma + \sum_i \ln \Phi \left(-\frac{\epsilon_i \lambda}{\sigma} \right) - \frac{1}{2\sigma^2} \sum_i \epsilon_i^2$$

The Normal-Exponential Model

Under the normal-exponential model, v_i is iid $N(0, \sigma_v^2)$ and u_i is iid exponential. Given the independence of error term components u_i and v_i , the joint density of v and u can be written as

$$f(u, v) = \frac{1}{\sqrt{2\pi}\sigma_u\sigma_v} \exp \left\{ -\frac{u}{\sigma_u} - \frac{v^2}{2\sigma_v^2} \right\}$$

The marginal density function of ϵ for the production function is

$$\begin{aligned} f(\epsilon) &= \int_0^\infty f(u, \epsilon) du \\ &= \left(\frac{1}{\sigma_u} \right) \Phi \left(-\frac{\epsilon}{\sigma_v} - \frac{\sigma_v}{\sigma_u} \right) \exp \left\{ \frac{\epsilon}{\sigma_u} + \frac{\sigma_v^2}{2\sigma_u^2} \right\} \end{aligned}$$

and the marginal density function for the cost function is equal to

$$f(\epsilon) = \left(\frac{1}{\sigma_u} \right) \Phi \left(\frac{\epsilon}{\sigma_v} - \frac{\sigma_v}{\sigma_u} \right) \exp \left\{ -\frac{\epsilon}{\sigma_u} + \frac{\sigma_v^2}{2\sigma_u^2} \right\}$$

The log-likelihood function for the normal-exponential production model with N producers is

$$\ln L = \text{constant} - N \ln \sigma_u + N \left(\frac{\sigma_v^2}{2\sigma_u^2} \right) + \sum_i \frac{\epsilon_i}{\sigma_u} + \sum_i \ln \Phi \left(\frac{\epsilon_i}{\sigma_v} - \frac{\sigma_v}{\sigma_u} \right)$$

The Normal-Truncated Normal Model

The normal-truncated normal model is a generalization of the normal-half normal model by allowing the mean of u_i to differ from zero. Under the normal-truncated normal model, the error term component v_i is iid $N^+(0, \sigma_v^2)$ and u_i is iid $N(\mu, \sigma_u^2)$. The joint density of v_i and u_i can be written as

$$f(u, v) = \frac{1}{\sqrt{2\pi}\sigma_u\sigma_v\Phi(\mu/\sigma_u)} \exp\left\{-\frac{(u-\mu)^2}{2\sigma_u^2} - \frac{v^2}{2\sigma_v^2}\right\}$$

The marginal density function of ϵ for the production function is

$$\begin{aligned} f(\epsilon) &= \int_0^\infty f(u, \epsilon) du \\ &= \frac{1}{\sqrt{2\pi}\sigma\Phi(\mu/\sigma_u)} \Phi\left(\frac{\mu}{\sigma\lambda} - \frac{\epsilon\lambda}{\sigma}\right) \exp\left\{-\frac{(\epsilon + \mu)^2}{2\sigma^2}\right\} \\ &= \frac{1}{\sigma}\phi\left(\frac{\epsilon + \mu}{\sigma}\right) \Phi\left(\frac{\mu}{\sigma\lambda} - \frac{\epsilon\lambda}{\sigma}\right) \left[\Phi\left(\frac{\mu}{\sigma_u}\right)\right]^{-1} \end{aligned}$$

and the marginal density function for the cost function is

$$f(\epsilon) = \frac{1}{\sigma}\phi\left(\frac{\epsilon - \mu}{\sigma}\right) \Phi\left(\frac{\mu}{\sigma\lambda} + \frac{\epsilon\lambda}{\sigma}\right) \left[\Phi\left(\frac{\mu}{\sigma_u}\right)\right]^{-1}$$

The log-likelihood function for the normal-truncated normal production model with N producers is

$$\begin{aligned} \ln L &= \text{constant} - N \ln \sigma - N \ln \Phi\left(\frac{\mu}{\sigma_u}\right) + \sum_i \ln \Phi\left(\frac{\mu}{\sigma\lambda} + \frac{\epsilon_i\lambda}{\sigma}\right) \\ &\quad - \frac{1}{2} \sum_i \left(\frac{\epsilon_i + \mu}{\sigma}\right)^2 \end{aligned}$$

For more detail on normal-half normal, normal-exponential, and normal-truncated models, see Kumbhakar and Knox Lovell (2000) and Coelli, Prasada Rao, and Battese (1998).

Heteroscedasticity and Box-Cox Transformation

Heteroscedasticity

If the variance of regression disturbance, (ϵ_i) , is heteroscedastic, the variance can be specified as a function of variables

$$E(\epsilon_i^2) = \sigma_i^2 = f(\mathbf{z}_i' \boldsymbol{\gamma})$$

The following table shows various functional forms of heteroscedasticity and the corresponding options to request each model.

No.	Model	Options
1	$f(\mathbf{z}'_i \boldsymbol{\gamma}) = \sigma^2(1 + \exp(\mathbf{z}'_i \boldsymbol{\gamma}))$	LINK=EXP (default)
2	$f(\mathbf{z}'_i \boldsymbol{\gamma}) = \sigma^2 \exp(\mathbf{z}'_i \boldsymbol{\gamma})$	LINK=EXP NOCONST
3	$f(\mathbf{z}'_i \boldsymbol{\gamma}) = \sigma^2(1 + \sum_{l=1}^L \gamma_l z_{li})$	LINK=LINEAR
4	$f(\mathbf{z}'_i \boldsymbol{\gamma}) = \sigma^2(1 + (\sum_{l=1}^L \gamma_l z_{li})^2)$	LINK=LINEAR SQUARE
5	$f(\mathbf{z}'_i \boldsymbol{\gamma}) = \sigma^2(\sum_{l=1}^L \gamma_l z_{li})$	LINK=LINEAR NOCONST
6	$f(\mathbf{z}'_i \boldsymbol{\gamma}) = \sigma^2((\sum_{l=1}^L \gamma_l z_{li})^2)$	LINK=LINEAR SQUARE NOCONST

For discrete choice models, σ^2 is normalized ($\sigma^2 = 1$) since this parameter is not identified. Note that in models 3 and 5, it may be possible that variances of some observations are negative. Although the QLIM procedure assigns a large penalty to move the optimization away from such region, it is possible that the optimization cannot improve the objective function value and gets locked in the region. Signs of such outcome include extremely small likelihood values or missing standard errors in the estimates. In models 2 and 6, variances are guaranteed to be greater or equal to zero, but it may be possible that variances of some observations are very close to zero. In these scenarios, standard errors may be missing. Models 1 and 4 do not have such problems. Variances in these models are always positive and never close to zero.

The heteroscedastic regression model is estimated using the following log-likelihood function:

$$\ell = -\frac{N}{2} \ln(2\pi) - \sum_{i=1}^N \frac{1}{2} \ln(\sigma_i^2) - \frac{1}{2} \sum_{i=1}^N \left(\frac{e_i}{\sigma_i}\right)^2$$

where $e_i = y_i - \mathbf{x}'_i \boldsymbol{\beta}$.

Box-Cox Modeling

The Box-Cox transformation on x is defined as

$$x^{(\lambda)} = \begin{cases} \frac{x^\lambda - 1}{\lambda} & \text{if } \lambda \neq 0 \\ \ln(x) & \text{if } \lambda = 0 \end{cases}$$

The Box-Cox regression model with heteroscedasticity is written as

$$\begin{aligned} y_i^{(\lambda_0)} &= \beta_0 + \sum_{k=1}^K \beta_k x_{ki}^{(\lambda_k)} + \epsilon_i \\ &= \mu_i + \epsilon_i \end{aligned}$$

where $\epsilon_i \sim N(0, \sigma_i^2)$ and transformed variables must be positive. In practice, too many transformation parameters cause numerical problems in model fitting. It is common to have the same Box-Cox transformation performed on all the variables — that is, $\lambda_0 = \lambda_1 = \dots = \lambda_K$. It is required for the magnitude

of transformed variables to be in the tolerable range if the corresponding transformation parameters are $|\lambda| > 1$.

The log-likelihood function of the Box-Cox regression model is written as

$$\ell = -\frac{N}{2} \ln(2\pi) - \sum_{i=1}^N \ln(\sigma_i) - \frac{1}{2\sigma_i^2} \sum_{i=1}^N e_i^2 + (\lambda_0 - 1) \sum_{i=1}^N \ln(y_i)$$

where $e_i = y_i^{(\lambda_0)} - \mu_i$.

When the dependent variable is discrete, censored, or truncated, the Box-Cox transformation can be applied only to explanatory variables.

Bivariate Limited Dependent Variable Modeling

The generic form of a bivariate limited dependent variable model is

$$\begin{aligned} y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + \epsilon_{1i} \\ y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + \epsilon_{2i} \end{aligned}$$

where the disturbances, ϵ_{1i} and ϵ_{2i} , have joint normal distribution with zero mean, standard deviations σ_1 and σ_2 , and correlation of ρ . y_1^* and y_2^* are latent variables. The dependent variables y_1 and y_2 are observed if the latent variables y_1^* and y_2^* fall in certain ranges:

$$\begin{aligned} y_1 &= y_{1i} \text{ if } y_{1i}^* \in D_1(y_{1i}) \\ y_2 &= y_{2i} \text{ if } y_{2i}^* \in D_2(y_{2i}) \end{aligned}$$

D is a transformation from (y_{1i}^*, y_{2i}^*) to (y_{1i}, y_{2i}) . For example, if y_1 and y_2 are censored variables with lower bound 0, then

$$\begin{aligned} y_1 &= y_{1i} \text{ if } y_{1i}^* > 0, & y_1 &= 0 \text{ if } y_{1i}^* \leq 0 \\ y_2 &= y_{2i} \text{ if } y_{2i}^* > 0, & y_2 &= 0 \text{ if } y_{2i}^* \leq 0 \end{aligned}$$

There are three cases for the log likelihood of (y_{1i}, y_{2i}) . The first case is that $y_{1i} = y_{1i}^*$ and $y_{2i} = y_{2i}^*$. That is, this observation is mapped to one point in the space of latent variables. The log likelihood is computed from a bivariate normal density,

$$\ell_i = \ln \left[\phi_2 \left(\frac{y_1 - \mathbf{x}_1'\boldsymbol{\beta}_1}{\sigma_1}, \frac{y_2 - \mathbf{x}_2'\boldsymbol{\beta}_2}{\sigma_2}, \rho \right) \right] - \ln \sigma_1 - \ln \sigma_2$$

where $\phi_2(u, v, \rho)$ is the density function for standardized bivariate normal distribution with correlation ρ ,

$$\phi_2(u, v, \rho) = \frac{e^{-(1/2)(u^2 + v^2 - 2\rho uv)/(1 - \rho^2)}}{2\pi(1 - \rho^2)^{1/2}}$$

The second case is that one observed dependent variable is mapped to a point of its latent variable and the other dependent variable is mapped to a segment in the space of its latent variable. For example, in the bivariate censored model specified, if observed $y_1 > 0$ and $y_2 = 0$, then $y_1^* = y_1$ and $y_2^* \in (-\infty, 0]$. In general, the log likelihood for one observation can be written as follows (the subscript i is dropped for simplicity): If one set is a single point and the other set is a range, without loss of generality, let $D_1(y_1) = \{y_1\}$ and $D_2(y_2) = [L_2, R_2]$,

$$\begin{aligned} \ell_i = & \ln \left[\phi \left(\frac{y_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1} \right) \right] - \ln \sigma_1 \\ & + \ln \left[\Phi \left(\frac{R_2 - \mathbf{x}_2' \boldsymbol{\beta}_2 - \rho \frac{y_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}}{\sigma_2} \right) - \Phi \left(\frac{L_2 - \mathbf{x}_2' \boldsymbol{\beta}_2 - \rho \frac{y_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}}{\sigma_2} \right) \right] \end{aligned}$$

where ϕ and Φ are the density function and the cumulative probability function for standardized univariate normal distribution.

The third case is that both dependent variables are mapped to segments in the space of latent variables. For example, in the bivariate censored model specified, if observed $y_1 = 0$ and $y_2 = 0$, then $y_1^* \in (-\infty, 0]$ and $y_2^* \in (-\infty, 0]$. In general, if $D_1(y_1) = [L_1, R_1]$ and $D_2(y_2) = [L_2, R_2]$, the log likelihood is

$$\ell_i = \ln \int_{\frac{L_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}}^{\frac{R_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}} \int_{\frac{L_2 - \mathbf{x}_2' \boldsymbol{\beta}_2}{\sigma_2}}^{\frac{R_2 - \mathbf{x}_2' \boldsymbol{\beta}_2}{\sigma_2}} \phi_2(u, v, \rho) du dv$$

Selection Models

In sample selection models, one or several dependent variables are observed when another variable takes certain values. For example, the standard Heckman selection model can be defined as

$$\begin{aligned} z_i^* &= \mathbf{w}_i' \boldsymbol{\gamma} + u_i \\ z_i &= \begin{cases} 1 & \text{if } z_i^* > 0 \\ 0 & \text{if } z_i^* \leq 0 \end{cases} \\ y_i &= \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i \quad \text{if } z_i = 1 \end{aligned}$$

where u_i and ϵ_i are jointly normal with zero mean, standard deviations of 1 and σ , and correlation of ρ . z is the variable that the selection is based on, and y is observed when z has a value of 1. Least squares regression using the observed data of y produces inconsistent estimates of $\boldsymbol{\beta}$. Maximum likelihood method is used to estimate selection models. It is also possible to estimate these models by using Heckman's method, which is more computationally efficient. But it can be shown that the resulting estimates, although consistent, are not asymptotically efficient under normality assumption. Moreover, this method often violates the constraint on correlation coefficient $|\rho| \leq 1$.

The log-likelihood function of the Heckman selection model is written as

$$\begin{aligned} \ell = & \sum_{i \in \{z_i=0\}} \ln[1 - \Phi(\mathbf{w}_i' \boldsymbol{\gamma})] \\ & + \sum_{i \in \{z_i=1\}} \left\{ \ln \phi \left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma} \right) - \ln \sigma + \ln \Phi \left(\frac{\mathbf{w}_i' \boldsymbol{\gamma} + \rho \frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}}{\sqrt{1 - \rho^2}} \right) \right\} \end{aligned}$$

Only one variable is allowed for the selection to be based on, but the selection may lead to several variables. For example, in the following switching regression model,

$$\begin{aligned}
 z_i^* &= \mathbf{w}_i' \boldsymbol{\gamma} + u_i \\
 z_i &= \begin{cases} 1 & \text{if } z_i^* > 0 \\ 0 & \text{if } z_i^* \leq 0 \end{cases} \\
 y_{1i} &= \mathbf{x}_{1i}' \boldsymbol{\beta}_1 + \epsilon_{1i} \quad \text{if } z_i = 0 \\
 y_{2i} &= \mathbf{x}_{2i}' \boldsymbol{\beta}_2 + \epsilon_{2i} \quad \text{if } z_i = 1
 \end{aligned}$$

z is the variable that the selection is based on. If $z = 0$, then y_1 is observed. If $z = 1$, then y_2 is observed. Because it is never the case that y_1 and y_2 are observed at the same time, the correlation between y_1 and y_2 cannot be estimated. Only the correlation between z and y_1 and the correlation between z and y_2 can be estimated. This estimation uses the maximum likelihood method.

A brief example of the code for this model can be found in “[Example 22.4: Sample Selection Model](#)” on page 1499.

The Heckman selection model can include censoring or truncation. For a brief example of the code for these models see “[Example 22.5: Sample Selection Model with Truncation and Censoring](#)” on page 1501. The following example shows a variable y_i that is censored from below at zero.

$$\begin{aligned}
 z_i^* &= \mathbf{w}_i' \boldsymbol{\gamma} + u_i \\
 z_i &= \begin{cases} 1 & \text{if } z_i^* > 0 \\ 0 & \text{if } z_i^* \leq 0 \end{cases} \\
 y_i^* &= \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i \quad \text{if } z_i = 1 \\
 y_i &= \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases}
 \end{aligned}$$

In this case, the log-likelihood function of the Heckman selection model needs to be modified to include the censored region.

$$\begin{aligned}
 \ell &= \sum_{\{i|z_i=0\}} \ln[1 - \Phi(\mathbf{w}_i' \boldsymbol{\gamma})] \\
 &+ \sum_{\{i|z_i=1, y_i=y_i^*\}} \left\{ \ln \left[\phi \left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma} \right) \right] - \ln \sigma + \ln \left[\Phi \left(\frac{\mathbf{w}_i' \boldsymbol{\gamma} + \rho \frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}}{\sqrt{1 - \rho^2}} \right) \right] \right\} \\
 &+ \sum_{\{i|z_i=1, y_i=0\}} \ln \int_{-\infty}^{\frac{-\mathbf{x}_i' \boldsymbol{\beta}}{\sigma}} \int_{-\mathbf{w}_i' \boldsymbol{\gamma}}^{\infty} \phi_2(u, v, \rho) du dv
 \end{aligned}$$

In case y_i is truncated from below at zero instead of censored, the likelihood function can be written as

$$\begin{aligned} \ell = & \sum_{\{i|z_i=0\}} \ln[1 - \Phi(\mathbf{w}'_i \boldsymbol{\gamma})] \\ & + \sum_{\{i|z_i=1\}} \left\{ \ln \left[\phi \left(\frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) \right] - \ln \sigma + \ln \left[\Phi \left(\frac{\mathbf{w}'_i \boldsymbol{\gamma} + \rho \frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma}}{\sqrt{1 - \rho^2}} \right) \right] - \ln [\Phi(\mathbf{x}'_i \boldsymbol{\beta} / \sigma)] \right\} \end{aligned}$$

Multivariate Limited Dependent Models

The multivariate model is similar to bivariate models. The generic form of the multivariate limited dependent variable model is

$$\begin{aligned} y_{1i}^* &= \mathbf{x}'_{1i} \boldsymbol{\beta}_1 + \epsilon_{1i} \\ y_{2i}^* &= \mathbf{x}'_{2i} \boldsymbol{\beta}_2 + \epsilon_{2i} \\ &\dots \\ y_{mi}^* &= \mathbf{x}'_{mi} \boldsymbol{\beta}_m + \epsilon_{mi} \end{aligned}$$

where m is the number of models to be estimated. The vector ϵ has multivariate normal distribution with mean 0 and variance-covariance matrix Σ . Similar to bivariate models, the likelihood may involve computing multivariate normal integrations. This is done using Monte Carlo integration. (See Genz (1992) and Hajivassiliou and McFadden (1998).)

When the number of equations, N , increases in a system, the number of parameters increases at the rate of N^2 because of the correlation matrix. When the number of parameters is large, sometimes the optimization converges but some of the standard deviations are missing. This usually means that the model is over-parameterized. The default method for computing the covariance is to use the inverse Hessian matrix. The Hessian is computed by finite differences, and in over-parameterized cases, the inverse cannot be computed. It is recommended that you reduce the number of parameters in such cases. Sometimes using the outer product covariance matrix (COVEST=OP option) may also help.

Tests on Parameters

Tests on Parameters

In general, the hypothesis tested can be written as

$$H_0 : \mathbf{h}(\theta) = 0$$

where $\mathbf{h}(\theta)$ is an r by 1 vector valued function of the parameters θ given by the r expressions specified in the TEST statement.

Let \hat{V} be the estimate of the covariance matrix of $\hat{\theta}$. Let $\hat{\theta}$ be the unconstrained estimate of θ and $\tilde{\theta}$ be the constrained estimate of θ such that $h(\tilde{\theta}) = 0$. Let

$$A(\theta) = \partial h(\theta) / \partial \theta \mid_{\hat{\theta}}$$

Using this notation, the test statistics for the three kinds of tests are computed as follows.

The Wald test statistic is defined as

$$W = h'(\hat{\theta}) \left(A(\hat{\theta}) \hat{V} A'(\hat{\theta}) \right)^{-1} h(\hat{\theta})$$

The Wald test is not invariant to reparameterization of the model (Gregory 1985; Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

The Lagrange multiplier test statistic is

$$LM = \lambda' A(\tilde{\theta}) \tilde{V} A'(\tilde{\theta}) \lambda$$

where λ is the vector of Lagrange multipliers from the computation of the restricted estimate $\tilde{\theta}$.

The likelihood ratio test statistic is

$$LR = 2 \left(L(\hat{\theta}) - L(\tilde{\theta}) \right)$$

where $\tilde{\theta}$ represents the constrained estimate of θ and L is the concentrated log-likelihood value.

For each kind of test, under the null hypothesis the test statistic is asymptotically distributed as a χ^2 random variable with r degrees of freedom, where r is the number of expressions in the TEST statement. The p -values reported for the tests are computed from the $\chi^2(r)$ distribution and are only asymptotically valid.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation to its small sample distribution than that of the other two tests. However, the Wald test has the lowest computational cost, since it does not require computation of the constrained estimate $\tilde{\theta}$.

The following is an example of using the TEST statement to perform a likelihood ratio test:

```
proc qlim;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0 /lr;
run;
```

Output to SAS Data Set

XBeta, Predicted, Residual

Xbeta is the structural part on the right-hand side of the model. Predicted value is the predicted dependent variable value. For censored variables, if the predicted value is outside the boundaries, it is reported as the closest boundary. For discrete variables, it is the level whose boundaries Xbeta falls between. Residual is defined only for continuous variables and is defined as

$$Residual = Observed - Predicted$$

Error Standard Deviation

Error standard deviation is σ_i in the model. It varies only when the HETERO statement is used.

Marginal Effects

Marginal effect is defined as a contribution of one control variable to the response variable. For the binary choice model with two response categories, $\mu_0 = -\infty$, $\mu_1 = 0$, $\mu_0 = -\infty$; and ordinal response model with M response categories, μ_0, \dots, μ_M , define

$$R_{i,j} = \mu_j - \mathbf{x}_i' \boldsymbol{\beta}$$

The probability that the unobserved dependent variable is contained in the j th category can be written as

$$P[\mu_{j-1} < y_i^* \leq \mu_j] = F(R_{i,j}) - F(R_{i,j-1})$$

The marginal effect of changes in the regressors on the probability of $y_i = j$ is then

$$\frac{\partial \text{Prob}[y_i = j]}{\partial \mathbf{x}} = [f(\mu_{j-1} - \mathbf{x}_i' \boldsymbol{\beta}) - f(\mu_j - \mathbf{x}_i' \boldsymbol{\beta})] \boldsymbol{\beta}$$

where $f(x) = \frac{dF(x)}{dx}$. In particular,

$$f(x) = \frac{dF(x)}{dx} = \begin{cases} \frac{1}{\sqrt{2\pi}} e^{-x^2/2} & (\text{probit}) \\ \frac{e^{-x}}{[1+e^{(-x)}]^2} & (\text{logit}) \end{cases}$$

The marginal effects in the Box-Cox regression model are

$$\frac{\partial E[y_i]}{\partial \mathbf{x}} = \boldsymbol{\beta} \frac{x^{\lambda_k-1}}{y^{\lambda_0-1}}$$

The marginal effects in the truncated regression model are

$$\frac{\partial E[y_i | L_i < y_i^* < R_i]}{\partial \mathbf{x}} = \boldsymbol{\beta} \left[1 - \frac{(\phi(a_i) - \phi(b_i))^2}{(\Phi(b_i) - \Phi(a_i))^2} + \frac{a_i \phi(a_i) - b_i \phi(b_i)}{\Phi(b_i) - \Phi(a_i)} \right]$$

where $a_i = \frac{L_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$ and $b_i = \frac{R_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$.

The marginal effects in the censored regression model are

$$\frac{\partial E[y | \mathbf{x}_i]}{\partial \mathbf{x}} = \boldsymbol{\beta} \times \text{Prob}[L_i < y_i^* < R_i]$$

Inverse Mills Ratio, Expected and Conditionally Expected Values

Expected and conditionally expected values are computed only for continuous variables. The inverse Mills ratio is computed for censored or truncated continuous, binary discrete, and selection endogenous variables.

Let L_i and R_i be the lower boundary and upper boundary, respectively, for the y_i . Define $a_i = \frac{L_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$ and $b_i = \frac{R_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$. Then the inverse Mills ratio is defined as

$$\lambda = \frac{(\phi(a_i) - \phi(b_i))}{(\Phi(b_i) - \Phi(a_i))}$$

for a continuous variable and defined as

$$\lambda = \frac{\phi(\mathbf{x}_i' \boldsymbol{\beta})}{\Phi(\mathbf{x}_i' \boldsymbol{\beta})}$$

for a binary discrete variable.

The expected value is the unconditional expectation of the dependent variable. For a censored variable, it is

$$E[y_i] = \Phi(a_i)L_i + (\mathbf{x}_i' \boldsymbol{\beta} + \lambda \sigma_i)(\Phi(b_i) - \Phi(a_i)) + (1 - \Phi(b_i))R_i$$

For a left-censored variable ($R_i = \infty$), this formula is

$$E[y_i] = \Phi(a_i)L_i + (\mathbf{x}_i' \boldsymbol{\beta} + \lambda \sigma_i)(1 - \Phi(a_i))$$

where $\lambda = \frac{\phi(a_i)}{1 - \Phi(a_i)}$.

For a right-censored variable ($L_i = -\infty$), this formula is

$$E[y_i] = (\mathbf{x}_i' \boldsymbol{\beta} + \lambda \sigma_i)\Phi(b_i) + (1 - \Phi(b_i))R_i$$

where $\lambda = -\frac{\phi(b_i)}{\Phi(b_i)}$.

For a noncensored variable, this formula is

$$E[y_i] = \mathbf{x}_i' \boldsymbol{\beta}$$

The conditional expected value is the expectation given that the variable is inside the boundaries:

$$E[y_i | L_i < y_i < R_i] = \mathbf{x}_i' \boldsymbol{\beta} + \lambda \sigma_i$$

Probability

Probability applies only to discrete responses. It is the marginal probability that the discrete response is taking the value of the observation. If the PROBALL option is specified, then the probability for all of the possible responses of the discrete variables is computed.

Technical Efficiency

Technical efficiency for each producer is computed only for stochastic frontier models.

In general, the stochastic production frontier can be written as

$$y_i = f(x_i; \boldsymbol{\beta}) \exp\{v_i\} TE_i$$

where y_i denotes producer i 's actual output, $f(\cdot)$ is the deterministic part of production frontier, $\exp\{v_i\}$ is a producer-specific error term, and TE_i is the technical efficiency coefficient, which can be written as

$$TE_i = \frac{y_i}{f(x_i; \beta) \exp\{v_i\}}.$$

In the case of a Cobb-Douglas production function, $TE_i = \exp\{-u_i\}$. See the section “[Stochastic Frontier Production and Cost Models](#)” on page 1478.

Cost frontier can be written in general as

$$E_i = c(y_i, w_i; \beta) \exp\{v_i\} / CE_i$$

where w_i denotes producer i 's input prices, $c(\cdot)$ is the deterministic part of cost frontier, $\exp\{v_i\}$ is a producer-specific error term, and CE_i is the cost efficiency coefficient, which can be written as

$$CE_i = \frac{c(x_i, w_i; \beta) \exp\{v_i\}}{E_i}$$

In the case of a Cobb-Douglas cost function, $CE_i = \exp\{-u_i\}$. See the section “[Stochastic Frontier Production and Cost Models](#)” on page 1478. Hence, both technical and cost efficiency coefficients are the same. The estimates of technical efficiency are provided in the following subsections.

Normal-Half Normal Model

Define $\mu_* = -\epsilon\sigma_u^2/\sigma^2$ and $\sigma_*^2 = \sigma_u^2\sigma_v^2/\sigma^2$. Then, as it is shown by Jondrow et al. (1982), conditional density is as follows:

$$f(u|\epsilon) = \frac{f(u, \epsilon)}{f(\epsilon)} = \frac{1}{\sqrt{2\pi}\sigma_*} \exp\left\{-\frac{(u - \mu_*)^2}{2\sigma_*^2}\right\} \Bigg/ \left[1 - \Phi\left(-\frac{\mu_*}{\sigma_*}\right)\right]$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\mu_*, \sigma_*^2)$.

Using this result, it follows that the estimate of technical efficiency (Battese and Coelli, 1988) is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \left[\frac{1 - \Phi(\sigma_* - \mu_{*i}/\sigma_*)}{1 - \Phi(-\mu_{*i}/\sigma_*)} \right] \exp\left\{-\mu_{*i} + \frac{1}{2}\sigma_*^2\right\}$$

The second version of the estimate (Jondrow et al., 1982) is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \mu_{*i} + \sigma_* \left[\frac{\phi(-\mu_{*i}/\sigma_*)}{1 - \Phi(-\mu_{*i}/\sigma_*)} \right] = \sigma_* \left[\frac{\phi(\epsilon_i\lambda/\sigma)}{1 - \Phi(\epsilon_i\lambda/\sigma)} - \left(\frac{\epsilon_i\lambda}{\sigma}\right) \right]$$

Normal-Exponential Model

Define $A = -\tilde{\mu}/\sigma_v$ and $\tilde{\mu} = -\epsilon - \sigma_v^2/\sigma_u$. Then, as it is shown by Kumbhakar and Lovell (2000), conditional density is as follows:

$$f(u|\epsilon) = \frac{1}{\sqrt{2\pi}\sigma_v\Phi(-\tilde{\mu}/\sigma_v)} \exp\left\{-\frac{(u - \tilde{\mu})^2}{2\sigma^2}\right\}$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\tilde{\mu}, \sigma_v^2)$.

Using this result, it follows that the estimate of technical efficiency is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \left[\frac{1 - \Phi(\sigma_v - \tilde{\mu}_i/\sigma_v)}{1 - \Phi(-\tilde{\mu}_i/\sigma_v)} \right] \exp \left\{ -\tilde{\mu}_i + \frac{1}{2}\sigma_v^2 \right\}$$

The second version of the estimate is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \tilde{\mu}_i + \sigma_v \left[\frac{\phi(-\tilde{\mu}_i/\sigma_v)}{1 - \Phi(-\tilde{\mu}_i/\sigma_v)} \right] = \sigma_v \left[\frac{\phi(A)}{\Phi(-A)} - A \right]$$

Normal-Truncated Normal Model

Define $\tilde{\mu} = (-\sigma_u^2\epsilon_i + \mu\sigma_v^2)/\sigma^2$ and $\sigma_*^2 = \sigma_u^2\sigma_v^2/\sigma^2$. Then, as it is shown by Kumbhakar and Lovell (2000), conditional density is as follows:

$$f(u|\epsilon) = \frac{1}{\sqrt{2\pi}\sigma_*[1 - \Phi(-\tilde{\mu}/\sigma_*)]} \exp \left\{ -\frac{(u - \tilde{\mu})^2}{2\sigma_*^2} \right\}$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\tilde{\mu}, \sigma_*^2)$.

Using this result, it follows that the estimate of technical efficiency is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \frac{1 - \Phi(\sigma_* - \tilde{\mu}_i/\sigma_*)}{1 - \Phi(-\tilde{\mu}_i/\sigma_*)} \exp \left\{ -\tilde{\mu}_i + \frac{1}{2}\sigma_*^2 \right\}$$

The second version of the estimate is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \tilde{\mu}_i + \sigma_* \left[\frac{\phi(\tilde{\mu}_i/\sigma_*)}{1 - \Phi(-\tilde{\mu}_i/\sigma_*)} \right]$$

OUTEST= Data Set

The OUTEST= data set contains all the parameters estimated in a MODEL statement. The OUTEST= option can be used when the PROC QLIM call contains one MODEL statement:

```
proc qlim data=a outest=e;
  model y = x1 x2 x3;
  endogenous y ~ censored(lb=0);
run;
```

Each parameter contains the estimate for the corresponding parameter in the corresponding model. In addition, the OUTEST= data set contains the following variables:

<code>_NAME_</code>	the name of the independent variable
<code>_TYPE_</code>	type of observation. PARM indicates the row of coefficients; STD indicates the row of standard deviations of the corresponding coefficients.
<code>_STATUS_</code>	convergence status for optimization

The rest of the columns correspond to the explanatory variables.

The OUTEST= data set contains one observation for the MODEL statement, giving the parameter estimates for that model. If the COVOUT option is specified, the OUTEST= data set includes additional observations for the MODEL statement, giving the rows of the covariance matrix of parameter estimates. For covariance observations, the value of the `_TYPE_` variable is COV, and the `_NAME_` variable identifies the parameter associated with that row of the covariance matrix. If the CORROUT option is specified, the OUTEST= data set includes additional observations for the MODEL statement, giving the rows of the correlation matrix of parameter estimates. For correlation observations, the value of the `_TYPE_` variable is CORR, and the `_NAME_` variable identifies the parameter associated with that row of the correlation matrix.

Naming

Naming of Parameters

When there is only one equation in the estimation, parameters are named in the same way as in other SAS procedures such as REG, PROBIT, and so on. The constant in the regression equation is called Intercept. The coefficients on independent variables are named by the independent variables. The standard deviation of the errors is called `_Sigma`. If there are Box-Cox transformations, the coefficients are named `_Lambdai`, where i increments from 1, or as specified by the user. The limits for the discrete dependent variable are named `_Limiti`. If the LIMIT=varying option is specified, then `_Limiti` starts from 1. If the LIMIT=varying option is not specified, then `_Limit1` is set to 0 and the limit parameters start from $i = 2$. If the HETERO statement is included, the coefficients of the independent variables in the hetero equation are called `_H.x`, where x is the name of the independent variable. If the parameter name includes interaction terms, it needs to be enclosed in quotation marks followed by N . The following example restricts the parameter that includes the interaction term to be greater than zero:

```
proc qlim data=a;
  model y = x1|x2;
  endogenous y ~ discrete;
  restrict "x1*x2"N>0;
run;
```

When there are multiple equations in the estimation, the parameters in the main equation are named in the format of `y.x`, where y is the name of the dependent variable and x is the name of the independent variable. The standard deviation of the errors is called `_Sigma.y`. The correlation of the errors is called

_Rho for bivariate model. For the model with three variables it is _Rho.y1.y2, _Rho.y1.y3, _Rho.y2.y3. The construction of correlation names for multivariate models is analogous. Box-Cox parameters are called _Lambda*i*.y and limit variables are called _Limit*i*.y. Parameters in the HETERO statement are named as _H.y.x. In the OUTEST= data set, all variables are changed from '.' to '_'.

Naming of Output Variables

The following table shows the option in the OUTPUT statement, with the corresponding variable names and their explanation.

Option	Name	Explanation
PREDICTED	P_y	Predicted value of y
RESIDUAL	RESID_y	Residual of y , (y -PredictedY)
XBETA	XBETA_y	Structure part ($\mathbf{x}'\boldsymbol{\beta}$) of y equation
ERRSTD	ERRSTD_y	Standard deviation of error term
PROB	PROB_y	Probability that y is taking the observed value in this observation (discrete y only)
PROBALL	PROB <i>i</i> _y	Probability that y is taking the i th value (discrete y only)
MILLS	MILLS_y	Inverse Mills ratio for y
EXPECTED	EXPCT_y	Unconditional expected value of y
CONDITIONAL	CEXPCT_y	Conditional expected value of y , condition on the truncation.
MARGINAL	MEFF_x	Marginal effect of x on y ($\frac{\partial y}{\partial x}$) with single equation
	MEFF_y_x	Marginal effect of x on y ($\frac{\partial y}{\partial x}$) with multiple equations
	MEFF_Pi_x	Marginal effect of x on y ($\frac{\partial Prob(y=i)}{\partial x}$) with single equation and discrete y
	MEFF_Pi_y_x	Marginal effect of x on y ($\frac{\partial Prob(y=i)}{\partial x}$) with multiple equations and discrete y
TE1	TE1	Technical efficiency estimate for each producer proposed by Battese and Coelli (1988)
TE2	TE2	Technical efficiency estimate for each producer proposed by Jondrow et al. (1982)

If you prefer to name the output variables differently, you can use the RENAME option in the data set. For example, the following statements rename the residual of y as *Resid*:

```
proc qlim data=one;
  model y = x1-x10 / censored;
  output out=outds(rename=(resid_y=resid)) residual;
run;
```

ODS Table Names

PROC QLIM assigns a name to each table it creates. You can use these names to denote the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the [Table 22.2](#).

Examples: QLIM Procedure

Example 22.1: Ordered Data Modeling

Cameron and Trivedi (1986) studied Australian Health Survey data. Variable definitions are given in Cameron and Trivedi (1998, p. 68).

The dependent variable, `dvisits`, has nine ordered values. The following SAS statements estimate the ordinal probit model:

```
/*-- Ordered Discrete Responses --*/
proc qlim data=docvisit;
    model dvisits = sex age agesq income levyplus
                  freepoor freerepa illness actdays hscore
                  chcond1 chcond2 / discrete;
run;
```

The output of the QLIM procedure for ordered data modeling is shown in [Output 22.1.1](#).

Output 22.1.1 Ordered Data Modeling

_Limit8	1	2.789796	0.156189	17.86	<.0001

By default, ordinal probit/logit models are estimated assuming that the first threshold or limit parameter (μ_1) is 0. However, this parameter can also be estimated when the LIMIT1=VARYING option is specified. The probability that y_i^* belongs to the j th category is defined as

$$P[\mu_{j-1} < y_i^* < \mu_j] = F(\mu_j - \mathbf{x}_i' \boldsymbol{\beta}) - F(\mu_{j-1} - \mathbf{x}_i' \boldsymbol{\beta})$$

where $F(\cdot)$ is the logistic or standard normal CDF, $\mu_0 = -\infty$ and $\mu_9 = \infty$. [Output 22.1.2](#) lists ordinal probit estimates computed in the following program. Note that the intercept term is suppressed for model identification when μ_1 is estimated.

```
/*-- Ordered Probit --*/
proc qlim data=docvisit;
  model dvisits = sex age agesq income levyplus
             freepoor freerepa illness actdays hscore
             chcond1 chcond2 / discrete(d=normal) limit1=varying;
run;
```

Example 22.2: Tobit Analysis

The following statements show a subset of the Mroz (1987) data set. In these data, Hours is the number of hours the wife worked outside the household in a given year, Yrs_Ed is the years of education, and Yrs_Exp is the years of work experience. A Tobit model will be fit to the hours worked with years of education and experience as covariates.

By the nature of the data it is clear that there are a number of women who committed some positive number of hours to outside work ($y_i > 0$ is observed). There are also a number of women who did not work at all ($y_i = 0$ is observed). This gives us the following model:

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$y_i = \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases}$$

where $\epsilon_i \sim iidN(0, \sigma^2)$. The set of explanatory variables is denoted by \mathbf{x}_i .

  model hours = yrs_ed yrs_exp;
  endogenous hours ~ censored(lb=0);
run;

```

The output of the QLIM procedure is shown in [Output 22.2.1](#).

Output 22.2.1 Tobit Analysis Results

Estimating a Tobit model					
The QLIM Procedure					
Model Fit Summary					
Number of Endogenous Variables				1	
Endogenous Variable				Hours	
Number of Observations				17	
Log Likelihood				-74.93700	
Maximum Absolute Gradient				1.18953E-6	
Number of Iterations				23	
Optimization Method				Quasi-Newton	
AIC				157.87400	
Schwarz Criterion				161.20685	
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	-5598.295129	27.692220	-202.16	<.0001
Yrs_Ed	1	373.123254	53.988877	6.91	<.0001
Yrs_Exp	1	63.336247	36.551299	1.73	0.0831
_Sigma	1	1582.859635	390.076480	4.06	<.0001

In the “Parameter Estimates” table there are four rows. The first three of these rows correspond to the vector estimate of the regression coefficients β . The last one is called `_Sigma`, which corresponds to the estimate of the error variance σ .

Example 22.3: Bivariate Probit Analysis

This example shows how to estimate a bivariate probit model. Note the `INIT` statement in the following program, which sets the initial values for some parameters in the optimization:

```
data a;
  keep y1 y2 x1 x2;
  do i = 1 to 500;
    x1 = rannor( 19283 );
    x2 = rannor( 19283 );
    u1 = rannor( 19283 );
    u2 = rannor( 19283 );
    y1l = 1 + 2 * x1 + 3 * x2 + u1;
    y2l = 3 + 4 * x1 - 2 * x2 + u1*.2 + u2;
    if ( y1l > 0 ) then y1 = 1;
    else y1 = 0;
    if ( y2l > 0 ) then y2 = 1;
    else y2 = 0;
  end;
end;
```

```

        output;
    end;
run;

/*-- Bivariate Probit --*/
proc qlim data=a method=qn;
    init y1.x1 2.8, y1.x2 2.1, _rho .1;
    model y1 = x1 x2;
    model y2 = x1 x2;
    endogenous y1 y2 ~ discrete;
run;

```

The output of the QLIM procedure is shown in [Output 22.3.1](#).

Output 22.3.1 Bivariate Probit Analysis Results

Example 22.4: Sample Selection Model

This example illustrates the use of PROC QLIM for sample selection models. The data set is the same one from Mroz (1987). The goal is to estimate a wage offer function for married women, accounting for potential selection bias. Of the 753 women, the wage is observed for 428 working women. The labor force participation equation estimated in the introductory example is used for selection. The wage equation

uses log wage (lwage) as the dependent variable. The explanatory variables in the wage equation are the woman's years of schooling (educ), wife's labor experience (exper), and square of experience (expersq). The program is as follows:

```

/*-- Sample Selection --*/
proc qlim data=mroz;
  model inlf = nwifeinc educ exper expersq
           age kidslt6 kidsge6 /discrete;
  model lwage = educ exper expersq / select(inlf=1);
run;

```

The output of the QLIM procedure is shown in [Output 22.4.1](#).

Output 22.4.1 Sample Selection

Binary Data					
The QLIM Procedure					
Model Fit Summary					
Number of Endogenous Variables		2			
Endogenous Variable		inlf lwage			
Number of Observations		753			
Log Likelihood		-832.88509			
Maximum Absolute Gradient		0.00502			
Number of Iterations		78			
Optimization Method		Quasi-Newton			
AIC		1694			
Schwarz Criterion		1759			
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
lwage.Intercept	1	-0.552716	0.260371	-2.12	0.0338
lwage.educ	1	0.108351	0.014861	7.29	<.0001
lwage.exper	1	0.042837	0.014878	2.88	0.0040
lwage.expersq	1	-0.000837	0.000417	-2.01	0.0449
_Sigma.lwage	1	0.663397	0.022706	29.22	<.0001
inlf.Intercept	1	0.266459	0.508954	0.52	0.6006
inlf.nwifeinc	1	-0.012132	0.004877	-2.49	0.0129
inlf.educ	1	0.131341	0.025383	5.17	<.0001
inlf.exper	1	0.123282	0.018728	6.58	<.0001
inlf.expersq	1	-0.001886	0.000601	-3.14	0.0017
inlf.age	1	-0.052829	0.008479	-6.23	<.0001
inlf.kidslt6	1	-0.867398	0.118647	-7.31	<.0001
inlf.kidsge6	1	0.035872	0.043476	0.83	0.4093
_Rho	1	0.026617	0.147073	0.18	0.8564

Note the correlation estimate is insignificant. This indicates that selection bias is not a big problem in the estimation of wage equation.

Example 22.5: Sample Selection Model with Truncation and Censoring

In this example the data are generated such that the selection variable is discrete and the variable Y is truncated from below by zero. The program follows, with the results shown in [Output 22.5.1](#):

```
data trunc;
  keep z y x1 x2;
  do i = 1 to 500;
    x1 = rannor( 19283 );
    x2 = rannor( 19283 );
    u1 = rannor( 19283 );
    u2 = rannor( 19283 );
    z1 = 1 + 2 * x1 + 3 * x2 + u1;
    y = 3 + 4 * x1 - 2 * x2 + u1*.2 + u2;
    if ( z1 > 0 ) then z = 1;
    else z = 0;
    if y>=0 then output;
  end;
run;

/*-- Sample Selection with Truncation --*/
proc qlim data=trunc method=qn;
  model z = x1 x2 / discrete;
  model y = x1 x2 / select(z=1) truncated(lb=0);
run;
```

Output 22.5.1 Sample Selection with Truncation

Example 22.6: Types of Tobit Models

The following five examples show how to estimate different types of Tobit models (see “Types of Tobit Models” on page 1475). [Output 22.6.1](#) through [Output 22.6.5](#) show the results of the corresponding programs.

Type 1 Tobit

```
data a1;
  keep y x;
  do i = 1 to 500;
    x = rannor( 19283 );
    u = rannor( 19283 );
    y1 = 1 + 2 * x + u;
    if ( y1 > 0 ) then y = y1;
    else y = 0;
    output;
  end;
run;
```

```

/*-- Type 1 Tobit --*/
proc qlim data=a1 method=qn;
  model y = x;
  endogenous y ~ censored(lb=0);
run;

```

Output 22.6.1 Type 1 Tobit

Example 22.7: Stochastic Frontier Models

This example illustrates the estimation of stochastic frontier production and cost models.

First, a production function model is estimated. The data for this example were collected by Christensen Associates; they represent a sample of 125 observations on inputs and output for 10 airlines between 1970 and 1984. The explanatory variables (inputs) are fuel (LF), materials (LM), equipment (LE), labor (LL), and property (LP), and (LQ) is an index that represents passengers, charter, mail, and freight transported.

The following statements create the dataset:

```

title1 'Stochastic Frontier Production Model';
data airlines;
  input TS FIRM NI LQ LF LM LE LL LP;
datalines;
1 1 15 -0.0484 0.2473 0.2335 0.2294 0.2246 0.2124
1 1 15 -0.0133 0.2603 0.2492 0.241 0.2216 0.1069
2 1 15 0.088 0.2666 0.3273 0.3365 0.2039 0.0865

... more lines ...

```

The following statements estimate a stochastic frontier exponential production model that uses Christensen Associates data:

```

/*-- Stochastic Frontier Production Model --*/
proc qlim data=airlines;
  model LQ=LF LM LE LL LP;
  endogenous LQ ~ frontier (type=exponential production);
run;

```

Figure 22.7.1 shows the results from this production model.

Output 22.7.1 Stochastic Frontier Production Model

Stochastic Frontier Production Model

Similarly, the stochastic frontier production function can be estimated with (type=half) or (type=truncated) options that represent half-normal and truncated normal production models.

In the next step, stochastic frontier cost function is estimated. The data for the cost model are provided by Christensen and Greene (1976). The data describe costs and production inputs of 145 U.S. electricity producers in 1955. The model being estimated follows the nonhomogenous version of the Cobb-Douglas cost function:

$$\log\left(\frac{\text{Cost}}{\text{FPrice}}\right) = \beta_0 + \beta_1 \log\left(\frac{\text{KPrice}}{\text{FPrice}}\right) + \beta_2 \log\left(\frac{\text{LPrice}}{\text{FPrice}}\right) + \beta_3 \log(\text{Output}) + \beta_4 \frac{1}{2} \log(\text{Output})^2 + \epsilon$$

All dollar values are normalized by fuel price. The quadratic log of the output is added to capture nonlinearities due to scale effects in cost functions. New variables, log_C_PF, log_PK_PF, log_PL_PF, log_y, and log_y_sq, are created to reflect transformations. The following statements create the data set and transformed variables:

```
data electricity;
```

```

input Firm Year Cost Output LPrice LShare KPrice KShare FPrice FShare;

Overview: SEVERITY Procedure

The SEVERITY procedure estimates parameters of any arbitrary continuous probability distribution that is used to model the magnitude (severity) of a continuous-valued event of interest. Some examples of such events are loss amounts paid by an insurance company and demand of a product as depicted by its sales. PROC SEVERITY is especially useful when the severity of an event does not follow typical distributions, such as the normal distribution, that are often assumed by standard statistical methods.

PROC SEVERITY provides a default set of probability distribution models that includes the Burr, exponential, gamma, generalized Pareto, inverse Gaussian (Wald), lognormal, Pareto, Tweedie, and Weibull distributions. In the simplest form, you can estimate the parameters of any of these distributions by using a list of severity values that are recorded in a SAS data set. The values can optionally be grouped by a set of BY variables. PROC SEVERITY computes the estimates of the model parameters, their standard errors, and their covariance structure by using the maximum likelihood method for each of the BY groups.

PROC SEVERITY can fit multiple distributions at the same time and choose the best distribution according to a specified selection criterion. Seven different statistics of fit can be used as selection criteria. They are log likelihood, Akaike's information criterion (AIC), corrected Akaike's information criterion (AICC), Schwarz Bayesian information criterion (BIC), Kolmogorov-Smirnov statistic (KS), Anderson-Darling statistic (AD), and Cramér-von Mises statistic (CvM).

You can request the procedure to output the status of the estimation process, the parameter estimates and their standard errors, the estimated covariance structure of the parameters, the statistics of fit, estimated cumulative distribution function (CDF) for each of the specified distributions, and the empirical distribution function (EDF) estimate (which is used to compute the KS, AD, and CvM statistics of fit).

The following key features of PROC SEVERITY make it unique among SAS procedures that can estimate continuous probability distributions:

- PROC SEVERITY enables you to fit a distribution model when the severity values are truncated or censored or both. You can specify any combination of the following types of censoring and truncation effects: left-censoring, right-censoring, left-truncation, or right-truncation. This is especially useful in applications with an insurance-type model where a severity (loss) is reported and recorded only if it is greater than the deductible amount (left-truncation) and where a severity value greater than or equal to the policy limit is recorded at the limit (right-censoring). Another useful application is that of interval-censored data, where you know both the lower limit (right-censoring) and upper limit (left-censoring) on the severity, but you do not know the exact value. The procedure also enables you to specify a *probability of observability* for the left-truncated data, which is a probability of observing values greater than the left-truncation threshold. This additional information can be useful in certain applications to more correctly model the distribution of the severity of events.

When truncation or censoring is specified, PROC SEVERITY can compute the empirical distribution function (EDF) estimate by using either Kaplan-Meier's product-limit estimator or Turnbull's estimator. The former is used by default when only one form of censoring effect (right-censoring or left-censoring) is specified, whereas the latter is used by default when both left-censoring and right-censoring effects are specified.

- PROC SEVERITY enables you to define any arbitrary continuous parametric distribution model and to estimate its parameters. You just need to define the key components of the distribution, such as its probability density function (PDF) and cumulative distribution function (CDF), as a set of functions and subroutines written with the FCMP procedure, which is part of Base SAS software. As long as the functions and subroutines follow certain rules, PROC SEVERITY can fit the distribution model defined by them.
- PROC SEVERITY can model the effect of exogenous or regressor variables on a probability distribution, as long as the distribution has a scale parameter. A linear combination of the regressor variables is assumed to affect the scale parameter via an exponential link function.

If a distribution does not have a scale parameter, then either it needs to have another parameter that can be derived from a scale parameter by using a supported transformation or it needs to be reparameterized to have a scale parameter. If neither of these is possible, then regression effects cannot be modeled.

- PROC SEVERITY enables you to specify your own objective function to be optimized for estimating the parameters of a model. You can write SAS programming statements to specify the contribution of each observation to the objective function. You can use keyword functions such as `_PDF_` and `_CDF_` in order to generalize the objective function to any distribution. If you do not specify your own objective function, then PROC SEVERITY estimates the parameters of a model by maximizing the likelihood function of the data.

These features and the core functionality are described in detail in the following sections.

Getting Started: SEVERITY Procedure

This section outlines the use of the SEVERITY procedure to fit continuous probability distribution models. It illustrates three different examples of different features of the procedure.

A Simple Example of Fitting Predefined Distributions

The simplest way to use PROC SEVERITY is to fit all the predefined distributions to a set of values and let the procedure identify the best fitting distribution.

Consider a lognormal distribution, whose probability density function (PDF) f and cumulative distribution function (CDF) F are as follows, respectively, where Φ denotes the CDF of the standard normal distribution:

$$f(x; \mu, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2} \quad \text{and} \quad F(x; \mu, \sigma) = \Phi\left(\frac{\log(x)-\mu}{\sigma}\right)$$

The following DATA step statements simulate a sample from a lognormal distribution with population parameters $\mu = 1.5$ and $\sigma = 0.25$, and store the sample in the variable Y of a data set Work.Test_sev1:

```
/*----- Simple Lognormal Example -----*/
data test_sev1(keep=y label='Simple Lognormal Sample');
  call streaminit(45678);
  label y='Response Variable';
  Mu = 1.5;
  Sigma = 0.25;
  do n = 1 to 100;
    y = exp(Mu) * rand('LOGNORMAL')**Sigma;
    output;
  end;
run;
```

The following statements fit all the predefined distribution models to the values of Y and identify the best distribution according to the corrected Akaike's information criterion (AICC):

```
proc severity data=test_sev1 crit=aicc;
  loss y;
  dist _predefined_;
run;
```

The PROC SEVERITY statement specifies the input data set along with the model selection criterion, the LOSS statement specifies the variable to be modeled, and the DIST statement with the _PREDEFINED_ keyword specifies that all the predefined distribution models be fitted.

Some of the default output displayed by this step is shown in Figure 23.1 through Figure 23.5. First, information about the input data set is displayed followed by the “Model Selection Table”, as shown in Figure 23.1. The model selection table displays the convergence status, the value of the selection criterion, and the selection status for each of the candidate models. The Converged column indicates whether the estimation process for a given distribution model has converged, might have converged, or failed. The Selected column indicates whether a given distribution has the best fit for the data according to the selection criterion. For this example, the lognormal distribution model is selected, because it has the lowest value for the selection criterion.

Figure 23.1 Data Set Information and Model Selection Table

The SEVERITY Procedure	
Input Data Set	
Name	WORK.TEST_SEV1
Label	Simple Lognormal Sample

Figure 23.1 *continued*

Model Selection Table			
Distribution	Converged	Corrected Akaike's Information Criterion	Selected
Burr	Yes	322.50845	No
Exp	Yes	508.12287	No
Gamma	Yes	320.50264	No
Igauss	Yes	319.61652	No
Logn	Yes	319.56579	Yes
Pareto	Yes	510.28172	No
Gpd	Yes	510.20576	No
Weibull	Yes	334.82373	No

Next, two comparative plots are prepared. These plots enable you to visually verify how the models differ from each other and from the nonparametric estimates. The plot in [Figure 23.2](#) displays the cumulative distribution function (CDF) estimates of all the models and the estimates of the empirical distribution function (EDF). The CDF plot indicates that the Exp (exponential), Pareto, and Gpd (generalized Pareto) distributions are a poor fit as compared to the EDF estimate. The Weibull distribution is also a poor fit, although not as poor as exponential, Pareto, and Gpd. The other four distributions seem to be quite close to each other and to the EDF estimate.

Figure 23.2 Comparison of EDF and CDF Estimates of the Fitted Models

The plot in [Figure 23.3](#) displays the probability density function (PDF) estimates of all the models and the nonparametric kernel and histogram estimates. The PDF plot enables better visual comparison between the Burr, Gamma, Igauss (inverse Gaussian), and Logn (lognormal) models. The Burr and Gamma differ significantly from the Igauss and Logn distributions in the central portion of the range of Y values, while the latter two fit the data almost identically. This provides a visual confirmation of the information in the “Model Selection Table” of [Figure 23.1](#), which indicates that the AICC values of Igauss and Logn distributions are very close.

Figure 23.3 Comparison of PDF Estimates of the Fitted Models

The comparative plots are followed by the estimation information for each of the candidate models. The information for the lognormal model, which is the best fitting model, is shown in Figure 23.4. The first table displays a summary of the distribution. The second table displays the convergence status. This is followed by a summary of the optimization process which indicates the technique used, the number of iterations, the number of times the objective function was evaluated, and the log likelihood attained at the end of the optimization. Since the model with lognormal distribution has converged, PROC SEVERITY displays its statistics of fit and parameter estimates. The estimates of $\mu=1.49605$ and $\sigma=0.26243$ are quite close to the population parameters of $\mu=1.5$ and $\sigma=0.25$ from which the sample was generated. The p -value for each estimate indicates the rejection of the null hypothesis that the estimate is 0, implying that both the estimates are significantly different from 0.

An Example with Left-Truncation and Right-Censoring

PROC SEVERITY enables you to specify that the response variable values are left-truncated or right-censored. The following DATA step expands the data set of the previous example to simulate a scenario that is typically encountered by an automobile insurance company. The values of the variable Y represent the loss values on claims that are reported to an auto insurance company. The variable THRESHOLD records the deductible on the insurance policy. If the actual value of Y is less than or equal to the deductible, then it is unobservable and does not get recorded. In other words, THRESHOLD specifies the left-truncation of Y. LIMIT records the policy limit. If the value of Y is equal to or greater than the recorded value, then the observation is right-censored.

```
/*----- Lognormal Model with left-truncation and censoring -----*/
data test_sev2(keep=y threshold limit
    label='A Lognormal Sample With Censoring and Truncation');
    set test_sev1;
    label y='Censored & Truncated Response';
    if _n_ = 1 then call streaminit(45679);

    /* make about 20% of the observations left-truncated */
    if (rand('UNIFORM') < 0.2) then
        threshold = y * (1 - rand('UNIFORM'));
    else
        threshold = .;
    /* make about 15% of the observations right-censored */
    iscens = (rand('UNIFORM') < 0.15);
    if (iscens) then
        limit = y;
    else
        limit = .;
run;
```

The following statements use the AICC criterion to analyze which of the four predefined distributions (log-normal, Burr, gamma, and Weibull) has the best fit for the data:

```
proc severity data=test_sev2 crit=aicc
    print=all plots(markcensored marktruncated)=pp;
    loss y / lt=threshold rc=limit;

    dist logn burr gamma weibull;
run;
```

The LOSS statement specifies the left-truncation and right-censoring variables. Each candidate distribution needs to be specified by using a separate DIST statement. The PRINT= option in the PROC SEVERITY statement requests that all the displayed output be prepared. The PLOTS= option in the PROC SEVERITY statement requests that the P-P plots for each candidate distribution be prepared in addition to the default plots. It also instructs the procedure to mark the left-truncated and right-censored observations in the CDF plot.

Some of the key results prepared by PROC SEVERITY are shown in Figure 23.6 through Figure 23.11. The descriptive statistics of Y are shown in the second table of Figure 23.6. In addition to the estimates of the range, mean, and standard deviation of Y, the table also indicates the number of observations that are right-censored, left-truncated, and both right-censored and left-truncated. The “Model Selection Table” in Figure 23.6 shows that models with all the candidate distributions have converged and that the Logn (lognormal) model has the best fit for the data according to the AICC criterion.

Figure 23.6 Summary Results for the Truncated and Censored Data

The SEVERITY Procedure

Logn	Yes	298.92672	Yes
Burr	Yes	302.66229	No
Gamma	Yes	299.45293	No
Weibull	Yes	309.26779	No

PROC SEVERITY also prepares a table that shows all the fit statistics for all the candidate models. It is useful to see which model would be the best fit according to each of the criteria. The table prepared for this example is shown in Figure 23.7. It indicates that the lognormal model is chosen by all the criteria.

Figure 23.7 Comparing All Statistics of Fit for the Truncated and Censored Data

Gamma	295.32921	299.32921	299.45293	304.53955	0.62511
Weibull	305.14408	309.14408	309.26779	314.35442	0.93307

All Fit Statistics Table		
Distribution	AD	CvM
Logn	0.34736*	0.05159*
Burr	0.36712	0.05726
Gamma	0.42921	0.05526
Weibull	1.40699	0.17465

The plot that compares EDF and CDF estimates is shown in [Figure 23.8](#). When left-truncation is specified, both the EDF and CDF estimates are conditional on the response variable being greater than the smallest left-truncation threshold in the sample. Notice the markers close to the X-axis of the plot. These indicate the values of Y that are left-truncated or right-censored.

Figure 23.8 EDF and CDF Estimates for the Truncated and Censored Data

In addition to the comparative plot, PROC SEVERITY produces a P-P plot for each of the models that has not failed to converge. It is a scatter plot of the EDF and the CDF estimates. The model for which the points are scattered closer to the unit-slope reference line is a better fit. The P-P plot for the lognormal distribution is shown in Figure 23.9. It indicates that the EDF and the CDF match very closely. In contrast, the P-P plot for the Weibull distribution, also shown in Figure 23.9, indicates a poor fit.

Figure 23.9 P-P Plots for Lognormal and Weibull Models Fitted to Truncated and Censored Data

Specifying Initial Values for Parameters

All the predefined distributions have parameter initialization functions built into them. For the current example, [Figure 23.10](#) shows the initial values that are obtained by the predefined method for the Burr distribution. It also shows the summary of the optimization process and the final parameter estimates.

Figure 23.10 Burr Model Summary for the Truncated and Censored Data

Initial Parameter Values and Bounds for Burr Distribution			
Parameter	Initial Value	Lower Bound	Upper Bound
Theta	4.78102	1.05367E-8	Infty
Alpha	2.00000	1.05367E-8	Infty
Gamma	2.00000	1.05367E-8	Infty

Optimization Summary for Burr Distribution	
Optimization Technique	Trust Region
Number of Iterations	8
Number of Function Evaluations	21
Log Likelihood	-148.20614

Parameter Estimates for Burr Distribution				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Theta	4.76980	0.62492	7.63	<.0001
Alpha	1.16363	0.58859	1.98	0.0509
Gamma	5.94081	1.05004	5.66	<.0001

You can specify a different set of initial values if estimates are available from fitting the distribution to similar data. For this example, the parameters of the Burr distribution can be initialized with the final parameter estimates of the Burr distribution that were obtained in the first example (shown in Figure 23.5). One of the ways in which you can specify the initial values is as follows:

```
/*----- Specifying initial values using INIT= option -----*/
proc severity data=test_sev2 crit=aicc print=all plots=none;
    loss y / lt=threshold rc=limit;

    dist burr(init=(theta=4.62348 alpha=1.15706 gamma=6.41227));
run;
```

The names of the parameters specified in the INIT option must match the names used in the definition of the distribution. The results obtained with these initial values are shown in Figure 23.11. These indicate that new set of initial values causes the optimizer to reach the same solution with fewer iterations and function evaluations as compared to the default initialization.

Gamma	5.94081	1.05004	5.66	<.0001

An Example of Modeling Regression Effects

Consider a scenario in which the magnitude of the response variable might be affected by some regressor (exogenous or independent) variables. The SEVERITY procedure enables you to model the effect of such variables on the distribution of the response variable via an exponential link function. In particular, if you have k random regressor variables denoted by x_j ($j = 1, \dots, k$), then the distribution of the response variable Y is assumed to have the form

$$Y \sim \exp\left(\sum_{j=1}^k \beta_j x_j\right) \cdot \mathcal{F}(\Theta)$$

where \mathcal{F} denotes the distribution of Y with parameters Θ and β_j ($j = 1, \dots, k$) denote the regression parameters (coefficients). For the effective distribution of Y to be a valid distribution from the same parametric

family as \mathcal{F} , it is necessary for \mathcal{F} to have a scale parameter. The effective distribution of Y can be written as

$$Y \sim \mathcal{F}(\theta, \Omega)$$

where θ denotes the scale parameter and Ω denotes the set of nonscale parameters. The scale θ is affected by the regressors as

$$\theta = \theta_0 \cdot \exp\left(\sum_{j=1}^k \beta_j x_j\right)$$

where θ_0 denotes a *base* value of the scale parameter.

Given this form of the model, PROC SEVERITY allows a distribution to be a candidate for modeling regression effects only if it has an untransformed or a log-transformed scale parameter.

All the predefined distributions, except the lognormal distribution, have a direct scale parameter (that is, a parameter that is a scale parameter without any transformation). For the lognormal distribution, the parameter μ is a log-transformed scale parameter. This can be verified by replacing μ with a parameter $\theta = e^\mu$, which results in the following expressions for the PDF f and the CDF F in terms of θ and σ , respectively, where Φ denotes the CDF of the standard normal distribution:

$$f(x; \theta, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x) - \log(\theta)}{\sigma}\right)^2} \quad \text{and} \quad F(x; \theta, \sigma) = \Phi\left(\frac{\log(x) - \log(\theta)}{\sigma}\right)$$

With this parameterization, the PDF satisfies the $f(x; \theta, \sigma) = \frac{1}{\theta} f(\frac{x}{\theta}; 1, \sigma)$ condition and the CDF satisfies the $F(x; \theta, \sigma) = F(\frac{x}{\theta}; 1, \sigma)$ condition. This makes θ a scale parameter. Hence, $\mu = \log(\theta)$ is a log-transformed scale parameter and the lognormal distribution is eligible for modeling regression effects.

The following DATA step simulates a lognormal sample whose scale is decided by the values of the three regressors X1, X2, and X3 as follows:

$$\mu = \log(\theta) = 1 + 0.75 X1 - X2 + 0.25 X3$$

```
/*----- Lognormal Model with Regressors -----*/
data test_sev3(keep=y x1-x3
    label='A Lognormal Sample Affected by Regressors');
    array x{*} x1-x3;
    array b{4} _TEMPORARY_ (1 0.75 -1 0.25);
    call streaminit(45678);
    label y='Response Influenced by Regressors';
    Sigma = 0.25;
    do n = 1 to 100;
        Mu = b(1); /* log of base value of scale */
        do i = 1 to dim(x);
            x(i) = rand('UNIFORM');
            Mu = Mu + b(i+1) * x(i);
        end;
        y = exp(Mu) * rand('LOGNORMAL')**Sigma;
        output;
    end;
run;
```

The following PROC SEVERITY step fits the lognormal, Burr, and gamma distribution models to this data. The regressors are specified in the SCALEMODEL statement.

```
proc severity data=test_sev3 crit=aicc print=all;
  loss y;
  scalemodel x1-x3;

  dist logn burr gamma;
run;
```

Some of the key results prepared by PROC SEVERITY are shown in Figure 23.12 through Figure 23.16. The descriptive statistics of all the variables are shown in Figure 23.12.

Figure 23.12 Summary Results for the Regression Example

The SEVERITY Procedure					
Input Data Set					
Name	WORK.TEST_SEV3				
Label	A Lognormal Sample Affected by Regressors				
Descriptive Statistics for Variable y					
Number of Observations	100				
Number of Observations Used for Estimation	100				
Minimum	1.17863				
Maximum	6.65269				
Mean	2.99859				
Standard Deviation	1.12845				
Descriptive Statistics for the Regressor Variables					
Variable	N	Minimum	Maximum	Mean	Standard Deviation
x1	100	0.0005115	0.97971	0.51689	0.28206
x2	100	0.01883	0.99937	0.47345	0.28885
x3	100	0.00255	0.97558	0.48301	0.29709

The comparison of the fit statistics of all the models is shown in Figure 23.13. It indicates that the lognormal model is the best model according to each of the likelihood-based statistics, whereas the gamma model is the best model according to two of the three EDF-based statistics.

The distribution information and the convergence results of the lognormal model are shown in [Figure 23.14](#). The iteration history gives you a summary of how the optimizer is traversing the surface of the log-likelihood function in its attempt to reach the optimum. Both the change in the log likelihood and the maximum gradient of the objective function with respect to any of the parameters typically approach 0 if the optimizer converges.

The final parameter estimates of the lognormal model are shown in [Figure 23.15](#). All the estimates are significantly different from zero. The estimate that is reported for the parameter *Mu* is the base value for the log-transformed scale parameter μ . Let x_i ($1 \leq i \leq 3$) denote the observed value for regressor X_i . If the lognormal distribution is chosen to model Y , then the effective value of the parameter μ varies with the observed values of regressors as

$$\mu = 1.04047 + 0.65221 x_1 - 0.91116 x_2 + 0.16243 x_3$$

These estimated coefficients are reasonably close to the population parameters (that is, within one or two standard errors).

Figure 23.15 Parameter Estimates for the Lognormal Model with Regressors

Parameter Estimates for Logn Distribution

x3	0.16243	0.07782	2.09	0.0395

The estimates of the gamma distribution model, which is the best model according to a majority of the EDF-based statistics, are shown in [Figure 23.16](#). The estimate that is reported for the parameter *Theta* is the base value for the scale parameter θ . If the gamma distribution is chosen to model Y , then the effective value of the scale parameter is $\theta = 0.14293 \exp(0.64562 x_1 - 0.89831 x_2 + 0.14901 x_3)$.

Specifies that the final EDF estimates be maximum likelihood estimates when the TURNBULL method is specified in the EMPIRICALCDF= option	PROC SEVERITY	ENSUREMLE
Specifies the relative convergence criterion when the TURNBULL method is specified in the EMPIRICALCDF= option	PROC SEVERITY	EPS=
Specifies the maximum number of iterations when the TURNBULL method is specified in the EMPIRICALCDF= option	PROC SEVERITY	MAXITER=
Specifies the threshold below which an EDF estimate is deemed zero when the TURNBULL method is specified in the EMPIRICALCDF= option	PROC SEVERITY	ZEROPROB=

Table 23.1 *continued*

Description	Statement	Option
Displayed Output and Plotting Options		
Specifies that all displayed and graphical output be turned off	PROC SEVERITY	NOPRINT
Specifies the graphical output to be displayed	PROC SEVERITY	PLOTS=
Specifies the output to be displayed	PROC SEVERITY	PRINT=
Specifies the verbosity of messages printed to the log	PROC SEVERITY	VERBOSE=

PROC SEVERITY Statement

PROC SEVERITY *options* ;

You can specify two types of *options* in the PROC SEVERITY statement. One set of *options* controls input and output. The other set of *options* controls the model estimation and selection process.

The following *options* control the input data sets used by PROC SEVERITY and various forms of output generated by PROC SEVERITY. The *options* are listed in alphabetical order:

COVOUT

specifies that the OUTEST= data set contain the estimate of the covariance structure of the parameters. This option has no effect if the OUTEST= option is not specified. Details of how the covariance is reported in OUTEST= data set are provided in the section “[OUTEST= Data Set](#)” on page 1601.

DATA=SAS-data-set

names the input data set. If the DATA= option is not specified, then the most recently created SAS data set is used.

INEST=SAS-data-set

names the input data set that contains the initial values of the parameter estimates to start the optimization process. The initial values specified in the INIT= option in the DIST statement take precedence over any initial values specified in this data set. Details of the variables in this data set are provided in the section “[INEST= Data Set](#)” on page 1599.

NOPRINT

turns off all displayed and graphical output. If specified, any value specified for the PRINT= and PLOTS= options is ignored.

OUTCDF=SAS-data-set

names the output data set to contain estimates of the cumulative distribution function (CDF) value at each of the observations. The information is output for each specified model whose parameter estimation process converges. The data set also contains the estimates of the empirical distribution function (EDF). Details of the variables in this data set are provided in the section “[OUTCDF= Data Set](#)” on page 1600.

OUTEST=SAS-data-set

names the output data set to contain estimates of the parameter values and their standard errors for each model whose parameter estimation process converges. Details of the variables in this data set are provided in the section “[OUTEST= Data Set](#)” on page 1601.

OUTMODELINFO=SAS-data-set

names the output data set to contain the status of each fitted model. The status information includes the convergence status of the optimization process that is used to estimate the parameters, the status of estimating the covariance matrix, and whether a model is the best according to the specified selection criterion. Details of the variables in this data set are provided in the section “[OUTMODELINFO= Data Set](#)” on page 1602.

OUTSTAT=SAS-data-set

names the output data set to contain the values of statistics of fit for each model whose parameter estimation process converges. Details of the variables in this data set are provided in the section “[OUTSTAT= Data Set](#)” on page 1603.

PLOTS <(global-plot-options)> <=(plot-request-option)>**PLOTS** <(global-plot-options)> <=(plot-request-options ...)>

specifies the desired graphical output. The *global-plot-options* and *plot-request-options* are separated by spaces.

The following *global-plot-options* are available:

HISTOGRAM

plots the histogram of the response variable on the PDF plots.

KERNEL

plots the kernel estimate of the probability density of the response variable on the PDF plots.

MARKCENSORED

marks right-censored observations, if any, in the PDF and CDF plots. This option has no effect if right-censoring is not specified in the LOSS statement or if both right-censoring and left-censoring are specified.

MARKTRUNCATED

marks left-truncated observations, if any, in the PDF and CDF plots. This option has no effect if left-truncation is not specified in the LOSS statement. This option does not mark observations that are right-truncated but not left-truncated.

ONLY

turns off the default graphical output and prepares only the requested plots.

The following *plot-request-options* are available:

ALL

displays all the graphical output.

CDF

prepares a plot that compares the cumulative distribution function (CDF) estimates of all the candidate distribution models and the empirical distribution function (EDF) estimate. The plot does not contain CDF estimates for models whose parameter estimation process does not converge.

CDFPERDIST

prepares a plot of the CDF estimates of each candidate distribution model. A plot is not prepared for models whose parameter estimation process does not converge.

NONE

displays none of the graphical output. If specified, this option overrides all the other plot request options. The default graphical output is also suppressed.

PDF

prepares a plot that compares the probability density function (PDF) estimates of all the candidate distribution models. The plot does not contain PDF estimates for models whose parameter estimation process does not converge.

PDFPERDIST

prepares a plot of the PDF estimates of each candidate distribution model. A plot is not prepared for models whose parameter estimation process does not converge.

PP

prepares the probability-probability plot (known as the P-P plot) that compares the CDF estimate of each candidate distribution model against the empirical distribution function (EDF). The data shown in this plot are used for computing the EDF-based statistics of fit.

If the PLOTS= option is not specified or the ONLY *global-plot-option* is not specified, then the default graphical output is equivalent to specifying PLOTS=(CDF PDF).

PRINT <(*global-display-option*)> <=*display-option*>

PRINT <(*global-display-option*)> <=(*display-options* ...)>

specifies the desired displayed output. The *display-options* are separated by spaces.

The following *global-display-option* is available:

ONLY

turns off the default displayed output and displays only the requested output.

The following *display-options* are available:

ALL

displays all the output.

ALLFITSTATS

displays the comparison of all the statistics of fit for all the models in one table. The table does not include the models whose parameter estimation process does not converge.

CONVSTATUS

displays the convergence status of the parameter estimation process.

DESCSTATS

displays the descriptive statistics for the response variable and the regressor variables, if they are specified.

ESTIMATES | PARMEST

displays the final estimates of parameters. The estimates are not displayed for models whose parameter estimation process does not converge.

INITIALVALUES

displays the initial values and bounds used for estimating each model.

NLOHISTORY

displays the iteration history of the nonlinear optimization process used for estimating the parameters.

NLOSUMMARY

displays the summary of the nonlinear optimization process used for estimating the parameters.

NONE

displays none of the output. If specified, this option overrides all the other display options. The default displayed output is also suppressed.

SELECTION | SELECT

displays the model selection table.

STATISTICS | FITSTATS

displays the statistics of fit for each model. The statistics of fit are not displayed for models whose parameter estimation process does not converge.

If the PRINT= option is not specified or the ONLY *global-display-option* is not specified, then the default displayed output is equivalent to specifying PRINT=(SELECTION CONVSTATUS NLOSUMMARY STATISTICS ESTIMATES).

VARDEF=option

specifies the denominator to use for computing the covariance estimates. You can specify one of the following values for *option*:

DF

specifies that the number of nonmissing observations minus the model degrees of freedom (number of parameters) be used.

N

specifies that the number of nonmissing observations be used.

The details of the covariance estimation are provided in the section “[Estimating Covariance and Standard Errors](#)” on page 1565.

VERBOSE=verbosity-level

specifies the amount of messages printed to the SAS log by PROC SEVERITY. A higher number prints messages with the same or more detail.

The following options control the model estimation and selection process:

CRITERION | CRITERIA | CRIT=*criterion-option*

specifies the model selection criterion.

If two or more models are specified for estimation, then the one with the best value for the selection criterion is chosen as the best model. If the OUTMODELINFO= data set is specified, then the best model's observation has a value of 1 for the `_SELECTED_` variable. You can specify one of the following *criterion-options*:

AD

specifies the Anderson-Darling (AD) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

AIC

specifies the Akaike's information criterion (AIC) as the selection criterion. A lower value is deemed better.

AICC

specifies the finite-sample corrected Akaike's information criterion (AICC) as the selection criterion. A lower value is deemed better.

BIC

specifies Schwarz Bayesian information criterion (BIC) as the selection criterion. A lower value is deemed better.

CUSTOM

specifies the custom objective function as the selection criterion. You can specify this only if you also specify the **OBJECTIVE=** option. A lower value is deemed better.

CVM

specifies the Cramér-von Mises (CvM) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

KS

specifies the Kolmogorov-Smirnov (KS) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

LOGLIKELIHOOD | LL

specifies $-2 * \log(L)$ as the selection criterion, where L is the likelihood of the data. A lower value is deemed better. This is the default.

More details about these *criterion-options* are provided in the section “[Statistics of Fit](#)” on page 1575.

EMPIRICALCDF | EDF=*method*

specifies the method to use for computing the nonparametric or empirical estimate of the cumulative distribution function of the data. You can specify one of the following values for *method*:

AUTOMATIC | AUTO

specifies that the method be chosen automatically based on the data specification. This option is the default. If no censoring or truncation is specified, then the standard empirical estimation method (STANDARD) is chosen. If right-censoring or left-censoring are both specified, then Turnbull's estimation method (TURNBULL) is chosen. For all other combinations of censoring and truncation, the Kaplan-Meier method (KAPLANMEIER) is chosen.

KAPLANMEIER | KM

specifies that the product limit estimator proposed by Kaplan and Meier (1958) be used. You cannot specify this method when both right-censoring and left-censoring are specified.

MODIFIEDKM | MKM <(options)>

specifies that the modified product limit estimator be used. This method allows Kaplan-Meier's product limit estimates to be more robust by ignoring the contributions to the estimate due to small risk-set sizes. The risk set is the set of observations at the risk of failing, where an observation is said to fail if it has not been processed yet and might experience censoring or truncation. The minimum risk-set size that makes it eligible to be included in the estimation can be specified either as an absolute lower bound on the size (RSLB= option) or a relative lower bound determined by the formula cn^α proposed by Lai and Ying (1991). Values of c and α can be specified by using the C= and ALPHA= options, respectively. By default, the relative lower bound is used with values of $c = 1$ and $\alpha = 0.5$. However, you can modify the default by using the following *options*:

ALPHA | A=number

specifies the value to use for α when the lower bound on the risk set size is defined as cn^α . This value must satisfy $0 < \alpha < 1$.

C=number

specifies the value to use for c when the lower bound on the risk set size is defined as cn^α . This value must satisfy $c > 0$.

RSLB=number

specifies the absolute lower bound on the risk set size to be included in the estimate.

You cannot specify this method when both right-censoring and left-censoring are specified.

STANDARD | STD

specifies that the standard empirical estimation method be used. This ignores any censoring or truncation information even if specified, and can thus result in estimates that are more biased than those obtained with other methods more suitable for such data. You cannot specify this method when both right-censoring and left-censoring are specified.

TURNBULL | EM <(options)>

specifies that the Turnbull's method be used. This method is used when both right-censoring and left-censoring are specified. An iterative expectation-maximization (EM) algorithm proposed by Turnbull (1976) is used to compute the empirical estimates. If truncation is also specified, then the modification suggested by Frydman (1994) is used. You can modify the default behavior of the EM algorithm by using the following *options*:

Experimental

ENSUREMLE

specifies that the final EDF estimates be maximum likelihood estimates. The Kuhn-Tucker conditions are computed for the likelihood maximization problem and checked to ensure that EM algorithm converges to maximum likelihood estimates. The method generalizes the method proposed by Gentleman and Geyer (1994) by taking into account the truncation information, if specified.

EPS=number

specifies the maximum relative error to be allowed between estimates of two consecutive iterations. This criterion is used to check the convergence of the algorithm. If you do not specify this option, then PROC SEVERITY uses a default value of 1.0E–8.

MAXITER=number

specifies the maximum number of iterations to attempt to find the empirical estimates. If you do not specify this option, then PROC SEVERITY uses a default value of 500.

ZEROPROB=number

specifies the threshold below which an empirical estimate of the probability is considered zero. This option is used to decide if the final estimate is a maximum likelihood estimate. This option does not have an effect if you do not specify the ENSUREMLE option. If you specify the ENSUREMLE option, but do not specify this option, then PROC SEVERITY uses a default value of 1.0E–8.

More details about each of the methods are provided in the section “[Empirical Distribution Function Estimation Methods](#)” on page 1569.

OBJECTIVE=symbol-name

names the symbol that represents the objective function in the specified SAS programming statements. For each model to be estimated, PROC SEVERITY executes the programming statements to compute the value of this symbol for each observation. The values are added across all observations to obtain the value of the objective function. The optimization algorithm estimates the model parameters such that the objective function value is *minimized*. A separate optimization problem is solved for each candidate distribution. If a BY statement is specified, then a separate optimization problem is solved for each candidate distribution within each BY group.

Experimental

More details about writing SAS programming statements to define your own objective function are provided in the section “[Custom Objective Functions \(Experimental\)](#)” on page 1596.

BY Statement

A BY statement can be used in the SEVERITY procedure to process the input data set in groups of observations defined by the BY variables.

When a BY statement appears, the procedure expects the input data set to be sorted in the order of the BY variables.

LOSS Statement

LOSS < *response-variable-name* > < / *censoring-truncation-options* > ;

The LOSS statement specifies the name of the response or loss variable whose distribution needs to be modeled. You can also specify additional options to indicate any truncation or censoring of the response. The specification of response variable is optional if at least one type of censoring is specified. You must specify a response variable if no censoring is specified. If you specify more than one LOSS statement, then the first statement is used.

All the analysis variables specified in this statement must be present in the input data set that is specified by using the DATA= option in the PROC SEVERITY statement. The response variable is expected to have nonmissing values. If the variable has a missing value in an observation, then a warning is written to the SAS log and that observation is ignored.

The following *censoring-truncation-options* can be used in the LOSS statement:

LEFTCENSORED | **LC**=*variable-name*

LEFTCENSORED | **LC**=*number*

specifies the left-censoring variable or a global left-censoring limit.

You can use the *variable-name* argument to specify a data set variable that contains the left-censoring limit. If the value of this variable is missing, then PROC SEVERITY assumes that such observations are not left-censored.

Alternatively, you can use the *number* argument to specify a left-censoring limit value that applies to all the observations in the data set. This limit must be a nonzero positive number.

By definition of left-censoring, an exact value of the response is not known when it is less than or equal to the left-censoring limit. If the response variable is specified and the value of that variable is less than or equal to the value of the left-censoring limit for some observations, then PROC SEVERITY treats such observations as left-censored and the value of the response variable is ignored. If the response variable is specified and the value of that variable is greater than the value of the left-censoring limit for some observations, then PROC SEVERITY assumes that such observations are not left-censored and the value of the left-censoring limit is ignored.

If both right-censoring and left-censoring limits are specified, then the left-censoring limit must be greater than or equal to the right-censoring limit. If both limits are identical, then the observation is assumed to be uncensored.

More details about left-censoring are provided in the section “[Censoring and Truncation](#)” on page 1561.

LEFTTRUNCATED | **LT**=*variable-name* < (*left-truncation-option*) >

LEFTTRUNCATED | **LT**=*number* < (*left-truncation-option*) >

specifies the left-truncation variable or a global left-truncation threshold.

You can use the *variable-name* argument to specify a data set variable that contains the left-truncation threshold. If the value of this variable is missing or 0 for some observations, then PROC SEVERITY assumes that such observations are not left-truncated.

Alternatively, you can use the *number* argument to specify a left-truncation threshold that applies to all the observations in the data set. This threshold must be a nonzero positive number.

It is assumed that the response variable contains the observed values. By definition of left-truncation, you can observe only a value that is greater than the left-truncation threshold. If a response variable value is less than or equal to the left-truncation threshold, a warning is printed to the SAS log, and the observation is ignored. More details about left-truncation are provided in the section “[Censoring and Truncation](#)” on page 1561.

The following left-truncation option can be specified for an alternative interpretation of the left-truncation threshold:

PROBOBSERVED | POBS=*number*

specifies the probability of observability, which is defined as the probability that the underlying severity event is observed (and recorded) for the specified left-threshold value.

The specified *number* must lie in the (0.0, 1.0] interval. A value of 1.0 is equivalent to specifying that there is no left-truncation, because it means that no severity events can occur with a value less than or equal to the threshold. If you specify value of 1.0, PROC SEVERITY prints a warning to the SAS log and proceeds by assuming that LEFTTRUNCATED= option is not specified.

More details are provided in the section “[Probability of Observability](#)” on page 1562.

RIGHTCENSORED | RC=*variable-name*

RIGHTCENSORED | RC=*number*

specifies the right-censoring variable or a global right-censoring limit.

You can use the *variable-name* argument to specify a data set variable that contains the right-censoring limit. If the value of this variable is missing, then PROC SEVERITY assumes that such observations are not right-censored.

Alternatively, you can use the *number* argument to specify a right-censoring limit value that applies to all the observations in the data set. This limit must be a nonzero positive number.

By definition of right-censoring, an exact value of the response is not known when it is greater than or equal to the right-censoring limit. If the response variable is specified and the value of that variable is greater than or equal to the value of the right-censoring limit for some observations, then PROC SEVERITY treats such observations as right-censored and the value of the response variable is ignored. If the response variable is specified and the value of that variable is less than the value of the right-censoring limit for some observations, then PROC SEVERITY assumes that such observations are not right-censored and the value of the right-censoring limit is ignored.

If both right-censoring and left-censoring limits are specified, then the left-censoring limit must be greater than or equal to the right-censoring limit. If both limits are identical, then the observation is assumed to be uncensored.

More details about right-censoring are provided in the section “[Censoring and Truncation](#)” on page 1561.

RIGHTTRUNCATED | **RT=***variable-name*

RIGHTTRUNCATED | **RT=***number*

specifies the right-truncation variable or a global right-truncation threshold.

You can use the *variable-name* argument to specify a data set variable that contains the right-truncation threshold. If the value of this variable is missing for some observations, then PROC SEVERITY assumes that such observations are not right-truncated.

Alternatively, you can use the *number* argument to specify a right-truncation threshold that applies to all the observations in the data set. This threshold must be a nonzero positive number.

It is assumed that the response variable contains the observed values. By definition of right-truncation, you can observe only a value that is less than or equal to the right-truncation threshold. If a response variable value is greater than the right-truncation threshold, a warning is printed to the SAS log, and the observation is ignored. More details about right-truncation are provided in the section “[Censoring and Truncation](#)” on page 1561.

WEIGHT Statement

WEIGHT *variable-name* ;

The WEIGHT statement specifies the name of a variable whose values represent the weight of each observation. PROC SEVERITY associates a weight of w to each observation, where w is the value of the WEIGHT variable for the observation. If the weight value is missing or less than or equal to 0, then the observation is ignored and a warning is written to the SAS log. When the WEIGHT statement is not specified, each observation is assigned a weight of 1. If you specify more than one WEIGHT statement, then the last statement is used.

The weights are normalized so that they add up to the actual sample size. In particular, weight of each observation is multiplied by $\frac{N}{\sum_{i=1}^N w_i}$, where N is the sample size.

SCALEMODEL Statement

SCALEMODEL *regressor-variable-list* ;

The SCALEMODEL statement specifies regression variables. All the variables specified in this statement must be present in the input data set that is specified by the DATA= option in the PROC SEVERITY statement. The scale parameter of each candidate distribution is linked to a linear combination of these regression variables along with an intercept. If a distribution does not have a scale parameter, then a model based on that distribution is not estimated. If you specify more than one SCALEMODEL statement, then the first statement is used.

The regressor variables are expected to have nonmissing values. If any of the variables has a missing value in an observation, then a warning is written to the SAS log and that observation is ignored.

More details about modeling regression effects are provided in the section “[Estimating Regression Effects](#)” on page 1566.

DIST Statement

DIST *distribution-name-or-keyword* < (*distribution-option*) < *distribution-name-or-keyword* < (*distribution-option*) > > ... > ;

The DIST statement specifies candidate distributions to be estimated by the SEVERITY procedure. You can specify multiple DIST statements, and each statement can contain one or more distribution specifications.

For your convenience, PROC SEVERITY provides the following 10 different predefined distributions (the name in the parentheses is the name to use in the DIST statement): Burr (BURR), exponential (EXP), gamma (GAMMA), generalized Pareto (GPD), inverse Gaussian or Wald (IGAUSS), lognormal (LOGN), Pareto (PARETO), Tweedie (TWEEDIE), scaled Tweedie (STWEEDIE), and Weibull (WEIBULL). These are described in detail in the section “[Predefined Distributions](#)” on page 1551.

You can specify any of the predefined distributions or any distribution that you have defined. If the specified distribution is not a predefined distribution, then you must submit the CMPLIB= system option with appropriate libraries before you submit the PROC SEVERITY step to enable the procedure to find the functions associated with your distribution. The predefined distributions are defined in the Sashelp.Svrtldist library. However, you are not required to specify this library in the CMPLIB= system option.

As a convenience, you can also use a shortcut keyword `_PREDEFINED_` to indicate that you want to fit all the predefined distributions. **NOTE:** The TWEEDIE and STWEEDIE distributions are not included by this keyword. If you want to fit these distributions, then you must specify them explicitly.

If you do not specify any DIST statement, then PROC SEVERITY does not fit any distributions and produces the empirical estimates of the cumulative distribution function provided that you have specified the OUTCDF= option or requested a CDF plot.

The following *distribution-option* values can be used in the DIST statement for a distribution name that is not a shortcut keyword:

INIT=(*name=value* ... *name=value*)

specifies the initial values to be used for the distribution parameters to start the parameter estimation process. The values must be specified by parameter names. The parameter names must match the names used in the model definition. For example, let a model M’s definition contain a M_PDF function with following signature:

```
function M_PDF(x, alpha, beta);
```

For this model, the names **alpha** and **beta** must be used for the INIT option. The names are case-insensitive. If you do not specify initial values for some parameters in the INIT statement, then a default value of 0.001 is assumed for those parameters. If you specify an incorrect parameter, PROC SEVERITY prints a warning to the SAS log and does not fit the model. All specified values must be nonmissing.

If you are modeling regression effects, then the initial value of the first distribution parameter (**alpha** in the preceding example) should be the initial *base* value of the scale parameter or log-transformed scale parameter. More details are provided in the section “[Estimating Regression Effects](#)” on page 1566.

The use of INIT= option is one of the three methods available for initializing the parameters. You can find more details in the section “[Parameter Initialization](#)” on page 1565. If none of the initialization methods is used, then PROC SEVERITY initializes all parameters to 0.001.

NLOPTIONS Statement

NLOPTIONS *options* ;

The SEVERITY procedure uses the nonlinear optimization (NLO) subsystem to perform the nonlinear optimization of the likelihood function to obtain the estimates of distribution and regression parameters. You can use the NLOPTIONS statement to control different aspects of this optimization process. For most problems, the default settings of the optimization process are adequate. However, in some cases it might be useful to change the optimization technique or to change the maximum number of iterations. The following statement uses the MAXITER= option to set the maximum number of iterations to 200 and uses the TECH= option to change the optimization technique to the double-dogleg optimization (DBLDOG) rather than the default technique, the trust region optimization (TRUREG), used in the SEVERITY procedure:

```
nloptions tech=dbldog maxiter=200;
```

A discussion of the full range of *options* that can be used with the NLOPTIONS statement is given in Chapter 6, “[Nonlinear Optimization Methods](#).” The SEVERITY procedure supports all of those options except the options that are related to displaying the optimization information. You can use the [PRINT=](#) option in the PROC SEVERITY statement to request the optimization summary and iteration history. If you specify more than one NLOPTIONS statement, then the first statement is used.

Programming Statements ([Experimental](#))

You can use a series of programming statements that use variables in the input data set specified by DATA= option in the PROC SEVERITY statement to assign a value to an objective function symbol. The objective function symbol must be specified using the [OBJECTIVE=](#) option in the PROC SEVERITY statement. If you do not specify the [OBJECTIVE=](#) option in the PROC SEVERITY statement, then the programming statements are ignored and models are estimated using the maximum likelihood method.

You can use most DATA step statements and functions in your program. Any additional functions, restrictions, and differences are listed in the section “[Custom Objective Functions \(\[Experimental\]\(#\)\)](#)” on page 1596.

Details: SEVERITY Procedure

Predefined Distributions

PROC SEVERITY assumes the following model for the response variable Y

$$Y \sim \mathcal{F}(\Theta)$$

where \mathcal{F} is a continuous probability distribution with parameters Θ . The model hypothesizes that the observed response is generated from a stochastic process that is governed by the distribution \mathcal{F} . This model is typically referred to as the error model. Given a representative input sample of response variable values, PROC SEVERITY estimates the model parameters for any distribution \mathcal{F} and computes the statistics of fit for each model. This enables you to find the distribution that is most likely to generate the observed sample.

A set of predefined distributions is provided with the SEVERITY procedure. A summary of the distributions is provided in [Table 23.2](#). For each distribution, the table lists the name of the distribution that should be used in the DIST statement, the parameters of the distribution along with their bounds, and the mathematical expressions for the probability density function (PDF) and cumulative distribution function (CDF) of the distribution.

All the predefined distributions, except LOGN and TWEEDIE, are parameterized such that their first parameter is the scale parameter. For LOGN, the first parameter μ is a log-transformed scale parameter. TWEEDIE does not have a scale parameter. The presence of scale parameter or a log-transformed scale parameter enables you to use all of the predefined distributions, except TWEEDIE, as a candidate for estimating regression effects.

A distribution model is associated with each predefined distribution. You can also define your own distribution model, which is a set of functions and subroutines that you define by using the FCMP procedure. See the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1579 for more details.

Table 23.2 Predefined SEVERITY Distributions

Name	Distribution	Parameters	PDF (f) and CDF (F)
BURR	Burr	$\theta > 0, \alpha > 0,$ $\gamma > 0$	$f(x) = \frac{\alpha \gamma z^\gamma}{x(1+z^\gamma)^{(\alpha+1)}}$ $F(x) = 1 - \left(\frac{1}{1+z^\gamma}\right)^\alpha$
EXP	Exponential	$\theta > 0$	$f(x) = \frac{1}{\theta} e^{-z}$ $F(x) = 1 - e^{-z}$
GAMMA	Gamma	$\theta > 0, \alpha > 0$	$f(x) = \frac{z^\alpha e^{-z}}{x \Gamma(\alpha)}$ $F(x) = \frac{\gamma(\alpha, z)}{\Gamma(\alpha)}$
GPD	Generalized Pareto	$\theta > 0, \xi > 0$	$f(x) = \frac{1}{\theta} (1 + \xi z)^{-1-1/\xi}$ $F(x) = 1 - (1 + \xi z)^{-1/\xi}$
IGAUSS	Inverse Gaussian (Wald)	$\theta > 0, \alpha > 0$	$f(x) = \frac{1}{\theta} \sqrt{\frac{\alpha}{2\pi z^3}} e^{-\frac{\alpha(z-1)^2}{2z}}$ $F(x) = \Phi\left((z-1)\sqrt{\frac{\alpha}{z}}\right) + \Phi\left(-(z+1)\sqrt{\frac{\alpha}{z}}\right) e^{2\alpha}$
LOGN	Lognormal	μ (no bounds), $\sigma > 0$	$f(x) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2}$ $F(x) = \Phi\left(\frac{\log(x)-\mu}{\sigma}\right)$
PARETO	Pareto	$\theta > 0, \alpha > 0$	$f(x) = \frac{\alpha \theta^\alpha}{(x+\theta)^{\alpha+1}}$ $F(x) = 1 - \left(\frac{\theta}{x+\theta}\right)^\alpha$
TWEEDIE	Tweedie ⁶	$\mu > 0, \phi > 0,$ $p > 1$	$f(x) = a(x, \phi) \exp\left[\frac{1}{\phi} \left(\frac{x\mu^{1-p}}{1-p} - \kappa(\mu, p)\right)\right]$ $F(x) = \int_0^x f(t) dt$
STWEEDIE	Scaled Tweedie ⁶	$\theta > 0, \lambda > 0,$ $1 < p < 2$	$f(x) = a(x, \theta, \lambda, p) \exp\left(-\frac{x}{\theta} - \lambda\right)$ $F(x) = \int_0^x f(t) dt$
WEIBULL	Weibull	$\theta > 0, \tau > 0$	$f(x) = \frac{1}{x} \tau z^\tau e^{-z^\tau}$ $F(x) = 1 - e^{-z^\tau}$

Notes:

1. $z = x/\theta$, wherever z is used.
2. θ denotes the scale parameter for all the distributions. For LOGN, $\log(\theta) = \mu$.
3. Parameters are listed in the order in which they are defined in the distribution model.
4. $\gamma(a, b) = \int_0^b t^{a-1} e^{-t} dt$ is the lower incomplete gamma function.
5. $\Phi(y) = \frac{1}{2} \left(1 + \operatorname{erf}\left(\frac{y}{\sqrt{2}}\right)\right)$ is the standard normal CDF.
6. See the section “[Tweedie Distributions](#)” on page 1553 for more details.

Tweedie Distributions

Tweedie distributions are a special case of the exponential dispersion family (Jørgensen, 1987) with a property that the variance of the distribution is equal to $\phi\mu^p$, where μ is the mean of the distribution, ϕ is a dispersion parameter, and p is an index parameter as discovered by Tweedie (1984). The distribution is defined for all values of p except for values of p in the open interval $(0, 1)$. Many important known distributions are a special case of Tweedie distributions including normal ($p=0$), Poisson ($p=1$), gamma ($p=2$), and the inverse Gaussian ($p=3$). Apart from these special cases, the probability density function (PDF) of the Tweedie distribution does not have an analytic expression. For $p > 1$, it has the form (Dunn and Smyth 2005),

$$f(x; \mu, \phi, p) = a(x, \phi) \exp \left[\frac{1}{\phi} \left(\frac{x\mu^{1-p}}{1-p} - \kappa(\mu, p) \right) \right]$$

where $\kappa(\mu, p) = \mu^{2-p}/(2-p)$ for $p \neq 2$ and $\kappa(\mu, p) = \log(\mu)$ for $p = 2$. The function $a(x, \phi)$ does not have an analytical expression. It is typically evaluated using series expansion methods described in Dunn and Smyth (2005).

For $1 < p < 2$, the Tweedie distribution is a compound Poisson-gamma mixture distribution, which is the distribution of S defined as

$$S = \sum_{i=1}^N X_i$$

where $N \sim \text{Poisson}(\lambda)$ and $X_i \sim \text{gamma}(\alpha, \theta)$ are iid gamma random variables with shape parameter α and scale parameter θ . At $X = 0$, the density is a probability mass that is governed by the Poisson distribution, and for values of $X > 0$, it is a mixture of gamma variates with Poisson mixing probability. The parameters λ , α and θ are related to the natural parameters μ , ϕ , and p of the Tweedie distribution as

$$\begin{aligned} \lambda &= \frac{\mu^{2-p}}{\phi(2-p)} \\ \alpha &= \frac{2-p}{p-1} \\ \theta &= \phi(p-1)\mu^{p-1} \end{aligned}$$

The mean of a Tweedie distribution is positive for $p > 1$.

Two predefined versions of the Tweedie distribution are provided with the SEVERITY procedure. The first version, named **TWEEDIE** and defined for $p > 1$, has the natural parameterization with parameters μ , ϕ , and p . The second version, named **STWEEDIE** and defined for $1 < p < 2$, is the version with a scale parameter. It corresponds to the compound Poisson-gamma distribution with gamma scale parameter θ , Poisson mean parameter λ , and the index parameter p . The index parameter decides the shape parameter α of the gamma distribution as

$$\alpha = \frac{2-p}{p-1}$$

The parameters θ and λ of the **STWEEDIE** distribution are related to the parameters μ and ϕ of the **TWEEDIE** distribution as

$$\begin{aligned} \mu &= \lambda\theta\alpha \\ \phi &= \frac{(\lambda\theta\alpha)^{2-p}}{\lambda(2-p)} = \frac{\theta}{(p-1)(\lambda\theta\alpha)^{p-1}} \end{aligned}$$

You can fit either version when there are no regression variables. Each version has its own merits. If you fit the TWEEDIE version, you have the direct estimate of the overall mean of the distribution. If you are interested in the most practical range of the index parameter $1 < p < 2$, then you can fit the STWEEDIE version, which provides you direct estimates of the Poisson and gamma components that comprise the distribution (an estimate of the gamma shape parameter α is easily obtained from the estimate of p).

If you want to estimate the effect of exogenous (regression) variables on the distribution, then you must use the STWEEDIE version, because PROC SEVERITY requires a distribution to have a scale parameter in order to estimate regression effects. See the section “[Estimating Regression Effects](#)” on page 1566 for more details. The gamma scale parameter θ is the scale parameter of the STWEEDIE distribution. If you are interested in determining the effect of regression variables on the mean of the distribution, you can do so by first fitting the STWEEDIE distribution to determine the effect of the regression variables on the scale parameter θ . Then, you can easily estimate how the mean of the distribution μ is affected by the regression variables using the relationship $\mu = c\theta$, where $c = \lambda\alpha = \lambda(2-p)/(p-1)$. The estimates of the regression parameters remain the same, whereas the estimate of the intercept parameter is adjusted by the estimates of the λ and p parameters.

Parameter Initialization for Predefined Distributions

The parameters are initialized by using the method of moments for all the distributions, except for the gamma and the Weibull distributions. For the gamma distribution, approximate maximum likelihood estimates are used. For the Weibull distribution, the method of percentile matching is used.

Given n observations of the severity value y_i ($1 \leq i \leq n$), the estimate of k th raw moment is denoted by m_k and computed as

$$m_k = \frac{1}{n} \sum_{i=1}^n y_i^k$$

The 100 p th percentile is denoted by π_p ($0 \leq p \leq 1$). By definition, π_p satisfies

$$F(\pi_p-) \leq p \leq F(\pi_p)$$

where $F(\pi_p-) = \lim_{h \downarrow 0} F(\pi_p - h)$. PROC SEVERITY uses the following practical method of computing π_p . Let $\hat{F}_n(y)$ denote the empirical distribution function (EDF) estimate at a severity value y . Let y_p^- and y_p^+ denote two consecutive values in the ascending sequence of y values such that $\hat{F}_n(y_p^-) < p$ and $\hat{F}_n(y_p^+) \geq p$. Then, the estimate $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = y_p^- + \frac{p - \hat{F}_n(y_p^-)}{\hat{F}_n(y_p^+) - \hat{F}_n(y_p^-)}(y_p^+ - y_p^-)$$

Let ϵ denote the smallest double-precision floating-point number such that $1 + \epsilon > 1$. This machine precision constant can be obtained by using the CONSTANT function in Base SAS software.

The details of how parameters are initialized for each predefined distribution are as follows:

BURR The parameters are initialized by using the method of moments. The k th raw moment of the Burr distribution is:

$$E[X^k] = \frac{\theta^k \Gamma(1 + k/\gamma) \Gamma(\alpha - k/\gamma)}{\Gamma(\alpha)}, \quad -\gamma < k < \alpha\gamma$$

Three moment equations $E[X^k] = m_k$ ($k = 1, 2, 3$) need to be solved for initializing the three parameters of the distribution. In order to get an approximate closed form solution, the second shape parameter $\hat{\gamma}$ is initialized to a value of 2. If $2m_3 - 3m_1m_2 > 0$, then simplifying and solving the moment equations yields the following feasible set of initial values:

$$\hat{\theta} = \sqrt{\frac{m_2m_3}{2m_3 - 3m_1m_2}}, \quad \hat{\alpha} = 1 + \frac{m_3}{2m_3 - 3m_1m_2}, \quad \hat{\gamma} = 2$$

If $2m_3 - 3m_1m_2 < \epsilon$, then the parameters are initialized as follows:

$$\hat{\theta} = \sqrt{m_2}, \quad \hat{\alpha} = 2, \quad \hat{\gamma} = 2$$

EXP The parameters are initialized by using the method of moments. The k th raw moment of the exponential distribution is:

$$E[X^k] = \theta^k \Gamma(k + 1), \quad k > -1$$

Solving $E[X] = m_1$ yields the initial value of $\hat{\theta} = m_1$.

GAMMA The parameter α is initialized by using its *approximate* maximum likelihood (ML) estimate. For a set of n iid observations y_i ($1 \leq i \leq n$), drawn from a gamma distribution, the log likelihood, l , is defined as follows:

$$\begin{aligned} l &= \sum_{i=1}^n \log \left(y_i^{\alpha-1} \frac{e^{-y_i/\theta}}{\theta^\alpha \Gamma(\alpha)} \right) \\ &= (\alpha - 1) \sum_{i=1}^n \log(y_i) - \frac{1}{\theta} \sum_{i=1}^n y_i - n\alpha \log(\theta) - n \log(\Gamma(\alpha)) \end{aligned}$$

Using a shorter notation of \sum to denote $\sum_{i=1}^n$ and solving the equation $\partial l / \partial \theta = 0$ yields the following ML estimate of θ :

$$\hat{\theta} = \frac{\sum y_i}{n\alpha} = \frac{m_1}{\alpha}$$

Substituting this estimate in the expression of l and simplifying gives

$$l = (\alpha - 1) \sum \log(y_i) - n\alpha - n\alpha \log(m_1) + n\alpha \log(\alpha) - n \log(\Gamma(\alpha))$$

Let d be defined as follows:

$$d = \log(m_1) - \frac{1}{n} \sum \log(y_i)$$

Solving the equation $\partial l / \partial \alpha = 0$ yields the following expression in terms of the digamma function, $\psi(\alpha)$:

$$\log(\alpha) - \psi(\alpha) = d$$

The digamma function can be approximated as follows:

$$\hat{\psi}(\alpha) \approx \log(\alpha) - \frac{1}{\alpha} \left(0.5 + \frac{1}{12\alpha + 2} \right)$$

This approximation is within 1.4% of the true value for all the values of $\alpha > 0$ except when α is arbitrarily close to the positive root of the digamma function (which is approximately 1.461632). Even for the values of α that are close to the positive root, the absolute error between true and approximate values is still acceptable ($|\hat{\psi}(\alpha) - \psi(\alpha)| < 0.005$ for $\alpha > 1.07$). Solving the equation that arises from this approximation yields the following estimate of α :

$$\hat{\alpha} = \frac{3 - d + \sqrt{(d - 3)^2 + 24d}}{12d}$$

If this approximate ML estimate is infeasible, then the method of moments is used. The k th raw moment of the gamma distribution is:

$$E[X^k] = \theta^k \frac{\Gamma(\alpha + k)}{\Gamma(\alpha)}, \quad k > -\alpha$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial value for α :

$$\hat{\alpha} = \frac{m_1^2}{m_2 - m_1^2}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance), then α is initialized as follows:

$$\hat{\alpha} = 1$$

After computing the estimate of α , the estimate of θ is computed as follows:

$$\hat{\theta} = \frac{m_1}{\hat{\alpha}}$$

Both the maximum likelihood method and the method of moments arrive at the same relationship between $\hat{\alpha}$ and $\hat{\theta}$.

GPD

The parameters are initialized by using the method of moments. Notice that for $\xi > 0$, the CDF of the generalized Pareto distribution (GPD) is:

$$\begin{aligned} F(x) &= 1 - \left(1 + \frac{\xi x}{\theta}\right)^{-1/\xi} \\ &= 1 - \left(\frac{\theta/\xi}{x + \theta/\xi}\right)^{1/\xi} \end{aligned}$$

This is equivalent to a Pareto distribution with scale parameter $\theta_1 = \theta/\xi$ and shape parameter $\alpha = 1/\xi$. Using this relationship, the parameter initialization method used for the PARETO distribution is used to get the following initial values for the parameters of the GPD distribution:

$$\hat{\theta} = \frac{m_1 m_2}{2(m_2 - m_1^2)}, \quad \hat{\xi} = \frac{m_2 - 2m_1^2}{2(m_2 - m_1^2)}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance) or $m_2 - 2m_1^2 < \epsilon$, then the parameters are initialized as follows:

$$\hat{\theta} = \frac{m_1}{2}, \quad \hat{\xi} = \frac{1}{2}$$

IGAUSS

The parameters are initialized by using the method of moments. Note that the standard parameterization of the inverse Gaussian distribution (also known as the Wald distribution), in terms of the location parameter μ and shape parameter λ , is as follows (Klugman, Panjer, and Willmot 1998, p. 583):

$$f(x) = \sqrt{\frac{\lambda}{2\pi x^3}} \exp\left(\frac{-\lambda(x - \mu)^2}{2\mu^2 x}\right)$$

$$F(x) = \Phi\left(\left(\frac{x}{\mu} - 1\right) \sqrt{\frac{\lambda}{x}}\right) + \Phi\left(-\left(\frac{x}{\mu} + 1\right) \sqrt{\frac{\lambda}{x}}\right) \exp\left(\frac{2\lambda}{\mu}\right)$$

For this parameterization, it is known that the mean is $E[X] = \mu$ and the variance is $Var[X] = \mu^3/\lambda$, which yields the second raw moment as $E[X^2] = \mu^2(1 + \mu/\lambda)$ (computed by using $E[X^2] = Var[X] + (E[X])^2$).

The predefined IGAUSS distribution in PROC SEVERITY uses the following alternate parameterization to allow the distribution to have a scale parameter, θ :

$$f(x) = \sqrt{\frac{\alpha\theta}{2\pi x^3}} \exp\left(\frac{-\alpha(x - \theta)^2}{2x\theta}\right)$$

$$F(x) = \Phi\left(\left(\frac{x}{\theta} - 1\right) \sqrt{\frac{\alpha\theta}{x}}\right) + \Phi\left(-\left(\frac{x}{\theta} + 1\right) \sqrt{\frac{\alpha\theta}{x}}\right) \exp(2\alpha)$$

The parameters θ (scale) and α (shape) of this alternate form are related to the parameters μ and λ of the preceding form such that $\theta = \mu$ and $\alpha = \lambda/\mu$. Using this relationship, the first and second raw moments of the IGAUSS distribution are:

$$E[X] = \theta$$

$$E[X^2] = \theta^2 \left(1 + \frac{1}{\alpha}\right)$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial values:

$$\hat{\theta} = m_1, \quad \hat{\alpha} = \frac{m_1^2}{m_2 - m_1^2}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance), then the parameters are initialized as follows:

$$\hat{\theta} = m_1, \quad \hat{\alpha} = 1$$

LOGN

The parameters are initialized by using the method of moments. The k th raw moment of the lognormal distribution is:

$$E[X^k] = \exp\left(k\mu + \frac{k^2\sigma^2}{2}\right)$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial values:

$$\hat{\mu} = 2 \log(m_1) - \frac{\log(m_2)}{2}, \quad \hat{\sigma} = \sqrt{\log(m_2) - 2 \log(m_1)}$$

PARETO The parameters are initialized by using the method of moments. The k th raw moment of the Pareto distribution is:

$$E[X^k] = \frac{\theta^k \Gamma(k+1) \Gamma(\alpha-k)}{\Gamma(\alpha)}, -1 < k < \alpha$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial values:

$$\hat{\theta} = \frac{m_1 m_2}{m_2 - 2m_1^2}, \quad \hat{\alpha} = \frac{2(m_2 - m_1^2)}{m_2 - 2m_1^2}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance) or $m_2 - 2m_1^2 < \epsilon$, then the parameters are initialized as follows:

$$\hat{\theta} = m_1, \quad \hat{\alpha} = 2$$

TWEEDIE The parameter p is initialized by assuming that the sample is generated from a gamma distribution with shape parameter α and by computing $\hat{p} = \frac{\hat{\alpha}+2}{\hat{\alpha}+1}$. The initial value $\hat{\alpha}$ is obtained from using the method previously described for the GAMMA distribution. The parameter μ is the mean of the distribution. Hence, it is initialized to the sample mean as

$$\hat{\mu} = m_1$$

Variance of a Tweedie distribution is equal to $\phi \mu^p$. Thus, the sample variance is used to initialize the value of ϕ as

$$\hat{\phi} = \frac{m_2 - m_1^2}{\hat{\mu} \hat{p}}$$

STWEEDIE STWEEDIE is a compound Poisson-gamma mixture distribution with mean $\mu = \lambda \theta \alpha$, where α is the shape parameter of the gamma random variables in the mixture and the parameter p is determined solely by α . First, the parameter p is initialized by assuming that the sample is generated from a gamma distribution with shape parameter α and by computing $\hat{p} = \frac{\hat{\alpha}+2}{\hat{\alpha}+1}$. The initial value $\hat{\alpha}$ is obtained from using the method previously described for the GAMMA distribution. As done for initializing the parameters of the TWEEDIE distribution, the sample mean and variance are used to compute the values $\hat{\mu}$ and $\hat{\phi}$ as

$$\hat{\mu} = m_1$$

$$\hat{\phi} = \frac{m_2 - m_1^2}{\hat{\mu} \hat{p}}$$

Based on the relationship between the parameters of TWEEDIE and STWEEDIE distributions described in the section “[Tweedie Distributions](#)” on page 1553, values of θ and λ are initialized as

$$\hat{\theta} = \hat{\phi}(\hat{p} - 1)\hat{\mu}^{p-1}$$

$$\hat{\lambda} = \frac{\hat{\mu}}{\hat{\theta} \hat{\alpha}}$$

WEIBULL The parameters are initialized by using the percentile matching method. Let $q1$ and $q3$ denote the estimates of the 25th and 75th percentiles, respectively. Using the formula for the CDF of Weibull distribution, they can be written as

$$1 - \exp(-(q1/\theta)^\tau) = 0.25$$

$$1 - \exp(-(q3/\theta)^\tau) = 0.75$$

Simplifying and solving these two equations yields the following initial values:

$$\hat{\theta} = \exp\left(\frac{r \log(q1) - \log(q3)}{r - 1}\right), \quad \hat{\tau} = \frac{\log(\log(4))}{\log(q3) - \log(\hat{\theta})}$$

where $r = \log(\log(4))/\log(\log(4/3))$. These initial values agree with those suggested in Klugman, Panjer, and Willmot (1998).

A summary of the initial values of all the parameters for all the predefined distributions is given in [Table 23.3](#). The table also provides the names of the parameters to use in the **INIT=** option in the **DIST** statement if you want to provide a different initial value.

Table 23.3 Parameter Initialization for Predefined Distributions

Distribution	Parameter	Name for INIT option	Default Initial Value
BURR	θ	theta	$\sqrt{\frac{m_2 m_3}{2m_3 - 3m_1 m_2}}$
	α	alpha	$1 + \frac{m_3}{2m_3 - 3m_1 m_2}$
	γ	gamma	2
EXP	θ	theta	m_1
GAMMA	θ	theta	m_1/α
	α	alpha	$\frac{3-d+\sqrt{(d-3)^2+24d}}{12d}$
GPD	θ	theta	$m_1 m_2 / (2(m_2 - m_1^2))$
	ξ	xi	$(m_2 - 2m_1^2) / (2(m_2 - m_1^2))$
IGAUSS	θ	theta	m_1
	α	alpha	$m_1^2 / (m_2 - m_1^2)$
LOGN	μ	mu	$2 \log(m_1) - \log(m_2)/2$
	σ	sigma	$\sqrt{\log(m_2) - 2 \log(m_1)}$
PARETO	θ	theta	$m_1 m_2 / (m_2 - 2m_1^2)$
	α	alpha	$2(m_2 - m_1^2) / (m_2 - 2m_1^2)$
TWEEDIE	μ	mu	m_1
	ϕ	phi	$(m_2 - m_1^2) / m_1^p$
	p	p	$(\alpha + 2) / (\alpha + 1)$
			where $\alpha = \frac{3-d+\sqrt{(d-3)^2+24d}}{12d}$
STWEEDIE	θ	theta	$(m_2 - m_1^2)(p - 1) / m_1$
	λ	lambda	$m_1^2 / (\alpha(m_2 - m_1^2)(p - 1))$
	p	p	$(\alpha + 2) / (\alpha + 1)$
			where $\alpha = \frac{3-d+\sqrt{(d-3)^2+24d}}{12d}$
WEIBULL	θ	theta	$\exp\left(\frac{r \log(q1) - \log(q3)}{r-1}\right)$
	τ	tau	$\log(\log(4)) / (\log(q3) - \log(\hat{\theta}))$

Notes:

- m_k denotes the k th raw moment
- $d = \log(m_1) - (\sum \log(y_i))/n$
- $q1$ and $q3$ denote the 25th and 75th percentiles, respectively
- $r = \log(\log(4)) / \log(\log(4/3))$

Censoring and Truncation

One of the key features of PROC SEVERITY is that it enables you to specify whether the severity event's magnitude is observable and if it is observable, then whether the exact value of the magnitude is known. If an event is unobservable when the magnitude is in certain intervals, then it is referred to as a truncation effect. If the exact magnitude of the event is not known, but it is known to have a value in a certain interval, then it is referred to as a censoring effect.

PROC SEVERITY allows a severity event to be subject to any combination of the following four censoring and truncation effects:

- **Left-truncation:** An event is said to be left-truncated if it is observed only when $Y > T^l$, where Y denotes the random variable for the magnitude and T^l denotes a random variable for the truncation threshold. You can specify left-truncation using the **LEFTTRUNCATED=** option in the LOSS statement.
- **Right-truncation:** An event is said to be right-truncated if it is observed only when $Y \leq T^r$, where Y denotes the random variable for the magnitude and T^r denotes a random variable for the truncation threshold. You can specify right-truncation using the **RIGHTTRUNCATED=** option in the LOSS statement.
- **Left-censoring:** An event is said to be left-censored if it is known that the magnitude is $Y \leq C^l$, but the exact value of Y is not known. C^l is a random variable for the censoring limit. You can specify left-censoring using the **LEFTCENSORED=** option in the LOSS statement.
- **Right-censoring:** An event is said to be right-censored if it is known that the magnitude is $Y > C^r$, but the exact value of Y is not known. C^r is a random variable for the censoring limit. You can specify right-censoring using the **RIGHTCENSORED=** option in the LOSS statement.

For each effect, you can specify a different threshold or limit for each observation or specify a single threshold or limit that applies to all the observations.

If all the four types of effects are present on an event, then the following relationship holds: $T^l < C^r \leq C^l \leq T^r$. PROC SEVERITY checks these relationships and write a warning to the SAS log if any is violated.

If the response variable is specified in the LOSS statement, then PROC SEVERITY also checks whether each observation satisfies the definitions of the specified censoring and truncation effects. If left-truncation is specified, then PROC SEVERITY ignores observations where $Y \leq T^l$, because such observations are not observable by definition. Similarly, if right-truncation is specified, then PROC SEVERITY ignores observations where $Y > T^r$. If left-censoring is specified, then PROC SEVERITY treats an observation with $Y > C^l$ as uncensored and ignores the value of C^l . The observations with $Y \leq C^l$ are considered as left-censored, and the value of Y is ignored. If right-censoring is specified, then PROC SEVERITY treats an observation with $Y \leq C^r$ as uncensored and ignores the value of C^r . The observations with $Y > C^r$ are considered as right-censored, and the value of Y is ignored. If both left-censoring and right-censoring are specified, it is referred to as interval-censoring. If $C^r < C^l$ is satisfied for an observation, then it is considered as interval-censored and the value of the response variable is ignored. If $C^r = C^l$ for an observation, then PROC SEVERITY assumes that observation to be uncensored. If all the observations in

a data set are censored in some form, then the specification of the response variable in the LOSS statement is optional, because the actual value of the response variable is not required for the purposes of estimating a model.

Specification of censoring and truncation affects the likelihood of the data (see the section “[Likelihood Function](#)” on page 1563) and how the empirical distribution function (EDF) is estimated (see the section “[Empirical Distribution Function Estimation Methods](#)” on page 1569).

Probability of Observability

For left-truncated data, PROC SEVERITY also enables you to provide additional information in the form of *probability of observability* by using the **PROBOBSERVED=** option. It is defined as the probability that the underlying severity event gets observed (and recorded) for the specified left-truncation threshold value. For example, if you specify a value of 0.75, then for every 75 observations recorded above a specified threshold, 25 more events have happened with a severity value less than or equal to the specified threshold. Although the exact severity value of those 25 events is not known, PROC SEVERITY can use the information about the number of those events.

In particular, for each left-truncated observation, PROC SEVERITY assumes a presence of $(1 - p)/p$ additional observations with $y_i = t_i$. These additional observations are then used for computing the likelihood (see the section “[Probability of Observability and Likelihood](#)” on page 1564) and an unconditional estimate of the empirical distribution function (see the section “[EDF Estimates and Truncation](#)” on page 1573).

Truncation and Conditional CDF Estimates

If left-truncation is specified without the probability of observability or if right-truncation is specified, then the EDF estimates computed by all methods except the STANDARD method are conditional on the truncation information. See the section “[EDF Estimates and Truncation](#)” on page 1573 for more details. In such cases, PROC SEVERITY uses conditional estimates of the CDF whenever they are used for computational or visual comparison with the EDF estimates.

Let $t_{\min}^l = \min_i \{t_i^l\}$ be the smallest value of the left-truncation threshold (t_i^l is the left-truncation threshold for observation i) and $t_{\max}^r = \max_i \{t_i^r\}$ be the largest value of the right-truncation threshold (t_i^r is the right-truncation threshold for observation i). If $\hat{F}(y)$ denotes the unconditional estimate of the CDF at y , then the conditional estimate $\hat{F}^c(y)$ is computed as follows:

- If probability of observability is not specified, then the EDF estimates are conditional on the left-truncation information. If an observation is both left-truncated and right-truncated, then

$$\hat{F}^c(y) = \frac{\hat{F}(y) - \hat{F}(t_{\min}^l)}{\hat{F}(t_{\max}^r) - \hat{F}(t_{\min}^l)}$$

If an observation is left-truncated but not right-truncated, then

$$\hat{F}^c(y) = \frac{\hat{F}(y) - \hat{F}(t_{\min}^l)}{1 - \hat{F}(t_{\min}^l)}$$

If an observation is right-truncated but not left-truncated, then

$$\hat{F}^c(y) = \frac{\hat{F}(y)}{\hat{F}(t_{\max}^r)}$$

- If probability of observability is specified, then EDF estimates are not conditional on the left-truncation information. If an observation is not right-truncated, then the conditional estimate is the same as the unconditional estimate. If an observation is right-truncated, then the conditional estimate is computed as

$$\hat{F}^c(y) = \frac{\hat{F}(y)}{\hat{F}(t_{\max}^r)}$$

If regressors are specified, then $\hat{F}(y)$, $\hat{F}(t_{\min}^l)$, and $\hat{F}(t_{\max}^r)$ are all computed from a mixture distribution, as described in the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1569.

Parameter Estimation Method

If you have not specified a custom objective function by specifying programming statements and the **OBJECTIVE=** option in the PROC SEVERITY statement, then PROC SEVERITY uses the maximum likelihood (ML) method to estimate the parameters of each model. A nonlinear optimization process is used to maximize the log of the likelihood function. If you have specified a custom objective function, then PROC SEVERITY uses a nonlinear optimization algorithm to estimate the parameters of each model that minimize the value of your specified objective function. More details are provided in the section “[Custom Objective Functions \(Experimental\)](#)” on page 1596.

Likelihood Function

Let $f_{\Theta}(x)$ and $F_{\Theta}(x)$ denote the PDF and CDF, respectively, evaluated at x for a set of parameter values Θ . Let Y denote the random response variable, and let y denote its value recorded in an observation in the input data set. Let T^l and T^r denote the random variables for the left-truncation and right-truncation threshold, respectively, and let t^l and t^r denote their values for an observation, respectively. If there is no left-truncation, then $t^l = \tau^l$, where τ^l is the smallest value in the support of the distribution; so $F(t^l) = 0$. If there is no right-truncation, then $t^r = \tau_h$, where τ_h is the largest value in the support of the distribution; so $F(t^r) = 1$. Let C^l and C^r denote the random variables for the left-censoring and right-censoring limit, respectively, and let c^l and c^r denote their values for an observation, respectively. If there is no left-censoring, then $c^l = \tau_h$, so $F(c^l) = 1$. If there is no right-censoring, then $c^r = \tau^l$, so $F(c^r) = 0$.

The set of input observations can be categorized into the following four subsets within each BY group:

- E is the set of uncensored and untruncated observations. The likelihood of an observation in E is

$$l_E = \Pr(Y = y) = f_{\Theta}(y)$$

- E_t is the set of uncensored observations that are truncated. The likelihood of an observation in E_t is

$$l_{E_t} = \Pr(Y = y | t^l < Y \leq t^r) = \frac{f_{\Theta}(y)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)}$$

- C is the set of censored observations that are not truncated. The likelihood of an observation C is

$$l_C = \Pr(c^r < Y \leq c^l) = F_{\Theta}(c^l) - F_{\Theta}(c^r)$$

- C_t is the set of censored observations that are truncated. The likelihood of an observation C_t is

$$l_{C_t} = \Pr(c^r < Y \leq c^l | t^l < Y \leq t^r) = \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)}$$

Note that $(E \cup E_t) \cap (C \cup C_t) = \emptyset$. Also, the sets E_t and C_t are empty when no truncation is specified, and the sets C and C_t are empty when no censoring is specified.

Given this, the likelihood of the data L is as follows:

$$L = \prod_E f_{\Theta}(y) \prod_{E_t} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)} \prod_C F_{\Theta}(c^l) - F_{\Theta}(c^r) \prod_{C_t} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)}$$

The maximum likelihood procedure used by PROC SEVERITY finds an optimal set of parameter values $\hat{\Theta}$ that maximizes $\log(L)$ subject to the boundary constraints on parameter values. For a distribution *dist*, such boundary constraints can be specified by using the *dist_LOWERBOUNDS* and *dist_UPPERBOUNDS* subroutines. See the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1579 for details. Some aspects of the optimization process can be controlled by using the *NLOPTIONS* statement.

Probability of Observability and Likelihood

If probability of observability is specified for the left-truncation, then PROC SEVERITY uses a modified likelihood function for each truncated observation. If the probability of observability is $p \in (0.0, 1.0]$, then for each left-truncated observation with truncation threshold t^l , there exist $(1 - p)/p$ observations with a response variable value less than or equal to t^l . Each such observation has a probability of $\Pr(Y \leq t^l) = F_{\Theta}(t^l)$. The right-truncation and censoring information does not apply to these added observations. Thus, following the notation of the section “[Likelihood Function](#)” on page 1563, the likelihood of the data is as follows:

$$L = \prod_E f_{\Theta}(y) \prod_{E_t, t^l = \tau^l} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r)} \prod_{E_t, t^l > \tau^l} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r)} F_{\Theta}(t^l)^{\frac{1-p}{p}} \\ \prod_C F_{\Theta}(c^l) - F_{\Theta}(c^r) \prod_{C_t, t^l = \tau^l} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r)} \prod_{C_t, t^l > \tau^l} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r)} F_{\Theta}(t^l)^{\frac{1-p}{p}}$$

Note that the likelihood of the observations that are not left-truncated (observations in sets E and C , and observations in sets E_t and C_t for which $t^l = \tau^l$) is not affected.

If you have specified a custom objective function, then PROC SEVERITY accounts for the probability of observability only while computing the empirical distribution function estimate. The parameter estimates are affected only by your custom objective function.

Estimating Covariance and Standard Errors

PROC SEVERITY computes an estimate of the covariance matrix of the parameters by using the asymptotic theory of the maximum likelihood estimators (MLE). If N denotes the number of observations used for estimating a parameter vector θ , then the theory states that as $N \rightarrow \infty$, the distribution of $\hat{\theta}$, the estimate of θ , converges to a normal distribution with mean θ and covariance \hat{C} such that $\mathbf{I}(\theta) \cdot \hat{C} \rightarrow 1$, where $\mathbf{I}(\theta) = -E[\nabla^2 \log(L(\theta))]$ is the information matrix for the likelihood of the data, $L(\theta)$. The covariance estimate is obtained by using the inverse of the information matrix.

In particular, if $\mathbf{G} = \nabla^2 \log(L(\theta))$ denotes the Hessian matrix of the log likelihood, then the covariance estimate is computed as

$$\hat{C} = \frac{N}{d} \mathbf{G}^{-1}$$

where d is a denominator determined by the **VARDEF=** option. If **VARDEF=N**, then $d = N$, which yields the asymptotic covariance estimate. If **VARDEF=DF**, then $d = N - k$, where k is number of parameters (the model's degrees of freedom). The **VARDEF=DF** option is the default, because it attempts to correct the potential bias introduced by the finite sample.

The standard error s_i of the parameter θ_i is computed as the square root of the i th diagonal element of the estimated covariance matrix; that is, $s_i = \sqrt{\hat{C}_{ii}}$.

If you have specified a custom objective function, then the covariance matrix of the parameters is still computed by inverting the information matrix, except that the Hessian matrix \mathbf{G} is computed as $\mathbf{G} = \nabla^2 \log(U(\theta))$, where U denotes your custom objective function.

Covariance and standard error estimates might not be available if the Hessian matrix is found to be singular at the end of the optimization process. This can especially happen if the optimization process stops without converging.

Parameter Initialization

PROC SEVERITY enables you to initialize parameters of a model in different ways. There can be two kinds of parameters in a model: distribution parameters and regression parameters.

The distribution parameters can be initialized by using one of the following three methods:

INIT= option	You can use the INIT= option in the DIST statement.
INEST= data set	You can use the INEST= data set.

PARMINIT subroutine You can define a *dist_PARMINIT* subroutine in the distribution model. See the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1579 for details.

Note that only one of the initialization methods is used. You cannot combine them. They are used in the following order:

- The method that uses the INIT= option takes the highest precedence. If you use the INIT= option to provide an initial value for at least one parameter, then other initialization methods (INEST= and PARMINIT) are not used. If you specify initial values for some but not all the parameters by using the INIT= option, then the uninitialized parameters are initialized to the default value of 0.001.
If this option is used when regression effects are specified, then the value of the first distribution parameter must be related to the initial value for the *base* value of the scale or log-transformed scale parameter. See the section “[Estimating Regression Effects](#)” on page 1566 for details.
- The method that uses the INEST= data set takes the second precedence. If there is a nonmissing value specified for even one distribution parameter, then the PARMINIT method is not used and any uninitialized parameters are initialized to the default value of 0.001.
- If none of the distribution parameters are initialized by using the INIT= option or the INEST= data set, but the distribution model defines a PARMINIT subroutine, then PROC SEVERITY invokes that subroutine with appropriate inputs to initialize the parameters. If the PARMINIT subroutine returns missing values for some parameters, then those parameters are initialized to the default value of 0.001.
- If none of the initialization methods are used, each distribution parameter is initialized to the default value of 0.001.

See the section “[Estimating Regression Effects](#)” on page 1566 for details on regression models and initialization of regression parameters.

Estimating Regression Effects

The SEVERITY procedure enables you to estimate the effects of regressor (exogenous) variables while fitting a distribution if the distribution has a scale parameter or a log-transformed scale parameter.

Let x_j ($j = 1, \dots, k$) denote the k regressor variables. Let β_j denote the regression parameter that corresponds to the regressor x_j . If regression effects are not specified, then the model for the response variable Y is of the form

$$Y \sim \mathcal{F}(\Theta)$$

where \mathcal{F} is the distribution of Y with parameters Θ . This model is typically referred to as the error model. The regression effects are modeled by extending the error model to the following form:

$$Y \sim \exp\left(\sum_{j=1}^k \beta_j x_j\right) \cdot \mathcal{F}(\Theta)$$

Under this model, the distribution of Y is valid and belongs to the same parametric family as \mathcal{F} if and only if \mathcal{F} has a scale parameter. Let θ denote the scale parameter and Ω denote the set of nonscale distribution parameters of \mathcal{F} . Then the model can be rewritten as

$$Y \sim \mathcal{F}(\theta, \Omega)$$

such that θ is affected by the regressors as

$$\theta = \theta_0 \cdot \exp\left(\sum_{j=1}^k \beta_j x_j\right)$$

where θ_0 is the *base* value of the scale parameter. Thus, the regression model consists of the following parameters: θ_0 , Ω , and β_j ($j = 1, \dots, k$).

Given this form of the model, distributions without a scale parameter cannot be considered when regression effects are to be modeled. If a distribution does not have a direct scale parameter, then PROC SEVERITY accepts it only if it has a log-transformed scale parameter — that is, if it has a parameter $p = \log(\theta)$.

Parameter Initialization for Regression Models

The regression parameters are initialized either by using the values you specify or by the default method.

- If you provide initial values for the regression parameters, then you must provide valid, nonmissing initial values for θ_0 and β_j parameters for all j .

You can specify the initial value for θ_0 using either the INEST= data set or the INIT= option in the DIST statement. If the distribution has a direct scale parameter (no transformation), then the initial value for the first parameter of the distribution is used as an initial value for θ_0 . If the distribution has a log-transformed scale parameter, then the initial value for the first parameter of the distribution is used as an initial value for $\log(\theta_0)$.

You can use only the INEST= data set to specify the initial values for β_j . The INEST= data set must contain nonmissing initial values for all the regressors specified in the SCALEMODEL statement. The only missing value allowed is the special missing value .R, which indicates that the regressor is linearly dependent on other regressors. If you specify .R for a regressor for one distribution in a BY group, you must specify it so for all the distributions in that BY group.

- If you do not specify valid initial values for θ_0 or β_j parameters for all j , then PROC SEVERITY initializes those parameters using the following method:

Let a random variable Y be distributed as $\mathcal{F}(\theta, \Omega)$, where θ is the scale parameter. By definition of the scale parameter, a random variable $W = Y/\theta$ is distributed as $\mathcal{G}(\Omega)$ such that $\mathcal{G}(\Omega) = \mathcal{F}(1, \Omega)$. Given a random error term e that is generated from a distribution $\mathcal{G}(\Omega)$, a value y from the distribution of Y can be generated as

$$y = \theta \cdot e$$

Taking the logarithm of both sides and using the relationship of θ with the regressors yields:

$$\log(y) = \log(\theta_0) + \sum_{j=1}^k \beta_j x_j + \log(e)$$

PROC SEVERITY makes use of the preceding relationship to initialize parameters of a regression model with distribution *dist* as follows:

1. The following linear regression problem is solved to obtain initial estimates of β_0 and β_j :

$$\log(y) = \beta_0 + \sum_{j=1}^k \beta_j x_j$$

The estimates of β_j ($j = 1, \dots, k$) in the solution of this regression problem are used to initialize the respective regression parameters of the model. The estimate of β_0 is later used to initialize the value of θ_0 .

The results of this regression are also used to detect whether any regressors are linearly dependent on the other regressors. If any such regressors are found, then a warning is written to the SAS log and the corresponding regressor is eliminated from further analysis. The estimates for linearly dependent regressors are denoted by a special missing value of .R in the OUTEST= data set and in any displayed output.

2. Let s_0 denote the initial value of the scale parameter.

If the distribution model of *dist* does not contain the *dist_PARMINIT* subroutine, then s_0 and all the nonscale distribution parameters are initialized to the default value of 0.001.

However, it is strongly recommended that each distribution's model contain the *dist_PARMINIT* subroutine. See the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1579 for more details. If that subroutine is defined, then s_0 is initialized as follows:

Each input value y_i of the response variable is transformed to its scale-normalized version w_i as

$$w_i = \frac{y_i}{\exp(\beta_0 + \sum_{j=1}^k \beta_j x_{ij})}$$

where x_{ij} denotes the value of j th regressor in the i th input observation. These w_i values are used to compute the input arguments for the *dist_PARMINIT* subroutine. The values that are computed by the subroutine for nonscale parameters are used as their respective initial values. If the distribution has an untransformed scale parameter, then s_0 is set to the value of the scale parameter that is computed by the subroutine. If the distribution has a log-transformed scale parameter P , then s_0 is computed as $s_0 = \exp(l_0)$, where l_0 is the value of P computed by the subroutine.

3. The value of θ_0 is initialized as

$$\theta_0 = s_0 \cdot \exp(\beta_0)$$

Reporting Estimates of Regression Parameters

When you request estimates to be written to the output (either ODS displayed output or in the OUTEST= data set), the estimate of the base value of the first distribution parameter is reported. If the first parameter is the log-transformed scale parameter, then the estimate of $\log(\theta_0)$ is reported; otherwise, the estimate of θ_0 is reported. The transform of the first parameter of a distribution *dist* is controlled by the *dist_SCALETRANSFORM* function that is defined for it.

CDF and PDF Estimates with Regression Effects

When regression effects are estimated, the estimate of the scale parameter depends on the values of the regressors and estimates of the regression parameters. This results in a potentially different distribution for each observation. In order to make estimates of the cumulative distribution function (CDF) and probability density function (PDF) comparable across distributions and comparable to the empirical distribution function (EDF), PROC SEVERITY reports the CDF and PDF estimates from a mixture distribution. This mixture distribution is an equally weighted mixture of N distributions, where N is the number of observations used for estimation. Each component of the mixture differs only in the value of the scale parameter.

In particular, let $f(y; \hat{\theta}_i, \hat{\Omega})$ and $F(y; \hat{\theta}_i, \hat{\Omega})$ denote the PDF and CDF, respectively, of the component distribution due to observation i , where y denotes the value of the response variable, $\hat{\theta}_i$ denotes the estimate of the scale parameter due to observation i , and $\hat{\Omega}$ denotes the set of estimates of all other parameters of the distribution. The value of θ_i is computed as

$$\hat{\theta}_i = \hat{\theta}_0 \cdot \exp\left(\sum_{j=1}^k \hat{\beta}_j x_{ij}\right)$$

where $\hat{\theta}_0$ is an estimate of the base value of the scale parameter, $\hat{\beta}_j$ are the estimates of regression coefficients, and x_{ij} is the value of regressor j in observation i . Then, the PDF and CDF estimates, $f^*(y)$ and $F^*(y)$, respectively, of the mixture distribution at y are computed as follows:

$$f^*(y) = \frac{1}{W} \sum_{i=1}^N w_i f(y; \hat{\theta}_i, \hat{\Omega})$$

$$F^*(y) = \frac{1}{W} \sum_{i=1}^N w_i F(y; \hat{\theta}_i, \hat{\Omega})$$

where w_i denotes the weight of observation i and W is the total weight ($W = \sum_{i=1}^N w_i$). If the WEIGHT statement is specified, then the weight is equal to the value of the specified weight variable; otherwise, the weight is equal to 1.

The CDF estimates reported in OUTCDF= data set and plotted in CDF plots are the $F^*(y)$ values. The PDF estimates plotted in PDF plots are the $f^*(y)$ values.

If truncation is specified, then the conditional CDF estimates are computed by using the $F^*(y)$ value along with the minimum and maximum truncation limits as described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1562.

Empirical Distribution Function Estimation Methods

The empirical distribution function (EDF) is a nonparametric estimate of the cumulative distribution function (CDF) of the distribution. PROC SEVERITY uses EDF estimates for computing the EDF-based statistics of fit.

If you specify both right-censoring and left-censoring, then the EDF is estimated using Turnbull’s method as described in the section “[EDF Estimation for Right-Censored and Left-Censored Data \(Experimental\)](#)”

on page 1572. If all the observations are uncensored or there is only one type of censoring, then a choice of methods is available as described in the section “EDF Estimation for No Censoring or Single Type of Censoring” on page 1570.

Notation

Let there be a set of N observations, each containing a quintuplet of values $(y_i, t_i^l, t_i^r, c_i^l, c_i^r)$, $i = 1, \dots, N$, where y_i is the value of the response variable, t_i^l is the value of the left-truncation threshold, t_i^r is the value of the right-truncation threshold, c_i^l is the value of the left-censoring limit, and c_i^r is the value of the right-censoring limit.

If an observation is not left-truncated, then $t_i^l = \tau^l$, where τ^l is the smallest value in the support of the distribution; so $F(t_i^l) = 0$. If an observation is not right-truncated, then $t_i^r = \tau_h$, where τ_h is the largest value in the support of the distribution; so $F(t_i^r) = 1$. If an observation is not left-censored, then $c_i^l = \tau_h$; so $F(c_i^l) = 1$. If an observation is not right-censored, then $c_i^r = \tau^l$; so $F(c_i^r) = 0$.

An indicator function $I[e]$ takes a value of 1 or 0 if the expression e is true or false, respectively.

EDF Estimation for No Censoring or Single Type of Censoring

These methods are described in detail assuming that all observations either uncensored or right-censored; that is, each observation is of the form $(y_i, t_i^l, t_i^r, \tau_h, c_i^r)$.

If all observations are either uncensored or left-censored, then each observation is of the form $(y_i, t_i^l, t_i^r, c_i^l, \tau_l)$. It is converted to an observation $(-y_i, -t_i^r, -t_i^l, \tau_h, -c_i^l)$; that is, the signs of all the response variable values are reversed, the new left-truncation threshold is equal to the negative of the original right-truncation threshold, the new right-truncation threshold is equal to the negative of the original left-truncation threshold, and the negative of the original left-censoring limit becomes the new right-censoring limit. With this transformation, each observation is either uncensored or right-censored. The methods described for handling uncensored or right-censored data are now applicable. After the EDF estimates are computed, the observations are transformed back to the original form and EDF estimates are adjusted such $F_n(y_i) = 1 - F_n(-y_i-)$, where $F_n(-y_i-)$ denotes the EDF estimate of the value slightly less than the transformed value $-y_i$.

A set of uncensored or right-censored observations can be converted to a set of observations of the form $(y_i, t_i^l, t_i^r, \delta_i)$, where δ_i is the indicator of right-censoring. $\delta_i = 0$ indicates a right-censored observation, in which case y_i is assumed to record the right-censoring limit c_i^r . $\delta_i = 1$ indicates an uncensored observation, and y_i records the exact observed value. In other words, $\delta_i = I[Y \leq C^r]$ and $y_i = \min(y_i, c_i^r)$.

Given this notation, the EDF is estimated as

$$F_n(y) = \begin{cases} 0 & \text{if } y < y^{(1)} \\ \hat{F}_n(y^{(k)}) & \text{if } y^{(k)} \leq y < y^{(k+1)}, k = 1, \dots, N-1 \\ \hat{F}_n(y^{(N)}) & \text{if } y^{(N)} \leq y \end{cases}$$

where $y^{(k)}$ denotes the k th order statistic of the set $\{y_i\}$ and $\hat{F}_n(y^{(k)})$ is the estimate computed at that value. The definition of \hat{F}_n depends on the estimation method. You can specify a particular method or

let PROC SEVERITY choose an appropriate method by using the `EMPIRICALCDF=` option in the PROC SEVERITY statement. Each method computes \hat{F}_n as follows:

STANDARD This method is the standard way of computing EDF. The EDF estimate at observation i is computed as follows:

$$\hat{F}_n(y_i) = \frac{1}{N} \sum_{j=1}^N I[y_j \leq y_i]$$

This method ignores any censoring and truncation information, even if it is specified. When no censoring or truncation information is specified, this is the default method chosen.

KAPLANMEIER The Kaplan-Meier (KM) estimator, also known as the product-limit estimator, was first introduced by Kaplan and Meier (1958) for censored data. Lynden-Bell (1971) derived a similar estimator for left-truncated data. PROC SEVERITY uses the definition that combines both censoring and truncation information (Klein and Moeschberger 1997, Lai and Ying 1991).

The EDF estimate at observation i is computed as

$$\hat{F}_n(y_i) = 1 - \prod_{\tau \leq y_i} \left(1 - \frac{n_\tau}{R_n(\tau)}\right)$$

where n_τ and $R_n(\tau)$ are defined as follows:

- $n_\tau = \sum_{k=1}^N I[y_k = \tau \text{ and } \tau \leq t_k^r \text{ and } \delta_k = 1]$, which is the number of uncensored observations ($\delta_k = 1$) for which the response variable value is equal to τ and τ is observable according to the right-truncation threshold of that observation ($\tau \leq t_k^r$).
- $R_n(\tau) = \sum_{k=1}^N I[y_k \geq \tau > t_k^l]$, which is the size (cardinality) of the risk set at τ . The term *risk set* has its origins in survival analysis; it contains the events that are at risk of failure at a given time, τ . In other words, it contains the events that have survived up to time τ and might fail at or after τ . For PROC SEVERITY, *time* is equivalent to the magnitude of the event and *failure* is equivalent to an uncensored and observable event, where observable means it satisfies the truncation thresholds.

If you do not explicitly specify a method of computing EDF, then this is the default method used if you specify either right-censoring or left-censoring, but not both. This is also the default method when you specify truncation without any censoring.

MODIFIEDKM The product-limit estimator used by the KAPLANMEIER method does not work well if the risk set size becomes very small. For right-censored data, the size can become small towards the right tail. For left-truncated data, the size can become small at the left tail and can remain so for the entire range of data. This was demonstrated by Lai and Ying (1991). They proposed a modification to the estimator that ignores the effects due to small risk set sizes.

The EDF estimate at observation i is computed as

$$\hat{F}_n(y_i) = 1 - \prod_{\tau \leq y_i} \left(1 - \frac{n_\tau}{R_n(\tau)} \cdot I[R_n(\tau) \geq cN^\alpha]\right)$$

where the definitions of n_τ and $R_n(\tau)$ are identical to those used for the KAPLAN-MEIER method described previously.

You can specify the values of c and α by using the **C=** and **ALPHA=** options. If you do not specify a value for c , the default value used is $c = 1$. If you do not specify a value for α , the default value used is $\alpha = 0.5$.

As an alternative, you can also specify an absolute lower bound, say L , on the risk set size by using the **RSLB=** option, in which case $I[R_n(\tau) \geq cN^\alpha]$ is replaced by $I[R_n(\tau) \geq L]$ in the definition.

EDF Estimation for Right-Censored and Left-Censored Data (Experimental)

If the response variable is subject to both left-censoring and right-censoring effects, then the SEVERITY procedure uses a method proposed by Turnbull (1976) to compute the nonparametric estimates of the cumulative distribution function. The original Turnbull's method is modified using the suggestions made by Frydman (1994) when truncation effects are present.

Let the input data consist of N observations in the form of quintuplets of values $(y_i, t_i^l, t_i^r, c_i^l, c_i^r), i = 1, \dots, N$ with notation described in the section “Notation” on page 1570. For each observation, let $A_i = (c_i^r, c_i^l]$ be the censoring interval; that is, the response variable value is known to lie in the interval A_i , but the exact value is not known. If an observation is uncensored, then $A_i = (y_i - \epsilon, y_i]$ for any arbitrarily small value of $\epsilon > 0$. If an observation is censored, then the value y_i is ignored. Similarly, for each observation, let $B_i = (t_i^l, t_i^r]$ be the truncation interval; that is, the observation is drawn from a truncated (conditional) distribution $F(y, B_i) = P(Y \leq y | Y \in B_i)$.

Two sets, L and R , are formed using A_i and B_i as follows:

$$\begin{aligned} L &= \{c_i^r, 1 \leq i \leq N\} \cup \{t_i^r, 1 \leq i \leq N\} \\ R &= \{c_i^l, 1 \leq i \leq N\} \cup \{t_i^l, 1 \leq i \leq N\} \end{aligned}$$

The sets L and R represent the left endpoints and right endpoints, respectively. A set of disjoint intervals $C_j = [q_j, p_j], 1 \leq j \leq M$ is formed such that $q_j \in L$ and $p_j \in R$ and $q_j \leq p_j$ and $p_j < q_{j+1}$. The value of M is dependent on the nature of censoring and truncation intervals in the input data. Turnbull (1976) showed that the maximum likelihood estimate (MLE) of the EDF can increase only inside intervals C_j . In other words, the MLE estimate is constant in the interval (p_j, q_{j+1}) . The likelihood is independent of the behavior of F_n inside any of the intervals C_j . Let s_j denote the increase in F_n inside an interval C_j . Then, the EDF estimate is as follows:

$$F_n(y) = \begin{cases} 0 & \text{if } y < q_1 \\ \sum_{k=1}^j s_k & \text{if } p_j < y < q_{j+1}, 1 \leq j \leq M-1 \\ 1 & \text{if } y > p_M \end{cases}$$

PROC SEVERITY reports the estimates $F_n(p_j+) = F_n(q_{j+1}-) = \sum_{k=1}^j s_k$ at points p_j and q_{j+1} and reports $F_n(q_1-) = 0$ at point q_1 , where $F_n(x+)$ denotes the limiting estimate at a point that is infinitesimally larger than x when approaching x from values larger than x and where $F_n(x-)$ denotes the limiting estimate at a point that is infinitesimally smaller than x when approaching x from values smaller than x .

PROC SEVERITY uses the expectation-maximization (EM) algorithm proposed by Turnbull (1976), who referred to the algorithm as the self-consistency algorithm. By default, the algorithm runs until one of the following criteria is met:

- **Relative-error criterion:** The maximum relative error between the two consecutive estimates of s_j falls below a threshold ϵ . If l indicates an index of the current iteration, then this can be formally stated as

$$\arg \max_{1 \leq j \leq M} \left\{ \frac{|s_j^l - s_j^{l-1}|}{s_j^{l-1}} \right\} \leq \epsilon$$

You can control the value of ϵ by specifying the **EPS=** suboption of the **EDF=TURNBULL** option in the PROC SEVERITY statement. The default value is 1.0E-8.

- **Maximum-iteration criterion:** The number of iterations exceeds an upper limit specified by the **MAX-ITER=** suboption of the **EDF=TURNBULL** option in the PROC SEVERITY statement. The default number of maximum iterations is 500.

The self-consistent estimates obtained in this manner might not be maximum likelihood estimates. Gentleman and Geyer (1994) suggested the use of the Kuhn-Tucker conditions for the maximum likelihood problem to ensure that the estimates are MLE. If you specify the **ENSUREMLE** suboption of the **EDF=TURNBULL** option in the PROC SEVERITY statement, then PROC SEVERITY computes the Kuhn-Tucker conditions at the end of each iteration to determine whether the estimates $\{s_j\}$ are MLE. If no truncation effects are specified, then the Kuhn-Tucker conditions derived by Gentleman and Geyer (1994) are used. If truncation effects are specified, then PROC SEVERITY uses modified Kuhn-Tucker conditions that account for the truncation effects. An integral part of checking the conditions is to determine whether an estimate s_j is zero or whether an estimate of the Lagrange multiplier or the reduced gradient associated with the estimate s_j is zero. PROC SEVERITY declares these values to be zero if they are less than or equal to a threshold δ . You can control the value of δ by specifying the **ZEROPROB=** suboption of the **EDF=TURNBULL** option in the PROC SEVERITY statement. The default value is 1.0E-8. The algorithm continues until the Kuhn-Tucker conditions are satisfied or the number of iterations exceeds the upper limit. The relative-error criterion stated previously is not used when the **ENSUREMLE** option is specified.

EDF Estimates and Truncation

If truncation is specified, then the estimate $\hat{F}_n(y)$ computed by any method other than the **STANDARD** method is a *conditional* estimate. In other words, $\hat{F}_n(y) = \Pr(Y \leq y | \tau_G < Y \leq \tau_H)$, where G and H denote the (unknown) distribution functions of the left-truncation threshold variable T^l and the right-truncation threshold variable T^r , respectively, τ_G denotes the smallest left-truncation threshold with a nonzero cumulative probability, and τ_H denotes the largest right-truncation threshold with a nonzero cumulative probability. Formally, $\tau_G = \inf\{s : G(s) > 0\}$ and $\tau_H = \sup\{s : H(s) > 0\}$. For computational purposes, PROC SEVERITY estimates τ_G and τ_H by t_{\min}^l and t_{\max}^r , respectively, defined as

$$t_{\min}^l = \min\{t_k^l : 1 \leq k \leq N\}$$

$$t_{\max}^r = \max\{t_k^r : 1 \leq k \leq N\}$$

These estimates are used to compute conditional estimates of the CDF as described in the section “**Truncation and Conditional CDF Estimates**” on page 1562.

If left-truncation is specified *with* the probability of observability p , then PROC SEVERITY uses the additional information provided by p to compute an estimate of the EDF that is not conditional on the left-truncation information. In particular, for each left-truncated observation i with response variable value y_i and truncation threshold t_i^l , an observation j is added with *weight* $w_j = (1 - p)/p$ and $y_j = t_i^l$. Each added observation is assumed to be uncensored and untruncated. Weight on each original observation i is assumed to be 1; that is, $w_i = 1$. Then, the specified EDF method is used by assuming no left-truncation. The EDF estimate that is obtained using this method is not conditional on the left-truncation information. For the KAPLANMEIER and MODIFIEDKM methods with uncensored or right-censored data, definitions of n_τ and $R_n(\tau)$ are modified to account for the weights on the observations. If N^a denotes the total number of observations including the added observations, then n_τ is defined as $n_\tau = \sum_{k=1}^{N^a} w_k I[y_k = \tau \text{ and } \tau \leq t_k^r \text{ and } \delta_k = 1]$, and $R_n(\tau)$ is defined as $R_n(\tau) = \sum_{k=1}^{N^a} w_k I[y_k \geq \tau]$. In the definition of $R_n(\tau)$, the left-truncation information is not used, because it was used along with p to add the observations. If the original data are a combination of left- and right-censored data, then Turnbull's method is applied to the appended set that contains no left-truncated observations.

Supplying EDF Estimates to Functions and Subroutines

The parameter initialization subroutines in distribution models and some predefined utility functions require EDF estimates. See the sections “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1579 and “[Predefined Utility Functions](#)” on page 1591 for details.

PROC SEVERITY supplies the EDF estimates to these subroutines and functions by using two arrays, x and F , the dimension of each array, and a type of the EDF estimates. The type identifies how the EDF estimates are computed and stored. They are as follows:

- Type 1 specifies that EDF estimates are computed using the STANDARD method; that is, the data used for estimation are neither censored nor truncated.
- Type 2 specifies that EDF estimates are computed using either the KAPLANMEIER or the MODIFIEDKM method; that is, the data used for estimation are subject to truncation and one type of censoring (left or right, but not both).
- Type 3 specifies that EDF estimates are computed using the TURNBULL method; that is, the data used for estimation are subject to both left- and right-censoring. The data might or might not be truncated.

For Types 1 and 2, the EDF estimates are stored in arrays x and F of dimension N such that the following holds:

$$F_n(y) = \begin{cases} 0 & \text{if } y < x[1] \\ F[k] & \text{if } x[k] \leq y < x[k+1], k = 1, \dots, N-1 \\ F[N] & \text{if } x[N] \leq y \end{cases}$$

where $[k]$ denotes k th element of the array ($[1]$ denotes the first element of the array).

For Type 3, the EDF estimates are stored in arrays x and F of dimension N such that the following holds:

$$F_n(y) = \begin{cases} 0 & \text{if } y < x[1] \\ \text{undefined} & \text{if } x[2k-1] \leq y < x[2k], k = 1, \dots, (N-1)/2 \\ F[2k] = F[2k+1] & \text{if } x[2k] \leq y < x[2k+1], k = 1, \dots, (N-1)/2 \\ F[N] & \text{if } x[N] \leq y \end{cases}$$

Although the behavior of EDF is theoretically undefined for the interval $[x[2k-1], x[2k]]$, for computational purposes, all predefined functions and subroutines assume that the EDF increases linearly from $F[2k-1]$ to $F[2k]$ in that interval if $x[2k-1] < x[2k]$. If $x[2k-1] = x[2k]$, which can happen when the EDF is estimated from a combination of uncensored and interval-censored data, the predefined functions and subroutines assume that $F_n(x[2k-1]) = F_n(x[2k]) = F[2k]$.

Statistics of Fit

PROC SEVERITY computes and reports various statistics of fit to indicate how well the estimated model fits the data. The statistics belong to two categories: likelihood-based statistics and EDF-based statistics. Statistics Neg2LogLike, AIC, AICC, and BIC are likelihood-based statistics, and statistics KS, AD, and CvM are EDF-based statistics. The following subsections provide definitions of each.

Likelihood-Based Statistics

Let $y_i, i = 1, \dots, N$ denote the response variable values. Let L be the likelihood as defined in the section “Likelihood Function” on page 1563. Let p denote the number of model parameters estimated. Note that $p = p_d + (k - k_r)$, where p_d is the number of distribution parameters, k is the number of regressors, if any, specified in the SCALEMODEL statement, and k_r is the number of regressors found to be linearly dependent (redundant) on other regressors. Given this notation, the likelihood-based statistics are defined as follows:

Neg2LogLike The log likelihood is reported as

$$\text{Neg2LogLike} = -2 \log(L)$$

The multiplying factor -2 makes it easy to compare it to the other likelihood-based statistics. A model with a smaller value of Neg2LogLike is deemed better.

AIC The Akaike’s information criterion (AIC) is defined as

$$\text{AIC} = -2 \log(L) + 2p$$

A model with a smaller value of AIC is deemed better.

AICC The corrected Akaike’s information criterion (AICC) is defined as

$$\text{AICC} = -2 \log(L) + \frac{2Np}{N - p - 1}$$

A model with a smaller value of AICC is deemed better. It corrects the finite-sample bias that AIC has when N is small compared to p . AICC is related to AIC as

$$\text{AICC} = \text{AIC} + \frac{2p(p+1)}{N - p - 1}$$

As N becomes large compared to p , AICC converges to AIC. AICC is usually recommended over AIC as a model selection criterion.

BIC The Schwarz Bayesian information criterion (BIC) is defined as

$$\text{BIC} = -2 \log(L) + p \log(N)$$

A model with a smaller value of BIC is deemed better.

EDF-Based Statistics

This class of statistics is based on the difference between the estimate of the cumulative distribution function (CDF) and the estimate of the empirical distribution function (EDF). Let $y_i, i = 1, \dots, N$ denote the sample of N values of the response variable. Let $r_i = \sum_{j=1}^N I[y_j \leq y_i]$ denote the number of observations with a value less than or equal to y_i , where I is an indicator function. Let $F_n(y_i)$ denote the EDF estimate that is computed by using the method specified in the [EMPIRICALCDF=](#) option. Let $Z_i = \hat{F}(y_i)$ denote the estimate of the CDF. Let $F_n(Z_i)$ denote the EDF estimate of Z_i values that are computed using the same method that is used to compute the EDF of y_i values. Using the probability integral transformation, if $F(y)$ is the true distribution of the random variable Y , then the random variable $Z = F(y)$ is uniformly distributed between 0 and 1 (D'Agostino and Stephens 1986, Ch. 4). Thus, comparing $F_n(y_i)$ with $\hat{F}(y_i)$ is equivalent to comparing $F_n(Z_i)$ with $\hat{F}(Z_i) = Z_i$ (uniform distribution).

Note the following two points regarding which CDF estimates are used for computing the test statistics:

- If regressor variables are specified, then the CDF estimates Z_i used for computing the EDF test statistics are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1569 for details.
- If the EDF estimates are conditional because of the truncation information, then each unconditional estimate Z_i is converted to a conditional estimate using the method described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1562.

In the following, it is assumed that Z_i denotes an appropriate estimate of the CDF if truncation or regression effects are specified. Given this, the EDF-based statistics of fit are defined as follows:

KS The Kolmogorov-Smirnov (KS) statistic computes the largest vertical distance between the CDF and the EDF. It is formally defined as follows:

$$\text{KS} = \sup_y |F_n(y) - F(y)|$$

If the STANDARD method is used to compute the EDF, then the following formula is used:

$$\begin{aligned} D^+ &= \max_i \left(\frac{r_i}{N} - Z_i \right) \\ D^- &= \max_i \left(Z_i - \frac{r_{i-1}}{N} \right) \\ \text{KS} &= \sqrt{N} \max(D^+, D^-) + \frac{0.19}{\sqrt{N}} \end{aligned}$$

Note that r_0 is assumed to be 0.

If the method used to compute the EDF is any method other than the STANDARD method, then the following formula is used:

$$\begin{aligned} D^+ &= \max_i (F_n(Z_i) - Z_i), \text{ if } F_n(Z_i) \geq Z_i \\ D^- &= \max_i (Z_i - F_n(Z_i)), \text{ if } F_n(Z_i) < Z_i \\ \text{KS} &= \sqrt{N} \max(D^+, D^-) + \frac{0.19}{\sqrt{N}} \end{aligned}$$

AD The Anderson-Darling (AD) statistic is a quadratic EDF statistic that is proportional to the expected value of the weighted squared difference between the EDF and CDF. It is formally defined as follows:

$$\text{AD} = N \int_{-\infty}^{\infty} \frac{(F_n(y) - F(y))^2}{F(y)(1 - F(y))} dF(y)$$

If the STANDARD method is used to compute the EDF, then the following formula is used:

$$\text{AD} = -N - \frac{1}{N} \sum_{i=1}^N [(2r_i - 1) \log(Z_i) + (2N + 1 - 2r_i) \log(1 - Z_i)]$$

If the method used to compute the EDF is any method other than the STANDARD method, then the statistic can be computed by using the following two pieces of information:

- If the EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM methods, then EDF is a step function such that the estimate $F_n(z)$ is a constant equal to $F_n(Z_{i-1})$ in interval $[Z_{i-1}, Z_i]$. If the EDF estimates are computed using the TURNBULL method, then there are two types of intervals: one in which the EDF curve is constant and the other in which the EDF curve is theoretically undefined. For computational purposes, it is assumed that the EDF curve is linear for the latter type of the interval. For each method, the EDF estimate $F_n(y)$ at y can be written as

$$F_n(z) = F_n(Z_{i-1}) + S_i(z - Z_{i-1}), \text{ for } z \in [Z_{i-1}, Z_i]$$

where S_i is the slope of the line defined as

$$S_i = \frac{F_n(Z_i) - F_n(Z_{i-1})}{Z_i - Z_{i-1}}$$

For the KAPLANMEIER or MODIFIEDKM method, $S_i = 0$ in each interval.

- Using the probability integral transform $z = F(y)$, the formula simplifies to

$$\text{AD} = N \int_{-\infty}^{\infty} \frac{(F_n(z) - z)^2}{z(1 - z)} dz$$

The computation formula can then be derived from the following approximation:

$$\begin{aligned} \text{AD} &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(F_n(z) - z)^2}{z(1 - z)} dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(F_n(Z_{i-1}) + S_i(z - Z_{i-1}) - z)^2}{z(1 - z)} dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(P_i - Q_i z)^2}{z(1 - z)} dz \end{aligned}$$

where $P_i = F_n(Z_{i-1}) - S_i Z_{i-1}$, $Q_i = 1 - S_i$, and K is the number of points at which the EDF estimate are computed. For the TURNBULL method, $K = 2k$ for some k .

Assuming $Z_0 = 0$, $Z_{K+1} = 1$, $F_n(0) = 0$, and $F_n(Z_K) = 1$ yields the following computation formula:

$$\begin{aligned} \text{AD} = & -N(Z_1 + \log(1 - Z_1) + \log(Z_K) + (1 - Z_K)) \\ & + N \sum_{i=2}^K [P_i^2 A_i - (Q_i - P_i)^2 B_i - Q_i^2 C_i] \end{aligned}$$

where $A_i = \log(Z_i) - \log(Z_{i-1})$, $B_i = \log(1 - Z_i) - \log(1 - Z_{i-1})$, and $C_i = Z_i - Z_{i-1}$.

If EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM method, then $P_i = F_n(Z_{i-1})$ and $Q_i = 1$, which simplifies the formula as

$$\begin{aligned} \text{AD} = & -N(1 + \log(1 - Z_1) + \log(Z_K)) \\ & + N \sum_{i=2}^K [F_n(Z_{i-1})^2 A_i - (1 - F_n(Z_{i-1}))^2 B_i] \end{aligned}$$

CvM The Cramér-von Mises (CvM) statistic is a quadratic EDF statistic that is proportional to the expected value of the squared difference between the EDF and CDF. It is formally defined as follows:

$$\text{CvM} = N \int_{-\infty}^{\infty} (F_n(y) - F(y))^2 dF(y)$$

If the STANDARD method is used to compute the EDF, then the following formula is used:

$$\text{CvM} = \frac{1}{12N} + \sum_{i=1}^N \left(Z_i - \frac{(2r_i - 1)}{2N} \right)^2$$

If the method used to compute the EDF is any method other than the STANDARD method, then the statistic can be computed by using the following two pieces of information:

- As described previously for the AD statistic, the EDF estimates are assumed to be piecewise linear such that the estimate $F_n(y)$ at y is

$$F_n(z) = F_n(Z_{i-1}) + S_i(z - Z_{i-1}), \text{ for } z \in [Z_{i-1}, Z_i]$$

where S_i is the slope of the line defined as

$$S_i = \frac{F_n(Z_i) - F_n(Z_{i-1})}{Z_i - Z_{i-1}}$$

For the KAPLANMEIER or MODIFIEDKM method, $S_i = 0$ in each interval.

- Using the probability integral transform $z = F(y)$, the formula simplifies to:

$$\text{CvM} = N \int_{-\infty}^{\infty} (F_n(z) - z)^2 dz$$

The computation formula can then be derived from the following approximation:

$$\begin{aligned}\text{CvM} &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} (F_n(z) - z)^2 dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} (F_n(Z_{i-1}) + S_i(z - Z_{i-1}) - z)^2 dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} (P_i - Q_i z)^2 dz\end{aligned}$$

where $P_i = F_n(Z_{i-1}) - S_i Z_{i-1}$, $Q_i = 1 - S_i$, and K is the number of points at which the EDF estimate are computed. For the TURNBULL method, $K = 2k$ for some k .

Assuming $Z_0 = 0$, $Z_{K+1} = 1$, and $F_n(0) = 0$ yields the following computation formula:

$$\text{CvM} = N \frac{Z_1^3}{3} + N \sum_{i=2}^{K+1} \left[P_i^2 A_i - P_i Q_i B_i - \frac{Q_i^2}{3} C_i \right]$$

where $A_i = Z_i - Z_{i-1}$, $B_i = Z_i^2 - Z_{i-1}^2$, and $C_i = Z_i^3 - Z_{i-1}^3$.

If EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM method, then $P_i = F_n(Z_{i-1})$ and $Q_i = 1$, which simplifies the formula as

$$\text{CvM} = \frac{N}{3} + N \sum_{i=2}^{K+1} [F_n(Z_{i-1})^2 (Z_i - Z_{i-1}) - F_n(Z_{i-1}) (Z_i^2 - Z_{i-1}^2)]$$

which is similar to the formula proposed by Koziol and Green (1976).

Defining a Distribution Model with the FCMP Procedure

A severity *distribution model* consists of a set of functions and subroutines that are defined using the FCMP procedure. The FCMP procedure is part of Base SAS software. Each function or subroutine must be named as `<distribution-name>_<keyword>`, where *distribution-name* is the identifying short name of the distribution and *keyword* identifies one of the functions or subroutines. The total length of the name should not exceed 32. Each function or subroutine must have a specific signature, which consists of the number of arguments, sequence and types of arguments, and return value type. The summary of all the recognized function and subroutine names and their expected behavior is given in [Table 23.4](#).

Consider following points when you define a distribution model:

- When you define a function or subroutine requiring parameter arguments, the names and order of those arguments must be the same. Arguments other than the parameter arguments can have any name, but they must satisfy the requirements on their type and order.
- When the SEVERITY procedure invokes any function or subroutine, it provides the necessary input values according to the specified signature, and expects the function or subroutine to prepare the output and return it according to the specification of the return values in the signature.

- You can typically use most of the SAS programming statements and SAS functions that you can use in a DATA step for defining the FCMP functions and subroutines. However, there are a few differences in the capabilities of the DATA step and the FCMP procedure. Refer to the documentation of the FCMP procedure to learn more.
- You must specify either the PDF or the LOGPDF function. Similarly, you must specify either the CDF or the LOGCDF function. All other functions are optional, except when necessary for correct definition of the distribution. It is strongly recommended that you define the PARMINIT subroutine to provide a good set of initial values for the parameters. The information provided by PROC SEVERITY to the PARMINIT subroutine enables you to use popular initialization approaches based on the method of moments and the method of percentile matching, but you can implement any algorithm to initialize the parameters by using the values of the response variable and the estimate of its empirical distribution function.
- The LOWERBOUNDS subroutines should be defined if the lower bound on at least one distribution parameter is different from the default lower bound of 0. If you define a LOWERBOUNDS subroutine but do not set a lower bound for some parameter inside the subroutine, then that parameter is assumed to have no lower bound (or a lower bound of $-\infty$). Hence, it is recommended that you explicitly return the lower bound for each parameter when you define the LOWERBOUNDS subroutine.
- The UPPERBOUNDS subroutines should be defined if the upper bound on at least one distribution parameter is different from the default upper bound of ∞ . If you define an UPPERBOUNDS subroutine but do not set an upper bound for some parameter inside the subroutine, then that parameter is assumed to have no upper bound (or a upper bound of ∞). Hence, it is recommended that you explicitly return the upper bound for each parameter when you define the UPPERBOUNDS subroutine.
- If you want to use the distribution in a model with regression effects, then make sure that the first parameter of the distribution is the scale parameter itself or a log-transformed scale parameter. If the first parameter is a log-transformed scale parameter, then you must define the SCALETRANSFORM function.
- In general, it is not necessary to define the gradient and Hessian functions, because PROC SEVERITY uses an internal system to evaluate the required derivatives. The internal system typically computes the derivatives analytically. But it might not be able to do so if your function definitions use other functions that it cannot differentiate analytically. In such cases, derivatives are approximated using a finite difference method and a note is written to the SAS log to indicate the components that are differentiated using such approximations. PROC SEVERITY does reasonably well with these finite difference approximations. But, if you know of a way to compute the derivatives of such components analytically, then you should define the gradient and Hessian functions.

In order to use your distribution with PROC SEVERITY, you need to record the FCMP library that contains the functions and subroutines for your distribution and other FCMP libraries that contain FCMP functions or subroutines used within your distribution's functions and subroutines. Specify all those libraries in the CMPLIB= system option by using the OPTIONS global statement. For more information about the OPTIONS statement, see the *SAS Statements: Reference*. For more information about the CMPLIB= system option, see the *SAS System Options: Reference*.

Each predefined distribution mentioned in the section “[Predefined Distributions](#)” on page 1551 has a distribution model associated with it. The functions and subroutines of all those models are available in the Sashelp.Svrtldist library. The order of the parameters in the signatures of the functions and subroutines is

the same as listed in Table 23.2. You do not need to use the CMPLIB= option in order to use the predefined distributions with PROC SEVERITY. However, if you need to use the functions or subroutines of the predefined distributions in SAS statements other than the PROC SEVERITY step (such as in a DATA step), then specify the Sashelp.Svrtldist library in the CMPLIB= system option by using the OPTIONS global statement prior to using them.

Table 23.4 shows functions and subroutines that define a distribution model, and subsections after the table provide more detail. The functions are listed in alphabetical order of the keyword suffix.

Table 23.4 List of Functions and Subroutines That Define a Distribution Model

Name	Type	Required	Expected to Return
<i>dist_CDF</i>	Function	YES ¹	Cumulative distribution function value
<i>dist_CDFGRADIENT</i>	Subroutine	NO	Gradient of the CDF
<i>dist_CDFHESSIAN</i>	Subroutine	NO	Hessian of the CDF
<i>dist_CONSTANTPARM</i>	Subroutine	NO	Constant parameters
<i>dist_DESCRIPTION</i>	Function	NO	Description of the distribution
<i>dist_LOGCDF</i>	Function	YES ¹	Log of cumulative distribution function value
<i>dist_LOGCDFGRADIENT</i>	Subroutine	NO	Gradient of the LOGCDF
<i>dist_LOGCDFHESSIAN</i>	Subroutine	NO	Hessian of the LOGCDF
<i>dist_LOGPDF</i>	Function	YES ²	Log of probability density function value
<i>dist_LOGPDFGRADIENT</i>	Subroutine	NO	Gradient of the LOGPDF
<i>dist_LOGPDFHESSIAN</i>	Subroutine	NO	Hessian of the LOGPDF
<i>dist_LOGSDF</i>	Function	NO	Log of survival function value
<i>dist_LOGSDFGRADIENT</i>	Subroutine	NO	Gradient of the LOGSDF
<i>dist_LOGSDFHESSIAN</i>	Subroutine	NO	Hessian of the LOGSDF
<i>dist_LOWERBOUNDS</i>	Subroutine	NO	Lower bounds on parameters
<i>dist_PARMINIT</i>	Subroutine	NO	Initial values for parameters
<i>dist_PDF</i>	Function	YES ²	Probability density function value
<i>dist_PDFGRADIENT</i>	Subroutine	NO	Gradient of the PDF
<i>dist_PDFHESSIAN</i>	Subroutine	NO	Hessian of the PDF
<i>dist_SCALETRANSFORM</i>	Function	NO	Type of relationship between the first distribution parameter and the scale parameter
<i>dist_SDF</i>	Function	NO	Survival function value
<i>dist_SDFGRADIENT</i>	Subroutine	NO	Gradient of the SDF
<i>dist_SDFHESSIAN</i>	Subroutine	NO	Hessian of the SDF
<i>dist_UPPERBOUNDS</i>	Subroutine	NO	Upper bounds on parameters

Notes:

1. Either the *dist_CDF* or the *dist_LOGCDF* function must be defined.
2. Either the *dist_PDF* or the *dist_LOGPDF* function must be defined.

The signature syntax and semantics of each function or subroutine are as follows:

dist_CDF

defines a function that returns the value of the cumulative distribution function (CDF) of the distribution at the specified values of the random variable and distribution parameters.

- *Type*: Function
- *Required*: YES
- *Number of arguments*: $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments*:
 - x Numeric value of the random variable at which the CDF value should be evaluated
 - p_1 Numeric value of the first parameter
 - p_2 Numeric value of the second parameter
 -
 - p_m Numeric value of the m th parameter
- *Return value*: Numeric value that contains the CDF value $F(x; p_1, p_2, \dots, p_m)$

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

$$F(x; p_1, p_2, \dots, p_m) = F\left(\frac{x}{p_1}; 1, p_2, \dots, p_m\right)$$

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

$$F(x; p_1, p_2, \dots, p_m) = F\left(\frac{x}{\exp(p_1)}; 0, p_2, \dots, p_m\right)$$

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_CDF(x, P1, P2);
  /* Code to compute CDF by using x, P1, and P2 */

  F = <computed CDF>;
  return (F);
endsub;
```

dist_CONSTANTPARM

defines a subroutine that specifies constant parameters. A parameter is *constant* if it is required for defining a distribution but is not subject to optimization in PROC SEVERITY. Constant parameters are required to be part of the model in order to compute the PDF or the CDF of the distribution. Typically, values of these parameters are known a priori or estimated using some means other than the maximum likelihood method used by PROC SEVERITY. You can estimate them inside the *dist_PARMINIT* subroutine. Once initialized, the parameters remain constant in the context of PROC SEVERITY; that is, they retain their initial value. PROC SEVERITY estimates only the nonconstant parameters.

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: k , where k is the number of constant parameters
- *Sequence and type of arguments*:
 constant parameter 1 Name of the first constant parameter

 constant parameter k Name of the k th constant parameter
- *Return value*: None

Here is a sample structure of the subroutine for a distribution named 'FOO' that has P3 and P5 as its constant parameters, assuming that distribution has at least three parameters:

```
subroutine FOO_CONSTANTPARM(p5, p3);
endsub;
```

The following points should be noted while specifying the constant parameters:

- At least one distribution parameter must be free to be optimized; that is, if a distribution has total m parameters, then k must be strictly less than m .
- If you want to use this distribution for modeling regression effects, then the first parameter must not be a constant parameter.
- The order of arguments in the signature of this subroutine does not matter as long as each argument's name matches the name of one of the parameters that are defined in the signature of the *dist_PDF* function.
- The constant parameters must be specified in signatures of all the functions and subroutines that accept distribution parameters as their arguments.
- You must provide a nonmissing initial value for each constant parameter by using one of the supported parameter initialization methods.

*dist_***DESCRIPTION**

defines a function that returns a description of the distribution.

- *Type*: Function
- *Required*: NO
- *Number of arguments*: None
- *Sequence and type of arguments*: Not applicable
- *Return value*: Character value containing a description of the distribution

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_DESCRIPTION() $48;
    length desc $48;
    desc = "A model for a continuous distribution named foo";
    return (desc);
endsub;
```

There is no restriction on the length of the description (the length of 48 used in the previous example is for illustration purposes only). However, if the length is greater than 256, then only the first 256 characters appear in the displayed output and in the `_DESCRIPTION_` variable of the `OUTMODELINFO=` data set. Hence, the recommended length of the description is less than or equal to 256.

`dist_LOGcore`

defines a function that returns natural logarithm of the specified *core* function of the distribution at the specified values of the random variable and distribution parameters. The *core* keyword can be PDF, CDF, or SDF.

- *Type*: Function
- *Required*: YES only if *core* is PDF or CDF and you have not defined that *core* function; otherwise, NO
- *Number of arguments*: $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments*:
 - x Numeric value of the random variable at which the natural logarithm of the *core* function should be evaluated
 - $p1$ Numeric value of the first parameter
 - $p2$ Numeric value of the second parameter
 -
 - pm Numeric value of the m th parameter
- *Return value*: Numeric value that contains the natural logarithm of the *core* function

Here is a sample structure of the function for the core function PDF of a distribution named 'FOO':

```
function FOO_LOGPDF(x, P1, P2);
  /* Code to compute LOGPDF by using x, P1, and P2 */

  l = <computed LOGPDF>;
  return (l);
endsub;
```

`dist_LOWERBOUNDS`

defines a subroutine that returns lower bounds for the parameters of the distribution. If this subroutine is not defined for a given distribution, then the SEVERITY procedure assumes a lower bound of 0 for each parameter. If a lower bound of l_i is returned for a parameter p_i , then the SEVERITY procedure assumes that $l_i < p_i$ (strict inequality). If a missing value is returned for some parameter, then the SEVERITY procedure assumes that there is no lower bound for that parameter (equivalent to a lower bound of $-\infty$).

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: m , where m is the number of distribution parameters
- *Sequence and type of arguments*:

- | | |
|-------|---|
| p1 | Output argument that returns the lower bound on the first parameter. This must be specified in the OUTARGS statement inside the subroutine's definition. |
| p2 | Output argument that returns the lower bound on the second parameter. This must be specified in the OUTARGS statement inside the subroutine's definition. |
| | |
| pm | Output argument that returns the lower bound on the m th parameter. This must be specified in the OUTARGS statement inside the subroutine's definition. |
- *Return value:* The results, lower bounds on parameter values, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named 'FOO':

```
subroutine FOO_LOWERBOUNDS(p1, p2);
    outargs p1, p2;

    p1 = <lower bound for P1>;
    p2 = <lower bound for P2>;
endsub;
```

*dist_***PARINIT**

defines a subroutine that returns the initial values for the distribution's parameters given an empirical distribution function (EDF) estimate.

- *Type:* Subroutine
- *Required:* NO
- *Number of arguments:* $m + 4$, where m is the number of distribution parameters
- *Sequence and type of arguments:*

- | | |
|-------|---|
| dim | Input numeric value that contains the dimension of the x, nx, and F array arguments. |
| x{*} | Input numeric array of dimension <i>dim</i> that contains values of the random variables at which the EDF estimate is available. It can be assumed that x contains values in an increasing order. In other words, if $i < j$, then $x[i] < x[j]$. |
| nx{*} | Input numeric array of dimension <i>dim</i> . Each $nx[i]$ contains the number of observations in the original data that have the value $x[i]$. |
| F{*} | Input numeric array of dimension <i>dim</i> . Each $F[i]$ contains the EDF estimate for $x[i]$. This estimate is computed by the SEVERITY procedure based on the EMPIRICALCDF= option. |
| Ftype | Input numeric value that contains the type of the EDF estimate that is stored in x and F. See the section “ Supplying EDF Estimates to Functions and Subroutines ” on page 1574 for definition of types. |
| p1 | Output argument that returns the initial value of the first parameter. This must be specified in the OUTARGS statement inside the subroutine's definition. |
| p2 | Output argument that returns the initial value of the second parameter. This must be specified in the OUTARGS statement inside the subroutine's definition. |
| | |
| pm | Output argument that returns the initial value of the m th parameter. This must be specified in the OUTARGS statement inside the subroutine's definition. |

- *Return value:* The results, initial values of the parameters, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named 'FOO':

```
subroutine FOO_PARMINIT(dim, x{*}, nx{*}, F{*}, Ftype, p1, p2);
    outargs p1, p2;

    /* Code to initialize values of P1 and P2 by using
       dim, x, nx, and F */

    p1 = <initial value for p1>;
    p2 = <initial value for p2>;
endsub;
```

dist_PDF

defines a function that returns the value of the probability density function (PDF) of the distribution at the specified values of the random variable and distribution parameters.

- *Type:* Function
- *Required:* YES
- *Number of arguments:* $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments:*

x Numeric value of the random variable at which the PDF value should be evaluated

$p1$ Numeric value of the first parameter

$p2$ Numeric value of the second parameter

.....

pm Numeric value of the m th parameter

- *Return value:* Numeric value that contains the PDF value $f(x; p_1, p_2, \dots, p_m)$

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

$$f(x; p_1, p_2, \dots, p_m) = \frac{1}{p_1} f\left(\frac{x}{p_1}; 1, p_2, \dots, p_m\right)$$

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

$$f(x; p_1, p_2, \dots, p_m) = \frac{1}{\exp(p_1)} f\left(\frac{x}{\exp(p_1)}; 0, p_2, \dots, p_m\right)$$

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_PDF(x, P1, P2);
    /* Code to compute PDF by using x, P1, and P2 */

    f = <computed PDF>;
    return (f);
endsub;
```

*dist_*SCALETRANSFORM

defines a function that returns a keyword to identify the transform that needs to be applied to the scale parameter to convert it to the first parameter of the distribution.

If you want to use this distribution for modeling regression effects, then the first parameter of this distribution must be a scale parameter. However, for some distributions, a typical or convenient parameterization might not have a scale parameter, but one of the parameters can be a simple transform of the scale parameter. As an example, consider a typical parameterization of the lognormal distribution with two parameters, location μ and shape σ , for which the PDF is defined as follows:

$$f(x; \mu, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2}$$

You can reparameterize this distribution to contain a parameter θ instead of the parameter μ such that $\mu = \log(\theta)$. The parameter θ would then be a scale parameter. However, if you want to specify the distribution in terms of μ and σ (which is a more recognized form of the lognormal distribution) and still allow it as a candidate distribution for estimating regression effects, then instead of writing another distribution with parameters θ and σ , you can simply define the distribution with μ as the first parameter and specify that it is the logarithm of the scale parameter.

- *Type:* Function
- *Required:* NO
- *Number of arguments:* None
- *Sequence and type of arguments:* Not applicable
- *Return value:* Character value that contains one of the following keywords:

LOG	specifies that the first parameter is the logarithm of the scale parameter.
IDENTITY	specifies that the first parameter is a scale parameter without any transformation.

If this function is not specified, then the IDENTITY transform is assumed.

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_SCALETRANSFORM() $8;
    length xform $8;
    xform = "IDENTITY";
    return (xform);
endsub;
```

dist_SDF

defines a function that returns the value of the survival distribution function (SDF) of the distribution at the specified values of the random variable and distribution parameters.

- *Type:* Function
- *Required:* NO
- *Number of arguments:* $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments:*
 - x Numeric value of the random variable at which the SDF value should be evaluated
 - p_1 Numeric value of the first parameter
 - p_2 Numeric value of the second parameter
 -
 - p_m Numeric value of the m th parameter
- *Return value:* Numeric value that contains the SDF value $S(x; p_1, p_2, \dots, p_m)$

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

$$S(x; p_1, p_2, \dots, p_m) = S\left(\frac{x}{p_1}; 1, p_2, \dots, p_m\right)$$

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

$$S(x; p_1, p_2, \dots, p_m) = S\left(\frac{x}{\exp(p_1)}; 0, p_2, \dots, p_m\right)$$

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_SDF(x, P1, P2);
  /* Code to compute SDF by using x, P1, and P2 */

  S = <computed SDF>;
  return (S);
endsub;
```

dist_UPPERBOUNDS

defines a subroutine that returns upper bounds for the parameters of the distribution. If this subroutine is not defined for a given distribution, then the SEVERITY procedure assumes that there is no upper bound for any of the parameters. If an upper bound of u_i is returned for a parameter p_i , then the SEVERITY procedure assumes that $p_i < u_i$ (strict inequality). If a missing value is returned for some parameter, then the SEVERITY procedure assumes that there is no upper bound for that parameter (equivalent to an upper bound of ∞).

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: m , where m is the number of distribution parameters
- *Sequence and type of arguments*:

p1	Output argument that returns the upper bound on the first parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.
p2	Output argument that returns the upper bound on the second parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.
....	
pm	Output argument that returns the upper bound on the m th parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.
- *Return value*: The results, upper bounds on parameter values, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named 'FOO':

```
subroutine FOO_UPPERBOUNDS(p1, p2);
  outargs p1, p2;

  p1 = <upper bound for P1>;
  p2 = <upper bound for P2>;
endsub;
```

*dist_core*GRADIENT

defines a subroutine that returns the gradient vector of the specified *core* function of the distribution at the specified values of the random variable and distribution parameters. The *core* keyword can be PDF, CDF, SDF, LOGPDF, LOGCDF, or LOGSDF.

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: $m + 2$, where m is the number of distribution parameters
- *Sequence and type of arguments*:

x	Numeric value of the random variable at which the gradient should be evaluated
p1	Numeric value of the first parameter
p2	Numeric value of the second parameter
....	
pm	Numeric value of the m th parameter
grad{*}	Output numeric array of size m that contains the gradient vector evaluated at the specified values. If h denotes the value of the <i>core</i> function, then the expected order of the values in the array is as follows: $\frac{\partial h}{\partial p_1} \frac{\partial h}{\partial p_2} \dots \frac{\partial h}{\partial p_m}$
- *Return value*: Numeric array that contains the gradient evaluated at x for the parameter values (p_1, p_2, \dots, p_m)

Here is a sample structure of the function for the core function CDF of a distribution named 'FOO':

```
subroutine FOO_CDFGRADIENT(x, P1, P2, grad{*});
    outargs grad;

    /* Code to compute gradient by using x, P1, and P2 */
    grad[1] = <partial derivative of CDF w.r.t. P1
              evaluated at x, P1, P2>;
    grad[2] = <partial derivative of CDF w.r.t. P2
              evaluated at x, P1, P2>;
endsub;
```

*dist_core*HESSEIAN

defines a subroutine that returns the Hessian matrix of the specified *core* function of the distribution at the specified values of the random variable and distribution parameters. The *core* keyword can be PDF, CDF, SDF, LOGPDF, LOGCDF, or LOGSDF.

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: $m + 2$, where m is the number of distribution parameters
- *Sequence and type of arguments*:

x	Numeric value of the random variable at which the Hessian matrix should be evaluated
p1	Numeric value of the first parameter
p2	Numeric value of the second parameter
....	
pm	Numeric value of the m th parameter
hess{*}	Output numeric array of size $m(m + 1)/2$ that contains the lower triangular portion of the Hessian matrix in a packed vector form, evaluated at the specified values. If h denotes the value of the <i>core</i> function, then the expected order of the values in the array is as follows: $\frac{\partial^2 h}{\partial p_1^2} \mid \frac{\partial^2 h}{\partial p_1 \partial p_2} \mid \frac{\partial^2 h}{\partial p_2^2} \mid \cdots \mid \frac{\partial^2 h}{\partial p_1 \partial p_m} \mid \frac{\partial^2 h}{\partial p_2 \partial p_m} \cdots \frac{\partial^2 h}{\partial p_m^2}$

- *Return value*: Numeric array that contains the lower triangular portion of the Hessian matrix evaluated at x for the parameter values (p_1, p_2, \dots, p_m)

Here is a sample structure of the subroutine for the core function LOGSDF of a distribution named 'FOO':

```
subroutine FOO_LOGSDFHESSEIAN(x, P1, P2, hess{*});
    outargs hess;

    /* Code to compute Hessian by using x, P1, and P2 */
    hess[1] = <second order partial derivative of LOGSDF
              w.r.t. P1 evaluated at x, P1, P2>;
    hess[2] = <second order partial derivative of LOGSDF
              w.r.t. P1 and P2 evaluated at x, P1, P2>;
    hess[3] = <second order partial derivative of LOGSDF
              w.r.t. P2 evaluated at x, P1, P2>;
endsub;
```

Predefined Utility Functions

The following predefined utility functions are provided with the SEVERITY procedure and are available in the Sashelp.Svrtdist library:

SVRTUTIL_EDF:

This function computes the empirical distribution function (EDF) estimate at the specified value of the random variable given the EDF estimate for a sample.

- *Type:* Function
- *Signature:* SVRTUTIL_EDF(y, n, x{*}, F{*}, Ftype)
- *Argument Description:*

y	Value of the random variable at which the EDF estimate is desired.
n	Dimension of the x and F input arrays.
x{*}	Input numeric array of dimension n that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.
F{*}	Input numeric array of dimension n in which each $F[i]$ contains the EDF estimate for $x[i]$. These values must be sorted in nondecreasing order.
Ftype	Type of the empirical estimate that is stored in the x and F arrays. See the section “Supplying EDF Estimates to Functions and Subroutines” on page 1574 for definition of types.
- *Return value:* The EDF estimate at y .

The type of the sample EDF estimate determines how the EDF estimate at y is computed. See the section [“Supplying EDF Estimates to Functions and Subroutines”](#) on page 1574 for more details.

SVRTUTIL_EMPLIMMOMENT:

This function computes the empirical estimate of the limited moment of specified order for the specified upper limit, given the EDF estimate for a sample.

- *Type:* Function
- *Signature:* SVRTUTIL_EMPLIMMOMENT(k, u, n, x{*}, F{*}, Ftype)
- *Argument Description:*

k	Order of the desired empirical limited moment.
u	Upper limit on the value of the random variable to be used in the computation of the desired empirical limited moment.
n	Dimension of the x and F input arrays.
x{*}	Input numeric array of dimension n that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.
F{*}	Input numeric array of dimension n in which each $F[i]$ contains the EDF estimate for $x[i]$. These values must be sorted in nondecreasing order.

Ftype Type of the empirical estimate that is stored in the x and F arrays. See the section “[Supplying EDF Estimates to Functions and Subroutines](#)” on page 1574 for definition of types.

- **Return value:** The desired empirical limited moment.

The empirical limited moment is computed by using the empirical estimate of the CDF. If $F_n(x)$ denotes the EDF at x , then the empirical limited moment of order k with upper limit u is defined as

$$E_n[(X \wedge u)^k] = k \int_0^u (1 - F_n(x))x^{k-1} dx$$

The SVRTUTIL_EMPLIMMOMENT function uses the piecewise linear nature of $F_n(x)$ as described in the section “[Supplying EDF Estimates to Functions and Subroutines](#)” on page 1574 to compute the integration.

SVRTUTIL_HILLCUTOFF:

This function computes an estimate of the value where the right tail of a distribution is expected to begin. The function implements the algorithm described in Danielsson et al. 2001. The description of the algorithm uses the following notation:

- n number of observations in the original sample
- B number of bootstrap samples to draw
- m_1 size of the bootstrap sample in the first step of the algorithm ($m_1 < n$)
- $x_{(i)}^{j,m}$ i th order statistic of j th bootstrap sample of size m ($1 \leq i \leq m, 1 \leq j \leq B$)
- $x_{(i)}$ i th order statistic of the original sample ($1 \leq i \leq n$)

Given the input sample x and values of B and m_1 , the steps of the algorithm are as follows:

1. Take B bootstrap samples of size m_1 from the original sample.
2. Find the integer k_1 that minimizes the bootstrap estimate of the mean squared error:

$$k_1 = \arg \min_{1 \leq k < m_1} Q(m_1, k)$$

3. Take B bootstrap samples of size $m_2 = m_1^2/n$ from the original sample.
4. Find the integer k_2 that minimizes the bootstrap estimate of the mean squared error:

$$k_2 = \arg \min_{1 \leq k < m_2} Q(m_2, k)$$

5. Compute the integer k_{opt} , which is used for computing the cutoff point:

$$k_{\text{opt}} = \frac{k_1^2}{k_2} \left(\frac{\log(k_1)}{2 \log(m_1) - \log(k_1)} \right)^{2 - 2 \log(k_1) / \log(m_1)}$$

6. Set the cutoff point equal to $x_{(k_{\text{opt}}+1)}$.

The bootstrap estimate of the mean squared error is computed as

$$Q(m, k) = \frac{1}{B} \sum_{j=1}^B \text{MSE}_j(m, k)$$

The mean squared error of j th bootstrap sample is computed as

$$\text{MSE}_j(m, k) = (M_j(m, k) - 2(\gamma_j(m, k))^2)^2$$

where $M_j(m, k)$ is a control variate proposed by Danielsson et al. 2001,

$$M_j(m, k) = \frac{1}{k} \sum_{i=1}^k \left(\log(x_{(m-i+1)}^{j,m}) - \log(x_{(m-k)}^{j,m}) \right)^2$$

and $\gamma_j(m, k)$ is the Hill's estimator of the tail index (Hill 1975),

$$\gamma_j(m, k) = \frac{1}{k} \sum_{i=1}^k \log(x_{(m-i+1)}^{j,m}) - \log(x_{(m-k)}^{j,m})$$

This algorithm has two tuning parameters, B and m_1 . The number of bootstrap samples B is chosen based on the availability of computational resources. The optimal value of m_1 is chosen such that the following ratio, $R(m_1)$, is minimized:

$$R(m_1) = \frac{(Q(m_1, k_1))^2}{Q(m_2, k_2)}$$

The SVRTUTIL_HILLCUTOFF utility function implements the preceding algorithm. It uses the grid search method to compute the optimal value of m_1 .

- *Type:* Function
- *Signature:* SVRTUTIL_HILLCUTOFF(n , $x\{*\}$, b , s , $status$)
- *Argument Description:*

n	Dimension of the array x .
$x\{*\}$	Input numeric array of dimension n that contains the sample.
b	Number of bootstrap samples used to estimate the mean squared error. If b is less than 10, then a default value of 50 is used.
s	Approximate number of steps used to search the optimal value of m_1 in the range $[n^{0.75}, n - 1]$. If s is less than or equal to 1, then a default value of 10 is used.
$status$	Output argument that contains the status of the algorithm. If the algorithm succeeds in computing a valid cutoff point, then <i>status</i> is set to 0. If the algorithm fails, then <i>status</i> is set to 1.
- *Return value:* The cutoff value where the right tail is estimated to start. If the size of the input sample is inadequate ($n \leq 5$), then a missing value is returned and *status* is set to a missing value. If the algorithm fails to estimate a valid cutoff value (*status* = 1), then the fifth largest value in the input sample is returned.

SVRTUTIL_PERCENTILE:

This function computes the specified empirical percentile given the EDF estimates.

- *Type:* Function
- *Signature:* SVRTUTIL_PERCENTILE(p , n , $x\{*\}$, $F\{*\}$, $Ftype$)

- *Argument Description:*

p	Desired percentile. The value must be in the interval (0,1). The function returns the 100 p th percentile.
n	Dimension of the x and F input arrays.
x{*}	Input numeric array of dimension n that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.
F{*}	Input numeric array of dimension n in which each $F[i]$ contains the EDF estimate for $x[i]$. These values must be sorted in nondecreasing order.
Ftype	Type of the empirical estimate that is stored in the x and F arrays. See the section “ Supplying EDF Estimates to Functions and Subroutines ” on page 1574 for definition of types.

- *Return value:* The 100 p th percentile of the input sample.

The method used to compute the percentile depends on the type of the EDF estimate (Ftype argument).

Ftype = 1 Smoothed empirical estimates are computed using the method described in Klugman, Panjer, and Willmot (1998). Let $\lfloor x \rfloor$ denote the greatest integer less than or equal to x . Define $g = \lfloor p(n+1) \rfloor$ and $h = p(n+1) - g$. Then the empirical percentile $\hat{\pi}_p$ is defined as

$$\hat{\pi}_p = (1-h)x[g] + hx[g+1]$$

This method does not work if $p < 1/(n+1)$ or $p > n/(n+1)$. If $p < 1/(n+1)$, then the function returns $\hat{\pi}_p = x[1]/2$, which assumes that the EDF is 0 in the interval $[0, x[1])$. If $p > n/(n+1)$, then $\hat{\pi}_p = x[n]$.

Ftype = 2 If $p < F[1]$, then $\hat{\pi}_p = x[1]/2$, which assumes that the EDF is 0 in the interval $[0, x[1])$. If $|p - F[i]| < \epsilon$ for some value of i and $i < n$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = \frac{x[i] + x[i+1]}{2}$$

where ϵ is a machine-precision constant as returned by the SAS function CONSTANT('MACEPS'). If $F[i-1] < p < F[i]$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = x[i]$$

If $p \geq F[n]$, then $\hat{\pi}_p = x[n]$.

Ftype = 3 If $p < F[1]$, then $\hat{\pi}_p = x[1]/2$, which assumes that the EDF is 0 in the interval $[0, x[1])$. If $|p - F[i]| < \epsilon$ for some value of i and $i < n$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = \frac{x[i] + x[i+1]}{2}$$

where ϵ is a machine-precision constant as returned by the SAS function CONSTANT('MACEPS'). If $F[i-1] < p < F[i]$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = x[i-1] + (p - F[i-1]) \frac{x[i] - x[i-1]}{F[i] - F[i-1]}$$

If $p \geq F[n]$, then $\hat{\pi}_p = x[n]$.

SVRTUTIL_RAWMOMENTS:

This subroutine computes the raw moments of a sample.

- *Type:* Subroutine
- *Signature:* SVRTUTIL_RAWMOMENTS(*n*, *x*{*}, *nx*{*}, *nRaw*, *raw*{*})
- *Argument Description:*

<i>n</i>	Dimension of the <i>x</i> and <i>nx</i> input arrays.
<i>x</i> {*}	Input numeric array of dimension <i>n</i> that contains distinct values of the random variable that are observed in the sample.
<i>nx</i> {*}	Input numeric array of dimension <i>n</i> in which each <i>nx</i> [<i>i</i>] contains the number of observations in the sample that have the value <i>x</i> [<i>i</i>].
<i>nRaw</i>	Desired number of raw moments. The output array <i>raw</i> contains the first <i>nRaw</i> raw moments.
<i>raw</i> {*}	Output array of raw moments. The <i>k</i> th element in the array (<i>raw</i> { <i>k</i> }) contains the <i>k</i> th raw moment, where $1 \leq k \leq nRaw$.
- *Return value:* Numeric array *raw* that contains the first *nRaw* raw moments. The array contains missing values if the sample has no observations (that is, if all the values in the *nx* array add up to zero).

SVRTUTIL_SORT:

This function sorts the given array of numeric values in an ascending or descending order.

- *Type:* Subroutine
- *Signature:* SVRTUTIL_SORT(*n*, *x*{*}, *flag*)
- *Argument Description:*

<i>n</i>	Dimension of the input array <i>x</i> .
<i>x</i> {*}	Numeric array that contains the values to be sorted at input. The subroutine uses the same array to return the sorted values.
<i>flag</i>	A numeric value that controls the sort order. If <i>flag</i> is 0, then the values are sorted in an ascending order. If <i>flag</i> has any value other than 0, then the values are sorted in descending order.
- *Return value:* Numeric array *x*, which is sorted in place (that is, the sorted array is stored in the same storage area occupied by the input array *x*).

You can use the following predefined functions when you define functions and subroutines using the FCMP procedure. They are summarized here for your information. See the FCMP procedure documentation in *Base SAS Procedures Guide* for more details.

INVCDF:

This function computes the quantile from any continuous probability distribution by numerically inverting the CDF of that distribution. You need to specify the CDF function of the distribution, the values of its parameters, and the cumulative probability to compute the quantile.

LIMMOMENT:

This function computes the limited moment of order k with upper limit u for any continuous probability distribution. The limited moment is defined as

$$\begin{aligned} E[(X \wedge u)^k] &= \int_0^u x^k f(x) dx + \int_u^\infty u^k f(x) dx \\ &= \int_0^u x^k f(x) dx + u^k (1 - F(u)) \end{aligned}$$

where $f(x)$ and $F(x)$ denote the PDF and the CDF of the distribution, respectively. The LIMMOMENT function uses the following alternate definition, which can be derived using integration-by-parts:

$$E[(X \wedge u)^k] = k \int_0^u (1 - F(x)) x^{k-1} dx$$

You need to specify the CDF function of the distribution, the values of its parameters, and the values of k and u to compute the limited moment.

Custom Objective Functions (Experimental)

You can use a series of programming statements that use variables in the input data set specified by `DATA=` option in the PROC SEVERITY statement to assign a value to an objective function symbol. The objective function symbol must be specified using the `OBJECTIVE=` option in the PROC SEVERITY statement.

The objective function can be programmed such that it is applicable to any distribution that is used in the model. For that purpose, PROC SEVERITY recognizes the following *keyword* functions in the programming statements:

<code>_PDF_(x)</code>	returns the probability density function (PDF) of a distribution evaluated at the current value of a data set variable <code>x</code> .
<code>_CDF_(x)</code>	returns the cumulative distribution function (CDF) of a distribution evaluated at the current value of a data set variable <code>x</code> .
<code>_SDF_(x)</code>	returns the survival distribution function (SDF) of a distribution evaluated at the current value of a data set variable <code>x</code> .
<code>_LOGPDF_(x)</code>	returns the natural logarithm of the PDF of a distribution evaluated at the current value of a data set variable <code>x</code> .
<code>_LOGCDF_(x)</code>	returns the natural logarithm of the CDF of a distribution evaluated at the current value of a data set variable <code>x</code> .
<code>_LOGSDF_(x)</code>	returns the natural logarithm of the SDF of a distribution evaluated at the current value of a data set variable <code>x</code> .
<code>_EDF_(x)</code>	returns the empirical distribution function (EDF) estimate evaluated at the current value of a data set variable <code>x</code> . Internally, PROC SEVERITY computes the estimate using the SVRTUTIL_EDF function as described in the section “ Predefined Utility Functions ” on page 1591. The EDF estimate required by the SVRTUTIL_EDF function is computed using the response variable values in the current BY group or in the entire input data set if no BY statement is specified.

`_EMPLIMMOMENT_(k, u)`

returns the empirical limited moment of order k evaluated at the current value of a data set variable u that represents the upper limit of the limited moment. The order k can also be a data set variable. Internally, PROC SEVERITY computes the moment using the SVRTUTIL_EMPLIMMOMENT function as described in the section “[Predefined Utility Functions](#)” on page 1591. The EDF estimate required by the SVRTUTIL_EMPLIMMOMENT function is computed using the response variable values in the current BY group or in the entire input data set if no BY statement is specified.

`_LIMMOMENT_(k, u)`

returns the limited moment of order k evaluated at the current value of a data set variable u that represents the upper limit of the limited moment. The order k can be a data set variable or a constant. Internally, for each candidate distribution, PROC SEVERITY computes the moment using the LIMMOMENT function as described in the section “[Predefined Utility Functions](#)” on page 1591.

All the preceding functions are right-hand side functions. They act as placeholders for distribution-specific functions, with the exception of `_EDF_` and `_EMPLIMMOMENT_` functions. As an example, let the data set `Work.Test` contain a response variable Y and a left-truncation threshold variable T . The following statements use the values in this data set to fit a model with distribution D such that the parameters of the model minimize the value of the objective function symbol `MYOBJ`:

```
options cmplib=(work.mydist);
proc severity data=work.test objective=myobj;
    loss y / lt=t;

    myobj = -_LOGPDF_(y);
    if (not(missing(t))) then
        myobj = myobj + log(1-_CDF_(t));

    dist d;
run;
```

The symbol `MYOBJ` is designated as an objective function symbol by using the `OBJECTIVE=` option in the PROC SEVERITY statement. The response variable Y and left-truncation variable T are specified in the LOSS statement. The distribution D is specified in the DIST statement. The remaining statements constitute a program that computes the value of the `MYOBJ` symbol.

Let the distribution D have parameters $P1$ and $P2$. In order to estimate the model for this distribution, PROC SEVERITY internally converts the generic program to the following program specific to distribution D :

```
myobj = -D_LOGPDF(y, p1, p2);
if (not(missing(t))) then
    myobj = myobj + log(1-D_CDF(t, p1, p2));
```

Note that the generic keyword functions `_LOGPDF_` and `_CDF_` have been replaced with distribution-specific functions `D_LOGPDF` and `D_CDF`, respectively, with appropriate distribution parameters. The `D_LOGPDF` and `D_CDF` functions must have been defined previously and are assumed to be available in the `Work.Mydist` library specified in the `CMPLIB=` option.

The program is executed for each observation in `Work.Test` to compute the value of `MYOBJ` by using the values of variables `Y` and `T` in that observation and internally computed values of the model parameters `P1` and `P2`. The values of `MYOBJ` are then added over all the observations of the data set or over all the observations of the current `BY` group if a `BY` statement is specified. The resulting aggregate value is the value of the objective function, and it is supplied to the optimizer. If the optimizer requires derivatives of the objective function, then `PROC SEVERITY` automatically differentiates `MYOBJ` with respect to the parameters `P1` and `P2`. The optimizer iterates over various combinations of the values of parameters `P1` and `P2`, each time computing a new value of the objective function and the needed derivatives of it, until it finds a combination that minimizes the objective function.

Note the following points when you define your own program to compute the custom objective function:

- The value of the objective function is always minimized by `PROC SEVERITY`. If you want to maximize the value of a certain objective, then add a statement that assigns the negated value of the maximization objective to the objective function symbol specified in the `OBJECTIVE=` option. Minimization of the negated objective is equivalent to the maximization of the original objective.
- If you are fitting multiple distributions in one `PROC SEVERITY` step and use any of the keyword functions in your program, then it is recommended that you do not explicitly use the parameters of any of the specified distributions in your programming statements.
- If you use a specific keyword function in your programming statements, then the corresponding distribution functions must be defined in a library specified in the `CMPLIB=` system option or in `Sashelp.Svrtdist`, the predefined functions library. In the preceding example, it is assumed that the functions `D_LOGPDF` and `D_CDF` are defined in the `Work.Mydist` library specified in the `CMPLIB=` option.
- You can use most `DATA` step statements and functions in your program. The `DATA` step file and the data set I/O statements (for example, `INPUT`, `FILE`, `SET`, and `MERGE`) are not available. However, some functionality of the `PUT` statement is supported. See the section “`PROC FCMP` and `DATA` Step Differences” in *Base SAS Procedures Guide* for more information. In addition to the differences listed in that section, the following differences exist:
 - Only numeric-valued variables can be used in `PROC SEVERITY` programming statements. This restriction also implies that you cannot use SAS functions or call routines that require character-valued arguments, unless you pass those arguments as constant (literal) strings or characters.
 - You cannot use functions that create lagged versions of a variable in `PROC SEVERITY` programming statements. If you need lagged versions, then you can use a `DATA` step prior to the `PROC SEVERITY` step to add those versions to the input data set.
- When coding your programming statements, avoid defining variables that begin with an underscore (`_`), because they might conflict with internal variables created by `PROC SEVERITY`.

Custom Objective Functions and Regression Effects

If you have specified regressors using the `SCALEMODEL` statement, then `PROC SEVERITY` automatically adds a statement prior to your programming statements to compute the value of the scale parameter or the log-transformed scale parameter of the distribution using the values of the regression variables and internally

created regression parameters. For example, if you have specified three regressors x_1 , x_2 , and x_3 in the **SCALEMODEL** statement, then for a model that contains the distribution **D** with scale parameter **S**, **PROC SEVERITY** prepends your program with a statement that is equivalent to the following statement:

$$S = _SEVTHETA0 * \exp(_SEVBETA1 * x_1 + _SEVBETA2 * x_2 + _SEVBETA3 * x_3);$$

If a model contains a distribution **D1** with a log-transformed scale parameter **M**, **PROC SEVERITY** prepends your program with a statement that is equivalent to the following statement:

$$M = _SEVTHETA0 + _SEVBETA1 * x_1 + _SEVBETA2 * x_2 + _SEVBETA3 * x_3;$$

The **_SEVTHETA0**, **_SEVBETA1**, **_SEVBETA2**, and **_SEVBETA3** are the internal regression parameters associated with the intercept and the regressors x_1 , x_2 , and x_3 , respectively.

Since the names of the internal regression parameters start with a prefix **_SEV**, if you use a variable in your program with a name that begins with **_SEV**, then **PROC SEVERITY** writes an error message to the SAS log and stops processing.

Input Data Sets

PROC SEVERITY accepts **DATA=** and **INEST=** data sets as input data sets. This section details the information they are expected to contain.

DATA= Data Set

The **DATA=** data set is expected to contain the values of the analysis variables specified in the **LOSS statement** and the **SCALEMODEL statement**.

If **BY** variables are specified in the **BY** statement, then the **DATA=** data set must contain all the variables specified in the **BY** statement and the data set must be sorted by the **BY** variables unless the **NOTSORTED** option is used in the **BY** statement.

INEST= Data Set

The **INEST=** data set is expected to contain the initial values of the parameters for the parameter estimation process.

If **BY** variables are specified in the **BY** statement, then the **INEST=** data set must contain all the variables specified in the **BY** statement. If the **NOTSORTED** option is not specified in the **BY** statement, then the **INEST=** data set must be sorted by the **BY** variables. However, it is not required to contain all the **BY** groups present in the **DATA=** data set. For the **BY** groups that are not present in the **INEST=** data set, the default parameter initialization method is used. If the **NOTSORTED** option is specified in the **BY** statement, then the **INEST=** data set must contain all the **BY** groups that are present in the **DATA=** data set and they must appear in the same order as they appear in the **DATA=** data set.

In addition to any variables specified in the BY statement, the data set must contain the following variables:

`_MODEL_` identifying name of the distribution for which the estimates are provided.
`_TYPE_` type of the estimate. The value of this variable must be EST for an observation to be valid.

`<Parameter 1> ... <Parameter M>`

M variables, named after the parameters of all candidate distributions, that contain initial values of the respective parameters. M is the cardinality of the union of parameter name sets from all candidate distributions. In an observation, estimates are read only from variables for parameters that correspond to the distribution specified by the `_MODEL_` variable.

If you specify a missing value for some parameters, then default initial values are used unless the parameter is initialized by using the `INIT=` option in the DIST statement. If you want to use the `dist_PARMINIT` subroutine for initializing the parameters of a model, then you should either not specify the model in the `INEST=` data set or specify missing values for all the distribution parameters in the `INEST=` data set and not use the `INIT=` option in the DIST statement.

If regressors are specified, then the initial value provided for the first parameter of each distribution must be the base value of the scale or log-transformed scale parameter. See the section “[Estimating Regression Effects](#)” on page 1566 for details.

`<Regressor 1> ... <Regressor K>`

If K regressors are specified in the [SCALEMODEL statement](#), then the `INEST=` data set must contain K variables that are named for each regressor. The variables contain initial values of the respective regression coefficients. If a regressor is linearly dependent on other regressors for a given BY group, then you can indicate this by providing a special missing value of .R for the respective variable. In a given BY group, if a variable is marked as linearly dependent for one model, then it must be marked so for all the models. Similarly, if a variable is not marked as linearly dependent for one model, then it must be marked so for all the models.

Output Data Sets

PROC SEVERITY writes OUTCDF=, OUTEST=, OUTMODELINFO=, and OUTSTAT= data sets when requested with respective options. The data sets and their contents are described in the following sections.

OUTCDF= Data Set

The OUTCDF= data set records the estimates of the cumulative distribution function (CDF) of each of the specified model distributions and an estimate of the empirical distribution function (EDF).

If BY variables are specified, then the data are organized in BY groups and the data set contains variables specified in the BY statement. In addition, it contains the following variables:

<response variable>	value of the response variable. The values are sorted. If there are multiple BY groups, the values are sorted within each BY group.
OBSNUM	observation number in the DATA= data set.
EDF	estimate of the empirical distribution function (EDF). This estimate is computed by using the EMPIRICALCDF= option specified in the PROC SEVERITY statement.
<distribution1>_CDF ... <distributionD>_CDF	estimate of the cumulative distribution function (CDF) for each of the D candidate distributions, computed by using the final parameter estimates for that distribution. This value is missing if parameter estimation process does not converge for the given distribution. If regressor variables are specified, then the reported estimates are from a mixture distribution. See the section “ CDF and PDF Estimates with Regression Effects ” on page 1569 for details.

If truncation is specified, then the data set contains the following additional variables:

<distribution1>_COND_CDF ... <distributionD>_COND_CDF	estimate of the conditional CDF for each of the D candidate distributions, computed by using the final parameter estimates for that distribution. This value is missing if parameter estimation process does not converge for the distribution. The conditional estimates are computed using the method described in the section “ Truncation and Conditional CDF Estimates ” on page 1562.
---	---

OUTEST= Data Set

The OUTEST= data set records the estimates of the model parameters. It also contains estimates of their standard errors and optionally, their covariance structure. If BY variables are specified, then the data are organized in BY groups and the data set contains variables specified in the BY statement.

If the COVOUT option is not specified, then the data set contains the following variables:

MODEL	identifying name of the distribution model. The observation contains information about this distribution.
TYPE	type of the estimates reported in this observation. It can take one of the following two values: EST point estimates of model parameters STDERR standard error estimates of model parameters
STATUS	status of the reported estimates. The possible values are listed in the section “ _STATUS_ Variable Values ” on page 1604.
<Parameter 1> ... <Parameter M>	M variables, named after the parameters of all candidate distributions, containing estimates of the respective parameters. M is the cardinality of the union of parameter name sets from all candidate distributions. In an observation, estimates are populated only

for parameters that correspond to the distribution specified by the `_MODEL_` variable. If `_TYPE_` is EST, then the estimates are missing if the model does not converge. If `_TYPE_` is STDERR, then the estimates are missing if covariance estimates cannot be obtained.

If regressors are specified, then the estimate reported for the first parameter of each distribution is the estimate of the base value of the scale or log-transformed scale parameter. See the section “[Estimating Regression Effects](#)” on page 1566 for details.

<Regressor 1> ... <Regressor K>

If K regressors are specified in the [SCALEMODEL statement](#), then the OUTEST= data set contains K variables that are named for each regressor. The variables contain estimates for their respective regression coefficients. If a regressor is deemed to be linearly dependent on other regressors for a given BY group, then a warning message is printed to the SAS log and a special missing value of .R is written in the respective variable. If `_TYPE_` is EST, then the estimates are missing if the model does not converge. If `_TYPE_` is STDERR, then the estimates are missing if covariance estimates cannot be obtained.

If the COVOUT option is specified, then the OUTEST= data set contains additional observations that contain the estimates of the covariance structure. Given the symmetric nature of the covariance structure, only the lower triangular portion is reported. In addition to the variables listed and described previously, the data set contains the following variables that are either new or have a modified description:

<code>_TYPE_</code>	type of the estimates reported in this observation. For observations that contain rows of the covariance structure, the value is COV.
<code>_STATUS_</code>	status of the reported estimates. For observations that contain rows of the covariance structure, the status is 0 if covariance estimation was successful. If estimation fails, the status is 1 and a single observation is reported with <code>_TYPE_=COV</code> and missing values for all the parameter variables.
<code>_NAME_</code>	Name of the parameter for the row of covariance matrix reported in the current observation.

OUTMODELINFO= Data Set

The OUTMODELINFO= data set records the information about each specified distribution. If BY variables are specified, then the data are organized in BY groups and the data set contains variables specified in the BY statement. In addition, it contains the following variables:

<code>_MODEL_</code>	identifying name of the distribution model. The observation contains information about this distribution.
<code>_DESCRIPTION_</code>	descriptive name of the model. This has a nonmissing value only if the DESCRIPTION function has been defined for this model.

`_PARMNAME1 ... _PARMNAME M`

M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables `_PARMNAME j` ($j > m$) are missing.

OUTSTAT= Data Set

The OUTSTAT= data set records statistics of fit and model selection information. If BY variables are specified, then the data are organized in BY groups and the data set contains variables specified in the BY statement. The data set contains the following variables:

<code>_MODEL_</code>	identifying name of the distribution model. The observation contains information about this distribution.
<code>_NMODELPRM_</code>	number of parameters in the distribution.
<code>_NESTPRM_</code>	number of estimated parameters. This includes the regression parameters, if any regressors are specified.
<code>_NOBS_</code>	number of nonmissing observations used for parameter estimation.
<code>_STATUS_</code>	status of the parameter estimation process for this model. The possible values are listed in the section “ _STATUS_ Variable Values ” on page 1604.
<code>_SELECTED_</code>	indicator of the best distribution model. If the value is 1, then this model is the best model for the current BY group according to the specified model selection criterion. This value is missing if parameter estimation process does not converge for this model.
Neg2LogLike	value of the log likelihood, multiplied by -2 , that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
AIC	value of the Akaike’s information criterion (AIC) that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
AICC	value of the corrected Akaike’s information criterion (AICC) that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
BIC	value of the Schwarz Bayesian information criterion (BIC) that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
KS	value of the Kolmogorov-Smirnov (KS) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
AD	value of the Anderson-Darling (AD) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.

CVM	value of the Cramér-von Mises (CvM) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
-----	--

STATUS Variable Values

The `_STATUS_` variable in the `OUTEST=` and `OUTSTAT=` data sets contains a value that indicates the status of the parameter estimation process for the respective distribution model. The variable can take the following values in the `OUTEST=` data set for `_TYPE_=EST` observations and in the `OUTSTAT=` data set:

- 0 The parameter estimation process converged for this model.
- 301 The parameter estimation process might not have converged for this model because there is no improvement in the objective function value. This might indicate that the initial values of the parameters are optimal, or you can try different convergence criteria in the **NLOPTIONS** statement.
- 302 The parameter estimation process might not have converged for this model because the number of iterations exceeded the maximum allowed value. You can try setting a larger value for the `MAXITER=` options in the **NLOPTIONS** statement.
- 303 The parameter estimation process might not have converged for this model because the number of objective function evaluations exceeded the maximum allowed value. You can try setting a larger value for the `MAXFUNC=` options in the **NLOPTIONS** statement.
- 304 The parameter estimation process might not have converged for this model because the time taken by the process exceeded the maximum allowed value. You can try setting a larger value for the `MAXTIME=` option in the **NLOPTIONS** statement.
- 400 The parameter estimation process did not converge for this model.

The `_STATUS_` variable can take the following values in the `OUTEST=` data set for `_TYPE_=STDERR` and `_TYPE_=COV` observations:

- 0 The covariance and standard error estimates are available and valid.
- 1 The covariance and standard error estimates are not available, because the process of computing covariance estimates failed.

Displayed Output

The SEVERITY procedure optionally produces displayed output by using the Output Delivery System (ODS). All output is controlled by the `PRINT=` option in the `PROC SEVERITY` statement. [Table 23.5](#) relates the `PRINT=` options to ODS tables.

Table 23.5 ODS Tables Produced in PROC SEVERITY

ODS Table Name	Description	Option
DescStats	Descriptive statistics for the response variable	PRINT=DESCSTATS
RegDescStats	Descriptive statistics for the regressor variables	PRINT=DESCSTATS
ModelSelection	Model selection summary	PRINT=SELECTION
AllFitStatistics	Statistics of fit for all the distribution models	PRINT=ALLFITSTATS
InitialValues	Initial parameter values and bounds	PRINT=INITIALVALUES
ConvergenceStatus	Convergence status of parameter estimation process	PRINT=CONVSTATUS
IterationHistory	Optimization iteration history	PRINT=NLOHISTORY
OptimizationSummary	Optimization summary	PRINT=NLOSUMMARY
StatisticsOfFit	Statistics of fit	PRINT=STATISTICS
ParameterEstimates	Final parameter estimates	PRINT=ESTIMATES
TurnbullSummary	Turnbull EDF estimation summary	PRINT=ALL

If PRINT= option is not specified, then by default PROC SEVERITY produces ModelSelection, ConvergenceStatus, OptimizationSummary, StatisticsOfFit, and ParameterEstimates ODS tables.

The TurnbullSummary table is produced only if you specify PRINT=ALL and Turnbull's method is used for computing EDF estimates.

PRINT=DESCSTATS

displays the descriptive statistics for the response variable. If regressor variables are specified, a table with their descriptive statistics is also displayed.

PRINT=SELECTION

displays the model selection table. The table shows the convergence status of each candidate model, and the value of the selection criterion along with an indication of the selected model.

PRINT=ALLFITSTATS

displays the comparison of all the statistics of fit for all the models in one table. The table does not include the models whose parameter estimation process does not converge. If all the models fail to converge, then this table is not produced. If the table contains more than one model, then the best model according to each statistic is indicated with an asterisk (*) in that statistic's column.

PRINT=INITIALVALUES

displays the initial values and bounds used for estimating each model.

PRINT=CONVSTATUS

displays the convergence status of the parameter estimation process.

PRINT=NLOHISTORY

displays the iteration history of the nonlinear optimization process used for estimating the parameters.

PRINT=NLOSUMMARY

displays the summary of the nonlinear optimization process used for estimating the parameters.

PRINT=STATISTICS

displays the statistics of fit for each model. The statistics of fit are not displayed for models whose parameter estimation process does not converge.

PRINT=ESTIMATES

displays the final estimates of parameters. The estimates are not displayed for models whose parameter estimation process does not converge.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#)” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the SEVERITY procedure.

ODS Graph Names

PROC SEVERITY assigns a name to each graph it creates by using ODS. You can use these names to selectively reference the graphs. The names are listed in [Table 23.6](#).

Table 23.6 ODS Graphics Produced by PROC SEVERITY

ODS Graph Name	Plot Description	PLOTS= Option
CDFPlot	Comparative CDF Plot	CDF
CDFDistPlot	CDF Plot per Distribution	CDFPERDIST
PDFPlot	Comparative PDF Plot	PDF
PDFDistPlot	PDF Plot per Distribution	PDFPERDIST
PPPlot	P-P Plot of CDF and EDF	PP

Comparative CDF Plot

The comparative CDF plot helps you visually compare the cumulative distribution function (CDF) estimates of all the candidate distribution models and the empirical distribution function (EDF) estimate. The plot does not contain CDF estimates for models whose parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the CDF or EDF estimates.

If truncation is specified, then conditional CDF estimates are plotted. Otherwise, unconditional CDF estimates are plotted. The conditional estimates are computed using the method described in the section [“Truncation and Conditional CDF Estimates”](#) on page 1562.

If left-truncation is specified and the MARKTRUNCATED option is specified, then the left-truncated observations are marked in the plot. If right-censoring is specified, left-censoring is not specified, and the MARKCENSORED option is specified, then the right-censored observations are marked in the plot.

If regressor variables are specified, then the plotted CDF estimates are from a mixture distribution. See the section [“CDF and PDF Estimates with Regression Effects”](#) on page 1569 for details.

CDF Plot per Distribution

The CDF plot per distribution shows the CDF estimates of each candidate distribution model unless that model’s parameter estimation process does not converge. The plot also contains estimates of the EDF. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the CDF or EDF estimates.

If truncation is specified, then conditional CDF estimates are plotted. Otherwise unconditional CDF estimates are plotted. The conditional estimates are computed using the method described in the section [“Truncation and Conditional CDF Estimates”](#) on page 1562.

If left-truncation is specified and the MARKTRUNCATED option is specified, then the left-truncated observations are marked in the plot. If right-censoring is specified, left-censoring is not specified, and the MARKCENSORED option is specified, then the right-censored observations are marked in the plot.

If regressor variables are specified, then the plotted CDF estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1569 for details.

Comparative PDF Plot

The comparative PDF plot helps you visually compare the probability density function (PDF) estimates of all the candidate distribution models. The plot does not contain PDF estimates for models whose parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the PDF estimates.

If the HISTOGRAM option is specified, then the plot also contains the histogram of response variable values. If the KERNEL option is specified, then the plot also contains the kernel density estimate for the response variable values.

If regressor variables are specified, then the plotted PDF estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1569 for details.

PDF Plot per Distribution

The PDF plot per distribution shows the PDF estimates of each candidate distribution model unless that model’s parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the PDF estimates.

If the HISTOGRAM option is specified, then the plot also contains the histogram of response variable values. If the KERNEL option is specified, then the plot also contains the kernel density estimate for the response variable values.

If regressor variables are specified, then the plotted PDF estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1569 for details.

P-P Plot of CDF and EDF

The P-P plot of CDF and EDF is the probability-probability plot that compares the CDF estimates of a distribution with the EDF estimates. A plot is not prepared for models whose parameter estimation process does not converge. The horizontal axis represents the CDF estimates of a candidate distribution and the vertical axis represents the EDF estimates.

This plot can be interpreted as displaying the data that are used for computing the EDF-based statistics of fit for the given candidate distribution. As described in the section “[EDF-Based Statistics](#)” on page 1576, these statistics are computed by comparing the EDF, denoted by $F_n(y)$, and the CDF, denoted by $F(y)$, at each of the response variable values y . Using the probability inverse transform $z = F(y)$, this is equivalent to comparing the EDF of the z , denoted by $F_n(z)$, and the CDF of z , denoted by $F(z)$ (D’Agostino and Stephens 1986, Ch. 4). Given that the CDF of z is a uniform distribution ($F(z) = z$), the EDF-based

statistics can be computed by comparing the EDF estimate of z with the estimate of z . The horizontal axis of the plot represents the estimated CDF $\hat{z} = \hat{F}(y)$. The vertical axis represents the estimated EDF of z , $\hat{F}_n(z)$. The plot contains a scatter plot of $(\hat{z}, \hat{F}_n(z))$ points and a reference line $F_n(z) = z$ that represents the expected uniform distribution of z . Points scattered closer to the reference line indicate a better fit than the points scattered away from the reference line.

If truncation is specified, then the EDF estimates are conditional as described in the section “[EDF Estimates and Truncation](#)” on page 1573. So, conditional estimates of CDF are displayed, which are computed using the method described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1562.

If regressor variables are specified, then the displayed CDF estimates, both unconditional and conditional, are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1569 for details.

Examples: SEVERITY Procedure

Example 23.1: Defining a Model for Gaussian Distribution

Suppose you want to fit a distribution model other than one of the predefined ones available to you. Suppose you want to define a model for the Gaussian distribution with the following typical parameterization of the PDF (f) and CDF (F):

$$f(x; \mu, \sigma) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(x - \mu)^2}{2\sigma^2}\right)$$

$$F(x; \mu, \sigma) = \frac{1}{2} \left(1 + \operatorname{erf}\left(\frac{x - \mu}{\sigma\sqrt{2}}\right)\right)$$

For PROC SEVERITY, a *distribution model* consists of a set of functions and subroutines that are defined with the FCMP procedure. Each function and subroutine should be written following certain rules. The details are provided in the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1579.

NOTE: The Gaussian distribution is not a commonly used severity distribution. It is used in this example primarily to illustrate the process of defining your own distribution models. Although the distribution has a support over the entire real line, you can fit the distribution with PROC SEVERITY only if the input sample contains nonnegative values.

The following SAS statements define a distribution model named NORMAL for the Gaussian distribution. The OUTLIB= option in the PROC FCMP statement stores the compiled versions of the functions and subroutines in the ‘models’ package of the Work.Sevexmpl library. The LIBRARY= option in the PROC FCMP statement enables this PROC FCMP step to use the SVRTUTIL_RAWMOMENTS utility subroutine that is available in the Sashelp.SvrtDIST library. The subroutine is described in the section “[Predefined Utility Functions](#)” on page 1591.

```

/*----- Define Normal Distribution with PROC FCMP -----*/
proc fcmp library=sashelp.svrtldist outlib=work.sevexmpl.models;
  function normal_pdf(x,Mu,Sigma);
    /* Mu      : Location */
    /* Sigma   : Standard Deviation */
    return ( exp(-(x-Mu)**2/(2 * Sigma**2)) /
              (Sigma * sqrt(2*constant('PI')))) );
  endsub;

  function normal_cdf(x,Mu,Sigma);
    /* Mu      : Location */
    /* Sigma   : Standard Deviation */
    z = (x-Mu)/Sigma;
    return (0.5 + 0.5*erf(z/sqrt(2)));
  endsub;

  subroutine normal_parminit(dim, x[*], nx[*], F[*], Ftype, Mu, Sigma);
    outargs Mu, Sigma;
    array m[2] / nosymbols;

    /* Compute estimates by using method of moments */
    call svrtutil_rawmoments(dim, x, nx, 2, m);
    Mu    = m[1];
    Sigma = sqrt(m[2] - m[1]**2);
  endsub;

  subroutine normal_lowerbounds(Mu, Sigma);
    outargs Mu, Sigma;
    Mu = .; /* Mu has no lower bound */
    Sigma = 0; /* Sigma > 0 */
  endsub;
quit;

```

The statements define the two functions required of any distribution model (NORMAL_PDF and NORMAL_CDF) and two optional subroutines (NORMAL_PARMINIT and NORMAL_LOWERBOUNDS). The name of each function or subroutine must follow a specific structure. It should start with the model's short or identifying name, which is 'NORMAL' in this case, followed by an underscore '_', followed by a keyword suffix such as 'PDF'. Each function or subroutine has a specific purpose. The details of all the functions and subroutines that you can define for a distribution model are provided in the section [“Defining a Distribution Model with the FCMP Procedure”](#) on page 1579. Following is the description of each function and subroutine defined in this example:

- The PDF and CDF suffixes define functions that return the probability density function and cumulative distribution function values, respectively, given the values of the random variable and the distribution parameters.
- The PARMINIT suffix defines a subroutine that returns the initial values for the parameters by using the sample data or the empirical distribution function (EDF) estimate computed from it. In this example, the parameters are initialized by using the method of moments. Hence, you do not need to use the EDF estimates, which are available in the F array. The first two raw moments of the Gaussian

distribution are as follows:

$$E[x] = \mu, E[x^2] = \mu^2 + \sigma^2$$

Given the sample estimates, m_1 and m_2 , of these two raw moments, you can solve the equations $E[x] = m_1$ and $E[x^2] = m_2$ to get the following estimates for the parameters: $\hat{\mu} = m_1$ and $\hat{\sigma} = \sqrt{m_2 - m_1^2}$. The NORMAL_PARMINIT subroutine implements this solution. It uses the SVRTUTIL_RAWMOMENTS utility subroutine to compute the first two raw moments.

- The LOWERBOUNDS suffix defines a subroutine that returns the lower bounds on the parameters. PROC SEVERITY assumes a default lower bound of 0 for all the parameters when a LOWERBOUNDS subroutine is not defined. For the parameter μ (*Mu*), there is no lower bound, so you need to define the NORMAL_LOWERBOUNDS subroutine. It is recommended that you assign bounds for all the parameters when you define the LOWERBOUNDS subroutine or its counterpart, the UPPERBOUNDS subroutine. Any unassigned value is returned as a missing value, which is interpreted by PROC SEVERITY to mean that the parameter is unbounded, and that might not be what you want.

You can now use this distribution model with PROC SEVERITY. Let the following DATA step statements simulate a normal sample with $\mu = 10$ and $\sigma = 2.5$.

```
/*----- Simulate a Normal sample -----*/
data testnorm(keep=y);
  call streaminit(12345);
  do i=1 to 100;
    y = rand('NORMAL', 10, 2.5);
    output;
  end;
run;
```

Prior to using your distribution with PROC SEVERITY, you must communicate the location of the library that contains the definition of the distribution and the locations of libraries that contain any functions and subroutines used by your distribution model. The following OPTIONS statement sets the CMPLIB= system option to include the FCMP library Work.Sevexmpl in the search path used by PROC SEVERITY to find FCMP functions and subroutines.

```
/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);
```

Now, you are ready to fit the NORMAL distribution model with PROC SEVERITY. The following statements fit the model to the values of Y in the Work.Testnorm data set:

```
/*--- Fit models with PROC SEVERITY ---*/
proc severity data=testnorm print=all;
  loss y;
  dist Normal;
run;
```

The DIST statement specifies the identifying name of the distribution model, which is 'NORMAL'. Neither is the INEST= option specified in the PROC SEVERITY statement nor is the INIT= option specified in the DIST statement. So, PROC SEVERITY initializes the parameters by invoking the NORMAL_PARMINIT subroutine.

Some of the results prepared by the preceding PROC SEVERITY step are shown in [Output 23.1.1](#) and [Output 23.1.2](#). The descriptive statistics of variable Y and the “Model Selection Table”, which includes just the normal distribution, are shown in [Output 23.1.1](#).

Output 23.1.1 Summary of Results for Fitting the Normal Distribution

The SEVERITY Procedure			
Input Data Set			
Name	WORK.TESTNORM		
Descriptive Statistics for Variable y			
Number of Observations			100
Number of Observations Used for Estimation			100
Minimum			3.88249
Maximum			16.00864
Mean			10.02059
Standard Deviation			2.37730
Model Selection Table			
Distribution	Converged	-2 Log Likelihood	Selected
Normal	Yes	455.97541	Yes

The initial values for the parameters, the optimization summary, and the final parameter estimates are shown in [Output 23.1.2](#). No iterations are required to arrive at the final parameter estimates, which are identical to the initial values. This confirms the fact that the maximum likelihood estimates for the Gaussian distribution are identical to the estimates obtained by the method of moments that was used to initialize the parameters in the NORMAL_PARMINIT subroutine.

Output 23.1.2 Details of the Fitted Normal Distribution Model

Number of Iterations		0		
Number of Function Evaluations		2		
Log Likelihood		-227.98770		
Parameter Estimates for Normal Distribution				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Mu	10.02059	0.23894	41.94	<.0001
Sigma	2.36538	0.16896	14.00	<.0001

The NORMAL distribution defined and illustrated here has no scale parameter, because all the following inequalities are true:

$$f(x; \mu, \sigma) \neq \frac{1}{\mu} f\left(\frac{x}{\mu}; 1, \sigma\right)$$

$$f(x; \mu, \sigma) \neq \frac{1}{\sigma} f\left(\frac{x}{\sigma}; \mu, 1\right)$$

$$F(x; \mu, \sigma) \neq F\left(\frac{x}{\mu}; 1, \sigma\right)$$

$$F(x; \mu, \sigma) \neq F\left(\frac{x}{\sigma}; \mu, 1\right)$$

This implies that you cannot estimate the effect of regressors on a model for the response variable based on this distribution.

Example 23.2: Defining a Model for Gaussian Distribution with a Scale Parameter

If you want to estimate the effects of regressors, then the model needs to be parameterized to have a scale parameter. While this might not be always possible, for the case of the Gaussian distribution it is possible by replacing the location parameter μ with another parameter, $\alpha = \mu/\sigma$, and defining the PDF (f) and the CDF (F) as follows:

$$f(x; \sigma, \alpha) = \frac{1}{\sigma \sqrt{2\pi}} \exp\left(-\frac{1}{2} \left(\frac{x}{\sigma} - \alpha\right)^2\right)$$

$$F(x; \sigma, \alpha) = \frac{1}{2} \left(1 + \operatorname{erf}\left(\frac{1}{\sqrt{2}} \left(\frac{x}{\sigma} - \alpha\right)\right)\right)$$

It can be verified that σ is the scale parameter, because both of the following equalities are true:

$$f(x; \sigma, \alpha) = \frac{1}{\sigma} f\left(\frac{x}{\sigma}; 1, \alpha\right)$$

$$F(x; \sigma, \alpha) = F\left(\frac{x}{\sigma}; 1, \alpha\right)$$

NOTE: The Gaussian distribution is not a commonly used severity distribution. It is used in this example primarily to illustrate the concept of parameterizing a distribution such that it has a scale parameter. Although the distribution has a support over the entire real line, you can fit the distribution with PROC SEVERITY only if the input sample contains nonnegative values.

The following statements use the alternate parameterization to define a new model named NORMAL_S. The definition is stored in the Work.Sevexmpl library.

```

/*----- Define Normal Distribution With Scale Parameter -----*/
proc fcmp library=sashelp.svrtldist outlib=work.sevexmpl.models;
  function normal_s_pdf(x, Sigma, Alpha);
    /* Sigma : Scale & Standard Deviation */
    /* Alpha : Scaled mean */
    return ( exp(-(x/Sigma - Alpha)**2/2) /
              (Sigma * sqrt(2*constant('PI'))) );
  endsub;

  function normal_s_cdf(x, Sigma, Alpha);
    /* Sigma : Scale & Standard Deviation */
    /* Alpha : Scaled mean */
    z = x/Sigma - Alpha;
    return (0.5 + 0.5*erf(z/sqrt(2)));
  endsub;

  subroutine normal_s_parminit(dim, x[*], nx[*], F[*], Ftype, Sigma, Alpha);
    outargs Sigma, Alpha;
    array m[2] / nosymbols;

    /* Compute estimates by using method of moments */
    call svrtutil_rawmoments(dim, x, nx, 2, m);
    Sigma = sqrt(m[2] - m[1]**2);
    Alpha = m[1]/Sigma;
  endsub;

  subroutine normal_s_lowerbounds(Sigma, Alpha);
    outargs Sigma, Alpha;
    Alpha = .; /* Alpha has no lower bound */
    Sigma = 0; /* Sigma > 0 */
  endsub;
quit;

```

An important point to note is that the scale parameter *Sigma* is the first distribution parameter (after the 'x' argument) listed in the signatures of NORMAL_S_PDF and NORMAL_S_CDF functions. *Sigma* is also the first distribution parameter listed in the signatures of other subroutines. This is required by PROC SEVERITY, so that it can identify which is the scale parameter. When regressor variables are specified, PROC SEVERITY checks whether the first parameter of each candidate distribution is a scale parameter (or

a log-transformed scale parameter if `dist_SCALETRANSFORM` subroutine is defined for the distribution with LOG as the transform). If it is not, then an appropriate message is written the SAS log and that distribution is not fitted.

Let the following DATA step statements simulate a sample from the normal distribution where the parameter σ is affected by the regressors as follows:

$$\sigma = \exp(1 + 0.5 X_1 + 0.75 X_3 - 2 X_4 + X_5)$$

The sample is simulated such that the regressor X_2 is linearly dependent on regressors X_1 and X_3 .

```
/*--- Simulate a Normal sample affected by Regressors ---*/
data testnorm_reg(keep=y x1-x5 Sigma);
  array x{*} x1-x5;
  array b{6} _TEMPORARY_ (1 0.5 . 0.75 -2 1);
  call streaminit(34567);
  label y='Normal Response Influenced by Regressors';

  do n = 1 to 100;
    /* simulate regressors */
    do i = 1 to dim(x);
      x(i) = rand('UNIFORM');
    end;
    /* make x2 linearly dependent on x1 and x3 */
    x(2) = x(1) + 5 * x(3);

    /* compute log of the scale parameter */
    logSigma = b(1);
    do i = 1 to dim(x);
      if (i ne 2) then
        logSigma = logSigma + b(i+1) * x(i);
    end;

    Sigma = exp(logSigma);
    y = rand('NORMAL', 25, Sigma);

    output;
  end;
run;
```

The following statements use PROC SEVERITY to fit the NORMAL_S distribution model along with some of the predefined distributions to the simulated sample:

```
/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);

/*----- Fit models with PROC SEVERITY -----*/
proc severity data=testnorm_reg print=all plots=none;
  loss y;
  scalemodel x1-x5;
  dist Normal_s burr logn pareto weibull;
run;
```

The “Model Selection Table” in [Output 23.2.1](#) indicates that all the models, except the Burr distribution model, have converged. Also, only three models, Normal_s, Burr, and Weibull, seem to have a good fit for

the data. The table that compares all the fit statistics indicates that Normal_s model is the best according to the likelihood-based statistics; however, the Burr model is the best according to the EDF-based statistics.

Output 23.2.1 Summary of Results for Fitting the Normal Distribution with Regressors

Weibull	4.22441		0.71985		

This prompts for further evaluation of why the model with Burr distribution has not converged. The initial values, convergence status, and the optimization summary for the Burr distribution are shown in [Output 23.2.2](#). The initial values table indicates that the regressor X2 is redundant, which is expected. More importantly, the convergence status indicates that it requires more than 50 iterations. PROC SEVERITY enables you to change several settings of the optimizer by using the [NLOPTIONS](#) statement. In this case, you can increase the limit of 50 on the iterations, change the convergence criterion, or change the technique to something other than the default trust-region technique.

Output 23.2.2 Details of the Fitted Burr Distribution Model

The SEVERITY Procedure			
Distribution Information			
Name			Burr
Description		Burr Distribution

Needs more than 50 iterations.			
Optimization Summary for Burr Distribution			
Optimization Technique		Trust Region	
Number of Iterations		50	
Number of Function Evaluations		130	
Log Likelihood		-306.40430	

The following PROC SEVERITY step uses the NLOPTIONS statement to change the convergence criterion and the limits on the iterations and function evaluations, exclude the lognormal and Pareto distributions that have been confirmed previously to fit the data poorly, and exclude the redundant regressor X2 from the model:

```

/*--- Refit and compare models with higher limit on iterations ---*/
proc severity data=testnorm_reg print=all plots=pp;
  loss y;
  scalemodel x1 x3-x5;
  dist Normal_s burr weibull;
  nloptions absfconv=2.0e-5 maxiter=100 maxfunc=500;
run;

```

The results shown in [Output 23.2.3](#) indicate that the Burr distribution has now converged and that the Burr and Weibull distributions have an almost identical fit for the data. The NORMAL_S distribution is still the best distribution according to the likelihood-based criteria.

Output 23.2.3 Summary of Results after Changing Maximum Number of Iterations

The SEVERITY Procedure					
Input Data Set					
Name	WORK.TESTNORM_REG				
Model Selection Table					
Distribution	Converged	-2 Log Likelihood	Selected		
Normal_s	Yes	603.95786	Yes		
Burr	Yes	612.78605	No		
Weibull	Yes	612.77496	No		
All Fit Statistics Table					
Distribution	-2 Log Likelihood	AIC	AICC	BIC	KS
Normal_s	603.95786*	615.95786*	616.86108*	631.58888*	1.56822*
Burr	612.78605	626.78605	628.00344	645.02224	1.59154
Weibull	612.77496	624.77496	625.67819	640.40598	1.59176
All Fit Statistics Table					
Distribution	AD	CvM			
Normal_s	4.25257	0.75658			
Burr	4.22313*	0.71959*			
Weibull	4.22441	0.71985			

The comparison of the PDF estimates of all the candidates is shown in [Output 23.2.4](#). Each plotted PDF estimate is an average computed over the N PDF estimates that are obtained with the scale parameter determined by each of the N observations in the input data set. The PDF plot shows that the Burr and Weibull models result in almost identical estimates. All the estimates have a slight left skew with the mode closer to $Y=25$, which is the mean of the simulated sample.

Output 23.2.4 Comparison of EDF and CDF Estimates of the Fitted Models

The P-P plots for the Normal_s and Burr distributions are shown in [Output 23.2.5](#). These plots show how the EDF estimates compare against the CDF estimates. Each plotted CDF estimate is an average computed over the N CDF estimates that are obtained with the scale parameter determined by each of the N observations in the input data set. Comparing the P-P plots of Normal_s and Burr distributions indicates that both fit the data almost similarly, but the Burr distribution fits the right tail slightly better, which explains why the EDF-based statistics prefer it over the Normal_s distribution.

Output 23.2.5 Comparison of EDF and CDF Estimates of NORMAL_S and BURR Models**Example 23.3: Defining a Model for Mixed-Tail Distributions**

In some applications, a few severity values tend to be extreme as compared to the typical values. The extreme values represent the worst case scenarios and cannot be discarded as outliers. Instead, their distribution must be modeled to prepare for their occurrences. In such cases, it is often useful to fit one distribution to the non-extreme values and another distribution to the extreme values. The *mixed-tail* distribution mixes two distributions: one for the *body* region, which contains the non-extreme values, and another for the *tail* region, which contains the extreme values. The tail distribution is typically a generalized Pareto distribution (GPD), because it is usually good for modeling the conditional excess severity above a threshold. The body distribution can be any distribution. The following definitions are used in describing a generic formulation of a mixed-tail distribution:

$g(x)$	PDF of the body distribution
$G(x)$	CDF of the body distribution
$h(x)$	PDF of the tail distribution
$H(x)$	CDF of the tail distribution
θ	scale parameter for the body distribution
Ω	set of nonscale parameters for the body distribution
ξ	shape parameter for the GPD tail distribution
x_r	normalized value of the response variable at which the tail starts
p_n	mixing probability

Given these notations, the PDF $f(x)$ and the CDF $F(x)$ of the mixed-tail distribution are defined as

$$f(x) = \begin{cases} \frac{p_n}{G(x_b)} g(x) & \text{if } x \leq x_b \\ (1 - p_n) h(x - x_b) & \text{if } x > x_b \end{cases}$$

$$F(x) = \begin{cases} \frac{p_n}{G(x_b)} G(x) & \text{if } x \leq x_b \\ p_n + (1 - p_n)H(x - x_b) & \text{if } x > x_b \end{cases}$$

where $x_b = \theta x_r$ is the value of the response variable at which the tail starts.

These definitions indicate the following:

- The body distribution is conditional on $X \leq x_b$, where X denotes the random response variable.
- The tail distribution is the generalized Pareto distribution of the $(X - x_b)$ values.
- The probability that a response variable value belongs to the body is p_n . Consequently the probability that the value belongs to the tail is $(1 - p_n)$.

The parameters of this distribution are θ , Ω , ξ , x_r , and p_n . The scale of the GPD tail distribution θ_t is computed as

$$\theta_t = \frac{G(x_b; \theta, \Omega) (1 - p_n)}{g(x_b; \theta, \Omega) p_n} = \theta \frac{G(x_r; \theta = 1, \Omega) (1 - p_n)}{g(x_r; \theta = 1, \Omega) p_n}$$

The parameter x_r is typically estimated using a tail index estimation algorithm. One such algorithm is the Hill's algorithm (Danielsson et al. 2001), which is implemented by the predefined utility function SVRTUTIL_HILLCUTOFF available to you in the Sashelp.Svrtldist library. The algorithm and the utility function are described in detail in the section “[Predefined Utility Functions](#)” on page 1591. The function computes an estimate of x_b , which can be used to compute an estimate of x_r because $x_r = x_b / \hat{\theta}$, where $\hat{\theta}$ is the estimate of the scale parameter of the body distribution.

The parameter p_n is typically determined by the domain expert based on the fraction of losses that are expected to belong to the tail.

The following SAS statements define the LOGNGPD distribution model for a mixed-tail distribution with the lognormal distribution as the body distribution and GPD as the tail distribution:

```
/*----- Define Lognormal Body-GPD Tail Mixed Distribution -----*/
proc fcmp library=sashelp.svrtldist outlib=work.sevexmpl.models;
  function LOGNGPD_DESCRIPTION() $256;
    length desc $256;
    desc1 = "Lognormal Body-GPD Tail Distribution.";
    desc2 = " Mu, Sigma, and Xi are free parameters.";
    desc3 = " Xr and Pn are constant parameters.";
    desc = desc1 || desc2 || desc3;
    return(desc);
  endsub;

  function LOGNGPD_SCALETRANSFORM() $3;
    length xform $3;
    xform = "LOG";
    return (xform);
  endsub;

  subroutine LOGNGPD_CONSTANTPARM(Xr, Pn);
  endsub;
```

```

function LOGNGPD_PDF(x, Mu, Sigma, Xi, Xr, Pn);
    cutoff = exp(Mu) * Xr;
    p = CDF('LOGN', cutoff, Mu, Sigma);
    if (x < cutoff + constant('MACEPS')) then do;
        return ((Pn/p)*PDF('LOGN', x, Mu, Sigma));
    end;
    else do;
        gpd_scale = p*((1-Pn)/Pn)/PDF('LOGN', cutoff, Mu, Sigma);
        h = (1+Xi*(x-cutoff)/gpd_scale)**(-1-(1/Xi))/gpd_scale;
        return ((1-Pn)*h);
    end;
endsub;

function LOGNGPD_CDF(x, Mu, Sigma, Xi, Xr, Pn);
    cutoff = exp(Mu) * Xr;
    p = CDF('LOGN', cutoff, Mu, Sigma);
    if (x < cutoff + constant('MACEPS')) then do;
        return ((Pn/p)*CDF('LOGN', x, Mu, Sigma));
    end;
    else do;
        gpd_scale = p*((1-Pn)/Pn)/PDF('LOGN', cutoff, Mu, Sigma);
        H = 1 - (1 + Xi*((x-cutoff)/gpd_scale))**(-1/Xi);
        return (Pn + (1-Pn)*H);
    end;
endsub;

subroutine LOGNGPD_PARMINIT(dim, x[*], nx[*], F[*], Ftype,
                           Mu, Sigma, Xi, Xr, Pn);
    outargs Mu, Sigma, Xi, Xr, Pn;

    if (missing(_status_) or _status_ = 1) then
        Xb = svrtutil_percentile(Pn, dim, x, F, Ftype);

    /* prepare arrays for excess values */
    i = 1;
    do while (i <= dim and x[i] < Xb+eps);
        i = i + 1;
    end;
    dime = dim-i+1;
    call dynamic_array(xe, dime);
    call dynamic_array(nxe, dime);
    j = 1;
    do while(i <= dim);
        xe[j] = x[i] - Xb;
        nxe[j] = nx[i];

```

```

        i = i + 1;
        j = j + 1;
    end;

    /* Initialize lognormal parameters */
    call logn_parminit(dim, x, nx, F, Ftype, Mu, Sigma);
    if (not(missing(Mu))) then
        Xr = Xb/exp(Mu);
    else
        Xr = .;

    /* Initialize GPD's shape parameter using excess values */
    call gpd_parminit(dime, xe, nxe, F, Ftype, theta_gpd, Xi);
endsub;

subroutine LOGNGPD_LOWERBOUNDS(Mu, Sigma, Xi, Xr, Pn);
    outargs Mu, Sigma, Xi, Xr, Pn;

    Mu    = .; /* Mu has no lower bound */
    Sigma = 0; /* Sigma > 0 */
    Xi    = 0; /* Xi > 0 */
endsub;
quit;

```

The following points should be noted regarding the LOGNGPD definition:

- The parameters x_r and p_n are not estimated with the maximum likelihood method used by PROC SEVERITY, so you need to specify them as *constant* parameters by defining the [dist_CONSTANTPARM](#) subroutine. The signature of LOGNGPD_CONSTANTPARM subroutine lists only the constant parameters Xr and Pn .
- The parameter x_r is estimated by first using the SVRTUTIL_HILLCUTOFF utility function to compute an estimate of the cutoff point \hat{x}_b and then computing $x_r = \hat{x}_b / e^{\hat{\mu}}$. If SVRTUTIL_HILLCUTOFF fails to compute a valid estimate, then the SVRTUTIL_PERCENTILE utility function is used to set \hat{x}_b to the p_n th percentile of the data. The parameter p_n is fixed to 0.8.
- The Sashelp.Svrtdist library is specified with the LIBRARY= option in the PROC FCMP statement to enable the LOGNGPD_PARMINIT subroutine to use the predefined utility functions (SVRTUTIL_HILLCUTOFF and SVRTUTIL_PERCENTILE) and parameter initialization subroutines (LOGN_PARMINIT and GPD_PARMINIT).
- The LOGNGPD_LOWERBOUNDS subroutine defines the lower bounds for all parameters. This subroutine is required because the parameter Mu has a non-default lower bound. The bounds for $Sigma$ and Xi must be specified. If they are not specified, they are returned as missing values, which get interpreted as having no lower bound by PROC SEVERITY. You need not specify any bounds for the constant parameters Xr and Pn , because they are not subject to optimization.

The following DATA step statements simulate a sample from a mixed-tail distribution with a lognormal body and GPD tail. The parameter p_n is fixed to 0.8, the same value used in the LOGNGPD_PARMINIT subroutine defined previously:

```

/*----- Simulate a sample for the mixed-tail distribution -----*/
data testmixdist(keep=y label='Lognormal Body-GPD Tail Sample');
  call streaminit(45678);
  label y='Response Variable';
  N = 100;
  Mu = 1.5;
  Sigma = 0.25;
  Xi = 1.5;
  Pn = 0.8;

  /* Generate data comprising the lognormal body */
  Nbody = N*Pn;
  do i=1 to Nbody;
    y = exp(Mu) * rand('LOGNORMAL')**Sigma;
    output;
  end;

  /* Generate data comprising the GPD tail */
  cutoff = quantile('LOGNORMAL', Pn, Mu, Sigma);
  gpd_scale = (1-Pn) / pdf('LOGNORMAL', cutoff, Mu, Sigma);
  do i=Nbody+1 to N;
    y = cutoff + ((1-rand('UNIFORM'))**(-Xi) - 1)*gpd_scale/Xi;
    output;
  end;
run;

```

The following statements use PROC SEVERITY to fit the LOGNGPD distribution model to the simulated sample. They also fit three other predefined distributions (BURR, LOGN, and GPD). The final parameter estimates are written to the Work.Parmest data set.

```

/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);

/*----- Fit LOGNGPD model with PROC SEVERITY -----*/
proc severity data=testmixdist print=all plots(histogram kernel)=all
  outest=parmest;
  loss y;
  dist logngpd burr logn gpd;
run;

```

Some of the results prepared by PROC SEVERITY are shown in [Output 23.3.1](#) through [Output 23.3.4](#). The “Model Selection Table” in [Output 23.3.1](#) indicates that all models converged. The last table in [Output 23.3.1](#) shows that the model with LOGNGPD distribution has the best fit according to almost all the statistics of fit. The Burr distribution model is the closest contender to the LOGNGPD model, but the GPD distribution model fits the data very poorly.

Output 23.3.1 Summary of Fitting Mixed-Tail Distribution

The SEVERITY Procedure	
Input Data Set	
Name	WORK.TESTMIXDIST
Label	Lognormal Body-GPD Tail Sample

Output 23.3.1 *continued*

Burr	0.57649	0.07860
Logn	3.27122	0.48448
Gpd	16.74156	3.31860

The plots in [Output 23.3.2](#) show that both the lognormal and GPD distributions fit the data poorly, GPD being the worst. The Burr distribution fits the data as well as the LOGNGPD distribution in the body region, but has a poorer fit in the tail region than the LOGNGPD distribution.

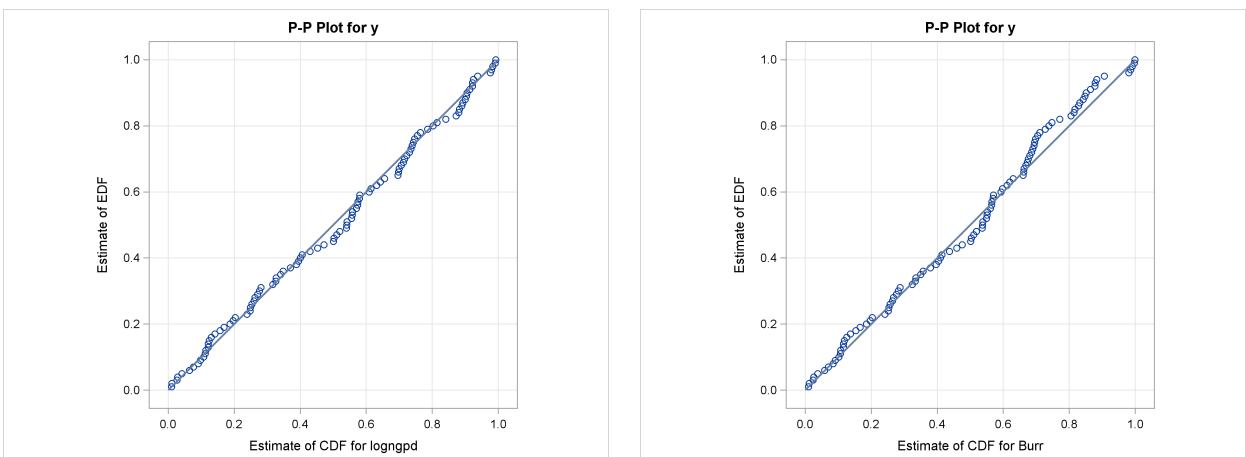

Output 23.3.2 Comparison of the CDF and PDF Estimates of the Fitted Models

Output 23.3.2 *continued*

The P-P plots of [Output 23.3.3](#) provide a better visual confirmation that the LOGNGPD distribution fits the tail region better than the Burr distribution.

Output 23.3.3 P-P Plots for the LOGNGPD and BURR Distribution Models

The detailed results for the LOGNGPD distribution are shown in [Output 23.3.4](#). The initial values table indicates the values computed by LOGNGPD_PARMINIT subroutine for the X_r and P_n parameters. It also uses the bounds columns to indicate the constant parameters. The last table in the figure shows the final parameter estimates. The estimates of all free parameters are significantly different than 0. As expected, the final estimates of the constant parameters X_r and P_n have not changed from their initial values.

Output 23.3.4 Detailed Results for the LOGNGPD Distribution

The following SAS statements use the parameter estimates to compute the value where the tail region is estimated to start ($x_b = e^{\hat{\mu}} \hat{x}_r$) and the scale of the GPD tail distribution ($\theta_t = \frac{G(x_b)(1-p_n)}{g(x_b)p_n}$):

```

/*----- Compute tail cutoff and tail distribution's scale -----*/
data xb_thetat(keep=x_b theta_t);
  set parmeset(where=(_MODEL_='logngpd' and _TYPE_='EST'));
  x_b = exp(Mu) * Xr;
  theta_t = (CDF('LOGN', x_b, Mu, Sigma) / PDF('LOGN', x_b, Mu, Sigma)) *
            ((1-Pn) / Pn);
run;

proc print data=xb_thetat noobs;
run;

```

Output 23.3.5 Start of the Tail and Scale of the GPD Tail Distribution

x_b	theta_t
6.18005	1.27865

The computed values of x_b and θ_t are shown as `x_b` and `theta_t` in [Output 23.3.5](#). Equipped with this additional derived information, you can now interpret the results of fitting the mixed-tail distribution as follows:

- The tail starts at $y \approx 6.18$. The primary benefit of using the scale-normalized cutoff (x_r) as the constant parameter instead of using the actual cutoff (x_b) is that the absolute cutoff gets optimized by virtue of optimizing the scale of the body region ($\theta = e^\mu$).
- The values $y \leq 6.18$ follow the lognormal distribution with parameters $\mu \approx 1.58$ and $\sigma \approx 0.32$. These parameter estimates are reasonably close to the parameters used for simulating the sample.
- The values $y_t = y - 6.18$ ($y_t > 0$) follow the GPD distribution with scale $\theta_t \approx 1.28$ and shape $\xi \approx 1.04$.

Example 23.4: Estimating Parameters Using Cramér-von Mises Estimator

PROC SEVERITY enables you to estimate model parameters by minimizing your own objective function. This example illustrates how you can use PROC SEVERITY to implement the Cramér-von Mises estimator. Let $F(y_i; \Theta)$ denote the estimate of CDF at y_i for a distribution with parameters Θ , and let $F_n(y_i)$ denote the empirical estimate of CDF (EDF) at y_i that is computed from a sample y_i , $1 \leq i \leq N$. Then, the Cramér-von Mises estimator of the parameters is defined as

$$\hat{\Theta} = \arg \min_{\Theta} \sum_{i=1}^N (F(y_i; \Theta) - F_n(y_i))^2$$

This estimator belongs to the class of minimum distance estimators. It attempts to estimate the parameters such that the squared distance between the CDF and EDF estimates is minimized.

The following PROC SEVERITY step uses the Cramér-von Mises estimator to fit four candidate distribution models, including the LOGNGPD mixed-tail distribution model that was defined in “[Example 23.3: Defining a Model for Mixed-Tail Distributions](#)” on page 1620. The input sample is the same as is used in that example.

```
options cmplib=(work.sevexmpl);

proc severity data=testmixdist obj=cvmobj print=all plots=pp;
  loss y;
  dist logngpd burr logn gpd;

  * Cramer-von Mises estimator (minimizes the distance *
  * between parametric and nonparametric estimates)   *;
  cvmobj = _cdf_(y);
  cvmobj = (cvmobj -_edf_(y))**2;
run;
```

The OBJ= option in the PROC SEVERITY statement specifies that the objective function cvmobj should be minimized. The programming statements compute the contribution of each observation in the input data set to the objective function cvmobj. The use of keyword functions _CDF_ and _EDF_ makes the program applicable to all the distributions.

Some of the key results prepared by PROC SEVERITY are shown in [Output 23.4.1](#). The “Model Selection Table” indicates that all models converged. When you specify a custom objective function, the default selection criterion is the value of the custom objective function. The “All Fit Statistics Table” indicates that LOGNGPD is the best distribution according to all the statistics of fit. Comparing the fit statistics of [Output 23.4.1](#) with those of [Output 23.3.1](#) indicates that the use of the Cramér-von Mises estimator has resulted in smaller values for all the EDF-based statistics of fit for all the models, which is expected from a minimum distance estimator.

Output 23.4.1 Summary of Cramér-von Mises Estimation

The P-P plots in [Output 23.4.2](#) provide a visual confirmation that the CDF estimates match the EDF estimates more closely when compared to the estimates that are obtained with the maximum likelihood estimator.

Output 23.4.2 P-P Plots for LOGNGPD Model with Maximum Likelihood (Left) and Cramér-von Mises (Right) Estimators**Example 23.5: Fitting a Scaled Tweedie Model with Regressors**

The Tweedie distribution is often used in the insurance industry to explain the effect of independent variables (regressors) on the distribution of losses. PROC SEVERITY provides a predefined scaled Tweedie distribution (STWEEDIE) that enables you to model the regression effects on the scale parameter. The scale regression model has its own advantages such as the ability to easily account for inflation effects. This ex-

ample illustrates how that model can be used to evaluate the effect of regressors on the *mean* of the Tweedie distribution, which is useful in problems such rate-making and pure premium modeling.

Assume a Tweedie process, whose mean μ is affected by k regressors x_j , $j = 1, \dots, k$ as follows:

$$\mu = \mu_0 \exp \left(\sum_{j=1}^k \beta_j x_j \right)$$

where μ_0 represents the base value of the mean (you can think of μ_0 as $\exp(\beta_0)$, where β_0 is the intercept). This model for the mean is identical to the popular generalized linear model for the mean with a logarithmic link function. More interestingly, it parallels the model used by PROC SEVERITY for the scale parameter θ , which is as follows

$$\theta = \theta_0 \exp \left(\sum_{j=1}^k \beta_j x_j \right)$$

where θ_0 represents the base value of the scale parameter. As described in the section “[Tweedie Distributions](#)” on page 1553, for the parameter range $p \in (1, 2)$, the mean of the Tweedie distribution is given by

$$\mu = \theta \lambda \frac{2-p}{p-1}$$

where λ is the Poisson mean parameter of the scaled Tweedie distribution. This relationship enables you to use the scale regression model to infer the effect of regressors on the mean of the distribution.

Let the data set `Work.Test_Sevtw` contain a sample generated from a Tweedie distribution with dispersion parameter $\phi = 0.5$, index parameter $p = 1.75$, and the mean parameter that is affected by three regression variables `x1`, `x2`, and `x3` as follows:

$$\mu = 5 \exp(0.25 x_1 - x_2 + 3 x_3)$$

Thus, the population values of regression parameters are $\mu_0 = 5$, $\beta_1 = 0.25$, $\beta_2 = -1$, and $\beta_3 = 3$. You can find the code used to generate the sample in the PROC SEVERITY sample program `sevex05.sas`.

The following PROC SEVERITY step uses the sample in `Work.Test_Sevtw` data set to estimate the parameters of the scale regression model for the predefined scaled Tweedie distribution (STWEEDIE) with the dual quasi-Newton (QUANEW) optimization technique:

```
proc severity data=test_sevtw outest=estw covout print=all plots=none;
  loss y;
  scalemodel x1-x3;

  dist stweedie;
  nloptions tech=quanew;
run;
```

The dual quasi-Newton technique is used because it requires only the first-order derivatives of the objective function, and it is harder to compute reasonably accurate estimates of the second-order derivatives of Tweedie distribution’s PDF with respect to the parameters.

Some of the key results prepared by PROC SEVERITY are shown in [Output 23.5.1](#) and [Output 23.5.2](#). The distribution information and the convergence results are shown in [Output 23.5.1](#).

Output 23.5.1 Convergence Results for the STWEEDIE Model with Regressors

The SEVERITY Procedure	
Distribution Information	
Name	stweedie
Description	Tweedie Distribution with Scale Parameter
Number of Distribution Parameters	3
Number of Regression Parameters	3
Convergence Status for stweedie Distribution	
Convergence criterion (FCONV=2.220446E-16) satisfied.	
Optimization Summary for stweedie Distribution	
Optimization Technique	Dual Quasi-Newton
Number of Iterations	42
Number of Function Evaluations	148
Log Likelihood	-1044.3

The final parameter estimates of the STWEEDIE regression model are shown in [Output 23.5.2](#). The estimate that is reported for the parameter Theta is the estimate of the base value θ_0 . The estimates of regression coefficients β_1 , β_2 , and β_3 are indicated by the rows of x1, x2, and x3, respectively.

Output 23.5.2 Parameter Estimates for the STWEEDIE Model with Regressors

Parameter Estimates for stweedie Distribution				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Theta	0.82604	0.28112	2.94	0.0036
Lambda	16.43457	13.70774	1.20	0.2315
P	1.75232	0.21462	8.16	<.0001
x1	0.28000	0.09879	2.83	0.0049
x2	-0.76652	0.10319	-7.43	<.0001
x3	3.03266	0.10144	29.89	<.0001

If your goal is to explain the effect of regressors on the scale parameter, then the output displayed in [Output 23.5.2](#) is sufficient. But, if you want to compute the effect of regressors on the mean of the distribution, then some postprocessing needs to be done. Using the relationship between μ and θ , μ can be written in terms of the parameters of the STWEEDIE model as

$$\mu = \theta_0 \exp \left(\sum_{j=1}^k \beta_j x_j \right) \lambda^{\frac{2-p}{p-1}}$$

This shows that the parameters β_j are identical for the mean and the scale model, and the base value μ_0 of the mean model is

$$\mu_0 = \theta_0 \lambda \frac{2-p}{p-1}$$

The estimate of μ_0 and the standard error associated with it can be computed by using the property of the functions of maximum likelihood estimators (MLE). If $g(\Omega)$ represents a totally differentiable function of parameters Ω , then the MLE of g has an asymptotic normal distribution with mean $g(\hat{\Omega})$ and covariance $C = (\partial \mathbf{g})' \Sigma (\partial \mathbf{g})$, where $\hat{\Omega}$ is the MLE of Ω , Σ is the estimate of covariance matrix of Ω , and $\partial \mathbf{g}$ is the gradient vector of g with respect to Ω evaluated at $\hat{\Omega}$. For μ_0 , the function is $g(\Omega) = \theta_0 \lambda (2-p)/(p-1)$. The gradient vector is

$$\begin{aligned} \partial \mathbf{g} &= \left(\frac{\partial g}{\partial \theta_0} \quad \frac{\partial g}{\partial \lambda} \quad \frac{\partial g}{\partial p} \quad \frac{\partial g}{\partial \beta_1} \cdots \frac{\partial g}{\partial \beta_k} \right) \\ &= \left(\frac{\mu_0}{\theta_0} \quad \frac{\mu_0}{\lambda} \quad \frac{-\mu_0}{(p-1)(2-p)} \quad 0 \dots 0 \right) \end{aligned}$$

You can write a DATA step that implements these computations by using the parameter and covariance estimates prepared by PROC SEVERITY step. The DATA step program is available in the sample program *sevex05.sas*. The estimates of μ_0 prepared by that program are shown in [Output 23.5.3](#). These estimates and the estimates of β_j as shown in [Output 23.5.2](#) are reasonably close (that is, within one or two standard errors) to the parameters of the population from which the sample in *Work.Test_Sevtw* data set was drawn.

Output 23.5.3 Estimate of the Base Value Mu0 of the Mean Parameter

Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Mu0	4.46928	0.42225	10.5845	0

Another effect of using the scaled Tweedie distribution to model the regression effects is that the regressors also affect the variance V of the Tweedie distribution. The variance is related to the mean as $V = \phi \mu^p$, where ϕ is the dispersion parameter. Using the relationship between the parameters TWEEDIE and STWEEDIE distributions as described in the section “[Tweedie Distributions](#)” on page 1553, the regression model for the dispersion parameter is

$$\begin{aligned} \log(\phi) &= (2-p) \log(\mu) - \log(\lambda(2-p)) \\ &= ((2-p)\mu_0 - \log(\lambda(2-p))) + (2-p) \sum_{j=1}^k \beta_j x_j \end{aligned}$$

Subsequently, the regression model for the variance is

$$\begin{aligned} \log(V) &= 2 \log(\mu) - \log(\lambda(2-p)) \\ &= (2\mu_0 - \log(\lambda(2-p))) + 2 \sum_{j=1}^k \beta_j x_j \end{aligned}$$

In summary, PROC SEVERITY enables you to estimate regression effects on various parameters and statistics of the Tweedie model.

Example 23.6: Fitting Distributions to Interval-Censored Data

In some applications, the data available for modeling might not be exact. A commonly encountered scenario is the use of grouped data from an external agency, which for several reasons, including privacy, does not provide information about individual loss events. The losses are grouped into disjoint bins, and you know only the range and number of values in each bin. Each group is essentially interval-censored, because you know that a loss magnitude is in certain interval, but you do not know the exact magnitude. This example illustrates how you can use PROC SEVERITY to model such data.

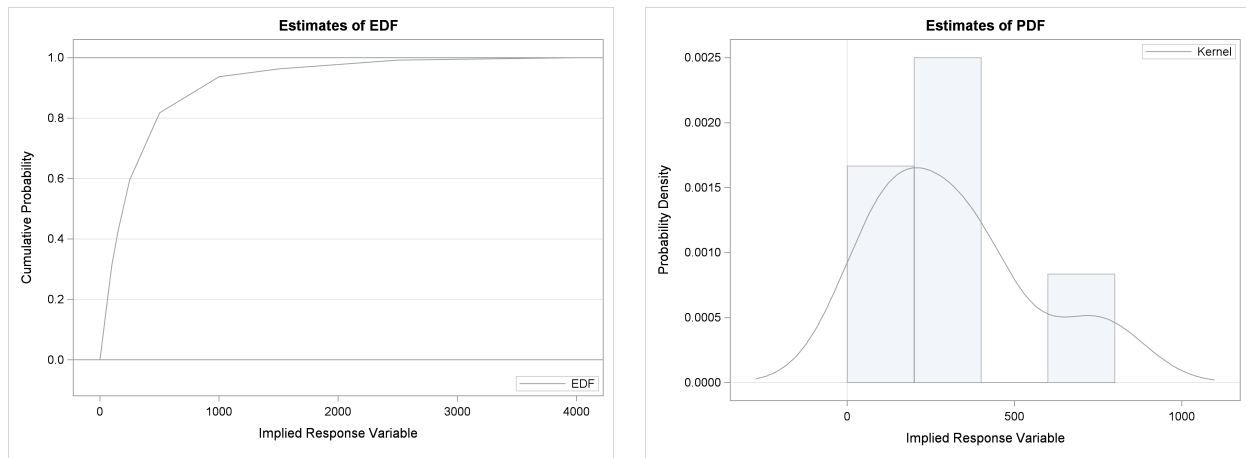

The following DATA step generates sample grouped data for dental insurance claims, which is taken from Klugman, Panjer, and Willmot (1998).

```
/* Grouped dental insurance claims data
   (Klugman, Panjer, and Willmot, 1998) */
data gdental;
    input lowerbd upperbd count @@;
    datalines;
0 25 30 25 50 31 50 100 57 100 150 42 150 250 65 250 500 84
500 1000 45 1000 1500 10 1500 2500 11 2500 4000 3
;
run;
```

Often, when you do not know the nature of the data, it is recommended that you first explore the nature of the sample distribution by examining the nonparametric estimates of PDF and CDF. The following PROC SEVERITY step prepares the nonparametric estimates, but it does not fit any distribution because there is no DIST statement specified:

```
/* Prepare nonparametric estimates */
proc severity data=gdental print=all plots(histogram kernel)=all;
    loss / rc=lowerbd lc=upperbd;
    weight count;
run;
```

The LOSS statement specifies the left and right boundary of each group as the right-censoring and left-censoring limits, respectively. The variable count records the number of losses in each group and is specified in the WEIGHT statement. Note that there is no response or loss variable specified in the LOSS statement, which is allowed as long as each observation in the input data set is censored. The nonparametric estimates prepared by this step are shown in [Output 23.6.1](#). The histogram, kernel density, and EDF plots all indicate that the data is heavy-tailed. For interval-censored data, PROC SEVERITY uses Turnbull's algorithm to compute the EDF estimates. The plot of Turnbull's EDF estimates is shown to be linear between the endpoints of a censored group. The linear relationship is chosen for convenient visualization and ease of computation of EDF-based statistics, but you should note that theoretically the behavior of Turnbull's EDF estimates is undefined within a group.

Output 23.6.1 Nonparametric Distribution Estimates for Interval-Censored Data

With the PRINT=ALL option, PROC SEVERITY prints the summary of the Turnbull EDF estimation process as shown in [Output 23.6.2](#). It indicates that the final EDF estimates have converged and are in fact maximum likelihood (ML) estimates. If they were not ML estimates, then you could have used the [ENSUREMLE](#) option to force the algorithm to search for ML estimates.

Output 23.6.2 Turnbull EDF Estimation Summary for Interval-Censored Data

Turnbull EDF Estimation Summary	
Technique	EM with Maximum Likelihood Check
Convergence Status	Converged
Number of Iterations	2
Maximum Absolute Relative Error	1.8406E-16
Maximum Absolute Reduced Gradient	1.7764E-15
Estimates	Maximum Likelihood

After exploring the nature of the data, you can now fit a set of heavy-tailed distributions to this data. The following PROC SEVERITY step fits all the predefined distributions to the data in Work.Gdental data set:

```

/* Fit all predefined distributions */
proc severity data=gdental print=all plots(histogram kernel)=all
    criterion=ad;
    loss / rc=lowerbd lc=upperbd;
    weight count;
    dist _predef_;
run;

```

Some of the key results prepared by PROC SEVERITY are shown in [Output 23.6.3](#) through [Output 23.6.4](#). According to the “Model Selection Table” in [Output 23.6.3](#), all distribution models have converged. The “All Fit Statistics Table” in [Output 23.6.3](#) indicates that the generalized Pareto distribution (GPD) has the best fit for data according to a majority of the likelihood-based statistics and that the Burr distribution (BURR) has the best fit according to all the EDF-based statistics.

Output 23.6.3 Statistics of Fit for Interval-Censored Data

Weibull	0.03293	0.00472			

The P-P plots of [Output 23.6.4](#) show that both GPD and BURR have a close fit between EDF and CDF estimates, although BURR has slightly better fit, which is also indicated by the EDF-based statistics. Given that BURR is a generalization of the GPD and that the plots do not offer strong evidence in support of the more complex distribution, GPD seems like a good choice for this data.

Output 23.6.4 P-P Plots of Burr and GPD for Interval-Censored Data

Overview: SIMILARITY Procedure

The SIMILARITY procedure computes similarity measures associated with time-stamped data, time series, and other sequentially ordered numeric data. PROC SIMILARITY computes similarity measures for time-stamped transactional data (transactions) with respect to time by accumulating the data into a time series format, and it computes similarity measures for sequentially ordered numeric data (sequences) by respecting the ordering of the data.

Given two ordered numeric sequences (input and target), a similarity measure is a metric that measures the distance between the input and target sequences while taking into account the ordering of the data. The SIMILARITY procedure computes similarity measures between an input sequence and a target sequence, in addition to similarity measures that “slide” the target sequence with respect to the input sequence. The “slides” can be by observation index (sliding-sequence similarity measures) or by seasonal index (seasonal-sliding-sequence similarity measures).

In order to compare the raw input and the raw target time-stamped data, the raw data must be accumulated to a time series format. After the input and target time series are formed, the two accumulated time series can be compared as two ordered numeric sequences.

For raw time-stamped data, after the transactional data are accumulated to form time series and any missing values are interpreted, each accumulated time series can be functionally transformed, if desired. Transformations are useful when you want to stabilize the time series before computing the similarity measures. Transformations performed by the SIMILARITY procedure include the following:

- log (LOG)
- square-root (SQRT)
- logistic (LOGISTIC)
- Box-Cox (BOXCOX)
- user-defined transformations

Each time series can be transformed further by using simple differencing or seasonal differencing or both. Additional time series transformations can be performed by using various time series transformation and analysis techniques provided by this procedure or other SAS/ETS procedures.

After optionally transforming each time series, the accumulated and transformed time series can be stored in an output data set (OUT= data set).

After optional accumulation and transformation, each of these time series are the “working series,” which can now be analyzed as sequences of numeric data. Each of these sequences can be a target sequence, an input sequence, or both a target and an input sequence. Throughout the remainder of this chapter, the term “original sequence” applies to both the original input and target sequence. The term “working sequence” applies to a version of both the original input and target sequence under investigation.

Each original sequence can be normalized prior to similarity analysis. Normalizations are useful when you want to compare the “shape” or “profile” of the time series. Normalizations performed by the SIMILARITY procedure include the following:

- standard (STANDARD)
- absolute (ABSOLUTE)
- user-defined normalizations

After each original sequence is optionally normalized, each working input sequence can be scaled to the target sequence prior to similarity analysis. Scaling is useful when you want to compare the input sequence to the target sequence while discounting the variation of the target sequence. Input sequence scaling performed by the SIMILARITY procedure include the following:

- standard (STANDARD)
- absolute (ABSOLUTE)
- user-defined scaling

After the working input sequence is optionally scaled to the target sequence, similarity measures can be computed. Similarity measures computed by the SIMILARITY procedure include:

- squared deviation (SQRDEV)
- absolute deviation (ABSDEV)
- mean square deviation (MSQRDEV)
- mean absolute deviation (MABSDEV)
- user-defined similarity measures

In computing the similarity measure between two time series, tasks are needed for transforming time series, normalizing sequences, scaling sequences, and computing metrics or measures. The SIMILARITY procedure provides built-in routines to perform these tasks. The SIMILARITY procedure also enables you to extend the procedure with user-defined routines.

All results of the similarity analysis can be stored in output data sets, printed, or graphed using the Output Delivery System (ODS).

The SIMILARITY procedure can process large amounts of time-stamped transactional data, time series, or sequential data. Therefore, the analysis results are useful for large-scale time series analysis, analogous time series forecasting, new product forecasting, or time series (temporal) data mining.

The SAS/ETS EXPAND procedure can be used for frequency conversion and transformations of time series. The TIMESERIES procedure can be used for large-scale time series analysis. The SAS/STAT DISTANCE procedure can be used to compute various measures of distance, dissimilarity, or similarity between observations (rows) of a SAS data set.

Getting Started: SIMILARITY Procedure

This section outlines the use of the SIMILARITY procedure and gives a cursory description of some of the analysis techniques that can be performed on time-stamped transactional data, time series, or sequentially ordered numeric data.

Given an input data set that contains numerous transaction variables recorded over time at no specific frequency, the SIMILARITY procedure can form equally spaced input and target time series as follows:

```
PROC SIMILARITY DATA=<input-data-set>
                OUT=<output-data-set>
                OUTSUM=<summary-data-set>;
  ID <time-ID-variable> INTERVAL=<frequency>
    ACCUMULATE=<statistic>;
  INPUT <input-time-stamp-variables>;
  TARGET <target-time-stamp-variables>;
RUN;
```

The SIMILARITY procedure forms time series from the input time-stamped transactional data. It can provide results in output data sets or in other output formats using the Output Delivery System (ODS). The examples in this section are more fully illustrated in the section “[Examples: SIMILARITY Procedure](#)” on page 1684.

Time-stamped transactional data are often recorded at no fixed interval. Analysts often want to use time series analysis techniques that require fixed-time intervals. Therefore, the transactional data must be accumulated to form a fixed-interval time series.

Suppose that a bank wants to analyze the transactions that are associated with each of its customers over time. Further, suppose that the data set WORK.TRANSACTIONS contains three variables that are related

to the customer transactions (CUSTOMER, DATE, and WITHDRAWAL) and one variable that contains an example fraudulent behavior (FRAUD).

The following statements illustrate how to use the SIMILARITY procedure to accumulate time-stamped transactional data to form a daily time series based on the accumulated daily totals of each type of transaction (WITHDRAWALS and FRAUD):

```
proc similarity data=transactions out=timedata;
  by customer;
  id date interval=day accumulate=total;
  input withdrawals;
  target fraud;
run;
```

The OUT=TIMEDATA option specifies that the resulting time series data for each customer are to be stored in the data set WORK.TIMEDATA. The INTERVAL=DAY option specifies that the transactions are to be accumulated on a daily basis. The ACCUMULATE=TOTAL option specifies that the sum of the transactions are to be accumulated. After the transactional data are accumulated into a time series format, the time series data can be normalized so that the “shape” or “profile” is analyzed.

For example, the following statements build on the previous statements and demonstrate normalization of the accumulated time series:

```
proc similarity data=transactions out=timedata;
  by customer;
  id date interval=day accumulate=total;
  input withdrawals / NORMALIZE=STANDARD;
  target fraud      / NORMALIZE=STANDARD;
run;
```

The NORMALIZE=STANDARD option specifies that each accumulated time series observation is normalized by subtracting the mean and then dividing by the standard deviation of the accumulated time series. The WORK.TIMEDATA data set now contains the accumulated and normalized time series data for each customer.

After the transactional data are accumulated into a time series format and normalized to a mean of zero and standard deviation of one, similarity analysis can be performed on the accumulated and normalized time series.

For example, the following statements build on the previous statements and demonstrate similarity analysis of the accumulated and normalized time series:

```
proc similarity data=transactions
               out=timedata OUTSUM=SUMMARY;
  by customer;
  id date interval=day accumulate=total;
  input withdrawals / normalize=standard;
  target fraud      / normalize=standard MEASURE=MABSDEV;
run;
```

The MEASURE=MABSDEV option specifies the accumulated and normalized time series data that are associated with the variables WITHDRAWALS and FRAUD are to be compared by using mean absolute deviation. The OUTSUM=SUMMARY option specifies that the similarity analysis summary for each customer is to be stored in the data set WORK.SUMMARY.

Syntax: SIMILARITY Procedure

The following statements are used with the SIMILARITY procedure.

```
PROC SIMILARITY options ;
  BY variables ;
  ID variable INTERVAL= interval options ;
  FCMPOPT options ;
  INPUT variable-list / options ;
  TARGET variable-list / options ;
```

Functional Summary

The statements and options that control the SIMILARITY procedure are summarized in the following table.

Table 24.1 SIMILARITY Functional Summary

Description	Statement	Option
Statements		
Specifies BY-group processing	BY	
Specifies the time ID variable	ID	
Specifies the FCMP options	FCMPOPT	
Specifies input variables to analyze	INPUT	
Specifies target variables to analyze	TARGET	
Data Set Options		
Specifies the input data set	PROC SIMILARITY	DATA=
Specifies the time series output data set	PROC SIMILARITY	OUT=
Specifies the measure summary output data set	PROC SIMILARITY	OUTMEASURE=
Specifies the path output data set	PROC SIMILARITY	OUTPATH=
Specifies the sequence output data set	PROC SIMILARITY	OUTSEQUENCE=
Specifies the summary output data set	PROC SIMILARITY	OUTSUM=
User-Defined Functions and Subroutine Options		
Specifies FCMP quiet mode	FCMPOPT	QUIET=
Specifies FCMP trace mode	FCMPOPT	TRACE=

Description	Statement	Option
Accumulation and Seasonality Options		
Specifies the accumulation frequency	ID	INTERVAL=
Specifies the length of seasonal cycle	PROC SIMILARITY	SEASONALITY=
Specifies the interval alignment	ID	ALIGN=
Specifies that the time ID variable values are not sorted	ID	NOTSORTED
Specifies the starting time ID value	ID	START=
Specifies the ending time ID value	ID	END=
Specifies the accumulation statistic	ID, INPUT, TARGET	ACCUMULATE=
Specifies the missing value interpretation	ID, INPUT, TARGET	SETMISS=
Specifies the zero value interpretation	ID, INPUT, TARGET	ZEROMISS=
Specifies the type of missing value trimming	INPUT, TARGET	TRIMMISS=
Time Series Transformation Options		
Specifies simple differencing	INPUT, TARGET	DIF=
Specifies seasonal differencing	INPUT, TARGET	SDIF=
Specifies the transformation	INPUT, TARGET	TRANSFORM=
Input Sequence Options		
Specifies normalization	INPUT	NORMALIZE=
Specifies scaling	INPUT	SCALE=
Target Sequence Options		
Specifies normalization	TARGET	NORMALIZE=
Similarity Measure Options		
Specifies the compression limits	TARGET	COMPRESS=
Specifies the expansion limits	TARGET	EXPAND=
Specifies the similarity measure	TARGET	MEASURE=
Specifies the similarity measure and path	TARGET	PATH=
Specifies the sequence slide	TARGET	SLIDE=
Printing and Graphical Control Options		
Specifies the time ID format	ID	FORMAT=
Specifies printed output	PROC SIMILARITY	PRINT=
Specifies detailed printed output	PROC SIMILARITY	PRINTDETAILS
Specifies graphical output	PROC SIMILARITY	PLOTS=
Miscellaneous Options		
Specifies that analysis variables are processed in ascending order	PROC SIMILARITY	SORTNAMES
Specifies the ordering of the processing of the input and target variables	PROC SIMILARITY	ORDER=

PROC SIMILARITY Statement

PROC SIMILARITY *options* ;

The following options can be used in the PROC SIMILARITY statement.

DATA=SAS-data-set

names the SAS data set that contains the time series, transactional, or sequence input data for the procedure. If the DATA= option is not specified, the most recently created SAS data set is used.

ORDER=order-option

specifies the order in which the variables listed in the INPUT and TARGET statements are to be processed. This ordering affects the OUTSEQUENCE=, OUTPATH=, OUTMEASURE=, and OUTSUM= data sets, in addition to the printed and graphical output. The SORTNAMES option also affects the ordering of the analysis. You must specify one of the following *order-options*:

INPUT	specifies that each INPUT variable be processed and then the TARGET variables be processed. The results are stored and printed based only on the INPUT variables.
INPUTTARGET	specifies that each INPUT variable be processed and then the TARGET variables be processed. The results are stored and printed based on both the INPUT and TARGET variables. This is the default.
TARGET	specifies that each TARGET variable be processed and then the INPUT variables be processed. The results are stored and printed based only on the TARGET variables.
TARGETINPUT	specifies that each TARGET variable be processed and then the INPUT variables be processed. The results are stored and printed based on both the TARGET and INPUT variables.

OUT=SAS-data-set

names the output data set to contain the time series variables specified in the subsequent INPUT and TARGET statements. If an ID variable is specified in the ID statement, it is also included in the OUT= data set. The values are accumulated based on the ID statement INTERVAL= option or the ACCUMULATE= options or both. The values are transformed based on the INPUT or TARGET statement TRANSFORM=, DIF=, and SDIF= options in this order. The OUT= data set is particularly useful when you want to further analyze, model, or forecast the resulting time series with other SAS/ETS procedures.

OUTMEASURE=SAS-data-set

names the output data set to contain the detailed similarity measures by time ID value. The form of the OUTMEASURE= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

OUTPATH=SAS-data-set

names the output data set to contain the path used to compute the similarity measures for each slide and warp. The form of the OUTPATH= data set is determined by the PROC SIMILARITY statement

SORTNAMES and ORDER= options. If a user-defined similarity measure is specified, the path cannot be determined; therefore, the OUTPATH= data set does not contain information related to this measure.

OUTSEQUENCE=SAS-data-set

names the output data set to contain the sequences used to compute the similarity measures for each slide and warp. The form of the OUTSEQUENCE= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

OUTSUM=SAS-data-set

names the output data set to contain the similarity measure summary. The OUTSUM= data set is particularly useful when analyzing large numbers of series and only the summary of the results are needed. The form of the OUTSUM= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

PLOTS=option

PLOTS=(options ...)

specifies the graphical output desired. To specify multiple *options*, separate them by spaces and enclose the group in parentheses. By default, the SIMILARITY procedure produces no graphical output. The following graphical *options* are available:

COSTS	plots graphics for time warp costs.
DISTANCES	plots graphics for similarity absolute and relative distances (OUTPATH= data set).
INPUTS	plots graphics for input variable time series (OUT= data set).
MAPS	plots graphics for time warp maps (OUTPATH= data set).
MEASURES	plots graphics for similarity measures (OUTMEASURE= data set).
NORMALIZED	plots graphics for both the input and target variable normalized sequence. These plots are displayed only when the INPUT or TARGET statement NORMALIZE= option is specified.
PATHS	plots time warp paths graphics (OUTPATH= data set).
SCALED	plots graphics for both the input variable scaled sequence. These plots are displayed only when the INPUT statement SCALE= option is specified.
SEQUENCES	plots graphics for both the input and target variable sequence (OUTSEQUENCE= data set).
TARGETS	plots graphics for the target variable time series (OUT= data set).
WARPS	plots graphics for time warps (OUTPATH= data set).
ALL	is the same as PLOTS=(INPUTS TARGETS SEQUENCES NORMALIZED SCALED DISTANCES PATHS MAPS WARPS COST MEASURES).

PRINT=option

PRINT=(options ...)

specifies the printed output desired. To specify multiple *options*, separate them by spaces and enclose the group in parentheses. By default, the SIMILARITY procedure produces no printed output. The following printing options are available:

DESCSTATS	prints the descriptive statistics for the working time series.
PATHS	prints the path statistics table. If a user-defined similarity measure is specified, the path cannot be determined; therefore, the PRINT=PATHS table is not printed for this measure.
COSTS	prints the cost statistics table.
WARPS	prints the warp summary table.
SLIDES	prints the slides summary table.
SUMMARY	prints the similarity measure summary table.
ALL	is the same as PRINT=(DESCSTATS PATHS COSTS WARPS SLIDES SUMMARY).

PRINTDETAILS

specifies that the output requested with the PRINT= option be printed in greater detail.

SEASONALITY=*integer*

specifies the length of the seasonal cycle where *integer* ranges from one to 10,000. For example, SEASONALITY=3 means that every group of three time periods forms a seasonal cycle. By default, the length of the seasonal cycle is 1 (no seasonality) or the length implied by the INTERVAL= option specified in the ID statement. For example, INTERVAL=MONTH implies that the length of the seasonal cycle is 12.

SORTNAMES

specifies that the variables specified in the INPUT and TARGET statements be processed in alphabetical order of the variable names. By default, the SIMILARITY procedure processes the variables in the order in which they are listed. The ORDER= option also affects the ordering in which the analysis is performed.

BY Statement

A BY statement can be used with PROC SIMILARITY to obtain separate dummy variable definitions for groups of observations defined by the BY variables.

When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the option NOTSORTED or DESCENDING in the BY statement for the SIMILARITY procedure. The NOTSORTED option does not mean that the data are unsorted, but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY-group processing, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

FCMPOPT Statement

FCMPOPT *options* ;

The FCMPOPT statement specifies the following *options* that are related to user-defined functions and subroutines:

QUIET=ON | OFF

specifies whether the nonfatal errors and warnings that are generated by the user-defined SAS language functions and subroutines are printed to the log. Nonfatal errors are usually associated with operations with missing values. The default is QUIET=ON.

TRACE=ON | OFF

specifies whether the user-defined SAS language functions and subroutines tracings are printed to the log. Tracings are the results of every operation executed. This option is generally used for debugging. The default is TRACE=OFF.

ID Statement

ID *variable* **INTERVAL=** *interval options* ;

The ID statement names a numeric variable that identifies observations in the input and output data sets. The ID variable's values are assumed to be SAS date, time, or datetime values. In addition, the ID statement specifies the (desired) frequency associated with the time series. The ID statement options also specify how the observations are accumulated and how the time ID values are aligned to form the time series. The options specified affect all variables listed in subsequent INPUT and TARGET statements. If an ID statement is specified, the INTERVAL= option must also be specified. The other ID statement options are optional. If an ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID.

The following options can be used with the ID statement:

ACCUMULATE=*option*

specifies how the data set observations are accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option. The ID variable contains the time ID values. Each time ID variable value corresponds to a specific time period. The accumulated values form the time series, which is used in subsequent analysis.

The ACCUMULATE= option is particularly useful when there are zero or more than one input observations that coincide with a particular time period (for example, time-stamped transactional data). The EXPAND procedure offers additional frequency conversions and transformations that can also be useful in creating a time series.

The following *options* determine how the observations are accumulated within each time period based on the ID variable and the frequency specified by the INTERVAL= option:

NONE	No accumulation occurs; the ID variable values must be equally spaced with respect to the frequency. This is the default option.
TOTAL	Observations are accumulated based on the total sum of their values.
AVERAGE AVG	Observations are accumulated based on the average of their values.
MINIMUM MIN	Observations are accumulated based on the minimum of their values.
MEDIAN MED	Observations are accumulated based on the median of their values.
MAXIMUM MAX	Observations are accumulated based on the maximum of their values.
N	Observations are accumulated based on the number of nonmissing observations.
NMISS	Observations are accumulated based on the number of missing observations.
NOBS	Observations are accumulated based on the number of observations.
FIRST	Observations are accumulated based on the first of their values.
LAST	Observations are accumulated based on the last of their values.
STDDEV STD	Observations are accumulated based on the standard deviation of their values.
CSS	Observations are accumulated based on the corrected sum of squares of their values.
USS	Observations are accumulated based on the uncorrected sum of squares of their values.

If the ACCUMULATE= option is specified, the SETMISSING= option is useful for specifying how accumulated missing values are treated. If missing values should be interpreted as zero, then SETMISSING=0 should be used. The section “[Details: SIMILARITY Procedure](#)” on page 1661 describes accumulation in greater detail.

ALIGN=option

controls the alignment of SAS dates that are used to identify output observations. The ALIGN= option accepts the following values: BEGINNING | BEG | B, MIDDLE | MID | M, and ENDING | END | E. ALIGN=BEGINNING is the default.

END=option

specifies a SAS date, datetime, or time value that represents the end of the data. If the last time ID variable value is less than the END= value, the series is extended with missing values. If the last time ID variable value is greater than the END= value, the series is truncated. For example, END=“&sysdate”D uses the automatic macro variable SYSDATE to extend or truncate the series to the current date. The START= and END= options can be used to ensure that data that are associated within each BY group contain the same number of observations.

FORMAT=*format*

specifies the SAS format for the time ID values. If the FORMAT= option is not specified, the default format is implied by the INTERVAL= option. For example, FORMAT=DATE9. specifies that the DATE9. SAS format be used. Notice that the terminating “.” is required when specifying a SAS format.

INTERVAL=*interval*

specifies the frequency of the accumulated time series. For example, if the input data set consists of quarterly observations, then INTERVAL=QTR should be used. If the SEASONALITY= option is not specified, the length of the seasonal cycle is implied from the INTERVAL= option. For example, INTERVAL=QTR implies a seasonal cycle of length 4. If the ACCUMULATE= option is also specified, the INTERVAL= option determines the time periods for the accumulation of observations.

NOTSORTED

specifies that the time ID values are not in sorted order. The SIMILARITY procedure sorts the data with respect to the time ID prior to analysis if the NOTSORTED option is specified.

SETMISSING=*option* | *number*

specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series. If a *number* is specified, missing values are set to that number. If a missing value indicates an unknown value, the SETMISSING= option should not be used. If a missing value indicates no value, then SETMISSING=0 should be used. You typically use SETMISSING=0 for transactional data, because no recorded data usually implies no activity. The following *options* can also be used to determine how missing values are assigned:

MISSING	Missing values are set to missing. This is the default option.
AVERAGE AVG	Missing values are set to the accumulated average value.
MINIMUM MIN	Missing values are set to the accumulated minimum value.
MEDIAN MED	Missing values are set to the accumulated median value.
MAXIMUM MAX	Missing values are set to the accumulated maximum value.
FIRST	Missing values are set to the accumulated first nonmissing value.
LAST	Missing values are set to the accumulated last nonmissing value.
PREVIOUS PREV	Missing values are set to the previous period's accumulated nonmissing value. Missing values at the beginning of the accumulated series remain missing.
NEXT	Missing values are set to the next period's accumulated nonmissing value. Missing values at the end of the accumulated series remain missing.

START=*option*

specifies a SAS date, datetime, or time value that represents the beginning of the data. If the first time ID variable value is greater than the START= value, the series is prepended with missing values. If the first time ID variable value is less than the START= value, the series is truncated. The START= and END= options can be used to ensure that data that are associated with each BY group contain the same number of observations.

ZEROMISS=option

specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series. The following *options* can also be used to determine how beginning and ending zero values are assigned:

NONE	Beginning and ending zeros are unchanged. This is the default.
LEFT	Beginning zeros are set to missing.
RIGHT	Ending zeros are set to missing.
BOTH	Both beginning and ending zeros are set to missing.

If the accumulated series is all missing or zero, the series is not changed.

INPUT Statement

INPUT *variable-list* < / *options* > ;

The INPUT statement lists the input numeric variables in the DATA= data set whose values are to be accumulated to form the time series or represent ordered numeric sequences (when no ID statement is specified).

An input data set variable can be specified in only one INPUT or TARGET statement. Any number of INPUT statements can be used. The following *options* can be used with an INPUT statement:

ACCUMULATE=option

specifies how the data set observations are accumulated within each time period for the variables listed in the INPUT statement. If the ACCUMULATE= option is not specified in the INPUT statement, accumulation is determined by the ACCUMULATE= option of the ID statement. If the ACCUMULATE= option is not specified in the ID statement or the INPUT statement, no accumulation is performed. See the ID statement ACCUMULATE= option for more details.

DIF=(numlist)

specifies the differencing to be applied to the accumulated time series. The list of differencing orders must be separated by spaces or commas. For example, DIF=(1,3) specifies first, then third order, differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the DIF= option. Simple differencing is useful when you want to detrend the time series before computing the similarity measures.

NORMALIZE=option

specifies the sequence normalization to be applied to the working input sequence. The following normalization *options* are provided:

NONE	No normalization is applied. This option is the default.
ABSOLUTE	Absolute normalization is applied.
STANDARD	Standard normalization is applied.
<i>User-Defined</i>	Normalization is computed by a user-defined subroutine that is created using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

Normalization is applied to the working input sequence, which can be a subset of the working input time series if the SLIDE=INDEX or SLIDE=SEASON option is specified.

SCALE=option

specifies the scaling of the working input sequence with respect to the working target sequence. Scaling is performed after normalization. The following scaling *options* are provided:

NONE	No scaling is applied. This option is the default.
ABSOLUTE	Absolute scaling is applied.
STANDARD	Standard scaling is applied.
<i>User-Defined</i>	Scaling is computed by a user-defined subroutine that is created using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

Scaling is applied to the working input sequence, which can be a subset of the working input time series if the SLIDE=INDEX or SLIDE=SEASON option is specified.

SDIF=(numlist)

specifies the seasonal differencing to be applied to the accumulated time series. The list of seasonal differencing orders must be separated by spaces or commas. For example, SDIF=(1,3) specifies first, then third, order seasonal differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the SDIF= option. Seasonal differencing is useful when you want to deseasonalize the time series before computing the similarity measures.

SETMISSING=option | number

SETMISS=option | number

specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the INPUT statement. If the SETMISSING= option is not specified in the INPUT statement, missing values are set based on the SETMISSING= option in the ID statement. If the SETMISSING= option is not specified in the ID statement or the INPUT statement, no missing value interpretation is performed. See the ID statement SETMISSING= option for more details.

TRANSFORM=option

specifies the time series transformation to be applied to the accumulated time series. The following transformations are provided:

NONE	No transformation is applied. This option is the default.
LOG	Logarithmic transformation is applied.
SQRT	Square-root transformation is applied.
LOGISTIC	Logistic transformation is applied.
BOXCOX(<i>number</i>)	Box-Cox transformation with parameter is applied, where the real <i>number</i> is between -5 and 5.
<i>User-Defined</i>	Transformation is computed by a user-defined subroutine that is created using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

When the TRANSFORM= option is specified, the time series must be strictly positive unless a user-defined function is used.

TRIMMISSING=option

TRIMMISSING=option

specifies how missing values (either actual or accumulated) are trimmed from the accumulated time series or ordered sequence for variables that are listed in the INPUT statement. The following trimming options are provided:

NONE	No missing value trimming is applied.
LEFT	Beginning missing values are trimmed.
RIGHT	Ending missing values are trimmed.
BOTH	Both beginning and ending missing value are trimmed. This is the default.

ZEROMISS=option

specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the INPUT statement. If the ZEROMISS= option is not specified in the INPUT statement, beginning and ending zero values are set based on the ZEROMISS= option of the ID statement. If the ZERO= option is not specified in the ID statement or the INPUT statement, no zero value interpretation is performed. See the ID statement ZEROMISS= option for more details.

TARGET Statement

TARGET *variable-list* < / *options* > ;

The TARGET statement lists the numeric target variables in the DATA= data set whose values are to be accumulated to form the time series or represent ordered numeric sequences (when no ID statement is specified).

An input data set variable can be specified in only one INPUT or TARGET statement. Any number of TARGET statements can be used. The following *options* can be used with a TARGET statement:

ACCUMULATE=option

specifies how the data set observations are accumulated within each time period for the variables listed in the TARGET statement. If the ACCUMULATE= option is not specified in the TARGET statement, accumulation is determined by the ACCUMULATE= option in the ID statement. If the ACCUMULATE= option is not specified in the ID statement or the TARGET statement, no accumulation is performed. See the ID statement ACCUMULATE= option for more details.

COMPRESS=option | (options)

specifies the sliding sequence (global) and warping (local) compression range of the target sequence with respect to the input sequence. Compression of the target sequence is the same as expansion of the input sequence and vice versa. The compression limits are defined based on the length of the target sequence and are imposed on the target sequence. The following compression options are provided:

GLOBALABS=*integer* specifies the absolute global compression, where *integer* ranges from zero to 10,000. GLOBALABS=0 implies no global compression, which is the default unless the GLOBALPCT= option is specified.

GLOBALPCT=*number* specifies global compression as a percentage of the length of the target sequence, where *number* ranges from zero to 100. GLOBALPCT=0 implies no global compression, which is the default. GLOBALPCT=100 implies maximum allowable compression.

LOCALABS=*integer* specifies the absolute local compression, where *integer* ranges from zero to 10,000. The default is maximum allowable absolute local compression unless the LOCALPCT= option is specified.

LOCALPCT=*number* specifies local compression as a percentage of the length of the input sequence, where *number* ranges from zero to 100. The percentage specified by the LOCALPCT= option must be less than the GLOBALPCT= option. LOCALPCT=0 implies no local compression. LOCALPCT=100 implies maximum allowable local compression. The default is LOCALPCT=100.

If the SLIDE=NONE or the SLIDE=SEASON option is specified in the TARGET statement, the global compression options are ignored. To disallow local compression, use the option COMPRESS=(LOCALPCT=0 LOCALABS=0).

If the SLIDE=INDEX option is specified, the global compression options are not ignored. To completely disallow both global and local compression, use the option COMPRESS=(GLOBALPCT=0 LOCALPCT=0) or COMPRESS=(GLOBALABS=0 LOCALABS=0). To allow only local compression, use the option COMPRESS=(GLOBALPCT=0 GLOBALABS=0). These are the default compression options.

The preceding options can be used in combination to specify the desired amount of global and local compression as the following examples illustrate, where L_c denotes the global compression limit and l_c denotes the local compression limit:

- COMPRESS=(GLOBALPCT=20) allows the global and local compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$.
- COMPRESS=(GLOBALPCT=20 GLOBALABS=10) allows the global and local compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$.
- COMPRESS=(LOCALPCT=10) allows the local compression to range from zero to $l_c = \min(\lfloor 0.1N_y \rfloor, (N_y - 1))$.
- COMPRESS=(LOCALPCT=20 LOCALABS=5) allows the local compression to range from zero to $l_c = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 5))$.
- COMPRESS=(GLOBALPCT=20 LOCALPCT=20) allows the global compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$ and allows the local compression to range from zero to $l_c = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$.
- COMPRESS=(GLOBALPCT=20 GLOBALABS=10 LOCALPCT=10 LOCALABS=5) allows the global compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$ and allows the local compression to range from zero to $l_c = \min(\lfloor 0.1N_y \rfloor, \min((N_y - 1), 5))$.

Suppose T_z is the length of the input time series and N_y is the length of the target sequence. The valid global compression limit, L_c , is always limited by the length of the target sequence: $0 \leq L_c < N_y$.

Suppose N_x is the length of the input sequence and N_y is the length of the target sequence. The *valid* local compression limit, l_c , is always limited by the lengths of the input and target sequence: $\max(0, (N_y - N_x)) \leq l_c < N_y$.

DIF=(numlist)

specifies the differencing to be applied to the accumulated time series. The list of differencing orders must be separated by spaces or commas. For example, DIF=(1,3) specifies first, then third, order differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the DIF= option. Simple differencing is useful when you want to detrend the time series before computing the similarity measures.

EXPAND=option | (options)

specifies the sliding sequence (global) and warping (local) expansion range of the target sequence with respect to the input sequence. Expansion of the target sequence is the same as compression of the input sequence and vice versa. The expansion limits are defined based on the length of the input sequence, but are imposed on the target sequence. The following expansion options are provided:

GLOBALABS=integer specifies the absolute global expansion, where *integer* ranges from zero to 10,000. GLOBALABS=0 implies no global expansion, which is the default unless the GLOBALPCT= option is specified.

GLOBALPCT=number specifies global expansion as a percentage of the length of the target sequence, where *number* ranges from zero to 100. GLOBALPCT=0 implies no global expansion, which is the default unless the GLOBALABS= option is specified. GLOBALPCT=100 implies maximum allowable global expansion.

LOCALABS=integer specifies the absolute local expansion, where *integer* ranges from zero to 10,000. The default is the maximum allowable absolute local expansion unless the LOCALPCT= option is specified.

LOCALPCT=number specifies local expansion as a percentage of the length of the target sequence, where *number* ranges from zero to 100. LOCALPCT=0 implies no local expansion. LOCALPCT=100 implies maximum allowable local expansion. The default is LOCALPCT=100.

If the SLIDE=NONE or the SLIDE=SEASON option is specified in the TARGET statement, the global expansion options are ignored. To disallow local expansion, use the option EXPAND=(LOCALPCT=0 LOCALABS=0).

If the SLIDE=INDEX option is specified, the global expansion options are not ignored. To completely disallow both global and local expansion, use the option EXPAND=(GLOBALPCT=0 LOCALPCT=0) or EXPAND=(GLOBALABS=0 LOCALABS=0). To allow only local expansion, use the option EXPAND=(GLOBALPCT=0 GLOBALABS=0). These are the default expansion options.

The preceding options can be used in combination to specify the desired amount of global and local expansion as the following examples illustrate, where L_e denotes the global expansion limit and l_e denotes the local expansion limit:

- EXPAND=(GLOBALPCT=20) allows the global and local expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$.

- EXPAND=(GLOBALPCT=20 GLOBALABS=10) allows the global expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$.
- EXPAND=(LOCALPCT=10) allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, (N_y - 1))$.
- EXPAND=(LOCALPCT=10 LOCALABS=5) allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, \min((N_y - 1), 5))$.
- EXPAND=(GLOBALPCT=20 LOCALPCT=10) allows the global expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$ and allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, (N_y - 1))$.
- EXPAND=(GLOBALPCT=20 GLOBALABS=10 LOCALPCT=10 LOCALABS=5) allows the global expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$ and allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, \min((N_y - 1), 5))$.

Suppose T_z is the length of the input time series and N_y is the length of the target sequence. The *valid* global expansion limit, L_e , is always limited by the length of the input time series: $0 \leq L_e < T_z$.

Suppose N_x is the length of the input sequence and N_y is the length of the target sequence. The *valid* local expansion limit, l_e , is always limited by the lengths of the input and target sequence: $\max(0, (N_x - N_y)) \leq l_e < N_x$.

MEASURE=option

specifies the similarity measure to be computed by using the working input and target sequences. The following similarity measures are provided:

SQRDEV	squared deviation. This option is the default.
ABSDEV	absolute deviation
MSQRDEV	mean squared deviation
MSQRDEVINP	mean squared deviation relative to the length of the input sequence
MSQRDEVTAR	mean squared deviation relative to the length of the target sequence
MSQRDEVMIN	mean squared deviation relative to the minimum valid path length
MSQRDEVMAX	mean squared deviation relative to the maximum valid path length
MABSDEV	mean absolute deviation
MABSDEVINP	mean absolute deviation relative to the length of the input sequence
MABSDEVTAR	mean absolute deviation relative to the length of the target sequence
MABSDEVMIN	mean absolute deviation relative to the minimum valid path length
MABSDEVMAX	mean absolute deviation relative to the maximum valid path length
User-Defined	The measure is computed by a user-defined function created by using the FCMP procedure, where <i>User-Defined</i> is the function name.

NORMALIZE=option

specifies the sequence normalization to be applied to the working target sequence. The following normalization options are provided:

NONE	No normalization is applied. This option is the default.
ABSOLUTE	Absolute normalization is applied.
STANDARD	Standard normalization is applied.
<i>User-Defined</i>	Normalization is computed by a user-defined subroutine that is created by using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

PATH=option

specifies the similarity measure and warping path information to be computed using the working input and target sequences. The following similarity measures and warping path are provided:

<i>User-Defined</i>	The measure and path are computed by a user-defined subroutine that is created by using the FCMP procedure, where <i>User-Defined</i> is the subroutine name
---------------------	--

For computational efficiency, the PATH= option should be only used when you want to compute both the similarity measure and the warping path information. If only the similarity measure is needed, use the MEASURE= option. If you specify both the MEASURE= and PATH= option in the TARGET statement, the PATH= option takes precedence.

SDIF=(numlist)

specifies the seasonal differencing to be applied to the accumulated time series. The list of seasonal differencing orders must be separated by spaces or commas. For example, SDIF=(1,3) specifies first, then third, order seasonal differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the SDIF= option. Seasonal differencing is useful when you want to deseasonalize the time series before computing the similarity measures.

SETMISSING=option | number**SETMISS=option | number**

option specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series for variables that are listed in the TARGET statement. If the SETMISSING= option is not specified in the TARGET statement, missing values are set based on the SETMISSING= option in the ID statement. If the SETMISSING= option is not specified in the ID statement or the TARGET statement, no missing value interpretation is performed. See the ID statement SETMISSING= option for more details.

SLIDE=option

specifies the sliding of the target sequence with respect to the input sequence. The following slides are provided:

NONE	No sequence sliding. The input time series is compared with the target sequence directly with no sliding. This option is the default.
INDEX	Slide by time index. The input time series is compared with the target sequence by observation index.
SEASON	Slide by seasonal index. The input time series is compared with the target sequence by seasonal index.

The SLIDE= option takes precedence over the COMPRESS= and EXPAND= options.

TRANSFORM=option

specifies the time series transformation to be applied to the accumulated time series. The following transformations are provided:

NONE	No transformation is applied. This option is the default.
LOG	Logarithmic transformation is applied.
SQRT	Square-root transformation is applied.
LOGISTIC	Logistic transformation is applied.
BOXCOX(<i>number</i>)	Box-Cox transformation with parameter is applied, where the real <i>number</i> is between -5 and 5
<i>User-Defined</i>	Transformation is computed by a user-defined subroutine that is created by using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

When the TRANSFORM= option is specified, the time series must be strictly positive unless a user-defined function is used.

TRIMMISSING=option**TRIMMISS= option**

specifies how missing values (either actual or accumulated) are trimmed from the accumulated time series or ordered sequence for variables that are listed in the TARGET statement. The following trimming options are provided:

NONE	No missing value trimming is applied.
LEFT	Beginning missing values are trimmed.
RIGHT	Ending missing values are trimmed.
BOTH	Both beginning and ending missing values are trimmed. This is the default.

ZEROMISS=option

specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the TARGET statement. If the ZEROMISS= option is not specified in the TARGET statement, beginning and ending values are set based on the ZEROMISS= option in the ID statement. See the ID statement ZEROMISS= option for more details.

Details: SIMILARITY Procedure

You can use the SIMILARITY procedure to do the following functions, which are done in the order shown. First, you can form time series data from transactional data with the options shown:

1. accumulation ACCUMULATE= option

- 2. missing value interpretation SETMISSING= option
- 3. zero value interpretation ZEROMISS= option

Next, you can transform the accumulated time series to form the working time series with the following options. Transformations are useful when you want to stabilize the time series before computing the similarity measures. Simple and seasonal differencing are useful when you want to detrend or deseasonalize the time series before computing the similarity measures. Often, but not always, the TRANSFORM=, DIF=, and SDIF= options should be specified in the same way for both the target and input variables.

- 4. time series transformation TRANSFORM= option
- 5. time series differencing DIF= and SDIF= option
- 6. time series missing value trimming TRIMMISSING= option
- 7. time series descriptive statistics PRINT=DESCSTATS option

After the working series is formed, you can treat it as an ordered sequence that can be normalized or scaled. Normalizations are useful when you want to compare the “shape” or “profile” of the time series. Scaling is useful when you want to compare the input sequence to the target sequence while discounting the variation of the target sequence.

- 8. normalization NORMALIZE= option
- 9. scaling SCALE= option

After the working sequences are formed, you can compute similarity measures between input and target sequences:

- 10. sliding SLIDE= option
- 11. warping COMPRESS= and EXPAND= option
- 12. similarity measure MEASURE= and PATH= option

The SLIDE= option specifies observation-index sliding, seasonal-index sliding, or no sliding. The COMPRESS= and EXPAND= options specify the warping limits. The MEASURE= and PATH= options specify how the similarity measures are computed.

Accumulation

If the ACCUMULATE= option is specified in the ID, INPUT, or TARGET statement, data set observations are accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option in the ID statement. The ID variable contains the time ID values. Each time ID value

corresponds to a specific time period. Accumulation is particularly useful when the input data set contains transactional data, whose observations are not spaced with respect to any particular time interval. The accumulated values form the time series, which is used in subsequent analyses.

For example, suppose a data set contains the following observations:

19MAR1999	10
19MAR1999	30
11MAY1999	50
12MAY1999	20
23MAY1999	20

If the INTERVAL=MONTH is specified, all of the preceding observations fall within three time periods of March 1999, April 1999, and May 1999. The observations are accumulated within each time period as follows:

If the ACCUMULATE=NONE option is specified, an error is generated because the ID variable values are not equally spaced with respect to the specified frequency (MONTH).

If the ACCUMULATE=TOTAL option is specified, the data are accumulated as follows:

01MAR1999	40
01APR1999	.
01MAY1999	90

If the ACCUMULATE=AVERAGE option is specified, the data are accumulated as follows:

01MAR1999	20
01APR1999	.
01MAY1999	30

If the ACCUMULATE=MINIMUM option is specified, the data are accumulated as follows:

01MAR1999	10
01APR1999	.
01MAY1999	20

If the ACCUMULATE=MEDIAN option is specified, the data are accumulated as follows:

01MAR1999	20
01APR1999	.
01MAY1999	20

If the ACCUMULATE=MAXIMUM option is specified, the data are accumulated as follows:

01MAR1999	30
01APR1999	.
01MAY1999	50

If the ACCUMULATE=FIRST option is specified, the data are accumulated as follows:

```
O1MAR1999    10
O1APR1999    .
O1MAY1999    50
```

If the ACCUMULATE=LAST option is specified, the data are accumulated as follows:

```
O1MAR1999    30
O1APR1999    .
O1MAY1999    20
```

If the ACCUMULATE=STDDEV option is specified, the data are accumulated as follows:

```
O1MAR1999    14.14
O1APR1999    .
O1MAY1999    17.32
```

As can be seen from the preceding examples, even though the data set observations contain no missing values, the accumulated time series can have missing values.

Missing Value Interpretation

Sometimes missing values should be interpreted as unknown values. But sometimes missing values are known, such as when missing values are created from accumulation and no observations should be interpreted as no (zero) value. In the former case, the SETMISSING= option in the ID, INPUT, or TARGET statement can be used to interpret how missing values are treated. The SETMISSING=0 option should be used when missing observations are to be treated as no (zero) values. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and interpreted time series is used in subsequent analyses.

The SETMISSING=0 option should be used with missing observations are to be treated as a zero value. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and interpreted time series is then used in subsequent analyses.

Zero Value Interpretation

When querying certain databases for time-stamped data based on a particular time range, time periods that contain no data are sometimes assigned zero values. For certain analyses, it is more desirable to assign these values to missing. Often, these beginning or ending zero values need to be interpreted as missing values. The ZEROMISS= option in the ID, INPUT, or TARGET statement specifies that the beginning, ending, or both the beginning and ending values are to be interpreted as zero values.

Time Series Transformation

Transformations are useful when you want to stabilize the time series before computing the similarity measures. There are four transformations available, for strictly positive series only. Let $y_t > 0$ be the original time series, and let w_t be the transformed series. The transformations are defined as follows:

Log is the logarithmic transformation,

$$w_t = \ln(y_t)$$

Logistic is the logistic transformation,

$$w_t = \ln(cy_t/(1 - cy_t))$$

where the scaling factor c is

$$c = (1 - e^{-6})10^{-\text{ceil}(\log_{10}(\max(y_t)))}$$

and $\text{ceil}(x)$ is the smallest integer greater than or equal to x .

Square root is the square root transformation,

$$w_t = \sqrt{y_t}$$

Box-Cox is the Box-Cox transformation,

$$w_t = \begin{cases} \frac{y_t^\lambda - 1}{\lambda} & \lambda \neq 0 \\ \ln(y_t) & \lambda = 0 \end{cases}$$

User-Defined is the transformation computed by a user-defined subroutine that is created by using the FCMP procedure, where *User-Defined* is the subroutine name.

Other time series transformations can be performed prior to invoking the SIMILARITY procedure by using the SAS/ETS EXPAND procedure or the DATA step.

Time Series Differencing

After optionally transforming the series, the accumulated series can be simply or seasonally differenced using the INPUT or TARGET statement DIF= and SDIF= options. Simple and seasonal differencing are useful when you want to detrend or deseasonalize the time series before computing the similarity measures.

For example, suppose y_t is a monthly time series. The following examples of the DIF= and SDIF= options demonstrate how to simply and seasonally difference the time series: DIF=(1,3) specifies first, then third, order differencing; SDIF=(1,3) specifies first, then third, order seasonal differencing.

Additionally, assuming that y_t is strictly positive, the INPUT or TARGET statement TRANSFORM= option and the DIF= and SDIF= options can be combined.

Time Series Missing Value Trimming

In some instances, missing values should be interpreted as an unknown observation, but other times, missing values are known and should be interpreted as a zero value. This is the case when missing values are created from accumulation, and a missing observation should be interpreted as having no value (meaning a value of zero). In the former case, the SETMISSING=option in the ID, INPUT, or TARGET, statement can be used to interpret how missing observations should be treated. By default, missing values, at the beginning and ending of the data set, are trimmed from the data set prior to analysis. This can be performed using TRIMMISS=both.

Time Series Descriptive Statistics

After a series has been optionally accumulated and transformed with missing values interpreted, descriptive statistics can be computed for the resulting working series by specifying the PRINT=DESCSTATS option. This option produces an ODS table that contains the sum, mean, minimum, maximum, and standard deviation of the working series.

Input and Target Sequences

After the input and target working series are formed, they can be treated as two ordered sequences. Given an input time sequence, x_i , for $i = 1$ to N_x , where i is the input sequence index, and a target time sequence, y_j , for $j = 1$ to N_y , where j is the target sequence index, these sequences are analyzed for similarity.

Sliding Sequences

Similarity measures can be computed between the target sequence and any contiguous subsequences of the input time series.

There are three types of sequence sliding:

- no sliding
- slide by time index
- slide by season index

For more information, see Leonard, Elsheimer, and Sloan (2008).

Time Warping

Time warping allows for the comparison between target and input sequences of differing lengths by compressing or expanding the input sequence with respect to the target sequence while respecting the order of the sequence elements.

For more information, see Leonard, Elsheimer, and Sloan (2008).

Sequence Normalization

The working (input or target) sequence can be normalized prior to further analysis. Let q_i be the original sequence with mean μ_q and standard deviation σ_q , and let r_i be the normalized sequence. The normalizations are defined as follows:

- Standard is the standard normalization

$$r_i = (q_i - \mu_q) / \sigma_q$$

- Absolute is the absolute normalization

$$r_i = (q_i - \min(q_i)) / (\max(q_i) - \min(q_i))$$

- User-defined is a user-defined normalization created by the FCMP procedure.

Sequence Scaling

The working input sequence can be scaled to the working target sequence. Sequence scaling is applied after normalization. Let y_j be the working target sequence with mean μ_y and standard deviation σ_y . Let x_i be the working input sequence and let q_i be the scaled sequence. The scaling is defined as follows:

- Standard is the standard normalization

$$q_i = (x_i - \mu_y) / \sigma_y$$

- Absolute is the absolute scaling

$$q_i = (x_i - \min(y_j)) / (\max(y_j) - \min(y_j))$$

- User-defined is a user-defined scaling created by the FCMP procedure.

Similarity Measures

The working input sequence can be compared to the working target sequence to create a similarity.

For more information, see Leonard, Elsheimer, and Sloan (2008).

User-Defined Functions and Subroutines

A user-defined routine can be written in the SAS language by using the FCMP procedure or in the C language by using both the FCMP procedure and the PROTO procedure, respectively. The SIMILARITY procedure cannot use C language routines directly. The procedure can use only SAS language routines that might or might not call C language routines. Creating user-defined routines is more completely described in the FCMP procedure and the PROTO procedure documentation. The FCMP and PROTO procedures are part of Base SAS software.

The SAS language provides integrated memory management and exception handling such as operations on missing values. The C language provides flexibility and allows the integration of existing C language libraries. However, proper memory management and exception handling are solely the responsibility of the user. Additionally, the support for standard C libraries is restricted. If you have a choice, it is highly recommended that you write user-defined functions and subroutines in the SAS language using the FCMP procedure.

For each of the tasks previously described, the following sections describe the required subroutine or function signature and provide examples of using a user-defined routine with the SIMILARITY procedure.

Time Series Transformations

A user-defined transformation subroutine has the following subroutine signature:

```
SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*] );
```

where the array-name is the time series to be transformed.

For example, to duplicate the functionality of the built-in TRANSFORM=LOG option in the INPUT and TARGET statement, the following SAS statements create a user-defined version of this transformation called MYTRANSFORM and store this subroutine in the catalog SASUSER.MYSIMILAR.

```
proc fcmp outlib=sasuser.mysimilar.package;

  subroutine mytransform( series[*] );

    outargs series;

    length = DIM(series);
```

```

do i = 1 to length;
  value = series[i];
  if value > 0 then do;
    series[i] = log( value );
  end;
  else do;
    series[i] = .;
  end;
end;

endsub;

run;

```

This user-defined subroutine can be specified in the TRANSFORM= option in the INPUT or TARGET statement as follows:

```

options cmlib = sasuser.mysimilar;

proc similarity ...;
...
input  myinput  / transform=mytransform;
target mytarget / transform=mytransform;
...
run;

```

Sequence Normalizations

A user-defined normalization subroutine has the following signature:

```
SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*] );
```

where the array-name is the sequence to be normalized.

For example, to duplicate the functionality of the built-in NORMALIZE=ABSOLUTE option in the INPUT and TARGET statement, the following SAS statements create a user-defined version of this normalization called MYNORMALIZE and store this subroutine in the catalog SASUSER.MYSIMILAR.

```

proc fcmp outlib=sasuser.mysimilar.package;

  subroutine mynormalize( sequence[*] );

    outargs sequence;

    length = DIM(sequence);
    minimum = .; maximum = .;

    do i = 1 to length;

```

```

        value = sequence[i];
        if nmiss(minimum) | nmiss(maximum) then do;
            minimum = value;
            maximum = value;
        end;
        if nmiss(value) = 0 then do;
            if value < minimum then minimum = value;
            if value > maximum then maximum = value;
        end;
    end;

    do i = 1 to length;
        value = sequence[i];
        if nmiss( value ) | minimum > maximum then do;
            sequence[i] = .;
        end;
        else do;
            sequence[i] = (value - minimum) / (maximum - minimum);
        end;
    end;

endsub;

run;

```

This user-defined subroutine can be specified in the NORMALIZE= option in the INPUT or TARGET statement as follows:

```

options cmlib = sasuser.mysimilar;

proc similarity ...;
    ...
    input  myinput  / normalize=mynormalize;
    target mytarget / normalize=mynormalize;
    ...
run;

```

Sequence Scaling

A user-defined scaling subroutine has the following signature:

```
SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*], <ARRAY-NAME>[*] );
```

where the first array-name is the target sequence and the second array-name is the input sequence to be scaled.

For example, to duplicate the functionality of the built-in SCALE=ABSOLUTE option in the INPUT statement, the following SAS statements create a user-defined version of this scaling called MYSCALE and store this subroutine in the catalog SASUSER.MYSIMILAR.

```

proc fcmp outlib=sasuser.mysimilar.package;

  subroutine myscale( target[*], input[*] );

    outargs input;

    length = DIM(target);
    minimum = .; maximum = .;

    do i = 1 to length;
      value = target[i];
      if nmiss(minimum) | nmiss(maximum) then do;
        minimum = value;
        maximum = value;
      end;
      if nmiss(value) = 0 then do;
        if value < minimum then minimum = value;
        if value > maximum then maximum = value;
      end;
    end;

    do i = 1 to length;
      value = input[i];
      if nmiss( value ) | minimum > maximum then do;
        input[i] = .;
      end;
      else do;
        input[i] = (value - minimum) / (maximum - minimum);
      end;
    end;

  endsub;

run;

```

This user-defined subroutine can be specified in the SCALE= option in the INPUT statement as follows:

```

options cmplib=sasuser.mysimilar;

proc similarity ...;
  ...
  input myinput / scale=myscale;
  ...
run;

```

Similarity Measures

A user-defined similarity measure function has the following signature:

```

FUNCTION <FUNCTION-NAME> ( <ARRAY-NAME>[*], <ARRAY-NAME>[*] );

```

where the first array-name is the target sequence and the second array-name is the input sequence. The return value of the function is the similarity measure associated with the target sequence and the input sequence.

For example, to duplicate the functionality of the built-in MEASURE=ABSDEV option in the TARGET statement with no warping, the following SAS statements create a user-defined version of this measure called MYMEASURE and store this subroutine in the catalog SASUSER.MYSIMILAR.

```
proc fcmp outlib=sasuser.mysimilar.package;

  function mymeasure( target[*], input[*] );

    length = min(DIM(target), DIM(input));
    sum = 0; num = 0;

    do i = 1 to length;
      x = input[i];
      w = target[i];
      if nmiss(x) = 0 & nmiss(w) = 0 then do;
        d = x - w;
        sum = sum + abs(d);
        num = num + 1;
      end;
    end;

    if num <= 0 then return(.);

    return(sum);

  endsub;

run;
```

This user-defined function can be specified in the MEASURE= option in the TARGET statement as follows:

```
options cmplib=sasuser.mysimilar;

proc similarity ...;
  ...
  target mytarget / measure=mymeasure;
  ...
run;
```

For another example, to duplicate the functionality of the built-in MEASURE=SQRDEV and MEASURE=ABSDEV options by using the C language, the following SAS statements create a user-defined C language version of these measures called DTW_SQRDEV_C and DTW_ABSDEV_C and store these functions in the catalog SASUSER.CSIMIL.CFUNCS. DTW refers to dynamic time warping. These C language functions can be then called by SAS language functions and subroutines.

```
proc proto package=sasuser.csimil.cfuncs;
```

```

mapmiss double = 999999999;

double dtw_sqrdev_c( double * target / iotype=input,
                    int      targetLength,
                    double * input / iotype=input,
                    int      inputLength );

externc dtw_sqrdev_c;
double dtw_sqrdev_c( double * target,
                    int      targetLength,
                    double * input,
                    int      inputLength )
{
    int      i,j;
    double   x,w,d;
    double * prev = (double *)malloc( sizeof(double)*targetLength);
    double * curr = (double *)malloc( sizeof(double)*inputLength);
    if ( prev == 0 || curr == 0 ) return 999999999;

    x = input[0];
    for ( j=0; j<targetLength; j++ ) {
        w = target[j];
        d = x - w;
        d = d*d;
        if ( j == 0 ) prev[j] = d;
        else          prev[j] = d + prev[j-1];
    }

    for (i=1; i<inputLength; i++ ) {
        x = input[i];

        j = 0;
        w = target[j];
        d = x - w;
        d = d*d;
        curr[j] = d + prev[j];

        for (j=1; j<targetLength; j++ ) {
            w = target[j];
            d = x - w;
            d = d*d;
            curr[j] = d + fmin( prev[j],
                               fmin( prev[j-1], curr[j])));
        }

        if ( i < targetLength ) {
            for( j=0; j<inputLength; j++ )
                prev[j] = curr[j];
        }
    }

    d = curr[inputLength-1];
    free( (char*) prev);
    free( (char*) curr);
}

```

```

        return( d );
    }
externcend;

double dtw_absdev_c( double * target / iotype=input,
                    int      targetLength,
                    double * input / iotype=input,
                    int      inputLength );
externc dtw_absdev_c;
double dtw_absdev_c( double * target,
                    int      targetLength,
                    double * input,
                    int      inputLength )
{
    int      i,j;
    double   x,w,d;
    double * prev = (double *)malloc( sizeof(double)*targetLength);
    double * curr = (double *)malloc( sizeof(double)*inputLength);
    if ( prev == 0 || curr == 0 ) return 999999999;

    x = input[0];
    for ( j=0; j<targetLength; j++ ) {
        w = target[j];
        d = x - w;
        d = fabs(d);
        if ( j == 0) prev[j] = d;
        else prev[j] = d + prev[j-1];
    }

    for (i=1; i<inputLength; i++ ) {
        x = input[i];

        j = 0;
        w = target[j];
        d = x - w;
        d = fabs(d);
        curr[j] = d + prev[j];

        for (j=1; j<targetLength; j++) {
            w = target[j];
            d = x - w;
            d = fabs(d);
            curr[j] = d + fmin( prev[j],
                               fmin( prev[j-1], curr[j] ));
        }

        if ( i < inputLength) {
            for ( j=0; j<targetLength; j++ )
                prev[j] = curr[j];
        }
    }

    d = curr[inputLength-1];

```

```

        free( (char*) prev);
        free( (char*) curr);
        return( d );
    }
externcend;

run;

```

The preceding SAS statements create two C language functions which can then be used in SAS language functions or subroutines or both. However, these functions cannot be directly used by the SIMILARITY procedure. In order to use these C language functions in the SIMILARITY procedure, two SAS language functions must be created that call these two C language functions. The following SAS statements create two user-defined SAS language versions of these measures called DTW_SQRDEV and DTW_ABSDEV and stores these functions in the catalog SASUSER.MYSIMILAR.FUNCS. These SAS language functions use the previously created C language function; the SAS language functions can then be used by the SIMILARITY procedure.

```

proc fcmp outlib=sasuser.mysimilar.funcs
    inlib=sasuser.cffuncs;

    function dtw_sqrdev( target[*], input[*] );
        dev = dtw_sqrdev_c(target,DIM(target),input,DIM(input));
        return( dev );
    endsub;

    function dtw_absdev( target[*], input[*] );
        dev = dtw_absdev_c(target,DIM(target),input,DIM(input));
        return( dev );
    endsub;

run;

```

This user-defined function can be specified in the MEASURE= option in the TARGET statement as follows:

```

options cmplib=sasuser.mysimilar;

proc similarity ...;
    ...
    target  mytarget    / measure=dtw_sqrdev;
    target  yourtarget  / measure=dtw_absdev;
    ...
run;

```

Similarity Measures and Warping Path

A user-defined similarity measure and warping path information function has the following signature:

```

FUNCTION <FUNCTION-NAME> ( <ARRAY-NAME>[*], <ARRAY-NAME>[*],

```

```
<ARRAY-NAME>[*], <ARRAY-NAME>[*],  
<ARRAY-NAME>[*] );
```

where the first array-name is the target sequence, the second array-name is the input sequence, the third array-name is the returned target sequence indices, the fourth array-name is the returned input sequence indices, the fifth array-name is the returned path distances. The returned value of the function is the similarity measure. The last three returned arrays are used to compute the path and cost statistics.

The returned sequence indices must represent a valid warping path; that is, integers greater than zero and less than or equal to the sequence length and recorded in ascending order. The returned path distances must be nonnegative numbers.

Output Data Sets

The SIMILARITY procedure can create the OUT=, OUTMEASURE=, OUTPATH=, OUTSEQUENCE=, and OUTSUM= data sets. In general, these data sets contain the variables listed in the BY statement. The ID statement time ID variable is also included in the data sets when the time dimension is important. If an analysis step related to an output data step fails, then the values of this step are not recorded or are set to missing in the related output data set, and appropriate error and warning messages are recorded in the SAS log.

OUT= Data Set

The OUT= data set contains the variables that are specified in the BY, ID, INPUT, and TARGET statements. If the ID statement is specified, the ID variable values are aligned and extended based on the ALIGN=, INTERVAL=, START=, and END= options. The values of the variables specified in the INPUT and TARGET statements are accumulated based on the ACCUMULATE= option, missing values are interpreted based on the SETMISSING= option, and zero values are interpreted using the ZEROMISS= option. The accumulated time series is transformed based on the TRANSFORM=, DIF=, and SDIF= options.

OUTMEASURE= Data Set

The OUTMEASURE= data set records the similarity measures between each INPUT and TARGET statement variable with respect to each time ID value. The form of the OUTMEASURE= data set depends on the SORTNAMES and ORDER= options. The OUTMEASURE= data set contains the variables specified in the BY statement in addition to the variables listed below.

For ORDER=INPUTTARGET and ORDER=TARGETINPUT, the OUTMEASURE= data set has the following form:

```
_INPUT_      input variable name
```

<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_INPSEQ_</code>	input sequence values
<code>_TARSEQ_</code>	target sequence values
<code>_SIM_</code>	similarity measures

The OUTMEASURE= data set is ordered by the variables `_INPUT_`, then `_TARGET_`, then `_TIMEID_` when ORDER=INPUTTARGET. The OUTMEASURE= data set is ordered by the variables `_TARGET_`, then `_INPUT_`, then `_TIMEID_` when ORDER=TARGETINPUT.

For ORDER=INPUT, the OUTMEASURE= data set has the following form:

<code>_INPUT_</code>	input variable name
<code>_TIMEID_</code>	time ID values
<code>_INPSEQ_</code>	input sequence values
<i>target-names</i>	similarity measures that are associated with each TARGET statement variable name

The OUTMEASURE= data set is ordered by the variables `_INPUT_`, then `_TIMEID_`.

For ORDER=TARGET, the OUTMEASURE= data set has the following form:

<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_TARSEQ_</code>	target sequence values
<i>input-names</i>	similarity measures that are associated with each INPUT statement variable name

The OUTMEASURE= data set is ordered by the variables `_TARGET_`, then `_TIMEID_`.

OUTPATH= Data Set

The OUTPATH= data set records the path analysis between each INPUT and TARGET statement variable. This data set records the path sequences for each slide index and for each warp index associated with the slide index. The sequence values recorded are normalized and scaled based on the NORMALIZE= and SCALE= options.

The OUTPATH= data set contains the variables specified in the BY statement and the following variables:

<code>_INPUT_</code>	input variable name
<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_SLIDE_</code>	slide index

<code>_WARP_</code>	warp index
<code>_INPSEQ_</code>	input sequence values
<code>_TARSEQ_</code>	target sequence values
<code>_INPPTH_</code>	input path index
<code>_TARPTH_</code>	target path index
<code>_METRIC_</code>	distance metric values

The Warp Index indicates the total amount of warping for each slide. A negative number represents compression of the target sequence. A positive number represents expansion of the target sequence. The Warp Index is always zero for `SLIDE=NONE` and `SLIDE=SEASON`.

The sorting of the `OUTPATH=` data set depends on the `SORTNAMES` and the `ORDER=` option.

The `OUTPATH=` data set is ordered by the variables `_INPUT_`, then `_TARGET_`, then `_TIMEID_` when `ORDER=INPUTTARGET` or `ORDER=INPUT`. The `OUTPATH=` data set is ordered by the variables `_TARGET_`, then `_INPUT_`, then `_TIMEID_` when `ORDER=TARGETINPUT` or `ORDER=TARGET`.

If there are a large number of slides or warps or both, this data set might be large.

OUTSEQUENCE= Data Set

The `OUTSEQUENCE=` data set records the input and target sequences that are associated with each `INPUT` and `TARGET` statement variable. This data set records the input and target sequence values for each slide index and for each warp index that is associated with the slide index. The sequence values that are recorded are normalized and scaled based on the `NORMALIZE=` and `SCALE=` options. This data set also contains the similarity measure associated with the two sequences.

The `OUTSEQUENCE=` data set contains the variables specified in the `BY` statement in addition to the following variables:

<code>_INPUT_</code>	input variable name
<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_SLIDE_</code>	slide index
<code>_WARP_</code>	warp index
<code>_INPSEQ_</code>	input sequence values
<code>_TARSEQ_</code>	target sequence values
<code>_SIM_</code>	similarity measure
<code>_STATUS_</code>	sequence status

The sorting of the `OUTSEQUENCE=` data set depends on the `SORTNAMES` and the `ORDER=` option.

The OUTSEQUENCE= data set is ordered by the variables `_INPUT_`, then `_TARGET_`, then `_TIMEID_` when `ORDER=INPUTTARGET` or `ORDER=INPUT`. The OUTSEQUENCE= data set is ordered by the variables `_TARGET_`, then `_INPUT_`, then `_TIMEID_` when `ORDER=TARGETINPUT` or `ORDER=TARGET`.

If there are a large number of slides or warps or both, this data set might be large.

OUTSUM= Data Set

The OUTSUM= data set summarizes the similarity measures between each INPUT and TARGET statement variable. The form of the OUTSUM= data set depends on the SORTNAMES and ORDER= option. If the SORTNAMES option is specified, each variable (INPUT or TARGET) is analyzed in ascending order. The OUTSUM= data set contains the variables specified in the BY statement in addition to the variables listed below.

For `ORDER=INPUTTARGET` and `ORDER=TARGETINPUT`, the OUTSUM= data set has the following form:

<code>_INPUT_</code>	input variable name
<code>_TARGET_</code>	target variable name
<code>_STATUS_</code>	status flag that indicates whether the requested analyses were successful
<code>_TIMEID_</code>	time ID values
<code>_SIM_</code>	similarity measure summary

The OUTSUM= data set is ordered by the variables `_INPUT_`, then `_TARGET_` when `ORDER=INPUTTARGET`. The OUTSUM= data set is ordered by the variables `_TARGET_`, then `_INPUT_` when `ORDER=TARGETINPUT`.

For `ORDER=INPUT`, the OUTSUM= data set has the following form:

<code>_INPUT_</code>	input variable name
<code>_STATUS_</code>	status flag that indicates whether the requested analyses were successful
<i>target-names</i>	similarity measure summary that is associated with each TARGET statement variable name

The OUTSUM= data set is ordered by the variable `_INPUT_`.

For `ORDER=TARGET`, the OUTSUM= data set has the following form:

<code>_TARGET_</code>	target variable name
<code>_STATUS_</code>	status flag that indicates whether the requested analyses were successful
<i>input-names</i>	similarity measure summary that is associated with each INPUT statement variable name

The OUTSUM= data set is ordered by the variable `_TARGET_`.

`_STATUS_` Variable Values

The `_STATUS_` variable contains a code that specifies whether the similarity analysis has been successful or not. The `_STATUS_` variable can take the following values:

0	Success
3000	Accumulation failure
4000	Missing value interpretation failure
6000	Series is all missing
7000	Transformation failure
8000	Differencing failure
9000	Unable to compute descriptive statistics
10000	Normalization failure
11000	Input contains imbedded missing values
12000	Target contains imbedded missing values
13000	Scaling failure
14000	Measure failure
15000	Path failure
16000	Slide summarization failure

Printed Output

The SIMILARITY procedure optionally produces printed output by using the Output Delivery System (ODS). By default, the procedure produces no printed output. All output is controlled by the `PRINT=` and `PRINTDETAILS` options in the `PROC SIMILARITY` statement.

The sort, order, and form of the printed output depends on both the `SORTNAMES` option and the `ORDER=` option. If the `SORTNAMES` option is specified, each variable (INPUT or TARGET) is analyzed in ascending order. For `ORDER=INPUTTARGET`, the printed output is ordered by the INPUT statement variables (row) and then by the TARGET statement variables (row). For `ORDER=TARGETINPUT`, the printed output is ordered by the TARGET statement variables (row) and then by the INPUT statement variables (row). For `ORDER=INPUT`, the printed output is ordered by the INPUT statement variables (row) and then by the TARGET statement variables (column). For `ORDER=TARGET`, the printed output is ordered by the TARGET statement variables (row) and then by the INPUT statement variables (column).

In general, if an analysis step related to printed output fails, the values of that step are not printed and appropriate error and warning messages are recorded in the SAS log. The printed output is similar to the output data set; these similarities are described as follows:

PRINT=COSTS

prints the costs statistics.

PRINT=DESCSTATS

prints the descriptive statistics.

PRINT=PATHS

prints the path statistics.

PRINT=SLIDES

prints the sliding sequence summary.

PRINT=SUMMARY

prints the summary of similarity measures similar to the OUTSUM= data set.

PRINT=WARPS

prints the warp summary.

PRINTDETAILS

prints each table with greater detail.

ODS Table Names

The following table relates the PRINT= options to ODS tables.

Table 24.2 ODS Tables Produced in PROC SIMILARITY

ODS Table Name	Description	Option
CostStatistics	Cost statistics	PRINT=COSTS
DescStats	Descriptive statistics	PRINT=DESCSTATS
PathLimits	Path limits	PRINT=PATHS
PathStatistics	Path statistics	PRINT=PATHS
SlideMeasuresSummary	Summary of measure per slide	PRINT=SLIDES

Table 24.2 (continued)

ODS Table Name	Description	Option
MeasuresSummary	Measures summary	PRINT=SUMMARY
InputMeasuresSummary	Measures summary	PRINT=SUMMARY
TargetMeasuresSummary	Measures summary	PRINT=SUMMARY
WarpMeasuresSummary	Summary of measure per warp	PRINT=WARPS

The tables are related to a single series within a BY group.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#)” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the SIMILARITY procedure.

ODS Graph Names

PROC SIMILARITY assigns a name to each graph it creates by using ODS. You can use these names to selectively reference the graphs. The names are listed in [Table 24.3](#).

Table 24.3 ODS Graphics Produced by PROC SIMILARITY

ODS Graph Name	Plot Description	Statement	PLOTS= Option
CostsPlot	Costs plot	SIMILARITY	PLOTS=COSTS
NormalizedSequencePlot	Normalized Sequence Plot	SIMILARITY	PLOTS=NORMALIZED
PathDistancePlot	Path distances plot	SIMILARITY	PLOTS=DISTANCES
PathDistanceHistogram	Path distances histogram	SIMILARITY	PLOTS=DISTANCES
PathRelativeDistancePlot	Path relative distances plot	SIMILARITY	PLOTS=DISTANCES
PathRelativeDistanceHistogram	Path relative distances histogram	SIMILARITY	PLOTS=DISTANCES
PathPlot	Path plot	SIMILARITY	PLOTS=PATHS
PathSequencesPlot	Path sequences plot	SIMILARITY	PLOTS=MAPS
PathSequencesScaledPlot	Scaled path sequences map plot	SIMILARITY	PLOTS=MAPS
ScaledSequencePlot	Scaled Sequence plot	SIMILARITY	PLOTS=SCALED

Table 24.3 (continued)

ODS Graph Name	Plot Description	Statement	PLOTS= Option
SequencePlot	Sequence plot	SIMILARITY	PLOTS=SEQUENCES
SeriesPlot	Input time series plot	SIMILARITY	PLOTS=INPUTS
SimilarityPlot	Similarity measures plot	SIMILARITY	PLOTS=MEASURES
TargetSequencePlot	Target sequence plot	SIMILARITY	PLOTS=TARGETS
WarpPlot	Warping plot	SIMILARITY	PLOTS=WARPS
WarpScaledPlot	Scaled warping plot	SIMILARITY	PLOTS=WARPS

Time Series Plots

The time series plots (SeriesPlot) illustrate the input time series to be compared. The horizontal axis represents the input series time ID values, and the vertical axis represents the input series values.

Sequence Plots

The sequence plots (SequencePlot) illustrate the target and input sequences to be compared. The horizontal axis represents the (target or input) sequence index, and the vertical axis represents the (target or input) sequence values.

Path Plots

The path plot (PathPlot) and path limits plot (PathLimitsPlot) illustrate the path through the distance matrix. The horizontal axis represents the input sequence index, and the vertical axis represents the target sequence index. The dots represent the path coordinates. The upper parallel line represents the compression limit, and the lower parallel line represents the expansion limit. These plots visualize the path through the distance matrix. Vertical movements indicate compression, and horizontal movements represent expansion of the target sequence with respect to the input sequence. These plots are useful for visualizing the amount of expansion and compression along the path.

Time Warp Plots

The time warp plot (WarpPlot) and scaled time warp plot (WarpScaledPlot) illustrate the time warping. The horizontal axis represents the (input and target) sequence index. The upper line plot represents the target sequence. The lower line plot represents the input sequence. The lines that connect the input and target sequence values represent the mapping between the input and target sequence indices along the optimal path. These plots visualize the warping of the time index with respect to the input and target sequence values. Expansion of a single target sequence value occurs when it is mapped to more than one input sequence value. Expansion of a single input sequence value occurs when it is mapped to more than one target sequence value. The plots are useful for visualizing the mapping between the input and target sequence values along the path. The plots are useful for comparing the path sequences or input and target sequence after time warping.

Path Sequence Plots

The path sequence plot (`PathSequencesPlot`) and scaled path sequence plot (`PathSequencesScaledPlot`) illustrate the sequence mapping along the optimal path. The horizontal axis represents the path index. The dashed line represents the time warped input sequence. The solid line represents the time warped target sequence. These plots visualize the mapping between the input and target sequence values with respect to the path index. The scaled plot with the input and target sequence values are scaled and evenly separated for visual convenience.

Path Distance Plots

The path distance plots (`PathDistancePlot`) and path relative distance plots (`PathRelativeDistancePlot`) illustrate the path (relative) distances. The horizontal axis represents the path index. The vertical needles represent the (relative) distances. The horizontal reference lines indicate one and two standard deviations.

The path distance histogram (`PathDistanceHistogram`) and path relative distance histogram (`PathDistanceRelativeHistogram`) illustrate the distribution of the path (relative) distances. The bars represent the histogram, and the solid line represents a normal distribution with the same mean and variance.

Cost Plots

The cost plot (`CostPlot`) and cost limits plot (`CostPlot`) illustrate the cost of traversing the distance matrix. The horizontal axis represents the input sequence index, and the vertical axis represents the target sequence index. The colors and shading within the plot illustrate the incremental cost of traversing the distance matrix. The upper parallel line represents the compression limit, and the lower parallel line represents the expansion limit.

Examples: SIMILARITY Procedure

Example 24.1: Accumulating Transactional Data into Time Series Data

This example uses the SIMILARITY procedure to illustrate the accumulation of time-stamped transactional data that has been recorded at no particular frequency into time series data at a specific frequency. After the time series is created, the various SAS/ETS procedures related to time series analysis, similarity analysis, seasonal adjustment and decomposition, modeling, and forecasting can be used to further analyze the time series data.

Suppose that the input data set `WORK.RETAIL` contains variables `STORE` and `TIMESTAMP` and numerous other numeric transaction variables. The BY variable `STORE` contains values that break up the transactions into groups (BY groups). The time ID variable `TIMESTAMP` contains SAS date values recorded at no

particular frequency. The other data set variables contain the numeric transaction values to be analyzed. It is further assumed that the input data set is sorted by the variables STORE and TIMESTAMP.

The following statements form monthly time series from the transactional data based on the median value (ACCUMULATE=MEDIAN) of the transactions recorded with each time period. The accumulated time series values for time periods with no transactions are set to zero instead of missing (SETMISS=0). Only transactions recorded between the first day of 1998 (START='01JAN1998'D) and last day of 2000 (END='31JAN2000'D) are considered and if needed are extended to include this range.

```
proc similarity data=work.retail out=mseries;
  by store;
  id timestamp interval=month
      accumulate=median
      setmiss=0
      start='01jan1998'd
      end  ='31dec2000'd;
  target _NUMERIC_;
run;
```

The monthly time series data are stored in the data WORK.MSERIES. Each BY group associated with the BY variable STORE contains an observation for each of the 36 months associated with the years 1998, 1999, and 2000. Each observation contains the variable STORE, TIMESTAMP, and each of the analysis variables in the input DATA= data set.

After each set of transactions has been accumulated to form the corresponding time series, the accumulated time series can be analyzed by using various time series analysis techniques. For example, exponentially weighted moving averages can be used to smooth each series. The following statements use the EXPAND procedure to smooth the analysis variable named STOREITEM.

```
proc expand data=mseries
  out=smoothed
  from=month;
  by store;
  id timestamp;
  convert storeitem=smooth / transform=(ewma 0.1);
run;
```

The smoothed series is stored in the data set WORK.SMOOTHED. The variable SMOOTH contains the smoothed series.

If the time ID variable TIMESTAMP contains SAS datetime values instead of SAS date values, the INTERVAL=, START=, and END= options in the SIMILARITY procedure must be changed accordingly, and the following statements could be used to accumulate the datetime transactions to a monthly interval:

```
proc similarity data=work.retail
  out=tseries;
  by store;
  id timestamp interval=dtmonth
      accumulate=median
      setmiss=0
      start='01jan1998:00:00:00'dt
      end  ='31dec2000:00:00:00'dt;
  target _NUMERIC_;
```

```
run;
```

The monthly time series data are stored in the data WORK.TSERIES, and the time ID values use a SAS datetime representation.

Example 24.2: Similarity Analysis

This simple example illustrates how to use similarity analysis to compare two time sequences. The following statements create an example data set that contains two time sequences of differing lengths:

```
data test;
input i y x;
datalines;
1 2 3
2 4 5
3 6 3
4 7 3
5 3 3
6 8 6
7 9 3
8 3 8
9 10 .
10 11 .
;
run;
```

The following statements perform similarity analysis on the example data set:

```
proc similarity data=test out=_null_
  print=all plot=all;
  input x;
  target y / measure=absdev;
run;
```

The DATA=TEST option specifies that the input data set WORK.TEST is to be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The PRINT=ALL and PLOTS=ALL options specify that all ODS tables and graphs are to be produced. The INPUT statement specifies that the input variable is X. The TARGET statement specifies that the target variable is Y and that the similarity measure is computed using absolute deviation (MEASURE=ABSDEV).

Output 24.2.16 Time Warp Plot

Output 24.2.17 Time Warp Scaled Plot

The following statements repeat the preceding similarity analysis on the example data set with warping limits:

```
proc similarity data=test out=_null_
  print=all plot=all;
  input x;
  target y / measure=absdev
             compress=(localabs=2)
             expand=(localabs=2);
run;
```

The COMPRESS=(LOCALABS=2) option limits local absolute compression to 2. The EXPAND=(LOCALABS=2) option limits local absolute expansion to 2.

Output 24.2.18 Path Plot with Warping Limits

Output 24.2.19 Warped Path Limits

Path Limits					
Limit	Specified Absolute	Specified Percentage	Minimum Allowed	Maximum Allowed	Applied
Compression	2	None	2	9	2
Expansion	2	None	0	7	2

Output 24.2.20 Cost Plot with Warping Limits

The following statements repeat the preceding similarity analysis on the example data set but store the results in output data sets:

```
proc similarity data=test out=series
  outsequence=sequences outpath=path outsum=summary;
  input x;
  target y / measure=absdev
             compress=(localabs=2)
             expand=(localabs=2);
run;
```

The OUT=SERIES, OUTSEQUENCE=SEQUENCES, OUTPATH=PATH, and OUTSUM=SUMMARY options specify that the output time series, time sequences, path analysis, and summary data sets be created, respectively.

Example 24.3: Sliding Similarity Analysis

This example illustrates how to use sliding similarity analysis to compare two time sequences. The SASHELP.WORKERS data set contains two similar time series variables (ELECTRIC and MASONRY), which represent employment over time. The following statements create an example data set that contains two time series of differing lengths, where the variable MASONRY has the first 12 and last 7 observations set to missing to simulate the lack of data associated with the target series:

```
data workers; set sashelp.workers;
  if '01JAN1978'D <= date < '01JAN1982'D then masonry = masonry;
  else masonry = .;
run;
```

The goal of sliding similarity measures analysis is find the slide index that corresponds to the most similar subsequence of the input series when compared to the target sequence. The following statements perform sliding similarity analysis on the example data set:

```
proc similarity data=workers out=_NULL_ print=(slides summary);
  id date interval=month;
  input electric;
  target masonry / slide=index measure=msqrdev
                  expand=(localabs=3 globalabs=3)
                  compress=(localabs=3 globalabs=3);
run;
```

The DATA=WORKERS option specifies that the input data set WORK.WORKERS is to be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The PRINT=(SLIDES SUMMARY) option specifies that the ODS tables related to the sliding similarity measures and their summary be produced. The INPUT statement specifies that the input variable is ELECTRIC. The TARGET statement specifies that the target variable is MASONRY and that the similarity measure be computed using mean squared deviation (MEASURE=MSQRDEV). The SLIDE=INDEX option specifies observation index sliding. The COMPRESS=(LOCALABS=3 GLOBALABS=3) option limits local and global absolute compression to 3. The EXPAND=(LOCALABS=3 GLOBALABS=3) option limits local and global absolute expansion to 3.

Output 24.3.1 Summary of the Slide Measures

The SIMILARITY Procedure					
Slide Measures Summary for Input=ELECTRIC and Target=MASONRY					
Slide Index	DATE	Slide Target Sequence Length	Slide Input Sequence Length	Slide Warping Amount	Slide Minimum Measure
0	JAN1977	48	51	3	497.6737
1	FEB1977	48	51	1	482.6777
2	MAR1977	48	51	0	474.1251
3	APR1977	48	51	0	490.7792
4	MAY1977	48	51	-2	533.0788
5	JUN1977	48	51	-3	605.8198
6	JUL1977	48	51	-3	701.7138
7	AUG1977	48	51	3	646.5918
8	SEP1977	48	51	3	616.3258
9	OCT1977	48	51	3	510.9836
10	NOV1977	48	51	3	382.1434
11	DEC1977	48	51	3	340.4702
12	JAN1978	48	51	2	327.0572
13	FEB1978	48	51	1	322.5460
14	MAR1978	48	51	0	325.2689
15	APR1978	48	51	-1	351.4161
16	MAY1978	48	51	-2	398.0490
17	JUN1978	48	50	-3	471.6931
18	JUL1978	48	49	-3	590.8089
19	AUG1978	48	48	0	595.2538
20	SEP1978	48	47	-1	689.2233
21	OCT1978	48	46	-2	745.8891
22	NOV1978	48	45	-3	679.1907

Output 24.3.2 Minimum Measure

Minimum Measure Summary	
Input Variable	MASONRY
ELECTRIC	322.5460

This analysis results in 23 slides based on the observation index. The minimum measure (322.5460) occurs at slide index 13 which corresponds to the time value FEB1978. Note that the original data set SASHELP.WORKERS was modified beginning at the time value JAN1978. This similarity analysis justifies the belief the ELECTRIC lags MASONRY by one month based on the time series cross-correlation analysis despite the lack of target data (MASONRY).

The goal of seasonal sliding similarity measures is to find the seasonal slide index that corresponds to the most similar seasonal subsequence of the input series when compared to the target sequence. The following statements repeat the preceding similarity analysis on the example data set with seasonal sliding:

```

proc similarity data=workers out=_NULL_ print=(slides summary);
  id date interval=month;
  input electric;
  target masonry / slide=season measure=msqrdev;
run;

```

Output 24.3.3 Summary of the Seasonal Slide Measures

The SIMILARITY Procedure					
Slide Measures Summary for Input=ELECTRIC and Target=MASONRY					
Slide Index	DATE	Slide Target Sequence Length	Slide Input Sequence Length	Slide Warping Amount	Slide Minimum Measure
0	JAN1977	48	48	0	1040.086
12	JAN1978	48	48	0	641.927

Output 24.3.4 Seasonal Minimum Measure

Minimum Measure Summary	
Input Variable	MASONRY
ELECTRIC	641.9273

The analysis differs from the previous analysis in that the slides are performed based on the seasonal index (SLIDE=SEASON) with no warping. With a seasonality of 12, two seasonal slides are considered at slide indices 0 and 12 with the minimum measure (641.9273) occurring at slide index 12 which corresponds to the time value JAN1978. Note that the original data set SASHELP.WORKERS was modified beginning at the time value JAN1978. This similarity analysis justifies the belief that ELECTRIC and MASONRY have similar seasonal properties based on seasonal decomposition analysis despite the lack of target data (MASONRY).

Example 24.4: Searching for Historical Analogies

This example illustrates how to search for historical analogies by using seasonal sliding similarity analysis of transactional time-stamped data. The SASHELP.TIMEDATA data set contains the variable (VOLUME), which represents activity over time. The following statements create an example data set that contains two time series of differing lengths, where the variable HISTORY represents the historical activity and RECENT represents the more recent activity:

```

data timedata; set sashelp.timedata;
  drop volume;
  recent = .;
  history = volume;
  if datetime >= '20AUG2000:00:00:00'DT then do;
    recent = volume;
    history = .;
  end;
run;

```

The goal of seasonal sliding similarity measures is to find the seasonal slide index that corresponds to the most similar seasonal subsequence of the input series when compared to the target sequence. The following statements perform similarity analysis on the example data set with seasonal sliding:

```

proc similarity data=timedata out=_NULL_ outsequence=sequences
  outsum=summary;
  id datetime interval=dtday accumulate=total
    start='27JUL1997:00:00:00'dt
    end='21OCT2000:11:59:59'DT;
  input history / normalize=absolute;
  target recent / slide=season normalize=absolute measure=mabsdev;
run;

```

The DATA=TIMEDATA option specifies that the input data set WORK.TIMEDATA be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The OUTSEQUENCE=SEQUENCES and OUTSUM=SUMMARY options specify the output sequences and summary data sets, respectively. The ID statement specifies that the time ID variable is DATETIME, which is to be accumulated on a daily basis (INTERVAL=DTDAY) by summing the transactions (ACCUMULATE=TOTAL). The ID statement also specifies that the data is accumulated on the weekly boundaries starting on the week of 27JUL1997 and ending on the week of 15OCT2000 (START='27JUL1997:00:00:00'DT END='21OCT2000:11:59:59'DT). The INPUT statement specifies that the input variable is HISTORY, which is to be normalized using absolute normalization (NORMALIZE=ABSOLUTE). The TARGET statement specifies that the target variable is RECENT, which is to be normalized by using absolute normalization (NORMALIZE=ABSOLUTE) and that the similarity measure be computed by using mean absolute deviation (MEASURE=MABSDEV). The SLIDE=SEASON options specifies season index sliding.

To illustrate the results of the similarity analysis, the output sequence data set must be subset by using the output summary data set.

```

data _NULL_; set summary;
  call symput('MEASURE', left(trim(putn(recent, 'BEST20.'))));
run;

data result; set sequences;
  by _SLIDE_;
  retain flag 0;
  if first._SLIDE_ then do;
    if (&measure - 0.00001 < _SIM_ < &measure + 0.00001)
      then flag = 1;
  end;
  if flag then output;
  if last._SLIDE_ then flag = 0;

```

```
run;
```

The following statements generate a cross series plot of the results:

```
proc timeseries data=result out=_NULL_ crossplot=series;
  id datetime interval=dtday;
  var _TARSEQ_;
  crossvar _INPSEQ_;
run;
```

The cross series plot illustrates that the historical time series analogy most similar to the most recent time series data that started on 20AUG2000 occurred on 02AUG1998.

Output 24.4.1 Cross Series Plot of the Historical Time Series

Example 24.5: Clustering Time Series

This example illustrates how to cluster time series using a similarity matrix. The WORK.APPLIANCES data set contains 24 variables that record sales histories. The following statements create a similarity matrix and store the matrix in the WORK.SIMMATRIX data set:

```
proc similarity data=output.applianceseries out=_null_ outsum=simmatrix;  
    target units_1--units_24;  
run;
```

The following statements cluster the rows of the similarity matrix.

```
proc cluster data=simmatrix(drop=_status_) outtree=tree method=ward noprint;  
    id _input_;  
run;
```

The following statements plot the dendrogram:

```
proc tree data=tree horizontal;  
run;
```

Overview: SIMLIN Procedure

The SIMLIN procedure reads the coefficients for a set of linear structural equations, which are usually produced by the SYSLIN procedure. PROC SIMLIN then computes the reduced form and, if input data are

given, uses the reduced form equations to generate predicted values. PROC SIMLIN is especially useful when dealing with sets of structural difference equations. The SIMLIN procedure can perform simulation or forecasting of the endogenous variables.

The SIMLIN procedure can be applied only to models that are:

- linear with respect to the parameters
- linear with respect to the variables
- square (as many equations as endogenous variables)
- nonsingular (the coefficients of the endogenous variables form an invertible matrix)

Getting Started: SIMLIN Procedure

The SIMLIN procedure processes the coefficients in a data set created by the SYSLIN procedure using the OUTEST= option or by another regression procedure such as PROC REG. To use PROC SIMLIN you must first produce the coefficient data set and then specify this data set on the EST= option of the PROC SIMLIN statement. You must also tell PROC SIMLIN which variables are endogenous and which variables are exogenous. List the endogenous variables in an ENDOGENOUS statement, and list the exogenous variables in an EXOGENOUS statement.

The following example illustrates the creation of an OUTEST= data set with PROC SYSLIN and the computation and printing of the reduced form coefficients for the model with PROC SIMLIN.

```
proc syslin data=in outest=e;
    model y1 = y2 x1;
    model y2 = y1 x2;
run;

proc simlin est=e;
    endogenous y1 y2;
    exogenous x1 x2;
run;
```

If the model contains lagged endogenous variables you must also use a LAGGED statement to tell PROC SIMLIN which variables contain lagged values, which endogenous variables they are lags of, and the number of periods of lagging. For dynamic models, the TOTAL and INTERIM= options can be used on the PROC SIMLIN statement to compute and print total and impact multipliers. (See "Dynamic Multipliers" later in this section for an explanation of multipliers.)

In the following example the variables Y1LAG1, Y2LAG1, and Y2LAG2 contain lagged values of the endogenous variables Y1 and Y2. Y1LAG1 and Y2LAG1 contain values of Y1 and Y2 for the previous observation, while Y2LAG2 contains 2 period lags of Y2. The LAGGED statement specifies the lagged relationships, and the TOTAL and INTERIM= options request multiplier analysis. The INTERIM=2 option

prints matrices showing the impact that changes to the exogenous variables have on the endogenous variables after 1 and 2 periods.

```
data in; set in;
  y1lag1 = lag(y1);
  y2lag1 = lag(y2);
  y2lag2 = lag2(y2);
run;

proc syslin data=in outest=e;
  model y1 = y2 y1lag1 y2lag2 x1;
  model y2 = y1 y2lag1 x2;
run;

proc simlin est=e total interim=2;
  endogenous y1 y2;
  exogenous x1 x2;
  lagged y1lag1 y1 1 y2lag1 y2 1 y2lag2 y2 2;
run;
```

After the reduced form of the model is computed, the model can be simulated by specifying an input data set on the PROC SIMLIN statement and using an OUTPUT statement to write the simulation results to an output data set. The following example modifies the PROC SIMLIN step from the preceding example to simulate the model and stores the results in an output data set.

```
proc simlin est=e total interim=2 data=in;
  endogenous y1 y2;
  exogenous x1 x2;
  lagged y1lag1 y1 1 y2lag1 y2 1 y2lag2 y2 2;
  output out=sim predicted=y1hat y2hat
         residual=y1resid y2resid;
run;
```

Prediction and Simulation

If an input data set is specified with the DATA= option in the PROC SIMLIN statement, the procedure reads the data and uses the reduced form equations to compute predicted and residual values for each of the endogenous variables. (If no data set is specified with the DATA= option, no simulation of the system is performed, and only the reduced form and multipliers are computed.)

The character of the prediction is based on the START= value. Until PROC SIMLIN encounters the START= observation, actual endogenous values are found and fed into the lagged endogenous terms. Once the START= observation is reached, dynamic simulation begins, where predicted values are fed into lagged endogenous terms until the end of the data set is reached.

The predicted and residual values generated here are different from those produced by the SYSLIN procedure since PROC SYSLIN uses the structural form with actual endogenous values. The predicted values

computed by the SIMLIN procedure solve the simultaneous equation system. These reduced-form predicted values are functions only of the exogenous and lagged endogenous variables and do not depend on actual values of current period endogenous variables.

Syntax: SIMLIN Procedure

The following statements can be used with PROC SIMLIN:

```
PROC SIMLIN options ;
  BY variables ;
  ENDOGENOUS variables ;
  EXOGENOUS variables ;
  ID variables ;
  LAGGED lag-var endogenous-var number ellipsis ;
  OUTPUT OUT=SAS-data-set options ;
```

Functional Summary

The statements and options controlling the SIMLIN procedure are summarized in the following table.

Description	Statement	Option
Data Set Options		
specify input data set containing structural coefficients	PROC SIMLIN	EST=
specify type of estimates read from EST= data set	PROC SIMLIN	TYPE=
write reduced form coefficients and multipliers to an output data set	PROC SIMLIN	OUTEST=
specify the input data set for simulation	PROC SIMLIN	DATA=
write predicted and residual values to an output data set	OUTPUT	
Printing Control Options		
print the structural coefficients	PROC SIMLIN	ESTPRINT
suppress printing of reduced form coefficients	PROC SIMLIN	NORED
suppress all printed output	PROC SIMLIN	NOPRINT
Dynamic Multipliers		
compute interim multipliers	PROC SIMLIN	INTERIM=
compute total multipliers	PROC SIMLIN	TOTAL
Declaring the Role of Variables		

Description	Statement	Option
specify BY-group processing	BY	
specify the endogenous variables	ENDOGENOUS	
specify the exogenous variables	EXOGENOUS	
specify identifying variables	ID	
specify lagged endogenous variables	LAGGED	
Controlling the Simulation		
specify the starting observation for dynamic simulation	PROC SIMLIN	START=

PROC SIMLIN Statement

PROC SIMLIN *options* ;

The following options can be used in the PROC SIMLIN statement:

DATA= *SAS-data-set*

specifies the SAS data set containing input data for the simulation. If the DATA= option is used, the data set specified must supply values for all exogenous variables throughout the simulation. If the DATA= option is not specified, no simulation of the system is performed, and only the reduced form and multipliers are computed.

EST= *SAS-data-set*

specifies the input data set containing the structural coefficients of the system. If EST= is omitted the most recently created SAS data set is used. The EST= data set is normally a "TYPE=EST" data set produced by the OUTEST= option of PROC SYSLIN. However, you can also build the EST= data set with a SAS DATA step. See "The EST= Data Set" later in this chapter for details.

ESTPRINT

prints the structural coefficients read from the EST= data set.

INTERIM= *n*

requests that interim multipliers be computed for interims 1 through *n*. If not specified, no interim multipliers are computed. This feature is available only if there are no lags greater than 1.

NOPRINT

suppresses all printed output.

NORED

suppresses the printing of the reduced form coefficients.

OUTEST= *SAS-data-set*

specifies an output SAS data set to contain the reduced form coefficients and multipliers, in addition to the structural coefficients read from the EST= data set. The OUTEST= data set has the same form

as the EST= data set. If the OUTEST= option is not specified, the reduced form coefficients and multipliers are not written to a data set.

START= *n*

specifies the observation number in the DATA= data set where the dynamic simulation is to be started. By default, the dynamic simulation starts with the first observation in the DATA= data set for which all variables (including lags) are not missing.

TOTAL

requests that the total multipliers be computed. This feature is available only if there are no lags greater than 1.

TYPE= *value*

specifies the type of estimates to be read from the EST= data set. The TYPE= value must match the value of the _TYPE_ variable for the observations that you want to select from the EST= data set (TYPE=2SLS, for example).

BY Statement

BY *variables* ;

A BY statement can be used with PROC SIMLIN to obtain separate analyses for groups of observations defined by the BY variables.

The BY statement can be applied to one or both of the EST= and the DATA= input data set. When a BY statement is used and both an EST= and a DATA= input data set are specified, PROC SIMLIN checks to see if one or both of the data sets contain the BY variables.

Thus, there are three ways of using the BY statement with PROC SIMLIN:

1. If the BY variables are found in the EST= data set only, PROC SIMLIN simulates over the entire DATA= data set once for each set of coefficients read from the BY groups in the EST= data set.
2. If the BY variables are found in the DATA= data set only, PROC SIMLIN performs separate simulations over each BY group in the DATA= data set, using the single set of coefficients in the EST= data set.
3. If the BY variables are found in both the EST= and the DATA= data sets, PROC SIMLIN performs separate simulations over each BY group in the DATA= data set using the coefficients from the corresponding BY group in the EST= data set.

ENDOGENOUS Statement

ENDOGENOUS *variables* ;

List the names of the endogenous (jointly dependent) variables in the ENDOGENOUS statement. The ENDOGENOUS statement can be abbreviated as ENDOG or ENDO.

EXOGENOUS Statement

EXOGENOUS *variables ;*

List the names of the exogenous (independent) variables in the EXOGENOUS statement. The EXOGENOUS statement can be abbreviated as EXOG or EXO.

ID Statement

ID *variables ;*

The ID statement can be used to restrict the variables copied from the DATA= data set to the OUT= data set. Use the ID statement to list the variables you want copied to the OUT= data set besides the exogenous, endogenous, lagged endogenous, and BY variables. If the ID statement is omitted, all the variables in the DATA= data set are copied to the OUT= data set.

LAGGED Statement

LAGGED *lag-var endogenous-var number ellipsis ;*

For each lagged endogenous variable, specify the name of the lagged variable, the name of the endogenous variable that was lagged, and the degree of the lag. Only one LAGGED statement is allowed.

The following is an example of the use of the LAGGED statement:

```
proc simlin est=e;
  endog y1 y2;
  lagged y1lag1 y1 1 y2lag1 y2 1 y2lag3 y2 3;
run;
```

This statement specifies that the variable Y1LAG1 contains the values of the endogenous variable Y1 lagged one period; the variable Y2LAG1 refers to the values of Y2 lagged one period; and the variable Y2LAG3 refers to the values of Y2 lagged three periods.

OUTPUT Statement

OUTPUT *OUT= SAS-data-set options ;*

The OUTPUT statement specifies that predicted and residual values be put in an output data set. A DATA= input data set must be supplied if the OUTPUT statement is used, and only one OUTPUT statement is allowed. The following options can be used in the OUTPUT statement:

OUT= *SAS-data-set*

names the output SAS data set to contain the predicted values and residuals. If OUT= is not specified, the output data set is named using the DATA n convention.

PREDICTED= *names*

P= *names*

names the variables in the output data set that contain the predicted values of the simulation. These variables correspond to the endogenous variables in the order in which they are specified in the ENDOGENOUS statement. Specify up to as many names as there are endogenous variables. If you specify names on the PREDICTED= option for only some of the endogenous variables, predicted values for the remaining variables are not output. The names must not match any variable name in the input data set.

RESIDUAL= *names*

R= *names*

names the variables in the output data set that contain the residual values from the simulation. The residuals are the differences between the actual values of the endogenous variables from the DATA= data set and the predicted values from the simulation. These variables correspond to the endogenous variables in the order in which they are specified in the ENDOGENOUS statement. Specify up to as many names as there are endogenous variables. The names must not match any variable name in the input data set.

The following is an example of the use of the OUTPUT statement. This example outputs predicted values for Y1 and Y2 and outputs residuals for Y1.

```
proc simlin est=e;
  endog y1 y2;
  output out=b predicted=y1hat y2hat
          residual=y1resid;
run;
```

Details: SIMLIN Procedure

The following sections explain the structural and reduced forms, dynamic multipliers, input data sets, and the model simulation process in more detail.

Defining the Structural Form

An EST= input data set supplies the coefficients of the equation system. The data set containing the coefficients is normally a "TYPE=EST" data set created by the OUTEST= option of PROC SYSLIN or another regression procedure. The data set contains the special variables _TYPE_, _DEPVAR_, and INTERCEPT. You can also supply the structural coefficients of the system to PROC SIMLIN in a data set produced by a SAS DATA step as long as the data set is of the form TYPE=EST. Refer to SAS/STAT software documentation for a discussion of the special TYPE=EST type of SAS data set.

Suppose that there is a $g \times 1$ vector of endogenous variables \mathbf{y}_t , an $l \times 1$ vector of lagged endogenous variables \mathbf{y}_t^L , and a $k \times 1$ vector of exogenous variables \mathbf{x}_t , including the intercept. Then, there are g structural equations in the simultaneous system that can be written

$$\mathbf{G}\mathbf{y}_t = \mathbf{C}\mathbf{y}_t^L + \mathbf{B}\mathbf{x}_t$$

where \mathbf{G} is the matrix of coefficients of current period endogenous variables, \mathbf{C} is the matrix of coefficients of lagged endogenous variables, and \mathbf{B} is the matrix of coefficients of exogenous variables. \mathbf{G} is assumed to be nonsingular.

Computing the Reduced Form

First, the SIMLIN procedure computes reduced form coefficients by premultiplying by \mathbf{G}^{-1} :

$$\mathbf{y}_t = \mathbf{G}^{-1}\mathbf{C}\mathbf{y}_t^L + \mathbf{G}^{-1}\mathbf{B}\mathbf{x}_t$$

This can be written as

$$\mathbf{y}_t = \Pi_1\mathbf{y}_t^L + \Pi_2\mathbf{x}_t$$

where $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$ and $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$ are the reduced form coefficient matrices.

The reduced form matrices $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$ and $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$ are printed unless the NORED option is specified in the PROC SIMLIN statement. The structural coefficient matrices \mathbf{G} , \mathbf{C} , and \mathbf{B} are printed when the ESTPRINT option is specified.

Dynamic Multipliers

For models that have only first-order lags, the equation of the reduced form of the system can be rewritten

$$\mathbf{y}_t = \mathbf{D}\mathbf{y}_{t-1} + \Pi_2\mathbf{x}_t$$

\mathbf{D} is a matrix formed from the columns of Π_1 plus some columns of zeros, arranged in the order in which the variables meet the lags. The elements of Π_2 are called *impact multipliers* because they show the immediate

effect of changes in each exogenous variable on the values of the endogenous variables. This equation can be rewritten as

$$\mathbf{y}_t = \mathbf{D}^2 \mathbf{y}_{t-2} + \mathbf{D} \Pi_2 \mathbf{x}_{t-1} + \Pi_2 \mathbf{x}_t$$

The matrix formed by the product $\mathbf{D} \Pi_2$ shows the effect of the exogenous variables one lag back; the elements in this matrix are called *interim multipliers* and are computed and printed when the INTERIM= option is specified in the PROC SIMLIN statement. The i th period interim multipliers are formed by $\mathbf{D}^i \Pi_2$.

The series can be expanded as

$$\mathbf{y}_t = \mathbf{D}^\infty \mathbf{y}_{t-\infty} + \sum_{i=0}^{\infty} \mathbf{D}^i \Pi_2 \mathbf{x}_{t-i}$$

A permanent and constant setting of a value for x has the following cumulative effect:

$$\left(\sum_{i=0}^{\infty} \mathbf{D}^i \right) \Pi_2 \mathbf{x} = (\mathbf{I} - \mathbf{D})^{-1} \Pi_2 \mathbf{x}$$

The elements of $(\mathbf{I} - \mathbf{D})^{-1} \Pi_2$ are called the *total multipliers*. Assuming that the sum converges and that $(\mathbf{I} - \mathbf{D})$ is invertible, PROC SIMLIN computes the total multipliers when the TOTAL option is specified in the PROC SIMLIN statement.

Multipliers for Higher Order Lags

The dynamic multiplier options require the system to have no lags of order greater than one. This limitation can be circumvented, since any system with lags greater than one can be rewritten as a system where no lag is greater than one by forming new endogenous variables that are single-period lags.

For example, suppose you have the third-order single equation

$$y_t = ay_{t-3} + b\mathbf{x}_t$$

This can be converted to a first-order three-equation system by introducing two additional endogenous variables, $y_{1,t}$ and $y_{2,t}$, and computing corresponding first-order lagged variables for each endogenous variable: y_{t-1} , $y_{1,t-1}$, and $y_{2,t-1}$. The higher order lag relations are then produced by adding identities to link the endogenous and identical lagged endogenous variables:

$$y_{1,t} = y_{t-1}$$

$$y_{2,t} = y_{1,t-1}$$

$$y_t = ay_{2,t-1} + b\mathbf{x}_t$$

This conversion using the SYSLIN and SIMLIN procedures requires three steps:

1. Add the extra endogenous and lagged endogenous variables to the input data set using a DATA step. Note that two copies of each lagged endogenous variable are needed for each lag reduced, one to serve as an endogenous variable and one to serve as a lagged endogenous variable in the reduced system.
2. Add IDENTITY statements to the PROC SYSLIN step to equate each added endogenous variable to its lagged endogenous variable copy.
3. In the PROC SIMLIN step, declare the added endogenous variables in the ENDOGENOUS statement and define the lag relations in the LAGGED statement.

See [Example 25.2](#) for an illustration of how to convert an equation system with higher-order lags into a larger system with only first-order lags.

EST= Data Set

Normally, PROC SIMLIN uses an EST= data set produced by PROC SYSLIN with the OUTEST= option. This data set is in the form expected by PROC SIMLIN. If there is more than one set of estimates produced by PROC SYSLIN, you must use the TYPE= option in the PROC SIMLIN statement to select the set to be simulated. Then PROC SIMLIN reads from the EST= data set only those observations with a _TYPE_ value corresponding to the TYPE= option (for example, TYPE=2SLS) or with a _TYPE_ value of IDENTITY.

The SIMLIN procedure can only solve square, nonsingular systems. If you have fewer equations than endogenous variables, you must specify IDENTITY statements in the PROC SYSLIN step to bring the system up to full rank. If there are g endogenous variables and $m < g$ stochastic equations with unknown parameters, then you use m MODEL statements to specify the equations with parameters to be estimated and you must use $g-m$ IDENTITY statements to complete the system.

You can build your own EST= data set with a DATA step rather than use PROC SYSLIN. The EST= data set must contain the endogenous variables, the lagged endogenous variables (if any), and the exogenous variables in the system (if any). If any of the equations have intercept terms, the variable INTERCEPT must supply these coefficients. The EST= data set should also contain the special character variable comp _DEPVAR_ to label the equations.

The EST= data set must contain one observation for each equation in the system. The values of the lagged endogenous variables must contain the **C** coefficients. The values of the exogenous variables and the INTERCEPT variable must contain the **B** coefficients. The values of the endogenous variables, however, must contain the negatives of the **G** coefficients. This is because the SYSLIN procedure writes the coefficients to the OUTEST= data set in the form

$$0 = \mathbf{H}\mathbf{y}_t + \mathbf{C}\mathbf{y}_t^L + \mathbf{B}\mathbf{x}_t$$

where $\mathbf{H} = -\mathbf{G}$.

See "Multipliers for Higher Order Lags" and [Example 25.2](#) later in this chapter for more information on building the EST= data set.

DATA= Data Set

The DATA= data set must contain all of the exogenous variables. Values for all of the exogenous variables are required for each observation for which predicted endogenous values are desired. To forecast past the end of the historical data, the DATA= data set should contain nonmissing values for all of the exogenous variables and missing values for the endogenous variables for the forecast periods, in addition to the historical data. (See [Example 25.1](#) for an illustration.)

In order for PROC SIMLIN to output residuals and compute statistics of fit, the DATA= data set must also contain the endogenous variables with nonmissing actual values for each observation for which residuals and statistics are to be computed.

If the system contains lags, initial values must be supplied for the lagged variables. This can be done by including either the lagged variables or the endogenous variables, or both, in the DATA= data set. If the lagged variables are not in the DATA= data set or if they have missing values in the early observations, PROC SIMLIN prints a warning and uses the endogenous variable values from the early observations to initialize the lags.

OUTEST= Data Set

The OUTEST= data set contains all the variables read from the EST= data set. The variables in the OUTEST= data set are as follows.

- the BY statement variables, if any
- `_TYPE_`, a character variable that identifies the type of observation
- `_DEPVAR_`, a character variable containing the name of the dependent variable for the observation
- the endogenous variables
- the lagged endogenous variables
- the exogenous variables
- INTERCEPT, a numeric variable containing the intercept values
- `_MODEL_`, a character variable containing the name of the equation
- `_SIGMA_`, a numeric variable containing the estimated error variance of the equation (output only if present in the EST= data set)

The observations read from the EST= data set that supply the structural coefficients are copied to the OUTEST= data set, except that the signs of endogenous coefficients are reversed. For these observations, the `_TYPE_` variable values are the same as in the EST= data set.

In addition, the OUTEST= data set contains observations with the following `_TYPE_` values:

REDUCED	the reduced form coefficients. The endogenous variables for this group of observations contain the inverse of the endogenous coefficient matrix \mathbf{G} . The lagged endogenous variables contain the matrix $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$. The exogenous variables contain the matrix $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$.
IMULT <i>i</i>	the interim multipliers, if the INTERIM= option is specified. There are gn observations for the interim multipliers, where g is the number of endogenous variables and n is the value of the INTERIM= n option. For these observations the _TYPE_ variable has the value IMULT <i>i</i> , where the interim number i ranges from 1 to n . The exogenous variables in groups of g observations that have a _TYPE_ value of IMULT <i>i</i> contain the matrix $\mathbf{D}^i \Pi_2$ of multipliers at interim i . The endogenous and lagged endogenous variables for this group of observations are set to missing.
TOTAL	the total multipliers, if the TOTAL option is specified. The exogenous variables in this group of observations contain the matrix $(\mathbf{I} - \mathbf{D})^{-1} \Pi_2$. The endogenous and lagged endogenous variables for this group of observations are set to missing.

OUT= Data Set

The OUT= data set normally contains all of the variables in the input DATA= data set, plus the variables named in the PREDICTED= and RESIDUAL= options in the OUTPUT statement.

You can use an ID statement to restrict the variables that are copied from the input data set. If an ID statement is used, the OUT= data set contains only the BY variables (if any), the ID variables, the endogenous and lagged endogenous variables (if any), the exogenous variables, plus the PREDICTED= and RESIDUAL= variables.

The OUT= data set contains an observation for each observation in the DATA= data set. When the actual value of an endogenous variable is missing in the DATA= data set, or when the DATA= data set does not contain the endogenous variable, the corresponding residual is missing.

Printed Output

Structural Form

The following items are printed as they are read from the EST= input data set. Structural zeros are printed as dots in the listing of these matrices.

1. Structural Coefficients for Endogenous Variables. This is the \mathbf{G} matrix, with g rows and g columns.
2. Structural Coefficients for Lagged Endogenous Variables. These coefficients make up the \mathbf{C} matrix, with g rows and l columns.
3. Structural Coefficients for Exogenous Variables. These coefficients make up the \mathbf{B} matrix, with g rows and k columns.

Reduced Form

1. The reduced form coefficients are obtained by inverting \mathbf{G} so that the endogenous variables can be directly expressed as functions of only lagged endogenous and exogenous variables.
2. Inverse Coefficient Matrix for Endogenous Variables. This is the inverse of the \mathbf{G} matrix.
3. Reduced Form for Lagged Endogenous Variables. This is $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$, with g rows and l columns. Each value is a dynamic multiplier that shows how past values of lagged endogenous variables affect values of each of the endogenous variables.
4. Reduced Form for Exogenous Variables. This is $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$, with g rows and k columns. Its values are called *impact multipliers* because they show the immediate effect of each exogenous variable on the value of the endogenous variables.

Multipliers

Interim and total multipliers show the effect of a change in an exogenous variable over time.

1. Interim Multipliers. These are the interim multiplier matrices. They are formed by multiplying Π_2 by powers of \mathbf{D} . The d th interim multiplier is $\mathbf{D}^d \Pi_2$. The interim multiplier of order d shows the effects of a change in the exogenous variables after d periods. Interim multipliers are only available if the maximum lag of the endogenous variables is 1.
2. Total Multipliers. This is the matrix of total multipliers, $\mathbf{T} = (\mathbf{I} - \mathbf{D})^{-1} \Pi_2$. This matrix shows the cumulative effect of changes in the exogenous variables. Total multipliers are only available if the maximum lag is one.

Statistics of Fit

If the DATA= option is used and the DATA= data set contains endogenous variables, PROC SIMLIN prints a statistics-of-fit report for the simulation. The statistics printed include the following. (Summations are over the observations for which both y_t and \hat{y}_t are nonmissing.)

1. the number of nonmissing errors. (Number of observations for which both y_t and \hat{y}_t are nonmissing.)
2. the mean error: $\frac{1}{n} \sum (y_t - \hat{y}_t)$
3. the mean percent error: $\frac{100}{n} \sum \frac{(y_t - \hat{y}_t)}{y_t}$
4. the mean absolute error: $\frac{1}{n} \sum |y_t - \hat{y}_t|$
5. the mean absolute percent error: $\frac{100}{n} \sum \frac{|y_t - \hat{y}_t|}{y_t}$
6. the root mean square error: $\sqrt{\frac{1}{n} \sum (y_t - \hat{y}_t)^2}$
7. the root mean square percent error: $\sqrt{\frac{100}{n} \sum \left(\frac{(y_t - \hat{y}_t)}{y_t}\right)^2}$

ODS Table Names

PROC SIMLIN assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 25.2 ODS Tables Produced in PROC SIMLIN

ODS Table Name	Description	Option
Endogenous	Structural Coefficients for Endogenous Variables	default
LaggedEndogenous	Structural Coefficients for Lagged Endogenous Variables	default
Exogenous	Structural Coefficients for Exogenous Variables	default
InverseCoeff	Inverse Coefficient Matrix for Endogenous Variables	default
RedFormLagEndo	Reduced Form for Lagged Endogenous Variables	default
RedFormExog	Reduced Form for Exogenous Variables	default
InterimMult	Interim Multipliers	INTERIM= option
TotalMult	Total Multipliers	TOTAL= option
FitStatistics	Fit statistics	default

Examples: SIMLIN Procedure

Example 25.1: Simulating Klein's Model I

In this example, the SIMLIN procedure simulates a model of the U.S. economy called Klein's Model I. The SAS data set KLEIN is used as input to the SYSLIN and SIMLIN procedures.

```
data klein;
  input year c p w i x wp g t k wsum;
  date=mdy(1,1,year);
  format date year.;
  y  = c + i + g - t;
  yr = year - 1931;
  klag = lag( k );
  plag = lag( p );
```

```

xlag = lag( x );
if year >= 1921;
label c   ='consumption'
      p   ='profits'
      w   ='private wage bill'
      i   ='investment'
      k   ='capital stock'
      y   ='national income'
      x   ='private production'
      wsum='total wage bill'
      wp  ='govt wage bill'
      g   ='govt demand'
      t   ='taxes'
      klag='capital stock lagged'
      plag='profits lagged'
      xlag='private product lagged'
      yr  ='year-1931';
datalines;
1920      .   12.7      .      .   44.9      .      .      .   182.8      .

... more lines ...

```

First, the model is specified and estimated using the SYSLIN procedure, and the parameter estimates are written to an OUTEST= data set. The printed output produced by the SYSLIN procedure is not shown here; see [Example 29.1](#) in [Chapter 29](#) for the printed output of the PROC SYSLIN step.

```

title1 'Simulation of Klein''s Model I using SIMLIN';
proc syslin 3sls data=klein outest=a;

instruments klag plag xlag wp g t yr;
endogenous c p w i x wsum k y;

consume: model      c = p plag wsum;
invest:  model      i = p plag klag;
labor:   model      w = x xlag yr;

product: identity x = c + i + g;
income:  identity y = c + i + g - t;
profit:  identity p = x - w - t;
stock:   identity k = klag + i;
wage:    identity wsum = w + wp;

run;

```

The OUTEST= data set A created by the SYSLIN procedure contains parameter estimates to be used by the SIMLIN procedure. The OUTEST= data set is shown in [Output 25.1.1](#).

Using the OUTEST= data set A produced by the SYSLIN procedure, the SIMLIN procedure can now compute the reduced form and simulate the model. The following statements perform the simulation.

```

title1 'Simulation of Klein''s Model I using SIMLIN';
proc simlin data=klein
    est=a type=3sls
    estprint
    total interim=2
    outest=b;
    endogenous c p w i x wsum k y;
    exogenous wp g t yr;
    lagged klag k 1   plag p 1   xlag x 1;
    id year;
    output out=c p=chat phat what ihat xhat wsumhat khat yhat
           r=cres pres wres ires xres wsumres kres yres;
run;

```

The reduced form coefficients and multipliers are added to the information read from EST= data set A and written to the OUTEST= data set B. The predicted and residual values from the simulation are written to the OUT= data set C specified in the OUTPUT statement.

The SIMLIN procedure first prints the structural coefficient matrices read from the EST= data set, as shown in [Output 25.1.2](#) through [Output 25.1.4](#).

proc sgplot data=c;
  scatter x=year y=c;
  series x=year y=chat / markers markerattrs=(symbol=plus);
  refline 1941.5 / axis=x;
run;
```

Output 25.1.11 Plot of Actual and Predicted Consumption

Example 25.2: Multipliers for a Third-Order System

This example shows how to fit and simulate a single equation dynamic model with third-order lags. It then shows how to convert the third-order equation into a three equation system with only first-order lags, so that the SIMLIN procedure can compute multipliers. (See the section "Multipliers for Higher Order Lags" earlier in this chapter for more information.)

The input data set TEST is created from simulated data. A partial listing of the data set TEST produced by PROC PRINT is shown in [Output 25.2.1](#).

Output 25.2.1 Partial Listing of Input Data Set

Overview: SPECTRA Procedure

The SPECTRA procedure performs spectral and cross-spectral analysis of time series. You can use spectral analysis techniques to look for periodicities or cyclical patterns in data.

The SPECTRA procedure produces estimates of the spectral and cross-spectral densities of a multivariate time series. Estimates of the spectral and cross-spectral densities of a multivariate time series are produced

using a finite Fourier transform to obtain periodograms and cross-periodograms. The periodogram ordinates are smoothed by a moving average to produce estimated spectral and cross-spectral densities. PROC SPECTRA can also test whether or not the data are white noise.

PROC SPECTRA uses the finite Fourier transform to decompose data series into a sum of sine and cosine waves of different amplitudes and wavelengths. The finite Fourier transform decomposition of the series x_t is

$$x_t = \frac{a_0}{2} + \sum_{k=1}^{m-1} f_k(a_k \cos \omega_k t + b_k \sin \omega_k t)$$

$$f_k = \begin{cases} 1/2 & \text{if } n \text{ is even and } k = m - 1 \\ 1 & \text{otherwise} \end{cases}$$

where

t	is the time subscript, $t = 0, 1, 2, \dots, n - 1$
x_t	are the equally spaced time series data
n	is the number of observations in the time series
m	is the number of frequencies in the Fourier decomposition: $m = \frac{n+2}{2}$ if n is even, $m = \frac{n+1}{2}$ if n is odd
k	is the frequency subscript, $k = 0, 1, 2, \dots, m - 1$
a_0	is the mean term: $a_0 = 2\bar{x}$
a_k	are the cosine coefficients
b_k	are the sine coefficients
ω_k	are the Fourier frequencies: $\omega_k = \frac{2\pi k}{n}$

Functions of the Fourier coefficients a_k and b_k can be plotted against frequency or against wave length to form *periodograms*. The amplitude periodogram J_k is defined as follows:

$$J_k = \frac{n}{2}(a_k^2 + b_k^2)$$

Several definitions of the term periodogram are used in the spectral analysis literature. The following discussion refers to the J_k sequence as the periodogram.

The periodogram can be interpreted as the contribution of the k th harmonic ω_k to the total sum of squares (in an analysis of variance sense) in the decomposition of the process into two-degree-of-freedom components for each of the m frequencies. When n is even, $\sin(\omega_{\frac{n}{2}})$ is zero, and thus the last periodogram value is a one-degree-of-freedom component.

The periodogram is a volatile and inconsistent estimator of the spectrum. The spectral density estimate is produced by smoothing the periodogram. Smoothing reduces the variance of the estimator but introduces a bias. The weight function used for the smoothing process, $W()$, often called the kernel or spectral window, is specified with the WEIGHTS statement. It is related to another weight function, $w()$, the lag window, that is used in other methods to taper the correlogram rather than to smooth the periodogram. Many specific

weighting functions have been suggested in the literature (Fuller 1976, Jenkins and Watts 1968, Priestly 1981). [Table 26.3](#) later in this chapter gives the relevant formulas when the WEIGHTS statement is used.

Letting i represent the imaginary unit $\sqrt{-1}$, the cross-periodogram is defined as follows:

$$J_k^{xy} = \frac{n}{2}(a_k^x a_k^y + b_k^x b_k^y) + i \frac{n}{2}(a_k^x b_k^y - b_k^x a_k^y)$$

The cross-spectral density estimate is produced by smoothing the cross-periodogram in the same way as the periodograms are smoothed using the spectral window specified by the WEIGHTS statement.

The SPECTRA procedure creates an output SAS data set whose variables contain values of the periodograms, cross-periodograms, estimates of spectral densities, and estimates of cross-spectral densities. The form of the output data set is described in the section “[OUT= Data Set](#)” on page 1750.

Getting Started: SPECTRA Procedure

To use the SPECTRA procedure, specify the input and output data sets and options for the analysis you want in the PROC SPECTRA statement, and list the variables to analyze in the VAR statement. The procedure produces no printed output unless the WHITESTEST option is specified in the PROC SPECTRA statement. The periodogram, spectral density, and other results are written to the OUT= data set, depending on the options used.

For example, to compute the Fourier transform of a variable X in a data set A, use the following statements:

```
proc spectra data=a out=b coef;
  var x;
run;
```

This PROC SPECTRA step writes the Fourier coefficients a_k and b_k to the variables COS_01 and SIN_01 in the output data set B.

When a WEIGHTS statement is specified, the periodogram is smoothed by a weighted moving average to produce an estimate of the spectral density of the series. The following statements write a spectral density estimate for X to the variable S_01 in the output data set B.

```
proc spectra data=a out=b s;
  var x;
  weights 1 2 3 4 3 2 1;
run;
```

When the VAR statement specifies more than one variable, you can perform cross-spectral analysis by specifying the CROSS option in the PROC SPECTRA statement. The CROSS option by itself produces the cross-periodograms for all two-way combinations of the variables listed in the VAR statement. For example, the following statements write the real and imaginary parts of the cross-periodogram of X and Y to the variables RP_01_02 and IP_01_02 in the output data set B.

```
proc spectra data=a out=b cross;
    var x y;
run;
```

To produce cross-spectral density estimates, specify both the CROSS option and the S option. The cross-periodogram is smoothed using the weights specified by the WEIGHTS statement in the same way as the spectral density. The squared coherency and phase estimates of the cross-spectrum are computed when the K and PH options are used.

The following example computes cross-spectral density estimates for the variables X and Y.

```
proc spectra data=a out=b cross s;
    var x y;
    weights 1 2 3 4 3 2 1;
run;
```

The real part and imaginary part of the cross-spectral density estimates are written to the variables CS_01_02 and QS_01_02, respectively.

Syntax: SPECTRA Procedure

The following statements are used with the SPECTRA procedure:

```
PROC SPECTRA options ;
    BY variables ;
    VAR variables ;
    WEIGHTS <weights> <kernel> ;
```

Functional Summary

Table 26.1 summarizes the statements and options that control the SPECTRA procedure.

Table 26.1 SPECTRA Functional Summary

Description	Statement	Option
Statements		
specify BY-group processing	BY	
specify the variables to be analyzed	VAR	
specify weights for spectral density estimates	WEIGHTS	
Data Set Options		
specify the input data set	PROC SPECTRA	DATA=

Table 26.1 *continued*

Description	Statement	Option
specify the output data set	PROC SPECTRA	OUT=
Output Control Options		
output the amplitudes of the cross-spectrum	PROC SPECTRA	A
output the Fourier coefficients	PROC SPECTRA	COEF
output the periodogram	PROC SPECTRA	P
output the spectral density estimates	PROC SPECTRA	S
output cross-spectral analysis results	PROC SPECTRA	CROSS
output squared coherency of the cross-spectrum	PROC SPECTRA	K
output the phase of the cross-spectrum	PROC SPECTRA	PH
Smoothing Options		
specify the Bartlett kernel	WEIGHTS	BART
specify the Parzen kernel	WEIGHTS	PARZEN
specify the quadratic spectral kernel	WEIGHTS	QS
specify the Tukey-Hanning kernel	WEIGHTS	TUKEY
specify the truncated kernel	WEIGHTS	TRUNCAT
Other Options		
subtract the series mean	PROC SPECTRA	ADJMEAN
specify an alternate quadrature spectrum estimate	PROC SPECTRA	ALTW
request tests for white noise	PROC SPECTRA	WHITETEST

PROC SPECTRA Statement

PROC SPECTRA *options* ;

The following options can be used in the PROC SPECTRA statement:

A

outputs the amplitude variables ($A_{nn \ mm}$) of the cross-spectrum.

ADJMEAN

CENTER

subtracts the series mean before performing the Fourier decomposition. This sets the first periodogram ordinate to 0 rather than $2n$ times the squared mean. This option is commonly used when the periodograms are to be plotted to prevent a large first periodogram ordinate from distorting the scale of the plot.

ALTW

specifies that the quadrature spectrum estimate is computed at the boundaries in the same way as the spectral density estimate and the cospectrum estimate are computed.

COEF

outputs the Fourier cosine and sine coefficients of each series.

CROSS

is used with the P and S options to output cross-periodograms and cross-spectral densities when more than one variable is listed in the VAR statement.

DATA=SAS-data-set

names the SAS data set that contains the input data. If the DATA= option is omitted, the most recently created SAS data set is used.

K

outputs the squared coherency variables (K_{nn_mm}) of the cross-spectrum. The K_{nn_mm} variables are identically 1 unless weights are given in the WEIGHTS statement and the S option is specified.

OUT=SAS-data-set

names the output data set created by PROC SPECTRA to store the results. If the OUT= option is omitted, the output data set is named by using the DATA n convention.

P

outputs the periodogram variables. The variables are named P_{nn} , where nn is an index of the original variable with which the periodogram variable is associated. When both the P and CROSS options are specified, the cross-periodogram variables RP_{nn_mm} and IP_{nn_mm} are also output.

PH

outputs the phase variables (PH_{nn_mm}) of the cross-spectrum.

S

outputs the spectral density estimates. The variables are named S_{nn} , where nn is an index of the original variable with which the estimate variable is associated. When both the S and CROSS options are specified, the cross-spectral variables CS_{nn_mm} and QS_{nn_mm} are also output.

WHITETEST

prints two tests of the hypothesis that the data are white noise. See the section “[White Noise Test](#)” on page 1749 for details.

Note that the CROSS, A, K, and PH options are meaningful only if more than one variable is listed in the VAR statement.

BY Statement

BY *variables* ;

A BY statement can be used with PROC SPECTRA to obtain separate analyses for groups of observations defined by the BY variables.

VAR Statement

VAR *variables* ;

The VAR statement specifies one or more numeric variables that contain the time series to analyze. The order of the variables in the VAR statement list determines the index, *nn*, used to name the output variables. The VAR statement is required.

WEIGHTS Statement

WEIGHTS *weight-constants / kernel-specification* ;

The WEIGHTS statement specifies the relative weights used in the moving average applied to the periodogram ordinates to form the spectral density estimates. A WEIGHTS statement must be used to produce smoothed spectral density estimates. You can specify the relative weights in two ways: you can specify them explicitly as explained in the section “[Using Weight Constants Specification](#)” on page 1745, or you can specify them implicitly by using the kernel specification as explained in the section “[Using Kernel Specifications](#)” on page 1745. If the WEIGHTS statement is not used, only the periodogram is produced.

Using Weight Constants Specification

Any number of weighting constants can be specified. The constants should be positive and symmetric about the middle weight. The middle constant (or the constant to the right of the middle if an even number of weight constants are specified) is the relative weight of the current periodogram ordinate. The constant immediately following the middle one is the relative weight of the next periodogram ordinate, and so on. The actual weights used in the smoothing process are the weights specified in the WEIGHTS statement scaled so that they sum to $\frac{1}{4\pi}$.

The moving average reflects at each end of the periodogram. The first periodogram ordinate is not used; the second periodogram ordinate is used in its place.

For example, a simple triangular weighting can be specified using the following WEIGHTS statement:

```
weights 1 2 3 2 1;
```

Using Kernel Specifications

You can specify five different kernels in the WEIGHTS statement. The syntax for the statement is

WEIGHTS [PARZEN][BART][TUKEY][TRUNCAT][QS] [*c e*] ;

where $c \geq 0$ and $e \geq 0$ are used to compute the bandwidth parameter as

$$l(q) = cq^e$$

and q is the number of periodogram ordinates +1:

$$q = \text{floor}(n/2) + 1$$

To specify the bandwidth explicitly, set $c =$ to the desired bandwidth and $e = 0$.

For example, a Parzen kernel can be specified using the following WEIGHTS statement:

```
weights parzen 0.5 0;
```

For details, see the section “[Kernels](#)” on page 1747.

Details: SPECTRA Procedure

Input Data

Observations in the data set analyzed by the SPECTRA procedure should form ordered, equally spaced time series. No more than 99 variables can be included in the analysis.

Data are often detrended before analysis by the SPECTRA procedure. This can be done by using the residuals output by a SAS regression procedure. Optionally, the data can be centered using the ADJMEAN option in the PROC SPECTRA statement, since the zero periodogram ordinate corresponding to the mean is of little interest from the point of view of spectral analysis.

Missing Values

Missing values are excluded from the analysis by the SPECTRA procedure. If the SPECTRA procedure encounters missing values for any variable listed in the VAR statement, the procedure determines the longest contiguous span of data that has no missing values for the variables listed in the VAR statement and uses that span for the analysis.

Computational Method

If the number of observations n factors into prime integers that are less than or equal to 23, and the product of the square-free factors of n is less than 210, then PROC SPECTRA uses the fast Fourier transform developed by Cooley and Tukey and implemented by Singleton (1969). If n cannot be factored in this way, then PROC SPECTRA uses a Chirp-Z algorithm similar to that proposed by Monro and Branch (1976). To reduce memory requirements, when n is small, the Fourier coefficients are computed directly using the defining formulas.

Kernels

Kernels are used to smooth the periodogram by using a weighted moving average of nearby points. A smoothed periodogram is defined by the following equation.

$$\hat{J}_i(l(q)) = \sum_{\tau=-l(q)}^{l(q)} w\left(\frac{\tau}{l(q)}\right) \tilde{J}_{i+\tau}$$

where $w(x)$ is the kernel or weight function. At the endpoints, the moving average is computed cyclically; that is,

$$\tilde{J}_{i+\tau} = \begin{cases} J_{i+\tau} & 0 \leq i + \tau \leq q \\ J_{-(i+\tau)} & i + \tau < 0 \\ J_{q-(i+\tau)} & i + \tau > q \end{cases}$$

The SPECTRA procedure supports the following kernels. They are listed with their default bandwidth functions.

Bartlett: KERNEL BART

$$\begin{aligned} w(x) &= \begin{cases} 1 - |x| & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(q) &= \frac{1}{2}q^{1/3} \end{aligned}$$

Parzen: KERNEL PARZEN

$$\begin{aligned} w(x) &= \begin{cases} 1 - 6|x|^2 + 6|x|^3 & 0 \leq |x| \leq \frac{1}{2} \\ 2(1 - |x|)^3 & \frac{1}{2} \leq |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(q) &= q^{1/5} \end{aligned}$$

Quadratic spectral: KERNEL QS

$$\begin{aligned} w(x) &= \frac{25}{12\pi^2 x^2} \left(\frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right) \\ l(q) &= \frac{1}{2}q^{1/5} \end{aligned}$$

Tukey-Hanning: KERNEL TUKEY

$$w(x) = \begin{cases} (1 + \cos(\pi x))/2 & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

$$l(q) = \frac{2}{3}q^{1/5}$$

Truncated: KERNEL TRUNCAT

$$w(x) = \begin{cases} 1 & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

$$l(q) = \frac{1}{4}q^{1/5}$$

A summary of the default values of the bandwidth parameters, *c* and *e*, associated with the kernel smoothers in PROC SPECTRA are listed below in [Table 26.2](#):

Table 26.2 Bandwidth Parameters

Kernel	<i>c</i>	<i>e</i>
Bartlett	1/2	1/3
Parzen	1	1/5
quadratic	1/2	1/5
Tukey-Hanning	2/3	1/5
truncated	1/4	1/5

Figure 26.1 Kernels for Smoothing

See Andrews (1991) for details about the properties of these kernels.

White Noise Test

PROC SPECTRA prints two test statistics for white noise when the WHITETEST option is specified: Fisher's Kappa (Davis 1941, Fuller 1976) and Bartlett's Kolmogorov-Smirnov statistic (Bartlett 1966, Fuller 1976, Durbin 1967).

If the time series is a sequence of independent random variables with mean 0 and variance σ^2 , then the periodogram, J_k , will have the same expected value for all k . For a time series with nonzero autocorrelation, each ordinate of the periodogram, J_k , will have different expected values. The Fisher's Kappa statistic tests whether the largest J_k can be considered different from the mean of the J_k . Critical values for the Fisher's Kappa test can be found in Fuller 1976.

The Kolmogorov-Smirnov statistic reported by PROC SPECTRA has the same asymptotic distribution as Bartlett's test (Durbin 1967). The Kolmogorov-Smirnov statistic compares the normalized cumulative periodogram with the cumulative distribution function of a uniform(0,1) random variable. The normalized cumulative periodogram, F_j , of the series is

$$F_j = \frac{\sum_{k=1}^j J_k}{\sum_{k=1}^m J_k}, j = 1, 2, \dots, m-1$$

where $m = \frac{n}{2}$ if n is even or $m = \frac{n-1}{2}$ if n is odd. The test statistic is the maximum absolute difference of the normalized cumulative periodogram and the uniform cumulative distribution function. Approximate p -values for Bartlett's Kolmogorov-Smirnov test statistics are provided with the test statistics. Small p -values cause you to reject the null-hypothesis that the series is white noise.

Transforming Frequencies

The variable FREQ in the data set created by the SPECTRA procedure ranges from 0 to π . Sometimes it is preferable to express frequencies in cycles per observation period, which is equal to $\frac{1}{2\pi}$ FREQ.

To express frequencies in cycles per unit time (for example, in cycles per year), multiply FREQ by $\frac{d}{2\pi}$, where d is the number of observations per unit of time. For example, for monthly data, if the desired time unit is years then d is 12. The period of the cycle is $\frac{2\pi}{d \times \text{FREQ}}$, which ranges from $\frac{2}{d}$ to infinity.

OUT= Data Set

The OUT= data set contains $\frac{n}{2} + 1$ observations, if n is even, or $\frac{n+1}{2}$ observations, if n is odd, where n is the number of observations in the time series or the span of data being analyzed if missing values are present in the data. See the section “Missing Values” on page 1746 for details.

The variables in the new data set are named according to the following conventions. Each variable to be analyzed is associated with an index. The first variable listed in the VAR statement is indexed as 01, the second variable as 02, and so on. Output variables are named by combining indexes with prefixes. The prefix always identifies the nature of the new variable, and the indices identify the original variables from which the statistics were obtained.

Variables that contain spectral analysis results have names that consist of a prefix, an underscore, and the index of the variable analyzed. For example, the variable S_01 contains spectral density estimates for the first variable in the VAR statement. Variables that contain cross-spectral analysis results have names that consist of a prefix, an underscore, the index of the first variable, another underscore, and the index of the second variable. For example, the variable A_01_02 contains the amplitude of the cross-spectral density estimate for the first and second variables in the VAR statement.

Table 26.3 shows the formulas and naming conventions used for the variables in the OUT= data set. Let X be variable number nn in the VAR statement list and let Y be variable number mm in the VAR statement list. Table 26.3 shows the output variables that contain the results of the spectral and cross-spectral analysis of X and Y .

In Table 26.3 the following notation is used. Let W_j be the vector of $2p + 1$ smoothing weights given by the WEIGHTS statement, normalized to sum to $\frac{1}{4\pi}$. Note that the weights are either explicitly provided using the constant specification or are implicitly determined by the kernel specification in the WEIGHTS statement.

The subscript of W_j runs from W_{-p} to W_p , so that W_0 is the middle weight in the list. Let $\omega_k = \frac{2\pi k}{n}$, where $k = 0, 1, \dots, \text{floor}(\frac{n}{2})$.

Table 26.3 Variables Created by PROC SPECTRA

Variable	Description
FREQ	frequency in radians from 0 to π (Note: Cycles per observation is $\frac{\text{FREQ}}{2\pi}$.)
PERIOD	period or wavelength: $\frac{2\pi}{\text{FREQ}}$ (Note: PERIOD is missing for FREQ=0.)
COS_nn	cosine transform of X: $a_k^x = \frac{2}{n} \sum_{t=1}^n X_t \cos(\omega_k(t-1))$
SIN_nn	sine transform of X: $b_k^x = \frac{2}{n} \sum_{t=1}^n X_t \sin(\omega_k(t-1))$
P_nn	periodogram of X: $J_k^x = \frac{n}{2} [(a_k^x)^2 + (b_k^x)^2]$
S_nn	spectral density estimate of X: $F_k^x = \sum_{j=-p}^p W_j J_{k+j}^x$ (except across endpoints)
RP_nn_mm	real part of cross-periodogram X and Y: $\text{real}(J_k^{xy}) = \frac{n}{2} (a_k^x a_k^y + b_k^x b_k^y)$
IP_nn_mm	imaginary part of cross-periodogram of X and Y: $\text{imag}(J_k^{xy}) = \frac{n}{2} (a_k^x b_k^y - b_k^x a_k^y)$
CS_nn_mm	cospectrum estimate (real part of cross-spectrum) of X and Y: $C_k^{xy} = \sum_{j=-p}^p W_j \text{real}(J_{k+j}^{xy})$ (except across endpoints)
QS_nn_mm	quadrature spectrum estimate (imaginary part of cross-spectrum) of X and Y: $Q_k^{xy} = \sum_{j=-p}^p W_j \text{imag}(J_{k+j}^{xy})$ (except across endpoints)
A_nn_mm	amplitude (modulus) of cross-spectrum of X and Y: $A_k^{xy} = \sqrt{(C_k^{xy})^2 + (Q_k^{xy})^2}$
K_nn_mm	coherency squared of X and Y: $K_k^{xy} = (A_k^{xy})^2 / (F_k^x F_k^y)$
PH_nn_mm	phase spectrum in radians of X and Y: $\Phi_k^{xy} = \arctan(Q_k^{xy} / C_k^{xy})$

Printed Output

By default PROC SPECTRA produces no printed output.

When the WHITETEST option is specified, the SPECTRA procedure prints the following statistics for each variable in the VAR statement:

1. the name of the variable
2. $M-1$, the number of two-degree-of-freedom periodogram ordinates used in the test
3. $\text{MAX}(P(*))$, the maximum periodogram ordinate
4. $\text{SUM}(P(*))$, the sum of the periodogram ordinates
5. Fisher's Kappa statistic
6. Bartlett's Kolmogorov-Smirnov test statistic
7. Approximate p -value for Bartlett's Kolmogorov-Smirnov test statistic

See the section “[White Noise Test](#)” on page 1749 for details.

ODS Table Names: SPECTRA procedure

PROC SPECTRA assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 26.4 ODS Tables Produced in PROC SPECTRA

ODS Table Name	Description	Option
WhiteNoiseTest	white noise test	WHITETEST
Kappa	Fishers Kappa statistic	WHITETEST
Bartlett	Bartletts Kolmogorov-Smirnov statistic	WHITETEST

Examples: SPECTRA Procedure

Example 26.1: Spectral Analysis of Sunspot Activity

This example analyzes Wolfer's sunspot data (Anderson 1971). The following statements read and plot the data.

```
title "Wolfer's Sunspot Data";
data sunspot;
    input year wolfer @@;
datalines;

    ... more lines ...

proc sgplot data=sunspot;
    series x=year y=wolfer / markers markerattrs=(symbol=circlefilled);
    xaxis values=(1740 to 1930 by 10);
    yaxis values=(0 to 1600 by 200);
run;
```

The plot of the sunspot series is shown in [Output 26.1.1](#).

Output 26.1.1 Plot of Original Sunspot Data

The spectral analysis of the sunspot series is performed by the following statements:

```
proc spectra data=sunspot out=b p s adjmean whitetest;
  var wolfer;
  weights 1 2 3 4 3 2 1;
run;

proc print data=b(obs=12);
run;
```

The PROC SPECTRA statement specifies the P and S options to write the periodogram and spectral density estimates to the OUT= data set B. The WEIGHTS statement specifies a triangular spectral window for smoothing the periodogram to produce the spectral density estimate. The ADJMEAN option zeros the frequency 0 value and avoids the need to exclude that observation from the plots. The WHITETEST option prints tests for white noise.

The Fisher's Kappa test statistic of 16.070 is larger than the 5% critical value of 7.2, so the null hypothesis that the sunspot series is white noise is rejected (see the table of critical values in Fuller (1976)).

The Bartlett's Kolmogorov-Smirnov statistic is 0.6501, and its approximate p -value is < 0.0001 . The small p -value associated with this test leads to the rejection of the null hypothesis that the spectrum represents white noise.

The printed output produced by PROC SPECTRA is shown in [Output 26.1.2](#). The output data set B created by PROC SPECTRA is shown in part in [Output 26.1.3](#).

Output 26.1.2 White Noise Test Results

Wolfer's Sunspot Data	
The SPECTRA Procedure	
Test for White Noise for Variable wolfer	
M-1	87
Max(P(*))	4062267
Sum(P(*))	21156512
Fisher's Kappa: $(M-1) * \text{Max}(P(*)) / \text{Sum}(P(*))$	
Kappa	16.70489
Bartlett's Kolmogorov-Smirnov Statistic:	
Maximum absolute difference of the standardized	
partial sums of the periodogram and the CDF of a	
uniform(0,1) random variable.	
Test Statistic	0.650055
Approximate P-Value	<.0001

Output 26.1.3 First 12 Observations of the OUT= Data Set

Wolfer's Sunspot Data				
Obs	FREQ	PERIOD	P_01	S_01
1	0.00000	.	0.00	59327.52
2	0.03570	176.000	3178.15	61757.98
3	0.07140	88.000	2435433.22	69528.68
4	0.10710	58.667	1077495.76	66087.57
5	0.14280	44.000	491850.36	53352.02
6	0.17850	35.200	2581.12	36678.14
7	0.21420	29.333	181163.15	20604.52
8	0.24990	25.143	283057.60	15132.81
9	0.28560	22.000	188672.97	13265.89
10	0.32130	19.556	122673.94	14953.32
11	0.35700	17.600	58532.93	16402.84
12	0.39270	16.000	213405.16	18562.13

The following statements plot the periodogram and spectral density estimate by the frequency and period.

```
proc sgplot data=b;
  series x=freq y=p_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
```

```

series x=period y=p_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
series x=freq y=s_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
series x=period y=s_01 / markers markerattrs=(symbol=circlefilled);
run;

```

The periodogram is plotted against the frequency in [Output 26.1.4](#) and plotted against the period in [Output 26.1.5](#). The spectral density estimate is plotted against the frequency in [Output 26.1.6](#) and plotted against the period in [Output 26.1.7](#).

Output 26.1.4 Plot of Periodogram by Frequency

Output 26.1.5 Plot of Periodogram by Period

Output 26.1.6 Plot of Spectral Density Estimate by Frequency

Output 26.1.7 Plot of Spectral Density Estimate by Period

Since PERIOD is the reciprocal of frequency, the plot axis for PERIOD is stretched for low frequencies and compressed at high frequencies. One way to correct for this is to use a WHERE statement to restrict the plots and exclude the low frequency components. The following statements plot the spectral density for periods less than 50.

```
proc sgplot data=b;
  where period < 50;
  series x=period y=s_01 / markers markerattrs=(symbol=circlefilled);
  refline 11 / axis=x;
run;
title;
```

The spectral analysis of the sunspot series confirms a strong 11-year cycle of sunspot activity. The plot makes this clear by drawing a reference line at the 11 year period, which highlights the position of the main peak in the spectral density.

Output 26.1.8 shows the plot. Contrast Output 26.1.8 with Output 26.1.7.

Output 26.1.8 Plot of Spectral Density Estimate by Period to 50 Years

Example 26.2: Cross-Spectral Analysis

This example uses simulated data to show cross-spectral analysis for two variables X and Y . X is generated by an AR(1) process; Y is generated as white noise plus an input from X lagged 2 periods. All output options are specified in the PROC SPECTRA statement. PROC CONTENTS shows the contents of the OUT= data set.

```
data a;
  x1 = 0; x11 = 0;
  do i = - 10 to 100;
    x = .4 * x1 + rannor(123);
    y = .5 * x11 + rannor(123);
    if i > 0 then output;
    x11 = x1; x1 = x;
  end;
run;

proc spectra data=a out=b cross coef a k p ph s;
```

```

var x y;
weights 1 1.5 2 4 8 9 8 4 2 1.5 1;
run;

proc contents data=b position;
run;

```

The PROC CONTENTS report for the output data set B is shown in [Output 26.2.1](#).

Output 26.2.1 Contents of PROC SPECTRA OUT= Data Set

The CONTENTS Procedure				
Alphabetic List of Variables and Attributes				
#	Variable	Type	Len	Label
16	A_01_02	Num	8	Amplitude of x by y
3	COS_01	Num	8	Cosine Transform of x
5	COS_02	Num	8	Cosine Transform of y
13	CS_01_02	Num	8	Cospectra of x by y
1	FREQ	Num	8	Frequency from 0 to PI
12	IP_01_02	Num	8	Imag Periodogram of x by y
15	K_01_02	Num	8	Coherency**2 of x by y
2	PERIOD	Num	8	Period
17	PH_01_02	Num	8	Phase of x by y
7	P_01	Num	8	Periodogram of x
8	P_02	Num	8	Periodogram of y
14	QS_01_02	Num	8	Quadrature of x by y
11	RP_01_02	Num	8	Real Periodogram of x by y
4	SIN_01	Num	8	Sine Transform of x
6	SIN_02	Num	8	Sine Transform of y
9	S_01	Num	8	Spectral Density of x
10	S_02	Num	8	Spectral Density of y

The following statements plot the amplitude of the cross-spectrum estimate against frequency and against period for periods less than 25.

```

proc sgplot data=b;
  series x=freq y=a_01_02 / markers markerattrs=(symbol=circlefilled);
  xaxis values=(0 to 4 by 1);
run;

```

The plot of the amplitude of the cross-spectrum estimate against frequency is shown in [Output 26.2.2](#).

Output 26.2.2 Plot of Cross-Spectrum Amplitude by Frequency

The plot of the cross-spectrum amplitude against period for periods less than 25 observations is shown in [Output 26.2.3](#).

```
proc sgplot data=b;
  where period < 25;
  series x=period y=a_01_02 / markers markerattrs=(symbol=circlefilled);
  xaxis values=(0 to 30 by 5);
run;
```

Output 26.2.3 Plot of Cross-Spectrum Amplitude by Period

Overview: SSM Procedure

(Linear) state space models (SSMs) are often used for analyzing continuous response variables that are recorded sequentially according to a numeric indexing variable. In many cases the indexing variable is time, and the observations are collected at regular time intervals—for example, hourly, weekly, or monthly. In such cases the resulting data are called time series data. In other cases the indexing variable might not be time, or the observations might not be equally spaced according to the indexing variable. These more general types of sequential data are called longitudinal data. Because of their sequential nature, these types of data exhibit some characteristic features. For example, chronologically closer measurements tend to be highly correlated while measurements farther apart are essentially uncorrelated, and data can be trending in a particular direction and can have seasonal or other periodic patterns. SSMs are specially designed to model such sequential data. They are applicable in both univariate and multivariate response situations and can easily incorporate predictor (independent variable) information when it is available.

The SSM procedure performs state space modeling of univariate and multivariate time series and longitudinal data. You can do the following with the SSM procedure:

- analyze a very general linear state space model
- use an expressive language to specify an SSM. An SSM specification consists of specifying a variety of matrices—for example, the state transition matrix and the covariance matrices of the state and observation disturbances. The SSM procedure provides language similar to a DATA step for specifying the elements of these matrices. The matrix elements can be user-defined functions of data variables and unknown parameters.
- easily specify several commonly needed univariate and multivariate SSMs by using only a few keywords. These include the principal univariate and multivariate structural models for regularly spaced data, and a variety of trend and cycle models for the longitudinal data.
- estimate unknown model parameters by (restricted) maximum likelihood. The likelihood function is computed by using the (diffuse) Kalman filter algorithm.
- output to a data set the series forecasts, residuals, and the full sample estimates of any linear combination of the underlying state variables. These estimates are obtained by using the (diffuse) Kalman filter and smoother algorithm.

Background

State space models are widely used in a variety of fields such as engineering, statistics, econometrics, and agriculture. There are numerous references that deal with state space modeling, particularly with the state space modeling of time series data. State space modeling of longitudinal data has received a little less attention. The primary reference for the modeling techniques implemented in the SSM procedure is Harvey (1989). It contains treatment of both the time series and longitudinal data. Other useful books about this subject are Durbin and Koopman (2001), Jones (1993), and Anderson and Moore (1979). Jones (1993) is exclusively devoted to the state space modeling of longitudinal data. In addition, the articles Wecker and Ansley (1983), Kohn and Ansley (1991), and de Jong and Mazzi (2001) are also quite informative. For the implementation details of the diffuse Kalman filter and smoother (the main computational tool used by the SSM procedure), the main references are a series of articles de Jong (1989, 1991), de Jong and Chu-Chun-Lin (2003), and the references therein.

Getting Started: SSM Procedure

This example illustrates how you can use the SSM procedure to analyze a bivariate time series. The following data set contains two variables, `f_KSI` and `r_KSI`, which are measured quarterly, starting on the first quarter of 1969. `f_KSI` represents the quarterly average of the log of the monthly totals of the front-seat passengers killed or seriously injured during the car accidents, and `r_KSI` represents a similar number for the rear-seat passengers. The data set has been extended at the end with eight missing values, which represent four quarters, to cause the SSM procedure to produce model forecasts for this span.

run;

```

These data have been analyzed in Durbin and Koopman (2001, chap. 9, sec. 3). The analysis presented here is similar but not the same. In order to simplify the illustration, the monthly data have been converted to quarterly data, and two predictors (the number of kilometers traveled and the real price of petrol) are excluded from the analysis. You can also use PROC SSM to carry out the more elaborate analysis in Durbin and Koopman (2001).

One of the original reasons for studying these data was to assess the effect on f_KSI of the enactment of a seat-belt law in February 1983 that compelled the front seat passengers to wear seat belts. A simple graphical inspection of the data (not shown here) reveals that f_KSI and r_KSI do not show a pronounced upward or downward trend but do show seasonal variation, and that these two series seem to move together. Additional inspection also shows that the seasonal effect is relatively stable throughout the data span. These considerations suggest the following model for $y = (f_KSI, r_KSI)$:

$$y_t = \begin{pmatrix} X_t \\ 0 \end{pmatrix} \beta + \mu_t + \gamma_t + \xi_t$$

All the terms on the right-hand side of this equation are assumed to be statistically independent. These terms are as follows:

- The predictor X_t (defined as `Q1_83_Shift` later in the program) denotes a variable that is 0 before the first quarter of 1983, and 1 thereafter. X_t is supposed to affect only f_KSI (the first element of y); it represents the enactment of the seat-belt law of 1983.
- μ_t denotes a bivariate random walk. It is supposed to capture the slowly changing level of the vector y_t . In order to capture the fact that f_KSI and r_KSI move together (that is, they are co-integrated), the covariance of the disturbance term of this random walk is assumed to be of lower than full rank.
- γ_t denotes a bivariate trigonometric seasonal term. In this model it is taken to be fixed (that is, the seasonal effects do not change over time).
- ξ_t denotes a bivariate white noise term, which captures the residual variation that is unexplained by the other terms in the model.

The preceding model is an example of a (bivariate) basic structural model (BSM). You can formulate this model as a state space model

$$\begin{aligned}
 y_t &= Z\alpha_t + \begin{pmatrix} X_t \\ 0 \end{pmatrix} \beta \\
 \alpha_{t+1} &= T\alpha_t + \eta_{t+1} \\
 \alpha_1 &= A_1\delta + \eta_1
 \end{aligned}$$

for some suitable matrices \mathbf{Z} , \mathbf{T} , and \mathbf{A}_1 , unobserved state vectors $\boldsymbol{\alpha}_t$, and disturbance vectors $\boldsymbol{\eta}_t$. The initial state vector $\boldsymbol{\alpha}_1$ is partially diffuse: it is the sum of a mean-zero Gaussian vector $\boldsymbol{\eta}_1$ and a term $\mathbf{A}_1\boldsymbol{\delta}$ that represents the contribution from a diffuse vector $\boldsymbol{\delta}$ (a diffuse vector is a Gaussian vector with infinite covariance). See the section “[The State Space Model and Notation](#)” on page 1786 for more information about the state space model notation. In fact, each of the terms $\boldsymbol{\mu}_t$, $\boldsymbol{\gamma}_t$, and $\boldsymbol{\xi}_t$ that appear in the right-hand side of the equation that defines the BSM in this example are also governed by their own state space models. The preceding state space model is obtained by combining these submodels. In particular, the state vector $\boldsymbol{\alpha}_t$, which is of dimension 10, is formed by combining the state vectors that are associated with these three terms: the state vectors that correspond to $\boldsymbol{\xi}_t$ and $\boldsymbol{\mu}_t$ are of dimension 2, and the dimension of state vector associated with $\boldsymbol{\gamma}_t$ (a bivariate seasonal of season length 4) is 6 (three seasonal effects correspond to f_KSI and three to r_KSI). See the section “[Predefined Structural Models](#)” on page 1799 for more information. Each of the 10-dimensional matrices, the transition matrix \mathbf{T} , and the disturbance-covariance matrix \mathbf{Q} (covariance of $\boldsymbol{\eta}_t$ for $t \geq 2$) are block diagonal with blocks that correspond to the \mathbf{T} and \mathbf{Q} matrices that are associated with the state space models for $\boldsymbol{\mu}_t$, $\boldsymbol{\gamma}_t$, and $\boldsymbol{\xi}_t$. The same holds for the system matrices \mathbf{A}_1 and \mathbf{Q}_1 that are associated with the initial state $\boldsymbol{\alpha}_1$.

The following statements specify and fit this model to f_KSI and r_KSI:

```
proc ssm data=seatBelt;
  id date interval=quarter;
  Q1_83_Shift = (date >= '1jan1983'd);
  state error(2) type=WN cov(g);
  component wn1 = error[1];
  component wn2 = error[2];
  state level(2) type=RW cov(rank=1) ;
  component rw1 = level[1];
  component rw2 = level[2];
  state season(2) type=season(length=4);
  component s1 = season[1];
  component s2 = season[2];
  model f_KSI = Q1_83_Shift rw1 s1 wn1;
  model r_KSI = rw2 s2 wn2;
  eval f_KSI_sa = rw1 + Q1_83_Shift;
  forecast out=for1;
run;
```

The PROC SSM statement specifies the input data set, `seatBelt`, which contains the response variables `f_KSI` and `r_KSI`. The optional ID statement specifies an index variable, `date`. The `INTERVAL=QUARTER` option in the ID statement indicates that the measurements were collected on a quarterly basis. Next, a programming statement defines `Q1_83_Shift`, the predictor that represents the enactment of the seat-belt law of 1983. It is used later in the MODEL statement for `f_KSI`. Separate STATE statements specify the terms $\boldsymbol{\mu}_t$, $\boldsymbol{\gamma}_t$, and $\boldsymbol{\xi}_t$ since they are statistically independent. The models that govern them, white noise for $\boldsymbol{\xi}_t$, random walk for $\boldsymbol{\mu}_t$, and trigonometric seasonal for $\boldsymbol{\gamma}_t$, can all be specified by using the TYPE= option of the STATE statement. When you use the TYPE= option, you can use the COV option to specify the information about the disturbance covariance in the state transition equation. The other details, such as the transition matrix specification and the specification of \mathbf{A}_1 in the initial conation, are inferred from the TYPE= option. For $\boldsymbol{\xi}_t$ (a white noise), \mathbf{A}_1 is zero and $\mathbf{Q}_t = \mathbf{Q}$ for all $t \geq 1$, where \mathbf{Q} is specified by the COV option. For $\boldsymbol{\mu}_t$ and $\boldsymbol{\gamma}_t$ the initial condition is fully diffuse—that is, \mathbf{A}_1 is an identity matrix of appropriate order and $\mathbf{Q}_1 = 0$. The total diffuse dimension of this model, $(k + d)$, is $9 = 1 + 8$ as a result of one predictor, `Q1_83_Shift`, and two fully diffuse state subsections, $\boldsymbol{\mu}_t$ and $\boldsymbol{\gamma}_t$. The components in the model are defined by suitable linear combinations of these different state subsections. The program

statements define the model as follows:

- **state error(2) type=WN cov(g);** defines ξ_t as a two-dimensional white noise, named error, with the covariance of general form. Then two COMPONENT statements define wn1 and wn2 as the first and second elements of error, respectively.
- **state level(2) type=RW cov(rank=1);** defines μ_t as a two-dimensional random walk, named level, with covariance of general form whose rank is restricted to 1. Then two COMPONENT statements define rw1 and rw2 as the first and second elements of level, respectively.
- **state season(2) type=season(length=4);** defines γ_t as a two-dimensional trigonometric seasonal of season length 4, named season, with zero covariance—signified by the absence of the COV option. Then two COMPONENT statements define s1 and s2 as appropriate linear combinations of season so that s1 represents the seasonal for f_KSI and s2 for r_KSI. Because TYPE=SEASON in the STATE statement, the COMPONENT statement appropriately interprets **component s1 = season[1];** as s1 being a dot product: $(1\ 0\ 0\ 0\ 1\ 0) * \text{season}$. See the section “Multivariate Season” on page 1802 for more information.
- **model f_KSI = Q1_83_Shift rw1 s1 wn1;** defines the model for f_KSI, and **model r_KSI = rw2 s2 wn2;** defines the model for r_KSI.

The SSM procedure fits the model and reports the parameter estimates, their approximate standard errors, and the likelihood-based goodness-of-fit measures by default. In order to output the one-step-ahead and full-sample estimates of the components in the model, you must specify an output data set in the FORECAST statement. In addition, you can use the EVAL statement to define specific linear combinations of the underlying state that should also be estimated. The statement **eval f_KSI_sa = rw1 + Q1_83_Shift;** is an example of one such linear combination. It defines f_KSI_sa, a linear combination that represents the seasonal adjustment of f_KSI. The output data set, for1, named in the FORECAST statement contains estimates of all the model components in addition to the estimate of f_KSI_sa.

The SSM procedure output begins with a factoid (not shown here) about the input data set that provides its name. Next, the model summary table, shown in Figure 27.1, provides basic model information, such as the dimension of the underlying state equation ($m = 10$), the diffuse dimension of the model ($(d + k) = 9$), and the number of parameters (5) in the model parameter vector θ . This information is very useful in determining the computational complexity of the model.

Figure 27.1 Bivariate Basic Structural Model

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	2
State Dimension	10
Dimension of the Diffuse Initial Condition	9
Number of Parameters	5

The index variable information is shown in [Figure 27.2](#). Among other things, it categorizes the data to be of regular type, which implies that the data are time series.

Figure 27.2 Index Variable Information

ID Variable Information				
Name	Start	End	MaxDelta	Type
date	1969:1	1985:4	1.00	Regular

[Figure 27.3](#) provides simple summary information about the response variables. It shows that `f_KSI` and `r_KSI` have four missing values each and no induced missing values since the predictor in the model, `Q1_83_Shift`, has no missing values.

Figure 27.3 Response Variable Summary

Response Variable Information							
Name	NObs	NMiss	Induced	Minimum	Maximum	Mean	StdDev
			NMiss				
f_KSI	68	4	0	6.16	7.09	6.71	0.21
r_KSI	68	4	0	5.56	6.41	5.97	0.19

The regression coefficient of `Q1_83_Shift`, shown in [Figure 27.4](#), is negative and is statistically significant. This is consistent with the expected drop in `f_KSI` after the enactment of the seat-belt law.

Figure 27.4 Regression Coefficient of `Q1_83_Shift`

Estimates of the Regression Parameters					
Response Variable	Regression Variable	Estimate	Approx Std Error	t Value	Approx Pr > t
f_KSI	Q1_83_Shift	-0.40836	0.02594	-15.74	<.0001

[Figure 27.5](#) shows the estimates of the elements of θ . For reporting purposes, the elements of θ are categorized as those specified by using a PARMS statement, and others are unknown elements of partially specified system matrices. In this example, no PARMS statement is used. The five parameters in θ correspond to unknown elements that are associated with the (partially) specified covariance matrices in the specifications of error and level. Whenever a covariance specification is of a general form and is not defined by a user-specified variable list, it is internally parameterized as a product of its Cholesky root: $\text{Cov} = \text{Root Root}'$. This ensures that the resulting covariance is positive semidefinite. The Cholesky root is constrained to be lower triangular, with positive diagonal elements. If rank constraints (such as the rank-one constraint on the covariance in the specification of level) are imposed, the number of free parameters in the Cholesky factor is reduced appropriately. See the section “[Covariance Parameterization](#)” on page 1804 for more information. In view of these considerations, the five parameters in θ are a result of three parameters from the Cholesky

root of error and two parameters that are associated with the Cholesky root of level.

Figure 27.5 Parameter Estimates

Maximum Likelihood Estimates of the Unknown System Parameters (Parameters Not Specified in the PARMS Statement)				
Component	Type	Parameter	Estimate	Approx Std Error
error	Disturbance Covariance	RootCov[1, 1]	0.03615	0.0073632
error	Disturbance Covariance	RootCov[2, 1]	0.03380	0.01131
error	Disturbance Covariance	RootCov[2, 2]	0.04620	0.0046973
level	Disturbance Covariance	RootCov[1, 1]	0.03752	0.0084330
level	Disturbance Covariance	RootCov[2, 1]	0.02230	0.0056906

Figure 27.6 shows the resulting covariance estimate of error after multiplying the Cholesky factors. The lower triangle (including diagonal) shows the covariances, and the upper triangle shows the correlations.

Figure 27.6 White Noise Covariance and Correlation Estimates

Estimate of the Error Covariance for the state error (covariances in the lower half and the correlations in the upper half)	
0.001307	0.590417
0.001222	0.003277

Similarly, Figure 27.7 shows the covariance estimate of level disturbance. Note that, because of the rank-one constraint, the correlation estimate is exactly equal to 1.0.

Figure 27.7 Covariance and Correlation Estimates of the Random Walk Disturbance

Estimate of the Error Covariance for the state level (covariances in the lower half and the correlations in the upper half)	
0.001408	1
0.000837	0.000497

Figure 27.8 shows the likelihood-based goodness-of-fit measures. This table is produced by using the fitted model to carry out the filtering operation on the data. You can use these goodness-of-fit measures to compare different models. The table also shows some other useful information—for example, it reports that S_{n,p_n} is of full rank (Initialized Diffuse State Elements = 9), which implies that the filtering process was successfully initialized. See the section “Likelihood Computation and Model Fitting Phase” on page 1794 for more information.

Figure 27.8 Likelihood-Based Goodness-Of-Fit Measures

Likelihood Based Fit Statistics	
Statistic	Value
Non-Missing Response Values Used	128
Estimated Parameters	5
Initialized Diffuse State Elements	9
Normalized Residual Sum of Squares	119
Full Log Likelihood	166.16
AIC (smaller is better)	-322.3
BIC (smaller is better)	-308.4
AICC (smaller is better)	-321.8
HQIC (smaller is better)	-316.7
CAIC (smaller is better)	-303.4

The output data set, `for1`, specified in the `FORECAST` statement contains one-step-ahead and full-sample estimates of all the model components and the user-specified components (defined by the `EVAL` statement). Their standard errors and the upper and lower confidence limits (by default, 95%) are also produced. In addition, `for1` contains estimates of additive-outliers—`ao_f_KSI` and `ao_r_KSI` (and their standard errors)—for `f_KSI` and `r_KSI`. The following `DATA` step adds a zero-one variable `extreme_f_KSI` to `for1`, which assigns the value 1 to observations with an unusually high or low value of `ao_f_KSI`.

```
data for1;
  set for1;
  if stderr_ao_f_KSI > 0 then
    ao_z_stat = ao_f_KSI/stderr_ao_f_KSI;
  else ao_z_stat = 0.0;
  extreme_f_KSI = (abs(ao_z_stat) > 2);
run;
```

The following statements use the `for1` data set to produce a time series plot of the seasonally adjusted `f_KSI` that highlights the additive outliers:

```
proc sgplot data=for1;
  title "Seasonally Adjusted f_KSI with 95% Confidence Band";
  band x=date lower=smoothed_lower_f_KSI_sa
    upper=smoothed_upper_f_KSI_sa ;
  series x=date y=smoothed_f_KSI_sa;
  reffline '1jan1985'd / axis=x lineattrs=(pattern=shortdash)
    LEGENDLABEL= "Start of Multi-Step Forecasts"
    name="Forecast Reference Line";
  scatter x=date y=f_KSI /group=extreme_f_KSI;
run;
```

The generated plot is shown in [Figure 27.9](#).

Figure 27.9 Plot of Seasonally Adjusted f_KSI that Highlights the Additive Outliers

The output data set, `for1`, also contains one-step-ahead residuals for f_KSI and r_KSI . You can use them for a variety of model diagnostic checks. For example, you can check the normality of the residuals by inspecting the residual-histogram. The following statements produce a residual-histogram for f_KSI :

```
proc sgplot data=for1;
  title "Residual Histogram for f_KSI: Normality Check";
  histogram residual_f_KSI;
  density residual_f_KSI/type=normal;
  density residual_f_KSI/type=kernel;
run;
```

Figure 27.10 shows the generated histogram along with the normal and kernel density estimates. It does not show any significant violation of the normality assumption.

Figure 27.10 Residual Histogram for f_KSI

Syntax: SSM Procedure

The SSM procedure uses the following statements:

```

PROC SSM < options > ;
  BY variables ;
  COMPONENT name = (variables) * state ;
  EVAL name = expression ;
  FORECAST < options > ;
  ID variable < option > ;
  IRREGULAR name < options > ;
  MODEL response = variables ;
  PARMS variables < / options > ;
  Programming statements ;
  STATE name( dim ) < options > ;
  TREND name( type ) < options > ;

```

All statements except the BY, ID, and the FORECAST statements can be used multiple times. The PROC SSM statement and at least one MODEL statement are required. In addition to these statements, you can use most DATA step programming statements to define new variables that are needed for specifying different parts of the state space model.

Functional Summary

Table 27.1 summarizes the statements and options that control the SSM procedure. Most commonly needed scenarios are listed; see the individual statements for additional details.

Table 27.1 Functional Summary

Description	Statement	Option
Data Set Options		
Specifies the input data set	PROC SSM	DATA=
Writes series and component forecasts to an output data set	FORECAST	OUT=
Model Specification		
Specifies the index variable	ID	
Defines variables as model parameters	PARMS	
Specifies a response variable and the associated observation equation	MODEL	
Specifies a state subsection	STATE	
Specifies the transition matrix of a state subsection	STATE	T
Specifies the disturbance covariance matrix of a state subsection	STATE	COV

Specifies a linear combination of components to be output	EVAL	
BY Groups		
Specifies BY group processing	BY	

PROC SSM Statement

PROC SSM *< option >* ;

The PROC SSM statement is required. The following *option* can be used in the PROC SSM statement:

DATA=SAS-data-set

specifies the name of the SAS data set that contains the variables needed for the analysis. If this option is not specified in the PROC SSM statement, the most recently created SAS data set is used.

BY Statement

BY *variables* ;

A BY statement can be used in the SSM procedure to process a data set in groups of observations that are defined by the BY variables. The model specified by using the MODEL and other statements is applied to all the groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The variables are one or more variables in the input data set.

COMPONENT Statement

COMPONENT *name* = (*var1 var2 ...*) * *state* ;

COMPONENT *name* = *state*[*integer*] ;

The COMPONENT statement specifies a component (a linear combination of state elements), named *name*. *name* can later be used as a right-hand side term in the MODEL statement, which defines the observation equation. Its estimate is output to the OUT= data set that is specified in the FORECAST statement.

The first form of the COMPONENT statement defines a component as a dot product of a state subsection *state* and a row vector (*var1 var2 ...*). The value of *state* must be the name of a state subsection defined by using a STATE statement elsewhere in the program. The row vector (*var1 var2 ...*), either a list of numbers or a list of variables, must be of the same dimension as the state subsection defined by *state*. This form—also called the explicit dot product form—of the component specification is unambiguous; however, it requires detailed knowledge of the state vector underlying the *state* specification. Suppose *state0* is a two-dimensional state defined by a STATE statement elsewhere in the program and *X1* and *X2* are (numeric) predictor variables. The following are valid examples of the dot product form of the COMPONENT statement:

```
component c1 = (x1 x2) * state0;
component c2 = (1 1) * state0;
```

The second form of the COMPONENT statement is a shortened version of the first form; it defines the component as a particular element of *state*—for example, *state*[3] defines the component as the third element of *state*. The specified *integer* must lie between 1 and *dim*, the dimension of *state*. The second form of component specification has another important use when the STATE statement that defines *state* uses the TYPE= option to set its type. In this case the second form of the component specification assumes additional meaning for the types LL, SEASON, and CYCLE. For example, if *state* is a three-dimensional seasonal component, *state*[2] signifies an appropriate linear combination of *state* that results in the second of the three seasonals that constitute the three-dimensional seasonal. Similar interpretation holds for the types LL and CYCLE. See the sections “Multivariate Season” on page 1802 and “Predefined Structural Models” on page 1799 for more information.

EVAL Statement

EVAL *name* = *number1***variable1* + *number2***variable2* + ... ;

The EVAL statement defines a linear combination, named *name*, of the right-hand side terms used in a MODEL statement. Any variables (for example, predictor variables and names of components) can be used in the expression of the EVAL statement; however, any observation disturbances defined by the IR-REGULAR statement cannot be used in this expression. Suppose C1 and C2 are two components (defined by COMPONENT statements elsewhere in the program), T1 is a trend component, and X1 is a regression variable used in a model. The following are valid examples of the EVAL statement:

```
eval e1 = c1 - c2;
eval e2 = t1 + c1 + x1;
eval e2 = t1 + 2*c1 - 1.5*x1;
```

The estimates of linear combinations defined by the EVAL statement (for example, E1, E2, and E3) are output to the OUT= data set that is specified in the FORECAST statement.

FORECAST Statement

FORECAST < *options* > ;

The FORECAST statement specifies an output data set to store the estimates of the model components and series forecasts.

ALPHA=*number*

specifies the significance level of the forecast confidence intervals. For example, ALPHA=0.05, which is the default, results in a 95% confidence interval.

OUT=*SAS-data-set*

specifies an output data set for the forecasts. The output data set contains the ID variable (if specified), the response variables, the one-step-ahead and out-of-sample response variable forecasts, the forecast confidence intervals, the smoothed values of the response series, and the one-step-ahead and smoothed

estimates of the model components—including expressions defined by using the EVAL statement. See the section “[OUT= Data Set](#)” on page 1808 for more information.

ID Statement

ID *variable* < *option* > ;

The ID statement names a numeric variable to associate a sequence value—usually related to a time stamp—to the observations in the input data set. The observations within a BY group must be ordered in ascending order by the ID variable. Often the ID variable’s values are SAS date, time, or datetime values, and each observation within a BY group has a unique ID value. Generally, however, the ID variable can be any numeric variable, and there can be multiple observations with the same ID value. If the ID values are SAS date, time, or datetime values, you can specify the frequency associated with the time series by using the INTERVAL= option. If an ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID. Whenever an ID variable is specified, a variable, `_ID_DELTA_`, is automatically created that can be used as any input data set variable in the programming statements. `_ID_DELTA_` contains the distance between two successive ID values. The first `_ID_DELTA_` value is arbitrarily taken as one. If the INTERVAL= option is specified, the distance between the ID values is measured in terms of the number of intervals; therefore, for regularly spaced data, `_ID_DELTA_` is identically equal to one. The following *option* can be used in the ID statement:

INTERVAL=*value*

specifies the time interval between observations. INTERVAL=*value* is used in conjunction with the ID variable to check that the input data are in proper order. For a complete discussion of the intervals supported, see Chapter 4, “[Date Intervals, Formats, and Functions](#).”

IRREGULAR Statement

IRREGULAR *name* < *option* > ;

The IRREGULAR statement specifies a one-dimensional white noise component, which can be used to specify the observation error in a MODEL statement. The following *option* can be used in the IRREGULAR statement:

VARIANCE=*variable* | *number*

specifies the variance of the white noise. Any nonnegative value, including zero, is permissible. If the *variable* contains unknown parameters, they are estimated from the data. Similarly, if the VARIANCE= option is not specified, the variance is estimated from the data.

MODEL Statement

MODEL *response* = *variables* ;

A MODEL statement specifies an observation equation that describes a response variable as a sum of regression effects and components defined in the program. The response variable must be a numeric variable from the input data set. The variables used in the right-hand side of the model expression can be numeric variables from the input data set, numeric variables defined by using programming statements, or names of components defined by using the COMPONENT, TREND, or IRREGULAR statements.

In the case of a multivariate model, a separate MODEL statement is needed for each of the response variables. In this case, the observation errors, defined by using an IRREGULAR statement, must be different in each MODEL statement.

PARMS Statement

PARMS *variable*< =*number*> *variable*< =*number*> < / *options* > ;

The PARMS statement declares the parameters of a model and optionally sets their initial values. You can also specify the lower and upper limits of their validity range. The parameters declared by using the PARMS statement are called *named parameters* throughout this chapter. A model can have additional parameters—any unspecified quantity in the model specification becomes part of the parameter vector.

LOWER=(*number1 number2 ...*)

LOWER=(*number*)

specifies the lower bounds for the specified parameters. The list can contain exactly one number, which is taken to be the lower bound for all the listed parameters in the statement, or it must contain as many values as the number of parameters specified. A missing value, denoted by ., is a permissible value, which signifies that the parameter has no lower bound.

UPPER=(*number1 number2 ...*)

UPPER=(*number*)

specifies the upper bounds for the specified parameters. The list can contain exactly one number, which is taken to be the upper bound for all the listed parameters in the statement, or it must contain as many values as the number of parameters specified. A missing value, denoted by ., is a permissible value, which signifies that the parameter has no upper bound.

Programming Statements

To define the model, you can use most of the programming statements that are allowed in the SAS DATA step. See the *SAS Language Reference: Dictionary* for more information. The syntax of programming statements used in PROC SSM is identical to that used in the MODEL procedure (see Chapter 19, “[The MODEL Procedure](#)”) and the NLMIXED procedure (see Chapter 63, “[The NLMIXED Procedure](#)” (*SAS/STAT User’s Guide*)). There is one more restriction: the data step lagging and differencing functions are not allowed.

STATE Statement

STATE *name (dim) < options >* ;

Recall the state equations that define the state space model (see the section “The State Space Model and Notation” on page 1786):

$$\begin{aligned}\alpha_{t+1} &= \mathbf{T}_t \alpha_t + \eta_{t+1} \\ \alpha_1 &= \mathbf{A}_1 \delta + \eta_1\end{aligned}$$

A STATE statement specifies a subsection of the overall state vector α_t . You can specify multiple STATE statements, each specifying a separate subsection. It is assumed that the subsections specified by using different STATE statements are mutually independent. This independence assumption implies a block-diagonal structure for the transition matrices \mathbf{T}_t and the disturbance covariances \mathbf{Q}_t for all $t \geq 1$. An appropriate block structure also applies to \mathbf{A}_1 . The *options* in the STATE statement provide complete control over the description of the relevant blocks of \mathbf{T}_t , \mathbf{Q}_t , and \mathbf{A}_1 . Generally, the argument *dim*—a positive integer in *name (dim)*—specifies the dimension of this subsection. However, when the **TYPE=** option is used, the meaning of *dim* is different. The **TYPE=** option simplifies the state specification task for some commonly needed models.

You can use the following *options* in the STATE statement to specify the system matrices \mathbf{T}_t , \mathbf{Q}_t , and \mathbf{A}_1 :

A1(nd)

specifies that the last *nd* elements of the state subsection should be treated as diffuse, which becomes the dimension of the relevant subsection of the diffuse vector δ . The \mathbf{A}_1 block is created by using appropriate columns of the identity matrix. *nd* must lie between one and *dim*. The absence of this option signifies that this subsection of α_t is nondiffuse. If both **COV1** and A1 options are specified, the last *nd* rows and columns of the matrix specified in **COV1** are taken to be zero. This option cannot be used together with the **RANK=** option of the **COV1** option.

COV(D) <= (var1 var2 ...) | (number1 number2 ...) >

COV(G) <= (var1 var2 ...) | (number1 number2 ...) >

COV(I) <= (variable) | (number) >

COV(RANK=integer)

specifies the relevant block of the disturbance covariance \mathbf{Q}_t (for $t \geq 2$) in the transition equation. Similar to the **T** option, the absence of this option signifies that this Q-block consists of only zeros. The structure of the Q-block is also similarly specified. However, the following differences exist:

- The list specified to form the covariance must result in a symmetric, positive semidefinite matrix. For an example, see [Example 27.4](#).
- You can specify a rank constraint on the Q-block by specifying **COV(RANK=integer)**, where the specified integer must lie between 1 and *dim*. A rank constraint is permissible only for the general form, and only when its elements are not specified by using a list.
- The convention of treating unset variables as structural zeros, used in specifying sparsity of the T-block, is not used in the Q-block specification. Whenever you explicitly specify the entries of

the Q-block by specifying a list of variables in parentheses, all variables in the list must evaluate to nonmissing values.

The following examples illustrate different ways of specifying a Q-block. It is assumed that $dim = 2$.

- COV(G) specifies a general form Q-block (contributes $(2 * (2 + 1))/2 = 3$ unspecified elements to the parameter vector θ).
- COV(RANK=1) specifies a rank-one Q-block.

COV1(D) <= (var1 var2 ...) | (number1 number2 ...)>

COV1(G) <= (var1 var2 ...) | (number1 number2 ...)>

COV1(I) <= (variable) | (number)>

COV1(RANK=integer)

specifies the relevant block of the initial state covariance Q_1 . The different options in this case have the same meaning as the options of the COV option. However, the following differences exist:

- If the elements of Q_1 are specified by a list of variables in parentheses, then these variables must evaluate to constant values. In particular, they can depend on parameters defined by the PARMS statements; however, they cannot depend on any of the input data columns.
- If the initial condition is partially diffuse (that is, the diffuse dimension nd specified in the A1 option is nonzero), the last nd rows and columns of the matrix specified in COV1 are taken to be zero. Moreover, if the elements of Q_1 are specified by a list, its number of elements must correspond to a matrix of dimension $(dim - nd)$.

T(D) <= (var1 var2 ...) | (number1 number2 ...)>

T(G) <= (var1 var2 ...) | (number1 number2 ...)>

T(I) <= (variable) | (number)>

specifies the relevant block of the transition matrix T_t . The absence of this option signifies that this block consists of only zeros. You can specify the structure of the T-block by specifying T(I) for the identity form, T(D) for the diagonal form, and T(G) for a general unstructured form. In addition, you can explicitly specify the entries of the T-block by specifying a list of numbers in parentheses, or by specifying in parentheses a list of variables that are defined by using the programming statements. The unspecified elements of the T-block are included in the list of parameters to be estimated from the data. If the elements of the T-block are supplied by a list in parentheses, the number of elements in the list depends on its structure. For the diagonal form, the list must contain exactly dim elements. In the case of the identity form—T(I)—the block is already fully specified; however, a specification $T(I)=(variable)$ is understood to mean that the identity block is scaled by the specified *variable* (or a *number*). In the general case—T(G)—the list must consist of $dim * dim$ elements, specified in a rowwise fashion. An inappropriate number of elements in the list results in a syntax error.

The following examples illustrate different ways of specifying the transition matrix. It is assumed that $dim = 2$.

- T(I) specifies that the T-block is a two-dimensional identity matrix.
- T(D) specifies that the T-block is a two-dimensional diagonal matrix. The two unspecified diagonal entries become part of the parameter vector θ .

- $T(D)=(1.1\ 2)$ fully specifies the two-dimensional diagonal T-block.
- $T(D)=(X_1\ X_2)$ specifies a two-dimensional diagonal T-block where the diagonal elements are dynamically calculated based on the values of the variables X_1 and X_2 . In this case the T-block can change with time if X_1 or X_2 change with time.
- $T(G)$ specifies a general form T-block (with $2^2 = 4$ unspecified elements).
- $T(G)=(X_1\ X_2\ X_3\ X_4)$ specifies a general form T-block where the first row is formed by X_1 and X_2 , and the second row is formed by X_3 and X_4 .

In practice the transition matrix is often sparse—that is, many of its elements are zero. The algorithms in the SSM procedure exploit this sparsity structure for computational efficiency. Whenever you explicitly specify the entries of the T-block by specifying a list of variables in parentheses, you can leave the variables that correspond to the zero elements *unset*. These unset variables are treated as structural zeros by the SSM procedure. The section “[Sparse Transition Matrix Specification](#)” on page 1791 further explains how to use this sparsity convention.

TYPE=WN

TYPE=RW

TYPE=LL (SLOPECOV(I | D | G) <= (var1, var2, ...) | (number1, number2, ...) >)

TYPE=LL (SLOPECOV(RANK=*integer*))

TYPE=SEASON(LENGTH=*integer*)

TYPE=CYCLE <(<CT> <RHO=*variable* | *number*> <PERIOD=*variable* | *number*>)>

specifies a state subsection that corresponds to the specified type. You can specify either a number or a variable for the RHO= and PERIOD= suboptions. The **T**, **COV1**, and **A1** options are not needed. In fact they are ignored, since the transition matrix T_t and the matrices in the initial condition (Q_1 and A_1) are implicitly defined by the choice of the type. However, the specification of the **COV** option does play a key role in the eventual form of Q_t —the covariance of the disturbance term in the transition equation. For the types LL, SEASON, and CYCLE, the dimension of the resulting state subsection is a certain multiple of *dim*, the dimension in the STATE statement. For example, the following specification results in a state subsection, named `cycleState`, of dimension $2*dim$:

```
state cycleState(dim) cov(g) type=cycle;
```

The name `cycleState` corresponds to the state underlying a *dim*-dimensional cycle component. All of these special state types require that the data be regular; the only exception is **TYPE=CYCLE(CT)**, which defines a continuous-time cycle and is applicable to any data type. [Table 27.2](#) summarizes some of this information for easy reference. Additional details about these state types are provided in the section “[Predefined Structural Models](#)” on page 1799.

The **TYPE=LL** specification results in a state that corresponds to a multivariate local linear trend. It is governed by two covariance matrices: the **COV** option specifies the covariance that corresponds to the level equation, and the **SLOPECOV** suboption specifies the covariance used in the slope equation. The form of the **SLOPECOV** suboption is exactly the same as that of the **COV** option.

The **TYPE=CYCLE** option results in a state that corresponds to a (stochastic) cycle. By default, this cycle is assumed to be for the regular data type. If **TYPE=CYCLE(CT)**, the resulting cycle is applicable to any data type. The CT option is available only for $dim = 1$; that is, only a univariate cycle is available for the irregular data type. The cycle specification depends on a covariance matrix

and two numbers: the damping factor **RHO** and the cycle period **PERIOD**. The covariance can be specified by the **COV** option. The damping factor is specified by the **RHO=** suboption; its value must lie between 0.0 and 1.0. The cycle period can be specified by the **PERIOD=** suboption. If the **CT** option is not included, the period value must be larger than 2.0. On the other hand, if the **CT** option is included, its value must be strictly positive. If these parameters are not specified, they are estimated from the data.

Table 27.2 Summary of Predefined State Types

Type	Description	Parameters	State Dimension
WN	<i>dim</i> -variate white noise	COV	<i>dim</i>
RW	<i>dim</i> -variate random walk	COV	<i>dim</i>
LL	<i>dim</i> -variate local linear	COV , SLOPECOV	$2 * dim$
SEASON(LENGTH=length)	<i>dim</i> -variate season	COV	$(length - 1) * dim$
CYCLE	<i>dim</i> -variate cycle	COV , RHO , PERIOD	$2 * dim$

TREND Statement

TREND *name* (*type*) < *options* > ;

The **TREND** statement defines a trend term in the model. Loosely speaking, a trend is a special type of component that captures the time-varying level of the data. The *options* in the **TREND** statement enable you to specify a wide variety of commonly used trend patterns. Each **TREND** specification in effect stands for a special pair of **STATE** and **COMPONENT** statements. You can specify more than one **TREND** specification. Each separate trend specification defines a component that is assumed to be independent of all other component specifications in the model.

Some of these trend specifications are applicable to all the data types—that is, they can be used for regular data types in addition to irregular data types, while the others require that the data be regular or regular-with-replication. Of course, the trend specification is only a part of the overall model specification. Therefore, the other parts of the model can imply additional constraints on the data type.

Table 27.3 lists the available trend models and their data requirements. The “type” column shows the admissible keywords that signify the particular trend type. For brevity, the “Data Type” column in Table 27.3 groups the regular and regular-with-replication data types into one category—regular. The section “Predefined Trend Models” on page 1797 provides additional details about these trend models.

Table 27.3 Summary of Trend Types

<i>type</i>	Data Type	Description	Parameters
RW	Regular	Random walk	Level σ^2
LL	Regular	Local linear	Level and slope σ_1^2, σ_2^2
DLL	Regular	Damped local linear	Level and slope σ_1^2, σ_2^2 , damping factor ϕ
PS(<i>order</i>)	Irregular	Polynomial spline of order up to 3	Level σ^2
DECAY	Irregular	A type of decay pattern	Level σ^2 , decay rate ϕ
DECAY(<i>OU</i>)	Irregular	Ornstein-Uhlenbeck decay pattern	Level σ^2 , decay rate ϕ
GROWTH	Irregular	A type of growth pattern	Level σ^2 , growth rate ϕ
GROWTH(<i>OU</i>)	Irregular	Ornstein-Uhlenbeck growth pattern	Level σ^2 , growth rate ϕ

The following example specifies polySpline as a trend of type polynomial spline of order 2:

```
trend polySpline(ps(2));
```

Similarly, the following statement defines dampedTrend as a damped local linear trend:

```
trend dampedTrend(dll) slopevar=x;
```

The variance parameter that governs the slope equation of this trend type is given by a variable *x*, which must be defined elsewhere in the program. The other parameters that define dampedTrend are left unspecified.

You can specify the following *options* in the TREND statement to specify the trend parameters. In addition, you can create a custom combination of given trend type by specifying the CROSS= option to create a more general trend. For an example of the use of CROSS= option, see the discussion of the second model in [Example 27.3](#).

CROSS=(var1, var2, ...)

creates a linear combination of one or more independent trend components based on the variables in the list. If the parameters of the trend are specified by options such as the LEVELVAR= option or the PHI= option, these parameters are shared by these constituent trends. For example, suppose that the CROSS= list contains two variables (X_1 and X_2) and the trend specification is of the type RW. The effect of CROSS=(X_1, X_2) is to create a component $\mu_t = X_1\mu_{1,t} + X_2\mu_{2,t}$ where $\mu_{1,t}$ and $\mu_{2,t}$ are two independent random walk trends. Moreover, if the random walk trend specification uses the LEVELVAR= option to specify the variance parameter, $\mu_{1,t}$ and $\mu_{2,t}$ share the same variance parameter; otherwise, two separate variance parameters are assigned to these random walks. The CROSS= option is useful for a variety of situations. For example, suppose X is an indicator variable that is 1 before certain time point t_0 and 0 thereafter; CROSS=(X) has the effect of turning off the trend component after time t_0 . Similarly, suppose G_1 and G_2 are indicators for gender—for example, $G_1 = (\text{GENDER}=\text{"M"})$ and $G_2 = (\text{GENDER}=\text{"F"})$. Then CROSS=(G_1, G_2) creates a trend that varies with the gender of the observation. The variables in the CROSS= list must be free of unknown parameters.

The CROSS= option can be computationally expensive; computationally it is equivalent to specifying as many separate trends as the number of variables in the specified list.

LEVELVAR=*variable* | *number*

specifies the disturbance variance parameter for all the trend types. For trend types LL and DLL, this option specifies σ_1^2 . Any nonnegative value, including zero, is permissible. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the LEVELVAR= option is not specified, σ^2 is estimated from the data.

PHI=*variable* | *number*

specifies the value of ϕ for trend types DLL, DECAY, DECAY(OU), GROWTH, and GROWTH(OU). For the type DLL, the specified value must be between 0.0 and 1.0. For types DECAY and DECAY(OU), ϕ must be strictly negative. For types GROWTH and GROWTH(OU), ϕ must be strictly positive. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the PHI= option is not specified, ϕ is estimated from the data.

SLOPEVAR=*variable* | *number*

specifies the second disturbance variance parameter, σ_2^2 , for trend types LL and DLL. Any nonnegative value, including zero, is permissible. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the SLOPEVAR= option is not specified, σ_2^2 is estimated from the data.

Details

Throughout this section, vectors and matrices are denoted by bold-faced letters. Generally, Greek letters (such as α , β , and ϵ) denote unobserved or latent quantities—often estimated by using the data—that represent model parameters, latent states, or noise variables. Letters such as X , Y , and Z are used to denote the observed data variables. Whenever it is unambiguous, it is assumed that the matrices have appropriate dimensions when they are being multiplied—in particular, the vectors behave as column-vectors or row-vectors as the need arises. On many occasions, matrices are described in-line—that is, they are described as parenthesized lists, in a rowwise fashion, with the rows separated by a comma. The term “dot product” is used to describe the scalar that results from the product of a row-vector with a (conforming) column vector.

The State Space Model and Notation

The (linear) state space model is described in the literature in a few different ways and with varying degree of generality. The description given in this section loosely follows the description given in Durbin and Koopman (2001) (chap. 6, sec. 4). This formulation of SSM is quite general; in particular, it includes nonstationary SSMs with time-varying system matrices and state equations with diffuse initial condition (precise definitions of these terms are given later in this subsection).

Suppose that observations are collected in a sequential fashion (indexed by a numeric variable τ) on some variables: vector $\mathbf{y} = (y_1, y_2, \dots, y_q)$, which denotes the q -variate response values, and the k -dimensional vector \mathbf{x} , which denotes the predictors. Suppose that the observation instances are $\tau_1 < \tau_2 < \dots < \tau_n$. The possibility that multiple observations are taken at a particular instance τ_i is not ruled out, and the successive observation instances need not be regularly spaced—that is, $(\tau_2 - \tau_1)$ need not equal $(\tau_3 - \tau_2)$. For $t = 1, 2, \dots, n$, suppose $p_t (\geq 1)$ denotes the number of observations recorded at instance τ_t . For

notational simplicity, an integer-valued secondary index t is used to index the data so that $t = 1$ corresponds to $\tau = \tau_1$, $t = 2$ corresponds to $\tau = \tau_2$, and so on. Consider the following model:

$$\begin{aligned} \mathbf{Y}_t &= \mathbf{Z}_t \boldsymbol{\alpha}_t + \mathbf{X}_t \boldsymbol{\beta} + \boldsymbol{\epsilon}_t && \text{Observation equation} \\ \boldsymbol{\alpha}_{t+1} &= \mathbf{T}_t \boldsymbol{\alpha}_t + \boldsymbol{\eta}_{t+1} && \text{State transition equation} \\ \boldsymbol{\alpha}_1 &= \mathbf{A}_1 \boldsymbol{\delta} + \boldsymbol{\eta}_1 && \text{Initial condition} \end{aligned}$$

The following list describes these equations:

- The *observation equation* describes the relationship between the $(q * p_t)$ -dimensional response vector \mathbf{Y}_t and the unobserved vectors $\boldsymbol{\alpha}_t$, $\boldsymbol{\beta}$, and $\boldsymbol{\epsilon}_t$. The q -variate responses are vertically stacked in a column to form this $(q * p_t)$ -dimensional response vector \mathbf{Y}_t . The m -dimensional vectors $\boldsymbol{\alpha}_t$ are called *states*, the k -dimensional vector $\boldsymbol{\beta}$ is the regression vector associated with predictors \mathbf{x} , and the $(q * p_t)$ -dimensional vectors $\boldsymbol{\epsilon}_t$ are called the *observation disturbances*. The matrices \mathbf{Z}_t (of dimension $(q * p_t) \times m$) and \mathbf{X}_t (of dimension $(q * p_t) \times k$) correspond to the *state effect* and the *regression effect*, respectively. The elements of \mathbf{X}_t are assumed to be fully known. The states $\boldsymbol{\alpha}_t$ and the disturbances $\boldsymbol{\epsilon}_t$ are *random* sequences. It is assumed that $\boldsymbol{\epsilon}_t$ is a sequence of independent, zero-mean, Gaussian random vectors with diagonal covariances, with the diagonal elements denoted by $\sigma_{t,i}^2, i = 1, 2, \dots, q * p_t$.
- The state sequence $\boldsymbol{\alpha}_t$ is assumed to follow a Markovian structure described by the *state transition equation* and the associated *initial condition*.
- The state transition equation postulates that a new instance of the state, $\boldsymbol{\alpha}_{t+1}$, is obtained by multiplying its previous instance, $\boldsymbol{\alpha}_t$, by an m -dimensional square matrix \mathbf{T}_t (called the state transition matrix) and by adding a random disturbance vector $\boldsymbol{\eta}_{t+1}$. The m -dimensional state disturbance vectors $\boldsymbol{\eta}_t$ are assumed to be independent, zero-mean, Gaussian random vectors with covariances \mathbf{Q}_t (not necessarily diagonal).
- The initial condition describes the starting condition of the state evolution equation. The starting state vector $\boldsymbol{\alpha}_1$ is assumed to be partially diffuse: it is the sum of a mean-zero Gaussian vector $\boldsymbol{\eta}_1$ and a term $\mathbf{A}_1 \boldsymbol{\delta}$ that represents the contribution from a d -dimensional diffuse vector $\boldsymbol{\delta}$ (a diffuse vector is a Gaussian vector with infinite covariance). The $m \times d$ matrix \mathbf{A}_1 is assumed to be completely known.
- The observation disturbances $\boldsymbol{\epsilon}_t$ and the state disturbances $\boldsymbol{\eta}_t$ (for $t \geq 1$) are assumed to be mutually independent. Either the elements of the matrices \mathbf{Z}_t , \mathbf{T}_t , and \mathbf{Q}_t and the diagonal elements of the observation disturbance covariances $\sigma_{t,i}^2$ are assumed to be completely known, or some of them can be functions of a small set of unknown parameters (to be estimated from the data). Suppose that this unknown set of parameters is denoted by $\boldsymbol{\theta}$.

Although this description of the state space model might appear involved, it conveniently covers many variants of the SSMs encountered in practice and precisely describes the most general case that can be handled by the SSM procedure. An important restriction to note about the preceding description of the model formulation is that it assumes that the matrices \mathbf{X}_t that appear in the observation equation are free of unknown parameters and that the covariances of the observation disturbances $\boldsymbol{\epsilon}_t$ are *diagonal*. In most practical situations, the model under consideration can be easily reformulated to a statistically equivalent form that conforms to this restriction.

For easy reference, [Table 27.4](#) summarizes the information contained in the SSM equations.

Table 27.4 State Space Model: Notation

$\tau_1, \tau_2, \dots, \tau_n$	Distinct index values at which the observations are recorded
n	Number of distinct index instances
p_t	Number of observations recorded at index τ_t , $t = 1, 2, \dots, n$
q	Number of response variables in the model
$\mathbf{Y}_t = (y_{t,1}, y_{t,2}, \dots, y_{t,q \times p_t})$	Vertically stacked vector of response values recorded at τ_t
$N = q * \sum_{t=1}^n p_t$	Total number of response values in the data set
k	Number of predictor (regressor) variables in the observation equation
\mathbf{X}_t	$(q * p_t) \times k$ matrix of predictor values recorded at τ_t
$\boldsymbol{\beta}$	k -dimensional regression vector associated with the predictors
$\boldsymbol{\epsilon}_t \sim N(0, (\sigma_{t,1}^2, \dots))$	$(q * p_t)$ -dimensional observation disturbance vector with diagonal covariance
m	Dimension of the state vectors $\boldsymbol{\alpha}_t$
$\boldsymbol{\alpha}_t$	m -dimensional state vector
\mathbf{Z}_t	$(q * p_t) \times m$ matrix associated with $\boldsymbol{\alpha}_t$ in the observation equation
\mathbf{T}_t	$m \times m$ state transition matrix
$\boldsymbol{\eta}_t \sim N(0, \mathbf{Q}_t)$	m -dimensional state disturbance vector
d	Dimension of the diffuse vector $\boldsymbol{\delta}$ in the state initial condition
$\boldsymbol{\delta} \sim N(0, \kappa \Sigma), \kappa \rightarrow \infty$	Diffuse vector in the state initial condition
\mathbf{A}_1	$m \times d$ constant matrix associated with $\boldsymbol{\delta}$
$\boldsymbol{\eta}_1 \sim N(0, \mathbf{Q}_1)$	m -dimensional state disturbance vector in the initial condition
$\boldsymbol{\theta}$	Parameter vector

Types of Data Organization

The state space model specification in the SSM procedure requires proper understanding of both the data organization and the form of the model. The SSMs that are appropriate for time series data might not be appropriate for irregularly spaced longitudinal data. The SSM procedure distinguishes three types of data organization based on the way the observations are sequenced by the index variable. If an index variable is not specified, it is assumed that the observations are sequenced according to the observation number.

Regular: The observations are recorded at regularly spaced intervals; that is, $\tau_1, \tau_2, \dots, \tau_n$ are regularly spaced. Moreover, at each observation instance τ_i a single observation is recorded; that is, $p_t = 1$ for all t . The standard time series data (both univariate and multivariate) fall in this category.

Regular with Replication: The observations are recorded at regularly spaced intervals, but $p_t > 1$ for at least one t . Here the word replication is used loosely—it does not mean that the multiple observations at τ_t are replications in the precise statistical sense. The panel or cross-sectional data types fall into this category. In the panel data case with p cross-sections, $p_t = p$ for all t .

Irregular: The observations are not recorded at regular intervals, and the number of observations p_t at each index instance can be different. The longitudinal data fall into this category.

It is not always easy to decide whether the specified model is appropriate for the given data type. Whenever possible, the SSM procedure issues a note regarding the possible mismatch between the specified model and the data type being analyzed.

Overview of Model Specification Syntax

An SSM specification involves the description of the terms in the observation equation, the state transition equation, and the initial condition. For example, the response variables, the predictor variables, and the elements of the state transition matrix \mathbf{T}_t must somehow be specified. The SSM procedure syntax is designed so that little effort is needed to specify the more commonly needed models, while a highly flexible language is available for specifying more complex models. Two syntax features help achieve this goal: the ability to build a complex specification by combining simpler subspecifications, and a programming language for creating lists of variables to be used later in the model specification.

The SSM procedure statements can be divided into two classes:

- **programming statements**, which are used to create lists of variables that can be used for a variety of purposes (for example, as the elements of the model system matrices)
- statements specific to the SSM procedure that formulate the state space model and control its other aspects such as the input data specification and the resulting output

Since the matrices involved in the model specification can be specified as lists of variables, which you separately create by using the programming statements, you can finely control all aspects of the model specification. These programming statements permit the use of most DATA step language features such as the conditional logic (IF-THEN-ELSE), ARRAY type variables, and all the mathematical functions available in the DATA step. You can also use programming statements to define predictor variables on the fly.

Building a Complex Model Specification

In addition to being able to specify the system matrices in a flexible way, you can also build a complex model specification in a modular way by combining simpler subspecifications. Suppose that the state vector for the model to be specified is composed of subsections that are statistically independent, which is a common scenario in practical modeling situations. For example, suppose that $\boldsymbol{\alpha}_t$ can be divided into two disjoint subsections $\boldsymbol{\alpha}_t^a$ and $\boldsymbol{\alpha}_t^b$, which are statistically independent. This entails a corresponding block-diagonal structure to the system matrices \mathbf{T}_t and \mathbf{Q}_t that govern the state equations. In this case the term $\mathbf{Z}_t \boldsymbol{\alpha}_t$ that appears in the observation equation also splits into the sum $\mathbf{Z}_t^a \boldsymbol{\alpha}_t^a + \mathbf{Z}_t^b \boldsymbol{\alpha}_t^b$ for appropriately partitioned matrices \mathbf{Z}_t^a and \mathbf{Z}_t^b . The model specification syntax of the SSM procedure makes building an SSM from such smaller pieces easy. Throughout this chapter, the linear combinations of the state subsections (such as $\mathbf{Z}_t^a \boldsymbol{\alpha}_t^a$) that appear in the observation equation are called *components*. An SSM specification in the SSM procedure is created by combining separate component specifications. In general, you specify a component in two steps: first you define a state subsection $\boldsymbol{\alpha}_t^a$ and then you define a matching linear combination $\mathbf{Z}_t^a \boldsymbol{\alpha}_t^a$. For some special components, such as some commonly needed *trend* components, you can combine these two steps into one keyword specification.

The following list summarizes the (nonprogramming) SSM procedure syntax statements used for model specification:

- The **ID** statement specifies the index variable (τ). It is assumed that the data within each BY group are ordered (in ascending order) according to the ID variable. The SSM procedure automatically

creates a variable, `_ID_DELTA_`, which contains the difference between the successive ID values. This variable is available for use by the programming statements to define time-varying system matrices. For example, in the case of SSMs used for modeling the longitudinal data, the T_t and Q_t matrices often depend on `_ID_DELTA_` (see [Example 27.4](#)).

- The **PARMS** statement specifies variables that serve as the parameters of the model. That is, it partially defines the model parameter vector θ . Other elements of θ are implicitly defined if your specification of the system matrices is not fully complete.
- The **STATE** statement specifies a subsection of the model state vector. Multiple STATE statements can be used in the model specification; each one defines a statistically independent subsection of the model state vector. For full customization, T_t and Q_t blocks that govern this subsection can be specified as lists of variables created by programming statements. However, you can obtain many commonly needed state subsection types simply by using the TYPE= option in this statement. For example, the use of TYPE=SEASON(LENGTH=12) results in a state subsection that can be used to define a monthly seasonal component.
- The **COMPONENT** statement specifies a linear combination that matches a state subsection previously defined by using a STATE statement. Thus, a matching pair of STATE and COMPONENT statements define a component.
- The **TREND** statement is used for easy specification of some commonly needed trend components.
- The **IRREGULAR** statement specifies the observation disturbance for a particular response variable.
- The **MODEL** statement specifies the observation equation for one of the response variables. A separate MODEL statement is needed for each response variable in the multivariate case. The MODEL statement specifies an equation in which the left-hand side is the response variable and the right-hand side is a list that contains components and regression variables.

Model Specification Steps

To illustrate the model specification steps, suppose y is a response variable and variables x_1 and x_2 are predictors. The following statements specify a model for y that includes two components named `cycle` and `randomWalk`, predictors x_1 and x_2 , and an observation disturbance named `whiteNoise`:

```
parms lambda / lower=(1.e-6) upper=(3.14);
parms cycleVar / lower=(1.e-6);
array cycleT{4} c1-c4;
c1 = cos(lambda);
c2 = sin(lambda);
c3 = -c2;
c4 = c1;
state s_cycle(2) T(g)=(cycleT) cov(I)=(cycleVar) a1(2);
component cycle=(1 0)*s_cycle;
trend randomWalk(rw);
irregular whiteNoise;
model y = x1 x2 randomWalk cycle whiteNoise;
```

The specification begins with a PARMS statement that defines two parameters, `lambda` and `cycleVar`, along with their lower and upper bounds (essentially zero and π for `lambda`, and zero and infinity for `cycleVar`). Next, programming statements define an array of variables, `cycleT`, which contains four variables, `c1–c4`; these variables are used later for defining the elements of the transition matrix of a state subsection. The STATE statement specifies the two-dimensional subsection `s_cycle`; the dimension appears within the parentheses after the name (`s_cycle(2)`). The T= option specifies the transition matrix for the `s_cycle` (`T(g)=(cycleT)`); the `g` in `T(g)` signifies that the form of the T matrix is *general*. The COV= option (`cov(I)=(cycleVar)`) specifies the covariance of the state disturbance (\mathbf{Q}_t for $t \geq 2$); because of the use of `I` in `cov(I)`, the covariance is of the form scaled identity, essentially a two-dimensional diagonal matrix with both diagonal elements equal to `cycleVar`. The initial condition for `s_cycle` is completely diffuse since the A1= option, which specifies \mathbf{A}_1 , specifies that the dimension of the diffuse vector $\boldsymbol{\delta}$ is 2: `a1(2)`. In this case there is no need to specify the covariance \mathbf{Q}_1 in the initial condition. The COMPONENT statement specifies the component cycle. It specifies cycle as a dot product of two vectors—(1 0) and `s_cycle`, which merely selects the first element of `s_cycle`: `component cycle=(1 0)*s_cycle`. The TREND statement defines a component named `randomWalk`; its type is `rw`, which signifies random walk. The IRREGULAR statement defines an observation disturbance named `whiteNoise`. Both the `randomWalk` and `whiteNoise` specifications are only partially complete—for example, the disturbance variance of `whiteNoise` is not specified. These unspecified variances, `trendVar`, which corresponds to `randomWalk`, and `wnVar`, which corresponds to `whiteNoise`, are automatically included in the list of unknown parameters, $\boldsymbol{\theta}$, along with the parameters defined by the PARMS statements. Thus, the parameter vector for this model is $\boldsymbol{\theta} = (\text{lambda } \text{cycleVar } \text{trendVar } \text{wnVar})$. Finally, the model specification is completed by the MODEL statement, which specifies the components of the observation equation: the response variable `y`, the predictors `x1` and `x2`, the components `randomWalk` and `cycle`, and the irregular term `whiteNoise`.

The preceding statements result in an SSM with a three-dimensional state vector, which is the result of combining the two-dimensional state subsection, `s_cycle`, and a one-dimensional subsection underlying the trend, `randomWalk`. In this specification, the initial state is completely diffuse with \mathbf{Q}_1 a null matrix, and \mathbf{A}_1 equal to the three-dimensional identity. The other state system matrices \mathbf{T}_t and \mathbf{Q}_t are time-invariant:

$$\mathbf{T} = \begin{bmatrix} \cos(\text{lambda}) & \sin(\text{lambda}) & 0 \\ -\sin(\text{lambda}) & \cos(\text{lambda}) & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad \mathbf{Q} = \begin{bmatrix} \text{cycleVar} & 0 & 0 \\ 0 & \text{cycleVar} & 0 \\ 0 & 0 & \text{trendVar} \end{bmatrix}$$

The observation equation is obvious with $\mathbf{Z} = [1 \ 0 \ 1]$.

Sparse Transition Matrix Specification

It often happens that the transition matrix \mathbf{T} (or \mathbf{T}_t in the time time-varying case) specified in a STATE statement is sparse—that is, many of its elements are zero. The algorithms in the SSM procedure exploit this sparsity for computational efficiency. In most cases the sparsity of a T-block can be inferred from the context. However, if the elements of the T-block are supplied by a list of variables in parentheses, it can be difficult to recognize elements that are structurally zero (this is because of the generality of the DATA step language used for defining the variables). In order to simplify the specification of such sparse transition matrix, SSM procedure has adopted a convention: the variables that correspond to structural zeros can (and should) be left *unset*—that is, these variables are declared, but no value is assigned to them. As an example, suppose that a three-dimensional state subsection has the following form of transition matrix for

some variables X1, X2, and X3 defined elsewhere in the program:

$$\mathbf{T} = \begin{bmatrix} X1 & 0 & 0 \\ X2 & X1 & 0 \\ X3 & 0 & X1 \end{bmatrix}$$

The following (incomplete) statements show how to specify such a T-block:

```
array tMat{3,3};
do i=1 to 3;
    tMat[i, i] = x1;
end;
tMat[2,1] = x2;
tMat[3,1] = x3;
state foo(3) T(g)=(tMat) ...;
```

In this specification only the nonzero elements of the tMat array, which contains $3 \times 3 = 9$ elements, are assigned a value. On the other hand, the following statements show an alternate way of specifying the same T-block. This specification explicitly sets the zeros in the T-block (the elements above the diagonal and tMat[3,2]) to zero.

```
array tMat{3,3};
do i=1 to 3;
    do j=1 to 3;
        if i=j then tMat[i, j] = x1;
        else if j > i then tMat[i, j] = 0;
    end;
end;
tMat[2,1] = x2;
tMat[3,1] = x3;
tMat[3,2] = 0;
state foo(3) T(g)=(tMat) ...;
```

The first specification is simpler, and is preferred. The second specification is mathematically equivalent (and generates the same output) but computationally less efficient since its sparsity structure cannot always be reliably inferred due to the generality of the DATA step language. In the first specification, the unset elements are recognized to be *structural* zeros while the set elements are treated as nonzero for sparsity purposes. See [Example 27.4](#) for a simple illustration. Proper sparsity specification can lead to significant computational savings for larger matrices.

Likelihood, Filtering, and Smoothing

The Kalman filter and smoother (KFS) algorithm is the main computational tool for using SSM for data analysis. This subsection briefly describes the basic quantities generated by this algorithm and their relationship to the output generated by the SSM procedure. For proper treatment of SSMs with a diffuse initial condition or when regression variables are present, a modified version of the traditional KFS, called *diffuse* Kalman filter and smoother (DKFS), is needed. A good discussion of the different variants of the traditional

and diffuse KFS can be found in Durbin and Koopman (2001). The DKFS implemented in the SSM procedure closely follows the treatment in de Jong and Chu-Chun-Lin (2003). Additional details can be found in these references.

The state space model equations (see the section “[The State Space Model and Notation](#)” on page 1786) imply that the combined response data vector $\mathbf{Y} = (\mathbf{Y}_1, \mathbf{Y}_2, \dots, \mathbf{Y}_n)$ has a Gaussian probability distribution. This probability distribution is *proper* if d , the dimension of the diffuse vector $\boldsymbol{\delta}$ in the initial condition, is zero and if k , the number of regression variables in the observation equation, is also zero (the regression parameter $\boldsymbol{\beta}$ is also treated as a diffuse vector). Otherwise, this probability distribution is *improper*. The KFS algorithm is a combination of two iterative phases: a forward pass through the data, called *filtering*, and a backward pass through the data, called *smoothing*, that uses the quantities generated during filtering. One of the advantages of using the SSM formulation to analyze the time series data is its ability to handle the missing values in the response variables. The KFS algorithm appropriately handles the missing values in \mathbf{Y} . For additional information about how PROC SSM handles missing values, see the section “[Missing Values](#)” on page 1804.

Filtering Pass

The filtering pass sequentially computes the following quantities for $t = 1, 2, \dots, n$ and $i = 1, 2, \dots, q * p_t$:

Table 27.5 KFS: Filtering Phase

$\hat{y}_{t,i} = E(y_{t,i} y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	One-step-ahead prediction of the response values
$v_{t,i} = y_{t,i} - \hat{y}_{t,i}$	One-step-ahead prediction residuals
$F_{t,i} = \text{Var}(y_{t,i} y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	Variance of the one-step-ahead prediction
$\hat{\boldsymbol{\alpha}}_{t,i} = E(\boldsymbol{\alpha}_t y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	One-step-ahead prediction of the state vector
$\mathbf{P}_{t,i} = \text{Cov}(\boldsymbol{\alpha}_t y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	Covariance of $\hat{\boldsymbol{\alpha}}_{t,i}$
$\mathbf{b}_{t,i}$	$(d + k)$ -dimensional vector
$\mathbf{S}_{t,i}$	$(d + k)$ -dimensional symmetric matrix
$(\hat{\boldsymbol{\delta}}_{\hat{\boldsymbol{\beta}}})_{t,i} = \mathbf{S}_{t,i}^{-1} \mathbf{b}_{t,i}$	Estimate of $\boldsymbol{\delta}$ and $\boldsymbol{\beta}$ using the data up to (t, i)
$\mathbf{S}_{t,i}^{-1}$	Covariance of $(\hat{\boldsymbol{\delta}}_{\hat{\boldsymbol{\beta}}})_{t,i}$

Here the notation $E(y_{t,i} | y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$ denotes the *conditional expectation* of $y_{t,i}$ given the history up to the index $(t, i - 1)$: $(y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$. Similarly $\text{Var}(y_{t,i} | y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$ denotes the corresponding conditional variance. $v_{t,i}$ is set to missing whenever $y_{t,i}$ is missing. In the diffuse case, the conditional expectations must be appropriately interpreted. The vector $\mathbf{b}_{t,i}$ and the matrix $\mathbf{S}_{t,i}$ contain some accumulated quantities that are needed for the estimation of $\boldsymbol{\delta}$ and $\boldsymbol{\beta}$. Of course, when $(d + k) = 0$ (the nondiffuse case), these quantities are not needed. In the diffuse case, as the matrix $\mathbf{S}_{t,i}$ is sequentially accumulated (starting at $t = 1, i = 1$), it might not be invertible until some $t = t_*, i = i_*$. The filtering process is called *initialized* after $t = t_*, i = i_*$. In some situations, this initialization might not happen even after the entire sample is processed—that is, the filtering process remains *uninitialized*. This can happen if the regression variables are collinear or if the data are not sufficient to estimate the initial condition $\boldsymbol{\delta}$ for some other reason.

The filtering process is used for a variety of purposes. One important use of filtering is to compute the likelihood of the data. In the model fitting phase, the unknown model parameters $\boldsymbol{\theta}$ are estimated by max-

imum likelihood. This requires repeated evaluation of the likelihood at different trial values of θ . After θ is estimated, it is treated as a known vector. The filtering process is used again with the fitted model in the forecasting phase, when the one-step-ahead forecasts and residuals based on the fitted model are provided. In addition, this filtering output is needed by the smoothing phase to produce the full-sample component estimates.

Likelihood Computation and Model Fitting Phase

In view of the Gaussian nature of the response vector, the likelihood of \mathbf{Y} , $\mathbf{L}(\mathbf{Y}, \theta)$, can be computed by using the *prediction-error decomposition*, which leads to the formula

$$-2 \log \mathbf{L}(\mathbf{Y}, \theta) = N_0 * \log 2\pi + \sum_{t=1}^n \sum_{i=1}^{q * p_t} \left(\log F_{t,i} + \frac{v_{t,i}^2}{F_{t,i}} \right) - \log(|\mathbf{S}_{n,p_n}^{-1}| - \mathbf{b}_{n,p_n}' \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n})$$

where $N_0 = (N - k - d)$, $|\mathbf{S}_{n,p_n}^{-1}|$ denotes the determinant of \mathbf{S}_{n,p_n}^{-1} , and \mathbf{b}_{n,p_n}' denotes the transpose of the column vector \mathbf{b}_{n,p_n} . In the preceding formula, the terms associated with the missing response values $y_{t,i}$ are excluded and N denotes the total number of nonmissing response values in the sample. If \mathbf{S}_{n,p_n} is not invertible, then a generalized inverse is used in place of \mathbf{S}_{n,p_n}^{-1} , and $|\mathbf{S}_{n,p_n}^{-1}|$ is computed based on the nonzero eigenvalues of \mathbf{S}_{n,p_n} . Moreover, in this case $N_0 = N - \text{Rank}(\mathbf{S}_{n,p_n})$. When \mathbf{Y} has proper distribution (that is, when $(d + k) = 0$), the terms that involve \mathbf{S}_{n,p_n} and \mathbf{b}_{n,p_n} are absent and the preceding likelihood is proper. Otherwise, it is called the diffuse likelihood or the restricted likelihood.

When the model specification contains any unknown parameters θ , they are estimated by maximizing the preceding likelihood function. This is done by using a nonlinear optimization process that involves repeated evaluations of $\mathbf{L}(\mathbf{Y}, \theta)$ at different values of θ . The maximum likelihood (ML) estimate of θ is denoted by $\hat{\theta}$. When the restricted likelihood is used for computing $\hat{\theta}$, the estimate is called the restricted maximum likelihood (REML) estimate. Approximate standard errors of $\hat{\theta}$ are computed by taking the square root of the diagonal elements of its (approximate) covariance matrix. This covariance is computed as $-\mathbf{H}^{-1}$ where \mathbf{H} is the Hessian (the matrix of the second-order partials) of $\log \mathbf{L}(\mathbf{Y}, \theta)$, evaluated at the optimum $\hat{\theta}$.

Let $\dim(\theta)$ denote the dimension of the parameter vector θ . After the parameter estimation is completed, a table, called “Likelihood-Based Fit Statistics” is printed. It summarizes the likelihood calculations at $\hat{\theta}$. The first half of this table contains the information shown in Table 27.6.

Table 27.6 Likelihood Computation Summary

Statistic	Formula
Nonmissing response values used	N
Estimated parameters	$\dim(\theta)$
Initialized diffuse state elements	$\text{Rank}(\mathbf{S}_{n,p_n})$
Normalized residual sum of squares	$\sum_{t=1}^n \sum_{i=1}^{q * p_t} \left(\frac{v_{t,i}^2}{F_{t,i}} \right) - \mathbf{b}_{n,p_n}' \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n}$
Full log likelihood	$\log \mathbf{L}(\mathbf{Y}, \hat{\theta})$

The second half of “Likelihood-Based Fit Statistics” table reports a variety of information-based criteria, which are functions of $-2 \log \mathbf{L}(\mathbf{Y}, \hat{\theta})$, N_0 , and $\dim(\theta)$. Table 27.7 summarizes the reported information criteria in smaller-is-better form:

Table 27.7 Information Criteria

Criterion	Formula	Reference
AIC	$-2 \log \mathbf{L} + 2 \dim(\theta)$	Akaike (1974)
AICC	$-2 \log \mathbf{L} + 2 \dim(\theta) N_0 / (N_0 - \dim(\theta) - 1)$	Hurvich and Tsai (1989) Burnham and Anderson (1998)
HQIC	$-2 \log \mathbf{L} + 2 \dim(\theta) \log \log(N_0)$	Hannan and Quinn (1979)
BIC	$-2 \log \mathbf{L} + \dim(\theta) \log(N_0)$	Schwarz (1978)
CAIC	$-2 \log \mathbf{L} + \dim(\theta)(\log(N_0) + 1)$	Bozdogan (1987)

Forecasting Phase

After the model fitting phase, the filtering process is repeated again to produce the model-based one-step-ahead response variable forecasts ($\hat{y}_{t,i}$), residuals ($v_{t,i}$), and their standard errors ($\sqrt{F_{t,i}}$). In addition, one-step-ahead forecasts of the components specified in the model statements, and any other user-defined linear combination of α_t , are also produced. These forecasts are set to missing until the index $t < t_*$ (that is, until the filtering process is initialized). If the filtering process remains uninitialized, then all the one-step-ahead forecast related quantities, (such as $\hat{y}_{t,i}$ and $v_{t,i}$) are reported as missing.

Smoothing Phase

After the filtering phase of KFS produces the one-step-ahead predictions of the response variables and the underlying state vectors, the smoothing phase of KFS produces the full-sample versions of these quantities—that is, rather than using the history up to $(t, i - 1)$, the entire sample \mathbf{Y} is used. The smoothing phase of KFS is a backward algorithm, which begins at $t = n$ and $i = q * p_n$ and goes back towards $t = 1$ and $i = 1$. It produces the following quantities:

Table 27.8 KFS: Smoothing Phase

$\tilde{y}_{t,i} = E(y_{t,i} \mathbf{Y})$	Interpolated response value
$\tilde{F}_{t,i} = \text{Var}(y_{t,i} \mathbf{Y})$	Variance of the interpolated response value
$\tilde{\alpha}_t = E(\alpha_t \mathbf{Y})$	Full-sample estimate of the state vector
$\tilde{\mathbf{P}}_t = \text{Cov}(\alpha_t \mathbf{Y})$	Covariance of $\tilde{\alpha}_t$
$\begin{pmatrix} \tilde{\delta} \\ \tilde{\beta} \end{pmatrix} = \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n}$	Full-sample estimate of δ and β
\mathbf{S}_{n,p_n}^{-1}	Covariance of $\begin{pmatrix} \tilde{\delta} \\ \tilde{\beta} \end{pmatrix}$
$\text{AO}_{t,i} = y_{t,i} - E(y_{t,i} \mathbf{Y}^{t,i})$	Estimate of additive outlier
$g_{t,i}$	Variance of $\text{AO}_{t,i}$

Note that if $y_{t,i}$ is not missing, then $\tilde{y}_{t,i} = E(y_{t,i} | \mathbf{Y}) = y_{t,i}$ and $\tilde{F}_{t,i} = \text{Var}(y_{t,i} | \mathbf{Y}) = 0$ since, given \mathbf{Y} , $y_{t,i}$ is completely known. Therefore, $\tilde{y}_{t,i}$ provides nontrivial information only when $y_{t,i}$ is missing—in which case $\tilde{y}_{t,i}$ represents the best estimate of $y_{t,i}$ based on the available data. The full sample estimates of components specified in the model equations are based on the corresponding linear combinations of $\tilde{\alpha}_t$. Similarly, their standard errors are computed by using appropriate functions of $\tilde{\mathbf{P}}_t$. The estimate of additive outlier, $\text{AO}_{t,i} = y_{t,i} - E(y_{t,i} | \mathbf{Y}^{t,i})$, is the difference between the observed response value $y_{t,i}$ and its estimate using all the data except $y_{t,i}$, which is denoted by $\mathbf{Y}^{t,i}$. The estimate $\text{AO}_{t,i}$ is missing when $y_{t,i}$ is

missing. For more information about the computation of additive outliers, see de Jong and Penzer (1998).

If the filtering process remains uninitialized until the end of the sample (that is, if \mathbf{S}_{n,p_n} is not invertible), some linear combinations of $\boldsymbol{\delta}$ and $\boldsymbol{\beta}$ are not estimable. This, in turn, implies that some linear combinations of $\boldsymbol{\alpha}_t$ are also inestimable. These inestimable quantities are reported as missing. For more information about the estimability of the state effects see Selukar (2010).

Contrasting PROC SSM with Other SAS Procedures

The SSM procedure complements several SAS/ETS procedures and the MIXED procedure in SAS/STAT software (see Chapter 58, “The MIXED Procedure” (*SAS/STAT User’s Guide*)). The statistical models underlying all these procedures can be formulated as state space models; however, in many cases this formulation effort can be considerable. Generally speaking, when a problem can be formulated and satisfactorily solved either by using the SSM procedure or by using one of these other procedures, the other procedures are likely to be more efficient. However, in many instances, the SSM procedure can solve more general problems, or offer more detailed analysis, or both. Throughout this discussion, it is assumed that the problem being solved can be modeled as a linear statistical model. In particular, situations that require models such as autoregressive conditional heteroscedasticity (ARCH) models are not considered. The following list provides a more specific comparison of the SSM procedure with different procedures:

- All the SAS/ETS time series analysis procedures (the ARIMA, ESM, UCM, VARMAX, STATESPACE, and PANEL procedures) require time series data and are not applicable to the longitudinal data.
- For univariate time series analysis, the modeling facilities provided by the ARIMA, ESM, and UCM procedures are adequate in most cases. The SSM procedure can handle cases that do not fit neatly into one of these categories.
- For multivariate time series data analysis, you can use the VARMAX procedure for vector ARIMA modeling and the STATESPACE procedure for state space modeling. The capabilities of the SSM procedure are complementary to these procedures. In particular, the predefined multivariate structural models available in the SSM procedure cannot be specified by either of these procedures. In addition, you can formulate a much wider range of multivariate models—for example, models for series with different frequencies, by using the SSM procedure.
- When the \mathbf{R} side effects are not too complicated (for example, if \mathbf{R} is diagonal), the model considered by the MIXED procedure is a special case of the model considered by the SSM procedure. In the case of diagonal \mathbf{R} , it is easy to see that the state vector $\boldsymbol{\alpha}_t$ is equal to $\boldsymbol{\gamma}$, the MIXED random-effects vector, for all $t \geq 1$, that is, $\boldsymbol{\alpha}_t$ is *time invariant*. Therefore, the random-effects MIXED model is obtained by setting $\mathbf{T} = \text{Identity}$, $\mathbf{Q}_t = \mathbf{0}$, $t \geq 2$, $\mathbf{Q}_1 = \mathbf{G}$ (the MIXED \mathbf{G} matrix), and $\mathbf{A}_1 = \mathbf{0}$.
- For the analysis of cross-sectional data, you can use the PANEL procedure. In this case, the SSM procedure capabilities are complementary. It can provide alternate models, REML estimates, richer missing value support, and the estimates of the unobserved components (see [Example 27.1](#)).

Predefined Trend Models

The statistical models that govern the predefined trend components available in the SSM procedure are divided into two groups: models that are applicable to equally spaced data (possibly with replication), and the models that are applicable more generally (the irregular data type). Each trend component can be described as a dot product $\mathbf{Z}\alpha_t$ for some (time-invariant) vector \mathbf{Z} and a state vector α_t . The component specification is complete after the vector \mathbf{Z} is specified and the system matrices that govern the equations of α_t are specified. For trend models for regular data, all the system matrices are time-invariant. For irregular data, \mathbf{T}_t and \mathbf{Q}_t depend on the spacing between the distinct time points: $(\tau_{t+1} - \tau_t)$.

Trend Models for Regular Data

These models are applicable when the data type is either regular or regular-with-replication. A good reference for these models is Harvey (1989).

Random Walk Trend

This model provides a trend pattern in which the level of the curve changes slowly. The rapidity of this change is inversely proportional to the disturbance variance σ^2 that governs the underlying state. It can be described as $\mathbf{Z}\alpha_t$, where $\mathbf{Z} = (1)$ and the (one-dimensional) state α_t follows a random walk:

$$\alpha_{t+1} = \alpha_t + \eta_{t+1}, \quad \eta_t \sim N(0, \sigma^2)$$

Here $\mathbf{T} = 1$ and $\mathbf{Q} = \sigma^2$. The initial condition is fully diffuse.

Local Linear Trend

This model provides a trend pattern in which both the level and the slope of the curve vary slowly. This variation in the level and the slope is controlled by two parameters: σ_1^2 controls the level variation, and σ_2^2 controls the slope variation. If $\sigma_1^2 = 0$, the resulting trend is called an *integrated random walk*. Here $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ 1, \ 0 \ 1)$, and $\mathbf{Q} = \text{Diag}(\sigma_1^2, \sigma_2^2)$. The initial condition is fully diffuse.

Damped Local Linear Trend

This trend pattern is similar to the local linear trend pattern. However, in the DLL trend the slope follows a first-order autoregressive model whereas in the LL trend the slope follows a random walk. The autoregressive parameter or the damping factor, ϕ , must lie between 0.0 and 1.0, which implies that the long-run forecast according to this pattern has a slope that tends to zero. Here $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ 1, \ 0 \ \phi)$, and $\mathbf{Q} = \text{Diag}(\sigma_1^2, \sigma_2^2)$. The initial condition is partially diffuse with $\mathbf{Q}_1 = \text{Diag}(0, \sigma_2^2/(1 - \phi * \phi))$.

Trend Models for Irregular Data

A good reference for these models is de Jong and Mazzi (2001). Throughout this section $h_t = (\tau_{t+1} - \tau_t)$ denotes the difference between the successive time points. The system matrices \mathbf{T}_t and \mathbf{Q}_t that govern these models depend on h_t . However, whenever the notation is unambiguous, the subscript t is omitted.

Polynomial Spline Trend

This model is a general-purpose tool for extracting a smooth trend from the noisy data. The order of the spline governs the order of the local polynomial that defines the spline. In the SSM procedure the order is restricted to be an integer 1, 2, or 3; the default order is 1. The order 1 spline corresponds to a random walk, the order 2 spline corresponds to an integrated random walk, and the order 3 spline provides a locally quadratic trend. The dimension of the state underlying this component is the same as the order of the spline. The system matrices for the different orders are described below (in all the cases the initial condition is fully diffuse):

- order=1: $\mathbf{Z} = (1)$, $\mathbf{T} = (1)$, and $\mathbf{Q} = \sigma^2(h)$
- order=2: $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ h, \ 0 \ 1)$, and $\mathbf{Q} = \sigma^2 \begin{pmatrix} \frac{h^3}{3} & \frac{h^2}{2} & \frac{h^2}{2} & h \end{pmatrix}$
- order=3: $\mathbf{Z} = (1 \ 0 \ 0)$, $\mathbf{T} = \begin{pmatrix} 1 & h & \frac{h^2}{2} & 0 & 1 & h & 0 & 0 & 1 \end{pmatrix}$, and

$$\mathbf{Q}[i, j] = \sigma^2 * \frac{h^{6-i-j+1}}{(6-i-j+1)(3-i)!(3-j)!} \quad 1 \leq i, j \leq 3$$

Decay and Growth Trends

There are two choices for the decay trend: DECAY and DECAY(OU). Similarly, there are two choices for the growth trend: GROWTH and GROWTH(OU). The “OU” stands for the Ornstein-Uhlenbeck form of these models. The decay trend is a sum of two correlated components: one component is a random walk, and the other component is a stationary autoregression. In its Ornstein-Uhlenbeck form, the random walk component is replaced by a constant. The growth trend (and its Ornstein-Uhlenbeck variant) has the same form as the decay trend except that the autoregression is nonstationary (in fact, it is explosive). Note that, in the case of the growth trend models, floating-point errors can result for even moderately long forecast horizons because of the explosive growth in the trend values.

The system matrices for the decay and the growth types in their respective cases are identical, except for the sign of the rate parameter ϕ : $\phi < 0.0$ for the decay type, and $\phi > 0.0$ for the growth type. In addition, the initial conditions for the growth models are fully diffuse; they are only partially diffuse for the decay models. The underlying state vector for all these models is two-dimensional.

The system matrices for the DECAY type are:

$$\begin{aligned} \mathbf{Z} &= (1 \ 1) \\ \mathbf{T} &= \text{Diag}(1, \exp(h\phi)) \\ \mathbf{Q} &= \frac{\sigma^2}{\phi^3} \begin{pmatrix} h\phi & 1 - \exp(h\phi) \\ 1 - \exp(h\phi) & (\exp(2h\phi) - 1)/2 \end{pmatrix} \end{aligned}$$

The initial condition is partially diffuse with $\mathbf{Q}_1 = \text{Diag}(0, \frac{-\sigma^2}{2\phi^3})$. The system matrices for the GROWTH type are the same (with $\phi > 0.0$), except that the initial condition is fully diffuse; so $\mathbf{Q}_1 = 0$.

For the DECAY(OU) type, \mathbf{Z} and \mathbf{T} are the same as DECAY, whereas

$$\mathbf{Q} = \text{Diag} \left(0, \sigma^2 \frac{(\exp(2h\phi) - 1)}{2\phi} \right) \quad \text{and} \quad \mathbf{Q}_1 = \text{Diag}(0, \frac{-\sigma^2}{2\phi})$$

The system matrices for the GROWTH(OU) type are the same (with $\phi > 0.0$), except that the initial condition is fully diffuse; so $\mathbf{Q}_1 = 0$.

Predefined Structural Models

A set of predefined models is available in the SSM procedure for models called structural models in the time series literature. These predefined models can be used to model trend, seasonal, and cyclical patterns in the univariate and multivariate time series. For the most part, the multivariate models are straightforward generalizations of the corresponding univariate models—for example, the multivariate random walk trend described later in this section generalizes the univariate random walk trend described in the section “[Random Walk Trend](#)” on page 1797. All of these models, with the exception of the continuous-time cycle model, are applicable only to the regular data type. The continuous-time cycle model is applicable to all the data types; however, it is available for the univariate case only.

To specify these models, you must first use the STATE statement with the correct **TYPE=** option. When you specify the **TYPE=** option, you do not need to specify other options of the STATE statement (for example, the **T** option, the **COV1** option, and the **A1** option). However, you must specify the **COV** option, which describes the covariance of the disturbance term that drives the state equation. Throughout this section, the symmetric matrix specified by using the **COV** option is denoted by Σ . For **TYPE=LL**, an additional matrix, specified by using the **SLOPECOV** suboption, also plays a role. It is denoted by Σ_{slope} . Subsequently you must specify one or more COMPONENT statements to define the (univariate) components based on this state subsection for their inclusion in the MODEL statement. These univariate components exhibit interesting behavior based on the structure of Σ (and Σ_{slope} , whenever applicable)—for example, imposing rank restrictions on Σ in the multivariate random walk results in these univariate trends moving together. For additional information about these models, see Harvey (1989).

The following example summarizes the steps needed to define a multivariate structural model by using a sequence of STATE and COMPONENT statements. For a full example, see the section “[Getting Started: SSM Procedure](#)” on page 1767. Suppose that a three-dimensional time series is being studied with response variables y_1 , y_2 , and y_3 . Suppose you want to specify the three-variate structural model

$$\mathbf{y}_t = \boldsymbol{\mu}_t + \boldsymbol{\psi}_t + \boldsymbol{\epsilon}_t$$

where $\mathbf{y}_t = (y_{1,t}, y_{2,t}, y_{3,t})$ denotes the response series, and $\boldsymbol{\mu}_t$, $\boldsymbol{\psi}_t$, and $\boldsymbol{\epsilon}_t$ denote the three-variate components, trend, cycle, and white noise, respectively. The three components of $\boldsymbol{\epsilon}_t$, the observation noise in the model, are not assumed to be independent. Therefore, you cannot specify them by using three **IRREGULAR** statements; you must include them in the state specification. The following (incomplete) statements show how to specify this model:

```
state whiteNoise(3) type=wn ...;
component wn1 = whiteNoise[1];
component wn2 = whiteNoise[2];
component wn3 = whiteNoise[3];

state randomWalk(3) type=rw ...;
component rw1 = randomWalk[1];
component rw2 = randomWalk[2];
```

```

component rw3 = randomWalk[3];

state cycleState(3) type=cycle ...;
component c1 = cycleState[1];
component c2 = cycleState[2];
component c3 = cycleState[3];

model y1 = rw1 c1 wn1;
model y2 = rw2 c2 wn2;
model y3 = rw3 c3 wn3;

```

The first STATE statement defines `whiteNoise`, a state subsection needed for defining a three-dimensional white noise component. In turn, `whiteNoise` is used to define the three univariate white noise components: `wn1`, `wn2`, and `wn3`. The components `wn1`, `wn2`, and `wn3` are correlated—their correlation structure is controlled by the covariance specification of `whiteNoise`. The second set of STATE and COMPONENT statements result in three correlated random walk trend components: `rw1`, `rw2`, and `rw3`. Finally, the last set of STATE and COMPONENT statements result in three correlated cycle components: `c1`, `c2`, and `c3`. In the end, the desired multivariate model is defined by including these (univariate) components in the appropriate MODEL statements.

In the preceding example, it is important to note the relationship between the dimension, denoted by *dim* throughout this section, specified in the STATE statement and the actual dimension of the resulting state subsection. Note that the three state subsections, `whiteNoise`, `randomWalk`, and `cycleState`, are defined by using the same *dim* specification: 3. However, the actual dimensions of these state subsections depend on their type; they do not need to equal this specified dimension. Here, `whiteNoise` and `randomWalk` do have the same size, 3, as the specified *dim*. However, the size of `cycleState`, which is of TYPE=CYCLE, is $2 * dim = 6$. Another important point to note: no matter what the underlying size of the state subsection, the desired univariate components were obtained by using an identical specification scheme in the COMPONENT statement. This happens because the component specification style based on the element operator—[]—in the COMPONENT statement behaves differently when the TYPE= option is used to define the state subsection (see the section “Multivariate Season” on page 1802 for an illustration).

The system matrices for all these models are time-invariant, with the exception of the continuous-time cycle model. In this section, α_t denotes the subsection of the overall model state α_t , and **T**, **Q**, and **A**₁ denote the corresponding blocks of the larger system matrices.

For the multivariate cycle system matrices described in the section “Multivariate Cycle” on page 1802, the Kronecker product notation is useful: if **A** is an $m \times n$ matrix and **B** is a $p \times q$ matrix, then the Kronecker product $\mathbf{A} \otimes \mathbf{B}$ is an $mp \times nq$ block matrix:

$$\mathbf{A} \otimes \mathbf{B} = \begin{bmatrix} a_{11}B & \cdots & a_{1n}B \\ \vdots & \ddots & \vdots \\ a_{m1}B & \cdots & a_{mn}B \end{bmatrix}$$

Multivariate White Noise

The STATE statement option TYPE=WN specifies white noise of dimension *dim*—that is, a sequence of zero mean, independent, Gaussian vectors with covariance Σ . The specification of the associated system

matrices is trivial: \mathbf{T} is zero, $\mathbf{Q} = \mathbf{\Sigma}$, and the initial condition is nondiffuse ($\mathbf{Q}_1 = \mathbf{\Sigma}$ and $\mathbf{A}_1 = 0$).

Multivariate white noise is needed to specify the observation equation noise term for the multivariate models for the time series data. Since the state space formulation for the SSM procedure requires the observation equation noise vector to have the diagonal form, you need to include the noise vector in the state. The noise term for the i th response variable is defined by a component that simply picks the i th element of this multivariate white noise. For example, the component `wn_i` defined as follows can be used as a noise term in the MODEL statement of the i th response variable:

```
state white(dim) type=wn ...;
component wn_i = white[i];
```

Multivariate Random Walk Trend

The STATE statement option `TYPE=RW` specifies a dim -dimensional random walk

$$\alpha_{t+1} = \alpha_t + \eta_{t+1}$$

where η_t is a sequence of zero mean, independent, Gaussian vectors with covariance $\mathbf{\Sigma}$. The specification of the associated system matrices is trivial: \mathbf{T} is a dim -dimensional identity matrix, \mathbf{I}_{dim} , $\mathbf{Q} = \mathbf{\Sigma}$, and the initial condition is fully diffuse ($\mathbf{Q}_1 = 0$ and $\mathbf{A}_1 = \mathbf{I}_{dim}$).

The multivariate random walk is a useful trend model for multivariate time series data. The trend term for the i th response variable is defined by a component that simply picks the i th ($1 \leq i \leq dim$) element of α_t . For example, the component `rw_i` defined as follows can be used as a trend term in the MODEL statement of the i th response variable:

```
state randomWalk(dim) type=rw ...;
component rw_i = randomWalk[i];
```

Multivariate Local Linear Trend

The STATE statement option `TYPE=LL` specifies a $(2*dim)$ -dimensional α_t , needed for defining a dim -dimensional local linear trend. The first dim elements of α_t correspond to the needed multivariate trend, and the subsequent dim elements are needed to capture the slope vector of this trend. α_t can be defined as

$$\alpha_{t+1} = \mathbf{T}\alpha_t + \eta_{t+1}$$

where η_t is a sequence of zero mean, independent, Gaussian vectors with covariance $\text{Diag}(\mathbf{\Sigma}, \mathbf{\Sigma}_{slope})$ and \mathbf{T} is a $2*dim$ -dimensional block matrix $\mathbf{T} = (\mathbf{I}_{dim} \mathbf{I}_{dim}, \mathbf{0} \mathbf{I}_{dim})$. The initial condition is fully diffuse ($\mathbf{Q}_1 = 0$ and $\mathbf{A}_1 = \mathbf{I}_{2*dim}$). This is a multivariate generalization of the univariate local linear trend.

The multivariate local linear trend is a useful trend model for multivariate time series data. The trend term for the i th response variable is defined by a component that simply picks the i th element ($1 \leq i \leq dim$) of α_t . For example, the component `ll_i` defined as follows can be used as a trend term in the MODEL statement of the i th response variable:

```
state localLin(dim) type=ll(slopecov..) ...;
component ll_i = localLin[i];
```

Multivariate Cycle

The STATE statement option **TYPE=CYCLE** specifies a $(2*dim)$ -dimensional α_t , needed for defining a dim -dimensional cycle. As in the LL case, the first dim elements of α_t correspond to the needed dim -dimensional cycle, and the remaining dim elements contain some auxiliary quantities. The cycle model defined in this subsection requires a regular data type—that is, the CT option is not included. Let ρ denote the damping factor, and $\lambda = 2\pi/period$ be the frequency associated with the cycle. The admissible parameter ranges are $0 < \rho \leq 1$ and $period > 2$, which implies that $0 < \lambda < \pi$. Let $\mathbf{C} = \rho(\cos(\lambda) \sin(\lambda), -\sin(\lambda) \cos(\lambda))$, a 2×2 matrix, and let $\mathbf{T} = \mathbf{C} \otimes \mathbf{I}_{dim}$, a $2*dim \times 2*dim$ matrix. With this notation, the transition equation associated with α_t is

$$\alpha_{t+1} = \mathbf{T}\alpha_t + \eta_{t+1}$$

where η_t is a sequence of zero mean, independent, $(2*dim)$ -dimensional Gaussian vectors with covariance $\text{Diag}(\Sigma, \Sigma)$. If $\rho = 1$, the initial condition is fully diffuse ($\mathbf{Q}_1 = 0$ and $\mathbf{A}_1 = \mathbf{I}_{2*dim}$). Otherwise, it is nondiffuse: $\mathbf{Q}_1 = \frac{1}{(1-\rho^2)}\text{Diag}(\Sigma, \Sigma)$ and $\mathbf{A}_1 = 0$.

The multivariate cycle is useful for capturing periodic behavior for multivariate time series data. The cycle term for the i th response variable is defined by a component that simply picks the i th element of α_t . For example, the component `cycle_i` defined as follows can be used as a cycle term in the MODEL statement of the i th response variable:

```
state cycleState(dim) type=cycle ...;
component cycle_i = cycleState[i];
```

Multivariate Season

The STATE statement option **TYPE=SEASON(LENGTH=s)** specifies a $((s-1)*dim)$ -dimensional α_t , needed for defining a dim -dimensional trigonometric season component with season length s . A (multivariate) trigonometric season component, γ , is a sum of (multivariate) cycles of different frequencies,

$$\gamma = \sum_{j=1}^{[s/2]} \gamma_j$$

where the constituent cycles γ_j , called harmonics, have frequencies $\lambda_j = 2\pi j/s$. All the harmonics are assumed to be statistically independent, have the same damping factor $\rho = 1$, and are governed by the disturbances with the same covariance matrix Σ . The number of harmonics, $[s/2]$, equals $s/2$ if s is even and $(s-1)/2$ if it is odd. This means that specifying **TYPE=SEASON(LENGTH=s)** is equivalent to specifying $[s/2]$ cycle specifications with correct frequencies, damping factor $\rho = 1$, and the COV option restricted to the same covariance Σ . The resulting α_t is necessarily $((s-1)*dim)$ -dimensional. When the season length s is even, the last harmonic cycle, $\gamma_{s/2}$, has frequency π and requires special attention. It is of dimension dim rather than $2*dim$ because its underlying state equation simplifies to a dim -variate autoregression with autoregression coefficient $-\mathbf{I}_{dim}$. As a result of this discussion, it is clear that the system matrices \mathbf{T} and \mathbf{Q} associated with the $((s-1)*dim)$ -dimensional α_t are block-diagonal with the blocks corresponding to the harmonics. The initial condition is fully diffuse.

For all the models discussed so far, the first dim elements of α_t provided the needed (multivariate) component. This is not the case for the (multivariate) season component. Extracting the i th seasonal component

from α_t requires accumulating the contributions from the $[s/2]$ harmonics associated with this i th seasonal, which are not organized contiguously in α_t . For example, suppose that dim is 2 and the season length s is 4. In this case $[s/2]$ is 2, and the bivariate seasonal component is a sum of two independent bivariate cycles, γ_1 and γ_2 . The cycle γ_1 has frequency $\pi/2$ and its underlying state, say α_t^a , has dimension $2 * dim = 4$. The last harmonic, γ_2 , has frequency π , and therefore its underlying state, say α_t^b , has dimension 2. The combined state $\alpha_t = (\alpha_t^a, \alpha_t^b)$ has dimension $6 = 4 + 2$. In order to extract the first bivariate seasonal component, you must extract the first components of bivariate cycles γ_1 and γ_2 , which in turn implies the first elements of α_t^a and α_t^b , respectively. Thus, obtaining the first bivariate seasonal component requires extracting the first and the fifth elements of the combined state α_t . Similarly, obtaining the second bivariate seasonal component requires extracting the second and the sixth elements of the combined state α_t . All this can be summarized by the dot product expressions

$$\begin{aligned}s_{1t} &= (1 \ 0 \ 0 \ 0 \ 1 \ 0) \alpha_t \\ s_{2t} &= (0 \ 1 \ 0 \ 0 \ 0 \ 1) \alpha_t\end{aligned}$$

where s_{1t} and s_{2t} denote the first and second components, respectively, of the bivariate seasonal component. Note that s_{1t} and s_{2t} are univariate seasonal components, each of season length 4, in their own right. They are correlated components; their correlation structure depends on Σ .

Obtaining the desired components of the multivariate seasonal component is made easy by a special syntax convention of the COMPONENT statement. Continuing with the previous example, the following examples illustrate two equivalent ways of obtaining s_{1t} and s_{2t} . The first set of statements explicitly specify the linear combinations needed for defining s_{1t} and s_{2t} :

```
state seasonState(2) type=season(length=4) ...;
component s_1=( 1  0  0  0  1  0 ) * seasonState;
component s_2=( 0  1  0  0  0  1 ) * seasonState;
```

The following simpler specification achieves the same result:

```
state seasonState(2) type=season(length=4) ...;
component s_1 = seasonState[1];
component s_2 = seasonState[2];
```

In the latter specification, the meaning of the element operator $[]$ changes if the state in question is defined by using the **TYPE=** option.

Continuous-Time Cycle

The STATE statement option **TYPE=CYCLE(CT)** specifies a two-dimensional α_t , needed for defining a univariate continuous time cycle. In this case the dimension, dim , used in the STATE statement must be 1. In particular, Σ becomes one-dimensional, which is denoted by σ^2 . This cycle can be used for any data type. As before, the parameters of the cycle are a damping factor ρ , $0 < \rho \leq 1$, and $period > 0$. Unlike in the discrete-time cycle described in the section “**Multivariate Cycle**” on page 1802, the *period* is not required to be larger than 2. Let $\lambda = 2\pi/period$ and let $h_t = (\tau_{t+1} - \tau_t)$ denote the difference between successive

time points. In this case, the system matrices **T** and **Q** that govern α_t depend on h_t . They are:

$$\begin{aligned}\mathbf{T} &= \rho^h (\cos(\lambda h) \sin(\lambda h), -\sin(\lambda h) \cos(\lambda h)) \\ \mathbf{Q} &= \frac{\sigma^2(1 - \rho^{2h})}{-2 \ln(\rho)} * \mathbf{I}_2 \quad \text{if } \rho < 1 \\ \mathbf{Q} &= \sigma^2 h \mathbf{I}_2 \quad \text{if } \rho = 1\end{aligned}$$

If $\rho < 1$, the initial condition is nondiffuse: $\mathbf{Q}_1 = \frac{\sigma^2}{-2 \ln(\rho)} \mathbf{I}_2$. For $\rho = 1$, the initial condition is fully diffuse.

The first element of α_t corresponds to the needed cycle, and the second element is an auxiliary quantity. You can define a cycle term based on this state as follows:

```
state cycleState(1) type=cycle(CT) ...;
component cycle = cycleState[1];
```

Note that the CT option must be included in the use of **TYPE=CYCLE**.

Covariance Parameterization

The covariance matrices specified by the **COV** and **COV1** options in the STATE statement must be positive semidefinite. When these matrices are of general form and are not user-specified, they are internally parameterized by their Cholesky root. Suppose that Σ , an $m \times m$ positive semidefinite matrix of rank r , is such a covariance matrix. Then, Σ can always be written as

$$\Sigma = RR'$$

where the (generalized) Cholesky root, R , is an $m \times r$ lower triangular matrix with nonnegative diagonal elements (that is, $R[i, j] = 0$ if $j > i$ and $R[i, i] \geq 0$, $1 \leq i \leq r$). The SSM procedure parameterizes Σ by the elements of its Cholesky root, which adds $r * (r + 1)/2 + r * (m - r)$ elements to the parameter vector θ .

Missing Values

For a variety of reasons the data might contain missing response and predictor values. Before starting the analysis of a particular BY group, SSM procedure makes an internal copy of the data. The actual analysis is done by using this copy. The data in the copy are first examined for missing values in the response, predictor, and the ID variables. No missing values are permitted in the ID variable (if it is specified). If all the missing values are associated with only the response variables, then the internal copy of the data is not altered. However, if any of the predictors are found to contain missing values, the internal copy of the data is altered as follows: any missing predictor value is replaced by zero, and the response values that are dependent on that predictor in the corresponding row are set to missing. These missing response values are called the *induced missing values*. The reported analysis is based on the (possibly altered) internal copy of the BY group.

Computational Issues

A Well-Behaved Model

The model defined by the state space model equations (see the section “[The State Space Model and Notation](#)” on page 1786) is very general. This generality is quite useful since it encompasses a wide variety of data generation processes. On the other hand, it also makes it easy to specify overly complex and numerically unstable models. If a suitable model is not already known and you are in the early phases of modeling, it is important to start with models that are relatively simple and well-behaved from the numerical standpoint. From the numerical and statistical considerations, two aspects of model formulation are particularly important: identifiability and numerical stability. A model is identifiable if the observed data has a distinct probability distribution for each admissible parameter vector. Unless proper care is taken, it is easy to specify an unidentifiable state space model. Similarly, predictions according to some types of state space models can display explosive growth or wild oscillations. This behavior is primarily governed by the transition matrix \mathbf{T} (or \mathbf{T}_t in the time-varying case). Unidentifiable models can run into difficulties during parameter estimation, and explosive growth (and wild oscillation) causes numerical problems associated with finite-precision arithmetic. Unfortunately, no simple identifiability check is available for a general state space model, and it is difficult to decide at the outset whether a specified model might suffer from numerical instability. See Harvey (1989, chap. 4, sec. 4) for a discussion of identifiability issues, and see Harvey (1989, chap. 3, sec. 3) for a discussion of the stability properties of time-invariant state space models. The following guidelines are likely to result in models that are identifiable and numerically stable:

- Build models by composing submodels that are known to be well-behaved. The predefined models provided by the SSM procedure are good submodel candidates (see the sections “[Predefined Trend Models](#)” on page 1797 and “[Predefined Structural Models](#)” on page 1799).
- Pay careful attention to the way the variety of system matrices are defined. The behavior of their elements, as functions of model parameters and other variables, must be well-understood. If these elements are defined by using the DATA steps, you can validate their behavior by running these DATA steps outside of the SSM procedure. In particular, note the following:
 - The transition matrix \mathbf{T} (or \mathbf{T}_t in the time-varying case) determines the explosiveness characteristics of the model; it must be well-behaved for all parameters.
 - The disturbance covariances \mathbf{Q}_t must be positive semidefinite for all parameters.
 - If the transition matrix \mathbf{T}_t or the disturbance covariance \mathbf{Q}_t are time-varying and the data contain replicate observations (observations with the same ID value), check that the elements of \mathbf{T}_t and \mathbf{Q}_t do not vary during replicate observations. This follows from the fact that the underlying state does not vary during replications (see the state equation in the section “[The State Space Model and Notation](#)” on page 1786 and the section “[Types of Data Organization](#)” on page 1788).

Convergence Problems

As explained in the section “[Likelihood Computation and Model Fitting Phase](#)” on page 1794, the model parameters are estimated by nonlinear optimization of the likelihood. This process is not guaranteed to succeed. For some data sets, the optimization algorithm can fail to converge. Nonconvergence can result

from a number of causes, including flat or ridged likelihood surfaces and ill-conditioned data. It is also possible for the algorithm to converge to a point that is not the global optimum of the likelihood.

If you experience convergence problems, consider the following:

- Data that are extremely large or extremely small can adversely affect results because of the internal tolerances used during the filtering steps of the likelihood calculation. Rescaling the data can improve stability.
- Examine your model for redundancies in the included components and regressors. The components or regressors that are nearly collinear to each other can cause the optimization process to become unstable.
- Lack of convergence can indicate model misspecification or a violation of the normality assumption.

Computer Resource Requirements

The computing resources required for the SSM procedure depend on several factors. The memory requirement for the procedure is largely dependent on the number of observations to be processed and the size of the state vector underlying the specified model. If n denotes the sample size and m denotes the size of the state vector, the memory requirement for the smoothing phase of the Kalman filter is of the order of $6 \times 8 \times n \times m^2$ bytes, ignoring the lower-order terms. If the smoothed component estimates are not needed, then the memory requirement is of the order of $6 \times 8 \times (m^2 + n)$ bytes. Besides m and n , the computing time for the parameter estimation depends on the size of the parameter vector θ and how many likelihood evaluations are needed to reach the optimum.

Displayed Output

The default printed output produced by the SSM procedure contains the following information:

- brief information about the input data set, including the data set name and label
- summary statistics for the response variables in the model, including the names of the variables, the total number of observations and the number of missing observations, the smallest and largest measurements, and the mean and standard deviation
- information about the index variable, including the index value of the first and the last observation, maximum difference between the successive index values, and the categorization of the data into regular, regular-with-replication, or irregular types
- estimates of the regression parameters if the model contains any predictors, including their standard errors, t statistics, and p -values
- convergence status of the likelihood optimization process if any parameters are estimated
- estimates of the free parameters at the end of the model fitting phase, including the parameter estimates and their approximate standard errors

- the likelihood-based goodness-of-fit statistics, including the full likelihood, the sum of squares of residuals normalized by their standard errors, and the information criteria: AIC, AICC, HQIC, BIC, and CAIC

ODS Table Names

The SSM procedure assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in [Table 27.9](#).

Table 27.9 ODS Tables Produced by PROC SSM

ODS Table Name	Description	Statement	Option
Tables That Summarize the Model Information			
ModelSummary	Summary information about the underlying state space model		Default
IdInformation	Summary information about the ID variable	ID	Default
ResponseInfo	Summary information about the response variables	MODEL	Default
Tables Related to Model Parameters and the Likelihood			
ConvergenceStatus	Convergence status of the estimation process		Default
RegressionEstimates	Estimates of the regression parameters		Default
FixedStateEstimates	Estimates of the time-invariant deterministic state elements		Default
ParameterEstimates	Estimates of the parameters specified by the PARMS statement	PARMS	Default
ParameterEstimates1	Estimates of the unknown elements in the model system matrices		Default
ErrorCov	Covariance estimate after multiplying the Cholesky roots		Default
FitSummary	Summary of the likelihood-based-fit-statistics		Default

OUT= Data Set

You can use the OUT= option in the FORECAST statement to store the series and component forecasts produced by the procedure. Which columns are included in the data set depends on the model specification. The model can have one or more response variables, a variety of components that appear in the MODEL statement, and components specified by the EVAL statement. The OUT= data set contains the one-step-ahead and full-sample estimates of the response variables, and all these components.

The following list describes the columns of the data set:

- the BY variables
- the ID variable, if specified by the ID statement
- Obs, a variable that contains the observation number
- the response series (more than one in the multivariate case)
- the following columns associated with the response series (the wildcard * is substituted by the name of one of the response variables):
 - FORECAST_* contains the one-step-ahead predicted values and the multistep forecasts of the response series
 - RESIDUAL_* contains the difference between the actual and forecast values
 - StdErr_* contains the standard error of prediction
 - Lower_* and Upper_* contain the lower and upper forecast confidence limits
 - Smoothed_* contains the smoothed values of the response variable
 - StdErr_Smoothed_* contains standard errors of the smoothed values of the response variable
 - AO_* contains the additive outlier estimate
 - StdErr_AO_* contains the standard error of the additive outlier estimate
- the following columns associated with the components (the wildcard * is substituted by the name of one of the components):
 - FORECAST_* contains the one-step-ahead predicted values and the multistep forecasts of the component
 - StdErr_* contains the standard error of prediction
 - Smoothed_* contains the smoothed values of the component
 - StdErr_Smoothed_* contains standard errors of the smoothed values of the component
 - Smoothed_Lower_* and Smoothed_Upper_* contain the lower and upper confidence limits of the smoothed component

Confidence limits are not produced for the smoothed series values or for the component forecasts; they are produced for the smoothed components.

Examples: SSM Procedure

Example 27.1: Panel Data: Two-Way Random-Effects Model

This example shows how you can use the SSM procedure to fit a two-way random-effects model to the panel data. Suppose $\mathbf{y} = (y_1, \dots, y_q)$ denotes a q -dimensional response vector that is associated with a cross-sectional study with q cross sections. The study data set contains \mathbf{y} measurements recorded at regular time intervals and might also contain predictor information. Here, unlike the multivariate time series setting, the \mathbf{y} values are stored in a single variable, and a separate variable called the cross-sectional variable indicates the membership of the observation to a particular cross section. Thus, for each time index t , the information in \mathbf{y}_t takes up q rows in the data set. The two-way random-effect model can be described as follows:

$$\mathbf{y}_t = \mathbf{X}_t \boldsymbol{\beta} + \boldsymbol{\gamma} + \xi_t \mathbf{1} + \boldsymbol{\epsilon}_t$$

Here the $(q \times k)$ matrix \mathbf{X}_t contains the regression variables that are associated with the k -dimensional regression vector $\boldsymbol{\beta}$, $\boldsymbol{\gamma}$ is a q -dimensional latent vector, ξ_t is a one-dimensional latent effect, $\mathbf{1}$ is a q -dimensional vector with all of its entries equal to one, and $\boldsymbol{\epsilon}_t$ is a q -dimensional latent vector. $\boldsymbol{\gamma}$ is called the cross-sectional effect, ξ_t is called the *time* effect, and $\boldsymbol{\epsilon}_t$ is called the observation noise. All these latent effects are assumed to be statistically independent. In addition, it is assumed that $\boldsymbol{\gamma}$ is a zero mean, Gaussian vector with scaled identity, $\sigma_c^2 \mathbf{I}_q$, as a covariance, ξ_t is a white noise sequence with variance σ_a^2 , and the observation noise $\boldsymbol{\epsilon}_t$ is a q -variate white noise sequence with covariance $\sigma_e^2 \mathbf{I}_q$. This model can be easily formulated as an SSM that can be analyzed by using the SSM procedure as follows:

- Since the random latent vector $\boldsymbol{\gamma}$ is time-invariant, it can be specified as a state subsection with an identity as the transition matrix and zero as the state disturbance vector. Its initial condition is nondiffuse with $\mathbf{Q}_1 = \sigma_c^2 \mathbf{I}_q$, a scaled identity.
- Since ξ_t affects all elements of \mathbf{y}_t , it must be included in the state. It can be modeled as a one-dimensional white noise state subsection.
- $\boldsymbol{\epsilon}_t$ can be modeled as observation noise, since its covariance is diagonal.

The Christenson Associates airline data, a frequently cited data set (Greene 2000), are used in this illustration. The data measure costs, prices of inputs, and utilization rates for six airlines over the time span 1970–1984. This is a cross-sectional data set with six cross sections that correspond to the six airlines; firmNumber is the cross-sectional variable and lC, the log-transformed costs, is the response variable. The following DATA step generates the data set:

```
data airline;
  input timePeriod firmNumber lC lQ lPF LF;
  label timePeriod = "Time period";
  label firmNumber = "Firm Number";
  label LF = "Load Factor (utilization index)";
  label lC = "Log transformed Costs";
  label lQ = "Log transformed Quantity";
  label lPF= "Log transformed Price of Fuel";
```

```

    year = intnx( 'year', '1jan1970'd, timePeriod-1 );
    format year year.;
datalines;
1    1    13.9471    -0.04839    11.5773    0.53449
1    2    13.2521    -0.65270    11.5502    0.49085
1    3    12.5648    -1.33781    11.6851    0.52433
1    4    11.8856    -2.44888    11.6526    0.43207

... more lines ...

```

As needed, these data are already ordered by the time index, year. For each year, there are six rows of observations—one row per airline. The following statements specify and fit a two-way random effects model to IC , the log-transformed costs. An intercept term, IQ , IPF , and LF are included as regressors.

```

proc SSM data=airline;
  id year interval=year;
  parms s2c/ lower=(1.e-6);
  array firmArray{6} f1-f6;
  do j=1 to 6;
    firmArray[j] = (firmNumber=j);
  end;
  intercept = 1.0;
  state panel_state(6) T(I) cov1(I)=(s2c);
  component panel = panel_state * (firmArray);
  state t_noise(1) type=wn cov(D);
  component teffect = t_noise[1];
  irregular wn ;
  model lC = intercept lQ lPF LF panel teffect wn;
  eval trendPlusReg = intercept + lQ + lPF + LF +
    panel + teffect;
  forecast out=for;
run;

```

The ID statement specifies year as an ID variable with yearly frequency. The PARMS statement defines $s2c$, a parameter that is restricted to be positive. $s2c$ is used later as the variance parameter for the panel effect. An array, firmArray , is defined, which is used later to pick the correct element of $\boldsymbol{\gamma}$ in a COMPONENT statement. A constant column, intercept , is defined to be used later as an intercept term. The state subsection panel_state corresponds to $\boldsymbol{\gamma}$, and the component panel extracts the proper element of $\boldsymbol{\gamma}$ by using firmArray . The component teffect corresponds to ξ_t , and wn specifies the observation noise ϵ_t . Finally the MODEL statement defines the model. A state linear combination, rendPlusReg , defined by the EVAL statement, is a sum of all effects in the model except the observation noise. An output data set, for , is specified to output all the estimated components. Some of the tables produced by running these statements are shown in [Output 27.1.1](#) through [Output 27.1.6](#).

The model summary, shown in [Output 27.1.1](#), shows that the model is defined by one MODEL statement, the dimension of the underlying state vector is 7 (since $\boldsymbol{\gamma}$ is six-dimensional and ξ_t is one-dimensional), the diffuse dimension is 4 (because of the four predictors in the model), and there are three parameters to be estimated.

Output 27.1.1 Model Summary Information

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	1
State Dimension	7
Dimension of the Diffuse Initial Condition	4
Number of Parameters	3

Output 27.1.2 provides information about the ID variable. It shows that there are multiple measurements—replications—at at least one time point. In this example you know that there are exactly six measurements at each time point.

Output 27.1.2 ID Variable Information

ID Variable Information				
Name	Start	End	MaxDelta	Type
year	1970	1984	1.00	Regular with replication

The **Output 27.1.3** provides likelihood information about the fitted model. See [Table 27.6](#) and [Table 27.7](#) for information about how to interpret this table.

Output 27.1.3 Likelihood Based Fit Statistics

Likelihood Based Fit Statistics	
Statistic	Value
Non-Missing Response Values Used	90
Estimated Parameters	3
Initialized Diffuse State Elements	4
Normalized Residual Sum of Squares	86
Full Log Likelihood	109.15
AIC (smaller is better)	-212.3
BIC (smaller is better)	-204.9
AICC (smaller is better)	-212
HQIC (smaller is better)	-209.3
CAIC (smaller is better)	-201.9

Output 27.1.4 shows the regression estimates.

Output 27.1.4 Regression Estimates

Estimates of the Regression Parameters					
Response Variable	Regression Variable	Estimate	Approx Std Error	t Value	Approx Pr > t
1C	intercept	9.36918	0.24003	39.03	<.0001
1C	1Q	0.86746	0.02510	34.56	<.0001
1C	1PF	0.43596	0.01700	25.64	<.0001
1C	1F	-0.98529	0.22369	-4.40	<.0001

The ML estimate of $s2c$, a parameter specified by the PARMS statement, is shown in [Output 27.1.5](#). It corresponds to σ_c^2 , the panel effect variance.

Output 27.1.5 Estimates of the Named Parameters

Maximum Likelihood Estimates of the Parameters Specified in the PARMS Statement			
Parameter	Estimate	Approx Std Error	
s2c	0.01516	0.0097921	

The estimates of the other unknown parameters in the model are shown in [Output 27.1.6](#). It shows the estimate of the variance of the irregular component wn , and the estimate of the variance of the time effect ξ_t .

Output 27.1.6 Estimates of the Unnamed Parameters

Maximum Likelihood Estimates of the Unknown System Parameters (Parameters Not Specified in the PARMS Statement)				
Component	Type	Parameter	Estimate	Approx Std Error
t_noise	Disturbance Covariance	Cov[1, 1]	0.00107	0.0006450
wn	Irregular	Variance	0.00274	0.0004721

Very often the main goal of a panel study is to estimate the regression effects, having taken into account the panel-specific intercepts (γ). However, you might also be interested in other issues. For example, the scatter plot in [Output 27.1.7](#) shows the smoothed estimates of ξ_t between 1970 and 1984, which can be thought of as shocks to the overall airline industry during this span. This plot is produced by using `smoothed_teffect`, the smoothed estimate of the `teffect` component in the model.

```
proc sgplot data=for;
  title "Yearly Disturbances to the Airline Industry";
  scatter x=year y=smoothed_teffect;
```

```
refline 0;
run;
```

Output 27.1.7 Scatter Plot of Smoothed Estimates of ξ_t

Similarly, you might wish to study the company-specific patterns implied by the fitted model. This can be done by using the smoothed estimate of `trendPlusReg`, a component defined by the `EVAL` statement in the program. The output data set, `for`, contains this estimate and contains its 95% confidence limits. However, `firmNumber`, the input data set variable that contains the company number, is not output to `for`. The following `DATA` step merges `for` with the input data set `airline`:

```
data for;
  merge for airline;
  by year;
run;
```

The following statements produce a panel of airline-specific trends. It is shown in [Output 27.1.8](#).

```
proc sgpanel data=for noautolegend;
  title 'Airline-specific Trends';
  panelby firmNumber / columns=3;
  band x=year lower=smoothed_lower_trendplusReg
      upper=smoothed_upper_trendplusReg;
```

```
scatter x=year y=lC;
series x=year y= smoothed_trendplusReg;
run;
```

Output 27.1.8 Airline-Specific Trends with 95% Confidence Bands

Example 27.2: Backcasting, Forecasting, and Interpolation

This example illustrates how you can do model-based extrapolation—backcasting, forecasting, or interpolation—of a response variable. All you need is to appropriately augment the input data set with the relevant ID and predictor information and assign missing values to the response variable in these places. Suppose that the response variable is named *Y*. Then, after an appropriate model is fit to the data, *smoothed_Y* (a variable in the output data set specified in the *OUT=* option in the *FORECAST* statement) contains the needed estimates of the extrapolated *Y* (the corresponding standard errors are in the variable *stderr_smoothed_Y*).

The following *DATA* step creates one such augmented data set by using a well-known data set that contains the recordings of the Nile river water level measured between the years 1871 and 1970. Suppose you want to backcast the Nile water level for two years before 1871, forecast it for two years after 1970, and interpolate its value for the year 1921—assuming that this value is missing in the available data set.

```

data nile;
  input level @@;
  year = intnx( 'year', '1jan1869'd, _n_-1 );
  format year year4.;
  if year = '1jan1921'd then level=.;
datalines;
. .
1120 1160 963 1210 1160 1160 813 1230 1370 1140
995 935 1110 994 1020 960 1180 799 958 1140
1100 1210 1150 1250 1260 1220 1030 1100 774 840
874 694 940 833 701 916 692 1020 1050 969
831 726 456 824 702 1120 1100 832 764 821
768 845 864 862 698 845 744 796 1040 759
781 865 845 944 984 897 822 1010 771 676
649 846 812 742 801 1040 860 874 848 890
744 749 838 1050 918 986 797 923 975 815
1020 906 901 1170 912 746 919 718 714 740
. .
;

```

It is also known that for this time span the Nile water level can be reasonably modeled as a sum of a random walk trend, a level shift in the year 1899, and the observation error. The following statements fit this model to the data. The forecast output is stored in `nileOut`.

```

proc ssm data=nile;
  id year interval=year;
  shift1899 = ( year >= '1jan1899'd );
  trend rw(rw);
  irregular wn;
  model level = shift1899 RW wn;
  forecast out=nileOut;
quit;

```

The following statements print the extrapolated values of the Nile water level, as shown in [Output 27.2.1](#).

```

proc print data=nileOut noobs;
  var year level smoothed_level stderr_smoothed_level;
  where level=.;
run;

```

Output 27.2.1 Extrapolated Nile Water Level

year	level	Smoothed_ level	StdErr_ Smoothed_ level
1869	.	1097.75	130.231
1870	.	1097.75	130.231
1921	.	851.13	128.864
1971	.	851.13	128.864
1972	.	851.13	128.864

Example 27.3: Smoothing of Repeated Measures Data

This example of a repeated measures study is taken from Diggle, Liang, and Zeger (1994, p. 100). The data consist of body weights of 27 cows, measured at 23 unequally spaced time points over a period of approximately 22 months. Following Diggle, Liang, and Zeger (1994), one animal is removed from the analysis, one observation is removed according to their Figure 5.7, and the time is shifted to start at 0 and is measured in 10-day increments. The design is a 2×2 factorial, and the factors are the infection of an animal with *M. paratuberculosis* and whether the animal is receiving iron dosing. The data set contains five variables: *cow* assigns a unique identification number—from 1 to 26—to each cow in the study, *tpoint* denotes the time of the growth measurement, *weight* denotes the growth measurement, *iron* is a dummy variable that indicates whether the animal is receiving iron or not, and *infection* is a dummy variable that indicates whether the animal is infected or not. The goal of the study is to assess the effect of iron and infection—and their possible interaction—on weight. The following DATA steps create this data set:

```
data times;
  input time1-time23;
  datalines;
122 150 166 179 219 247 276 296 324 354 380 445
478 508 536 569 599 627 655 668 723 751 781
;

data cows;
  if _n_ = 1 then merge times;
  array t{23} time1 - time23;
  array w{23} weight1 - weight23;
  input cow iron infection weight1-weight23 @@;
  do i=1 to 23;
    weight = w{i};
    tpoint = (t{i}-t{1})/10;
    output;
  end;
  keep cow iron infection tpoint weight;
  datalines;
1 0 0 4.7 4.905 5.011 5.075 5.136 5.165 5.298 5.323

... more lines ...
```

The following DATA step adds *ironInf*, a grouping variable that is used later during the plotting of the results. In the next step, the data are sorted by the index variable, *tpoint*.

```
data cows;
  set cows;
  ironInf = "No Iron and No Infection";
  if iron=1 and infection=1 then ironInf = "Iron and Infection";
  else if iron=1 and infection=0 then ironInf = "No Iron and Infection";
  else if iron=0 and infection=1 then ironInf = "Iron and No Infection";
  else ironInf = "No Iron and No Infection";
  run;

proc sort data=cows;
```

```

    by tpoint ;
run;

```

To assess the effect of iron and infection on weight, the natural growth profile of the animals must also be accounted for. Here two alternate models for this problem are considered. The first model assumes that the observed weight of an animal is the sum of a common growth profile, which is modeled by a polynomial spline trend of order 2, the regression effects of iron and infection, and the observation error—modeled as white noise. An interaction term, for interaction between iron and infection, was found to be insignificant and is not included. In the second model, the common growth profile and the regression variables of the first model are replaced by four environment specific growth profiles.

The following statements fit the first model:

```

proc ssm data=cows;
  id tpoint;
  trend growth(ps(2));
  irregular wn;
  model weight = iron infection growth wn;
  eval pattern = iron + infection + growth;
  forecast out=for;
quit;

```

Output 27.3.1 shows that the state dimension of this model is 2 (corresponding to the polynomial trend specification of order 2), the number of diffuse elements in the initial condition is 4 (corresponding to the trend and the two regressors iron and infection), and the number of unknown parameters is 2 (corresponding to the variance parameters of trend and irregular).

Output 27.3.1 Model1: Model Summary Information

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	1
State Dimension	2
Dimension of the Diffuse Initial Condition	4
Number of Parameters	2

Output 27.3.2 shows that the ID variable is irregularly spaced with replication.

Output 27.3.2 ID Variable Information

ID Variable Information				
Name	Start	End	MaxDelta	Type
tpoint	0	65.9000	6.50	Irregular with replication

The estimated regression coefficients of iron and infection, shown in [Output 27.3.3](#), are significant and negative. This implies that both iron and infection adversely affect the response variable, weight.

Output 27.3.3 Model 1: Regression Estimates

Estimates of the Regression Parameters					
Response Variable	Regression Variable	Estimate	Approx Std Error	t Value	Approx Pr > t
weight	iron	-0.07476	0.0076114	-9.82	<.0001
weight	infection	-0.12921	0.0085924	-15.04	<.0001

The variance estimates of the trend component and the irregular component are shown in [Output 27.3.4](#).

Output 27.3.4 Model 1: Estimates of Unnamed Parameters

Maximum Likelihood Estimates of the Unknown System Parameters (Parameters Not Specified in the PARMS Statement)					
Component	Type	Parameter	Estimate	Approx Std Error	
growth	PS(2) Trend	Level Variance	0.00001625	9.01304E-6	
wn	Irregular	Variance	0.00858	0.0005034	

After examining the model fit, it is useful to study how well the patterns implied by the model follow the data. pattern, defined by the EVAL statement, is a sum of the trend component and the regression effects. A graphical examination of the smoothed estimate of pattern is done next. The following DATA step merges the output data set specified in the FORECAST statement, for, with the input data set, cows. In particular, this adds ironInf (a grouping variable from cows) to for.

```
data for;
  merge for cows;
  by tpoint;
run;
```

The following statements produce the graphs of smoothed_pattern, grouped according to the environment condition (see [Output 27.3.5](#)). The plot clearly shows that the control group “No Iron and No Infection” has the best growth profile, while the worst growth profile is for the group “Iron and Infection.”

```
proc sgplot data=for noautolegend;
  title 'Common Growth Profile Adjusted by Iron and Infection Status';
  band x=tpoint lower=smoothed_lower_pattern
    upper=smoothed_upper_pattern / group=ironInf name="band";
  series x=tpoint y=smoothed_pattern / group=ironInf name="series";
  keylegend "series";
run;
```

Output 27.3.5 Model 1: Growth Profile Comparison with 95% Confidence Bands

The following statements produce a panel of plots that show how well `smoothed_pattern` follows the observed data:

```
proc sgpanel data=for noautolegend;
  title 'Growth Plots Grouped by Iron and Infection';
  label tpoint='Time' ;
  panelby iron infection / columns=2;
  band x=tpoint lower=smoothed_lower_pattern
        upper=smoothed_upper_pattern ;
  scatter x=tpoint y=weight;
  series x=tpoint y=smoothed_pattern ;
run;
```

Output 27.3.6 shows that the model fits the data reasonably well.

Output 27.3.6 Model 1: Smoothed Model Fit Lines

The following statements fit the second model. In this model separate polynomial trends are fit according to different settings of iron and infection by specifying an appropriate list of (dummy) variables in the **CROSS=** option of the trend specification.

```
proc ssm data=cows;
  id tpoint;
  a1 = (iron=1 and infection=1);
  a2 = (iron=1 and infection=0);
  a3 = (iron=0 and infection=1);
  a4 = (iron=0 and infection=0);
```

```

trend growth(ps(2)) cross=(a1-a4);
irregular wn;
model weight = growth wn;
forecast out=for1;
quit;

```

As a result of the **CROSS=** option, the trend component growth is actually a sum of four separate trends that correspond to the different iron-infection settings. Denoting growth by μ_t and the four independent trends by $\mu_{1,t}$, $\mu_{2,t}$, $\mu_{3,t}$, and $\mu_{4,t}$,

$$\mu_t = a1 * \mu_{1,t} + a2 * \mu_{2,t} + a3 * \mu_{3,t} + a4 * \mu_{4,t}$$

where a1, a2, a3, and a4 are the dummy variables specified in the **CROSS=** option. This shows that, for any given setting (say, the one for a4) μ_t is simply the corresponding trend $\mu_{4,t}$. The model summary, shown in [Output 27.3.7](#), reflects the increased state dimension and the increased number of parameters.

Output 27.3.7 Model2: Model Summary Information

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	1
State Dimension	8
Dimension of the Diffuse Initial Condition	8
Number of Parameters	5

[Output 27.3.8](#) shows the parameter estimates for this model.

Output 27.3.8 Model2: Estimates of Unnamed Parameters (Partial Output)

Component	Type	Parameter	Estimate
growth(Cross = a1)	PS(2) Trend	Level Variance	0.00001279
growth(Cross = a2)	PS(2) Trend	Level Variance	0.00000872
growth(Cross = a3)	PS(2) Trend	Level Variance	0.00000907
growth(Cross = a4)	PS(2) Trend	Level Variance	0.00000845
wn	Irregular	Variance	0.00839

Next, the smoothed estimate of trend (growth) is graphically studied. The following DATA step prepares the data for the grouped plots of smoothed_growth by merging for1 with the input data set cows. As before, the reason is merely to include ironInf (the grouping variable).

```

data for1;
  merge for1 cows;
  by tpoint;
run;

```

The following statements produce the graphs of smoothed μ_t for the desired settings (since the grouping variable ironInf exactly corresponds to these settings). Once again, the plot in [Output 27.3.9](#) clearly shows

that the control group “No Iron and No Infection” has the best growth profile, while the worst growth profile is for the group “Iron and Infection.” However, unlike the first model, the profile curves are not merely shifted versions of a common profile.

```
proc sgplot data=for1 noautolegend;
  title 'Iron and Infection Status-Specific Growth Profiles';
  band x=tpoint lower=smoothed_lower_growth
      upper=smoothed_upper_growth / group=ironInf name="band";
  series x=tpoint y=smoothed_growth / group=ironInf name="series";
  keylegend "series";
run;
```

Output 27.3.9 Model 2: Growth Profile Comparison with 95% Confidence Bands

Example 27.4: A User-Defined Trend Model

This example shows how to specify a continuous-time trend model discussed in Harvey (1989, chap. 9, sec. 9.2.1). This model is not one of the predefined trend models in the SSM procedure. The system matrices

that govern the two-dimensional state of this model are

$$\mathbf{T} = \begin{bmatrix} 1 & h \\ 0 & 1 \end{bmatrix}$$

$$\mathbf{Q} = \begin{bmatrix} h\sigma_1^2 + \frac{h^3\sigma_2^2}{3} & \frac{h^2\sigma_2^2}{2} \\ \frac{h^2\sigma_2^2}{2} & h\sigma_2^2 \end{bmatrix}$$

where $h = h_t = (\tau_{t+1} - \tau_t)$ denotes the difference between the successive time points, and the parameters σ_1^2 and σ_2^2 are called the level variance and the slope variance, respectively. The initial condition is fully diffuse. The trend component corresponds to the first element of this state vector. The second element of the state vector corresponds to the slope of this trend component. This model reduces to the polynomial spline model of order 2 if the level variance $\sigma_1^2 = 0$. See the section “[Polynomial Spline Trend](#)” on page 1798.

The following statements specify a trend-plus-noise model to model the growth of cows in the previous example ([Example 27.3](#)). The only cows that are considered are the ones that received iron and are infected.

```
proc ssm data=cows;
  where iron=1 and infection=1;
  id tpoint;
  parms var1 var2 / lower=(1.e-8 1.e-8);
  array tMat{2,2};
  tMat[1,1] = 1;
  tMat[2,2] = 1;
  tMat[1,2] = _ID_DELTA_;
  array covMat{2,2};
  covMat[1,1] = var1*_ID_DELTA_ + var2*_ID_DELTA_**3/3;
  covMat[1,2] = var2*_ID_DELTA_**2/2;
  covMat[2,1] = covMat[1,2] ;
  covMat[2,2] = var2*_ID_DELTA_;
  state harveyLL(2) T(g)=(tMat) cov(g)=(covMat) a1(2);
  component trend = harveyLL[1];
  component slope = harveyLL[2];
  irregular wn;
  model weight = trend wn;
  forecast out=for;
run;
```

The program is easy to follow. The PARMS statement declares var1 and var2 as positive parameters, which correspond to σ_1^2 and σ_2^2 , respectively. The programming statements define arrays tMat and covMat, which later become the matrices \mathbf{T} and \mathbf{Q} , respectively. Note that the element tMat[2,1] is left unassigned, since it is a structural zero of \mathbf{T} (see the section “[Sparse Transition Matrix Specification](#)” on page 1791 for more information). Recall that the predefined variable _ID_DELTA_ contains the value of h_t , which is needed for defining the elements of \mathbf{T} and \mathbf{Q} (see the section “[ID Statement](#)” on page 1779). The STATE statement defines the trend state vector, harveyLL, and the COMPONENT statement defines the trend component, trend, by selecting the first element of harveyLL. An additional COMPONENT statement defines the slope component, slope, as the second element of harveyLL. The slope component (which represents the cow’s growth rate) is not part of the observation equation; it is specified so that its estimate is output to for (the OUT= data set specified in the FORECAST statement). The observation noise is defined by the IRREGULAR statement, and the MODEL statement defines the trend-plus-noise model.

The estimates of var1 and var2 are shown in [Output 27.4.1](#). It shows that the estimate of the level variance is nearly zero, implying that the fitted trend model is identical to the polynomial spline trend of order 2.

Output 27.4.1 Estimates of the Named Parameters

The SSM Procedure		
Maximum Likelihood Estimates of the Parameters Specified in the PARMS Statement		
Parameter	Estimate	Approx Std Error
var1	1E-8	0.0008486
var2	0.00001236	.

The estimate of the noise variance is shown in [Output 27.4.2](#).

Output 27.4.2 Estimates of the Unnamed Parameters

Maximum Likelihood Estimates of the Unknown System Parameters (Parameters Not Specified in the PARMS Statement)				
Component	Type	Parameter	Estimate	Approx Std Error
wn	Irregular	Variance	0.00954	0.0009094

The following statements produce the plot of the fit of this trend model (shown in [Output 27.4.3](#)).

```
proc sgplot data=for;
  title "Model Fit: Two-Parameter Polynomial Spline of Order 2";
  series x=tpoint y=smoothed_trend;
  scatter x=tpoint y=weight;
run;
```

Output 27.4.3 A User-Defined Trend Model

The following statements produce the plot of the estimate of the slope component (shown in [Output 27.4.4](#)). This plot complements the preceding plot of trend; it shows the pattern of decline in the growth rate as the animals age.

```
proc sgplot data=for;
  title "Smoothed Estimate of Growth-Rate";
  series x=tpoint y=smoothed_slope;
run;
```

Output 27.4.4 Estimate of the slope Component

Overview: STATESPACE Procedure

The STATESPACE procedure uses the state space model to analyze and forecast multivariate time series. The STATESPACE procedure is appropriate for jointly forecasting several related time series that have dynamic interactions. By taking into account the autocorrelations among all the variables in a set, the STATESPACE procedure can give better forecasts than methods that model each series separately.

By default, the STATESPACE procedure automatically selects a state space model appropriate for the time series, making the procedure a good tool for automatic forecasting of multivariate time series. Alternatively, you can specify the state space model by giving the form of the state vector and the state transition and innovation matrices.

The methods used by the STATESPACE procedure assume that the time series are jointly stationary. Non-stationary series must be made stationary by some preliminary transformation, usually by differencing. The STATESPACE procedure enables you to specify differencing of the input data. When differencing is specified, the STATESPACE procedure automatically integrates forecasts of the differenced series to produce forecasts of the original series.

The State Space Model

The *state space model* represents a multivariate time series through auxiliary variables, some of which might not be directly observable. These auxiliary variables are called the *state vector*. The state vector summarizes all the information from the present and past values of the time series that is relevant to the prediction of future values of the series. The observed time series are expressed as linear combinations of the state variables. The state space model is also called a Markovian representation, or a canonical representation, of a multivariate time series process. The state space approach to modeling a multivariate stationary time series is summarized in Akaike (1976).

The state space form encompasses a very rich class of models. Any Gaussian multivariate stationary time series can be written in a state space form, provided that the dimension of the predictor space is finite. In particular, any autoregressive moving average (ARMA) process has a state space representation and, conversely, any state space process can be expressed in an ARMA form (Akaike 1974). More details on the relation of the state space and ARMA forms are given in the section “[Relation of ARMA and State Space Forms](#)” on page 1861.

Let \mathbf{x}_t be the $r \times 1$ vector of observed variables, after differencing (if differencing is specified) and subtracting the sample mean. Let \mathbf{z}_t be the state vector of dimension s , $s \geq r$, where the first r components of \mathbf{z}_t consist of \mathbf{x}_t . Let the notation $\mathbf{x}_{t+k|t}$ represent the conditional expectation (or prediction) of \mathbf{x}_{t+k} based on the information available at time t . Then the last $s - r$ elements of \mathbf{z}_t consist of elements of $\mathbf{x}_{t+k|t}$, where $k > 0$ is specified or determined automatically by the procedure.

There are various forms of the state space model in use. The form of the state space model used by the STATESPACE procedure is based on Akaike (1976). The model is defined by the following *state transition equation* :

$$\mathbf{z}_{t+1} = \mathbf{F}\mathbf{z}_t + \mathbf{G}\mathbf{e}_{t+1}$$

In the state transition equation, the $s \times s$ coefficient matrix \mathbf{F} is called the *transition matrix*; it determines the dynamic properties of the model.

The $s \times r$ coefficient matrix \mathbf{G} is called the *input matrix*; it determines the variance structure of the transition equation. For model identification, the first r rows and columns of \mathbf{G} are set to an $r \times r$ identity matrix.

The input vector \mathbf{e}_t is a sequence of independent normally distributed random vectors of dimension r with mean $\mathbf{0}$ and covariance matrix Σ_{ee} . The random error \mathbf{e}_t is sometimes called the innovation vector or shock vector.

In addition to the state transition equation, state space models usually include a *measurement equation* or *observation equation* that gives the observed values \mathbf{x}_t as a function of the state vector \mathbf{z}_t . However, since PROC STATESPACE always includes the observed values \mathbf{x}_t in the state vector \mathbf{z}_t , the measurement equation in this case merely represents the extraction of the first r components of the state vector.

The measurement equation used by the STATESPACE procedure is

$$\mathbf{x}_t = [\mathbf{I}_r \mathbf{0}] \mathbf{z}_t$$

where \mathbf{I}_r is an $r \times r$ identity matrix. In practice, PROC STATESPACE performs the extraction of \mathbf{x}_t from \mathbf{z}_t without reference to an explicit measurement equation.

In summary:

\mathbf{x}_t	is an observation vector of dimension r .
\mathbf{z}_t	is a state vector of dimension s , whose first r elements are \mathbf{x}_t and whose last $s - r$ elements are conditional prediction of future \mathbf{x}_t .
\mathbf{F}	is an $s \times s$ transition matrix.
\mathbf{G}	is an $s \times r$ input matrix, with the identity matrix \mathbf{I}_r forming the first r rows and columns.
\mathbf{e}_t	is a sequence of independent normally distributed random vectors of dimension r with mean $\mathbf{0}$ and covariance matrix Σ_{ee} .

How PROC STATESPACE Works

The design of the STATESPACE procedure closely follows the modeling strategy proposed by Akaike (1976). This strategy employs canonical correlation analysis for the automatic identification of the state space model.

Following Akaike (1976), the procedure first fits a sequence of unrestricted vector autoregressive (VAR) models and computes Akaike's information criterion (AIC) for each model. The vector autoregressive models are estimated using the sample autocovariance matrices and the Yule-Walker equations. The order of the VAR model that produces the smallest Akaike information criterion is chosen as the order (number of lags into the past) to use in the canonical correlation analysis.

The elements of the state vector are then determined via a sequence of canonical correlation analyses of the sample autocovariance matrices through the selected order. This analysis computes the sample canonical correlations of the past with an increasing number of steps into the future. Variables that yield significant

correlations are added to the state vector; those that yield insignificant correlations are excluded from further consideration. The importance of the correlation is judged on the basis of another information criterion proposed by Akaike. See the section “[Canonical Correlation Analysis Options](#)” on page 1845 for details. If you specify the state vector explicitly, these model identification steps are omitted.

After the state vector is determined, the state space model is fit to the data. The free parameters in the **F**, **G**, and Σ_{ee} matrices are estimated by approximate maximum likelihood. By default, the **F** and **G** matrices are unrestricted, except for identifiability requirements. Optionally, conditional least squares estimates can be computed. You can impose restrictions on elements of the **F** and **G** matrices.

After the parameters are estimated, the Kalman filtering technique is used to produce forecasts from the fitted state space model. If differencing was specified, the forecasts are integrated to produce forecasts of the original input variables.

Getting Started: STATESPACE Procedure

The following introductory example uses simulated data for two variables X and Y. The following statements generate the X and Y series.

```
data in;
  x=10;  y=40;
  x1=0;  y1=0;
  a1=0;  b1=0;
  iseed=123;
  do t=-100 to 200;
    a=rannor(iseed);
    b=rannor(iseed);
    dx = 0.5*x1 + 0.3*y1 + a - 0.2*a1 - 0.1*b1;
    dy = 0.3*x1 + 0.5*y1 + b;
    x = x + dx + .25;
    y = y + dy + .25;
    if t >= 0 then output;
    x1 = dx; y1 = dy;
    a1 = a; b1 = b;
  end;
  keep t x y;
run;
```

The simulated series X and Y are shown in [Figure 28.1](#).

Figure 28.1 Example Series

Automatic State Space Model Selection

The STATESPACE procedure is designed to automatically select the best state space model for forecasting the series. You can specify your own model if you want, and you can use the output from PROC STATESPACE to help you identify a state space model. However, the easiest way to use PROC STATESPACE is to let it choose the model.

Stationarity and Differencing

Although PROC STATESPACE selects the state space model automatically, it does assume that the input series are stationary. If the series are nonstationary, then the process might fail. Therefore the first step is to examine your data and test to see if differencing is required. (See the section “[Stationarity and Differencing](#)” on page 1850 for further discussion of this issue.)

The series shown in [Figure 28.1](#) are nonstationary. In order to forecast X and Y with a state space model, you must difference them (or use some other detrending method). If you fail to difference when needed

and try to use PROC STATESPACE with nonstationary data, an inappropriate state space model might be selected, and the model estimation might fail to converge.

The following statements identify and fit a state space model for the first differences of X and Y, and forecast X and Y 10 periods ahead:

```
proc statespace data=in out=out lead=10;
  var x(1) y(1);
  id t;
run;
```

The DATA= option specifies the input data set and the OUT= option specifies the output data set for the forecasts. The LEAD= option specifies forecasting 10 observations past the end of the input data. The VAR statement specifies the variables to forecast and specifies differencing. The notation X(1) Y(1) specifies that the state space model analyzes the first differences of X and Y.

Descriptive Statistics and Preliminary Autoregressions

The first page of the printed output produced by the preceding statements is shown in Figure 28.2.

Figure 28.2 Descriptive Statistics and VAR Order Selection

The STATESPACE Procedure								
Number of Observations		200						
Variable	Mean	Standard Error						
x	0.144316	1.233457	Has been differenced. With period(s) = 1.					
y	0.164871	1.304358	Has been differenced. With period(s) = 1.					
The STATESPACE Procedure								
Information Criterion for Autoregressive Models								
Lag=0	Lag=1	Lag=2	Lag=3	Lag=4	Lag=5	Lag=6	Lag=7	Lag=8
149.697	8.387786	5.517099	12.05986	15.36952	21.79538	24.00638	29.88874	33.55708
Information Criterion for Autoregressive Models								
			Lag=9	Lag=10				
			41.17606	47.70222				

Figure 28.2 *continued*

Schematic Representation of Correlations											
Name/Lag	0	1	2	3	4	5	6	7	8	9	10
x	++	++	++	++	++	++	+	..	+	+	..
y	++	++	++	++	++	+	+	+	+
+ is > 2*std error, - is < -2*std error, . is between											

Descriptive statistics are printed first, giving the number of nonmissing observations after differencing and the sample means and standard deviations of the differenced series. The sample means are subtracted before the series are modeled (unless the NOCENTER option is specified), and the sample means are added back when the forecasts are produced.

Let X_t and Y_t be the observed values of X and Y, and let x_t and y_t be the values of X and Y after differencing and subtracting the mean difference. The series \mathbf{x}_t modeled by the STATESPACE procedure is

$$\mathbf{x}_t = \begin{bmatrix} x_t \\ y_t \end{bmatrix} = \begin{bmatrix} (1 - B)X_t - 0.144316 \\ (1 - B)Y_t - 0.164871 \end{bmatrix}$$

where B represents the backshift operator.

After the descriptive statistics, PROC STATESPACE prints the Akaike information criterion (AIC) values for the autoregressive models fit to the series. The smallest AIC value, in this case 5.517 at lag 2, determines the number of autocovariance matrices analyzed in the canonical correlation phase.

A schematic representation of the autocorrelations is printed next. This indicates which elements of the autocorrelation matrices at different lags are significantly greater than or less than 0.

The second page of the STATESPACE printed output is shown in Figure 28.3.

Figure 28.3 Partial Autocorrelations and VAR Model

Schematic Representation of Partial Autocorrelations											
Name/Lag	1	2	3	4	5	6	7	8	9	10	
x	++	+	
y	++	
+ is > 2*std error, - is < -2*std error, . is between											
Yule-Walker Estimates for Minimum AIC											
-----Lag=1-----				-----Lag=2-----							
	x		y		x		y				
x	0.257438		0.202237		0.170812		0.133554				
y	0.292177		0.469297		-0.00537		-0.00048				

Figure 28.3 shows a schematic representation of the partial autocorrelations, similar to the autocorrelations shown in Figure 28.2. The selection of a second order autoregressive model by the AIC statistic looks reasonable in this case because the partial autocorrelations for lags greater than 2 are not significant.

Next, the Yule-Walker estimates for the selected autoregressive model are printed. This output shows the coefficient matrices of the vector autoregressive model at each lag.

Selected State Space Model Form and Preliminary Estimates

After the autoregressive order selection process has determined the number of lags to consider, the canonical correlation analysis phase selects the state vector. By default, output for this process is not printed. You can use the CANCELL option to print details of the canonical correlation analysis. See the section “[Canonical Correlation Analysis Options](#)” on page 1845 for an explanation of this process.

After the state vector is selected, the state space model is estimated by approximate maximum likelihood. Information from the canonical correlation analysis and from the preliminary autoregression is used to form preliminary estimates of the state space model parameters. These preliminary estimates are used as starting values for the iterative estimation process.

The form of the state vector and the preliminary estimates are printed next, as shown in Figure 28.4.

Figure 28.4 Preliminary Estimates of State Space Model

The STATESPACE Procedure		
Selected Statespace Form and Preliminary Estimates		
State Vector		
$\mathbf{x}(T;T)$	$\mathbf{y}(T;T)$	$\mathbf{x}(T+1;T)$
Estimate of Transition Matrix		
0	0	1
0.291536	0.468762	-0.00411
0.24869	0.24484	0.204257
Input Matrix for Innovation		
1	0	
0	1	
0.257438	0.202237	
Variance Matrix for Innovation		
0.945196	0.100786	
0.100786	1.014703	

Figure 28.4 first prints the state vector as $X[T;T] \ Y[T;T] \ X[T+1;T]$. This notation indicates that the state vector is

$$\mathbf{z}_t = \begin{bmatrix} x_{t|t} \\ y_{t|t} \\ x_{t+1|t} \end{bmatrix}$$

The notation $x_{t+1|t}$ indicates the conditional expectation or prediction of x_{t+1} based on the information available at time t , and $x_{t|t}$ and $y_{t|t}$ are x_t and y_t , respectively.

The remainder of Figure 28.4 shows the preliminary estimates of the transition matrix \mathbf{F} , the input matrix \mathbf{G} , and the covariance matrix Σ_{ee} .

Estimated State Space Model

The next page of the STATESPACE output prints the final estimates of the fitted model, as shown in Figure 28.5. This output has the same form as in Figure 28.4, but it shows the maximum likelihood estimates instead of the preliminary estimates.

Figure 28.5 Fitted State Space Model

The STATESPACE Procedure		
Selected Statespace Form and Fitted Model		
State Vector		
$\mathbf{x}(T;T)$	$\mathbf{y}(T;T)$	$\mathbf{x}(T+1;T)$
Estimate of Transition Matrix		
0	0	1
0.297273	0.47376	-0.01998
0.2301	0.228425	0.256031
Input Matrix for Innovation		
1	0	
0	1	
0.257284	0.202273	
Variance Matrix for Innovation		
0.945188	0.100752	
0.100752	1.014712	

The estimated state space model shown in Figure 28.5 is

$$\begin{bmatrix} x_{t+1|t+1} \\ y_{t+1|t+1} \\ x_{t+2|t+1} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 \\ 0.297 & 0.474 & -0.020 \\ 0.230 & 0.228 & 0.256 \end{bmatrix} \begin{bmatrix} x_t \\ y_t \\ x_{t+1|t} \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0.257 & 0.202 \end{bmatrix} \begin{bmatrix} e_{t+1} \\ n_{t+1} \end{bmatrix}$$

$$\text{var} \begin{bmatrix} e_{t+1} \\ n_{t+1} \end{bmatrix} = \begin{bmatrix} 0.945 & 0.101 \\ 0.101 & 1.015 \end{bmatrix}$$

The next page of the STATESPACE output lists the estimates of the free parameters in the **F** and **G** matrices with standard errors and *t* statistics, as shown in Figure 28.6.

Figure 28.6 Final Parameter Estimates

Parameter Estimates				
Parameter	Estimate	Standard Error	t Value	
F(2,1)	0.297273	0.129995	2.29	
F(2,2)	0.473760	0.115688	4.10	
F(2,3)	-0.01998	0.313025	-0.06	
F(3,1)	0.230100	0.126226	1.82	
F(3,2)	0.228425	0.112978	2.02	
F(3,3)	0.256031	0.305256	0.84	
G(3,1)	0.257284	0.071060	3.62	
G(3,2)	0.202273	0.068593	2.95	

Convergence Failures

The maximum likelihood estimates are computed by an iterative nonlinear maximization algorithm, which might not converge. If the estimates fail to converge, warning messages are printed in the output.

If you encounter convergence problems, you should recheck the stationarity of the data and ensure that the specified differencing orders are correct. Attempting to fit state space models to nonstationary data is a common cause of convergence failure. You can also use the MAXIT= option to increase the number of iterations allowed, or experiment with the convergence tolerance options DETTOL= and PARMTOL=.

Forecast Data Set

The following statements print the output data set. The WHERE statement excludes the first 190 observations from the output, so that only the forecasts and the last 10 actual observations are printed.

```
proc print data=out;
  id t;
  where t > 190;
run;
```

The PROC PRINT output is shown in Figure 28.7.

Figure 28.7 OUT= Data Set Produced by PROC STATESPACE

The OUT= data set produced by PROC STATESPACE contains the VAR and ID statement variables. In addition, for each VAR statement variable, the OUT= data set contains the variables FOR_i , RES_i , and STD_i . These variables contain the predicted values, residuals, and forecast standard errors for the i th variable in the VAR statement list. In this case, X is listed first in the VAR statement, so FOR1 contains the forecasts of X, while FOR2 contains the forecasts of Y.

The following statements plot the forecasts and actuals for the series.

```
proc sgplot data=out noautolegend;
  where t > 150;
  series x=t y=for1 / markers
    markerattrs=(symbol=circle color=blue)
    lineattrs=(pattern=solid color=blue);
  series x=t y=for2 / markers
    markerattrs=(symbol=circle color=blue)
    lineattrs=(pattern=solid color=blue);
  series x=t y=x / markers
    markerattrs=(symbol=circle color=red)
    lineattrs=(pattern=solid color=red);
  series x=t y=y / markers
    markerattrs=(symbol=circle color=red)
    lineattrs=(pattern=solid color=red);
  refline 200.5 / axis=x;
run;
```

The forecast plot is shown in [Figure 28.8](#). The last 50 observations are also plotted to provide context, and a reference line is drawn between the historical and forecast periods.

Figure 28.8 Plot of Forecasts

Controlling Printed Output

By default, the STATESPACE procedure produces a large amount of printed output. The NOPRINT option suppresses all printed output. You can suppress the printed output for the autoregressive model selection process with the PRINTOUT=NONE option. The descriptive statistics and state space model estimation output are still printed when PRINTOUT=NONE is specified. You can produce more detailed output with the PRINTOUT=LONG option and by specifying the printing control options CANCELL, COVB, and PRINT.

Specifying the State Space Model

Instead of allowing the STATESPACE procedure to select the model automatically, you can use FORM and RESTRICT statements to specify a state space model.

Specifying the State Vector

Use the FORM statement to control the form of the state vector. You can use this feature to force PROC STATESPACE to estimate and forecast a model different from the model it would select automatically. You can also use this feature to reestimate the automatically selected model (possibly with restrictions) without repeating the canonical correlation analysis.

The FORM statement specifies the number of lags of each variable to include in the state vector. For example, the statement FORM X 3; forces the state vector to include $x_{t|t}$, $x_{t+1|t}$, and $x_{t+2|t}$. The following statement specifies the state vector $(x_{t|t}, y_{t|t}, x_{t+1|t})$, which is the same state vector selected in the preceding example:

```
form x 2 y 1;
```

You can specify the form for only some of the variables and allow PROC STATESPACE to select the form for the other variables. If only some of the variables are specified in the FORM statement, canonical correlation analysis is used to determine the number of lags included in the state vector for the remaining variables not specified by the FORM statement. If the FORM statement includes specifications for all the variables listed in the VAR statement, the state vector is completely defined and the canonical correlation analysis is not performed.

Restricting the F and G matrices

After you know the form of the state vector, you can use the RESTRICT statement to fix some parameters in the **F** and **G** matrices to specified values. One use of this feature is to remove insignificant parameters by restricting them to 0.

In the introductory example shown in the preceding section, the F[2,3] parameter is not significant. (The parameters estimation output shown in [Figure 28.6](#) gives the t statistic for F[2,3] as -0.06 . F[3,3] and F[3,1] also have low significance with $t < 2$.)

The following statements reestimate this model with F[2,3] restricted to 0. The FORM statement is used to specify the state vector and thus bypass the canonical correlation analysis.

```
proc statespace data=in out=out lead=10;
  var x(1) y(1);
  id t;
  form x 2 y 1;
  restrict f(2,3)=0;
run;
```

The final estimates produced by these statements are shown in [Figure 28.10](#).

Syntax: STATESPACE Procedure

The STATESPACE procedure uses the following statements:

PROC STATESPACE *options* ;
BY *variable* ... ;
FORM *variable value* ... ;
ID *variable* ;
INITIAL *F (row,column)=value ... G(row,column)=value ...* ;
RESTRICT *F (row,column)=value ... G (row,column)=value ...* ;
VAR *variable (difference, difference, ...) ...* ;

Functional Summary

Table 28.1 summarizes the statements and options used by PROC STATESPACE.

Table 28.1 STATESPACE Functional Summary

Description	Statement	Option
Input Data Set Options		
specify the input data set	PROC STATESPACE	DATA=
prevent subtraction of sample mean	PROC STATESPACE	NOCENTER
specify the ID variable	ID	
specify the observed series and differencing	VAR	
Options for Autoregressive Estimates		
specify the maximum order	PROC STATESPACE	ARMAX=
specify maximum lag for autocovariances	PROC STATESPACE	LAGMAX=
output only minimum AIC model	PROC STATESPACE	MINIC
specify the amount of detail printed	PROC STATESPACE	PRINTOUT=
write preliminary AR models to a data set	PROC STATESPACE	OUTAR=
Options for Canonical Correlation Analysis		
print the sequence of canonical correlations	PROC STATESPACE	CANCORR
specify upper limit of dimension of state vector	PROC STATESPACE	DIMMAX=
specify the minimum number of lags	PROC STATESPACE	PASTMIN=
specify the multiplier of the degrees of freedom	PROC STATESPACE	SIGCORR=
Options for State Space Model Estimation		
specify starting values	INITIAL	
print covariance matrix of parameter estimates	PROC STATESPACE	COVB
specify the convergence criterion	PROC STATESPACE	DETTOL=
specify the convergence criterion	PROC STATESPACE	PARMTOL=
print the details of the iterations	PROC STATESPACE	ITPRINT
specify an upper limit of the number of lags	PROC STATESPACE	KLAG=
specify maximum number of iterations allowed	PROC STATESPACE	MAXIT=
suppress the final estimation	PROC STATESPACE	NOEST

Description	Statement	Option
write the state space model parameter estimates to an output data set	PROC STATESPACE	OUTMODEL=
use conditional least squares for final estimates	PROC STATESPACE	RESIDEST
specify criterion for testing for singularity	PROC STATESPACE	SINGULAR=
Options for Forecasting		
start forecasting before end of the input data	PROC STATESPACE	BACK=
specify the time interval between observations	PROC STATESPACE	INTERVAL=
specify multiple periods in the time series	PROC STATESPACE	INTPER=
specify how many periods to forecast	PROC STATESPACE	LEAD=
specify the output data set for forecasts	PROC STATESPACE	OUT=
print forecasts	PROC STATESPACE	PRINT
Options to Specify the State Space Model		
specify the state vector	FORM	
specify the parameter values	RESTRICT	
BY Groups		
specify BY-group processing	BY	
Printing		
suppresses all printed output	NOPRINT	

PROC STATESPACE Statement

PROC STATESPACE *options* ;

The following options can be specified in the PROC STATESPACE statement.

Printing Options

NOPRINT

suppresses all printed output.

Input Data Options

DATA=SAS-data-set

specifies the name of the SAS data set to be used by the procedure. If the DATA= option is omitted, the most recently created SAS data set is used.

LAGMAX=k

specifies the number of lags for which the sample autocovariance matrix is computed. The LAG-

MAX= option controls the number of lags printed in the schematic representation of the autocorrelations.

The sample autocovariance matrix of lag i , denoted as \mathbf{C}_i , is computed as

$$\mathbf{C}_i = \frac{1}{N-1} \sum_{t=1+i}^N \mathbf{x}_t \mathbf{x}_{t-i}'$$

where \mathbf{x}_t is the differenced and centered data and N is the number of observations. (If the NOCENTER option is specified, 1 is not subtracted from N .) LAGMAX= k specifies that \mathbf{C}_0 through \mathbf{C}_k are computed. The default is LAGMAX=10.

NOCENTER

prevents subtraction of the sample mean from the input series (after any specified differencing) before the analysis.

Options for Preliminary Autoregressive Models

ARMAX= n

specifies the maximum order of the preliminary autoregressive models. The ARMAX= option controls the autoregressive orders for which information criteria are printed, and controls the number of lags printed in the schematic representation of partial autocorrelations. The default is ARMAX=10. See the section “[Preliminary Autoregressive Models](#)” on page 1851 for details.

MINIC

writes to the OUTAR= data set only the preliminary Yule-Walker estimates for the VAR model that produces the minimum AIC. See the section “[OUTAR= Data Set](#)” on page 1863 for details.

OUTAR=SAS-data-set

writes the Yule-Walker estimates of the preliminary autoregressive models to a SAS data set. See the section “[OUTAR= Data Set](#)” on page 1863 for details.

PRINTOUT=SHORT | LONG | NONE

determines the amount of detail printed. PRINTOUT=LONG prints the lagged covariance matrices, the partial autoregressive matrices, and estimates of the residual covariance matrices from the sequence of autoregressive models. PRINTOUT=NONE suppresses the output for the preliminary autoregressive models. The descriptive statistics and state space model estimation output are still printed when PRINTOUT=NONE is specified. PRINTOUT=SHORT is the default.

Canonical Correlation Analysis Options

CANCORR

prints the canonical correlations and information criterion for each candidate state vector considered. See the section “[Canonical Correlation Analysis Options](#)” on page 1845 for details.

DIMMAX= n

specifies the upper limit to the dimension of the state vector. The DIMMAX= option can be used to limit the size of the model selected. The default is DIMMAX=10.

PASTMIN=*n*

specifies the minimum number of lags to include in the canonical correlation analysis. The default is PASTMIN=0. See the section “[Canonical Correlation Analysis Options](#)” on page 1845 for details.

SIGCORR=*value*

specifies the multiplier of the degrees of freedom for the penalty term in the information criterion used to select the state space form. The default is SIGCORR=2. The larger the value of the SIGCORR= option, the smaller the state vector tends to be. Hence, a large value causes a simpler model to be fit. See the section “[Canonical Correlation Analysis Options](#)” on page 1845 for details.

State Space Model Estimation Options

COVB

prints the inverse of the observed information matrix for the parameter estimates. This matrix is an estimate of the covariance matrix for the parameter estimates.

DETTOL=*value*

specifies the convergence criterion. The DETTOL= and PARMTOL= option values are used together to test for convergence of the estimation process. If, during an iteration, the relative change of the parameter estimates is less than the PARMTOL= value and the relative change of the determinant of the innovation variance matrix is less than the DETTOL= value, then iteration ceases and the current estimates are accepted. The default is DETTOL=1E-5.

ITPRINT

prints the iterations during the estimation process.

KLAG=*n*

sets an upper limit for the number of lags of the sample autocovariance matrix used in computing the approximate likelihood function. If the data have a strong moving average character, a larger KLAG= value might be necessary to obtain good estimates. The default is KLAG=15. See the section “[Parameter Estimation](#)” on page 1857 for details.

MAXIT=*n*

sets an upper limit to the number of iterations in the maximum likelihood or conditional least squares estimation. The default is MAXIT=50.

NOEST

suppresses the final maximum likelihood estimation of the selected model.

OUTMODEL=*SAS-data-set*

writes the parameter estimates and their standard errors to a SAS data set. See the section “[OUTMODEL= Data Set](#)” on page 1864 for details.

PARMTOL=*value*

specifies the convergence criterion. The DETTOL= and PARMTOL= option values are used together to test for convergence of the estimation process. If, during an iteration, the relative change of the parameter estimates is less than the PARMTOL= value and the relative change of the determinant of the innovation variance matrix is less than the DETTOL= value, then iteration ceases and the current estimates are accepted. The default is PARMTOL=0.001.

RESIDEST

computes the final estimates by using conditional least squares on the raw data. This type of estimation might be more stable than the default maximum likelihood method but is usually more computationally expensive. See the section “[Parameter Estimation](#)” on page 1857 for details about the conditional least squares method.

SINGULAR=value

specifies the criterion for testing for singularity of a matrix. A matrix is declared singular if a scaled pivot is less than the SINGULAR= value when sweeping the matrix. The default is SINGULAR=1E-7.

Forecasting Options

BACK=n

starts forecasting n periods before the end of the input data. The BACK= option value must not be greater than the number of observations. The default is BACK=0.

INTERVAL=interval

specifies the time interval between observations. The INTERVAL= value is used in conjunction with the ID variable to check that the input data are in order and have no missing periods. The INTERVAL= option is also used to extrapolate the ID values past the end of the input data. See Chapter 4, “[Date Intervals, Formats, and Functions](#),” for details about the INTERVAL= values allowed.

INTPER=n

specifies that each input observation corresponds to n time periods. For example, the options INTERVAL=MONTH and INTPER=2 specify bimonthly data and are equivalent to specifying INTERVAL=MONTH2. If the INTERVAL= option is not specified, the INTPER= option controls the increment used to generate ID values for the forecast observations. The default is INTPER=1.

LEAD=n

specifies how many forecast observations are produced. The forecasts start at the point set by the BACK= option. The default is LEAD=0, which produces no forecasts.

OUT=SAS-data-set

writes the residuals, actual values, forecasts, and forecast standard errors to a SAS data set. See the section “[OUT= Data Set](#)” on page 1862 for details.

PRINT

prints the forecasts.

BY Statement

BY *variable ...* ;

A BY statement can be used with the STATESPACE procedure to obtain separate analyses on observations in groups defined by the BY variables.

FORM Statement

FORM *variable value* ... ;

The FORM statement specifies the number of times a variable is included in the state vector. Values can be specified for any variable listed in the VAR statement. If a value is specified for each variable in the VAR statement, the state vector for the state space model is entirely specified, and automatic selection of the state space model is not performed.

The FORM statement forces the state vector, \mathbf{z}_t , to contain a specific variable a given number of times. For example, if Y is one of the variables in \mathbf{x}_t , then the statement

form y 3;

forces the state vector to contain Y_t , $Y_{t+1|t}$, and $Y_{t+2|t}$, possibly along with other variables.

The following statements illustrate the use of the FORM statement:

```
proc statespace data=in;
  var x y;
  form x 3 y 2;
run;
```

These statements fit a state space model with the following state vector:

$$\mathbf{z}_t = \begin{bmatrix} x_{t|t} \\ y_{t|t} \\ x_{t+1|t} \\ y_{t+1|t} \\ x_{t+2|t} \end{bmatrix}$$

ID Statement

ID *variable* ;

The ID statement specifies a variable that identifies observations in the input data set. The variable specified in the ID statement is included in the OUT= data set. The values of the ID variable are extrapolated for the forecast observations based on the values of the INTERVAL= and INTPER= options.

INITIAL Statement

INITIAL *F (row,column)= value ... G(row, column)= value ... ;*

The INITIAL statement gives initial values to the specified elements of the **F** and **G** matrices. These initial values are used as starting values for the iterative estimation.

Parts of the **F** and **G** matrices represent fixed structural identities. If an element specified is a fixed structural element instead of a free parameter, the corresponding initialization is ignored.

The following is an example of an INITIAL statement:

```
initial f(3,2)=0 g(4,1)=0 g(5,1)=0;
```

RESTRICT Statement

RESTRICT *F(row,column)= value ... G(row,column)= value ... ;*

The RESTRICT statement restricts the specified elements of the **F** and **G** matrices to the specified values.

To use the restrict statement, you need to know the form of the model. Either specify the form of the model with the FORM statement, or do a preliminary run (perhaps with the NOEST option) to find the form of the model that PROC STATESPACE selects for the data.

The following is an example of a RESTRICT statement:

```
restrict f(3,2)=0 g(4,1)=0 g(5,1)=0 ;
```

Parts of the **F** and **G** matrices represent fixed structural identities. If a restriction is specified for an element that is a fixed structural element instead of a free parameter, the restriction is ignored.

VAR Statement

VAR *variable (difference, difference, ...) ... ;*

The VAR statement specifies the variables in the input data set to model and forecast. The VAR statement also specifies differencing of the input variables. The VAR statement is required.

Differencing is specified by following the variable name with a list of difference periods separated by commas. See the section “[Stationarity and Differencing](#)” on page 1850 for more information about differencing of input variables.

The order in which variables are listed in the VAR statement controls the order in which variables are included in the state vector. Usually, potential inputs should be listed before potential outputs.

For example, assuming the input data are monthly, the following VAR statement specifies modeling and forecasting of the one period and seasonal second difference of X and Y:

```
var x(1,12) y(1,12);
```

In this example, the vector time series analyzed is

$$\mathbf{x}_t = \begin{bmatrix} (1 - B)(1 - B^{12})X_t - \bar{x} \\ (1 - B)(1 - B^{12})Y_t - \bar{y} \end{bmatrix}$$

where B represents the back shift operator and \bar{x} and \bar{y} represent the means of the differenced series. If the NOCENTER option is specified, the mean differences are not subtracted.

Details: STATESPACE Procedure

Missing Values

The STATESPACE procedure does not support missing values. The procedure uses the first contiguous group of observations with no missing values for any of the VAR statement variables. Observations at the beginning of the data set with missing values for any VAR statement variable are not used or included in the output data set.

Stationarity and Differencing

The state space model used by the STATESPACE procedure assumes that the time series are stationary. Hence, the data should be checked for stationarity. One way to check for stationarity is to plot the series. A graph of series over time can show a time trend or variability changes.

You can also check stationarity by using the sample autocorrelation functions displayed by the ARIMA procedure. The autocorrelation functions of nonstationary series tend to decay slowly. See Chapter 7, “[The ARIMA Procedure](#),” for more information.

Another alternative is to use the STATIONARITY= option in the IDENTIFY statement in PROC ARIMA to apply Dickey-Fuller tests for unit roots in the time series. See Chapter 7, “[The ARIMA Procedure](#),” for more information about Dickey-Fuller unit root tests.

The most popular way to transform a nonstationary series to stationarity is by differencing. Differencing of the time series is specified in the VAR statement. For example, to take a simple first difference of the series X , use this statement:

```
var x(1);
```

In this example, the change in X from one period to the next is analyzed. When the series has a seasonal pattern, differencing at a period equal to the length of the seasonal cycle can be desirable. For example, suppose the variable X is measured quarterly and shows a seasonal cycle over the year. You can use the following statement to analyze the series of changes from the same quarter in the previous year:

```
var x(4);
```

To difference twice, add another differencing period to the list. For example, the following statement analyzes the series of second differences $(X_t - X_{t-1}) - (X_{t-1} - X_{t-2}) = X_t - 2X_{t-1} + X_{t-2}$:

```
var x(1,1);
```

The following statement analyzes the seasonal second difference series:

```
var x(1,4);
```

The series that is being modeled is the 1-period difference of the 4-period difference:

$$(X_t - X_{t-4}) - (X_{t-1} - X_{t-5}) = X_t - X_{t-1} - X_{t-4} + X_{t-5}.$$

Another way to obtain stationary series is to use a regression on time to detrend the data. If the time series has a deterministic linear trend, regressing the series on time produces residuals that should be stationary. The following statements write residuals of X and Y to the variable RX and RY in the output data set DETREND.

```
data a;
  set a;
  t=_n_;
run;

proc reg data=a;
  model x y = t;
  output out=detrend r=rx ry;
run;
```

You then use PROC STATESPACE to forecast the detrended series RX and RY. A disadvantage of this method is that you need to add the trend back to the forecast series in an additional step. A more serious disadvantage of the detrending method is that it assumes a deterministic trend. In practice, most time series appear to have a stochastic rather than a deterministic trend. Differencing is a more flexible and often more appropriate method.

There are several other methods to handle nonstationary time series. For more information and examples, see Brockwell and Davis (1991).

Preliminary Autoregressive Models

After computing the sample autocovariance matrices, PROC STATESPACE fits a sequence of vector autoregressive models. These preliminary autoregressive models are used to estimate the autoregressive order of the process and limit the order of the autocovariances considered in the state vector selection process.

Yule-Walker Equations for Forward and Backward Models

Unlike a univariate autoregressive model, a multivariate autoregressive model has different forms, depending on whether the present observation is being predicted from the past observations or from the future observations.

Let \mathbf{x}_t be the r -component stationary time series given by the VAR statement after differencing and subtracting the vector of sample means. (If the NOCENTER option is specified, the mean is not subtracted.) Let n be the number of observations of \mathbf{x}_t from the input data set.

Let \mathbf{e}_t be a vector white noise sequence with mean vector $\mathbf{0}$ and variance matrix Σ_p , and let \mathbf{n}_t be a vector white noise sequence with mean vector $\mathbf{0}$ and variance matrix Ω_p . Let p be the order of the vector autoregressive model for \mathbf{x}_t .

The forward autoregressive form based on the past observations is written as follows:

$$\mathbf{x}_t = \sum_{i=1}^p \Phi_i^p \mathbf{x}_{t-i} + \mathbf{e}_t$$

The backward autoregressive form based on the future observations is written as follows:

$$\mathbf{x}_t = \sum_{i=1}^p \Psi_i^p \mathbf{x}_{t+i} + \mathbf{n}_t$$

Letting E denote the expected value operator, the autocovariance sequence for the \mathbf{x}_t series, Γ_i , is

$$\Gamma_i = E\mathbf{x}_t \mathbf{x}_{t-i}'$$

The Yule-Walker equations for the autoregressive model that matches the first p elements of the autocovariance sequence are

$$\begin{bmatrix} \Gamma_0 & \Gamma_1 & \cdots & \Gamma_{p-1} \\ \Gamma_1' & \Gamma_0 & \cdots & \Gamma_{p-2} \\ \vdots & \vdots & \ddots & \vdots \\ \Gamma_{p-1}' & \Gamma_{p-2}' & \cdots & \Gamma_0 \end{bmatrix} \begin{bmatrix} \Phi_1^p \\ \Phi_2^p \\ \vdots \\ \Phi_p^p \end{bmatrix} = \begin{bmatrix} \Gamma_1 \\ \Gamma_2 \\ \vdots \\ \Gamma_p \end{bmatrix}$$

and

$$\begin{bmatrix} \Gamma_0 & \Gamma_1' & \cdots & \Gamma_{p-1}' \\ \Gamma_1 & \Gamma_0 & \cdots & \Gamma_{p-2}' \\ \vdots & \vdots & \ddots & \vdots \\ \Gamma_{p-1} & \Gamma_{p-2} & \cdots & \Gamma_0 \end{bmatrix} \begin{bmatrix} \Psi_1^p \\ \Psi_2^p \\ \vdots \\ \Psi_p^p \end{bmatrix} = \begin{bmatrix} \Gamma_1' \\ \Gamma_2' \\ \vdots \\ \Gamma_p' \end{bmatrix}$$

Here Φ_i^p are the coefficient matrices for the past observation form of the vector autoregressive model, and Ψ_i^p are the coefficient matrices for the future observation form. More information about the Yule-Walker equations in the multivariate setting can be found in Whittle (1963) and Ansley and Newbold (1979).

The innovation variance matrices for the two forms can be written as follows:

$$\Sigma_p = \Gamma_0 - \sum_{i=1}^p \Phi_i^p \Gamma_i'$$

$$\Omega_p = \Gamma_0 - \sum_{i=1}^p \Psi_i^p \Gamma_i$$

The autoregressive models are fit to the data by using the preceding Yule-Walker equations with Γ_i replaced by the sample covariance sequence \mathbf{C}_i . The covariance matrices are calculated as

$$\mathbf{C}_i = \frac{1}{N-1} \sum_{t=i+1}^N \mathbf{x}_t \mathbf{x}_{t-i}'$$

Let $\hat{\Phi}_p$, $\hat{\Psi}_p$, $\hat{\Sigma}_p$, and $\hat{\Omega}_p$ represent the Yule-Walker estimates of Φ_p , Ψ_p , Σ_p , and Ω_p , respectively. These matrices are written to an output data set when the OUTAR= option is specified.

When the PRINTOUT=LONG option is specified, the sequence of matrices $\hat{\Sigma}_p$ and the corresponding correlation matrices are printed. The sequence of matrices $\hat{\Sigma}_p$ is used to compute Akaike information criteria for selection of the autoregressive order of the process.

Akaike Information Criterion

The Akaike information criterion (AIC) is defined as $-2(\text{maximum of log likelihood}) + 2(\text{number of parameters})$. Since the vector autoregressive models are estimates from the Yule-Walker equations, not by maximum likelihood, the exact likelihood values are not available for computing the AIC. However, for the vector autoregressive model the maximum of the log likelihood can be approximated as

$$\ln(L) \approx -\frac{n}{2} \ln(|\hat{\Sigma}_p|)$$

Thus, the AIC for the order p model is computed as

$$AIC_p = n \ln(|\hat{\Sigma}_p|) + 2pr^2$$

You can use the printed AIC array to compute a likelihood ratio test of the autoregressive order. The log-likelihood ratio test statistic for testing the order p model against the order $p-1$ model is

$$-n \ln(|\hat{\Sigma}_p|) + n \ln(|\hat{\Sigma}_{p-1}|)$$

This quantity is asymptotically distributed as a χ^2 with r^2 degrees of freedom if the series is autoregressive of order $p-1$. It can be computed from the AIC array as

$$AIC_{p-1} - AIC_p + 2r^2$$

You can evaluate the significance of these test statistics with the PROBCHI function in a SAS DATA step or with a χ^2 table.

Determining the Autoregressive Order

Although the autoregressive models can be used for prediction, their primary value is to aid in the selection of a suitable portion of the sample covariance matrix for use in computing canonical correlations. If the multivariate time series \mathbf{x}_t is of autoregressive order p , then the vector of past values to lag p is considered to contain essentially all the information relevant for prediction of future values of the time series.

By default, PROC STATESPACE selects the order p that produces the autoregressive model with the smallest AIC_p . If the value p for the minimum AIC_p is less than the value of the PASTMIN= option, then p is set to the PASTMIN= value. Alternatively, you can use the ARMAX= and PASTMIN= options to force PROC STATESPACE to use an order you select.

Significance Limits for Partial Autocorrelations

The STATESPACE procedure prints a schematic representation of the partial autocorrelation matrices that indicates which partial autocorrelations are significantly greater than or significantly less than 0. Figure 28.11 shows an example of this table.

Figure 28.11 Significant Partial Autocorrelations

Schematic Representation of Partial Autocorrelations										
Name/Lag	1	2	3	4	5	6	7	8	9	10
x	++	+.
y	++
+ is > 2*std error, - is < -2*std error, . is between										

The partial autocorrelations are from the sample partial autoregressive matrices $\hat{\Phi}_p^p$. The standard errors used for the significance limits of the partial autocorrelations are computed from the sequence of matrices Σ_p and Ω_p .

Under the assumption that the observed series arises from an autoregressive process of order $p - 1$, the p th sample partial autoregressive matrix $\hat{\Phi}_p^p$ has an asymptotic variance matrix $\frac{1}{n}\Omega_p^{-1} \otimes \Sigma_p$.

The significance limits for $\hat{\Phi}_p^p$ used in the schematic plot of the sample partial autoregressive sequence are derived by replacing Ω_p and Σ_p with their sample estimators to produce the variance estimate, as follows:

$$\widehat{Var}(\hat{\Phi}_p^p) = \left(\frac{1}{n - rp} \right) \hat{\Omega}_p^{-1} \otimes \hat{\Sigma}_p$$

Canonical Correlation Analysis

Given the order p , let \mathbf{p}_t be the vector of current and past values relevant to prediction of \mathbf{x}_{t+1} :

$$\mathbf{p}_t = (\mathbf{x}'_t, \mathbf{x}'_{t-1}, \dots, \mathbf{x}'_{t-p})'$$

Let \mathbf{f}_t be the vector of current and future values:

$$\mathbf{f}_t = (\mathbf{x}'_t, \mathbf{x}'_{t+1}, \dots, \mathbf{x}'_{t+p})'$$

In the canonical correlation analysis, consider submatrices of the sample covariance matrix of \mathbf{p}_t and \mathbf{f}_t . This covariance matrix, \mathbf{V} , has a block Hankel form:

$$\mathbf{V} = \begin{bmatrix} \mathbf{C}_0 & \mathbf{C}'_1 & \mathbf{C}'_2 & \cdots & \mathbf{C}'_p \\ \mathbf{C}'_1 & \mathbf{C}'_2 & \mathbf{C}'_3 & \cdots & \mathbf{C}'_{p+1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{C}'_p & \mathbf{C}'_{p+1} & \mathbf{C}'_{p+2} & \cdots & \mathbf{C}'_{2p} \end{bmatrix}$$

State Vector Selection Process

The canonical correlation analysis forms a sequence of potential state vectors \mathbf{z}_t^j . Examine a sequence \mathbf{f}_t^j of subvectors of \mathbf{f}_t , form the submatrix \mathbf{V}^j that consists of the rows and columns of \mathbf{V} that correspond to the components of \mathbf{f}_t^j , and compute its canonical correlations.

The smallest canonical correlation of \mathbf{V}^j is then used in the selection of the components of the state vector. The selection process is described in the following discussion. For more details about this process, see Akaike (1976).

In the following discussion, the notation $\mathbf{x}_{t+k|t}$ denotes the wide sense conditional expectation (best linear predictor) of \mathbf{x}_{t+k} , given all \mathbf{x}_s with s less than or equal to t . In the notation $x_{i,t+1}$, the first subscript denotes the i th component of \mathbf{x}_{t+1} .

The initial state vector \mathbf{z}_t^1 is set to \mathbf{x}_t . The sequence \mathbf{f}_t^j is initialized by setting

$$\mathbf{f}_t^1 = (\mathbf{z}_t^{1'}, x_{1,t+1|t})' = (\mathbf{x}_t', x_{1,t+1|t})'$$

That is, start by considering whether to add $x_{1,t+1|t}$ to the initial state vector \mathbf{z}_t^1 .

The procedure forms the submatrix \mathbf{V}^1 that corresponds to \mathbf{f}_t^1 and computes its canonical correlations. Denote the smallest canonical correlation of \mathbf{V}^1 as ρ_{min} . If ρ_{min} is significantly greater than 0, $x_{1,t+1|t}$ is added to the state vector.

If the smallest canonical correlation of \mathbf{V}^1 is not significantly greater than 0, then a linear combination of \mathbf{f}_t^1 is uncorrelated with the past, \mathbf{p}_t . Assuming that the determinant of \mathbf{C}_0 is not 0, (that is, no input series is a constant), you can take the coefficient of $x_{1,t+1|t}$ in this linear combination to be 1. Denote the coefficients of \mathbf{z}_t^1 in this linear combination as ℓ . This gives the relationship:

$$x_{1,t+1|t} = \ell' \mathbf{x}_t$$

Therefore, the current state vector already contains all the past information useful for predicting $x_{1,t+1}$ and any greater leads of $x_{1,t}$. The variable $x_{1,t+1|t}$ is not added to the state vector, nor are any terms $x_{1,t+k|t}$ considered as possible components of the state vector. The variable x_1 is no longer active for state vector selection.

The process described for $x_{1,t+1|t}$ is repeated for the remaining elements of \mathbf{f}_t . The next candidate for inclusion in the state vector is the next component of \mathbf{f}_t that corresponds to an active variable. Components of \mathbf{f}_t that correspond to inactive variables that produced a zero ρ_{min} in a previous step are skipped.

Denote the next candidate as $x_{l,t+k|t}$. The vector \mathbf{f}_t^j is formed from the current state vector and $x_{l,t+k|t}$ as follows:

$$\mathbf{f}_t^j = (\mathbf{z}_t^{j'}, x_{l,t+k|t})'$$

The matrix \mathbf{V}^j is formed from \mathbf{f}_t^j and its canonical correlations are computed. The smallest canonical correlation of \mathbf{V}^j is judged to be either greater than or equal to 0. If it is judged to be greater than 0, $x_{l,t+k|t}$ is added to the state vector. If it is judged to be 0, then a linear combination of \mathbf{f}_t^j is uncorrelated with the \mathbf{p}_t , and the variable x_l is now inactive.

The state vector selection process continues until no active variables remain.

Testing Significance of Canonical Correlations

For each step in the canonical correlation sequence, the significance of the smallest canonical correlation ρ_{min} is judged by an information criterion from Akaike (1976). This information criterion is

$$-n \ln(1 - \rho_{min}^2) - \lambda(r(p + 1) - q + 1)$$

where q is the dimension of \mathbf{f}_t^j at the current step, r is the order of the state vector, p is the order of the vector autoregressive process, and λ is the value of the SIGCORR= option. The default is SIGCORR=2. If this information criterion is less than or equal to 0, ρ_{min} is taken to be 0; otherwise, it is taken to be significantly greater than 0. (Do not confuse this information criterion with the AIC.)

Variables in $\mathbf{x}_{t+p|t}$ are not added in the model, even with positive information criterion, because of the singularity of \mathbf{V} . You can force the consideration of more candidate state variables by increasing the size of the \mathbf{V} matrix by specifying a PASTMIN= option value larger than p .

Printing the Canonical Correlations

To print the details of the canonical correlation analysis process, specify the CANCORR option in the PROC STATESPACE statement. The CANCORR option prints the candidate state vectors, the canonical correlations, and the information criteria for testing the significance of the smallest canonical correlation.

Bartlett's χ^2 and its degrees of freedom are also printed when the CANCORR option is specified. The formula used for Bartlett's χ^2 is

$$\chi^2 = -(n - .5(r(p + 1) - q + 1)) \ln(1 - \rho_{min}^2)$$

with $r(p + 1) - q + 1$ degrees of freedom.

Figure 28.12 shows the output of the CANCORR option for the introductory example shown in the “Getting Started: STATESPACE Procedure” on page 1832.

```
proc statespace data=in out=out lead=10 cancorr;
  var x(1) y(1);
  id t;
run;
```

Figure 28.12 Canonical Correlations Analysis

The STATESPACE Procedure Canonical Correlations Analysis					
$\mathbf{x}(T;T)$	$\mathbf{y}(T;T)$	$\mathbf{x}(T+1;T)$	Information Criterion	Chi Square	DF
1	1	0.237045	3.566167	11.4505	4

New variables are added to the state vector if the information criteria are positive. In this example, $\mathbf{y}_{t+1|t}$ and $\mathbf{x}_{t+2|t}$ are not added to the state space vector because the information criteria for these models are negative.

If the information criterion is nearly 0, then you might want to investigate models that arise if the opposite decision is made regarding ρ_{min} . This investigation can be accomplished by using a FORM statement to specify part or all of the state vector.

Preliminary Estimates of \mathbf{F}

When a candidate variable $x_{l,t+k|t}$ yields a zero ρ_{min} and is not added to the state vector, a linear combination of \mathbf{f}_t^j is uncorrelated with the \mathbf{p}_t . Because of the method used to construct the \mathbf{f}_t^j sequence, the coefficient of $x_{l,t+k|t}$ in \mathbf{l} can be taken as 1. Denote the coefficients of \mathbf{z}_t^j in this linear combination as \mathbf{l} .

This gives the relationship:

$$x_{l,t+k|t} = \mathbf{l}'\mathbf{z}_t^j$$

The vector \mathbf{l} is used as a preliminary estimate of the first r columns of the row of the transition matrix \mathbf{F} corresponding to $x_{l,t+k-1|t}$.

Parameter Estimation

The model is $\mathbf{z}_{t+1} = \mathbf{F}\mathbf{z}_t + \mathbf{G}\mathbf{e}_{t+1}$, where \mathbf{e}_t is a sequence of independent multivariate normal innovations with mean vector $\mathbf{0}$ and variance Σ_{ee} . The observed sequence \mathbf{x}_t composes the first r components of \mathbf{z}_t , and thus $\mathbf{x}_t = \mathbf{H}\mathbf{z}_t$, where \mathbf{H} is the $r \times s$ matrix $[\mathbf{I}_r \ \mathbf{0}]$.

Let \mathbf{E} be the $r \times n$ matrix of innovations:

$$\mathbf{E} = [\mathbf{e}_1 \quad \cdots \quad \mathbf{e}_n]$$

If the number of observations n is reasonably large, the log likelihood L can be approximated up to an additive constant as follows:

$$L = -\frac{n}{2} \ln(|\Sigma_{ee}|) - \frac{1}{2} \text{trace}(\Sigma_{ee}^{-1} \mathbf{E} \mathbf{E}')$$

The elements of Σ_{ee} are taken as free parameters and are estimated as follows:

$$\mathbf{S}_0 = \frac{1}{n} \mathbf{E} \mathbf{E}'$$

Replacing Σ_{ee} by \mathbf{S}_0 in the likelihood equation, the log likelihood, up to an additive constant, is

$$\mathbf{L} = -\frac{n}{2} \ln(|\mathbf{S}_0|)$$

Letting B be the backshift operator, the formal relation between \mathbf{x}_t and \mathbf{e}_t is

$$\begin{aligned} \mathbf{x}_t &= \mathbf{H}(\mathbf{I} - B\mathbf{F})^{-1} \mathbf{G} \mathbf{e}_t \\ \mathbf{e}_t &= (\mathbf{H}(\mathbf{I} - B\mathbf{F})^{-1} \mathbf{G})^{-1} \mathbf{x}_t = \sum_{i=0}^{\infty} \Xi_i \mathbf{x}_{t-i} \end{aligned}$$

Letting \mathbf{C}_i be the i th lagged sample covariance of \mathbf{x}_t and neglecting end effects, the matrix \mathbf{S}_0 is

$$\mathbf{S}_0 = \sum_{i,j=0}^{\infty} \Xi_i \mathbf{C}_{-i+j} \Xi_j'$$

For the computation of \mathbf{S}_0 , the infinite sum is truncated at the value of the KLAG= option. The value of the KLAG= option should be large enough that the sequence Ξ_i is approximately 0 beyond that point.

Let $\boldsymbol{\theta}$ be the vector of free parameters in the \mathbf{F} and \mathbf{G} matrices. The derivative of the log likelihood with respect to the parameter $\boldsymbol{\theta}$ is

$$\frac{\partial L}{\partial \boldsymbol{\theta}} = -\frac{n}{2} \text{trace} \left(\mathbf{S}_0^{-1} \frac{\partial \mathbf{S}_0}{\partial \boldsymbol{\theta}} \right)$$

The second derivative is

$$\frac{\partial^2 L}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} = \frac{n}{2} \left(\text{trace} \left(\mathbf{S}_0^{-1} \frac{\partial \mathbf{S}_0}{\partial \boldsymbol{\theta}'} \mathbf{S}_0^{-1} \frac{\partial \mathbf{S}_0}{\partial \boldsymbol{\theta}} \right) - \text{trace} \left(\mathbf{S}_0^{-1} \frac{\partial^2 \mathbf{S}_0}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} \right) \right)$$

Near the maximum, the first term is unimportant and the second term can be approximated to give the following second derivative approximation:

$$\frac{\partial^2 L}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} \cong -n \text{trace} \left(\mathbf{S}_0^{-1} \frac{\partial \mathbf{E}}{\partial \boldsymbol{\theta}} \frac{\partial \mathbf{E}'}{\partial \boldsymbol{\theta}'} \right)$$

The first derivative matrix and this second derivative matrix approximation are computed from the sample covariance matrix \mathbf{C}_0 and the truncated sequence Ξ_i . The approximate likelihood function is maximized by a modified Newton-Raphson algorithm that employs these derivative matrices.

The matrix \mathbf{S}_0 is used as the estimate of the innovation covariance matrix, Σ_{ee} . The negative of the inverse of the second derivative matrix at the maximum is used as an approximate covariance matrix for the parameter estimates. The standard errors of the parameter estimates printed in the parameter estimates tables are taken from the diagonal of this covariance matrix. The parameter covariance matrix is printed when the COVB option is specified.

If the data are nearly nonstationary, a better estimate of Σ_{ee} and the other parameters can sometimes be obtained by specifying the RESIDEST option. The RESIDEST option estimates the parameters by using conditional least squares instead of maximum likelihood.

The residuals are computed using the state space equation and the sample mean values of the variables in the model as start-up values. The estimate of \mathbf{S}_0 is then computed using the residuals from the i th observation on, where i is the maximum number of times any variable occurs in the state vector. A multivariate Gauss-Marquardt algorithm is used to minimize $|\mathbf{S}_0|$. See Harvey (1981a) for a further description of this method.

Forecasting

Given estimates of \mathbf{F} , \mathbf{G} , and Σ_{ee} , forecasts of \mathbf{x}_t are computed from the conditional expectation of \mathbf{z}_t .

In forecasting, the parameters \mathbf{F} , \mathbf{G} , and Σ_{ee} are replaced with the estimates or by values specified in the RESTRICT statement. One-step-ahead forecasting is performed for the observation \mathbf{x}_t , where $t \leq n - b$. Here n is the number of observations and b is the value of the BACK= option. For the observation \mathbf{x}_t , where $t > n - b$, m -step-ahead forecasting is performed for $m = t - n + b$. The forecasts are generated recursively with the initial condition $\mathbf{z}_0 = \mathbf{0}$.

The m -step-ahead forecast of \mathbf{z}_{t+m} is $\mathbf{z}_{t+m|t}$, where $\mathbf{z}_{t+m|t}$ denotes the conditional expectation of \mathbf{z}_{t+m} given the information available at time t . The m -step-ahead forecast of \mathbf{x}_{t+m} is $\mathbf{x}_{t+m|t} = \mathbf{H}\mathbf{z}_{t+m|t}$, where the matrix $\mathbf{H} = [\mathbf{I}_r \mathbf{0}]$.

Let $\Psi_i = \mathbf{F}^i \mathbf{G}$. Note that the last $s - r$ elements of \mathbf{z}_t consist of the elements of $\mathbf{x}_{u|t}$ for $u > t$.

The state vector \mathbf{z}_{t+m} can be represented as

$$\mathbf{z}_{t+m} = \mathbf{F}^m \mathbf{z}_t + \sum_{i=0}^{m-1} \Psi_i \mathbf{e}_{t+m-i}$$

Since $\mathbf{e}_{t+i|t} = \mathbf{0}$ for $i > 0$, the m -step-ahead forecast $\mathbf{z}_{t+m|t}$ is

$$\mathbf{z}_{t+m|t} = \mathbf{F}^m \mathbf{z}_t = \mathbf{F} \mathbf{z}_{t+m-1|t}$$

Therefore, the m -step-ahead forecast of \mathbf{x}_{t+m} is

$$\mathbf{x}_{t+m|t} = \mathbf{H} \mathbf{z}_{t+m|t}$$

The m -step-ahead forecast error is

$$\mathbf{z}_{t+m} - \mathbf{z}_{t+m|t} = \sum_{i=0}^{m-1} \Psi_i \mathbf{e}_{t+m-i}$$

The variance of the m -step-ahead forecast error is

$$\mathbf{V}_{z,m} = \sum_{i=0}^{m-1} \Psi_i \Sigma_{ee} \Psi_i'$$

Letting $\mathbf{V}_{z,0} = \mathbf{0}$, the variance of the m -step-ahead forecast error of \mathbf{z}_{t+m} , $\mathbf{V}_{z,m}$, can be computed recursively as follows:

$$\mathbf{V}_{z,m} = \mathbf{V}_{z,m-1} + \Psi_{m-1} \Sigma_{ee} \Psi_{m-1}'$$

The variance of the m -step-ahead forecast error of \mathbf{x}_{t+m} is the $r \times r$ left upper submatrix of $\mathbf{V}_{z,m}$; that is,

$$\mathbf{V}_{x,m} = \mathbf{H} \mathbf{V}_{z,m} \mathbf{H}'$$

Unless the NOCENTER option is specified, the sample mean vector is added to the forecast. When differencing is specified, the forecasts $\mathbf{x}_{t+m|t}$ plus the sample mean vector are integrated back to produce forecasts for the original series.

Let \mathbf{y}_t be the original series specified by the VAR statement, with some 0 values appended that correspond to the unobserved past observations. Let B be the backshift operator, and let $\Delta(B)$ be the $s \times s$ matrix polynomial in the backshift operator that corresponds to the differencing specified by the VAR statement. The off-diagonal elements of Δ_i are 0. Note that $\Delta_0 = \mathbf{I}_s$, where \mathbf{I}_s is the $s \times s$ identity matrix. Then $\mathbf{z}_t = \Delta(B)\mathbf{y}_t$.

This gives the relationship

$$\mathbf{y}_t = \Delta^{-1}(B)\mathbf{z}_t = \sum_{i=0}^{\infty} \Lambda_i \mathbf{z}_{t-i}$$

where $\Delta^{-1}(B) = \sum_{i=0}^{\infty} \Lambda_i B^i$ and $\Lambda_0 = \mathbf{I}_s$.

The m -step-ahead forecast of \mathbf{y}_{t+m} is

$$\mathbf{y}_{t+m|t} = \sum_{i=0}^{m-1} \Lambda_i \mathbf{z}_{t+m-i|t} + \sum_{i=m}^{\infty} \Lambda_i \mathbf{z}_{t+m-i}$$

The m -step-ahead forecast error of \mathbf{y}_{t+m} is

$$\sum_{i=0}^{m-1} \Lambda_i (\mathbf{z}_{t+m-i} - \mathbf{z}_{t+m-i|t}) = \sum_{i=0}^{m-1} \left(\sum_{u=0}^i \Lambda_u \Psi_{i-u} \right) \mathbf{e}_{t+m-i}$$

Letting $\mathbf{V}_{y,0} = \mathbf{0}$, the variance of the m -step-ahead forecast error of \mathbf{y}_{t+m} , $\mathbf{V}_{y,m}$, is

$$\begin{aligned}\mathbf{V}_{y,m} &= \sum_{i=0}^{m-1} \left(\sum_{u=0}^i \Lambda_u \Psi_{i-u} \right) \Sigma_{ee} \left(\sum_{u=0}^i \Lambda_u \Psi_{i-u} \right)' \\ &= \mathbf{V}_{y,m-1} + \left(\sum_{u=0}^{m-1} \Lambda_u \Psi_{m-1-u} \right) \Sigma_{ee} \left(\sum_{u=0}^{m-1} \Lambda_u \Psi_{m-1-u} \right)'\end{aligned}$$

Relation of ARMA and State Space Forms

Every state space model has an ARMA representation, and conversely every ARMA model has a state space representation. This section discusses this equivalence. The following material is adapted from Akaike (1974), where there is a more complete discussion. Pham-Dinh-Tuan (1978) also contains a discussion of this material.

Suppose you are given the following ARMA model:

$$\Phi(B)\mathbf{x}_t = \Theta(B)\mathbf{e}_t$$

or, in more detail,

$$\mathbf{x}_t - \Phi_1 \mathbf{x}_{t-1} - \cdots - \Phi_p \mathbf{x}_{t-p} = \mathbf{e}_t + \Theta_1 \mathbf{e}_{t-1} + \cdots + \Theta_q \mathbf{e}_{t-q} \quad (1)$$

where \mathbf{e}_t is a sequence of independent multivariate normal random vectors with mean $\mathbf{0}$ and variance matrix Σ_{ee} , B is the backshift operator ($B\mathbf{x}_t = \mathbf{x}_{t-1}$), $\Phi(B)$ and $\Theta(B)$ are matrix polynomials in B , and \mathbf{x}_t is the observed process.

If the roots of the determinantal equation $|\Phi(B)| = 0$ are outside the unit circle in the complex plane, the model can also be written as

$$\mathbf{x}_t = \Phi^{-1}(B)\Theta(B)\mathbf{e}_t = \sum_{i=0}^{\infty} \Psi_i \mathbf{e}_{t-i}$$

The Ψ_i matrices are known as the impulse response matrices and can be computed as $\Phi^{-1}(B)\Theta(B)$.

You can assume $p > q$ since, if this is not initially true, you can add more terms Φ_i that are identically 0 without changing the model.

To write this set of equations in a state space form, proceed as follows. Let $\mathbf{x}_{t+i|t}$ be the conditional expectation of \mathbf{x}_{t+i} given \mathbf{x}_w for $w \leq t$. The following relations hold:

$$\begin{aligned}\mathbf{x}_{t+i|t} &= \sum_{j=i}^{\infty} \Psi_j \mathbf{e}_{t+i-j} \\ \mathbf{x}_{t+i|t+1} &= \mathbf{x}_{t+i|t} + \Psi_{i-1} \mathbf{e}_{t+1}\end{aligned}$$

However, from equation (1) you can derive the following relationship:

$$\mathbf{x}_{t+p|t} = \Phi_1 \mathbf{x}_{t+p-1|t} + \cdots + \Phi_p \mathbf{x}_t \quad (2)$$

Hence, when $i = p$, you can substitute for $\mathbf{x}_{t+p|t}$ in the right-hand side of equation (2) and close the system of equations.

This substitution results in the following model in the state space form $\mathbf{z}_{t+1} = \mathbf{F}\mathbf{z}_t + \mathbf{G}\mathbf{e}_{t+1}$:

$$\begin{bmatrix} \mathbf{x}_{t+1} \\ \mathbf{x}_{t+2|t+1} \\ \vdots \\ \mathbf{x}_{t+p|t+1} \end{bmatrix} = \begin{bmatrix} 0 & \mathbf{I} & 0 & \cdots & 0 \\ 0 & 0 & \mathbf{I} & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \Phi_p & \Phi_{p-1} & \cdots & \Phi_1 & \end{bmatrix} \begin{bmatrix} \mathbf{x}_t \\ \mathbf{x}_{t+1|t} \\ \vdots \\ \mathbf{x}_{t+p-1|t} \end{bmatrix} + \begin{bmatrix} \mathbf{I} \\ \Psi_1 \\ \vdots \\ \Psi_{p-1} \end{bmatrix} \mathbf{e}_{t+1}$$

Note that the state vector \mathbf{z}_t is composed of conditional expectations of \mathbf{x}_t and the first r components of \mathbf{z}_t are equal to \mathbf{x}_t .

The state space form can be cast into an ARMA form by solving the system of difference equations for the first r components.

When converting from an ARMA form to a state space form, you can generate a state vector larger than needed; that is, the state space model might not be a minimal representation. When going from a state space form to an ARMA form, you can have nontrivial common factors in the autoregressive and moving average operators that yield an ARMA model larger than necessary.

If the state space form used is not a minimal representation, some but not all components of $\mathbf{x}_{t+i|t}$ might be linearly dependent. This situation corresponds to $[\Phi_p \Theta_{p-1}]$ being of less than full rank when $\Phi(B)$ and $\Theta(B)$ have no common nontrivial left factors. In this case, \mathbf{z}_t consists of a subset of the possible components of $[\mathbf{x}_{t+i|t}]$ $i = 1, 2, \dots, p-1$. However, once a component of $\mathbf{x}_{t+i|t}$ (for example, the j th one) is linearly dependent on the previous conditional expectations, then all subsequent j th components of $\mathbf{x}_{t+k|t}$ for $k > i$ must also be linearly dependent. Note that in this case, equivalent but seemingly different structures can arise if the order of the components within \mathbf{x}_t is changed.

OUT= Data Set

The forecasts are contained in the output data set specified by the OUT= option in the PROC STATESPACE statement. The OUT= data set contains the following variables:

- the BY variables
- the ID variable
- the VAR statement variables. These variables contain the actual values from the input data set.
- FOR*i*, numeric variables that contain the forecasts. The variable FOR*i* contains the forecasts for the *i*th variable in the VAR statement list. Forecasts are one-step-ahead predictions until the end of the data or until the observation specified by the BACK= option.
- RES*i*, numeric variables that contain the residual for the forecast of the *i*th variable in the VAR statement list. For forecast observations, the actual values are missing and the RES*i* variables contain missing values.

- STD_i , numeric variables that contain the standard deviation for the forecast of the i th variable in the VAR statement list. The values of the STD_i variables can be used to construct univariate confidence limits for the corresponding forecasts. However, such confidence limits do not take into account the covariance of the forecasts.

OUTAR= Data Set

The OUTAR= data set contains the estimates of the preliminary autoregressive models. The OUTAR= data set contains the following variables:

- ORDER, a numeric variable that contains the order p of the autoregressive model that the observation represents
- AIC, a numeric variable that contains the value of the information criterion AIC_p
- SIGF l , numeric variables that contain the estimate of the innovation covariance matrices for the forward autoregressive models. The variable SIGF l contains the l th column of $\hat{\Sigma}_p$ in the observations with ORDER= p .
- SIGB l , numeric variables that contain the estimate of the innovation covariance matrices for the backward autoregressive models. The variable SIGB l contains the l th column of $\hat{\Omega}_p$ in the observations with ORDER= p .
- FOR k_l , numeric variables that contain the estimates of the autoregressive parameter matrices for the forward models. The variable FOR k_l contains the l th column of the lag k autoregressive parameter matrix $\hat{\Phi}_k^p$ in the observations with ORDER= p .
- BAC k_l , numeric variables that contain the estimates of the autoregressive parameter matrices for the backward models. The variable BAC k_l contains the l th column of the lag k autoregressive parameter matrix $\hat{\Psi}_k^p$ in the observations with ORDER= p .

The estimates for the order p autoregressive model can be selected as those observations with ORDER= p . Within these observations, the k,l th element of Φ_i^p is given by the value of the FOR i_l variable in the k th observation. The k,l th element of Ψ_i^p is given by the value of BAC i_l variable in the k th observation. The k,l th element of Σ_p is given by SIGF l in the k th observation. The k,l th element of Ω_p is given by SIGB l in the k th observation.

Table 28.2 shows an example of the OUTAR= data set, with ARMAX=3 and \mathbf{x}_t of dimension 2. In Table 28.2, (i, j) indicate the i,j th element of the matrix.

The estimated autoregressive parameters can be used in the IML procedure to obtain autoregressive estimates of the spectral density function or forecasts based on the autoregressive models.

OUTMODEL= Data Set

The OUTMODEL= data set contains the estimates of the **F** and **G** matrices and their standard errors, the names of the components of the state vector, and the estimates of the innovation covariance matrix. The variables contained in the OUTMODEL= data set are as follows:

- the BY variables
- STATEVEC, a character variable that contains the name of the component of the state vector corresponding to the observation. The STATEVEC variable has the value STD for standard deviations observations, which contain the standard errors for the estimates given in the preceding observation.
- F_j, numeric variables that contain the columns of the **F** matrix. The variable F_j contains the jth column of **F**. The number of F_j variables is equal to the value of the DIMMAX= option. If the model is of smaller dimension, the extraneous variables are set to missing.
- G_j, numeric variables that contain the columns of the **G** matrix. The variable G_j contains the jth column of **G**. The number of G_j variables is equal to *r*, the dimension of **x_t** given by the number of variables in the VAR statement.
- SIG_j, numeric variables that contain the columns of the innovation covariance matrix. The variable SIG_j contains the jth column of Σ_{ee} . There are *r* variables SIG_j.

Table 28.3 shows an example of the OUTMODEL= data set, with $\mathbf{x}_t = (x_t, y_t)'$, $\mathbf{z}_t = (x_t, y_t, x_{t+1|t})'$, and DIMMAX=4. In Table 28.3, $F_{i,j}$ and $G_{i,j}$ are the *i,j*th elements of **F** and **G** respectively. Note that all elements for F_4 are missing because **F** is a 3 × 3 matrix.

Table 28.3 Value in the OUTMODEL= Data Set

Printed Output

The printed output produced by the STATESPACE procedure includes the following:

1. descriptive statistics, which include the number of observations used, the names of the variables, their means and standard deviations (Std), and the differencing operations used
2. the Akaike information criteria for the sequence of preliminary autoregressive models
3. if the PRINTOUT=LONG option is specified, the sample autocovariance matrices of the input series at various lags
4. if the PRINTOUT=LONG option is specified, the sample autocorrelation matrices of the input series
5. a schematic representation of the autocorrelation matrices, showing the significant autocorrelations
6. if the PRINTOUT=LONG option is specified, the partial autoregressive matrices. (These are Φ_p^p as described in the section “[Preliminary Autoregressive Models](#)” on page 1851.)
7. a schematic representation of the partial autocorrelation matrices, showing the significant partial autocorrelations
8. the Yule-Walker estimates of the autoregressive parameters for the autoregressive model with the minimum AIC
9. if the PRINTOUT=LONG option is specified, the autocovariance matrices of the residuals of the minimum AIC model. This is the sequence of estimated innovation variance matrices for the solutions of the Yule-Walker equations.
10. if the PRINTOUT=LONG option is specified, the autocorrelation matrices of the residuals of the minimum AIC model
11. If the CANCELL option is specified, the canonical correlations analysis for each potential state vector considered in the state vector selection process. This includes the potential state vector, the canonical correlations, the information criterion for the smallest canonical correlation, Bartlett's χ^2 statistic (“Chi Square”) for the smallest canonical correlation, and the degrees of freedom of Bartlett's χ^2 .
12. the components of the chosen state vector

13. the preliminary estimate of the transition matrix, **F**, the input matrix, **G**, and the variance matrix for the innovations, Σ_{ee}
14. if the ITPRINT option is specified, the iteration history of the likelihood maximization. For each iteration, this shows the iteration number, the number of step halvings, the determinant of the innovation variance matrix, the damping factor Lambda, and the values of the parameters.
15. the state vector, printed again to aid interpretation of the following listing of **F** and **G**
16. the final estimate of the transition matrix **F**
17. the final estimate of the input matrix **G**
18. the final estimate of the variance matrix for the innovations Σ_{ee}
19. a table that lists the estimates of the free parameters in **F** and **G** and their standard errors and *t* statistics
20. if the COVB option is specified, the covariance matrix of the parameter estimates
21. if the COVB option is specified, the correlation matrix of the parameter estimates
22. if the PRINT option is specified, the forecasts and their standard errors

ODS Table Names

PROC STATESPACE assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 28.4 ODS Tables Produced in PROC STATESPACE

ODS Table Name	Description	Option
NObs	number of observations	default
Summary	simple summary statistics table	default
InfoCriterion	information criterion table	default
CovLags	covariance matrices of input series	PRINTOUT=LONG
CorrLags	correlation matrices of input series	PRINTOUT=LONG
PartialAR	partial autoregressive matrices	PRINTOUT=LONG
YWEstimates	Yule-Walker estimates for minimum AIC	default
CovResiduals	covariance of residuals	PRINTOUT=LONG
CorrResiduals	residual correlations from AR models	PRINTOUT=LONG
StateVector	state vector table	default
CorrGraph	schematic representation of correlations	default
TransitionMatrix	transition matrix	default
InputMatrix	input matrix	default
VarInnov	variance matrix for the innovation	default
CovB	covariance of parameter estimates	COVB
CorrB	correlation of parameter estimates	COVB

Table 28.4 *continued*

ODS Table Name	Description	Option
CanCorr	canonical correlation analysis	CANCORR
IterHistory	iterative fitting table	ITPRINT
ParameterEstimates	parameter estimates table	default
Forecasts	forecasts table	PRINT
ConvergenceStatus	convergence status table	default

Examples: STATESPACE Procedure

Example 28.1: Series J from Box and Jenkins

This example analyzes the gas furnace data (series J) from Box and Jenkins. (The data are not shown; see Box and Jenkins (1976) for the data.)

First, a model is selected and fit automatically using the following statements.

```

title1 'Gas Furnace Data';
title2 'Box & Jenkins Series J';
title3 'Automatically Selected Model';

proc statespace data=seriesj cancorr;
    var x y;
run;

```

The results for the automatically selected model are shown in [Output 28.1.1](#).

The two series are believed to have a transfer function relation with the gas rate (variable X) as the input and the CO₂ concentration (variable Y) as the output. Since the parameter estimates shown in [Output 28.1.1](#) support this kind of model, the model is reestimated with the feedback parameters restricted to 0. The following statements fit the transfer function (no feedback) model.

```

title3 'Transfer Function Model';
proc statespace data=seriesj printout=none;
  var x y;
  restrict f(3,2)=0 f(3,4)=0
           g(3,2)=0 g(4,1)=0 g(5,1)=0;
run;

```

The last two pages of the output are shown in [Output 28.1.8](#).

Overview: SYSLIN Procedure

The SYSLIN procedure estimates parameters in an interdependent system of linear regression equations.

Ordinary least squares (OLS) estimates are biased and inconsistent when current period endogenous variables appear as regressors in other equations in the system. The errors of a set of related regression equations are often correlated, and the efficiency of the estimates can be improved by taking these correlations into account. The SYSLIN procedure provides several techniques that produce consistent and asymptotically efficient estimates for systems of regression equations.

The SYSLIN procedure provides the following estimation methods:

- ordinary least squares (OLS)
- two-stage least squares (2SLS)
- limited information maximum likelihood (LIML)
- K-class
- seemingly unrelated regressions (SUR)
- iterated seemingly unrelated regressions (ITSUR)
- three-stage least squares (3SLS)
- iterated three-stage least squares (IT3SLS)
- full information maximum likelihood (FIML)
- minimum expected loss (MELO)

Other features of the SYSLIN procedure enable you to:

- impose linear restrictions on the parameter estimates
- test linear hypotheses about the parameters
- write predicted and residual values to an output SAS data set
- write parameter estimates to an output SAS data set
- write the crossproducts matrix (SSCP) to an output SAS data set
- use raw data, correlations, covariances, or cross products as input

Getting Started: SYSLIN Procedure

This section introduces the use of the SYSLIN procedure. The problem of dependent regressors is introduced using a supply and demand example. This section explains the terminology used for variables in a system of regression equations and introduces the SYSLIN procedure statements for declaring the roles the variables play. The syntax used for the different estimation methods and the output produced is shown.

An Example Model

In simultaneous systems of equations, endogenous variables are determined jointly rather than sequentially. Consider the following supply and demand functions for some product:

$$Q_D = a_1 + b_1 P + c_1 Y + d_1 S + \epsilon_1 (\text{demand})$$

$$Q_S = a_2 + b_2 P + c_2 U + \epsilon_2 (\text{supply})$$

$$Q = Q_D = Q_S (\text{market equilibrium})$$

The variables in this system are as follows:

Q_D	quantity demanded
Q_S	quantity supplied
Q	the observed quantity sold, which equates quantity supplied and quantity demanded in equilibrium
P	price per unit
Y	income
S	price of substitutes
U	unit cost

ϵ_1	the random error term for the demand equation
ϵ_2	the random error term for the supply equation

In this system, quantity demanded depends on price, income, and the price of substitutes. Consumers normally purchase more of a product when prices are lower and when income and the price of substitute goods are higher. Quantity supplied depends on price and the unit cost of production. Producers supply more when price is high and when unit cost is low. The actual price and quantity sold are determined jointly by the values that equate demand and supply.

Since price and quantity are jointly endogenous variables, both structural equations are necessary to adequately describe the observed values. A critical assumption of OLS is that the regressors are uncorrelated with the residual. When current endogenous variables appear as regressors in other equations (endogenous variables depend on each other), this assumption is violated and the OLS parameter estimates are biased and inconsistent. The bias caused by the violated assumptions is called *simultaneous equation bias*. Neither the demand nor supply equation can be estimated consistently by OLS.

Variables in a System of Equations

Before explaining how to use the SYSLIN procedure, it is useful to define some terms. The variables in a system of equations can be classified as follows:

- *Endogenous variables*, which are also called *jointly dependent* or *response variables*, are the variables determined by the system. Endogenous variables can also appear on the right-hand side of equations.
- *Exogenous variables* are independent variables that do not depend on any of the endogenous variables in the system.
- *Predetermined variables* include both the exogenous variables and *lagged endogenous variables*, which are past values of endogenous variables determined at previous time periods. PROC SYSLIN does not compute lagged values; any lagged endogenous variables must be computed in a preceding DATA step.
- *Instrumental variables* are predetermined variables used in obtaining predicted values for the current period endogenous variables by a first-stage regression. The use of instrumental variables characterizes estimation methods such as two-stage least squares and three-stage least squares. Instrumental variables estimation methods substitute these first-stage predicted values for endogenous variables when they appear as regressors in model equations.

Using PROC SYSLIN

First specify the input data set and estimation method in the PROC SYSLIN statement. If any model uses dependent regressors, and you are using an instrumental variables regression method, declare the dependent regressors with an ENDOGENOUS statement and declare the instruments with an INSTRUMENTS statement. Next, use MODEL statements to specify the structural equations of the system.

The use of different estimation methods is shown by the following examples. These examples use the simulated dataset WORK.IN given below.

```
data in;
  label q = "Quantity"
        p = "Price"
        s = "Price of Substitutes"
        y = "Income"
        u = "Unit Cost";
  drop i e1 e2;
  p = 0; q = 0;
  do i = 1 to 60;
    y = 1 + .05*i + .15*rannor(123);
    u = 2 + .05*rannor(123) + .05*rannor(123);
    s = 4 - .001*(i-10)*(i-110) + .5*rannor(123);
    e1 = .15 * rannor(123);
    e2 = .15 * rannor(123);
    demandx = 1 + .3 * y + .35 * s + e1;
    supplyx = -1 - 1 * u + e2 - .4*e1;
    q = 1.4/2.15 * demandx + .75/2.15 * supplyx;
    p = ( - q + supplyx ) / -1.4;
    output;
  end;
run;
```

OLS Estimation

PROC SYSLIN performs OLS regression if you do not specify a method of estimation in the PROC SYSLIN statement. OLS does not use instruments, so the ENDOGENOUS and INSTRUMENTS statements can be omitted.

The following statements estimate the supply and demand model shown previously:

```
proc syslin data=in;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

The PROC SYSLIN output for the demand equation is shown in [Figure 29.1](#), and the output for the supply equation is shown in [Figure 29.2](#).

u	1	-1.07757	0.234150	-4.60	<.0001	Unit Cost

For each MODEL statement, the output first shows the model label and dependent variable name and label. This is followed by an analysis-of-variance table for the model, which shows the model, error, and total mean squares, and an F test for the no-regression hypothesis. Next, the procedure prints the root mean squared error, dependent variable mean and coefficient of variation, and the R^2 and adjusted R^2 statistics.

Finally, the table of parameter estimates shows the estimated regression coefficients, standard errors, and t tests. You would expect the price coefficient in a demand equation to be negative. However, note that the OLS estimate of the price coefficient P in the demand equation (0.1233) has a positive sign. This could be caused by simultaneous equation bias.

Two-Stage Least Squares Estimation

In the supply and demand model, P is an endogenous variable, and consequently the OLS estimates are biased. The following example estimates this model using two-stage least squares.

```
proc syslin data=in 2sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

The 2SLS option in the PROC SYSLIN statement specifies the two-stage least squares method. The ENDOGENOUS statement specifies that P is an endogenous regressor for which first-stage predicted values are substituted. You need to declare an endogenous variable in the ENDOGENOUS statement only if it is used as a regressor; thus although Q is endogenous in this model, it is not necessary to list it in the ENDOGENOUS statement.

Usually, all predetermined variables that appear in the system are used as instruments. The INSTRUMENTS statement specifies that the exogenous variables Y , U , and S are used as instruments for the first-stage regression to predict P .

The 2SLS results are shown in [Figure 29.3](#) and [Figure 29.4](#). The first-stage regressions are not shown. To see the first-stage regression results, use the FIRST option in the PROC SYSLIN statement.

Error	57	1.082503	0.018991			
Corrected Total	59	10.03724				
Root MSE		0.13781	R-Square	0.89910		
Dependent Mean		1.30095	Adj R-Sq	0.89556		
Coeff Var		10.59291				
Parameter Estimates						
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t	Variable Label
Intercept	1	-0.51878	0.490999	-1.06	0.2952	Intercept
p	1	1.333080	0.059271	22.49	<.0001	Price
u	1	-1.14623	0.243491	-4.71	<.0001	Unit Cost

The 2SLS output is similar in form to the OLS output. However, the 2SLS results are based on predicted values for the endogenous regressors from the first stage instrumental regressions. This makes the analysis-of-variance table and the R^2 statistics difficult to interpret. See the sections “[ANOVA Table for Instrumental Variables Methods](#)” on page 1912 and “[The R-Square Statistics](#)” on page 1913 for details.

Note that, unlike the OLS results, the 2SLS estimate for the P coefficient in the demand equation (–1.115) is negative.

LIML, K-Class, and MELO Estimation

To obtain limited information maximum likelihood, general K-class, or minimum expected loss estimates, use the ENDOGENOUS, INSTRUMENTS, and MODEL statements as in the 2SLS case but specify the LIML, K=, or MELO option instead of 2SLS in the PROC SYSLIN statement. The following statements show this for K-class estimation.

```
proc syslin data=in k=.5;
    endogenous p;
    instruments y u s;
    demand: model q = p y s;
    supply: model q = p u;
run;
```

For more information about these estimation methods, see the section “[Estimation Methods](#)” on page 1910 and consult econometrics textbooks.

SUR, 3SLS, and FIML Estimation

In a multivariate regression model, the errors in different equations might be correlated. In this case, the efficiency of the estimation might be improved by taking these cross-equation correlations into account.

Seemingly Unrelated Regression

Seemingly unrelated regression (SUR), also called joint generalized least squares (JGLS) or Zellner estimation, is a generalization of OLS for multi-equation systems. Like OLS, the SUR method assumes that all the regressors are independent variables, but SUR uses the correlations among the errors in different equations to improve the regression estimates. The SUR method requires an initial OLS regression to compute residuals. The OLS residuals are used to estimate the cross-equation covariance matrix.

The SUR option in the PROC SYSLIN statement specifies seemingly unrelated regression, as shown in the following statements:

```
proc syslin data=in sur;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

INSTRUMENTS and ENDOGENOUS statements are not needed for SUR, because the SUR method assumes there are no endogenous regressors. For SUR to be effective, the models must use different regressors. SUR produces the same results as OLS unless the model contains at least one regressor not used in the other equations.

Three-Stage Least Squares

The three-stage least squares method generalizes the two-stage least squares method to take into account the correlations between equations in the same way that SUR generalizes OLS. Three-stage least squares requires three steps: first-stage regressions to get predicted values for the endogenous regressors; a two-stage least squares step to get residuals to estimate the cross-equation correlation matrix; and the final 3SLS estimation step.

The 3SLS option in the PROC SYSLIN statement specifies the three-stage least squares method, as shown in the following statements.

```
proc syslin data=in 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

The 3SLS output begins with a two-stage least squares regression to estimate the cross-model correlation matrix. This output is the same as the 2SLS results shown in [Figure 29.3](#) and [Figure 29.4](#), and is not repeated here. The next part of the 3SLS output prints the cross-model correlation matrix computed from the 2SLS residuals. This output is shown in [Figure 29.5](#) and includes the cross-model covariances, correlations, the inverse of the correlation matrix, and the inverse covariance matrix.

Figure 29.6 *continued*

Parameter Estimates						
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t	Variable Label
Intercept	1	-0.51878	0.490999	-1.06	0.2952	Intercept
p	1	1.333080	0.059271	22.49	<.0001	Price
u	1	-1.14623	0.243491	-4.71	<.0001	Unit Cost

This output first prints the system weighted mean squared error and system weighted R^2 statistics. The system weighted MSE and system weighted R^2 measure the fit of the joint model obtained by stacking all the models together and performing a single regression with the stacked observations weighted by the inverse of the model error variances. See the section “[The R-Square Statistics](#)” on page 1913 for details.

Next, the table of 3SLS parameter estimates for each model is printed. This output has the same form as for the other estimation methods.

Note that, in some cases, the 3SLS and 2SLS results can be the same. Such a case could arise because of the same principle that causes OLS and SUR results to be identical, unless an equation includes a regressor not used in the other equations of the system. However, the application of this principle is more complex when instrumental variables are used. When all the exogenous variables are used as instruments, linear combinations of all the exogenous variables appear in the third-stage regressions through substitution of first-stage predicted values.

In this example, 3SLS produces different (and, it is hoped, more efficient) estimates for the demand equation. However, the 3SLS and 2SLS results for the supply equation are the same. This is because the supply equation has one endogenous regressor and one exogenous regressor not used in other equations. In contrast, the demand equation has fewer endogenous regressors than exogenous regressors not used in other equations in the system.

Full Information Maximum Likelihood

The FIML option in the PROC SYSLIN statement specifies the full information maximum likelihood method, as shown in the following statements.

```
proc syslin data=in fiml;
  endogenous p q;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

The FIML results are shown in [Figure 29.7](#).

Computing Reduced Form Estimates

A system of structural equations with endogenous regressors can be represented as functions of only the predetermined variables. For this to be possible, there must be as many equations as endogenous variables. If there are more endogenous variables than regression models, you can use **IDENTITY** statements to complete the system. See the section “[Reduced Form Estimates](#)” on page 1915 for details.

The **REDUCED** option in the **PROC SYSLIN** statement prints reduced form estimates. The following statements show this by using the 3SLS estimates of the structural parameters.

```
proc syslin data=in 3sls reduced;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

The first four pages of this output were as shown previously and are not repeated here. (See Figure 29.3, Figure 29.4, Figure 29.5, and Figure 29.6.) The final page of the output from this example contains the reduced form coefficients from the 3SLS structural estimates, as shown in Figure 29.8.

Restricting Parameter Estimates

You can impose restrictions on the parameter estimates with **RESTRICT** and **SRESTRICT** statements. The **RESTRICT** statement imposes linear restrictions on parameters in the equation specified by the preceding **MODEL** statement. The **SRESTRICT** statement imposes linear restrictions that relate parameters in different models.

To impose restrictions involving parameters in different equations, use the **SRESTRICT** statement. Specify the parameters in the linear hypothesis as *model-label.regressor-name*. (If the **MODEL** statement does not have a label, you can use the dependent variable name as the label for the model, provided the dependent variable uniquely labels the model.)

Tests for the significance of the restrictions are printed when **RESTRICT** or **SRESTRICT** statements are used. You can label **RESTRICT** and **SRESTRICT** statements to identify the restrictions in the output.

The RESTRICT statement in the following example restricts the price coefficient in the demand equation to equal 0.015. The SRESTRICT statement restricts the estimate of the income coefficient in the demand equation to be 0.01 times the estimate of the unit cost coefficient in the supply equation.

```
proc syslin data=in 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  peq015: restrict p = .015;
  supply: model q = p u;
  yeq01u: srestrict demand.y = .01 * supply.u;
run;
```

The restricted estimation results are shown in [Figure 29.9](#).

Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t	Variable Label
RESTRICT	-1	342.3605	38.12094	8.98	<.0001	YEQ01U

The standard error for P in the demand equation is 0, since the value of the P coefficient was specified by the **RESTRICT** statement and not estimated from the data. The “Parameter Estimates” table for the demand equation contains an additional row for the restriction specified by the **RESTRICT** statement. The parameter estimate for the restriction is the value of the Lagrange multiplier used to impose the restriction. The restriction is highly significant ($t = 6.777$), which means that the data are not consistent with the restriction, and the model does not fit as well with the restriction imposed. See the section “**RESTRICT Statement**” on page 1903 for details.

Following the “Parameter Estimates” table for the supply equation, the results for the cross model restrictions are printed. This shows that the restriction specified by the **SRESTRICT** statement is not consistent with the data ($t = 8.98$). See the section “**SRESTRICT Statement**” on page 1904 for details.

Testing Parameters

You can test linear hypotheses about the model parameters with **TEST** and **STEST** statements. The **TEST** statement tests hypotheses about parameters in the equation specified by the preceding **MODEL** statement. The **STEST** statement tests hypotheses that relate parameters in different models.

For example, the following statements test the hypothesis that the price coefficient in the demand equation is equal to 0.015.

```
proc syslin data=in 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  test_1: test p = .015;
  supply: model q = p u;
run;
```

The **TEST** statement results are shown in Figure 29.10. This reports an F test for the hypothesis specified by the **TEST** statement. In this case, the F statistic is 6.79 (3.879/.571) with 1 and 113 degrees of freedom. The p value for this F statistic is 0.0104, which indicates that the hypothesis tested is almost but not quite rejected at the 0.01 level. See the section “**TEST Statement**” on page 1907 for details.

To test hypotheses that involve parameters in different equations, use the `STEST` statement. Specify the parameters in the linear hypothesis as *model-label.regressor-name*. (If the `MODEL` statement does not have a label, you can use the dependent variable name as the label for the model, provided the dependent variable uniquely labels the model.)

For example, the following statements test the hypothesis that the income coefficient in the demand equation is 0.01 times the unit cost coefficient in the supply equation:

```
proc syslin data=in 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
  stest1: stest demand.y = .01 * supply.u;
run;
```

The `STEST` statement results are shown in Figure 29.11. The form and interpretation of the `STEST` statement results are like the `TEST` statement results. In this case, the *F* test produces a *p* value less than 0.0001, and strongly rejects the hypothesis tested. See the section “[STEST Statement](#)” on page 1906 for details.

You can combine TEST and STEST statements with RESTRICT and SRESTRICT statements to perform hypothesis tests for restricted models. Of course, the validity of the TEST and STEST statement results depends on the correctness of any restrictions you impose on the estimates.

Saving Residuals and Predicted Values

You can store predicted values and residuals from the estimated models in a SAS data set. Specify the OUT= option in the PROC SYSLIN statement and use the OUTPUT statement to specify names for new variables to contain the predicted and residual values.

For example, the following statements store the predicted quantity from the supply and demand equations in a data set PRED:

```
proc syslin data=in out=pred 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  output predicted=q_demand;
  supply: model q = p u;
  output predicted=q_supply;
run;
```

Plotting Residuals

You can plot the residuals against the regressors by using the PROC SGPLOT. For example, the following statements plot the 2SLS residuals for the demand model against price, income, and price of substitutes.

```
proc syslin data=in 2sls out=out;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  output residual=residual_q;
run;

proc sgplot data=out;
  scatter x=p y=residual_q;
  refline 0 / axis=y;
run;

proc sgplot data=out;
  scatter x=y y=residual_q;
  refline 0 / axis=y;
run;

proc sgplot data=out;
  scatter x=s y=residual_q;
  refline 0 / axis=y;
run;
```

The plot for income is shown in [Figure 29.12](#). The other plots are not shown.

Figure 29.12 Plot of Residuals against Income

Syntax: SYSLIN Procedure

The SYSLIN procedure uses the following statements:

```

PROC SYSLIN options ;
  BY variables ;
  ENDOGENOUS variables ;
  IDENTITY identities ;
  INSTRUMENTS variables ;
  MODEL response = regressors / options ;
  OUTPUT PREDICTED= variable RESIDUAL= variable ;
  RESTRICT restrictions ;
  SRESTRICT restrictions ;
  STEST equations ;
  TEST equations ;
  VAR variables ;
  WEIGHT variable ;

```

Functional Summary

The SYSLIN procedure statements and options are summarized in the following table.

Description	Statement	Option
Data Set Options		
specify the input data set	PROC SYSLIN	DATA=
specify the output data set	PROC SYSLIN	OUT=
write parameter estimates to an output data set	PROC SYSLIN	OUTEST=
write covariances to the OUTEST= data set	PROC SYSLIN	OUTCOV OUTCOV3
write the SSCP matrix to an output data set	PROC SYSLIN	OUTSSCP=
Estimation Method Options		
specify full information maximum likelihood estimation	PROC SYSLIN	FIML
specify iterative SUR estimation	PROC SYSLIN	ITSUR
specify iterative 3SLS estimation	PROC SYSLIN	IT3SLS
specify K-class estimation	PROC SYSLIN	K=
specify limited information maximum likelihood estimation	PROC SYSLIN	LIML
specify minimum expected loss estimation	PROC SYSLIN	MELO
specify ordinary least squares estimation	PROC SYSLIN	OLS

Description	Statement	Option
specify seemingly unrelated estimation	PROC SYSLIN	SUR
specify two-stage least squares estimation	PROC SYSLIN	2SLS
specify three-stage least squares estimation	PROC SYSLIN	3SLS
specify Fuller's modification to LIML	PROC SYSLIN	ALPHA=
specify convergence criterion	PROC SYSLIN	CONVERGE=
specify maximum number of iterations	PROC SYSLIN	MAXIT=
use diagonal of S instead of S	PROC SYSLIN	SDIAG
exclude RESTRICT statements in final stage	PROC SYSLIN	NOINCLUDE
specify criterion for testing for singularity	PROC SYSLIN	SINGULAR=
specify denominator for variance estimates	PROC SYSLIN	VARDEF=
Printing Control Options		
print all results	PROC SYSLIN	ALL
print first-stage regression statistics	PROC SYSLIN	FIRST
print estimates and SSE at each iteration	PROC SYSLIN	ITPRINT
print the reduced form estimates	PROC SYSLIN	REDUCED
print descriptive statistics	PROC SYSLIN	SIMPLE
print uncorrected SSCP matrix	PROC SYSLIN	USSCP
print correlations of the parameter estimates	MODEL	CORRB
print covariances of the parameter estimates	MODEL	COVB
print Durbin-Watson statistics	MODEL	DW
print Basmann's test	MODEL	OVERID
plot residual values against regressors	MODEL	PLOT
print standardized parameter estimates	MODEL	STB
print unrestricted parameter estimates	MODEL	UNREST
print the model crossproducts matrix	MODEL	XPX
print the inverse of the crossproducts matrix	MODEL	I
suppress printed output	MODEL	NOPRINT
suppress all printed output	PROC SYSLIN	NOPRINT
Model Specification		
specify structural equations	MODEL	
suppress the intercept parameter	MODEL	NOINT
specify linear relationship among variables	IDENTITY	
perform weighted regression	WEIGHT	
Tests and Restrictions on Parameters		
place restrictions on parameter estimates	RESTRICT	
place restrictions on parameter estimates	SRESTRICT	
test linear hypothesis	STEST	
test linear hypothesis	TEST	

Description	Statement	Option
Other Statements		
specify BY-group processing	BY	
specify the endogenous variables	ENDOGENOUS	
specify instrumental variables	INSTRUMENTS	
write predicted and residual values to a data set	OUTPUT	
name variable for predicted values	OUTPUT	PREDICTED=
name variable for residual values	OUTPUT	RESIDUAL=
include additional variables in $X'X$ matrix	VAR	

PROC SYSLIN Statement

PROC SYSLIN *options* ;

The following options can be used with the PROC SYSLIN statement.

Data Set Options

DATA=SAS-data-set

specifies the input data set. If the DATA= option is omitted, the most recently created SAS data set is used. In addition to ordinary SAS data sets, PROC SYSLIN can analyze data sets of TYPE=CORR, TYPE=COV, TYPE=UCORR, TYPE=UCOV, and TYPE=SSCP. See the section “[Special TYPE= Input Data Sets](#)” on page 1909 for details.

OUT=SAS-data-set

specifies an output SAS data set for residuals and predicted values. The OUT= option is used in conjunction with the OUTPUT statement. See the section “[OUT= Data Set](#)” on page 1917 for details.

OUTEST=SAS-data-set

writes the parameter estimates to an output data set. See the section “[OUTEST= Data Set](#)” on page 1917 for details.

OUTCOV

COVOUT

writes the covariance matrix of the parameter estimates to the OUTEST= data set in addition to the parameter estimates.

OUTCOV3

COV3OUT

writes covariance matrices for each model in a system to the OUTEST= data set when the 3SLS, SUR, or FIML option is used.

OUTSSCP=SAS-data-set

writes the sum-of-squares-and-crossproducts matrix to an output data set. See the section “[OUTSSCP= Data Set](#)” on page 1919 for details.

Estimation Method Options

2SLS

specifies the two-stage least squares estimation method.

3SLS

specifies the three-stage least squares estimation method.

ALPHA=value

specifies Fuller’s modification to the LIML estimation method. See the section “[Fuller’s Modification to LIML](#)” on page 1916 for details.

CONVERGE=value

specifies the convergence criterion for the iterative estimation methods IT3SLS, ITSUR, and FIML. The default is CONVERGE=0.0001.

FIML

specifies the full information maximum likelihood estimation method.

ITSUR

specifies the iterative seemingly unrelated estimation method.

IT3SLS

specifies the iterative three-stage least squares estimation method.

K=value

specifies the K-class estimation method.

LIML

specifies the limited information maximum likelihood estimation method.

MAXITER=n

specifies the maximum number of iterations allowed for the IT3SLS, ITSUR, and FIML estimation methods. The MAXITER= option can be abbreviated as MAXIT=. The default is MAXITER=30.

MELO

specifies the minimum expected loss estimation method.

NOINCLUDE

excludes the RESTRICT statements from the final stage for the 3SLS, IT3SLS, SUR, and ITSUR estimation methods.

OLS

specifies the ordinary least squares estimation method. This is the default.

SDIAG

uses the diagonal of **S** instead of **S** to do the estimation, where **S** is the covariance matrix of equation errors. See the section “[Uncorrelated Errors across Equations](#)” on page 1916 for details.

SINGULAR=value

specifies a criterion for testing singularity of the crossproducts matrix. This is a tuning parameter used to make PROC SYSLIN more or less sensitive to singularities. The value must be between 0 and 1. The default is SINGULAR=1E-8.

SUR

specifies the seemingly unrelated estimation method.

Printing Control Options**ALL**

specifies the CORRB, COVB, DW, I, OVERID, PLOT, STB, and XPX options for every MODEL statement.

FIRST

prints first-stage regression statistics for the endogenous variables regressed on the instruments. This output includes sums of squares, estimates, variances, and standard deviations.

ITPRINT

prints parameter estimates, system-weighted residual sum of squares, and R^2 at each iteration for the IT3SLS and ITSUR estimation methods. For the FIML method, the ITPRINT option prints parameter estimates, negative of log-likelihood function, and norm of gradient vector at each iteration.

NOPRINT

suppresses all printed output. Specifying NOPRINT in the PROC SYSLIN statement is equivalent to specifying NOPRINT in every MODEL statement.

REDUCED

prints the reduced form estimates. If the REDUCED option is specified, you should specify any IDENTITY statements needed to make the system square. See the section “[Reduced Form Estimates](#)” on page 1915 for details.

SIMPLE

prints descriptive statistics for the dependent variables. The statistics printed include the sum, mean, uncorrected sum of squares, variance, and standard deviation.

USSCP

prints the uncorrected sum-of-squares-and-crossproducts matrix.

USSCP2

prints the uncorrected sum-of-squares-and-crossproducts matrix for all variables used in the analysis, including predicted values of variables generated by the procedure.

VARDEF=DF | N | WEIGHT | WGT

specifies the denominator to use in calculating cross-equation error covariances and parameter standard errors and covariances. The default is VARDEF=DF, which corrects for model degrees of freedom. VARDEF=N specifies no degrees-of-freedom correction. VARDEF=WEIGHT specifies the sum of the observation weights. VARDEF=WGT specifies the sum of the observation weights minus the model degrees of freedom. See the section “[Computation of Standard Errors](#)” on page 1915 for details.

BY Statement

BY *variables* ;

A BY statement can be used with PROC SYSLIN to obtain separate analyses on observations in groups defined by the BY variables.

ENDOGENOUS Statement

ENDOGENOUS *variables* ;

The ENDOGENOUS statement declares the jointly dependent variables that are projected in the first-stage regression through the instrument variables. The ENDOGENOUS statement is not needed for the SUR, ITSUR, or OLS estimation methods. The default ENDOGENOUS list consists of all the dependent variables in the MODEL and IDENTITY statements that do not appear in the INSTRUMENTS statement.

IDENTITY Statement

IDENTITY *equation* ;

The IDENTITY statement specifies linear relationships among variables to write to the OUTEST= data set. It provides extra information in the OUTEST= data set but does not create or compute variables. The OUTEST= data set can be processed by the SIMLIN procedure in a later step.

The IDENTITY statement is also used to compute reduced form coefficients when the REDUCED option in the PROC SYSLIN statement is specified. See the section “[Reduced Form Estimates](#)” on page 1915 for details.

The *equation* given by the IDENTITY statement has the same form as equations in the MODEL statement. A label can be specified for an IDENTITY statement as follows:

label : **IDENTITY** ... ;

INSTRUMENTS Statement

INSTRUMENTS *variables* ;

The INSTRUMENTS statement declares the variables used in obtaining first-stage predicted values. All the instruments specified are used in each first-stage regression. The INSTRUMENTS statement is required for the 2SLS, 3SLS, IT3SLS, LIML, MELO, and K-class estimation methods. The INSTRUMENTS statement is not needed for the SUR, ITSUR, OLS, or FIML estimation methods.

MODEL Statement

MODEL *response = regressors / options* ;

The MODEL statement regresses the response variable on the left side of the equal sign against the regressors listed on the right side.

Models can be given labels. Model labels are used in the printed output to identify the results for different models. Model labels are also used in SRESTRICT and STEST statements to refer to parameters in different models. If no label is specified, the response variable name is used as the label for the model. The model label is specified as follows:

label : **MODEL** ...;

The following options can be used in the MODEL statement after a slash (/).

ALL

specifies the CORRB, COVB, DW, I, OVERID, PLOT, STB, and XPX options.

ALPHA=*value*

specifies the α parameter for Fuller's modification to the LIML estimation method. See the section "[Fuller's Modification to LIML](#)" on page 1916 for details.

CORRB

prints the matrix of estimated correlations between the parameter estimates.

COVB

prints the matrix of estimated covariances between the parameter estimates.

DW

prints Durbin-Watson statistics and autocorrelation coefficients for the residuals. If there are missing values, d' is calculated according to Savin and White (1978). Use the DW option only if the data set to be analyzed is an ordinary SAS data set with time series observations sorted in time order. The Durbin-Watson test is not valid for models with lagged dependent regressors.

I

prints the inverse of the crossproducts matrix for the model, $(\mathbf{X}'\mathbf{X})^{-1}$. If restrictions are specified, the crossproducts matrix printed is adjusted for the restrictions. See the section "[Computational Details](#)" on page 1914 for details.

K=value

specifies K-class estimation.

NOINT

suppresses the intercept parameter from the model.

NOPRINT

suppresses the normal printed output.

OVERID

prints Basmann's (1960) test for over identifying restrictions. See the section "[Overidentification Restrictions](#)" on page 1916 for details.

PLOT

plots residual values against regressors. A plot of the residuals for each regressor is printed.

STB

prints standardized parameter estimates. Sometimes known as a standard partial regression coefficient, a standardized parameter estimate is a parameter estimate multiplied by the standard deviation of the associated regressor and divided by the standard deviation of the response variable.

UNREST

prints parameter estimates computed before restrictions are applied. The UNREST option is valid only if a RESTRICT statement is specified.

XPX

prints the model crossproducts matrix, $X'X$. See the section "[Computational Details](#)" on page 1914 for details.

OUTPUT Statement

OUTPUT < *PREDICTED=variable* > < *RESIDUAL=variable* > ;

The OUTPUT statement writes predicted values and residuals from the preceding model to the data set specified by the OUT= option in the PROC SYSLIN statement. An OUTPUT statement must come after the MODEL statement to which it applies. The OUT= option must be specified in the PROC SYSLIN statement.

The following options can be specified in the OUTPUT statement:

PREDICTED=variable

names a new variable to contain the predicted values for the response variable. The PREDICTED= option can be abbreviated as PREDICT=, PRED=, or P=.

RESIDUAL=variable

names a new variable to contain the residual values for the response variable. The RESIDUAL= option can be abbreviated as RESID= or R=.

For example, the following statements create an output data set named B. In addition to the variables in the input data set, the data set B contains the variable YHAT, with values that are predicted values of the response variable Y, and YRESID, with values that are the residual values of Y.

```
proc syslin data=a out=b;
  model y = x1 x2;
  output p=yhat r=yresid;
run;
```

For example, the following statements create an output data set named PRED. In addition to the variables in the input data set, the data set PRED contains the variables Q_DEMAND and Q_SUPPLY, with values that are predicted values of the response variable Q for the demand and supply equations respectively, and R_DEMAND and R_SUPPLY, with values that are the residual values of the demand and supply equations respectively.

```
proc syslin data=in out=pred;
  demand: model q = p y s;
  output p=q_demand r=r_demand;
  supply: model q = p u;
  output p=q_supply r=r_supply;
run;
```

See the section “[OUT= Data Set](#)” on page 1917 for details.

RESTRICT Statement

RESTRICT *equation* , ... , *equation* ;

The RESTRICT statement places restrictions on the parameter estimates for the preceding MODEL statement. Any number of RESTRICT statements can follow a MODEL statement. Each restriction is written as a linear equation. If more than one restriction is specified in a single RESTRICT statement, the restrictions are separated by commas.

Parameters are referred to by the name of the corresponding regressor variable. Each name used in the equation must be a regressor in the preceding MODEL statement. The keyword INTERCEPT is used to refer to the intercept parameter in the model.

RESTRICT statements can be given labels. The labels are used in the printed output to distinguish results for different restrictions. Labels are specified as follows:

label : **RESTRICT** ...;

The following is an example of the use of the RESTRICT statement, in which the coefficients of the regressors X1 and X2 are required to sum to 1.

```
proc syslin data=a;
  model y = x1 x2;
```

```

    restrict x1 + x2 = 1;
run;

```

Variable names can be multiplied by constants. When no equal sign appears, the linear combination is set equal to 0. Note that the parameters associated with the variables are restricted, not the variables themselves. Here are some examples of valid RESTRICT statements:

```

restrict x1 + x2 = 1;
restrict x1 + x2 - 1;
restrict 2 * x1 = x2 + x3 , intercept + x4 = 0;
restrict x1 = x2 = x3 = 1;
restrict 2 * x1 - x2;

```

Restricted parameter estimates are computed by introducing a Lagrangian parameter λ for each restriction (Pringle and Rayner 1971). The estimates of these Lagrangian parameters are printed in the “Parameter Estimates” table. If a restriction cannot be applied, its parameter value and degrees of freedom are listed as 0.

The Lagrangian parameter λ measures the sensitivity of the sum of squared errors (SSE) to the restriction. If the restriction is changed by a small amount ϵ , the SSE is changed by $2\lambda\epsilon$.

The t ratio tests the significance of the restrictions. If λ is zero, the restricted estimates are the same as the unrestricted.

Any number of restrictions can be specified on a RESTRICT statement, and any number of RESTRICT statements can be used. The estimates are computed subject to all restrictions specified. However, restrictions should be consistent and not redundant.

NOTE: The RESTRICT statement is not supported for the FIML estimation method.

SRESTRICT Statement

SRESTRICT *equation* , . . . , *equation* ;

The SRESTRICT statement imposes linear restrictions that involve parameters in two or more MODEL statements. The SRESTRICT statement is like the RESTRICT statement but is used to impose restrictions across equations, whereas the RESTRICT statement applies only to parameters in the immediately preceding MODEL statement.

Each restriction is written as a linear equation. Parameters are referred to as *label.variable*, where *label* is the model label and *variable* is the name of the regressor to which the parameter is attached. (If the MODEL statement does not have a label, you can use the dependent variable name as the label for the model, provided the dependent variable uniquely labels the model.) Each variable name used must be a regressor in the indicated MODEL statement. The keyword INTERCEPT is used to refer to intercept parameters.

SRESTRICT statements can be given labels. The labels are used in the printed output to distinguish results for different restrictions. Labels are specified as follows:

label : **SRESTRICT** ...;

The following is an example of the use of the SRESTRICT statement, in which the coefficient for the regressor X2 is constrained to be the same in both models.

```
proc syslin data=a 3sls;
  endogenous y1 y2;
  instruments x1 x2;
  model y1 = y2 x1 x2;
  model y2 = y1 x2;
  srestrict y1.x2 = y2.x2;
run;
```

When no equal sign is used, the linear combination is set equal to 0. Thus, the restriction in the preceding example can also be specified as

```
srestrict y1.x2 - y2.x2;
```

Any number of restrictions can be specified on an SRESTRICT statement, and any number of SRESTRICT statements can be used. The estimates are computed subject to all restrictions specified. However, restrictions should be consistent and not redundant.

When a system restriction is requested for a single equation estimation method (such as OLS or 2SLS), PROC SYSLIN produces the restricted estimates by actually using a corresponding system method. For example, when SRESTRICT is specified along with OLS, PROC SYSLIN produces the restricted OLS estimates via a two-step process equivalent to using SUR estimation with the SDIAG option. First, the unrestricted OLS results are produced. Then, the GLS (SUR) estimation with the system restriction is performed, using the diagonal of the covariance matrix of the residuals. When SRESTRICT is specified along with 2SLS, PROC SYSLIN produces the restricted 2SLS estimates via a multistep process equivalent to using 3SLS estimation with the SDIAG option. First, the unrestricted 2SLS results are produced. Then, the GLS (3SLS) estimation with the system restriction is performed, using the diagonal of the covariance matrix of the residuals.

The results of the SRESTRICT statements are printed after the parameter estimates for all the models in the system. The format of the SRESTRICT statement output is the same as the “Parameter Estimates” table. In this output the parameter estimate is the Lagrangian parameter λ used to impose the restriction.

The Lagrangian parameter λ measures the sensitivity of the system sum of square errors to the restriction. The system SSE is the system MSE shown in the printed output multiplied by the degrees of freedom. If the restriction is changed by a small amount ϵ , the system SSE is changed by $2\lambda\epsilon$.

The t ratio tests the significance of the restriction. If λ is zero, the restricted estimates are the same as the unrestricted estimates.

The model degrees of freedom are not adjusted for the cross-model restrictions imposed by SRESTRICT statements.

NOTE: The SRESTRICT statement is not supported for the LIML and the FIML estimation methods.

STEST Statement

STEST *equation* , ... , *equation* / *options* ;

The STEST statement performs an F test for the joint hypotheses specified in the statement.

The hypothesis is represented in matrix notation as

$$\mathbf{L}\beta = \mathbf{c}$$

and the F test is computed as

$$\frac{(\mathbf{L}b - \mathbf{c})'(\mathbf{L}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{L}')^{-1}(\mathbf{L}b - \mathbf{c})}{m\hat{\sigma}^2}$$

where b is the estimate of β , m is the number of restrictions, and $\hat{\sigma}^2$ is the system weighted mean squared error. See the section “[Computational Details](#)” on page 1914 for information about the matrix $\mathbf{X}'\mathbf{X}$.

Each hypothesis to be tested is written as a linear equation. Parameters are referred to as *label.variable*, where *label* is the model label and *variable* is the name of the regressor to which the parameter is attached. (If the MODEL statement does not have a label, you can use the dependent variable name as the label for the model, provided the dependent variable uniquely labels the model.) Each variable name used must be a regressor in the indicated MODEL statement. The keyword INTERCEPT is used to refer to intercept parameters.

STEST statements can be given labels. The label is used in the printed output to distinguish different tests. Any number of STEST statements can be specified. Labels are specified as follows:

label : **STEST** ...;

The following is an example of the STEST statement:

```
proc syslin data=a 3sls;
  endogenous y1 y2;
  instruments x1 x2;
  model y1 = y2 x1 x2;
  model y2 = y1 x2;
  stest y1.x2 = y2.x2;
run;
```

The test performed is exact only for ordinary least squares, given the OLS assumptions of the linear model. For other estimation methods, the F test is based on large sample theory and is only approximate in finite samples.

If RESTRICT or SRESTRICT statements are used, the tests computed by the STEST statement are conditional on the restrictions specified. The validity of the tests can be compromised if incorrect restrictions are imposed on the estimates.

The following are examples of STEST statements:

```
stest a.x1 + b.x2 = 1;
stest 2 * b.x2 = c.x3 + c.x4 ,
      a.intercept + b.x2 = 0;
stest a.x1 = c.x2 = b.x3 = 1;
stest 2 * a.x1 - b.x2 = 0;
```

The PRINT option can be specified in the STEST statement after a slash (/):

PRINT

prints intermediate calculations for the hypothesis tests.

NOTE: The STEST statement is not supported for the FIML estimation method.

TEST Statement

TEST *equation* , ... , *equation* / *options* ;

The TEST statement performs F tests of linear hypotheses about the parameters in the preceding MODEL statement. Each equation specifies a linear hypothesis to be tested. If more than one equation is specified, the equations are separated by commas.

Variable names must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. The keyword INTERCEPT is used to refer to the model intercept.

TEST statements can be given labels. The label is used in the printed output to distinguish different tests. Any number of TEST statements can be specified. Labels are specified as follows:

label : **TEST** ...;

The following is an example of the use of TEST statement, which tests the hypothesis that the coefficients of X1 and X2 are the same:

```
proc syslin data=a;
  model y = x1 x2;
  test x1 = x2;
run;
```

The following statements perform F tests for the hypothesis that the coefficients of X1 and X2 are equal, for the hypothesis that the sum of the X1 and X2 coefficients is twice the intercept, and for the joint hypothesis.

```
proc syslin data=a;
  model y = x1 x2;
  x1eqx2: test x1 = x2;
  sumeq2i: test x1 + x2 = 2 * intercept;
```

```
joint:  test x1 = x2, x1 + x2 = 2 * intercept;
run;
```

The following are additional examples of TEST statements:

```
test x1 + x2 = 1;
test x1 = x2 = x3 = 1;
test 2 * x1 = x2 + x3, intercept + x4 = 0;
test 2 * x1 - x2;
```

The TEST statement performs an F test for the joint hypotheses specified. The hypothesis is represented in matrix notation as follows:

$$\mathbf{L}\boldsymbol{\beta} = \mathbf{c}$$

The F test is computed as

$$\frac{(\mathbf{L}\mathbf{b} - \mathbf{c})'(\mathbf{L}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{L}')^{-1}(\mathbf{L}\mathbf{b} - \mathbf{c})}{m\hat{\sigma}^2}$$

where \mathbf{b} is the estimate of $\boldsymbol{\beta}$, m is the number of restrictions, and $\hat{\sigma}^2$ is the model mean squared error. See the section “[Computational Details](#)” on page 1914 for information about the matrix $\mathbf{X}'\mathbf{X}$.

The test performed is exact only for ordinary least squares, given the OLS assumptions of the linear model. For other estimation methods, the F test is based on large sample theory and is only approximate in finite samples.

If RESTRICT or SRESTRICT statements are used, the tests computed by the TEST statement are conditional on the restrictions specified. The validity of the tests can be compromised if incorrect restrictions are imposed on the estimates.

The PRINT option can be specified in the TEST statement after a slash (/):

PRINT

prints intermediate calculations for the hypothesis tests.

NOTE: The TEST statement is not supported for the FIML estimation method.

VAR Statement

```
VAR variables ;
```

The VAR statement is used to include variables in the crossproducts matrix that are not specified in any MODEL statement. This statement is rarely used with PROC SYSLIN and is used only with the OUTSSCP= option in the PROC SYSLIN statement.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement is used to perform weighted regression. The WEIGHT statement names a variable in the input data set whose values are relative weights for a weighted least squares fit. If the weight value is proportional to the reciprocal of the variance for each observation, the weighted estimates are the best linear unbiased estimates (BLUE).

Details: SYSLIN Procedure

Input Data Set

PROC SYSLIN does not compute new values for regressors. For example, if you need a lagged variable, you must create it with a DATA step. No values are computed by IDENTITY statements; all values must be in the input data set.

Special TYPE= Input Data Sets

The input data set for most applications of the SYSLIN procedure contains standard rectangular data. However, PROC SYSLIN can also process input data in the form of a crossproducts, covariance, or correlation matrix. Data sets that contain such matrices are identified by values of the TYPE= data set option.

These special kinds of input data sets can be used to save computer time. It takes nk^2 operations, where n is the number of observations and k is the number of variables, to calculate cross products; the regressions are of the order k^3 . When n is in the thousands and k is much smaller, you can save most of the computer time in later runs of PROC SYSLIN by reusing the SSCP matrix rather than recomputing it.

The SYSLIN procedure can process TYPE=CORR, COV, UCORR, UCOV, or SSCP data sets. TYPE=CORR and TYPE=COV data sets, usually created by the CORR procedure, contain means and standard deviations, and correlations or covariances. TYPE=SSCP data sets, usually created in previous runs of PROC SYSLIN, contain sums of squares and cross products. See the *SAS/STAT User's Guide* for more information about special SAS data sets.

When special SAS data sets are read, you must specify the TYPE= data set option. PROC CORR and PROC SYSLIN automatically set the type for output data sets; however, if you create the data set by some other means, you must specify its type with the TYPE= data set option.

When the special data sets are used, the DW (Durbin-Watson test) and PLOT options in the MODEL statement cannot be performed, and the OUTPUT statements are not valid.

Estimation Methods

A brief description of the methods used by the SYSLIN procedure follows. For more information about these methods, see the references at the end of this chapter.

There are two fundamental methods of estimation for simultaneous equations: least squares and maximum likelihood. There are two approaches within each of these categories: single equation methods (also referred to as limited information methods) and system methods (also referred to as full information methods). System methods take into account cross-equation correlations of the disturbances in estimating parameters, while single equation methods do not.

OLS, 2SLS, MELO, K-class, SUR, ITSUR, 3SLS, and IT3SLS use the least squares method; LIML and FIML use the maximum likelihood method.

OLS, 2SLS, MELO, K-class, and LIML are single equation methods. The system methods are SUR, ITSUR, 3SLS, IT3SLS, and FIML.

Single Equation Estimation Methods

Single equation methods do not take into account correlations of errors across equations. As a result, these estimators are not asymptotically efficient compared to full information methods; however, there are instances in which they may be preferred. (See the section “[Choosing a Method for Simultaneous Equations](#)” on page 1912 for details.)

Let y_i be the dependent endogenous variable in equation i , and X_i and Y_i be the matrices of exogenous and endogenous variables appearing as regressors in the same equation.

The 2SLS method owes its name to the fact that, in a first stage, the instrumental variables are used as regressors to obtain a projected value \hat{Y}_i that is uncorrelated with the residual in equation i . In a second stage, \hat{Y}_i replaces Y_i on the right-hand side to obtain consistent least squares estimators.

Normally, the predetermined variables of the system are used as the instruments. It is possible to use variables other than predetermined variables from your system as instruments; however, the estimation might not be as efficient. For consistent estimates, the instruments must be uncorrelated with the residual and correlated with the endogenous variables.

The LIML method results in consistent estimates that are equal to the 2SLS estimates when an equation is exactly identified. LIML can be viewed as a least-variance ratio estimation or as a maximum likelihood estimation. LIML involves minimizing the ratio $\lambda = (rvar_eq)/(rvar_sys)$, where $rvar_eq$ is the residual variance associated with regressing the weighted endogenous variables on all predetermined variables that appear in that equation, and $rvar_sys$ is the residual variance associated with regressing weighted endogenous variables on all predetermined variables in the system.

The MELO method computes the minimum expected loss estimator. MELO estimators “minimize the posterior expectation of generalized quadratic loss functions for structural coefficients of linear structural models” (Judge et al. 1985, p. 635).

K-class estimators are a class of estimators that depends on a user-specified parameter k . A k value less than 1 is recommended but not required. The parameter k can be deterministic or stochastic, but its probability

limit must equal 1 for consistent parameter estimates. When all the predetermined variables are listed as instruments, they include all the other single equation estimators supported by PROC SYSLIN. The instance when some of the predetermined variables are not listed among the instruments is not supported by PROC SYSLIN for the general K-class estimation. However, it is supported for the other methods.

For $k = 1$, the K-class estimator is the 2SLS estimator, while for $k = 0$, the K-class estimator is the OLS estimator. The K-class interpretation of LIML is that $k = \lambda$. Note that k is stochastic in the LIML method, unlike for OLS and 2SLS.

MELO is a Bayesian K-class estimator. It yields estimates that can be expressed as a matrix-weighted average of the OLS and 2SLS estimates. MELO estimators have finite second moments and hence finite risk. Other frequently used K-class estimators might not have finite moments under some commonly encountered circumstances, and hence there can be infinite risk relative to quadratic and other loss functions.

One way of comparing K-class estimators is to note that when $k=1$, the correlation between regressor and the residual is completely corrected for. In all other cases, it is only partially corrected for.

See “[Computational Details](#)” on page 1914 for more details about K-class estimators.

SUR and 3SLS Estimation Methods

SUR might improve the efficiency of parameter estimates when there is contemporaneous correlation of errors across equations. In practice, the contemporaneous correlation matrix is estimated using OLS residuals. Under two sets of circumstances, SUR parameter estimates are the same as those produced by OLS: when there is no contemporaneous correlation of errors across equations (the estimate of the contemporaneous correlation matrix is diagonal) and when the independent variables are the same across equations.

Theoretically, SUR parameter estimates are always at least as efficient as OLS in large samples, provided that your equations are correctly specified. However, in small samples the need to estimate the covariance matrix from the OLS residuals increases the sampling variability of the SUR estimates. This effect can cause SUR to be less efficient than OLS. If the sample size is small and the cross-equation correlations are small, then OLS is preferred to SUR. The consequences of specification error are also more serious with SUR than with OLS.

The 3SLS method combines the ideas of the 2SLS and SUR methods. Like 2SLS, the 3SLS method uses \hat{Y} instead of Y for endogenous regressors, which results in consistent estimates. Like SUR, the 3SLS method takes the cross-equation error correlations into account to improve large sample efficiency. For 3SLS, the 2SLS residuals are used to estimate the cross-equation error covariance matrix.

The SUR and 3SLS methods can be iterated by recomputing the estimate of the cross-equation covariance matrix from the SUR or 3SLS residuals and then computing new SUR or 3SLS estimates based on this updated covariance matrix estimate. Continuing this iteration until convergence produces ITSUR or IT3SLS estimates.

FIML Estimation Method

The FIML estimator is a system generalization of the LIML estimator. The FIML method involves minimizing the determinant of the covariance matrix associated with residuals of the reduced form of the equation system. From a maximum likelihood standpoint, the LIML method involves assuming that the errors are

normally distributed and then maximizing the likelihood function subject to restrictions on a particular equation. FIML is similar, except that the likelihood function is maximized subject to restrictions on all of the parameters in the model, not just those in the equation being estimated.

NOTE: The RESTRICT, SRESTRICT, TEST, and STEST statements are not supported when the FIML method is used.

Choosing a Method for Simultaneous Equations

A number of factors should be taken into account in choosing an estimation method. Although system methods are asymptotically most efficient in the absence of specification error, system methods are more sensitive to specification error than single equation methods.

In practice, models are never perfectly specified. It is a matter of judgment whether the misspecification is serious enough to warrant avoidance of system methods.

Another factor to consider is sample size. With small samples, 2SLS might be preferred to 3SLS. In general, it is difficult to say much about the small sample properties of K-class estimators because the results depend on the regressors used.

LIML and FIML are invariant to the normalization rule imposed but are computationally more expensive than 2SLS or 3SLS.

If the reason for contemporaneous correlation among errors across equations is a common, omitted variable, it is not necessarily best to apply SUR. SUR parameter estimates are more sensitive to specification error than OLS. OLS might produce better parameter estimates under these circumstances. SUR estimates are also affected by the sampling variation of the error covariance matrix. There is some evidence from Monte Carlo studies that SUR is less efficient than OLS in small samples.

ANOVA Table for Instrumental Variables Methods

In the instrumental variables methods (2SLS, LIML, K-class, MELO), first-stage predicted values are substituted for the endogenous regressors. As a result, the regression sum of squares (RSS) and the error sum of squares (ESS) do not sum to the total corrected sum of squares for the dependent variable (TSS). The analysis-of-variance table included in the second-stage results gives these sums of squares and the mean squares that are used for the F test, but this table is not a variance decomposition in the usual sense.

The F test shown in the instrumental variables case is a valid test of the no-regression hypothesis that the true coefficients of all regressors are 0. However, because of the first-stage projection of the regression mean square, this is a Wald-type test statistic, which is asymptotically F but not exactly F -distributed in finite samples. Thus, for small samples the F test is only approximate when instrumental variables are used.

The R-Square Statistics

As explained in the section “ANOVA Table for Instrumental Variables Methods” on page 1912, when instrumental variables are used, the regression sum of squares (RSS) and the error sum of squares (ESS) do not sum to the total corrected sum of squares. In this case, there are several ways that the R^2 statistic can be defined.

The definition of R^2 used by the SYSLIN procedure is

$$R^2 = \frac{RSS}{RSS + ESS}$$

This definition is consistent with the F test of the null hypothesis that the true coefficients of all regressors are zero. However, this R^2 might not be a good measure of the goodness of fit of the model.

System Weighted R-Square and System Weighted Mean Squared Error

The system weighted R^2 , printed for the 3SLS, IT3SLS, SUR, ITSUR, and FIML methods, is computed as follows.

$$R^2 = \mathbf{Y}'\mathbf{W}\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}'\mathbf{W}\mathbf{Y}/\mathbf{Y}'\mathbf{W}\mathbf{Y}$$

In this equation, the matrix $\mathbf{X}'\mathbf{X}$ is $\mathbf{R}'\mathbf{W}\mathbf{R}$ and \mathbf{W} is the projection matrix of the instruments:

$$\mathbf{W} = \mathbf{S}^{-1} \otimes \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$$

The matrix \mathbf{Z} is the instrument set, \mathbf{R} is the regressor set, and \mathbf{S} is the estimated cross-model covariance matrix.

The system weighted MSE, printed for the 3SLS, IT3SLS, SUR, ITSUR, and FIML methods, is computed as follows:

$$MSE = \frac{1}{tdf}(\mathbf{Y}'\mathbf{W}\mathbf{Y} - \mathbf{Y}'\mathbf{W}\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}'\mathbf{W}\mathbf{Y})$$

In this equation, tdf is the sum of the error degrees of freedom for the equations in the system.

Computational Details

This section discusses various computational details.

Computation of Least Squares-Based Estimators

Let the system be composed of G equations and let the i th equation be expressed in this form:

$$y_i = Y_i \beta_i + X_i \gamma_i + \mathbf{u}$$

where

y_i is the vector of observations on the dependent variable

Y_i is the matrix of observations on the endogenous variables included in the equation

β_i is the vector of parameters associated with Y_i

X_i is the matrix of observations on the predetermined variables included in the equation

γ_i is the vector of parameters associated with X_i

\mathbf{u} is a vector of errors

Let $\hat{V}_i = Y_i - \hat{Y}_i$, where \hat{Y}_i is the projection of Y_i onto the space spanned by the instruments matrix \mathbf{Z} .

Let

$$\delta_i = \begin{bmatrix} \beta_i \\ \gamma_i \end{bmatrix}$$

be the vector of parameters associated with both the endogenous and exogenous variables.

The K-class of estimators (Theil 1971) is defined by

$$\hat{\delta}_{i,k} = \begin{bmatrix} Y_i' Y_i - k \hat{V}_i' \hat{V}_i & Y_i' X_i \\ X_i' Y_i & X_i' X_i \end{bmatrix}^{-1} \begin{bmatrix} (Y_i - k \hat{V}_i)' y_i \\ X_i' y_i \end{bmatrix}$$

where k is a user-defined value.

Let

$$\mathbf{R} = [Y_i X_i]$$

and

$$\hat{\mathbf{R}} = [\hat{Y}_i X_i]$$

The 2SLS estimator is defined as

$$\hat{\delta}_{i,2SLS} = [\hat{R}_i' \hat{R}_i]^{-1} \hat{R}_i' y_i$$

Let \mathbf{y} and $\boldsymbol{\delta}$ be the vectors obtained by stacking the vectors of dependent variables and parameters for all G equations, and let \mathbf{R} and $\hat{\mathbf{R}}$ be the block diagonal matrices formed by R_i and \hat{R}_i , respectively.

The SUR and ITSUR estimators are defined as

$$\hat{\boldsymbol{\delta}}_{(IT)SUR} = \left[\mathbf{R}' (\hat{\Sigma}^{-1} \otimes \mathbf{I}) \mathbf{R} \right]^{-1} \mathbf{R}' (\hat{\Sigma}^{-1} \otimes \mathbf{I}) \mathbf{y}$$

while the 3SLS and IT3SLS estimators are defined as

$$\hat{\boldsymbol{\delta}}_{(IT)3SLS} = \left[\hat{\mathbf{R}}' (\hat{\Sigma}^{-1} \otimes \mathbf{I}) \hat{\mathbf{R}} \right]^{-1} \hat{\mathbf{R}}' (\hat{\Sigma}^{-1} \otimes \mathbf{I}) \mathbf{y}$$

where \mathbf{I} is the identity matrix, and $\hat{\Sigma}$ is an estimator of the cross-equation correlation matrix. For 3SLS, $\hat{\Sigma}$ is obtained from the 2SLS estimation, while for SUR it is derived from the OLS estimation. For IT3SLS and ITSUR, it is obtained iteratively from the previous estimation step, until convergence.

Computation of Standard Errors

The VARDEF= option in the PROC SYSLIN statement controls the denominator used in calculating the cross-equation covariance estimates and the parameter standard errors and covariances. The values of the VARDEF= option and the resulting denominator are as follows:

N	uses the number of nonmissing observations.
DF	uses the number of nonmissing observations less the degrees of freedom in the model.
WEIGHT	uses the sum of the observation weights given by the WEIGHTS statement.
WDF	uses the sum of the observation weights given by the WEIGHTS statement less the degrees of freedom in the model.

The VARDEF= option does not affect the model mean squared error, root mean squared error, or R^2 statistics. These statistics are always based on the error degrees of freedom, regardless of the VARDEF= option. The VARDEF= option also does not affect the dependent variable coefficient of variation (CV).

Reduced Form Estimates

The REDUCED option in the PROC SYSLIN statement computes estimates of the reduced form coefficients. The REDUCED option requires that the equation system be square. If there are fewer models than endogenous variables, IDENTITY statements can be used to complete the equation system.

The reduced form coefficients are computed as follows. Represent the equation system, with all endogenous variables moved to the left-hand side of the equations and identities, as

$$\mathbf{B}\mathbf{Y} = \mathbf{\Gamma}\mathbf{X}$$

Here \mathbf{B} is the estimated coefficient matrix for the endogenous variables \mathbf{Y} , and $\mathbf{\Gamma}$ is the estimated coefficient matrix for the exogenous (or predetermined) variables \mathbf{X} .

The system can be solved for \mathbf{Y} as follows, provided \mathbf{B} is square and nonsingular:

$$\mathbf{Y} = \mathbf{B}^{-1} \mathbf{\Gamma} \mathbf{X}$$

The reduced form coefficients are the matrix $\mathbf{B}^{-1} \mathbf{\Gamma}$.

Uncorrelated Errors across Equations

The SDIAG option in the PROC SYSLIN statement computes estimates by assuming uncorrelated errors across equations. As a result, when the SDIAG option is used, the 3SLS estimates are identical to 2SLS estimates, and the SUR estimates are the same as the OLS estimates.

Overidentification Restrictions

The OVERID option in the MODEL statement can be used to test for overidentifying restrictions on parameters of each equation. The null hypothesis is that the predetermined variables that do not appear in any equation have zero coefficients. The alternative hypothesis is that at least one of the assumed zero coefficients is nonzero. The test is approximate and rejects the null hypothesis too frequently for small sample sizes.

The formula for the test is given as follows. Let $y_i = \beta_i \mathbf{Y}_i + \gamma_i \mathbf{Z}_i + e_i$ be the i th equation. \mathbf{Y}_i are the endogenous variables that appear as regressors in the i th equation, and \mathbf{Z}_i are the instrumental variables that appear as regressors in the i th equation. Let N_i be the number of variables in \mathbf{Y}_i and \mathbf{Z}_i .

Let $v_i = y_i - \mathbf{Y}_i \hat{\beta}_i$. Let \mathbf{Z} represent all instrumental variables, T be the total number of observations, and K be the total number of instrumental variables. Define \hat{l} as follows:

$$\hat{l} = \frac{v_i' (\mathbf{I} - \mathbf{Z}_i (\mathbf{Z}_i' \mathbf{Z}_i)^{-1} \mathbf{Z}_i') v_i}{v_i' (\mathbf{I} - \mathbf{Z} (\mathbf{Z}' \mathbf{Z})^{-1} \mathbf{Z}') v_i}$$

Then the test statistic

$$\frac{T - K}{K - N_i} (\hat{l} - 1)$$

is distributed approximately as an F with $K - N_i$ and $T - K$ degrees of freedom. See Basmann (1960) for more information.

Fuller's Modification to LIML

The ALPHA= option in the PROC SYSLIN and MODEL statements parameterizes Fuller's modification to LIML. This modification is $k = \gamma - (\alpha/(n - g))$, where α is the value of the ALPHA= option, γ is the LIML k value, n is the number of observations, and g is the number of predetermined variables. Fuller's modification is not used unless the ALPHA= option is specified. See Fuller (1977) for more information.

Missing Values

Observations that have a missing value for any variable in the analysis are excluded from the computations.

OUT= Data Set

The output SAS data set produced by the OUT= option in the PROC SYSLIN statement contains all the variables in the input data set and the variables that contain predicted values and residuals specified by OUTPUT statements.

The residuals are computed as actual values minus predicted values. Predicted values never use lags of other predicted values, as would be desirable for dynamic simulation. For these applications, PROC SIMLIN is available to predict or simulate values from the estimated equations.

OUTEST= Data Set

The OUTEST= option produces a TYPE=EST output SAS data set that contains estimates from the regressions. The variables in the OUTEST= data set are as follows:

BY variables	identifies the BY statement variables that are included in the OUTEST= data set.
TYPE	identifies the estimation type for the observations. The _TYPE_ value INST indicates first-stage regression estimates. Other values indicate the estimation method used: 2SLS indicates two-stage least squares results, 3SLS indicates three-stage least squares results, LIML indicates limited information maximum likelihood results, and so forth. Observations added by IDENTITY statements have the _TYPE_ value IDENTITY.
STATUS	identifies the convergence status of the estimation. _STATUS_ equals 0 when convergence criteria are met. Otherwise, _STATUS_ equals 1 when the estimation converges with a note, 2 when it converges with a warning, or 3 when it fails to converge.
MODEL	identifies the model label. The model label is the label specified in the MODEL statement or the dependent variable name if no label is specified. For first-stage regression estimates, _MODEL_ has the value FIRST.
DEPVAR	identifies the name of the dependent variable for the model.
NAME	identifies the names of the regressors for the rows of the covariance matrix, if the COVOUT option is specified. _NAME_ has a blank value for the parameter estimates observations. The _NAME_ variable is not included in the OUTEST= data set unless the COVOUT option is used to output the covariance of parameter estimates matrix.
SIGMA	contains the root mean squared error for the model, which is an estimate of the standard deviation of the error term. The _SIGMA_ variable contains the same values reported as Root MSE in the printed output.

INTERCEPT	identifies the intercept parameter estimates.
regressors	identifies the regressor variables from all the MODEL statements that are included in the OUTEST= data set. Variables used in IDENTIFY statements are also included in the OUTEST= data set.

The parameter estimates are stored under the names of the regressor variables. The intercept parameters are stored in the variable INTERCEPT. The dependent variable of the model is given a coefficient of -1 . Variables that are not in a model have missing values for the OUTEST= observations for that model.

Some estimation methods require computation of preliminary estimates. All estimates computed are output to the OUTEST= data set. For each BY group and each estimation, the OUTEST= data set contains one observation for each MODEL or IDENTITY statement. Results for different estimations are identified by the `_TYPE_` variable.

For example, consider the following statements:

```
proc syslin data=a outest=est 3sls;
  by b;
  endogenous y1 y2;
  instruments x1-x4;
  model y1 = y2 x1 x2;
  model y2 = y1 x3 x4;
  identity x1 = x3 + x4;
run;
```

The 3SLS method requires both a preliminary 2SLS stage and preliminary first-stage regressions for the endogenous variable. The OUTEST= data set thus contains three different kinds of estimates. The observations for the first-stage regression estimates have the `_TYPE_` value INST. The observations for the 2SLS estimates have the `_TYPE_` value 2SLS. The observations for the final 3SLS estimates have the `_TYPE_` value 3SLS.

Since there are two endogenous variables in this example, there are two first-stage regressions and two `_TYPE_=INST` observations in the OUTEST= data set. Since there are two model statements, there are two OUTEST= observations with `_TYPE_=2SLS` and two observations with `_TYPE_=3SLS`. In addition, the OUTEST= data set contains an observation with the `_TYPE_` value IDENTITY that contains the coefficients specified by the IDENTITY statement. All these observations are repeated for each BY group in the input data set defined by the values of the BY variable B.

When the COVOUT option is specified, the estimated covariance matrix for the parameter estimates is included in the OUTEST= data set. Each observation for parameter estimates is followed by observations that contain the rows of the parameter covariance matrix for that model. The row of the covariance matrix is identified by the variable `_NAME_`. For observations that contain parameter estimates, `_NAME_` is blank. For covariance observations, `_NAME_` contains the regressor name for the row of the covariance matrix and the regressor variables contain the covariances.

See [Example 29.1](#) for an example of the OUTEST= data set.

OUTSSCP= Data Set

The OUTSSCP= option produces a TYPE=SSCP output SAS data set that contains sums of squares and cross products. The data set contains all variables used in the MODEL, IDENTITY, and VAR statements. Observations are identified by the variable _NAME_.

The OUTSSCP= data set can be useful when a large number of observations are to be explored in many different SYSLIN runs. The sum-of-squares-and-crossproducts matrix can be saved with the OUTSSCP= option and used as the DATA= data set on subsequent SYSLIN runs. This is much less expensive computationally because PROC SYSLIN never reads the original data again. In the step that creates the OUTSSCP= data set, include in the VAR statement all the variables you expect to use.

Printed Output

The printed output produced by the SYSLIN procedure is as follows:

1. If the SIMPLE option is used, a table of descriptive statistics is printed that shows the sum, mean, sum of squares, variance, and standard deviation for all the variables used in the models.
2. If the FIRST option is specified and an instrumental variables method is used, first-stage regression results are printed. The results show the regression of each endogenous variable on the variables in the INSTRUMENTS list.
3. The results of the second-stage regression are printed for each model. (See the following section [“Printed Output for Each Model”](#) on page 1920 for details.)
4. If a systems method like 3SLS, SUR, or FIML is used, the cross-equation error covariance matrix is printed. This matrix is shown four ways: the covariance matrix itself, the correlation matrix form, the inverse of the correlation matrix, and the inverse of the covariance matrix.
5. If a systems method like 3SLS, SUR, or FIML is used, the system weighted mean squared error and system weighted R^2 statistics are printed. The system weighted MSE and R^2 measure the fit of the joint model obtained by stacking all the models together and performing a single regression with the stacked observations weighted by the inverse of the model error variances.
6. If a systems method like 3SLS, SUR, or FIML is used, the final results are printed for each model.
7. If the REDUCED option is used, the reduced form coefficients are printed. These consist of the structural coefficient matrix for the endogenous variables, the structural coefficient matrix for the exogenous variables, the inverse of the endogenous coefficient matrix, and the reduced form coefficient matrix. The reduced form coefficient matrix is the product of the inverse of the endogenous coefficient matrix and the exogenous structural coefficient matrix.

Printed Output for Each Model

The results printed for each model include the analysis-of-variance table, the “Parameter Estimates” table, and optional items requested by TEST statements or by options in the MODEL statement.

The printed output produced for each model is described in the following.

The analysis-of-variance table includes the following:

- the model degrees of freedom, sum of squares, and mean square
- the error degrees of freedom, sum of squares, and mean square. The error mean square is computed by dividing the error sum of squares by the error degrees of freedom and is not affected by the VARDEF= option.
- the corrected total degrees of freedom and total sum of squares. Note that for instrumental variables methods, the model and error sums of squares do not add to the total sum of squares.
- the F ratio, labeled “F Value,” and its significance, labeled “PROB>F,” for the test of the hypothesis that all the nonintercept parameters are 0
- the root mean squared error. This is the square root of the error mean square.
- the dependent variable mean
- the coefficient of variation (CV) of the dependent variable
- the R^2 statistic. This R^2 is computed consistently with the calculation of the F statistic. It is valid for hypothesis tests but might not be a good measure of fit for models estimated by instrumental variables methods.
- the R^2 statistic adjusted for model degrees of freedom, labeled “Adj R-SQ”

The “Parameter Estimates” table includes the following:

- estimates of parameters for regressors in the model and the Lagrangian parameter for each restriction specified
- a degrees of freedom column labeled DF. Estimated model parameters have 1 degree of freedom. Restrictions have a DF of –1. Regressors or restrictions dropped from the model due to collinearity have a DF of 0.
- the standard errors of the parameter estimates
- the t statistics, which are the parameter estimates divided by the standard errors
- the significance of the t tests for the hypothesis that the true parameter is 0, labeled “Pr > |t|.” As previously noted, the significance tests are strictly valid in finite samples only for OLS estimates but are asymptotically valid for the other methods.

- the standardized regression coefficients, if the STB option is specified. This is the parameter estimate multiplied by the ratio of the standard deviation of the regressor to the standard deviation of the dependent variable.
- the labels of the regressor variables or restriction labels

In addition to the analysis-of-variance table and the “Parameter Estimates” table, the results printed for each model can include the following:

- If TEST statements are specified, the test results are printed.
- If the DW option is specified, the Durbin-Watson statistic and first-order autocorrelation coefficient are printed.
- If the OVERID option is specified, the results of Basman’s test for overidentifying restrictions are printed.
- If the PLOT option is used, plots of residual against each regressor are printed.
- If the COVB or CORRB options are specified, the results for each model also include the covariance or correlation matrix of the parameter estimates. For systems methods like 3SLS and FIML, the COVB and CORB output is printed for the whole system after the output for the last model, instead of separately for each model.

The third-stage output for 3SLS, SUR, IT3SLS, ITSUR, and FIML does not include the analysis-of-variance table. When a systems method is used, the second-stage output does not include the optional output, except for the COVB and CORRB matrices.

ODS Table Names

PROC SYSLIN assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. If the estimation method used is 3SLS, IT3SLS, ITSUR or SUR, you can obtain tables by specifying ODS OUTPUT CorrResiduals, InvCorrResiduals, InvCovResiduals.

Table 29.2 ODS Tables Produced in PROC SYSLIN

ODS Table Name	Description	Option
ANOVA	Summary of the SSE, MSE for the equations	default
AugXPXMat	Model crossproducts	XPX or USSCP
AutoCorrStat	Autocorrelation statistics	DW
ConvergenceStatus	Convergence status	default
CorrB	Correlations of parameters	CORRB
CorrResiduals	Correlations of residuals	
CovB	Covariance of parameters	COVB
CovResiduals	Covariance of residuals	

Table 29.2 (continued)

ODS Table Name	Description	Option
EndoMat	Endogenous variables	REDUCED
ExogMat	Exogenous variables	REDUCED
FitStatistics	Statistics of fit	default
InvCorrResiduals	Inverse correlations of residuals	
InvCovResiduals	Inverse covariance of residuals	
InvEndoMat	Inverse endogenous variables	REDUCED
InvXPX	$X'X$ inverse for system	I
IterHistory	Iteration printing	ITPRINT
MissingValues	Missing values generated by the program	default
ModelVars	Name and label for the model	default
ParameterEstimates	Parameter estimates	default
RedMat	Reduced form	REDUCED
SimpleStatistics	Descriptive statistics	SIMPLE

ODS Graphics

This section describes the use of ODS for creating graphics with the SYSLIN procedure.

ODS Graph Names

PROC SYSLIN assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when you use ODS. The names are listed in [Table 29.3](#).

To request these graphs, you must specify the ODS GRAPHICS statement.

Table 29.3 ODS Graphics Produced by PROC SYSLIN

ODS Graph Name	Plot Description
DiagnosticsPanel	All applicable plots listed below
ActualByPredicted	Predicted versus actual plot
QQPlot	Q-Q plot of residuals
ResidualHistogram	Histogram of the residuals
ResidualPlot	Residual plot

Examples: SYSLIN Procedure

Example 29.1: Klein's Model I Estimated with LIML and 3SLS

This example uses PROC SYSLIN to estimate the classic Klein Model I. For a discussion of this model, see Theil (1971). The following statements read the data.

```
*-----Klein's Model I-----*
| By L.R. Klein, Economic Fluctuations in the United States, 1921-1941 |
| (1950), NY: John Wiley.  A macro-economic model of the U.S. with  |
| three behavioral equations, and several identities. See Theil, p.456. |
*-----*
data klein;
input year c p w i x wp g t k wsum;
    date=mdy(1,1,year);
    format date monyy.;
    y  =c+i+g-t;
    yr =year-1931;
    klag=lag(k);
    plag=lag(p);
    xlag=lag(x);
    label year='Year'
           date='Date'
           c  ='Consumption'
           p  ='Profits'
           w  ='Private Wage Bill'
           i  ='Investment'
           k  ='Capital Stock'
           y  ='National Income'
           x  ='Private Production'
           wsum='Total Wage Bill'
           wp  ='Govt Wage Bill'
           g  ='Govt Demand'
           i  ='Taxes'

```

... more lines ...

The following statements estimate the Klein model using the limited information maximum likelihood method. In addition, the parameter estimates are written to a SAS data set with the OUTEST= option.

```
proc syslin data=klein outest=b liml;
  endogenous c p w i x wsum k y;
  instruments klag plag xlag wp g t yr;
  consume: model c = p plag wsum;
  invest:  model i = p plag klag;
  labor:   model w = x xlag yr;
run;

proc print data=b;
run;
```

The PROC SYSLIN estimates are shown in [Output 29.1.1](#) through [Output 29.1.3](#).

Example 29.2: Grunfeld's Model Estimated with SUR

The following example was used by Zellner in his classic 1962 paper on seemingly unrelated regressions. Different stock prices often move in the same direction at a given point in time. The SUR technique might provide more efficient estimates than OLS in this situation.

The following statements read the data. (The prefix GE stands for General Electric and WH stands for Westinghouse.)

```
*-----Zellner's Seemingly Unrelated Technique-----*
| A. Zellner, "An Efficient Method of Estimating Seemingly |
| Unrelated Regressions and Tests for Aggregation Bias," |
| JASA 57(1962) pp.348-364 |
| |
| J.C.G. Boot, "Investment Demand: an Empirical Contribution |
| to the Aggregation Problem," IER 1(1960) pp.3-30. |
| |
| Y. Grunfeld, "The Determinants of Corporate Investment," |
| Unpublished thesis, Chicago, 1958 |
*-----*

data grunfeld;
  input year ge_i ge_f ge_c wh_i wh_f wh_c;
```

```

label ge_i = 'Gross Investment, GE'
      ge_c = 'Capital Stock Lagged, GE'
      ge_f = 'Value of Outstanding Shares Lagged, GE'
      wh_i = 'Gross Investment, WH'
      wh_c = 'Capital Stock Lagged, WH'
      wh_f = 'Value of Outstanding Shares Lagged, WH';
datalines;

... more lines ...

```

The following statements compute the SUR estimates for the Grunfeld model.

```

proc syslin data=grunfeld sur;
  ge:      model ge_i = ge_f ge_c;
  westing: model wh_i = wh_f wh_c;
run;

```

The PROC SYSLIN output is shown in [Output 29.2.1](#) through [Output 29.2.5](#).

Example 29.3: Illustration of ODS Graphics

This example illustrates the use of ODS graphics. This is a continuation of the section “[Example 29.1: Klein’s Model I Estimated with LIML and 3SLS](#)” on page 1923. These graphical displays are requested by specifying the ODS GRAPHICS statement before running PROC SYSLIN. For information about the graphics available in the SYSLIN procedure, see the section “[ODS Graphics](#)” on page 1922.

The following statements show how to generate ODS graphics plots with the SYSLIN procedure. The plots of residuals for each one of the equations in the model are displayed in [Figure 29.3.1](#) through [Figure 29.3.3](#).

Overview: TCOUNTREG Procedure

The TCOUNTREG procedure is an experimental version of the COUNTREG procedure. The main difference of the new procedure is the addition of panel estimation and variable selection capabilities.

The TCOUNTREG (count regression) procedure analyzes regression models in which the dependent variable takes nonnegative integer or count values. The dependent variable is usually an *event count*, which refers to the number of times an event occurs. For example, an event count might represent the number of ship accidents per year for a given fleet. In count regression, the conditional mean $E(y_i | \mathbf{x}_i)$ of the dependent variable y_i is assumed to be a function of a vector of covariates \mathbf{x}_i .

The Poisson (log-linear) regression model is the most basic model that explicitly takes into account the nonnegative integer-valued aspect of the outcome. With this model, the probability of an event count is determined by a Poisson distribution, where the conditional mean of the distribution is a function of a vector of covariates. However, the basic Poisson regression model is limited because it forces the conditional mean of the outcome to equal the conditional variance. This assumption is often violated in real-life data. Negative binomial regression is an extension of Poisson regression in which the conditional variance can exceed the conditional mean. Also, an often encountered characteristic of count data is that the number of zeros in the sample exceeds the number of zeros predicted by either the Poisson or negative binomial model. Zero-inflated Poisson (ZIP) and zero-inflated negative binomial (ZINB) models explicitly model the production of zero counts to account for excess zeros and also enable the conditional variance of the outcome to differ from the conditional mean.

Under zero-inflated models, additional zeros occur with probability φ_i , which is determined by a separate model, $\varphi_i = F(\mathbf{z}_i' \boldsymbol{\gamma})$, where F is the normal or logistic distribution function that results in a probit or logistic model and \mathbf{z}_i is a set of covariates.

PROC TCOUNTREG supports the following models for count data:

- Poisson regression
- negative binomial regression with quadratic (NEGBIN2) and linear (NEGBIN1) variance functions (Cameron and Trivedi 1986)
- zero-inflated Poisson (ZIP) model (Lambert 1992)
- zero-inflated negative binomial (ZINB) model
- fixed effects and random effects Poisson models for panel data

- fixed effects and random effects negative binomial models for panel data

In recent years, count data models have been used extensively in economics, political science, and sociology. For example, Hausman, Hall, and Griliches (1984) examine the effects of research and development expenditures on the number of patents received by U.S. companies. Cameron and Trivedi (1986) study factors that affect the number of doctor visits. Greene (1994) studies the number of derogatory reports to a credit reporting agency for a group of credit card applicants. As a final example, Long (1997) analyzes the number of doctoral publications in the final three years of Ph.D. studies.

The TCOUNTREG procedure uses maximum likelihood estimation. When a model with a dependent count variable is estimated using linear ordinary least squares (OLS) regression, the count nature of the dependent variable is ignored. This can lead to negative predicted counts and to parameter estimates with undesirable properties in terms of statistical efficiency, consistency, and unbiasedness unless the mean of the counts is high, in which case the Gaussian approximation and linear regression might be satisfactory.

Getting Started: TCOUNTREG Procedure

The TCOUNTREG procedure is similar in use to other regression model procedures in the SAS System. For example, the following statements are used to estimate a Poisson regression model:

```
proc tcountreg data=one ;
    model y = x / dist=poisson ;
run;
```

The response variable *y* is numeric and has nonnegative integer values. To allow for variance greater than the mean, specify the DIST=NEGBIN option to fit the negative binomial model instead of the Poisson.

The following example illustrates the use of PROC TCOUNTREG. The data are taken from Long (1997) and can be found in the SAS/ETS Sample Library. This study examines how factors such as gender (*fem*), marital status (*mar*), number of young children (*kid5*), prestige of the graduate program (*phd*), and number of articles published by a scientist's mentor (*ment*) affect the number of articles (*art*) published by the scientist.

The first 10 observations are shown in [Figure 30.1](#).

Figure 30.1 Article Count Data

Obs	art	fem	mar	kid5	phd	ment
1	3	0	1	2	1.38000	8.0000
2	0	0	0	0	4.29000	7.0000
3	4	0	0	0	3.85000	47.0000
4	1	0	1	1	3.59000	19.0000
5	1	0	1	0	1.81000	0.0000
6	1	0	1	1	3.59000	6.0000
7	0	0	1	1	2.12000	10.0000
8	0	0	1	0	4.29000	2.0000
9	3	0	1	2	2.58000	2.0000
10	3	0	1	1	1.80000	4.0000

The following SAS statements estimate the Poisson regression model:

```
proc tcountreg data=long97data;
  model art = fem mar kid5 phd ment / dist=poisson;
run;
```

The “Model Fit Summary” table, shown in [Figure 30.2](#), lists several details about the model. By default, the TCOUNTREG procedure uses the Newton-Raphson optimization technique. The maximum log-likelihood value is shown, in addition to two information measures, Akaike’s information criterion (AIC) and Schwarz’s Bayesian information criterion (SBC), which can be used to compare competing Poisson models. Smaller values of these criteria indicate better models.

Figure 30.2 Estimation Summary Table for a Poisson Regression

The TCOUNTREG Procedure	
Model Fit Summary	
Dependent Variable	art
Number of Observations	915
Data Set	WORK.LONG97DATA
Model	Poisson
Log Likelihood	-1651
Maximum Absolute Gradient	3.5741E-9
Number of Iterations	5
Optimization Method	Newton-Raphson
AIC	3314
SBC	3343

The parameter estimates of the model and their standard errors are shown in [Figure 30.3](#). All covariates are significant predictors of the number of articles, except for the prestige of the program (phd), which has a p -value of 0.6271.

Figure 30.3 Parameter Estimates of Poisson Regression

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.304617	0.102982	2.96	0.0031
fem	1	-0.224594	0.054614	-4.11	<.0001
mar	1	0.155243	0.061375	2.53	0.0114
kid5	1	-0.184883	0.040127	-4.61	<.0001
phd	1	0.012823	0.026397	0.49	0.6271
ment	1	0.025543	0.002006	12.73	<.0001

The following statements fit the negative binomial model. Although the Poisson model requires that the conditional mean and conditional variance be equal, the negative binomial model allows for overdispersion; that is, the conditional variance can exceed the conditional mean.

```
proc tcountreg data=long97data;
  model art = fem mar kid5 phd ment / dist=negbin(p=2) method=qn;
run;
```

The fit summary is shown in [Figure 30.4](#), and parameter estimates are listed in [Figure 30.5](#).

Figure 30.4 Estimation Summary Table for a Negative Binomial Regression

The TCOUNTREG Procedure	
Model Fit Summary	
Dependent Variable	art
Number of Observations	915
Data Set	WORK.LONG97DATA
Model	NegBin
Log Likelihood	-1561
Maximum Absolute Gradient	1.75584E-6
Number of Iterations	16
Optimization Method	Quasi-Newton
AIC	3136
SBC	3170

Figure 30.5 Parameter Estimates of Negative Binomial Regression

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.256144	0.138560	1.85	0.0645
fem	1	-0.216418	0.072672	-2.98	0.0029
mar	1	0.150489	0.082106	1.83	0.0668
kid5	1	-0.176415	0.053060	-3.32	0.0009
phd	1	0.015271	0.036040	0.42	0.6718
ment	1	0.029082	0.003470	8.38	<.0001
_Alpha	1	0.441620	0.052967	8.34	<.0001

The parameter estimate for `_Alpha` of 0.4416 is an estimate of the dispersion parameter in the negative binomial distribution. A t test for the hypothesis $H_0 : \alpha = 0$ is provided. It is highly significant, indicating overdispersion ($p < 0.0001$).

The null hypothesis $H_0 : \alpha = 0$ can be also tested against the alternative $\alpha > 0$ by using the likelihood ratio test, as described by Cameron and Trivedi (1998, pp. 45, 77–78). The likelihood ratio test statistic is equal to $-2(\mathcal{L}_P - \mathcal{L}_{NB}) = -2(-1651 + 1561) = 180$, where \mathcal{L}_P and \mathcal{L}_{NB} are the log likelihoods for the Poisson and negative binomial models, respectively. The likelihood ratio test is highly significant, providing strong evidence of overdispersion.

Syntax: TCOUNTREG Procedure

The TCOUNTREG procedure is controlled by the following statements:

```

PROC TCOUNTREG < options > ;
  BOUNDS bound1 < , bound2 ... > ;
  BY variables ;
  CLASS variables ;
  FREQ variable ;
  ID variable ;
  INIT initvalue1 < , initvalue2 ... > ;
  MODEL dependent = < regressors > < / options > ;
  NLOPTIONS < options > ;
  OUTPUT < OUT=SAS-data-set > < output-options > ;
  RESTRICT restriction1 < , restriction2 ... > ;
  WEIGHT variable < / options > ;
  ZEROMODEL dependent variable ~ < zero-inflated regressors > < / options > ;

```

There can only be one **MODEL** statement. The **ZEROMODEL** statement, if used, must appear after the **MODEL** statement, and the **CLASS** statement must precede the **MODEL** statement. If a **FREQ** or **WEIGHT** statement is specified more than once, the variable specified in the first instance is used.

Functional Summary

Table 30.1 summarizes statements and options used with the TCOUNTREG procedure.

Table 30.1 TCOUNTREG Functional Summary

Description	Statement	Option
Data Set Options		
Specifies the input data set	TCOUNTREG	DATA=
Writes parameter estimates to an output data set	TCOUNTREG	OUTEST=
Writes estimates of $\mathbf{x}_i'\boldsymbol{\beta}$ and $\mathbf{z}_i'\boldsymbol{\gamma}$ to an output data set	OUTPUT	OUT=
Declaring the Role of Variables		
Specifies BY-group processing	BY	
Specifies classification variables	CLASS	
Specifies a frequency variable	FREQ	
Specifies a weight variable	WEIGHT	
Specifies the ID variable for panel data analysis	ID	
Printing Control Options		
Prints the correlation matrix of the estimates	MODEL	CORRB
Prints the covariance matrix of the estimates	MODEL	COVB
Prints a summary iteration listing	MODEL	ITPRINT
Suppresses the normal printed output	TCOUNTREG	NOPRINT
Requests all printing options	MODEL	PRINTALL
Options to Control the Optimization Process		
Specifies maximum number of iterations allowed	MODEL	MAXITER=
Selects the iterative minimization method to use	TCOUNTREG	METHOD=
Sets boundary restrictions on parameters	BOUNDS	
Sets initial values for parameters	INIT	
Sets linear restrictions on parameters	RESTRICT	
Specifies the optimization options	NLOPTIONS	See Chapter 6, “Non-linear Optimization Methods”
Model Estimation Options		
Specifies the type of model	MODEL	DIST=
Specifies the type of model	TCOUNTREG	DIST=
Specifies the type of covariance matrix	MODEL	COVEST=
Specifies the type of error components model for panel data	MODEL	ERRORCOMP=
Suppresses the intercept parameter	MODEL	NOINT
Specifies the offset variable	MODEL	OFFSET=
Specifies the zero-inflated offset variable	ZEROMODEL	OFFSET=

Description	Statement	Option
Specifies the zero-inflated link function	ZEROMODEL	LINK=
Specifies variable selection	MODEL	SELECT=()
Output Control Options		
Includes covariances in the OUTEST= data set	TCOUNTREG	COVOUT
Outputs the probability of response variable taking the current value	OUTPUT	PROB=
Outputs probabilities for particular response values	OUTPUT	PROBCOUNT()
Outputs expected value of response variable	OUTPUT	PRED=
Outputs estimates of $\mathbf{X}\beta = \mathbf{x}_i' \boldsymbol{\beta}$	OUTPUT	XBETA=
Outputs estimates of $\mathbf{Z}\gamma = \mathbf{z}_i' \boldsymbol{\gamma}$	OUTPUT	ZGAMMA=
Outputs the probability of the response variable taking a zero value as a result of the zero-generating process	OUTPUT	PROBZERO=

PROC TCOUNTREG Statement

PROC TCOUNTREG <options> ;

The following options can be used in the PROC TCOUNTREG statement:

Data Set Options

DATA=SAS-data-set

specifies the input SAS data set. If the DATA= option is not specified, PROC TCOUNTREG uses the most recently created SAS data set.

Output Data Set Options

OUTEST=SAS-data-set

writes the parameter estimates to the specified output data set.

COVOUT

writes the covariance matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

Printing Options

NOPRINT

suppresses all printed output.

CORRB

prints the correlation matrix of the parameter estimates. This option can also be specified in the MODEL statement.

COVB

prints the covariance matrix of the parameter estimates. This option can also be specified in the MODEL statement.

Estimation Control Options

COVEST=*value*

specifies the type of covariance matrix of the parameter estimates. The quasi-maximum-likelihood-estimates are computed with COVEST=QML. The default is COVEST=HESSIAN. The supported covariance types are as follows:

OP	specifies the covariance from the outer product matrix.
HESSIAN	specifies the covariance from the Hessian matrix.
QML	specifies the covariance from the outer product and Hessian matrices.

Options to Control the Optimization Process

PROC TCOUNTREG uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. All the NLO options are available in the NLOPTIONS statement. For details, see the “[NLOPTIONS Statement](#)” on page 1952. In addition, the following option is supported in the PROC TCOUNTREG statement:

METHOD=*value*

specifies the iterative minimization method to use. The default is METHOD=NRA.

CONGRA	specifies the conjugate-gradient method.
DBLDOG	specifies the double-dogleg method.
QN	specifies the quasi-Newton method.
NMSIMP	specifies Nelder-Mead simplex method.
NRA	specifies the Newton-Raphson method.
NRRIDG	specifies the Newton-Raphson ridge method.
TR	specifies the trust region method.

BOUNDS Statement

BOUNDS *bound1* < , *bound2* ... > ;

The BOUNDS statement imposes simple boundary constraints on the parameter estimates. BOUNDS statement constraints refer to the parameters estimated by the TCOUNTREG procedure. You can specify any number of BOUNDS statements as follows.

Each *bound* is composed of parameter names, constants, and inequality operators as follows:

item operator item < operator item operator item ... >

Each *item* is a constant, a parameter name, or a list of parameter names. Each *operator* is <, >, <=, or >=. Parameter names are as shown in the ESTIMATE column of the “Parameter Estimates” table or can be seen in the OUTEST= data set.

You can use both the BOUNDS statement and the RESTRICT statement to impose boundary constraints; however, the BOUNDS statement provides a simpler syntax for specifying these kinds of constraints. See also the section “[RESTRICT Statement](#)” on page 1953.

The following BOUNDS statement constrains the estimates of the parameter for *z* to be negative, the parameters for *x1* through *x10* to be between zero and one, and the parameter for *x1* in the zero-inflation model to be less than one:

```
bounds z < 0,
       0 < x1-x10 < 1,
       Inf_x1 < 1;
```

BY Statement

BY *variables* ;

A BY statement can be used with PROC TCOUNTREG to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the input data set should be sorted in the order of the BY variables.

CLASS Statement

CLASS *variables* ;

The CLASS statement names the classification variables that are used to group (classify) data in the analysis. Classification variables can be either character or numeric.

Class levels are determined from the formatted values of the CLASS *variables*. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in the *SAS Language Reference: Dictionary* for details. The CLASS statement must precede the MODEL statement.

FREQ Statement

FREQ *variable* ;

The FREQ statement specifies a variable whose values represent the frequency of occurrence of each observation. PROC TCOUNTREG treats each observation as if it appears n times, where n is the value of the FREQ variable for the observation. If the frequency value is not an integer, it is truncated to an integer; if it is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not specified, each observation is assigned a frequency of 1. If you specify more than one FREQ statement, then the first statement is used.

ID Statement

ID *variable* ;

The ID statement must be used with PROC TCOUNTREG to specify an identification variable when a panel data model is estimated. The identification variable is a cross section ID variable.

INIT Statement

INIT *initvalue1* < , *initvalue2* ... > ;

The INIT statement sets initial values for parameters in the optimization.

Each *initvalue* is written as a parameter or parameter list, followed by an optional equal sign (=), followed by a number:

parameter < => *number*

For continuous regressors, the names of the parameters are the same as the corresponding variables. For a regressor that is a CLASS variable, the parameter name combines the corresponding CLASS variable name with the variable level. For interaction and nested regressors, the parameter names combine the names of each regressor. The names of the parameters can be seen in the OUTEST= data set. By default, initial values are determined by OLS regression. Initial values can be displayed with the ITPRINT option in the PROC statement.

MODEL Statement

MODEL *dependent* = <regressors> </ options> ;

The MODEL statement specifies the dependent variable and independent covariates (regressors) for the regression model. If you specify no regressors, PROC TCOUNTREG fits a model that contains only an

intercept. The dependent count variable should take on only nonnegative integer values in the input data set. PROC TCOUNTREG rounds any positive noninteger count values to the nearest integer. PROC TCOUNTREG ignores any observations with a negative count.

Only one MODEL statement can be specified. The following options can be used in the MODEL statement after a slash (/).

DIST=*value*

specifies a type of model to be analyzed. If you specify this option in both the MODEL statement and the PROC TCOUNTREG statement, then only the value in the MODEL statement is used. The following model types are supported:

POISSON | P specifies a Poisson regression model.

NEGBIN(P=1) specifies a negative binomial regression model with a linear variance function.

NEGBIN(P=2) | NEGBIN specifies a negative binomial regression model with a quadratic variance function.

ZIPOISSON | ZIP specifies a zero-inflated Poisson regression. The ZEROMODEL statement must be specified when this model type is specified.

ZINEGBIN | ZINB specifies a zero-inflated negative binomial regression. The ZEROMODEL statement must be specified when this model type is specified.

ERRORCOMP=*value*

specifies a type of conditional panel model to be analyzed. The following model types are supported:

FIXED specifies a fixed-effect error component regression model.

RANDOM specifies a random-effect error component regression model.

NOINT

suppresses the intercept parameter.

OFFSET=*variable*

specifies a variable in the input data set to be used as an offset variable. The offset variable appears as a covariate in the model with its parameter restricted to 1. The offset variable cannot be the response variable, the zero-inflation offset variable (if any), or one of the explanatory variables. The “Model Fit Summary” table gives the name of the data set variable used as the offset variable; it is labeled as “Offset.”

SELECT=(INFO(option) | PEN(option))

specifies variable selection.

SELECT= INFO specifies that the variable selection method is based on an information criterion. For more information, see the section “[Variable Selection Using an Information Criterion](#)” on page 1967. The following *options* are available for SELECT=INFO:

DIRECTION=FORWARD | BACKWARD

specifies the searching algorithm used in the variable selection method. The default is FORWARD.

CRITER=AIC | SBC

specifies the information criterion used for the variable selection. The default is SBC.

MAXSTEPS=value

specifies the maximum number of steps allowed in the search algorithm. The default is infinite; that is, the algorithm does not stop until the stopping criterion is satisfied.

LSTOP=value

specifies the stopping criterion. *value* represents the percentage of decrease or increase in the AIC or SBC that is required for the algorithm to proceed; it must be a positive number less than 1. The default is zero.

SELECT=PEN specifies that the variable selection method is penalized likelihood. For more information, see the section [“Variable Selection Using Penalized Likelihood”](#) on page 1967. The following *options* are available for SELECT=PEN:

LLASTEPS=value

specifies the maximum number of iterations in the algorithm of local linear approximations. The default is 5.

GCVLENGTH=value

specifies the number of different values that is used for the generalized cross-validation (GCV) tuning parameter. The value corresponds to λ in the computations described in the section [“Variable Selection Using Penalized Likelihood”](#) on page 1967. The default value is 20.

GCV

specifies that the generalized cross-validation (GCV) approach be used. For more information, see the section [“The GCV Approach”](#) on page 1969.

GCV1

specifies that the GCV1 approach be used. For more information, see the section [“The GCV1 Approach”](#) on page 1970. GCV1 is the default.

Printing Options

CORRB

prints the correlation matrix of the parameter estimates. The CORRB option can also be specified in the PROC TCOUNTREG statement.

COVB

prints the covariance matrix of the parameter estimates. The COVB can also be specified in the PROC TCOUNTREG statement.

ITPRINT

prints the objective function and parameter estimates at each iteration. The objective function is the negative log-likelihood function. The ITPRINT option can also be specified in the PROC TCOUNTREG statement.

PRINTALL

requests all printing options. The PRINTALL option can also be specified in the PROC TCOUNTREG statement.

NLOPTIONS Statement

NLOPTIONS <options> ;

The NLOPTIONS statement provides the options to control the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. For a list of all the options of the NLOPTIONS statement, see Chapter 6, “Nonlinear Optimization Methods.”

OUTPUT Statement

OUTPUT <OUT=SAS-data-set> <output-options> ;

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimates of $\mathbf{x}'_i\boldsymbol{\beta}$, the expected value of the response variable, and the probability of the response variable taking on the current value or other values that you specify. In a zero-inflated model, you can additionally request that the output data set contain the estimates of $\mathbf{z}'_i\boldsymbol{\gamma}$ and the probability that the response is zero as a result of the zero-generating process. Except for the probability of the current value, these statistics can be computed for all observations in which the regressors are not missing, even if the response is missing. By adding observations with missing response values to the input data set, you can compute these statistics for new observations or for settings of the regressors that are not present in the data without affecting the model fit.

You can specify only one OUTPUT statement. You can specify the following *output-options*:

OUT=SAS-data-set

names the output data set.

XBETA=name

names the variable that contains estimates of $\mathbf{x}'_i\boldsymbol{\beta}$.

PRED=name

names the variable that contains the predicted value of the response variable.

PROB=name

names the variable that contains the probability of the response variable taking the current value, $\Pr(Y = y_i)$.

PROBCOUNT(value1 <value2...>)

outputs the probability of the response variable taking particular values. Each value should be a nonnegative integer. Nonintegers are rounded to the nearest integer. *value* can also be a list of the form X TO Y BY Z. For example, PROBCOUNT(0 1 2 TO 10 BY 2 15) requests predicted probabilities

for counts 0, 1, 2, 4, 5, 6, 8, 10, and 15. This option is not available for the fixed and random effect panel models.

ZGAMMA=*name*

names the variable that contains estimates of $\mathbf{z}_i' \boldsymbol{\gamma}$.

PROBZERO=*name*

names the variable that contains the value of φ_i , the probability of the response variable taking on the value of zero as a result of the zero-generating process. It is written to the output file only if the model is zero-inflated. This is not the overall probability of a zero response; that is provided by the PROBCOUNT(0) option.

RESTRICT Statement

RESTRICT *restriction1* <, *restriction2* ... > ;

The RESTRICT statement imposes linear restrictions on the parameter estimates. You can specify any number of RESTRICT statements.

Each *restriction* is written as an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

expression operator expression

The *operator* can be =, <, >, <=, or >=.

Restriction expressions can be composed of parameter names, constants, and the operators times (*), plus (+), and minus (−). The restriction expressions must be a linear function of the parameters. For continuous regressors, the names of the parameters are the same as the corresponding variables. For a regressor that is a CLASS variable, the parameter name combines the corresponding CLASS variable name with the variable level. For interaction and nested regressors, the parameter names combine the names of each regressor. The names of the parameters can be seen in the OUTEST= data set.

Lagrange multipliers are reported in the “Parameter Estimates” table for all the active linear constraints. They are identified with the names Restrict1, Restrict2, and so on. The probabilities of these Lagrange multipliers are computed using a beta distribution (LaMotte 1994). Nonactive (nonbinding) restrictions have no effect on the estimation results and are not noted in the output.

The following RESTRICT statement constrains the negative binomial dispersion parameter α to 1, which restricts the conditional variance to be $\mu + \mu^2$:

```
restrict _Alpha = 1;
```

WEIGHT Statement

WEIGHT *variable* </ *option* > ;

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters. The log likelihood for each observation is multiplied by the corresponding weight variable value.

If the weight of an observation is nonpositive, that observation is not used in the estimation.

The following option can be added to the WEIGHT statement after a slash (/).

NONNORMALIZE

does not normalize the weights. By default, the weights are normalized so that they add up to the actual sample size. Weights w_i are normalized by multiplying them by $\frac{n}{\sum_{i=1}^n w_i}$, where n is the sample size. If the weights are required to be used as is, then specify the NONNORMALIZE option.

ZEROMODEL Statement

ZEROMODEL *dependent variable* ~ < zero-inflated regressors > < /options > ;

The ZEROMODEL statement is required if either ZIP or ZINB is specified in the DIST= option in the MODEL statement. If ZIP or ZINB is specified, then the ZEROMODEL statement must follow immediately after the MODEL statement. The dependent variable in the ZEROMODEL statement must be the same as the dependent variable in the MODEL statement.

The zero-inflated (ZI) regressors appear in the equation that determines the probability (φ_i) of a zero count. Each of these q variables has a parameter to be estimated in the regression. For example, let \mathbf{z}'_i be the i th observation's $1 \times (q + 1)$ vector of values of the q ZI explanatory variables (w_0 is set to 1 for the intercept term). Then φ_i is a function of $\mathbf{z}'_i \boldsymbol{\gamma}$, where $\boldsymbol{\gamma}$ is the $(q + 1) \times 1$ vector of parameters to be estimated. (The ZI intercept is γ_0 ; the coefficients for the q ZI covariates are $\gamma_1, \dots, \gamma_q$.) If this option is omitted, then only the intercept term γ_0 is estimated. The “Parameter Estimates” table in the displayed output gives the estimates for the ZI intercept and ZI explanatory variables; they are labeled with the prefix “Inf_”. For example, the ZI intercept is labeled “Inf_intercept”. If you specify Age (a variable in your data set) as a ZI explanatory variable, then the “Parameter Estimates” table labels the corresponding parameter estimate “Inf_Age”.

The following options can be specified in the ZEROMODEL statement following a slash (/):

LINK=value

specifies the distribution function used to compute probability of zeros. The following distribution functions are supported:

LOGISTIC	specifies the logistic distribution.
NORMAL	specifies the standard normal distribution.

If this option is omitted, then the default ZI link function is logistic.

OFFSET=variable

specifies a variable in the input data set to be used as a zero-inflated (ZI) offset variable. The ZI offset variable is included as a term, with coefficient restricted to 1, in the equation that determines the probability (φ_i) of a zero count. The ZI offset variable cannot be the response variable, the offset

variable (if any), or one of the explanatory variables. The name of the data set variable used as the ZI offset variable is displayed in the “Model Fit Summary” output, where it is labeled as “Inf_offset”.

Details: TCOUNTREG Procedure

Specification of Regressors

Each term in a model, called *regressor*, is a variable or combination of variables. Regressors are specified with a special notation that uses variable names and operators. There are two kinds of variables: *classification (CLASS) variables* and *continuous variables*. There are two primary operators: *crossing* and *nesting*. A third operator, the *bar operator*, is used to simplify effect specification.

In the SAS System, *classification (CLASS) variables* are declared in the **CLASS** statement. (They can also be called *categorical*, *qualitative*, *discrete*, or *nominal variables*.) Classification variables can be either *numeric* or *character*. The values of a classification variable are called *levels*. For example, the classification variable Sex has the levels “male” and “female.”

In a model, an independent variable that is not declared in the **CLASS** statement is assumed to be continuous. *Continuous variables*, which must be numeric, are used for covariates. For example, the heights and weights of subjects are continuous variables. A response variable is a *discrete count variable* and must also be numeric.

Types of Regressors

Seven different types of regressors are used in the TCOUNTREG procedure. In the following list, assume that A, B, C, D, and E are **CLASS** variables and that X1 and X2 are continuous variables:

- Regressors are specified by writing continuous variables by themselves: X1 X2.
- Polynomial regressors are specified by joining (crossing) two or more continuous variables with asterisks: X1*X1 X1*X2.
- Dummy regressors are specified by writing CLASS variables by themselves: A B C.
- Dummy interactions are specified by joining classification variables with asterisks: A*B B*C A*B*C.
- Nested regressors are specified by following a dummy variable or dummy interaction with a classification variable or list of classification variables enclosed in parentheses. The dummy variable or dummy interaction is nested within the regressor listed in parentheses: B(A) C(B*A) D*(E(C*B*A)). In this example, B(A) is read “B nested within A.”
- Continuous-by-class regressors are written by joining continuous variables and classification variables with asterisks: X1*A.

- Continuous-nesting-class regressors consist of continuous variables followed by a classification variable interaction enclosed in parentheses: $X1(A) \quad X1*X2(A*B)$.

One example of the general form of an effect that involves several variables is

$$X1*X2*A*B*C(D*E)$$

This example contains an interaction of continuous terms with classification terms that are nested within more than one classification variable. The continuous list comes first, followed by the dummy list, followed by the nesting list in parentheses. Note that asterisks can appear within the nested list but not immediately before the left parenthesis.

The **MODEL** statement and several other statements use these effects. Some examples of **MODEL** statements that use various kinds of effects are shown in the following table, where a, b, and c represent classification variables. Variables x and z are continuous.

Specification	Type of Model
<code>model y=x;</code>	Simple regression
<code>model y=x z;</code>	Multiple regression
<code>model y=x x*x;</code>	Polynomial regression
<code>model y=a;</code>	Regression with one classification variable
<code>model y=a b c;</code>	Regression with multiple classification variables
<code>model y=a b a*b;</code>	Regression with classification variables and their interactions
<code>model y=a b(a) c(b a);</code>	Regression with classification variables and their interactions
<code>model y=a x;</code>	Regression with both countibuous and classification variables
<code>model y=a x(a);</code>	Separate-slopes regression
<code>model y=a x x*a;</code>	Homogeneity-of-slopes regression

The Bar Operator

You can shorten the specification of a large factorial model by using the bar operator. For example, two ways of writing the model for a full three-way factorial model follow:

```
model Y = A B C    A*B A*C B*C    A*B*C;
```

```
model Y = A|B|C;
```

When the bar (|) is used, the right and left sides become effects, and the cross of them becomes an effect. Multiple bars are permitted. The expressions are expanded from left to right, using rules 2–4 given in Searle (1971, p. 390).

- Multiple bars are evaluated from left to right. For instance, A|B|C is evaluated as follows:

$$\begin{aligned}
 A|B|C &\rightarrow \{A|B\}|C \\
 &\rightarrow \{A\ B\ A*B\}|C \\
 &\rightarrow A\ B\ A*B\ C\ A*C\ B*C\ A*B*C
 \end{aligned}$$

- Crossed and nested groups of variables are combined. For example, $A(B)|C(D)$ generates $A*C(B\ D)$, among other terms.
- Duplicate variables are removed. For example, $A(C)|B(C)$ generates $A*B(C\ C)$, among other terms, and the extra C is removed.
- Effects are discarded if a variable occurs on both the crossed and nested parts of an effect. For instance, $A(B)|B(D\ E)$ generates $A*B(B\ D\ E)$, but this effect is eliminated immediately.

You can also specify the maximum number of variables involved in any effect that results from bar evaluation by specifying that maximum number, preceded by an @ sign, at the end of the bar effect. For example, the specification $A|B|C@2$ would result in only those effects that contain two or fewer variables: in this case, $A\ B\ A*B\ C\ A*C$ and $B*C$.

More examples of using the | and @ operators follow:

$A C(B)$	is equivalent to	$A\ C(B)\ A*C(B)$
$A(B) C(B)$	is equivalent to	$A(B)\ C(B)\ A*C(B)$
$A(B) B(D\ E)$	is equivalent to	$A(B)\ B(D\ E)$
$A B(A) C$	is equivalent to	$A\ B(A)\ C\ A*C\ B*C(A)$
$A B(A) C@2$	is equivalent to	$A\ B(A)\ C\ A*C$
$A B C D@2$	is equivalent to	$A\ B\ A*B\ C\ A*C\ B*C\ D\ A*D\ B*D\ C*D$
$A*B(C*D)$	is equivalent to	$A*B(C\ D)$

Missing Values

Any observation in the input data set with a missing value for one or more of the regressors is ignored by PROC TCOUNTREG and not used in the model fit. PROC TCOUNTREG rounds any positive noninteger count values to the nearest integer. PROC TCOUNTREG ignores any observations with a negative count, a zero or negative weight, or a frequency less than 1.

If there are observations in the input data set with missing response values but with nonmissing regressors, PROC TCOUNTREG can compute several statistics and store them in an output data set by using the OUTPUT statement. For example, you can request that the output data set contain the estimates of $\mathbf{x}'_i\boldsymbol{\beta}$, the expected value of the response variable, and the probability of the response variable taking on values that you specify. In a zero-inflated model, you can additionally request that the output data set contain the estimates of $\mathbf{z}'_i\boldsymbol{\gamma}$, and the probability that the response is zero as a result of the zero-generating process. The presence of such observations (with missing response values) does not affect the model fit.

Poisson Regression

The most widely used model for count data analysis is Poisson regression. This assumes that y_i , given the vector of covariates \mathbf{x}_i , is independently Poisson-distributed with

$$P(Y_i = y_i | \mathbf{x}_i) = \frac{e^{-\mu_i} \mu_i^{y_i}}{y_i!}, \quad y_i = 0, 1, 2, \dots$$

and the mean parameter (that is, the mean number of events per period) is given by

$$\mu_i = \exp(\mathbf{x}_i' \boldsymbol{\beta})$$

where $\boldsymbol{\beta}$ is a $(k + 1) \times 1$ parameter vector. (The intercept is β_0 ; the coefficients for the k regressors are β_1, \dots, β_k .) Taking the exponential of $\mathbf{x}_i' \boldsymbol{\beta}$ ensures that the mean parameter μ_i is nonnegative. It can be shown that the conditional mean is given by

$$E(y_i | \mathbf{x}_i) = \mu_i = \exp(\mathbf{x}_i' \boldsymbol{\beta})$$

The name *log-linear model* is also used for the Poisson regression model since the logarithm of the conditional mean is linear in the parameters:

$$\ln[E(y_i | \mathbf{x}_i)] = \ln(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta}$$

Note that the conditional variance of the count random variable is equal to the conditional mean in the Poisson regression model:

$$V(y_i | \mathbf{x}_i) = E(y_i | \mathbf{x}_i) = \mu_i$$

The equality of the conditional mean and variance of y_i is known as *equidispersion*.

The marginal effect of a regressor is given by

$$\frac{\partial E(y_i | \mathbf{x}_i)}{\partial x_{ji}} = \exp(\mathbf{x}_i' \boldsymbol{\beta}) \beta_j = E(y_i | \mathbf{x}_i) \beta_j$$

Thus, a one-unit change in the j th regressor leads to a *proportional* change in the conditional mean $E(y_i | \mathbf{x}_i)$ of β_j .

The standard estimator for the Poisson model is the maximum likelihood estimator (MLE). Since the observations are independent, the log-likelihood function is written as

$$\mathcal{L} = \sum_{i=1}^N w_i (-\mu_i + y_i \ln \mu_i - \ln y_i!) = \sum_{i=1}^N w_i (-e^{\mathbf{x}_i' \boldsymbol{\beta}} + y_i \mathbf{x}_i' \boldsymbol{\beta} - \ln y_i!)$$

where w_i is defined as follows:

- | | |
|-------|---|
| 1 | if neither the WEIGHT nor the FREQ statement is used. |
| W_i | where W_i are the nonnormalized values of the variable specified in the WEIGHT statement in which the NONNORMALIZE option is specified. |

$\frac{\sum_{i=1}^n W_i}{\sum_{i=1}^n F_i W_i}$	where W_i are the nonnormalized values of the variable specified in the WEIGHT statement.
F_i	where F_i are the values of the variable specified in the FREQ statement.
$W_i F_i$	if both the WEIGHT statement, without the NONNORMALIZE option, and the FREQ statement are specified.
$\frac{\sum_{i=1}^n F_i}{\sum_{i=1}^n F_i W_i} W_i F_i$	if both the FREQ and the WEIGHT statements are specified.

The gradient and the Hessian are, respectively,

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N w_i (y_i - \mu_i) \mathbf{x}_i = \sum_{i=1}^N w_i (y_i - e^{\mathbf{x}_i' \boldsymbol{\beta}}) \mathbf{x}_i$$

$$\frac{\partial^2 \mathcal{L}}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'} = - \sum_{i=1}^N w_i \mu_i \mathbf{x}_i \mathbf{x}_i' = - \sum_{i=1}^N w_i e^{\mathbf{x}_i' \boldsymbol{\beta}} \mathbf{x}_i \mathbf{x}_i'$$

The Poisson model has been criticized for its restrictive property that the conditional variance equals the conditional mean. Real-life data are often characterized by *overdispersion* (that is, the variance exceeds the mean). Allowing for overdispersion can improve model predictions since the Poisson restriction of equal mean and variance results in the underprediction of zeros when overdispersion exists. The most commonly used model that accounts for overdispersion is the negative binomial model.

Negative Binomial Regression

The Poisson regression model can be generalized by introducing an unobserved heterogeneity term for observation i . Thus, the individuals are assumed to differ randomly in a manner that is not fully accounted for by the observed covariates. This is formulated as

$$E(y_i | \mathbf{x}_i, \tau_i) = \mu_i \tau_i = e^{\mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i}$$

where the unobserved heterogeneity term $\tau_i = e^{\epsilon_i}$ is independent of the vector of regressors \mathbf{x}_i . Then the distribution of y_i conditional on \mathbf{x}_i and τ_i is Poisson with conditional mean and conditional variance $\mu_i \tau_i$:

$$f(y_i | \mathbf{x}_i, \tau_i) = \frac{\exp(-\mu_i \tau_i) (\mu_i \tau_i)^{y_i}}{y_i!}$$

Let $g(\tau_i)$ be the probability density function of τ_i . Then, the distribution $f(y_i | \mathbf{x}_i)$ (no longer conditional on τ_i) is obtained by integrating $f(y_i | \mathbf{x}_i, \tau_i)$ with respect to τ_i :

$$f(y_i | \mathbf{x}_i) = \int_0^\infty f(y_i | \mathbf{x}_i, \tau_i) g(\tau_i) d\tau_i$$

An analytical solution to this integral exists when τ_i is assumed to follow a gamma distribution. This solution is the negative binomial distribution. When the model contains a constant term, it is necessary to

assume that $E(e^{\epsilon_i}) = E(\tau_i) = 1$, in order to identify the mean of the distribution. Thus, it is assumed that τ_i follows a $\text{gamma}(\theta, \theta)$ distribution with $E(\tau_i) = 1$ and $V(\tau_i) = 1/\theta$,

$$g(\tau_i) = \frac{\theta^\theta}{\Gamma(\theta)} \tau_i^{\theta-1} \exp(-\theta \tau_i)$$

where $\Gamma(x) = \int_0^\infty z^{x-1} \exp(-z) dz$ is the gamma function and θ is a positive parameter. Then, the density of y_i given \mathbf{x}_i is derived as

$$\begin{aligned} f(y_i|\mathbf{x}_i) &= \int_0^\infty f(y_i|\mathbf{x}_i, \tau_i) g(\tau_i) d\tau_i \\ &= \frac{\theta^\theta \mu_i^{y_i}}{y_i! \Gamma(\theta)} \int_0^\infty e^{-(\mu_i + \theta)\tau_i} \tau_i^{\theta+y_i-1} d\tau_i \\ &= \frac{\theta^\theta \mu_i^{y_i} \Gamma(y_i + \theta)}{y_i! \Gamma(\theta) (\theta + \mu_i)^{\theta+y_i}} \\ &= \frac{\Gamma(y_i + \theta)}{y_i! \Gamma(\theta)} \left(\frac{\theta}{\theta + \mu_i} \right)^\theta \left(\frac{\mu_i}{\theta + \mu_i} \right)^{y_i} \end{aligned}$$

Making the substitution $\alpha = \frac{1}{\theta}$ ($\alpha > 0$), the negative binomial distribution can then be rewritten as

$$f(y_i|\mathbf{x}_i) = \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left(\frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \left(\frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i}, \quad y_i = 0, 1, 2, \dots$$

Thus, the negative binomial distribution is derived as a gamma mixture of Poisson random variables. It has conditional mean

$$E(y_i|\mathbf{x}_i) = \mu_i = e^{\mathbf{x}_i' \boldsymbol{\beta}}$$

and conditional variance

$$V(y_i|\mathbf{x}_i) = \mu_i \left[1 + \frac{1}{\theta} \mu_i \right] = \mu_i [1 + \alpha \mu_i] > E(y_i|\mathbf{x}_i)$$

The conditional variance of the negative binomial distribution exceeds the conditional mean. Overdispersion results from neglected unobserved heterogeneity. The negative binomial model with variance function $V(y_i|\mathbf{x}_i) = \mu_i + \alpha \mu_i^2$, which is quadratic in the mean, is referred to as the NEGBIN2 model (Cameron and Trivedi 1986). To estimate this model, specify `DIST=NEGBIN(p=2)` in the `MODEL` statement. The Poisson distribution is a special case of the negative binomial distribution where $\alpha = 0$. A test of the Poisson distribution can be carried out by testing the hypothesis that $\alpha = \frac{1}{\theta_i} = 0$. A Wald test of this hypothesis is provided (it is the reported t statistic for the estimated α in the negative binomial model).

The log-likelihood function of the negative binomial regression model (NEGBIN2) is given by

$$\begin{aligned} \mathcal{L} &= \sum_{i=1}^N w_i \left\{ \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1}) - \ln(y_i!) \right. \\ &\quad \left. - (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta})) + y_i \ln(\alpha) + y_i \mathbf{x}_i' \boldsymbol{\beta} \right\} \end{aligned}$$

$$\Gamma(y+a)/\Gamma(a) = \prod_{j=0}^{y-1} (j+a)$$

if y is an integer. See “[Poisson Regression](#)” on page 1958 for the definition of w_i .

The gradient is

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N w_i \frac{y_i - \mu_i}{1 + \alpha \mu_i} \mathbf{x}_i$$

and

$$\frac{\partial \mathcal{L}}{\partial \alpha} = \sum_{i=1}^N w_i \left\{ -\alpha^{-2} \sum_{j=0}^{y_i-1} \frac{1}{(j + \alpha^{-1})} + \alpha^{-2} \ln(1 + \alpha \mu_i) + \frac{y_i - \mu_i}{\alpha(1 + \alpha \mu_i)} \right\}$$

Cameron and Trivedi (1986) consider a general class of negative binomial models with mean μ_i and variance function $\mu_i + \alpha \mu_i^p$. The NEGBIN2 model, with $p = 2$, is the standard formulation of the negative binomial model. Models with other values of p , $-\infty < p < \infty$, have the same density $f(y_i | \mathbf{x}_i)$ except that α^{-1} is replaced everywhere by $\alpha^{-1} \mu_i^{2-p}$. The negative binomial model NEGBIN1, which sets $p = 1$, has variance function $V(y_i | \mathbf{x}_i) = \mu_i + \alpha \mu_i$, which is linear in the mean. To estimate this model, specify `DIST=NEGBIN(p=1)` in the `MODEL` statement.

The log-likelihood function of the NEGBIN1 regression model is given by

$$\begin{aligned} \mathcal{L} = & \sum_{i=1}^N w_i \left\{ \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1} \exp(\mathbf{x}_i' \boldsymbol{\beta})) \right. \\ & \left. - \ln(y_i!) - (y_i + \alpha^{-1} \exp(\mathbf{x}_i' \boldsymbol{\beta})) \ln(1 + \alpha) + y_i \ln(\alpha) \right\} \end{aligned}$$

See the section “[Poisson Regression](#)” on page 1958 for the definition of w_i .

The gradient is

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N w_i \left\{ \left(\sum_{j=0}^{y_i-1} \frac{\mu_i}{(j\alpha + \mu_i)} \right) \mathbf{x}_i - \alpha^{-1} \ln(1 + \alpha) \mu_i \mathbf{x}_i \right\}$$

and

$$\frac{\partial \mathcal{L}}{\partial \alpha} = \sum_{i=1}^N w_i \left\{ - \left(\sum_{j=0}^{y_i-1} \frac{\alpha^{-1} \mu_i}{(j\alpha + \mu_i)} \right) - \alpha^{-2} \mu_i \ln(1 + \alpha) - \frac{(y_i + \alpha^{-1} \mu_i)}{1 + \alpha} + \frac{y_i}{\alpha} \right\}$$

Zero-Inflated Count Regression Overview

The main motivation for zero-inflated count models is that real-life data frequently display overdispersion and excess zeros. Zero-inflated count models provide a way of modeling the excess zeros in addition to

allowing for overdispersion. In particular, for each observation, there are two possible data generation processes. The result of a Bernoulli trial is used to determine which of the two processes is used. For observation i , Process 1 is chosen with probability φ_i and Process 2 with probability $1 - \varphi_i$. Process 1 generates only zero counts. Process 2 generates counts from either a Poisson or a negative binomial model. In general,

$$y_i \sim \begin{cases} 0 & \text{with probability } \varphi_i \\ g(y_i) & \text{with probability } 1 - \varphi_i \end{cases}$$

Therefore, the probability of $\{Y_i = y_i\}$ can be described as

$$\begin{aligned} P(y_i = 0 | \mathbf{x}_i) &= \varphi_i + (1 - \varphi_i)g(0) \\ P(y_i | \mathbf{x}_i) &= (1 - \varphi_i)g(y_i), \quad y_i > 0 \end{aligned}$$

where $g(y_i)$ follows either the Poisson or the negative binomial distribution. You can specify the probability φ with the PROBZERO= option in the OUTPUT statement.

When the probability φ_i depends on the characteristics of observation i , φ_i is written as a function of $\mathbf{z}'_i \boldsymbol{\gamma}$, where \mathbf{z}'_i is the $1 \times (q + 1)$ vector of zero-inflation covariates and $\boldsymbol{\gamma}$ is the $(q + 1) \times 1$ vector of zero-inflation coefficients to be estimated. (The zero-inflation intercept is γ_0 ; the coefficients for the q zero-inflation covariates are $\gamma_1, \dots, \gamma_q$.) The function F that relates the product $\mathbf{z}'_i \boldsymbol{\gamma}$ (which is a scalar) to the probability φ_i is called the zero-inflation link function,

$$\varphi_i = F_i = F(\mathbf{z}'_i \boldsymbol{\gamma})$$

In the TCOUNTREG procedure, the zero-inflation covariates are indicated in the ZEROMODEL statement. Furthermore, the zero-inflation link function F can be specified as either the logistic function,

$$F(\mathbf{z}'_i \boldsymbol{\gamma}) = \Lambda(\mathbf{z}'_i \boldsymbol{\gamma}) = \frac{\exp(\mathbf{z}'_i \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}'_i \boldsymbol{\gamma})}$$

or the standard normal cumulative distribution function (also called the probit function),

$$F(\mathbf{z}'_i \boldsymbol{\gamma}) = \Phi(\mathbf{z}'_i \boldsymbol{\gamma}) = \int_0^{\mathbf{z}'_i \boldsymbol{\gamma}} \frac{1}{\sqrt{2\pi}} \exp(-u^2/2) du$$

The zero-inflation link function is indicated in the LINK option in ZEROMODEL statement. The default ZI link function is the logistic function.

Zero-Inflated Poisson Regression

In the zero-inflated Poisson (ZIP) regression model, the data generation process referred to earlier as Process 2 is

$$g(y_i) = \frac{\exp(-\mu_i) \mu_i^{y_i}}{y_i!}$$

where $\mu_i = e^{\mathbf{x}_i' \boldsymbol{\beta}}$. Thus the ZIP model is defined as

$$\begin{aligned} P(y_i = 0 | \mathbf{x}_i, \mathbf{z}_i) &= F_i + (1 - F_i) \exp(-\mu_i) \\ P(y_i | \mathbf{x}_i, \mathbf{z}_i) &= (1 - F_i) \frac{\exp(-\mu_i) \mu_i^{y_i}}{y_i!}, \quad y_i > 0 \end{aligned}$$

The conditional expectation and conditional variance of y_i are given by

$$\begin{aligned} E(y_i | \mathbf{x}_i, \mathbf{z}_i) &= \mu_i (1 - F_i) \\ V(y_i | \mathbf{x}_i, \mathbf{z}_i) &= E(y_i | \mathbf{x}_i, \mathbf{z}_i) (1 + \mu_i F_i) \end{aligned}$$

Note that the ZIP model (as well as the ZINB model) exhibits overdispersion since $V(y_i | \mathbf{x}_i, \mathbf{z}_i) > E(y_i | \mathbf{x}_i, \mathbf{z}_i)$.

In general, the log-likelihood function of the ZIP model is

$$\mathcal{L} = \sum_{i=1}^N w_i \ln [P(y_i | \mathbf{x}_i, \mathbf{z}_i)]$$

After a specific link function (either logistic or standard normal) for the probability φ_i is chosen, it is possible to write the exact expressions for the log-likelihood function and the gradient.

ZIP Model with Logistic Link Function

First, consider the ZIP model in which the probability φ_i is expressed with a logistic link function—namely,

$$\varphi_i = \frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})}$$

The log-likelihood function is

$$\begin{aligned} \mathcal{L} &= \sum_{\{i: y_i=0\}} w_i \ln [\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))] \\ &\quad + \sum_{\{i: y_i>0\}} w_i \left[y_i \mathbf{x}_i' \boldsymbol{\beta} - \exp(\mathbf{x}_i' \boldsymbol{\beta}) - \sum_{k=2}^{y_i} \ln(k) \right] \\ &\quad - \sum_{i=1}^N w_i \ln [1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})] \end{aligned}$$

See the section “[Poisson Regression](#)” on page 1958 for the definition of w_i .

The gradient for this model is given by

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \boldsymbol{\gamma}} &= \sum_{\{i: y_i=0\}} w_i \left[\frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))} \right] \mathbf{z}_i - \sum_{i=1}^N w_i \left[\frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})} \right] \mathbf{z}_i \\ \frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} &= \sum_{\{i: y_i=0\}} w_i \left[\frac{-\exp(\mathbf{x}_i' \boldsymbol{\beta}) \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))}{\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))} \right] \mathbf{x}_i + \sum_{\{i: y_i>0\}} w_i [y_i - \exp(\mathbf{x}_i' \boldsymbol{\beta})] \mathbf{x}_i \end{aligned}$$

ZIP Model with Standard Normal Link Function

Next, consider the ZIP model in which the probability φ_i is expressed with a standard normal link function: $\varphi_i = \Phi(\mathbf{z}_i' \boldsymbol{\gamma})$. The log-likelihood function is

$$\begin{aligned} \mathcal{L} &= \sum_{\{i: y_i=0\}} w_i \ln \{ \Phi(\mathbf{z}_i' \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}_i' \boldsymbol{\gamma})] \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta})) \} \\ &+ \sum_{\{i: y_i>0\}} w_i \left\{ \ln [1 - \Phi(\mathbf{z}_i' \boldsymbol{\gamma})] - \exp(\mathbf{x}_i' \boldsymbol{\beta}) + y_i \mathbf{x}_i' \boldsymbol{\beta} - \sum_{k=2}^{y_i} \ln(k) \right\} \end{aligned}$$

See the section “[Poisson Regression](#)” on page 1958 for the definition of w_i .

The gradient for this model is given by

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \boldsymbol{\gamma}} &= \sum_{\{i: y_i=0\}} w_i \frac{\varphi(\mathbf{z}_i' \boldsymbol{\gamma}) [1 - \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))]}{\Phi(\mathbf{z}_i' \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}_i' \boldsymbol{\gamma})] \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))} \mathbf{z}_i \\ &- \sum_{\{i: y_i>0\}} w_i \frac{\varphi(\mathbf{z}_i' \boldsymbol{\gamma})}{[1 - \Phi(\mathbf{z}_i' \boldsymbol{\gamma})]} \mathbf{z}_i \end{aligned}$$

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} &= \sum_{\{i: y_i=0\}} w_i \frac{-[1 - \Phi(\mathbf{z}_i' \boldsymbol{\gamma})] \exp(\mathbf{x}_i' \boldsymbol{\beta}) \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))}{\Phi(\mathbf{z}_i' \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}_i' \boldsymbol{\gamma})] \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))} \mathbf{x}_i \\ &+ \sum_{\{i: y_i>0\}} w_i [y_i - \exp(\mathbf{x}_i' \boldsymbol{\beta})] \mathbf{x}_i \end{aligned}$$

Zero-Inflated Negative Binomial Regression

The zero-inflated negative binomial (ZINB) model in PROC TCOUNTREG is based on the negative binomial model with quadratic variance function ($p=2$). The ZINB model is obtained by specifying a negative binomial distribution for the data generation process referred to earlier as Process 2:

$$g(y_i) = \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left(\frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \left(\frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i}$$

Thus the ZINB model is defined to be

$$\begin{aligned} P(y_i = 0 | \mathbf{x}_i, \mathbf{z}_i) &= F_i + (1 - F_i) (1 + \alpha \mu_i)^{-\alpha^{-1}} \\ P(y_i | \mathbf{x}_i, \mathbf{z}_i) &= (1 - F_i) \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left(\frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \\ &\times \left(\frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i}, \quad y_i > 0 \end{aligned}$$

In this case, the conditional expectation and conditional variance of y_i are

$$E(y_i | \mathbf{x}_i, \mathbf{z}_i) = \mu_i (1 - F_i)$$

$$V(y_i | \mathbf{x}_i, \mathbf{z}_i) = E(y_i | \mathbf{x}_i, \mathbf{z}_i) [1 + \mu_i (F_i + \alpha)]$$

As with the ZIP model, the ZINB model exhibits overdispersion because the conditional variance exceeds the conditional mean.

ZINB Model with Logistic Link Function

In this model, the probability φ_i is given by the logistic function—namely,

$$\varphi_i = \frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})}$$

The log-likelihood function is

$$\begin{aligned} \mathcal{L} = & \sum_{\{i: y_i=0\}} w_i \ln \left[\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + (1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta}))^{-\alpha^{-1}} \right] \\ & + \sum_{\{i: y_i>0\}} w_i \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1}) \\ & + \sum_{\{i: y_i>0\}} w_i \{ -\ln(y_i!) - (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta})) + y_i \ln(\alpha) + y_i \mathbf{x}_i' \boldsymbol{\beta} \} \\ & - \sum_{i=1}^N w_i \ln [1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})] \end{aligned}$$

See the section “[Poisson Regression](#)” on page 1958 for the definition of w_i .

The gradient for this model is given by

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \boldsymbol{\gamma}} = & \sum_{\{i: y_i=0\}} w_i \left[\frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + (1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta}))^{-\alpha^{-1}}} \right] \mathbf{z}_i \\ & - \sum_{i=1}^N w_i \left[\frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})} \right] \mathbf{z}_i \\ \\ \frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = & \sum_{\{i: y_i=0\}} w_i \left[\frac{-\exp(\mathbf{x}_i' \boldsymbol{\beta})(1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta}))^{-\alpha^{-1}-1}}{\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + (1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta}))^{-\alpha^{-1}}} \right] \mathbf{x}_i \\ & + \sum_{\{i: y_i>0\}} w_i \left[\frac{y_i - \exp(\mathbf{x}_i' \boldsymbol{\beta})}{1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta})} \right] \mathbf{x}_i \end{aligned}$$

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \alpha} = & \sum_{\{i:y_i=0\}} w_i \frac{\alpha^{-2} [(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) \ln(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) - \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})]}{\exp(\mathbf{z}'_i \boldsymbol{\gamma}) (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{(1+\alpha)/\alpha} + (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))} \\ & + \sum_{\{i:y_i>0\}} w_i \left\{ -\alpha^{-2} \sum_{j=0}^{y_i-1} \frac{1}{(j + \alpha^{-1})} + \alpha^{-2} \ln(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) + \frac{y_i - \exp(\mathbf{x}'_i \boldsymbol{\beta})}{\alpha(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))} \right\} \end{aligned}$$

ZINB Model with Standard Normal Link Function

For this model, the probability φ_i is specified with the standard normal distribution function (probit function): $\varphi_i = \Phi(\mathbf{z}'_i \boldsymbol{\gamma})$. The log-likelihood function is

$$\begin{aligned} \mathcal{L} = & \sum_{\{i:y_i=0\}} w_i \ln \left\{ \Phi(\mathbf{z}'_i \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{-\alpha^{-1}} \right\} \\ & + \sum_{\{i:y_i>0\}} w_i \ln [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] \\ & + \sum_{\{i:y_i>0\}} w_i \sum_{j=0}^{y_i-1} \{\ln(j + \alpha^{-1})\} \\ & - \sum_{\{i:y_i>0\}} w_i \ln(y_i!) \\ & - \sum_{\{i:y_i>0\}} w_i (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) \\ & + \sum_{\{i:y_i>0\}} w_i y_i \ln(\alpha) \\ & + \sum_{\{i:y_i>0\}} w_i y_i \mathbf{x}'_i \boldsymbol{\beta} \end{aligned}$$

See the section “Poisson Regression” on page 1958 for the definition of w_i .

The gradient for this model is given by

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \boldsymbol{\gamma}} = & \sum_{\{i:y_i=0\}} w_i \left[\frac{\varphi(\mathbf{z}'_i \boldsymbol{\gamma}) [1 - (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{-\alpha^{-1}}]}{\Phi(\mathbf{z}'_i \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{-\alpha^{-1}}} \right] \mathbf{z}_i \\ & - \sum_{\{i:y_i>0\}} w_i \left[\frac{\varphi(\mathbf{z}'_i \boldsymbol{\gamma})}{1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})} \right] \mathbf{z}_i \end{aligned}$$

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \sum_{\{i:y_i=0\}} w_i \frac{-[1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] \exp(\mathbf{x}'_i \boldsymbol{\beta}) (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{-(1+\alpha)/\alpha}}{\Phi(\mathbf{z}'_i \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{-\alpha^{-1}}} \mathbf{x}_i$$

$$\begin{aligned}
& + \sum_{\{i: y_i > 0\}} w_i \left[\frac{y_i - \exp(\mathbf{x}'_i \boldsymbol{\beta})}{1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})} \right] \mathbf{x}_i \\
\\
\frac{\partial \mathcal{L}}{\partial \alpha} &= \sum_{\{i: y_i = 0\}} w_i \frac{[1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] \alpha^{-2} [(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) \ln(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) - \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})]}{\Phi(\mathbf{z}'_i \boldsymbol{\gamma}) (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{(1+\alpha)/\alpha} + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))} \\
& + \sum_{\{i: y_i > 0\}} w_i \left\{ -\alpha^{-2} \sum_{j=0}^{y_i-1} \frac{1}{(j + \alpha^{-1})} + \alpha^{-2} \ln(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) + \frac{y_i - \exp(\mathbf{x}'_i \boldsymbol{\beta})}{\alpha(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))} \right\}
\end{aligned}$$

Variable Selection

Variable Selection Using an Information Criterion

This type of variable selection uses either Akaike's information criterion (AIC) or the Schwartz Bayesian criterion (SBC) and either a forward selection method or a backward elimination method.

Forward selection starts from a small subset of variables. In each step, the variable that gives the largest decrease in the value of the information criterion specified in the CRITER= option (AIC or SBC) is added. The process stops when the next candidate to be added does not reduce the value of the information criterion by more than the amount specified in the LSTOP= option in the MODEL statement.

Backward elimination starts from a larger subset of variables. In each step, one variable is dropped based on the information criterion chosen.

Variable Selection Using Penalized Likelihood

Variable selection in the linear regression context can be achieved by adding some form of penalty on the regression coefficients. One particular such form is L_1 norm penalty, which leads to LASSO:

$$\min_{\boldsymbol{\beta}} \|Y - X\boldsymbol{\beta}\|^2 + \lambda \sum_{j=1}^p |\beta_j|$$

This penalty method is becoming more popular in linear regression, because of the computational development in the recent years. However, how to generalize the penalty method for variable selection to the more general statistical models is not trivial. Some work has been done for the generalized linear models, in the sense that the likelihood depends on the data through a linear combination of the parameters and the data:

$$l(\boldsymbol{\beta}|x) = l(x^T \boldsymbol{\beta})$$

In the more general form, the likelihood as a function of the parameters can be denoted by $l(\theta) = \sum_i l_i(\theta)$, where θ is a vector that can include any parameters and $l(\cdot)$ is the likelihood for each observation. For example, in the Poisson model, $\theta = (\beta_0, \beta_1, \dots, \beta_p)$, and in the negative binomial model $\theta = (\beta_0, \beta_1, \dots, \beta_p, \alpha)$. The following discussion introduces the penalty method using the Poisson model as an example, but it applies similarly to the negative binomial model. The penalized likelihood function takes the form

$$Q(\beta) = \sum_i l_i(\beta) - n \sum_{j=1}^p p_{\lambda_j}(|\beta_j|) \quad (30.1)$$

Some desired properties for the penalty functions are *unbiasedness*, *sparsity*, and *continuity*. Unbiasedness means that the coefficients should be unbiased for significant variables. Sparsity means that the coefficients can be exactly zero when the penalty is large enough. Continuity means that the solution of the penalized problem is continuous in the data, which means that a small perturbation of the data does not change the estimation significantly.

The L_1 norm penalty function used in the calculation is specified as:

$$p_{\lambda}(|\beta|) = \lambda$$

The main challenge for this penalized likelihood method is on the computation side. The penalty function is nondifferentiable at zero, which poses a computational problem for the optimization. To get around this nondifferentiability problem, Fan and Li (2001) suggest a local quadratic approximation for the penalty function. However, it is later found that the numerical performance is not satisfactory in a few aspects. Zou and Li (2008) proposed local linear approximation (LLA) to solve the problem (30.1) numerically. The algorithm replaces the penalty function with a linear approximation around a fixed point $\beta^{(0)}$:

$$p_{\lambda}(|\beta_j|) \approx p_{\lambda}(|\beta_j^{(0)}|) + p'_{\lambda}(|\beta_j^{(0)}|) (|\beta_j| - |\beta_j^{(0)}|)$$

Then the problem can be solved iteratively. Start from $\beta^{(0)} = \hat{\beta}_M$, which denotes the usual MLE estimate. For iteration k ,

$$\beta^{(k+1)} = \arg \max_{\beta} \left\{ \sum_i l_i(\beta) - n \sum_{j=1}^p p'_{\lambda}(|\beta_j^{(k)}|) |\beta_j| \right\}$$

The algorithm stops when $\|\beta^{(k+1)} - \beta^{(k)}\|$ is small. To save computing time, you can also choose a maximum number of iterations. This number can be specified by the LLASTEPS= option.

The objective function is nondifferentiable. The optimization problem can be solved using an optimization methods with constraints, by a variable transformation

$$\beta_j = \beta_j^+ - \beta_j^-, \beta_j^+ \geq 0, \beta_j^- \geq 0 \quad (30.2)$$

For each fixed tuning parameter λ , you can solve the preceding optimization problem to obtain an estimate for β . Due to the property of the L_1 norm penalty, some of the coefficients in β can be exactly zero. The remaining question is to choose the best tuning parameter λ . You can use either of the approaches described in the following subsections.

The GCV Approach

In this approach, the generalized cross-validation criteria (GCV) is computed for each value of λ on a predetermined grid $\{\lambda_1, \dots, \lambda_L\}$; the value of λ that achieves the minimum of the GCV is the optimal tuning parameter. The maximum value λ_L can be determined by lemma 1 in Park and Hastie (2007) as follows. Suppose β_0 is free of penalty in the objective function. Let $\hat{\beta}_0$ be the MLE of β_0 by forcing the rest of the parameters to be zero. Then the maximum value of λ is

$$\begin{aligned}\lambda_L &= \arg \max_{\lambda} \left\{ \max_{\lambda} : \left| \frac{\partial l}{\partial \beta_j}(\hat{\beta}_0) \right| \leq n P'_{\lambda}(|\beta_j|), j = 1, \dots, p \right\} \\ &= \arg \max_{\lambda} \left\{ \left| \frac{1}{n} \frac{\partial l}{\partial \beta_j}(\hat{\beta}_0) \right|, j = 1, \dots, p \right\}\end{aligned}$$

You can compute the GCV by using the LASSO framework. In the last step of Newton-Raphson approximation, you have

$$\frac{1}{2} \min_{\beta} \left\| (\nabla^2 l(\beta^{(k)}))^{1/2} (\beta - \beta^{(k)}) + (\nabla^2 l(\beta^{(k)}))^{-1/2} \nabla l(\beta^{(k)}) \right\|^2 + n \sum_{j=1}^p p'_{\lambda}(|\beta_j^{(k)}|) |\beta_j|$$

The solution $\hat{\beta}$ satisfies

$$\hat{\beta} - \beta^{(k)} = -(\nabla^2 l(\beta^{(k)}) - 2W^-)^{-1} (\nabla l(\beta^{(k)}) - 2\mathbf{b})$$

where

$$\begin{aligned}W^- &= n \text{diag}(W_1^-, \dots, W_p^-) \\ W_j^- &= \begin{cases} \frac{p'_{\lambda}(|\beta_j^{(k)}|)}{|\beta_j|}, & \text{if } \beta_j \neq 0 \\ 0, & \text{if } \beta_j = 0 \end{cases} \\ \mathbf{b} &= n \text{diag}(p'_{\lambda}(|\beta_1^{(k)}|) \text{sgn}(\beta_1), \dots, p'_{\lambda}(|\beta_p^{(k)}|) \text{sgn}(\beta_p))\end{aligned}$$

Note that the intercept term has no penalty on its absolute value, and therefore the W_j^- term that corresponds to the intercept is 0. More generally, you can make any parameter (such as the α in the negative binomial model) in the likelihood function free of penalty, and you treat them the same as the intercept.

The effective number of parameters is

$$\begin{aligned}e(\lambda) &= \text{tr} \left\{ \left(\nabla^2 l(\beta^{(k)}) \right)^{1/2} \left(\nabla^2 l(\beta^{(k)}) - 2W^- \right)^{-1} \left(\nabla^2 l(\beta^{(k)}) \right)^{1/2} \right\} \\ &= \text{tr} \left\{ \left(\nabla^2 l(\beta^{(k)}) - 2W^- \right)^{-1} \nabla^2 l(\beta^{(k)}) \right\}\end{aligned}$$

and the generalized cross-validation error is

$$\text{GCV}(\lambda) = \frac{l(\hat{\beta})}{n[1 - e(\lambda)/n]^2}$$

The GCV1 Approach

Another form of GCV uses the number of nonzero coefficients as the degrees-of-freedom:

$$e_1(\lambda) = \sum_{j=0}^p \mathbf{1}_{[\beta_j \neq 0]}$$

$$\text{GCV}_1(\lambda) = \frac{l(\hat{\beta})}{n[1 - e_1(\lambda)/n]^2}$$

The standard errors follow the sandwich formula

$$\begin{aligned} \text{cov}(\hat{\beta}) &= \left\{ \nabla^2 l(\beta^{(k)}) - 2W^- \right\}^{-1} \widehat{\text{cov}} \left(\nabla l(\beta^{(k)}) - 2\mathbf{b} \right) \left\{ \nabla^2 l(\beta^{(k)}) - 2W^- \right\}^{-1} \\ &= \left\{ \nabla^2 l(\beta^{(k)}) - 2W^- \right\}^{-1} \widehat{\text{cov}} \left(\nabla l(\beta^{(k)}) \right) \left\{ \nabla^2 l(\beta^{(k)}) - 2W^- \right\}^{-1} \end{aligned}$$

It is common practice to report only the standard errors of the nonzero parameters.

Panel Data Analysis

Panel Data Poisson Regression with Fixed Effects

The count regression model for panel data can be derived from the Poisson regression model. Consider the multiplicative one-way panel data model,

$$y_{it} \sim \text{Poisson}(\mu_{it})$$

where

$$\mu_{it} = \alpha_i \lambda_{it} = \alpha_i \exp(\mathbf{x}'_{it} \boldsymbol{\beta}), \quad i = 1, \dots, N, \quad t = 1, \dots, T$$

Here, α_i are the individual effects.

In the fixed effects model, the α_i are unknown parameters. The fixed effects model can be estimated by eliminating α_i by conditioning on $\sum_t y_{it}$.

In the random effects model, the α_i are independent and identically distributed (iid) random variables, in contrast to the fixed effects model. The random effects model can then be estimated by assuming a distribution for α_i .

In the Poisson fixed effects model, conditional on λ_{it} and parameter α_i , y_{it} is iid Poisson distributed with parameter $\mu_{it} = \alpha_i \lambda_{it} = \alpha_i \exp(\mathbf{x}'_{it} \boldsymbol{\beta})$, and x_{it} does not include an intercept. Then, the conditional joint density for the outcomes within the i th panel is

$$\begin{aligned} P[y_{i1}, \dots, y_{iT_i} | \sum_{t=1}^{T_i} y_{it}] &= P[y_{i1}, \dots, y_{iT_i}, \sum_{t=1}^{T_i} y_{it}] / P[\sum_{t=1}^{T_i} y_{it}] \\ &= P[y_{i1}, \dots, y_{iT_i}] / P[\sum_{t=1}^{T_i} y_{it}] \end{aligned}$$

Since y_{it} is iid Poisson(μ_{it}), $P[y_{i1}, \dots, y_{iT_i}]$ is the product of T_i Poisson densities. Also, $(\sum_{t=1}^{T_i} y_{it})$ is Poisson($\sum_{t=1}^{T_i} \mu_{it}$). Then,

$$\begin{aligned}
 P[y_{i1}, \dots, y_{iT_i} | \sum_{t=1}^{T_i} y_{it}] &= \frac{\sum_{t=1}^{T_i} (\exp(-\mu_{it}) \mu_{it}^{y_{it}} / y_{it}!)}{\exp(-\sum_{t=1}^{T_i} \mu_{it}) (\sum_{t=1}^{T_i} \mu_{it})^{\sum_{t=1}^{T_i} y_{it}} / (\sum_{t=1}^{T_i} y_{it})!} \\
 &= \frac{\exp(-\sum_{t=1}^{T_i} \mu_{it}) (\prod_{t=1}^{T_i} \mu_{it}^{y_{it}}) (\prod_{t=1}^{T_i} y_{it}!)}{\exp(-\sum_{t=1}^{T_i} \mu_{it}) \prod_{t=1}^{T_i} (\sum_{s=1}^{T_i} \mu_{is})^{y_{it}} / (\sum_{t=1}^{T_i} y_{it})!} \\
 &= \frac{(\sum_{t=1}^{T_i} y_{it})!}{(\prod_{t=1}^{T_i} y_{it}!)} \prod_{t=1}^{T_i} \left(\frac{\mu_{it}}{\sum_{s=1}^{T_i} \mu_{is}} \right)^{y_{it}} \\
 &= \frac{(\sum_{t=1}^{T_i} y_{it})!}{(\prod_{t=1}^{T_i} y_{it}!)} \prod_{t=1}^{T_i} \left(\frac{\lambda_{it}}{\sum_{s=1}^{T_i} \lambda_{is}} \right)^{y_{it}}
 \end{aligned}$$

Thus, the conditional log-likelihood function of the fixed effects Poisson model is given by

$$\mathcal{L} = \sum_{i=1}^N \left[\ln \left(\left(\sum_{t=1}^{T_i} y_{it} \right)! \right) - \sum_{t=1}^{T_i} \ln(y_{it}!) + \sum_{t=1}^{T_i} y_{it} \ln \left(\frac{\lambda_{it}}{\sum_{s=1}^{T_i} \lambda_{is}} \right) \right]$$

The gradient is

$$\begin{aligned}
 \frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} &= \sum_{i=1}^N \sum_{t=1}^{T_i} y_{it} \mathbf{x}_{it} - \sum_{i=1}^N \sum_{t=1}^{T_i} \left[\frac{y_{it} \sum_{s=1}^{T_i} (\exp(\mathbf{x}'_{is} \boldsymbol{\beta}) \mathbf{x}_{is})}{\sum_{s=1}^{T_i} \exp(\mathbf{x}'_{is} \boldsymbol{\beta})} \right] \\
 &= \sum_{i=1}^N \sum_{t=1}^{T_i} y_{it} (\mathbf{x}_{it} - \bar{\mathbf{x}}_i)
 \end{aligned}$$

where

$$\bar{\mathbf{x}}_i = \sum_{s=1}^{T_i} \left(\frac{\exp(\mathbf{x}'_{is} \boldsymbol{\beta})}{\sum_{k=1}^{T_i} \exp(\mathbf{x}'_{ik} \boldsymbol{\beta})} \right) \mathbf{x}_{is}$$

Panel Data Poisson Regression with Random Effects

In the Poisson random effects model, conditional on λ_{it} and parameter α_i , y_{it} is iid Poisson distributed with parameter $\mu_{it} = \alpha_i \lambda_{it} = \alpha_i \exp(\mathbf{x}'_{it} \boldsymbol{\beta})$, and the individual effects, α_i , are assumed to be iid random variables. The joint density for observations in all time periods for the i th individual, $P[y_{i1}, \dots, y_{iT_i} | \lambda_{i1}, \dots, \lambda_{iT_i}]$, can be obtained after the density $g(\alpha)$ of α_i is specified.

Let

$$\alpha_i \sim \text{iid gamma}(\theta, \theta)$$

so that $E(\alpha_i) = 1$ and $V(\alpha_i) = 1/\theta$:

$$g(\alpha_i) = \frac{\theta^\theta}{\Gamma(\theta)} \alpha_i^{\theta-1} \exp(-\theta\alpha_i)$$

Let $\lambda_i = (\lambda_{i1}, \dots, \lambda_{iT_i})$. Since y_{it} is conditional on λ_{it} and parameter α_i is iid Poisson($\mu_{it} = \alpha_i \lambda_{it}$), the conditional joint probability for observations in all time periods for the i th individual, $P[y_{i1}, \dots, y_{iT_i} | \lambda_i, \alpha_i]$, is the product of T_i Poisson densities:

$$\begin{aligned} P[y_{i1}, \dots, y_{iT_i} | \lambda_i, \alpha_i] &= \prod_{t=1}^{T_i} P[y_{it} | \lambda_{it}, \alpha_i] \\ &= \prod_{t=1}^{T_i} \left[\frac{\exp(-\mu_{it}) \mu_{it}^{y_{it}}}{y_{it}!} \right] \\ &= \left[\prod_{t=1}^{T_i} \frac{e^{-\alpha_i \lambda_{it}} (\alpha_i \lambda_{it})^{y_{it}}}{y_{it}!} \right] \\ &= \left[\prod_{t=1}^{T_i} \lambda_{it}^{y_{it}} / y_{it}! \right] \left(e^{-\alpha_i \sum_t \lambda_{it}} \alpha_i^{\sum_t y_{it}} \right) \end{aligned}$$

Then, the joint density for the i th panel conditional on just the λ can be obtained by integrating out α_i :

$$\begin{aligned} P[y_{i1}, \dots, y_{iT_i} | \lambda_i] &= \int_0^\infty P[y_{i1}, \dots, y_{iT_i} | \lambda_i, \alpha_i] g(\alpha_i) d\alpha_i \\ &= \frac{\theta^\theta}{\Gamma(\theta)} \left[\prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it}}}{y_{it}!} \right] \int_0^\infty \exp(-\alpha_i \sum_t \lambda_{it}) \alpha_i^{\sum_t y_{it}} \alpha_i^{\theta-1} \exp(-\theta\alpha_i) d\alpha_i \\ &= \frac{\theta^\theta}{\Gamma(\theta)} \left[\prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it}}}{y_{it}!} \right] \int_0^\infty \exp \left[-\alpha_i \left(\theta + \sum_t \lambda_{it} \right) \right] \alpha_i^{\theta + \sum_t y_{it} - 1} d\alpha_i \\ &= \left[\prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it}}}{y_{it}!} \right] \frac{\Gamma(\theta + \sum_t y_{it})}{\Gamma(\theta)} \\ &\quad \times \left(\frac{\theta}{\theta + \sum_t \lambda_{it}} \right)^\theta \left(\theta + \sum_t \lambda_{it} \right)^{-\sum_t y_{it}} \\ &= \left[\prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it}}}{y_{it}!} \right] \frac{\Gamma(\alpha^{-1} + \sum_t y_{it})}{\Gamma(\alpha^{-1})} \\ &\quad \times \left(\frac{\alpha^{-1}}{\alpha^{-1} + \sum_t \lambda_{it}} \right)^{\alpha^{-1}} \left(\alpha^{-1} + \sum_t \lambda_{it} \right)^{-\sum_t y_{it}} \end{aligned}$$

where $\alpha (= 1/\theta)$ is the overdispersion parameter. This is the density of the Poisson random effects model with gamma-distributed random effects. For this distribution, $E(y_{it}) = \lambda_{it}$ and $V(y_{it}) = \lambda_{it} + \alpha \lambda_{it}^2$; that is, there is overdispersion.

Then the log-likelihood function is written as

$$\begin{aligned}\mathcal{L} = & \sum_{i=1}^N \left\{ \sum_{t=1}^{T_i} \ln \left(\frac{\lambda_{it}^{y_{it}}}{y_{it}!} \right) + \alpha^{-1} \ln(\alpha^{-1}) - \alpha^{-1} \ln \left(\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it} \right) \right\} + \\ & \sum_{i=1}^N \left\{ - \left(\sum_{t=1}^{T_i} y_{it} \right) \ln \left(\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it} \right) + \right. \\ & \left. \ln \left[\Gamma \left(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it} \right) \right] - \ln(\Gamma(\alpha^{-1})) \right\}\end{aligned}$$

The gradient is

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} &= \sum_{i=1}^N \left\{ \sum_{t=1}^{T_i} y_{it} \mathbf{x}_{it} - \frac{\alpha^{-1} \sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it}}{\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it}} \right\} - \\ & \sum_{i=1}^N \left\{ \left(\sum_{t=1}^{T_i} y_{it} \right) \frac{\sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it}}{\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it}} \right\} \\ \frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} &= \sum_{i=1}^N \left\{ \sum_{t=1}^{T_i} y_{it} \mathbf{x}_{it} - \frac{(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it})(\sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it})}{\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it}} \right\}\end{aligned}$$

and

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial \alpha} &= \sum_{i=1}^N \left\{ -\alpha^{-2} \left[[1 + \ln(\alpha^{-1})] - \frac{(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it})}{(\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it})} - \ln \left(\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it} \right) \right] \right\} \\ &+ \sum_{i=1}^N \left\{ -\alpha^{-2} \left[\frac{\Gamma'(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it})}{\Gamma(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it})} - \frac{\Gamma'(\alpha^{-1})}{\Gamma(\alpha^{-1})} \right] \right\}\end{aligned}$$

where $\lambda_{it} = \exp(\mathbf{x}'_{it} \boldsymbol{\beta})$, $\Gamma'(\cdot) = d\Gamma(\cdot)/d(\cdot)$ and $\Gamma'(\cdot)/\Gamma(\cdot)$ is the digamma function.

Panel Data Negative Binomial Regression with Fixed Effects

This section shows the derivation of a negative binomial model with fixed effects. Keep the assumptions of the Poisson-distributed dependent variable

$$y_{it} \sim \text{Poisson}(\mu_{it})$$

But now let the Poisson parameter be random with gamma distribution and parameters (λ_{it}, δ) ,

$$\mu_{it} \sim \Gamma(\lambda_{it}, \delta)$$

where one of the parameters is the exponentially affine function of independent variables $\lambda_{it} = \exp(\mathbf{x}_{it}'\beta)$. Use integration by parts to obtain the distribution of y_{it} ,

$$\begin{aligned} P[y_{it}] &= \int_0^\infty \frac{e^{-\mu_{it}} \mu_{it}^{y_{it}}}{y_{it}!} f(\mu_{it}) d\mu_{it} \\ &= \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)} \left(\frac{\delta}{1 + \delta}\right)^{\lambda_{it}} \left(\frac{1}{1 + \delta}\right)^{y_{it}} \end{aligned}$$

which is a negative binomial distribution with parameters (λ_{it}, δ) . Conditional joint distribution is given as

$$\begin{aligned} P[y_{i1}, \dots, y_{iT_i} | \sum_{t=1}^{T_i} y_{it}] &= \left(\prod_{t=1}^{T_i} \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)} \right) \\ &\quad \times \left(\frac{\Gamma(\sum_{t=1}^{T_i} \lambda_{it}) \Gamma(\sum_{t=1}^{T_i} y_{it} + 1)}{\Gamma(\sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})} \right). \end{aligned}$$

Hence, the conditional fixed-effects negative binomial log-likelihood is

$$\begin{aligned} \mathcal{L} &= \sum_{i=1}^N \left[\log \Gamma \left(\sum_{t=1}^{T_i} \lambda_{it} \right) + \log \Gamma \left(\sum_{t=1}^{T_i} y_{it} + 1 \right) - \log \Gamma \left(\sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it} \right) \right] \\ &\quad + \sum_{i=1}^N \sum_{t=1}^{T_i} [\log \Gamma(\lambda_{it} + y_{it}) - \log \Gamma(\lambda_{it}) - \log \Gamma(y_{it} + 1)]. \end{aligned}$$

The gradient is

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \beta} &= \sum_{i=1}^N \left[\left(\frac{\Gamma'(\sum_{t=1}^{T_i} \lambda_{it})}{\Gamma(\sum_{t=1}^{T_i} \lambda_{it})} - \frac{\Gamma'(\sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})}{\Gamma(\sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})} \right) \sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it} \right] \\ &\quad + \sum_{i=1}^N \frac{\Gamma'(\sum_{t=1}^{T_i} y_{it} + 1)}{\Gamma(\sum_{t=1}^{T_i} y_{it} + 1)} \\ &\quad + \sum_{i=1}^N \sum_{t=1}^{T_i} \left[\left(\frac{\Gamma'(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it} + y_{it})} - \frac{\Gamma'(\lambda_{it})}{\Gamma(\lambda_{it})} \right) \lambda_{it} \mathbf{x}_{it} - \frac{\Gamma'(y_{it} + 1)}{\Gamma(y_{it} + 1)} \right]. \end{aligned}$$

Panel Data Negative Binomial Regression with Random Effects

This section describes the derivation of negative binomial model with random effects. Suppose

$$y_{it} \sim \text{Poisson}(\mu_{it})$$

with the Poisson parameter distributed as gamma,

$$\mu_{it} \sim \Gamma(v_i \lambda_{it}, \delta)$$

where its parameters are also random:

$$v_i \lambda_{it} = \exp(\mathbf{x}'_{it} \beta + \eta_{it})$$

Assume that the distribution of a function of v_i is beta with parameters (a, b) :

$$\frac{v_i}{1 + v_i} \sim \text{Beta}(a, b).$$

Explicitly, the beta density with $[0, 1]$ domain is

$$f(z) = [B(a, b)]^{-1} z^{a-1} (1 - z)^{b-1}$$

where $B(a, b)$ is the beta function. Then, conditional joint distribution of dependent variables is

$$P[y_{i1}, \dots, y_{iT_i} | \mathbf{x}_{i1}, \dots, \mathbf{x}_{iT_i}, v_i] = \prod_{t=1}^{T_i} \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)} \left(\frac{1}{1 + v_i} \right)^{\lambda_{it}} \left(\frac{v_i}{1 + v_i} \right)^{y_{it}}$$

Integrating out the variable v_i yields the following conditional distribution function:

$$\begin{aligned} P[y_{i1}, \dots, y_{iT_i} | \mathbf{x}_{i1}, \dots, \mathbf{x}_{iT_i}] &= \int_0^1 \left[\prod_{t=1}^{T_i} \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)} z_i^{\lambda_{it}} (1 - z_i)^{y_{it}} \right] f(z_i) dz_i \\ &= \frac{\Gamma(a + b) \Gamma(a + \sum_{t=1}^{T_i} \lambda_{it}) \Gamma(b + \sum_{t=1}^{T_i} y_{it})}{\Gamma(a) \Gamma(b) \Gamma(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})} \\ &\quad \times \prod_{t=1}^{T_i} \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)}. \end{aligned}$$

Consequently, the conditional log-likelihood function for a negative binomial model with random effects is

$$\begin{aligned} \mathcal{L} &= \sum_{i=1}^N \left[\log \Gamma(a + b) + \log \Gamma\left(a + \sum_{t=1}^{T_i} \lambda_{it}\right) + \log \Gamma\left(b + \sum_{t=1}^{T_i} y_{it}\right) \right] \\ &\quad - \sum_{i=1}^N \left[\log \Gamma(a) + \log \Gamma(b) + \log \Gamma\left(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it}\right) \right] \\ &\quad + \sum_{i=1}^N \sum_{t=1}^{T_i} [\log \Gamma(\lambda_{it} + y_{it}) - \log \Gamma(\lambda_{it}) - \log \Gamma(y_{it} + 1)]. \end{aligned}$$

The gradient is

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \beta} = & \sum_{i=1}^N \left[\frac{\Gamma' \left(a + \sum_{t=1}^{T_i} \lambda_{it} \right)}{\Gamma \left(a + \sum_{t=1}^{T_i} \lambda_{it} \right)} \sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it} + \frac{\Gamma' \left(b + \sum_{t=1}^{T_i} y_{it} \right)}{\Gamma \left(b + \sum_{t=1}^{T_i} y_{it} \right)} \right] \\ & - \sum_{i=1}^N \left[\frac{\Gamma' \left(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it} \right)}{\Gamma \left(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it} \right)} \sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it} \right] \\ & + \sum_{i=1}^N \sum_{t=1}^{T_i} \left[\left(\frac{\Gamma' (\lambda_{it} + y_{it})}{\Gamma (\lambda_{it} + y_{it})} - \frac{\Gamma' (\lambda_{it})}{\Gamma (\lambda_{it})} \right) \lambda_{it} \mathbf{x}_{it} - \frac{\Gamma' (y_{it} + 1)}{\Gamma (y_{it} + 1)} \right], \end{aligned}$$

and

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial a} = & \sum_{i=1}^N \left[\frac{\Gamma' (a + b)}{\Gamma (a + b)} + \frac{\Gamma' \left(a + \sum_{t=1}^{T_i} \lambda_{it} \right)}{\Gamma \left(a + \sum_{t=1}^{T_i} \lambda_{it} \right)} \right] \\ & - \sum_{i=1}^N \left[\frac{\Gamma' (a)}{\Gamma (a)} + \frac{\Gamma' \left(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it} \right)}{\Gamma \left(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it} \right)} \right], \end{aligned}$$

and

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial b} = & \sum_{i=1}^N \left[\frac{\Gamma' (a + b)}{\Gamma (a + b)} + \frac{\Gamma' \left(b + \sum_{t=1}^{T_i} y_{it} \right)}{\Gamma \left(b + \sum_{t=1}^{T_i} y_{it} \right)} \right] \\ & - \sum_{i=1}^N \left[\frac{\Gamma' (b)}{\Gamma (b)} + \frac{\Gamma' \left(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it} \right)}{\Gamma \left(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it} \right)} \right]. \end{aligned}$$

Computational Resources

The time and memory required by PROC TCOUNTREG are proportional to the number of parameters in the model and the number of observations in the data set being analyzed. Less time and memory are required for smaller models and fewer observations. Also affecting these resources are the method chosen to calculate the variance-covariance matrix and the optimization method. All optimization methods available through the METHOD= option have similar memory use requirements.

The processing time might differ for each method depending on the number of iterations and functional calls needed. The data set is read into memory to save processing time. If not enough memory is available to hold the data, the TCOUNTREG procedure stores the data in a utility file on disk and rereads the data as needed from this file. When this occurs, the execution time of the procedure increases substantially. The gradient and the variance-covariance matrix must be held in memory. If the model has p parameters including the intercept, then at least $8 * (p + p * (p + 1)/2)$ bytes are needed. If the quasi-maximum likelihood method

is used to estimate the variance-covariance matrix (COVEST=QML), an additional $8 * p * (p + 1)/2$ bytes of memory are needed.

Time is also a function of the number of iterations needed to converge to a solution for the model parameters. The number of iterations needed cannot be known in advance. The MAXITER= option can be used to limit the number of iterations that PROC TCOUNTREG does. The convergence criteria can be altered by nonlinear optimization options available in the PROC TCOUNTREG statement. For a list of all the nonlinear optimization options, see Chapter 6, “Nonlinear Optimization Methods.”

Nonlinear Optimization Options

PROC TCOUNTREG uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. In the PROC TCOUNTREG statement, you can specify nonlinear optimization options that are then passed to the NLO subsystem. For a list of all the nonlinear optimization options, see Chapter 6, “Nonlinear Optimization Methods.”

Covariance Matrix Types

The TCOUNTREG procedure enables you to specify the estimation method for the covariance matrix. The COVEST=HESSIAN option estimates the covariance matrix based on the inverse of the Hessian matrix, COVEST=OP uses the outer product of gradients, and COVEST=QML produces the covariance matrix based on both the Hessian and outer product matrices. The default is COVEST=HESSIAN.

While all three methods produce asymptotically equivalent results, they differ in computational intensity and produce results that might differ in finite samples. The COVEST=OP option provides the covariance matrix that is typically the easiest to compute. In some cases, the OP approximation is considered more efficient than the Hessian or QML approximations because it contains fewer random elements. The QML approximation is computationally the most complex because both the outer product of gradients and the Hessian matrix are required. In most cases, OP or Hessian approximations are preferred to QML. The need to use QML approximation arises in some cases when the model is misspecified and the information matrix equality does not hold.

Displayed Output

PROC TCOUNTREG produces the following displayed output.

Iteration History for Parameter Estimates

If you specify the ITPRINT or PRINTALL options in the PROC TCOUNTREG statement, PROC TCOUNTREG displays a table that contains the following information for each iteration. Some information is

specific to the model-fitting procedure chosen (for example, Newton-Raphson, trust region, quasi-Newton).

- iteration number
- number of restarts since the fitting began
- number of function calls
- number of active constraints at the current solution
- value of the objective function (-1 times the log-likelihood value) at the current solution
- change in the objective function from previous iteration
- value of the maximum absolute gradient element
- step size (for Newton-Raphson and quasi-Newton methods)
- slope of the current search direction (for Newton-Raphson and quasi-Newton methods)
- lambda (for trust region method)
- radius value at current iteration (for trust region method)

Model Fit Summary

The “Model Fit Summary” table contains the following information:

- dependent (count) variable name
- number of observations used
- number of missing values in data set, if any
- data set name
- type of model that was fit
- offset variable name, if any
- zero-inflated link function, if any
- zero-inflated offset variable name, if any
- log-likelihood value at solution
- maximum absolute gradient at solution
- number of iterations
- AIC value at solution (a smaller value indicates better fit)
- SBC value at solution (a smaller value indicates better fit)

Under the “Model Fit Summary” is a statement about whether the algorithm successfully converged.

Parameter Estimates

The “Parameter Estimates” table gives the estimates of the model parameters. In zero-inflated (ZI) models, estimates are also given for the ZI intercept and ZI regressor parameters labeled with the prefix “Inf_”. For example, the ZI intercept is labeled “Inf_intercept”. If you specify “Age” as a ZI regressor, then the “Parameter Estimates” table labels the corresponding parameter estimate “Inf_Age”. If you do not list any ZI regressors, then only the ZI intercept term is estimated.

“_Alpha” is the negative binomial dispersion parameter. The t statistic given for “_Alpha” is a test of overdispersion.

Last Evaluation of the Gradient

If you specify the model option ITPRINT, the TCOUNTREG procedure displays the last evaluation of the gradient vector.

Covariance of Parameter Estimates

If you specify the COVB option in the MODEL statement or in the PROC TCOUNTREG statement, the TCOUNTREG procedure displays the estimated covariance matrix, defined as the inverse of the information matrix at the final iteration.

Correlation of Parameter Estimates

If you specify the CORRB option in the MODEL statement or in the PROC TCOUNTREG statement, PROC TCOUNTREG displays the estimated correlation matrix. It is based on the Hessian matrix used at the final iteration.

OUTPUT OUT= Data Set

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimates of $\mathbf{x}_i' \boldsymbol{\beta}$, the expected value of the response variable, and the probability of the response variable taking on the current value or other values that you specify. In a zero-inflated model, you can also request that the output data set contain the estimates of $\mathbf{z}_i' \boldsymbol{\gamma}$, and the probability that the response is zero as a result of the zero-generating process.

Except for the probability of the current value, these statistics can be computed for all observations in which the regressors are not missing, even if the response is missing. By adding observations with missing response values to the input data set, you can compute these statistics for new observations or for settings of the regressors that are not present in the data without affecting the model fit.

OUTEST= Data Set

The OUTEST= data set has two rows: the first row (with `_TYPE_='PARM'`) contains each of the parameter estimates in the model, and the second row (with `_TYPE_='STD'`) contains the standard errors for the parameter estimates in the model.

If you use the COVOUT option in the PROC TCOUNTREG statement, the OUTEST= data set also contains the covariance matrix for the parameter estimates. The covariance matrix appears in the observations with `_TYPE_='COV'`, and the `_NAME_` variable labels the rows with the parameter names.

The names of the parameters are used as variable names. These are the same names as used in the INIT, BOUNDS, and RESTRICT statements.

ODS Table Names

PROC TCOUNTREG assigns a name to each table it creates. You can use these names to denote the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 30.2.

Table 30.2 ODS Tables Produced in PROC TCOUNTREG

ODS Table Name	Description	Option
ODS Tables Created by the MODEL Statement		
ClassLevels	Class levels	Default
FitSummary	Summary of nonlinear estimation	Default
ConvergenceStatus	Convergence status	Default

Examples: TCOUNTREG Procedure

Example 30.1: Basic Models

Data Description and Objective

The data set docvisit contains information for approximately 5,000 Australian individuals about the number and possible determinants of doctor visits that were made during a two-week interval. This data set contains a subset of variables taken from the Racd3 data set used by Cameron and Trivedi (1998). The docvisit data set can be found in the SAS/ETS Sample Library.

The variable doctorco represents doctor visits. Additional variables in the data set that you want to evaluate as determinants of doctor visits include sex (coded 0=male, 1=female), age (age in years divided by 100), illness (number of illnesses during the two-week interval, with five or more coded as five), income (annual income in Australian dollars divided by 1,000), and hscore (a general health questionnaire score, where a high score indicates bad health). Summary statistics for these variables are computed in the following statements and presented in [Output 30.1.1](#).

```
proc means data=docvisit;
  var doctorco sex age illness income hscore;
run;
```

Output 30.1.1 Summary Statistics

The MEANS Procedure					
Variable	N	Mean	Std Dev	Minimum	Maximum
doctorco	5190	0.3017341	0.7981338	0	9.0000000
sex	5190	0.5206166	0.4996229	0	1.0000000

Poisson Model

The following statements fit a Poisson model to the data by using the covariates SEX, ILLNESS, INCOME, and HSCORE:

```
proc tcountreg data=docvisit;
  model doctorco=sex illness income hscore / dist=poisson printall;
run;
```

In this example, the DIST= option in the MODEL statement specifies the POISSON distribution. In addition, the PRINTALL option displays the correlation and covariance matrices for the parameters, log-likelihood values, and convergence information in addition to the parameter estimates. The parameter estimates for this model are shown in [Output 30.1.2](#).

Output 30.1.2 Parameter Estimates of Poisson Model

The TCOUNTREG Procedure					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	-1.855552	0.074545	-24.89	<.0001
sex	1	0.235583	0.054362	4.33	<.0001
illness	1	0.270326	0.017080	15.83	<.0001
income	1	-0.242095	0.077829	-3.11	0.0019
hscore	1	0.096313	0.009089	10.60	<.0001

Using the CLASS statement

If some regressors are categorical in nature (meaning that these variables can take only a few discrete qualitative values), specify them in the CLASS statement. In this example, SEX is categorical because it takes only two values. A class variable can be numeric or character.

Consider the following extension:

```
proc tcountreg data=docvisit;
  class sex;
  model doctorco=sex illness income hscore / dist=poisson;
run;
```

The partial output is given in [Output 30.1.3](#).

Output 30.1.3 Parameter Estimates of Poisson Model with CLASS statement

The TCOUNTREG Procedure					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	-1.619969	0.063985	-25.32	<.0001
sex 0	1	-0.235583	0.054362	-4.33	<.0001
sex 1	0	0	.	.	.
illness	1	0.270326	0.017080	15.83	<.0001
income	1	-0.242095	0.077829	-3.11	0.0019
hscore	1	0.096313	0.009089	10.60	<.0001

If the CLASS statement is present, the TCOUNTREG procedure creates as many indicator or dummy variables as there are categories in a class variable and uses them as independent variables. In order to avoid collinearity with the intercept, the last-created dummy variable is assigned a zero coefficient by default. This means that only the dummy variable that is associated with the first level of sex (male=0) is used as a regressor. Consequently, the estimated coefficient for this dummy variable is the negative of the one for the original SEX variable in [Output 30.1.2](#) because the reference level has switched from male to female.

Now consider a more practical task. The previous example implicitly assumed that each additional illness during the two-week interval has the same effect. In other words, this variable was thought of as a continuous variable. But this variable has only six values, and it is quite possible that the number of illnesses has a nonlinear effect on doctor visits. In order to check this conjecture, the following statements specify ILLNESS in the CLASS statement so that it is represented in the model by a set of six dummy variables that can account for any type of nonlinearity:

```
proc tcountreg data=docvisit;
  class sex illness;
  model doctorco=sex illness income hscore / dist=poisson;
run;
```

The parameter estimates are displayed in [Output 30.1.4](#).

Output 30.1.4 Parameter Estimates of Poisson Model with CLASS statement

The TCOUNTREG Procedure					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	-0.385930	0.088062	-4.38	<.0001
sex 0	1	-0.219118	0.054190	-4.04	<.0001
sex 1	0	0	.	.	.
illness 0	1	-1.934983	0.121267	-15.96	<.0001
illness 1	1	-0.698307	0.089732	-7.78	<.0001
illness 2	1	-0.471100	0.090742	-5.19	<.0001
illness 3	1	-0.488481	0.099127	-4.93	<.0001
illness 4	1	-0.272372	0.107593	-2.53	0.0114
illness 5	0	0	.	.	.
income	1	-0.253583	0.077441	-3.27	0.0011
hscore	1	0.094590	0.009025	10.48	<.0001

Each ILLNESS parameter in this model represents the difference between each effect of ILLNESS and ILLNESS=5. Note that these estimates for different ILLNESS categories do not increase linearly, but instead show a relatively large jump from zero illnesses to one followed by relatively smaller increases.

Zero-Inflated Poisson model

Suppose that you suspect that the population of individuals can be viewed as two distinct groups: a low-risk group, consisting of individuals who never go to the doctor, and a high-risk group, consisting of individuals who do go to the doctor. You might suspect that the data have this structure both because the sample variance

of DOCTORCO (0.64) exceeds its sample mean (0.30), which suggests overdispersion, and also because a large fraction of the DOCTORCO observations (80%) have the value zero. Estimating a zero-inflated model is one way to deal with overdispersion that results from excess zeros.

Suppose also that you suspect that the covariate AGE has an impact on whether an individual belongs to the low-risk group. For example, younger individuals might have illnesses of much lower severity when they do get sick and be less likely to visit a doctor, all else being equal. The following statements estimate a zero-inflated Poisson regression with AGE as a covariate in the zero-generation process:

```
proc tcountreg data=docvisit;
  model doctorco=sex illness income hscore / dist=zip;
  zeromodel doctorco ~ age;
run;
```

In this case, the ZEROMODEL statement that follows the MODEL statement specifies that both an intercept and the variable AGE be used to estimate the likelihood of zero doctor visits. [Output 30.1.5](#) shows the resulting parameter estimates.

Output 30.1.5 Parameter Estimates for ZIP Model

The TCOUNTREG Procedure					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	-1.033387	0.096973	-10.66	<.0001
sex	1	0.122511	0.062566	1.96	0.0502
illness	1	0.237478	0.019997	11.88	<.0001
income	1	-0.143945	0.087810	-1.64	0.1012
hscore	1	0.088386	0.010043	8.80	<.0001
Inf_Intercept	1	0.986557	0.131339	7.51	<.0001
Inf_age	1	-2.090923	0.270580	-7.73	<.0001

The estimates of the zero-inflated intercept (Inf_Intercept) and the zero-inflated regression coefficient for AGE (Inf_age) are approximately 0.99 and -2.09, respectively. Since the zero-inflation model uses a logistic link by default, you can estimate the probabilities for individuals of ages 20, 50, and 70 as follows:

$$\begin{aligned}
 \text{20 years: } & \frac{e^{(0.99-2.09*.20)}}{1 + e^{(0.99-2.09*.20)}} = 0.64 \\
 \text{50 years: } & \frac{e^{(0.99-2.09*.50)}}{1 + e^{(0.99-2.09*.50)}} = 0.49 \\
 \text{70 years: } & \frac{e^{(0.99-2.09*.70)}}{1 + e^{(0.99-2.09*.70)}} = 0.38
 \end{aligned}$$

That is, the estimated probability of belonging to the low-risk group is about 0.64 for a 20-year-old individual, 0.49 for a 50-year-old individual, and only 0.38 for a 70-year-old individual. This supports the suspicion that older individuals are more likely to have a positive number of doctor visits.

Alternative models to account for the overdispersion are the negative binomial and the zero-inflated negative binomial models, which can be fit using the DIST=NEGBIN and DIST=ZINB options, respectively.

Example 30.2: ZIP and ZINB Models for Data Exhibiting Extra Zeros

In the study by Long (1997) of the number of published articles by scientists (see the section “Getting Started: TCOUNTREG Procedure” on page 1941), the observed proportion of scientists who publish no articles is 0.3005. The following statements use PROC FREQ to compute the proportion of scientists who publish each observed number of articles. [Output 30.2.1](#) shows the results.

```
proc freq data=long97data;
  table art / out=obs;
run;
```

Output 30.2.1 Proportion of Scientists Who Publish a Certain Number of Articles

The FREQ Procedure				
art	Frequency	Percent	Cumulative Frequency	Cumulative Percent
0	275	30.05	275	30.05
1	246	26.89	521	56.94
2	178	19.45	699	76.39
3	84	9.18	783	85.57
4	67	7.32	850	92.90
5	27	2.95	877	95.85
6	17	1.86	894	97.70
7	12	1.31	906	99.02
8	1	0.11	907	99.13
9	2	0.22	909	99.34
10	1	0.11	910	99.45
11	1	0.11	911	99.56
12	2	0.22	913	99.78
16	1	0.11	914	99.89
19	1	0.11	915	100.00

PROC TCOUNTREG is then used to fit Poisson and negative binomial models to the data. For each model, the PROBCOUNT option computes the probability that the number of published articles is m , for $m = 0$ to 10. The following statements compute the estimates for Poisson and negative binomial models. The MEAN procedure is then used to compute the average probability of a zero response.

```
proc tcountreg data=long97data;
  model art=fem mar kid5 phd ment / dist=poisson;
  output out=predpoi probcount(0 to 10);
run;

proc means mean data=predpoi;
  var p_0;
run;
```

The output from the Poisson model for the TCOUNTREG and MEAN procedures is shown in [Output 30.2.2](#).

For each model, the predicted proportion of zero articles can be calculated as the average predicted probability of zero articles across all scientists. Under the Poisson model, the predicted proportion of zero articles is 0.2092, which considerably underestimates the observed proportion. The negative binomial more closely estimates the proportion of zeros (0.3036). Also, the test of the dispersion parameter, $_Alpha$, in the negative binomial model indicates significant overdispersion ($p < 0.0001$). As a result, the negative binomial model is preferred to the Poisson model.

Another way to account for the large number of zeros in this data set is to fit a zero-inflated Poisson (ZIP) or a zero-inflated negative binomial (ZINB) model. In the following statements, `DIST=ZIP` requests the ZIP model. In the `ZEROMODEL` statement, you can specify the predictors, \mathbf{z} , for the process that generated the additional zeros. The `ZEROMODEL` statement also specifies the model for the probability φ . By default,

a logistic model is used for φ . The default can be changed using the LINK= option. In this particular ZIP model, all variables used to model the article counts are also used to model φ .

```
proc tcountreg data=long97data;
  model art = fem mar kid5 phd ment / dist=zip;
  zeromodel art ~ fem mar kid5 phd ment;
  output out=predzip probcount(0 to 10);
run;

proc means data=predzip mean;
  var p_0;
run;
```

The parameters of the ZIP model are displayed in [Output 30.2.4](#). The first set of parameters gives the estimates of β in the model for the Poisson process mean. Parameters with the prefix “Inf_” are the estimates of γ in the logistic model for φ .

	0.2985679
-----	-----

The proportion of zeros predicted by the ZIP model is 0.2986, which is much closer to the observed proportion than the Poisson model. But [Output 30.2.6](#) shows that both models deviate from the observed proportions at one, two, and three articles.

The ZINB model is specified by the DIST=ZINB option. All variables are again used to model both the number of articles and φ . The METHOD=QN option specifies that the quasi-Newton method be used to fit the model rather than the default Newton-Raphson method. These options are implemented in the following statements:

```
proc tcountreg data=long97data;
  model art=fem mar kid5 phd ment / dist=zinb method=qn;
  zeromodel art ~ fem mar kid5 phd ment;
  output out=predzinb probcount(0 to 10);
run;

proc means data=predzinb mean;
  var p_0;
run;
```

The estimated parameters of the ZINB model are shown in [Output 30.2.5](#). The test for overdispersion again indicates a preference for the negative binomial version of the zero-inflated model ($p < 0.0001$). The ZINB model also does a good job of estimating the proportion of zeros (0.3119), and it follows the observed proportions well, though possibly not as well as the negative binomial model.

    xaxis label='Number of Articles';
    series y=obs x=art / name='obs' legendlabel='Observed'
        lineattrs=(color=black thickness=4px);
    series y=col1 x=art / name='poi' legendlabel='Poisson'
        lineattrs=(color=blue);
    series y=col2 x=art / name='nb' legendlabel='Negative Binomial'
        lineattrs=(color=red);
    series y=col3 x=art / name='zip' legendlabel='ZIP'
        lineattrs=(color=blue pattern=2);
    series y=col4 x=art / name='zinb' legendlabel='ZINB'
        lineattrs=(color=red pattern=2);
    discretelegend 'poi' 'zip' 'nb' 'zinb' 'obs' / title='Models:'
        location=inside position=ne across=2 down=3;
run;

```

For each of the four fitted models, [Output 30.2.6](#) shows the average predicted count probability for each article count across all scientists. The Poisson model clearly underestimates the proportion of zero articles published, while the other three models are quite accurate at zero. All of the models do well at the larger numbers of articles.

Output 30.2.6 Average Predicted Count Probability

Example 30.3: Variable Selection

This example demonstrates two algorithms of automatic variable selection in the TCOUNTREG procedure. This method is most effective when the number of possible candidates for explaining the variation of some variable is large. For clarity of exposition, this example uses only a small number of variables. The data set ARTICLE published by Long (1997) contains six variables. This data set was already used in “[Example 30.2: ZIP and ZINB Models for Data Exhibiting Extra Zeros](#)” on page 1985. The dependent variable called art records the number of articles published by a graduate student in the last three years of their program. Explanatory factors include sex of a student (fem), his or her marital status (mar), number of children (kid5), prestige of the program (phd), and publishing activity of the academic adviser (ment). All these variables intuitively suggest their affect on students’ primary academic output.

First, for comparison purposes, estimate the simple Poisson model. The choice of model is specified by DIST= option in the MODEL statement.

```
proc tcountreg data = long97data;
  model art = fem mar kid5 phd ment / dist = poisson;
```

```
run;
```

The output of these statements is shown in [Figure 30.3.1](#).

Output 30.3.1 Poisson Model for the Number of Published Articles

ment	1	0.025543	0.002006	12.73	<.0001

Note that the Newton-Raphson optimization algorithm took five steps to converge. All parameters, except for one, are significant at a 1% or 5% level, while phd is not significant even at the 10% level.

In this case, it might be easy to identify variables with limited explanatory power. However, if the number of variables were large, the manual selection could be time demanding and inaccurate. For a large number of variables, you would be better off by applying one of the automatic algorithms of variable selection. The following statements use the penalized likelihood method, which is indicated by `SELECT=PEN` option in the `MODEL` statement:

```
proc tcountreg data = long97data method = qn;
  model art = fem mar kid5 phd ment / dist = poisson
                    select = PEN;
run;
```

The output of these statements is shown in [Output 30.3.2](#).

Output 30.3.2 Poisson Model for the Number of Published Articles with Penalized Likelihood Method

The TCOUNTREG Procedure					
Model Fit Summary					
Dependent Variable					art
Number of Observations					915
Data Set				WORK.LONG97DATA	
Model				Poisson	
Log Likelihood				-1651	
Maximum Absolute Gradient				4.20414E-6	
Number of Iterations				7	
Optimization Method				Quasi-Newton	
AIC				3312	
SBC				3336	
Algorithm converged.					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.345174	0.060125	5.74	<.0001
fem	1	-0.225303	0.054615	-4.13	<.0001
mar	1	0.152175	0.061067	2.49	0.0127
kid5	1	-0.184993	0.040139	-4.61	<.0001
ment	1	0.025761	0.001950	13.21	<.0001

The “Parameter Estimates” table shows that the variable *phd* was dropped from the model.

The next statements use the information criterion by specifying the SELECT=INFO option. The direction of search is chosen to be FORWARD, and the information criterion is AIC. In order to achieve the same selection of variables as for the penalized likelihood method, 0.001 is specified for the percentage of decrease in the information criterion necessary for the algorithm to stop.

```
proc tcountreg data = long97data;
  model art = fem mar kid5 phd ment / dist      = poisson
                                select      = INFO
                                ( direction = forward
                                criter      = AIC
                                lstop      = 0.001 );
run;
```

The output of these statements is shown in [Figure 30.3.3](#).

Output 30.3.3 Poisson Model for the Number of Published Articles with Search Method Using Information Criterion

The TCOUNTREG Procedure					
Stepwise Selection Information					
Step	Effect Entered	Effect Removed	AIC	SBC	
0	Intercept		3487.146950	3491.965874	
1	ment		3341.286487	3350.924335	
2	fem		3330.744604	3345.201376	
3	kid5		3316.593036	3335.868733	
4	mar		3312.348824	3336.443445	
Model Fit Summary					
Dependent Variable			art		
Number of Observations			915		
Data Set			WORK.LONG97DATA		
Model			Poisson		
Log Likelihood			-1651		
Maximum Absolute Gradient			8.13749E-8		
Number of Iterations			0		
Optimization Method			Newton-Raphson		
AIC			3312		
SBC			3336		
Algorithm converged.					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.345174	0.060125	5.74	<.0001
fem	1	-0.225303	0.054615	-4.13	<.0001
mar	1	0.152175	0.061067	2.49	0.0127
kid5	1	-0.184993	0.040139	-4.61	<.0001
ment	1	0.025761	0.001950	13.21	<.0001

From the output, it is clear that the same set of variables was chosen as the result of information criterion algorithm. Note that the forward optimization algorithm starts with the constant as the only explanatory variable.

Examples: TIMEID Procedure	2010
Example 31.1: Examining a Weekly Time ID Variable	2010
Example 31.2: Inferring a Date Interval	2018
Example 31.3: Examining Multiple BY Groups	2019

Overview: TIMEID Procedure

The TIMEID procedure evaluates a variable in an input data set for its suitability as a time ID variable in SAS procedures and solutions that are used for time series analysis. PROC TIMEID assesses how well a time interval specification fits SAS date or datetime values, or observation numbers used to index a time series. The time interval used in this analysis can be either specified explicitly as input to PROC TIMEID or inferred by the procedure based on values of the time ID variable. The TIMEID procedure produces diagnostic information in the form of data sets and ODS tabular and plotted output. These diagnostic results summarize characteristics of the time ID variable that can help determine its use as an index in other time series procedures and solutions.

PROC TIMEID is intended for use as a tool to either identify the time interval of a variable or prepare problematic data sets for use in subsequent time series analyses. In particular, this procedure can be used to

investigate inconsistencies between time ID values and the ID statement options used in other SAS procedures and solutions.

Getting Started: TIMEID Procedure

When a data set contains a time ID variable with corrupted, missing, or duplicate values, PROC TIMEID can help isolate and identify these problematic observations. For a data set with a small number of ID variable anomalies and a known time interval, a graphical depiction of the problem areas can be created using the following statements:

```
proc timeid data=<input-dataset> plot=values;
  id <time-ID-variable> interval=<frequency>;
run;
```

For larger data sets whose quality is unknown, it can be useful to get a general overview of the relative number of observations with problematic time ID values. The following statements graphically summarize the prevalence of anomalous time ID values:

```
proc timeid data=<input-dataset> plot=(intervalcounts offsets spans);
  id <time-ID-variable> interval=<frequency>;
run;
```

When prior knowledge of the time interval that separates observations is incomplete, PROC TIMEID can be used to infer the interval by omitting the INTERVAL= option from the ID statement as in the following statements:

```
proc timeid data=<input-dataset> outinterval=<output-dataset>;
  id <time-ID-variable>;
run;
```

Syntax: TIMEID Procedure

The TIMEID procedure uses the following statements:

```
PROC TIMEID options ;
  BY variables ;
  ID variable <options> ;
```

Functional Summary

The statements and options that control the TIMEID procedure are summarized in Table 31.1.

Table 31.1 Syntax Summary

Description	Statement	Option
Statements		
Specifies data sets and options	PROC TIMEID	
Specifies BY-group processing	BY	
Specifies the time ID variable	ID	
Data Set Options		
Specifies the input data set	PROC TIMEID	DATA=
Specifies the maximum number of ID values to analyze	PROC TIMEID	NBYOBS=
Specifies the output frequency count data set	PROC TIMEID	OUTFREQ=
Specifies the output interval data set	PROC TIMEID	OUTINTERVAL=
Specifies the detailed output interval data set	PROC TIMEID	OUTINTERVALDETAILS=
Time ID Options		
Specifies the interval alignment	ID	ALIGN=
Specifies that duplicate time ID values can be present in DATA= data set	ID	DUPLICATES
Specifies the time interval between observations	ID	INTERVAL=
Specifies that time ID variable values are not sorted	ID	NOTSORTED
Printing and Plotting Options		
Specifies the time ID format	ID	FORMAT=
Specifies the types of graphical output	PROC TIMEID	PLOT=
Specifies the types of printed output	PROC TIMEID	PRINT=
Miscellaneous Options		
Limits error and warning messages	PROC TIMEID	MAXERROR=

PROC TIMEID Statement

PROC TIMEID *options* ;

The following options can be used in the PROC TIMEID statement:

DATA=SAS-data-set

names the SAS data set that contains the input data for the procedure. If the DATA= option is not specified, the most recently created SAS data set is used.

MAXERROR=number

limits the number of warning and error messages produced during the execution of the procedure to the specified value. The default is MAXERRORS=50. This option is particularly useful in BY-group processing where it can be used to suppress recurring messages.

NBYOBS=number

limits the number of observations that are used to analyze the time ID variable. The NBYOBS= option should be used instead of the OBS= data set option when BY variables are specified. The NBYOBS= option excludes observations from incomplete BY groups in the analysis. This option guarantees that any truncation of the DATA= data set occurs at a BY-group boundary. Only BY groups that are completely contained within the first *number* of observations are processed. When the NBYOBS= option is omitted, all observations are processed.

OUTFREQ=SAS-data-set

names the output data set to contain the frequency counts of each unique value of the time ID variable. The frequency counts are performed on time ID values that are recorded in the DATA= data set. The time ID values are not aligned with respect to an interval prior to computation of the frequency counts. See the section “[OUTFREQ= Data Set](#)” on page 2006 for details.

OUTINTERVAL=SAS-data-set

names the output data set to contain the time ID interval information that is summarized across all BY groups in the DATA= data set. See the section “[OUTINTERVAL= Data Set](#)” on page 2006 for details.

OUTINTERVALDETAILS=SAS-data-set

names the output data set to contain the time ID interval information for each BY group. See the section “[OUTINTERVALDETAILS= Data Set](#)” on page 2007 for details.

PLOT(*global-option*)=*request-option* | (*request-options*)

specifies the graphical output desired. By default, the TIMEID procedure produces no graphical output. The following *global-options* are available:

UNPACK | UNPACKPANELS suppresses paneling.

By default, multiple plots can appear in some output panels. Specify UNPACKPANELS to get each plot in a separate panel. The following plot *request-options* are available:

COUNTS | INTCNTS | INTERVALCOUNTS

plots a histogram of the time ID interval counts.

OFFSETS	plots a histogram of the time offsets for the time ID values.
PERIODS SPANS	plots a histogram of the spans between adjacent time ID values.
VALUES	plots a panel of the counts, offsets, and spans for each of the time ID values.
ALL	is equivalent to specifying PLOT=(INTERVALCOUNTS SPANS OFFSETS VALUES).

See the section “[Time ID Diagnostics](#)” on page 2002 for details.

PRINT=*option* | (*options*)

specifies the printed output desired. By default, the TIMEID procedure produces no printed output. The following printing options are available:

COUNTS INTCNTS INTERVALCOUNTS	prints a table that contains the counts of time ID values per interval.
INTERVAL	prints a summary of information about the time interval.
OFFSETS	prints a table that contains the time offsets for the time ID values.
PERIODS SPANS	prints tables that contain statistics on the spans between adjacent time ID values.
VALUES	prints tables that contain offset span and count information for the time ID values.
ALL	is equivalent to specifying PRINT=(INTERVALCOUNTS SPANS INTERVAL OFFSETS VALUES).

See the section “[Time ID Diagnostics](#)” on page 2002 for details.

BY Statement

BY *variables* ;

A BY statement can be used with PROC TIMEID to obtain separate analyses for groups of observations defined by the BY variables.

ID Statement

ID *variable* < *options* > ;

The ID statement names a numeric variable that identifies observations in the input and output data sets. The ID variable’s values are assumed to be SAS date or datetime values. The ID statement options specify how the time ID values are spaced and aligned relative to a SAS date or datetime interval. The INTERVAL= option specifies the fundamental spacing that is used as the basis for counting intervals, offsets, and spans in the data. Specification of the ID variable in an ID statement is required.

ALIGN=alignment

specifies the alignment of the identifying SAS date or datetime that is used to represent intervals. The value of the ALIGN= option is used in the analysis of the time ID variable. The ALIGN= option accepts the following values: BEGINNING | BEG | B, MIDDLE | MID | M, ENDING | END | E, and INFER. For example, ALIGN=BEGIN specifies that the identifying date for the interval is the beginning date in the interval. If the ALIGN= option is not specified, then the default alignment is BEGIN. ALIGN=INFER specifies that the alignment of values within time intervals be inferred from the time ID values.

DUPLICATES

specifies that multiple observations in the DATA= data set can fall within the same time interval as defined by the time ID variable. When this option is omitted and multiple time ID values are encountered in a single time interval, error messages are written to the SAS log.

FORMAT=format

specifies the SAS format used for time ID values in the data sets and in printed and plotted output that is generated by PROC TIMEID. If the FORMAT= option is not specified, the format applied to the input time ID variable is used. If neither of these formats is specified, the format is inferred from the INTERVAL= option.

INTERVAL=interval

specifies the proposed time interval and shift that describe the time ID values in the input data set. See Chapter 4, “[Date Intervals, Formats, and Functions](#),” for more information about the intervals that can be specified. See the section “[Time ID Diagnostics](#)” on page 2002 for more information about how the INTERVAL= option determines the nature of diagnostic information reported by the TIMEID procedure.

If no interval is specified, the procedure attempts to infer an interval from the input time ID values. See the section “[Inferring Time Intervals and Alignments](#)” on page 2005 for details about how the time interval is inferred.

NOTSORTED

specifies that the observations in the DATA= data set are not sorted by the time ID variable. When this option is omitted, error messages are generated for time ID values that are not sorted in ascending order.

Details: TIMEID Procedure

Time ID Diagnostics

For a specified time interval, PROC TIMEID decomposes the raw time ID values in an input data set into the following three quantities, whose values are represented by nonnegative integers at each unique time ID value in the input series:

interval counts the number of observations that share each time interval in the data set.

offsets the numerical difference between a time ID value and the aligned value for that time interval. The unit of measure used to express this distance is days for date values and seconds for datetime values. The offset is computed for each time ID value, t_i , by using the following SAS expression:

$$\text{offset}_i = t_i - \text{INTNX}(\text{interval}, t_i, 0, \text{alignment})$$

spans the number of intervals between each time ID value and the previous time ID value. The spans value is equivalent to the number returned by the following SAS expression:

$$\text{spans}_i = \text{INTCK}(\text{interval}, t_{i-1}, t_i)$$

Diagnostic Output Representation

The TIMEID procedure produces time ID diagnostics as both time-ID-based and count-based frequency distributions to expose many of the possible problems that can occur in a time ID variable. The time-ID-based frequency distributions that are generated with the PLOT= option provide a detailed view of time ID values that can isolate problems with specific ID values. [Figure 31.1](#) shows a time series that has a span of 10 observations in a weekday series based on the results of the PLOT=(VALUES SPANS) option. The single large bar in the spans plot shows where data are omitted.

Figure 31.1 Time ID Decomposition

The count-based frequency distributions summarize features of the time ID variable. Individual printed and plotted outputs are available to describe the distribution of the number of spans, offsets, and interval counts that occur in the time ID variable. [Figure 31.2](#) illustrates a count-based frequency distribution of the spans within the weekday series.

Figure 31.2 Span Count Distribution

The large bar at the span of 1 shows that most of the observations are correctly separated by one interval. The bar at 11 indicates that one observation is separated by 11 intervals from the preceding value of the time ID variable. This further illustrates a span of 10 omitted observations.

Inferring Time Intervals and Alignments

When the `INTERVAL=` option is not specified in the `ID` statement, a time interval is inferred from the time ID values in the input data set. The technique used to infer a time interval involves searching for the interval that fits the greatest number of time ID values. First, time ID values are sampled from the input data set to generate a set of candidate intervals. Then the candidate interval that is consistent with greatest number of time ID values is chosen to represent the time series.

When the `ALIGN=INFER` option is specified, the convention that is used to specify time interval alignment is inferred from the time ID variable values by using a similar technique. When both the time interval and its alignment are to be inferred, each of the possible alignments, `BEGIN`, `MIDDLE`, and `END`, are considered in the search. Precedence in the search is given to intervals with the `BEGIN` alignment.

Data Set Output

The TIMEID procedure creates the OUTFREQ=, OUTINTERVAL=, and OUTINTERVALDETAILS= data sets. The OUTFREQ= and OUTINTERVALDETAILS= data sets contain the variables that are specified in the BY statement along with variables that characterize the time ID values. The OUTINTERVAL= option creates a data set without BY variables. The information in this data set summarizes time ID diagnostic information across all BY groups in the DATA= data set.

OUTFREQ= Data Set

The OUTFREQ= data set contains a single observation for each value of the time ID variable in the input data set for each BY group. Additionally, the following variables are written to the OUTFREQ= data set:

COUNT	number of the occurrences of the time ID value
PERCENT	percentage of all time ID values

OUTINTERVAL= Data Set

The OUTINTERVAL= data set contains information that is similar to the variables written to the OUTINTERVALDETAILS= data set; however, the OUTINTERVAL= data set summarizes the information across all BY groups into a single observation. The following variables are written to the OUTINTERVAL= data set:

TIMEID	time ID variable
START	smallest time ID interval
END	largest time ID interval
STARTSHARED	largest starting time ID interval
ENDSHARED	smallest ending time ID interval
NOBS	number of observations
N	number of nonmissing observations
NMISS	number of missing observations
NBY	number of BY groups
NINVALID	number of invalid observations
STATUS	status flag that indicates whether the requested analyses were successful:
0	The analysis completed successfully.
1	interval consistent but data contains gaps
2	interval not consistent with data
10	missing or invalid values found
20	ID values not sorted

	21	duplicate ID values detected
	30	fewer than 3 values found
	4000	Inference of a time interval from the data set failed.
	5000	Diagnosis of the DATA= data set for the specified time interval failed.
MSG		a message that provides further details when the STATUS variable is not zero
INTERVAL		time interval that is specified or recommended
INTNAME		time interval base name that is specified or recommended
MULTIPLIER		time interval multiplier that is specified or recommended
SHIFT_INDEX		time interval shift index that is specified or recommended
ALIGNMENT		time interval alignment that is specified or recommended
SEASONALITY		seasonality determined from specified or recommended time interval
TOTALSEASONCYCLES		total number of seasonal cycles spanned by all the observations
SEASONCYCLESSHARED		number of seasonal cycles that are shared among all BY groups
FORMAT		format of the time ID variable

The START, END, STARTSHARED, and ENDSHARED variables are reported using the interval and alignment specified in the ID statement or inferred from the time ID values.

OUTINTERVALDETAILS= Data Set

The OUTINTERVALDETAILS= data set contains statistics about the time interval that is specified in the ID statement or inferred from the time ID values for each BY group. The following variables represent these statistics:

TIMEID	time ID variable name
START	starting time ID interval
END	ending time ID interval
NOBS	number of observations
N	number of nonmissing observations
NMISS	number of missing observations
NINVALID	number of invalid observations
NINTCNTS	number of unique interval count values
PCTINTCNTS	percentage of interval counts greater than one
MININTCNT	minimum of interval counts
MAXINTCNT	maximum of interval counts
MEANINTCNT	mean of interval counts
STDINTCNT	standard deviation of interval counts
MEDINTCNT	median of interval counts

NOFFSETS	number of time ID offset
PCTOFFSETS	percentage of time ID offset
MINOFFSET	minimum of time ID offsets
MAXOFFSET	maximum of time ID offsets
MEANOFFSET	mean of time ID offsets
STDOFFSET	standard deviation of time ID offsets
MEDOFFSET	median of time ID offsets
NSPANS	number of spans between time ID values
PCTSPANS	percentage of spans between time ID values
MINSPAN	maximum of spans between time ID values
MAXSPAN	minimum of spans between time ID values
MEANSPAN	mean of spans between time ID values
STDSPAN	standard deviation of spans between time ID values
MEDSPAN	median of spans between time ID values
STATUS	status flag that indicates whether the requested analyses were successful:
0	The analysis completed successfully.
1	interval consistent but data contains gaps
2	interval not consistent with data
10	missing or invalid values found
20	ID values not sorted
21	duplicate ID values detected
30	fewer than 3 values found
4000	Inference of a time interval from the data set failed .
5000	Diagnosis of the DATA= data set for specified time interval failed.
MSG	a message that provides further details when the STATUS variable is not zero
INTERVAL	time interval specified or recommended
INTNAME	time interval base name specified or recommended
MULTIPLIER	time interval multiplier specified or recommended
SHIFT_INDEX	time interval shift index specified or recommended
ALIGNMENT	time interval alignment specified or recommended
SEASONALITY	seasonality determined from specified or recommended time interval
NSEASONCYCLES	number of seasonal cycles spanned by the time ID values
FORMAT	format of the time ID variable

The START and END variables are reported using the interval and alignment specified in the ID statement or inferred from the time ID values.

Printed Tabular Output

The TIMEID procedure optionally produces printed output by using the Output Delivery System (ODS). By default, the procedure produces no printed output. The appearance of the printed tabular output is controlled by the PRINT= option in the PROC TIMEID statement.

Table 31.2 relates the PRINT= options to the names of the ODS tables.

Table 31.2 ODS Tables Produced in PROC TIMEID

ODS Name	Description	PRINT= Option
DataSet	Information about the input data set	ALL
Decomposition	Time ID counts, offsets, and spans	VALUES
Interval	Information about the time interval	INTERVAL
IntervalCountsComponent	Frequency distribution of interval counts	INTERVALCOUNTS
IntervalCountsStatistics	Statistics on interval count frequency distribution	INTERVALCOUNTS
OffsetsComponent	Frequency distribution of offsets	OFFSETS
OffsetStatistics	Statistics on offset frequency distribution	OFFSETS
SpansComponent	Frequency distribution of spans	SPANS
SpanStatistics	Statistics on the span frequency distribution	SPANS
Values	Time ID value counts	VALUES
ValueSummary	Summary of the number of valid observations	VALUES

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

The TIMEID procedure uses ODS Graphics to produce plotted output as specified by the PLOT= option. Table 31.3 relates the PLOT= options to the names of the ODS Graphics objects.

Table 31.3 ODS Graphics Produced by the PLOT= Option in PROC TIMEID

ODS Graph Name	Plot Description	PLOT= Option
DecompositionPlot	Panel of spans, offsets, and counts for each time interval	VALUES
IntervalCountsComponentPlot	Histogram of interval counts	INTERVALCOUNTS
IntervalCountsPlot	Plot of counts for each time interval value	VALUES
OffsetComponentPlot	Histogram of time ID offsets	OFFSETS
OffsetsPlot	Plot of offsets for each time interval value	VALUES
SpanComponentPlot	Histogram of span sizes between time ID values	SPANS
SpansPlot	Plot of spans for each time interval value	VALUES
ValuesPlot	Plot of counts of each time ID value	VALUES

Examples: TIMEID Procedure

Example 31.1: Examining a Weekly Time ID Variable

This example illustrates how problems in a weekly time series can be visualized and quantified using the TIMEID procedure's diagnostic capabilities.

The following DATA step creates a data set that contains time values spaced in three week intervals where some weeks have been skipped or duplicated and some have been recorded on different weekdays.

```
data triweek;
    format date date.;
    input date : date. @@;
datalines;
28DEC48 18JAN49 08FEB49 01MAR49 22MAR49 12APR49 03MAY49 24MAY49
17JUN49 05JUL49 26JUL49 16AUG49 06SEP49 27SEP49 18OCT49 08NOV49

... more lines ...
```

The following TIMEID procedure statements generate an ODS display of the time series that characterizes interval counts, offsets, and spans in the time ID variable.

```
proc timeid data=triweek print=all plot=all;
    id date interval=week3;
run;
```

The Time ID decomposition listing and plot shown in [Output 31.1.1](#) and [Output 31.1.2](#) summarize how well the WEEK3 interval fits the time ID values by showing the number of counts, offsets, and spans for each time interval that is represented by the DATE variable. The listing in [Output 31.1.1](#) has been truncated to include only the first 10 observations. The Time ID plots in [Output 31.1.2](#) indicate that there are duplicated time ID values for a three-week time interval in the Counts plot. The duplicated time intervals have a Count value of 2. The Offsets plot shows which days in the 21 day cycle have been used to record each time interval in the series. The Spans plot records values of 2 for six time intervals where no observations were recorded in the previous interval. The three component plots are histogram summaries of the diagnostic quantities plotted against individual intervals in the decomposition plots. The component plots can be useful in diagnosing time series that contain many time intervals.

Output 31.1.1 Time ID Decomposition Listing

Time Component					
Value

7	17APR49	16	1		1
8	08MAY49	16	1		1
9	29MAY49	19	1		1
10	19JUN49	16	1		1

Output 31.1.2 Time ID Decomposition Plot

Output 31.1.3 and **Output 31.1.4** describe the distribution of counts of duplicated WEEK3 intervals in the TriWeek data set. For this data set there are 134 intervals that contain one DATE value, and 10 intervals that contain two DATE values.

Output 31.1.3 Time ID Interval Counts Listings

The TIMEID Procedure				
Component				
Value	Interval	Frequency	Percentage	
Index	Count			
1	1	132	91.666667	
2	2	12	8.333333	

Output 31.1.3 *continued*

Statistics Summary			
Minimum	Maximum	Mean	Standard Deviation
1	2	1.0833333	1.3008873

Output 31.1.4 Time ID Interval Counts Histogram

The offsets diagnostics [Output 31.1.5](#) and [Output 31.1.6](#) show the distribution of days in the 21-day WEEK3 interval used to record the time intervals in the series. The observations in the TriWeek data set represent intervals with five different offsets from the beginning of the WEEK3 interval: 0, 16, 18, 19 and 20. The high prevalence of intervals with offset 16 indicates that the TriWeek data set would be represented better using the WEEK3.17 interval.

Output 31.1.5 Time ID Offsets Listings

The TIMEID Procedure				
Component				
Value	Offset	Frequency	Percentage	
Index				
1	0	1	0.694444	
2	16	138	95.833333	
3	18	1	0.694444	
4	19	1	0.694444	
5	20	3	2.083333	
Statistics Summary				
Minimum	Maximum	Mean	Standard Deviation	
0	20	16.006944	1.7006205	

Output 31.1.6 Time ID Offsets Histogram

The span diagnostics [Output 31.1.7](#) and [Output 31.1.8](#) show the distribution of the span sizes between successive DATE values. The TriWeek data set has three different span sizes of widths 0, 1 and 2. Here one span corresponds to the width of a WEEK3 interval.

Output 31.1.7 Time ID Span Listings

The TIMEID Procedure				
Component				
Value Index	Span	Frequency	Percentage	
1	0	1	0.704225	
2	1	135	95.070423	
3	2	6	4.225352	
Statistics Summary				
Minimum	Maximum	Mean	Standard Deviation	
0	2	1.0352113	0.6367974	

Output 31.1.8 Time ID Span Histogram

Output 31.1.9 and Output 31.1.10 show the distribution of time ID values before alignment to the WEEK3 interval. The listing in Output 31.1.9 has been truncated to include only the first 10 observations.

Output 31.1.9 Unaligned Time ID Listings

Time ID Values for DATE				
Value Index	date	Frequency	Percentage	
1	28DEC48	1	0.694444	
2	18JAN49	1	0.694444	
3	08FEB49	1	0.694444	
4	01MAR49	1	0.694444	
5	22MAR49	1	0.694444	
6	12APR49	1	0.694444	
7	03MAY49	1	0.694444	
8	24MAY49	1	0.694444	
9	17JUN49	1	0.694444	
10	05JUL49	1	0.694444	

Output 31.1.10 Unaligned Time ID Histogram

Example 31.2: Inferring a Date Interval

This example illustrates how a time ID variable can be inferred from a data set when a sufficient number of observations are present.

```
data workdays;
  format day weekdate.;
  input day : date. @@;
  datalines;
01AUG09 06AUG09 11AUG09 14AUG09 19AUG09 22AUG09
27AUG09 01SEP09 04SEP09 09SEP09 12SEP09 17SEP09
;

proc timeid data=workdays print=interval;
  id day;
run;
```

The 12 observations in the WorkDays data set are enough to determine that the DAY time ID variable is represented by the WEEKDAY12W3 interval. The WEEKDAY12W3 interval corresponds to every third day of the week excluding Sundays and Mondays. Characteristics of this interval are shown in [Output 31.2.1](#).

Output 31.2.1 Inferred Time Interval Information

The TIMEID Procedure	
Time Interval Analysis Summary	
Time ID Variable	day
Time Interval	WEEKDAY12W3
Base Name	WEEKDAY
Multiplier	3
Shift	0
Length of Seasonal Cycle	5
Time ID Format	WEEKDATE.
Start	Saturday, August 1, 2009
End	Thursday, September 17, 2009

Example 31.3: Examining Multiple BY Groups

This example illustrates how a time ID variable can be examined independently over each BY group and summarized over all observations in the DATA= data set.

```
data bygroups;
  format tid date.;
  input tid : date. by @@;
datalines;

... more lines ...
```

The following TIMEID procedure statements generate two data sets that summarize a data set with four BY groups.

```
proc timeid data=bygroups outintervaldetails=int outinterval=intsum;
  id tid;
  by by;
run;
```

The summarized information in [Output 31.3.1](#) shows that BY groups 2, 3, and 4 in the ByGroups data set contain some duplicate values and spans, and group 1 conforms exactly to the WEEKDAY17W interval. This listing also shows that the date ranges in these two BY groups start and end on different days and that they overlap between December 7, 2009, and December 28, 2009.

Output 31.3.1 Selected Variables in the Combined OUTINTERVALDETAILS= OUTINTERVAL= Data Sets

Overview: TIMESERIES Procedure

The TIMESERIES procedure analyzes time-stamped transactional data with respect to time and accumulates the data into a time series format. The procedure can perform trend and seasonal analysis on the transactions. After the transactional data are accumulated, time domain and frequency domain analysis can be performed on the accumulated time series.

For seasonal analysis of the transaction data, various statistics can be computed for each season. For trend analysis of the transaction data, various statistics can be computed for each time period. The analysis is similar to applying the MEANS procedure of Base SAS software to each season or time period of concern.

After the transactional data are accumulated to form a time series and any missing values are interpreted, the accumulated time series can be functionally transformed using log, square root, logistic, or Box-Cox transformations. The time series can be further transformed using simple and/or seasonal differencing. After functional and difference transformations have been applied, the accumulated and transformed time series can be stored in an output data set. This working time series can then be analyzed further using various time series analysis techniques provided by this procedure or other SAS/ETS procedures.

Time series analyses performed by the TIMESERIES procedure include:

- descriptive (global) statistics
- seasonal decomposition/adjustment analysis
- correlation analysis
- cross-correlation analysis
- spectral analysis

All results of the transactional or time series analysis can be stored in output data sets or printed using the Output Delivery System (ODS).

The TIMESERIES procedure can process large amounts of time-stamped transactional data. Therefore, the analysis results are useful for large-scale time series analysis or (temporal) data mining. All of the results can be stored in output data sets in either a time series format (default) or in a coordinate format (transposed). The time series format is useful for preparing the data for subsequent analysis with other SAS/ETS procedures. For example, the working time series can be further analyzed, modeled, and forecast with other SAS/ETS procedures. The coordinate format is useful when using this procedure with SAS/STAT procedures or SAS Enterprise Miner. For example, clustering time-stamped transactional data can be achieved by using the results of this procedure with the clustering procedures of SAS/STAT and the nodes of SAS Enterprise Miner.

The EXPAND procedure can be used for the frequency conversion and transformations of time series output from this procedure.

Getting Started: TIMESERIES Procedure

This section outlines the use of the TIMESERIES procedure and gives a cursory description of some of the analysis techniques that can be performed on time-stamped transactional data.

Given an input data set that contains numerous transaction variables recorded over time at no specific frequency, the TIMESERIES procedure can form time series as follows:

```
PROC TIMESERIES DATA=<input-data-set>
                OUT=<output-data-set>;
  ID <time-ID-variable> INTERVAL=<frequency>
    ACCUMULATE=<statistic>;
  VAR <time-series-variables>;
RUN;
```

The TIMESERIES procedure forms time series from the input time-stamped transactional data. It can provide results in output data sets or in other output formats by using the Output Delivery System (ODS).

Time-stamped transactional data are often recorded at no fixed interval. Analysts often want to use time series analysis techniques that require fixed-time intervals. Therefore, the transactional data must be accumulated to form a fixed-interval time series.

Suppose that a bank wants to analyze the transactions associated with each of its customers over time. Further, suppose that the data set WORK.TRANSACTIONS contains four variables that are related to these transactions: CUSTOMER, DATE, WITHDRAWAL, and DEPOSITS. The following examples illustrate possible ways to analyze these transactions by using the TIMESERIES procedure.

To accumulate the time-stamped transactional data to form a daily time series based on the accumulated daily totals of each type of transaction (WITHDRAWALS and DEPOSITS), the following TIMESERIES procedure statements can be used:

```

proc timeseries data=transactions
                out=timeseries;
    by customer;
    id date interval=day accumulate=total;
    var withdrawals deposits;
run;

```

The OUT=TIMESERIES option specifies that the resulting time series data for each customer is to be stored in the data set WORK.TIMESERIES. The INTERVAL=DAY option specifies that the transactions are to be accumulated on a daily basis. The ACCUMULATE=TOTAL option specifies that the sum of the transactions is to be calculated. After the transactional data is accumulated into a time series format, many of the procedures provided with SAS/ETS software can be used to analyze the resulting time series data.

For example, the ARIMA procedure can be used to model and forecast each customer's withdrawal data by using an ARIMA(0,1,1)(0,1,1)_s model (where the number of seasons is $s=7$ days in a week) using the following statements:

```

proc arima data=timeseries;
    identify var=withdrawals(1,7) noprint;
    estimate q=(1)(7) outest=estimates noprint;
    forecast id=date interval=day out=forecasts;
quit;

```

The OUTEST=ESTIMATES data set contains the parameter estimates of the model specified. The OUT=FORECASTS data set contains forecasts based on the model specified. See the SAS/ETS ARIMA procedure for more detail.

A single set of transactions can be very large and must be summarized in order to analyze them effectively. Analysts often want to examine transactional data for trends and seasonal variation. To analyze transactional data for trends and seasonality, statistics must be computed for each time period and season of concern. For each observation, the time period and season must be determined and the data must be analyzed based on this determination.

The following statements illustrate how to use the TIMESERIES procedure to perform trend and seasonal analysis of time-stamped transactional data.

```

proc timeseries data=transactions out=out
                outseason=season outtrend=trend;
    by customer;
    id date interval=day accumulate=total;
    var withdrawals deposits;
run;

```

Since the INTERVAL=DAY option is specified, the length of the seasonal cycle is seven (7) where the first season is Sunday and the last season is Saturday. The output data set specified by the OUTSEASON=SEASON option contains the seasonal statistics for each day of the week by each customer. The output data set specified by the OUTTREND=TREND option contains the trend statistics for each day of the calendar by each customer.

Often it is desired to seasonally decompose into seasonal, trend, cycle, and irregular components or to seasonally adjust a time series. The following techniques describe how the changing seasons influence the time series.

The following statements illustrate how to use the *TIMESERIES* procedure to perform seasonal adjustment/decomposition analysis of time-stamped transactional data.

```
proc timeseries data=transactions
    out=out
    outdecomp=decompose;
    by customer;
    id date interval=day accumulate=total;
    var withdrawals deposits;
run;
```

The output data set specified by the *OUTDECOMP=DECOMPOSE* data set contains the decomposed/adjusted time series for each customer.

A single time series can be very large. Often, a time series must be summarized with respect to time lags in order to be efficiently analyzed using time domain techniques. These techniques help describe how a current observation is related to the past observations with respect to the time (season) lag.

The following statements illustrate how to use the *TIMESERIES* procedure to perform time domain analysis of time-stamped transactional data.

```
proc timeseries data=transactions
    out=out
    outcorr=timedomain;
    by customer;
    id date interval=day accumulate=total;
    var withdrawals deposits;
run;
```

The output data set specified by the *OUTCORR=TIMEDOMAIN* data set contains the time domain statistics, such as sample autocorrelations and partial autocorrelations, by each customer.

Sometimes time series data contain underlying patterns that can be identified using spectral analysis techniques. Two kinds of spectral analyses on univariate data can be performed using the *TIMESERIES* procedure. They are singular spectrum analysis and Fourier spectral analysis.

Singular spectrum analysis (SSA) is a technique for decomposing a time series into additive components and categorizing these components based on the magnitudes of their contributions. SSA uses a single parameter, the window length, to quantify patterns in a time series without relying on prior information about the series' structure. The window length represents the maximum lag that is considered in the analysis, and it corresponds to the dimensionality of the principle components analysis (PCA) on which SSA is based. The components are combined into groups to categorize their roles in the SSA decomposition.

Fourier spectral analysis decomposes a time series into a sum of harmonics. In the discrete Fourier transform, the contribution of components at evenly spaced frequencies are quantified in a periodogram and summarized in spectral density estimates.

The following statements illustrate how to use the *TIMESERIES* procedure to analyze time-stamped transactional data without prior information about the series' structure.

```
proc timeseries data=transactions
    outssa=ssa
    outspectra=spectra;
```

```

    by customer;
    id date interval=day accumulate=total;
    var withdrawals deposits;
run;

```

The output data set specified by the OUTSSA=SSA data set contains a singular spectrum analysis of the withdrawals and deposits data. The data set specified by OUTSPECTRA=SPECTRA contains a Fourier spectral decomposition of the same data.

By default, the TIMESERIES procedure produces no printed output.

Syntax: TIMESERIES Procedure

The TIMESERIES Procedure uses the following statements:

PROC TIMESERIES Statement

PROC TIMESERIES *options* ;

The following options can be used in the PROC TIMESERIES statement:

DATA= *SAS-data-set*

names the SAS data set that contains the input data for the procedure to create the time series. If the DATA= option is not specified, the most recently created SAS data set is used.

CROSSPLOTS= *option* | (*options*)

specifies the cross-variable graphical output desired. By default, the TIMESERIES procedure produces no graphical output. The following plotting options are available:

SERIES plots the time series (OUT= data set).

CCF plots the cross-correlation functions (OUTCROSSCORR= data set).

ALL same as PLOTS=(SERIES CCF).

For example, CROSSPLOTS=SERIES plots the two time series. The CROSSPLOTS= option produces graphical output for these results by using the Output Delivery System (ODS). The CROSS-

PLOTS= option produces results similar to the data sets listed in parentheses next to the preceding options.

MAXERROR= *number*

limits the number of warning and error messages that are produced during the execution of the procedure to the specified value. The default is MAXERRORS=50. This option is particularly useful in BY-group processing where it can be used to suppress the recurring messages.

OUT= *SAS-data-set*

names the output data set to contain the time series variables specified in the subsequent VAR and CROSSVAR statements. If BY variables are specified, they are also included in the OUT= data set. If an ID variable is specified, it is also included in the OUT= data set. The values are accumulated based on the ID statement INTERVAL= or the ACCUMULATE= option or both. The OUT= data set is particularly useful when you want to further analyze, model, or forecast the resulting time series with other SAS/ETS procedures.

OUTCORR= *SAS-data-set*

names the output data set to contain the univariate time domain statistics.

OUTCROSSCORR= *SAS-data-set*

names the output data set to contain the cross-correlation statistics.

OUTDECOMP= *SAS-data-set*

names the output data set to contain the decomposed and/or seasonally adjusted time series.

OUTPROCINFO= *SAS-data-set*

names the output data set to contain information in the SAS log, specifically the number of notes, errors, and warnings and the number of series processed, analyses requested, and analyses failed.

OUTSEASON= *SAS-data-set*

names the output data set to contain the seasonal statistics. The statistics are computed for each season as specified by the ID statement INTERVAL= option or the PROC TIMESERIES statement SEASONALITY= option. The OUTSEASON= data set is particularly useful when analyzing transactional data for seasonal variations.

OUTSPECTRA= *SAS-data-set*

names the output data set to contain the univariate frequency domain analysis results.

OUTSSA= *SAS-data-set*

names the output data set to contain the singular spectrum analysis result series.

OUTSUM= *SAS-data-set*

names the output data set to contain the descriptive statistics. The descriptive statistics are based on the accumulated time series when the ACCUMULATE= and/or SETMISSING= options are specified in the ID or VAR statements. The OUTSUM= data set is particularly useful when analyzing large numbers of series and a summary of the results are needed.

OUTTREND= *SAS-data-set*

names the output data set to contain the trend statistics. The statistics are computed for each time period as specified by the ID statement INTERVAL= option. The OUTTREND= data set is particularly useful when analyzing transactional data for trends.

PLOTS= *option* | (*options*)

specifies the univariate graphical output desired. By default, the TIMESERIES procedure produces no graphical output. The following plotting options are available:

SERIES	plots the time series (OUT= data set).				
RESIDUAL	plots the residual time series (OUT= data set).				
HISTOGRAM	plots a histogram of the time series values				
CYCLES	plots the seasonal cycles (OUT= data set).				
CORR	plots the correlation panel (OUTCORR= data set).				
ACF	plots the autocorrelation function (OUTCORR= data set).				
PACF	plots the partial autocorrelation function (OUTCORR= data set).				
IACF	plots the inverse autocorrelation function (OUTCORR= data set).				
WN	plots the white noise probabilities (OUTCORR= data set).				
DECOMP	plots the seasonal adjustment panel (OUTDECOMP= data set).				
TCS	plots the trend-cycle-seasonal component (OUTDECOMP= data set).				
TCC	plots the trend-cycle component (OUTDECOMP= data set).				
SIC	plots the seasonal-irregular component (OUTDECOMP= data set).				
SC	plots the seasonal component (OUTDECOMP= data set).				
SA	plots the seasonal adjusted component (OUTDECOMP= data set).				
PCSA	plots the percent change in the seasonal adjusted component (OUTDECOMP= data set).				
IC	plots the irregular component (OUTDECOMP= data set).				
TC	plots the trend component (OUTDECOMP= data set).				
CC	plots the cycle component (OUTDECOMP= data set).				
PERIODOGRAM< <i>option</i> >	plots the periodogram (OUTSPECTRA= data set). The available options for modifying the periodogram are <table> <tr> <td>MAXFREQ=<i>number</i></td><td>specifies the maximum frequency in radians to include in the plot</td></tr> <tr> <td>MINPERIOD=<i>number</i></td><td>specifies the minimum period to include in the plot</td></tr> </table>	MAXFREQ= <i>number</i>	specifies the maximum frequency in radians to include in the plot	MINPERIOD= <i>number</i>	specifies the minimum period to include in the plot
MAXFREQ= <i>number</i>	specifies the maximum frequency in radians to include in the plot				
MINPERIOD= <i>number</i>	specifies the minimum period to include in the plot				
SPECTRUM< <i>option</i> >	plots the spectral density estimate (OUTSPECTRA= data set). The available options for modifying the spectrum plot are <table> <tr> <td>MAXFREQ=<i>number</i></td><td>specifies the maximum frequency in radians to include in the plot</td></tr> <tr> <td>MINPERIOD=<i>number</i></td><td>specifies the minimum period to include in the plot</td></tr> </table>	MAXFREQ= <i>number</i>	specifies the maximum frequency in radians to include in the plot	MINPERIOD= <i>number</i>	specifies the minimum period to include in the plot
MAXFREQ= <i>number</i>	specifies the maximum frequency in radians to include in the plot				
MINPERIOD= <i>number</i>	specifies the minimum period to include in the plot				
SSA	plots the singular spectrum analysis results (OUTSSA= data set).				

ALL	same as PLOTS=(SERIES HISTOGRAM ACF PACF IACF WN SSA PERIODOGRAM SPECTRUM).
BASIC	same as PLOTS=(SERIES HISTOGRAM CYCLES CORR DECOMP)

For example, PLOTS=SERIES plots the time series. The PLOTS= option produces graphical output for these results by using the Output Delivery System (ODS). The PLOTS= option produces results similar to the data sets listed in parentheses next to the preceding options.

PRINT= *option* | (*options*)

specifies the printed output desired. By default, the TIMESERIES procedure produces no printed output. The following printing options are available:

DECOMP	prints the seasonal decomposition/adjustment table (OUTDECOMP= data set).
SEASONS	prints the seasonal statistics table (OUTSEASON= data set).
DESCSTATS	prints the descriptive statistics for the accumulated time series (OUTSUM= data set).
SUMMARY	prints the descriptive statistics table for all time series (OUTSUM= data set).
TRENDS	prints the trend statistics table (OUTTREND= data set).
SSA	prints the singular spectrum analysis results (OUTSSA= data set).
ALL	same as PRINT=(DESCSTATS SUMMARY).

For example, PRINT=SEASONS prints the seasonal statistics. The PRINT= option produces printed output for these results by using the Output Delivery System (ODS). The PRINT= option produces results similar to the data sets listed in parentheses next to the preceding options.

PRINTDETAILS

specifies that output requested with the PRINT= option be printed in greater detail.

SEASONALITY= *number*

specifies the length of the seasonal cycle. For example, SEASONALITY=3 means that every group of three time periods forms a seasonal cycle. By default, the length of the seasonal cycle is one (no seasonality) or the length implied by the INTERVAL= option specified in the ID statement. For example, INTERVAL=MONTH implies that the length of the seasonal cycle is 12.

SORTNAMES

specifies that the variables specified in the VAR and CROSSVAR statements be processed in sorted order by the variable names. This option allows the output data sets to be presorted by the variable names.

BY Statement

A BY statement can be used with PROC TIMESERIES to obtain separate dummy variable definitions for groups of observations defined by the BY variables.

When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the option NOTSORTED or DESCENDING in the BY statement for the TIMESERIES procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CORR Statement

CORR *statistics* < / *options* > ;

A CORR statement can be used with the TIMESERIES procedure to specify options related to time domain analysis of the accumulated time series. Only one CORR statement is allowed.

The following time domain statistics are available:

LAG	time lag
N	number of variance products
ACOV	autocovariances
ACF	autocorrelations
ACFSTD	autocorrelation standard errors
ACF2STD	an indicator of whether autocorrelations are less than (–1), greater than (1), or within (0) two standard errors of zero
ACFNORM	normalized autocorrelations
ACFPROB	autocorrelation probabilities
ACFLPROB	autocorrelation log probabilities
PACF	partial autocorrelations
PACFSTD	partial autocorrelation standard errors
PACF2STD	an indicator of whether partial autocorrelation are less than (–1), greater than (1), or within (0) two standard errors of zero
PACFNORM	partial normalized autocorrelations
PACFPROB	partial autocorrelation probabilities

PACFLPROB	partial autocorrelation log probabilities
IACF	inverse autocorrelations
IACFSTD	inverse autocorrelation standard errors
IACF2STD	an indicator of whether the inverse autocorrelation is less than (−1), greater than (1) or within (0) two standard errors of zero
IACFNORM	normalized inverse autocorrelations
IACFPROB	inverse autocorrelation probabilities
IACFLPROB	inverse autocorrelation log probabilities
WN	white noise test statistics
WNPROB	white noise test probabilities
WNLPROB	white noise test log probabilities

If none of the correlation statistics are specified, the default is as follows:

```
corr lag n acov acf acfstd pacf pacfstd iacf iacfstd wn wnprob;
```

The following options can be specified in the CORR statement following the slash (/):

NLAG= *number*

specifies the number of lags to be stored in the OUTCORR= data set or to be plotted. The default is 24 or three times the length of the seasonal cycle, whichever is smaller. The LAGS= option takes precedence over the NLAG= option.

LAGS= (*numlist*)

specifies the list of lags to be stored in OUTCORR= data set or to be plotted. The list of lags must be separated by spaces or commas. For example, LAGS=(1,3) specifies the first then third lag.

NPARMS= *number*

specifies the number of parameters used in the model that created the residual time series. The number of parameters determines the degrees of freedom associated with the Ljung-Box statistics. The default is NPARMS=0. This option is useful when analyzing the residuals of a time series model with the number of parameters specified by NPARMS=*number* option.

TRANSPPOSE= NO|YES

specifies which values are recorded as column names in the OUTCORR= data set. TRANSPPOSE=YES specifies that lags be recorded as the column names instead of correlation statistics as the column names. The TRANSPPOSE=NO option is useful for graphing the correlation results with SAS/GRAPH procedures. The TRANSPPOSE=YES option is useful for analyzing the correlation results with other SAS procedures such as the CLUSTER procedure of SAS/STAT or SAS Enterprise Miner software. The default is TRANSPPOSE=NO.

CROSSCORR Statement

CROSSCORR *statistics* < / *options* > ;

A CROSSCORR statement can be used with the TIMESERIES procedure to specify options that are related to cross-correlation analysis of the accumulated time series. Only one CROSSCORR statement is allowed.

The following time domain statistics are available:

LAG	time lag
N	number of variance products
CCOV	cross covariances
CCF	cross-correlations
CCFSTD	cross-correlation standard errors
CCF2STD	an indicator of whether cross-correlations are less than (−1), greater than (1), or within (0) two standard errors of zero
CCFNORM	normalized cross-correlations
CCFPROB	cross-correlation probabilities
CCFLPROB	cross-correlation log probabilities

If none of the cross-correlation statistics are specified, the default is as follows:

```
crosscorr lag n ccov ccf ccfstd;
```

The following options can be specified in the CROSSCORR statement following the slash (/):

NLAG= *number*

specifies the number of lags to be stored in the OUTCROSSCORR= data set or to be plotted. The default is 24 or three times the length of the seasonal cycle, whichever is smaller. The LAGS= option takes precedence over the NLAG= option.

LAGS=(*numlist*)

specifies a list of lags to be stored in OUTCROSSCORR= data set or to be plotted. The list of lags must be separated by spaces or commas. For example, LAGS=(1,3) specifies the first then third lag.

TRANSPPOSE= NO|YES

specifies which values are recorded as column names in the OUTCROSSCORR= data set. TRANSPPOSE=YES specifies that the lags be recorded as the column names instead of the cross-correlation statistics. The TRANSPPOSE=NO option is useful for graphing the cross-correlation results with SAS/GRAPH procedures. The TRANSPPOSE=YES option is useful for analyzing the cross-correlation results with other procedures such as the CLUSTER procedure of SAS/STAT or SAS Enterprise Miner software. The default is TRANSPPOSE=NO.

DECOMP Statement

DECOMP *components* < / *options* > ;

A DECOMP statement can be used with the TIMESERIES procedure to specify options related to classical seasonal decomposition of the time series data. Only one DECOMP statement is allowed. The options specified affect all variables listed in the VAR statements. Decomposition can be performed only when the length of the seasonal cycle specified by the PROC TIMESERIES statement SEASONALITY= option or implied by the ID statement INTERVAL= option is greater than one.

The following seasonal decomposition components are available:

ORIG ORIGINAL	original series
TCC TRENDCYCLE	trend-cycle component
SIC SEASONIRREGULAR	seasonal-irregular component
SC SEASONAL	seasonal component
SCSTD	seasonal component standard errors
TCS TRENDCYCLESEASON	trend-cycle-seasonal component
IC IRREGULAR	irregular component
SA ADJUSTED	seasonally adjusted series
PCSA	percent change seasonally adjusted series
TC	trend component
CC CYCLE	cycle component

If none of the components are specified, the default is as follows:

```
decomp orig tcc sc ic sa;
```

The following options can be specified in the DECOMP statement following the slash (/):

MODE= *option*

specifies the type of decomposition to be used to decompose the time series. The following values can be specified for the MODE= option:

ADD ADDITIVE	additive decomposition
MULT MULTIPLICATIVE	multiplicative decomposition
LOGADD LOGADDITIVE	log-additive decomposition
PSEUDOADD PSEUDOADDITIVE	pseudo-additive decomposition
MULTORADD	multiplicative or additive decomposition, depending on data

Multiplicative and log additive decomposition require strictly positive time series. If the accumulated time series contains nonpositive values and the `MODE=MULT` or `MODE=LOGADD` option is specified, an error results. Pseudo-additive decomposition requires a nonnegative-valued time series. If the accumulated time series contains negative values and the `MODE=PSEUDOADD` option is specified, an error results. The `MODE=MULTORADD` option specifies that multiplicative decomposition be used when the accumulated time series contains only positive values, that pseudo-additive decomposition be used when the accumulated time series contains only nonnegative values, and that additive decomposition be used otherwise. The default is `MODE=MULTORADD`.

LAMBDA= *number*

specifies the Hodrick-Prescott filter parameter for trend-cycle decomposition. The default is `LAMBDA=1600`. Filtering applies when the trend component or the cycle component is requested. If filtering is not specified, this option is ignored.

NPRIODS= *number*

specifies the number of time periods to be stored in the `OUTDECOMP=` data set when the `TRANSPPOSE=YES` option is specified. If the `TRANSPPOSE=NO` option is specified, the `NPRIODS=` option is ignored. If the `NPRIODS=` option is positive, the first or beginning time periods are recorded. If the `NPRIODS=` option is negative, the last or ending time periods are recorded. The `NPRIODS=` option specifies the number of `OUTDECOMP=` data set variables to contain the seasonal decomposition and is therefore limited to the maximum allowed number of SAS variables. If the number of time periods exceeds this limit, a warning is printed in the log and the number of periods stored is reduced to the limit.

If the `NPRIODS=` option is not specified, all of the periods specified between the `ID` statement `START=` and `END=` options are stored. If at least one of the `START=` or `END=` options is not specified, the default magnitude is the seasonality specified by the `SEASONALITY=` option in the `PROC TIMESERIES` statement or implied by the `INTERVAL=` option in the `ID` statement. If only the `START=` option or both the `START=` and `END=` options are specified and the seasonality is zero, the default is `NPRIODS=5`. If only the `END=` option or neither the `START=` nor `END=` option is specified and the seasonality is zero, the default is `NPRIODS=-5`.

TRANSPPOSE= `NO` | `YES`

specifies which values are recorded as column names in the `OUTDECOMP=` data set. `TRANSPPOSE=YES` specifies that the time periods be recorded as the column names instead of the statistics. The first and last time periods stored in the `OUTDECOMP=` data set correspond to the period of the `ID` statement `START=` option and `END=` option, respectively. If only the `ID` statement `END=` option is specified, the last time ID value of each accumulated time series corresponds to the last time period column. If only the `ID` statement `START=` option is specified, the first time ID value of each accumulated time series corresponds to the first time period column. If neither the `START=` option nor the `END=` option is specified with the `ID` statement, the first time ID value of each accumulated time series corresponds to the first time period column. The `TRANSPPOSE=NO` option is useful for analyzing or displaying the decomposition results with `SAS/GRAPH` procedures. The `TRANSPPOSE=YES` option is useful for analyzing the decomposition results with other SAS procedures or SAS Enterprise Miner software. The default is `TRANSPPOSE=NO`.

ID Statement

ID *variable* **INTERVAL=***interval* < *options* > ;

The ID statement names a numeric variable that identifies observations in the input and output data sets. The ID variable's values are assumed to be SAS date or datetime values. In addition, the ID statement specifies the (desired) frequency associated with the time series. The ID statement *options* also specify how the observations are accumulated and how the time ID values are aligned to form the time series. The information specified affects all variables listed in subsequent VAR statements. If the ID statement is specified, the INTERVAL= must also be used. If an ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID.

The following *options* can be used with the ID statement:

ACCUMULATE= *option*

specifies how the data set observations are to be accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option. The ID variable contains the time ID values. Each time ID variable value corresponds to a specific time period. The accumulated values form the time series, which is used in subsequent analysis.

The ACCUMULATE= option is useful when there are zero or more than one input observations that coincide with a particular time period (for example, time-stamped transactional data). The EXPAND procedure offers additional frequency conversions and transformations that can also be useful in creating a time series.

The following *options* determine how the observations are accumulated within each time period based on the ID variable and the frequency specified by the INTERVAL= option:

NONE	No accumulation occurs; the ID variable values must be equally spaced with respect to the frequency. This is the default option.
TOTAL	Observations are accumulated based on the total sum of their values.
AVERAGE AVG	Observations are accumulated based on the average of their values.
MINIMUM MIN	Observations are accumulated based on the minimum of their values.
MEDIAN MED	Observations are accumulated based on the median of their values.
MAXIMUM MAX	Observations are accumulated based on the maximum of their values.
N	Observations are accumulated based on the number of nonmissing observations.
NMISS	Observations are accumulated based on the number of missing observations.
NOBS	Observations are accumulated based on the number of observations.
FIRST	Observations are accumulated based on the first of their values.
LAST	Observations are accumulated based on the last of their values.
STDDEV STD	Observations are accumulated based on the standard deviation of their values.
CSS	Observations are accumulated based on the corrected sum of squares of their values.

USS Observations are accumulated based on the uncorrected sum of squares of their values.

If the **ACCUMULATE=** option is specified, the **SETMISSING=** option is useful for specifying how accumulated missing values are to be treated. If missing values should be interpreted as zero, then **SETMISSING=0** should be used. The section “[Details: TIMESERIES Procedure](#)” on page 2048 describes accumulation in greater detail.

ALIGN= *option*

controls the alignment of SAS dates used to identify output observations. The **ALIGN=** option accepts the following values: **BEGINNING** | **BEG** | **B**, **MIDDLE** | **MID** | **M**, and **ENDING** | **END** | **E**. **BEGINNING** is the default.

BOUNDARYALIGN= *option*

controls how the **ACCUMULATE=** option is processed for the two boundary time intervals, which include the **START=** and **END=** time ID values. Some time ID values might fall inside the first and last accumulation intervals but fall outside the **START=** and **END=** boundaries. In these cases the **BOUNDARYALIGN=** option determines which values to include in the accumulation operation. You can specify the following *options*:

NONE	No values outside the START= and END= boundaries are accumulated.
START	All observations in the first time interval are accumulated.
END	All observations in the last time interval are accumulated.
BOTH	All observations in the first and last are accumulated.

If no option is specified, the default value **BOUNDARYALIGN=NONE** is used. The section “[Details: TIMESERIES Procedure](#)” on page 2048 describes the **BOUNDARYALIGN=** accumulation option in greater detail.

END= *option*

specifies a SAS date or datetime value that represents the end of the data. If the last time ID variable value is less than the **END=** value, the series is extended with missing values. If the last time ID variable value is greater than the **END=** value, the series is truncated. For example, **END=&sysdate** uses the automatic macro variable **SYSDATE** to extend or truncate the series to the current date. The **START=** and **END=** options can be used to ensure that data associated within each **BY** group contains the same number of observations.

FORMAT= *format*

specifies the SAS format for the time ID values. If the **FORMAT=** option is not specified, the default format is implied from the **INTERVAL=** option.

INTERVAL= *interval*

specifies the frequency of the accumulated time series. For example, if the input data set consists of quarterly observations, then **INTERVAL=QTR** should be used. If the **PROC TIMESERIES** statement **SEASONALITY=** option is not specified, the length of the seasonal cycle is implied from the **INTERVAL=** option. For example, **INTERVAL=QTR** implies a seasonal cycle of length 4. If the **ACCUMULATE=** option is also specified, the **INTERVAL=** option determines the time periods for the accumulation of observations. The **INTERVAL=** option is required and must be the first option specified in the ID statement.

NOTSORTED

specifies that the time ID values not be in sorted order. The TIMESERIES procedure sorts the data with respect to the time ID prior to analysis.

SETMISSING= *option* | *number*

specifies how missing values (either actual or accumulated) are to be interpreted in the accumulated time series. If a number is specified, missing values are set to the number. If a missing value indicates an unknown value, this option should not be used. If a missing value indicates no value, SETMISSING=0 should be used. You would typically use SETMISSING=0 for transactional data because no recorded data usually implies no activity. The following options can also be used to determine how missing values are assigned:

MISSING	Missing values are set to missing. This is the default option.
AVERAGE AVG	Missing values are set to the accumulated average value.
MINIMUM MIN	Missing values are set to the accumulated minimum value.
MEDIAN MED	Missing values are set to the accumulated median value.
MAXIMUM MAX	Missing values are set to the accumulated maximum value.
FIRST	Missing values are set to the accumulated first nonmissing value.
LAST	Missing values are set to the accumulated last nonmissing value.
PREVIOUS PREV	Missing values are set to the previous period's accumulated nonmissing value. Missing values at the beginning of the accumulated series remain missing.
NEXT	Missing values are set to the next period's accumulated nonmissing value. Missing values at the end of the accumulated series remain missing.

START= *option*

specifies a SAS date or datetime value that represents the beginning of the data. If the first time ID variable value is greater than the START= value, the series is prepended with missing values. If the first time ID variable value is less than the START= value, the series is truncated. The START= and END= options can be used to ensure that data associated with each by group contains the same number of observations.

SEASON Statement

SEASON *statistics* < / *options* > ;

A SEASON statement can be used with the TIMESERIES procedure to specify options that are related to seasonal analysis of the time-stamped transactional data. Only one SEASON statement is allowed. The options specified affect all variables specified in the VAR statements. Seasonal analysis can be performed only when the length of the seasonal cycle specified by the PROC TIMESERIES statement SEASONALITY= option or implied by the ID statement INTERVAL= option is greater than one.

The following seasonal statistics are available:

NOBS	number of observations
N	number of nonmissing observations
NMISS	number of missing observations
MINIMUM	minimum value
MAXIMUM	maximum value
RANGE	range value
SUM	summation value
MEAN	mean value
STDDEV	standard deviation
CSS	corrected sum of squares
USS	uncorrected sum of squares
MEDIAN	median value

If none of the season statistics are specified, the default is as follows:

```
season n min max mean std;
```

The following option can be specified in the SEASON statement following the slash (/):

TRANSPOSE= NO | YES

specifies which values are recorded as column names in the OUTSEASON= data set. TRANSPOSE=YES specifies that the seasonal indices be recorded as the column names instead of the statistics. The TRANSPOSE=NO option is useful for graphing the seasonal analysis results with SAS/GRAPH procedures. The TRANSPOSE=YES option is useful for analyzing the seasonal analysis results with SAS procedures or SAS Enterprise Miner software. The default is TRANSPOSE=NO.

SPECTRA Statement

```
SPECTRA statistics < / options > ;
```

A SPECTRA statement can be used with the TIMESERIES procedure to specify which statistics appear in the OUTSPECTRA= data set. The SPECTRA statement *options* are used in performing a spectral analysis on the variables listed in the VAR statement. These *options* affect values that are produced in the PROC TIMESERIES statement's OUTSPECTRA= data set, and in the periodogram and spectral density estimate. Only one SPECTRA statement is allowed.

The following univariate frequency domain statistics are available:

FREQ	frequency in radians from 0 to π
PERIOD	period or wavelength
COS	cosine transform

SIN	sine transform
P	periodogram
S	spectral density estimates

If none of the frequency domain statistics are specified, the default is as follows:

```
spectra period p;
```

The following *options* can be specified in the SPECTRA statement following the slash (/):

ADJUSTMEAN | CENTER= NO | YES

specifies whether or not the series should be adjusted by its mean prior to performing the Fourier decomposition. This sets the first periodogram ordinate to 0 rather than to $2n$ times the squared mean. This option is commonly used when the periodograms are to be plotted to prevent a large first periodogram ordinate from distorting the scale of the plot. ADJUSTMEAN=YES specifies the series should be transformed by subtracting its mean. ADJUSTMEAN=NO specifies no adjustment of the series should be performed. The default is ADJUSTMEAN=NO.

ALPHA= num

specifies the width of a window drawn around the spectral density estimate in a spectral density versus frequency plot. Based on approximations proposed by Brockwell and Davis (1991), periodogram ordinates fall within this window with a confidence level of $1 - \text{ALPHA}$. The value ALPHA must be between 0 and 1; the default is 0.5.

kernel **DOMAIN=domain C=c EXP|EXPON=e**

specifies the smoothing function used to calculate a spectral density estimate as the moving average of periodogram ordinates. The kernel function is an alternative way to using the WEIGHTS option as a smoothing function. The available *kernel* values are:

PARZEN	Parzen kernel
BARTLETT	Bartlett kernel
TUKEY	Tukey-Hanning kernel
TRUNC TRUNCAT	truncated kernel
QS QUADR	quadratic spectral kernel

The DOMAIN= option specifies how the smoothing function is interpreted. The available *domain* values are:

FREQUENCY	smooths the periodogram ordinates.
TIME	applies the kernel as a filter to the time series autocovariance function

By default DOMAIN=FREQUENCY, and smoothing is applied in the same manner as weights are applied when the WEIGHTS= option is used. Each of the kernel functions can be further parameterized with a kernel scale factor by using the C= and EXPON= options. A summary of the default values of the kernel scale parameters, c and e , that are associated with each of the kernel functions together with their kernel scale factor values, M , for a series with 100 periodogram ordinates is listed in [Table 32.2](#).

Table 32.2 Default Kernel Scale Factor Parameters

Kernel	c	e	M
Bartlett	1/2	1/3	2.32
Parzen	1	1/5	2.51
Quadratic	1/2	1/5	1.26
Tukey-Hanning	2/3	1/5	1.67
Truncated	1/4	1/5	0.63

For example, to apply the truncated kernel by using default scale factor parameters in the frequency domain, the following SPECTRA statement could be used:

```
spectra / truncat;
```

Details of the kernel function parameterization and the DOMAIN= option are provided in the section “[Using Kernel Specifications](#)” on page 2059.

WEIGHTS *numlist*

specifies the relative weights used in computing a spectral density estimate as the moving average smoothing of periodogram ordinates. If neither a WEIGHTS option nor a kernel function is specified, the spectral density estimate is identical to the unmodified periodogram. The following SPECTRA statement uses the WEIGHTS option to specify equal weighting for each of the three adjacent periodogram ordinates centered on each spectral density estimate:

```
spectra / weights 1 1 1;
```

Further description of how the weights are applied is provided in the section “[Using Specification of Weight Constants](#)” on page 2060.

SSA Statement

SSA < / *options* > ;

An SSA statement can be used with the TIMESERIES procedure to specify *options* that are related to singular spectrum analysis (SSA) of the accumulated time series. Only one SSA statement is allowed.

The following *options* can be specified in the SSA statement following the slash (/).

ADJUSTMEAN | CENTER= NO | YES

specifies whether or not the series should be adjusted by its mean prior to performing the singular spectrum analysis. ADJUSTMEAN=YES specifies the series should be transformed by subtracting its mean. ADJUSTMEAN=NO specifies no adjustment of the series should be performed. The default is ADJUSTMEAN=NO.

GROUPS= (numlist)...(numlist)

specifies the lists that categorize window lags into groups. The window lags must be separated by spaces or commas. For example, GROUPS=(1,3) (2,4) specifies that the first and third window lags form the first group and the second and fourth window lags form the second group. If no GROUPS= option is specified, the window lags are divided into two groups based on the THRESHOLDPCT= value.

For example, the following SSA statement specifies three groups:

```
ssa / groups=(1 3) (2 4 5) (6);
```

The first group contains the first and third principal components; the second group contains the second, fourth, and fifth principal components; and the third group contains the sixth principal component.

By default, the first group contains the principal components whose contributions to the series sum to greater than the THRESHOLDPCT= value of 90%, and the second group contains the remaining components.

LENGTH = number

specifies the window length to be used in the analysis. It represents the maximum lag used in the SSA autocovariance calculations. The number specified by the LENGTH= option must be greater than one and less than 1000. When the SEASONALITY= option is provided or inferred by the INTERVAL= option in the ID statement the default window length is the smaller of two times the length of the seasonal cycle and one half the length of the time series. When no seasonality value is available the default window length is the smaller of 12 and one half the length of the time series.

For example, the following SSA statement specifies a window length of 10:

```
ssa / length=10;
```

If no window length option is specified and the INTERVAL=MONTH or SEASONALITY=12 options are specified, a window length of 24 is used. If the specified window length is greater than one-half the length of the accumulated time series, the window length is reduced and a warning message is printed to the log.

NPERIODS= number

specifies the number of time periods to be stored in the OUTSSA= data set when the TRANSPPOSE=YES option is specified. If the TRANSPPOSE option is not specified, the NPERIODS= option is ignored. The NPERIODS= option specifies the number of OUTSSA= data set variables to contain the groups.

If the NPERIODS= option is not specified, all of the periods specified between the ID statement START= and END= options are stored. If at least one of the START= or END= options is not specified, the default magnitude is the seasonality specified by the SEASONALITY= option in the PROC TIMESERIES statement or implied by the INTERVAL= option in the ID statement. If only the START= option or both the START= and END= options are specified and the seasonality is zero, the default is NPERIODS=5. If only the END= option or neither the START= nor END= option is specified and the seasonality is zero, the default is NPERIODS=-5.

THRESHOLDPCT= *percent*

specifies a percentage used to divide the SSA components into two groups based on the cumulative percentage of their singular values. The percentage specified by the THRESHOLDPCT= option must be greater than zero and less than 100. The default is THRESHOLDPCT=90.

For example, the following SSA statement specifies 80%:

```
ssa / THRESHOLDPCT=80;
```

The size of the second group must be at least one, and it must be less than the window length. The percentage is adjusted to achieve this requirement.

For example, the following SSA statement specifies a THRESHOLDPCT= of 0%, which effectively sets the size of the second group to one less than the window length:

```
ssa / THRESHOLDPCT = 0;
```

The following SSA statement specifies a THRESHOLDPCT= of 100%, which implies that the size of the last group is one:

```
ssa / THRESHOLDPCT= 100;
```

TRANSPOSE= NO | YES

specifies which values are recorded as column names in the OUTSSA= data set. TRANSPOSE=YES specifies that the time periods be recorded as the column names instead of the specified groups as the column names. The first and last time period stored in the OUTSSA= data set corresponds to the period of the ID statement START= and END= options, respectively. If only the ID statement END= option is specified, the last time ID value of each accumulated time series corresponds to the last time period column. If only the ID statement START= option is specified, the first time ID value of each accumulated time series corresponds to the first time period column. If neither the START= option nor the END= option is specified with the ID statement, the first time ID value of each accumulated time series corresponds to the first time period column. The TRANSPOSE=NO option is useful for displaying the SSA results. The TRANSPOSE=YES option is useful for analyzing the SSA results using SAS Enterprise Miner software. The default is TRANSPOSE=NO.

TREND Statement

TREND *statistics* < / *options* > ;

A TREND statement can be used with the TIMESERIES procedure to specify options related to trend analysis of the time-stamped transactional data. Only one TREND statement is allowed. The options specified affect all variables specified in the VAR statements.

The following trend statistics are available:

NOBS number of observations

N	number of nonmissing observations
NMISS	number of missing observations
MINIMUM	minimum value
MAXIMUM	maximum value
RANGE	range value
SUM	summation value
MEAN	mean value
STDDEV	standard deviation
CSS	corrected sum of squares
USS	uncorrected sum of squares
MEDIAN	median value

If none of the trend statistics are specified, the default is as follows:

```
trend n min max mean std;
```

The following options can be specified in the TREND statement following the slash (/):

NPERIODS= *number*

specifies the number of time periods to be stored in the OUTTREND= data set when the TRANSPOSE=YES option is specified. If the TRANSPOSE option is not specified, the NPERIODS= option is ignored. The NPERIODS= option specifies the number of OUTTREND= data set variables to contain the trend statistics and is therefore limited to the maximum allowed number of SAS variables.

If the NPERIODS= option is not specified, all of the periods specified between the ID statement START= and END= options are stored. If at least one of the START= or END= options is not specified, the default magnitude is the seasonality specified by the SEASONALITY= option in the PROC TIMESERIES statement or implied by the INTERVAL= option in the ID statement. If only the START= option or both the START= and END= options are specified and the seasonality is zero, the default is NPERIODS=5. If only the END= option or neither the START= nor END= option is specified and the seasonality is zero, the default is NPERIODS=-5.

TRANSPOSE= NO | YES

specifies which values are recorded as column names in the OUTTREND= data set. TRANSPOSE=YES specifies that the time periods be recorded as the column names instead of the statistics as the column names. The first and last time periods stored in the OUTTREND= data set correspond to the period of the ID statement START= and END= options, respectively. If only the ID statement END= option is specified, the last time ID value of each accumulated time series corresponds to the last time period column. If only the ID statement START= option is specified, the first time ID value of each accumulated time series corresponds to the first time period column. If neither the START= option nor the END= option is specified with the ID statement, the first time ID value of each accumulated time series corresponds to the first time period column. The TRANSPOSE=NO option is useful for analyzing or displaying the trend analysis results with SAS/GRAPH procedures. The TRANSPOSE=YES option is useful for analyzing the trend analysis results with other SAS procedures or SAS Enterprise Miner software. The default is TRANSPOSE=NO.

VAR and CROSSVAR Statements

VAR *variable-list* < / *options* > ;

CROSSVAR *variable-list* < / *options* > ;

The VAR and CROSSVAR statements list the numeric variables in the DATA= data set whose values are to be accumulated to form the time series.

An input data set variable can be specified in only one VAR or CROSSVAR statement. Any number of VAR and CROSSVAR statements can be used. The following options can be used with the VAR and CROSSVAR statements:

ACCUMULATE= *option*

specifies how the data set observations are to be accumulated within each time period for the variables listed in the VAR or CROSSVAR statement. If the ACCUMULATE= option is not specified in the VAR or CROSSVAR statement, accumulation is determined by the ACCUMULATE= option of the ID statement. See the ID statement ACCUMULATE= option for more details.

DIF=(*numlist*)

specifies the differencing to be applied to the accumulated time series. The list of differencing orders must be separated by spaces or commas. For example, DIF=(1,3) specifies first then third order differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the DIF= option.

SDIF=(*numlist*)

specifies the seasonal differencing to be applied to the accumulated time series. The list of seasonal differencing orders must be separated by spaces or commas. For example, SDIF=(1,3) specifies first then third order seasonal differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the SDIF= option.

SETMISS= *option* | *number*

SETMISSING= *option* | *number*

specifies how missing values (either actual or accumulated) are to be interpreted in the accumulated time series for variables listed in the VAR or CROSSVAR statement. If the SETMISSING= option is not specified in the VAR or CROSSVAR statement, missing values are set based on the SETMISSING= option of the ID statement. See the ID statement SETMISSING= option for more details.

TRANSFORM= *option*

specifies the time series transformation to be applied to the accumulated time series. The following transformations are provided:

NONE	No transformation is applied. This option is the default.
LOG	logarithmic transformation
SQRT	square-root transformation
LOGISTIC	logistic transformation

BOXCOX(*n*) Box-Cox transformation with parameter number where the number is between -5 and 5

When the TRANSFORM= option is specified, the time series must be strictly positive.

Details: TIMESERIES Procedure

The TIMESERIES procedure can be used to perform trend and seasonal analysis on transactional data. For trend analysis, various sample statistics are computed for each time period defined by the time ID variable and INTERVAL= option. For seasonal analysis, various sample statistics are computed for each season defined by the INTERVAL= or the SEASONALITY= option. For example, if the transactional data ranges from June 1990 to January 2000 and the data are to be accumulated on a monthly basis, then the trend statistics are computed for every month: June 1990, July 1990, ..., January 2000. The seasonal statistics are computed for each season: January, February, ..., December.

The TIMESERIES procedure can be used to form time series data from transactional data. The accumulated time series can then be analyzed using time series techniques. The data is analyzed in the following order:

- | | |
|---------------------------------|--|
| 1. accumulation | ACCUMULATE= option in the ID, VAR, or CROSSVAR statement |
| 2. missing value interpretation | SETMISSING= option in the ID, VAR, or CROSSVAR statement |
| 3. time series transformation | TRANSFORM= option in the VAR or CROSSVAR statement |
| 4. time series differencing | DIF= and SDIF= options in the VAR or CROSSVAR statement |
| 5. descriptive statistics | OUTSUM= option and the PRINT=DESCSTATS option |
| 6. seasonal decomposition | DECOMP statement or the OUTDECOMP= option in the PROC TIMESERIES statement |
| 7. correlation analysis | CORR statement or the OUTCORR= option in the PROC TIMESERIES statement |
| 8. singular spectrum analysis | SSA statement or the OUTSSA= option in the PROC TIMESERIES statement |
| 9. Fourier spectral analysis | SPECTRA statement or the OUTSPECTRA= option in the PROC TIMESERIES statement |
| 10. cross-correlation analysis | CROSSCORR statement or the OUTCROSSCORR= option in the PROC TIMESERIES statement |

Accumulation

If the `ACCUMULATE=` option in the `ID`, `VAR`, or `CROSSVAR` statement is specified, data set observations are accumulated within each time period. The frequency (width of each time interval) is specified by the `INTERVAL=` option. The `ID` variable contains the time `ID` values. Each time `ID` value corresponds to a specific time period. Accumulation is useful when the input data set contains transactional data, whose observations are not spaced with respect to any particular time interval. The accumulated values form the time series, which is used in subsequent analyses.

For example, suppose a data set contains the following observations:

19MAR1999	10
19MAR1999	30
11MAY1999	50
12MAY1999	20
23MAY1999	20

If the `INTERVAL=MONTH` is specified, all of the above observations fall within a three-month period of time between March 1999 and May 1999. The observations are accumulated within each time period as follows:

If the `ACCUMULATE=NONE` option is specified, an error is generated because the `ID` variable values are not equally spaced with respect to the specified frequency (`MONTH`).

If the `ACCUMULATE=TOTAL` option is specified, the resulting time series is:

01MAR1999	40
01APR1999	.
01MAY1999	90

If the `ACCUMULATE=AVERAGE` option is specified, the resulting time series is:

01MAR1999	20
01APR1999	.
01MAY1999	30

If the `ACCUMULATE=MINIMUM` option is specified, the resulting time series is:

01MAR1999	10
01APR1999	.
01MAY1999	20

If the `ACCUMULATE=MEDIAN` option is specified, the resulting time series is:

01MAR1999	20
01APR1999	.
01MAY1999	20

If the ACCUMULATE=MAXIMUM option is specified, the resulting time series is:

```
01MAR1999    30
01APR1999    .
01MAY1999    50
```

If the ACCUMULATE=FIRST option is specified, the resulting time series is:

```
01MAR1999    10
01APR1999    .
01MAY1999    50
```

If the ACCUMULATE=LAST option is specified, the resulting time series is:

```
01MAR1999    30
01APR1999    .
01MAY1999    20
```

If the ACCUMULATE=STDDEV option is specified, the resulting time series is:

```
01MAR1999    14.14
01APR1999    .
01MAY1999    17.32
```

As can be seen from the above examples, even though the data set observations contain no missing values, the accumulated time series can have missing values.

Boundary Alignment

When the BOUNDARYALIGN= option is used to qualify the START= or END= options, additional time series values can be incorporated into the accumulation operation. For instance, if a data set contains the following observations

```
01JAN1999    10
01FEB1999    10
01MAR1999    10
01APR1999    10
01MAY1999    10
01JUN1999    10
```

and the options START='/01FEB1999'd, END='/01APR1999'd, INTERVAL=QUARTER, and ACCUMULATE=TOTAL are specified, using the BOUNDARYALIGN= option results in the following accumulated time series:

If BOUNDARYALIGN=START is specified, the accumulated time series is

```
01JAN1999  30
01APR1999  10
```

If BOUNDARYALIGN=END is specified, the accumulated time series is

```
01JAN1999  20
01APR1999  30
```

If BOUNDARYALIGN=BOTH is specified, the accumulated time series is

```
01JAN1999  30
01APR1999  30
```

If BOUNDARYALIGN=NONE is specified, the accumulated time series is

```
01JAN1999  20
01APR1999  10
```

Missing Value Interpretation

Sometimes missing values should be interpreted as unknown values. But sometimes missing values are known, such as when missing values are created from accumulation and no observations should be interpreted as no value—that is, zero. In the former case, the SETMISSING= option can be used to interpret how missing values are treated. The SETMISSING=0 option should be used when missing observations are to be treated as no (zero) values. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and interpreted time series is used in subsequent analyses.

Time Series Transformation

There are four transformations available for strictly positive series only. Let $y_t > 0$ be the original time series, and let w_t be the transformed series. The transformations are defined as follows:

Log is the logarithmic transformation.

$$w_t = \ln(y_t)$$

Logistic is the logistic transformation.

$$w_t = \ln(cy_t/(1 - cy_t))$$

where the scaling factor c is

$$c = (1 - 10^{-6})10^{-\text{ceil}(\log_{10}(\max(y_t)))}$$

and $\text{ceil}(x)$ is the smallest integer greater than or equal to x .

Square root is the square root transformation.

$$w_t = \sqrt{y_t}$$

Box Cox is the Box-Cox transformation.

$$w_t = \begin{cases} \frac{y_t^\lambda - 1}{\lambda}, & \lambda \neq 0 \\ \ln(y_t), & \lambda = 0 \end{cases}$$

More complex time series transformations can be performed by using the EXPAND procedure of SAS/ETS.

Time Series Differencing

After optionally transforming the series, the accumulated series can be simply or seasonally differenced by using the VAR and CROSSVAR statement DIF= and SDIF= options. For example, suppose y_t is a monthly time series. The following examples of the DIF= and SDIF= options demonstrate how to simply and seasonally difference the time series.

```
dif=(1) sdif=(1)
dif=(1,12)
```

Additionally, when y_t is strictly positive and the TRANSFORM=, DIF=, and SDIF= options are combined in the VAR and CROSSVAR statements, the transformation operation is performed before the differencing operations.

Descriptive Statistics

Descriptive statistics can be computed from the working series by specifying the OUTSUM= option or PRINT=DESCSTATS.

Seasonal Decomposition

Seasonal decomposition/analysis can be performed on the working series by specifying the OUTDECOMP= option, the PRINT=DECOMP option, or one of the PLOTS= options associated with decomposition in the PROC TIMESERIES statement. The DECOMP statement enables you to specify options related to decomposition. The TIMESERIES procedure uses classical decomposition. More complex seasonal decomposition/adjustment analysis can be performed by using the X11 or the X12 procedure of SAS/ETS.

The DECOMP statement MODE= option determines the mode of the seasonal adjustment decomposition to be performed. There are four modes: multiplicative (MODE=MULT), additive (MODE=ADD),

pseudo-additive (MODE=PSEUDOADD), and log-additive (MODE=LOGADD) decomposition. The default is MODE=MULTORADD which specifies MODE=MULT for series that are strictly positive, MODE=PSEUDOADD for series that are nonnegative, and MODE=ADD for series that are not nonnegative.

When MODE=LOGADD is specified, the components are exponentiated to the original metric.

The DECOMP statement LAMBDA= option specifies the Hodrick-Prescott filter parameter (Hodrick and Prescott 1980). The default is LAMBDA=1600. The Hodrick-Prescott filter is used to decompose the trend-cycle component into the trend component and cycle component in an additive fashion. A smaller parameter assigns less significance to the cycle; that is, LAMBDA=0 implies no cycle component.

The notation and keywords associated with seasonal decomposition/adjustment analysis are defined in [Table 32.3](#).

Table 32.3 Seasonal Adjustment Formulas

Component	Keyword	MODE= Option	Formula
original series	ORIGINAL	MULT	$O_t = TC_t S_t I_t$
		ADD	$O_t = TC_t + S_t + I_t$
		LOGADD	$\log(O_t) = TC_t + S_t + I_t$
		PSEUDOADD	$O_t = TC_t(S_t + I_t - 1)$
trend-cycle component	TCC	MULT	centered moving average of O_t
		ADD	centered moving average of O_t
		LOGADD	centered moving average of $\log(O_t)$
		PSEUDOADD	centered moving average of O_t
seasonal-irregular component	SIC	MULT	$SI_t = S_t I_t = O_t / TC_t$
		ADD	$SI_t = S_t + I_t = O_t - TC_t$
		LOGADD	$SI_t = S_t + I_t = \log(O_t) - TC_t$
		PSEUDOADD	$SI_t = S_t + I_t - 1 = O_t / TC_t$
seasonal component	SC	MULT	seasonal Averages of SI_t
		ADD	seasonal Averages of SI_t
		LOGADD	seasonal Averages of SI_t
		PSEUDOADD	seasonal Averages of SI_t
irregular component	IC	MULT	$I_t = SI_t / S_t$
		ADD	$I_t = SI_t - S_t$
		LOGADD	$I_t = SI_t - S_t$
		PSEUDOADD	$I_t = SI_t - S_t + 1$
trend-cycle-seasonal component	TCS	MULT	$TCS_t = TC_t S_t = O_t / I_t$
		ADD	$TCS_t = TC_t + S_t = O_t - I_t$
		LOGADD	$TCS_t = TC_t + S_t = O_t - I_t$
		PSEUDOADD	$TCS_t = TC_t S_t$
trend component	TC	MULT	$T_t = TC_t - C_t$
		ADD	$T_t = TC_t - C_t$
		LOGADD	$T_t = TC_t - C_t$
		PSEUDOADD	$T_t = TC_t - C_t$
cycle component	CC	MULT	$C_t = TC_t - T_t$
		ADD	$C_t = TC_t - T_t$
		LOGADD	$C_t = TC_t - T_t$
		PSEUDOADD	$C_t = TC_t - T_t$
seasonally adjusted series	SA	MULT	$SA_t = O_t / S_t = TC_t I_t$
		ADD	$SA_t = O_t - S_t = TC_t + I_t$
		LOGADD	$SA_t = O_t / \exp(S_t) = \exp(TC_t + I_t)$
		PSEUDOADD	$SA_t = TC_t I_t$

The trend-cycle component is computed from the s -period centered moving average as follows:

$$TC_t = \sum_{k=-\lfloor s/2 \rfloor}^{\lfloor s/2 \rfloor} y_{t+k}/s$$

The seasonal component is obtained by averaging the seasonal-irregular component for each season.

$$S_{k+js} = \sum_{t=k \bmod s} \frac{SI_t}{T/s}$$

where $0 \leq j \leq T/s$ and $1 \leq k \leq s$. The seasonal components are normalized to sum to one (multiplicative) or zero (additive).

Correlation Analysis

Correlation analysis can be performed on the working series by specifying the OUTCORR= option or one of the PLOTS= options that are associated with correlation. The CORR statement enables you to specify options that are related to correlation analysis.

Autocovariance Statistics

LAGS	$h \in \{0, \dots, H\}$
N	N_h is the number of observed products at lag h , ignoring missing values
ACOV	$\hat{\gamma}(h) = \frac{1}{T} \sum_{t=h+1}^T (y_t - \bar{y})(y_{t-h} - \bar{y})$
ACOV	$\hat{\gamma}(h) = \frac{1}{N_h} \sum_{t=h+1}^T (y_t - \bar{y})(y_{t-h} - \bar{y})$ when embedded missing values are present

Autocorrelation Statistics

ACF	$\hat{\rho}(h) = \hat{\gamma}(h)/\hat{\gamma}(0)$
ACFSTD	$Std(\hat{\rho}(h)) = \sqrt{\frac{1}{T} \left(1 + 2 \sum_{j=1}^{h-1} \hat{\rho}(j)^2 \right)}$
ACFNORM	$Norm(\hat{\rho}(h)) = \hat{\rho}(h)/Std(\hat{\rho}(h))$
ACFPROB	$Prob(\hat{\rho}(h)) = 2(1 - \Phi(Norm(\hat{\rho}(h))))$
ACFLPROB	$LogProb(\hat{\rho}(h)) = -\log_{10}(Prob(\hat{\rho}(h)))$
ACF2STD	$Flag(\hat{\rho}(h)) = \begin{cases} 1 & \hat{\rho}(h) > 2Std(\hat{\rho}(h)) \\ 0 & -2Std(\hat{\rho}(h)) < \hat{\rho}(h) < 2Std(\hat{\rho}(h)) \\ -1 & \hat{\rho}(h) < -2Std(\hat{\rho}(h)) \end{cases}$

Partial Autocorrelation Statistics

PACF	$\hat{\phi}(h) = \Gamma_{(0,h-1)}\{\gamma_j\}_{j=1}^h$
PACFSTD	$Std(\hat{\phi}(h)) = 1/\sqrt{N_0}$
PCFNORM	$Norm(\hat{\phi}(h)) = \hat{\phi}(h)/Std(\hat{\phi}(h))$
PACFPROB	$Prob(\hat{\phi}(h)) = 2(1 - \Phi(Norm(\hat{\phi}(h))))$
PACFLPROB	$LogProb(\hat{\phi}(h)) = -\log_{10}(Prob(\hat{\phi}(h)))$

$$\text{PACF2STD} \quad \text{Flag}(\hat{\varphi}(h)) = \begin{cases} 1 & \hat{\varphi}(h) > 2\text{Std}(\hat{\varphi}(h)) \\ 0 & -2\text{Std}(\hat{\varphi}(h)) < \hat{\varphi}(h) < 2\text{Std}(\hat{\varphi}(h)) \\ -1 & \hat{\varphi}(h) < -2\text{Std}(\hat{\varphi}(h)) \end{cases}$$

Inverse Autocorrelation Statistics

$$\begin{aligned} \text{IACF} & \quad \hat{\theta}(h) \\ \text{IACFSTD} & \quad \text{Std}(\hat{\theta}(h)) = 1/\sqrt{N_0} \\ \text{IACFNORM} & \quad \text{Norm}(\hat{\theta}(h)) = \hat{\theta}(h)/\text{Std}(\hat{\theta}(h)) \\ \text{IACFPROB} & \quad \text{Prob}(\hat{\theta}(h)) = 2 \left(1 - \Phi(|\text{Norm}(\hat{\theta}(h))|) \right) \\ \text{IACFLPROB} & \quad \text{LogProb}(\hat{\theta}(h)) = -\log_{10}(\text{Prob}(\hat{\theta}(h))) \\ \text{IACF2STD} & \quad \text{Flag}(\hat{\theta}(h)) = \begin{cases} 1 & \hat{\theta}(h) > 2\text{Std}(\hat{\theta}(h)) \\ 0 & -2\text{Std}(\hat{\theta}(h)) < \hat{\theta}(h) < 2\text{Std}(\hat{\theta}(h)) \\ -1 & \hat{\theta}(h) < -2\text{Std}(\hat{\theta}(h)) \end{cases} \end{aligned}$$

White Noise Statistics

$$\begin{aligned} \text{WN} & \quad Q(h) = T(T+2) \sum_{j=1}^h \rho(j)^2 / (T-j) \\ \text{WN} & \quad Q(h) = \sum_{j=1}^h N_j \rho(j)^2 \text{ when embedded missing values are present} \\ \text{WNPROB} & \quad \text{Prob}(Q(h)) = \chi_{\max(1, h-p)}(Q(h)) \\ \text{WNLPROB} & \quad \text{LogProb}(Q(h)) = -\log_{10}(\text{Prob}(Q(h))) \end{aligned}$$

Cross-Correlation Analysis

Cross-correlation analysis can be performed on the working series by specifying the OUTCROSSCORR= option or one of the CROSSPLOTS= options that are associated with cross-correlation. The CROSSCORR statement enables you to specify options that are related to cross-correlation analysis.

Cross-Correlation Statistics

The cross-correlation statistics for the variable x supplied in a VAR statement and variable y supplied in a CROSSVAR statement are:

$$\begin{aligned} \text{LAGS} & \quad h \in \{0, \dots, H\} \\ \text{N} & \quad N_h \text{ is the number of observed products at lag } h, \text{ ignoring missing values} \\ \text{CCOV} & \quad \hat{\gamma}_{x,y}(h) = \frac{1}{T} \sum_{t=h+1}^T (x_t - \bar{x})(y_{t-h} - \bar{y}) \\ \text{CCOV} & \quad \hat{\gamma}_{x,y}(h) = \frac{1}{N_h} \sum_{t=h+1}^T (x_t - \bar{x})(y_{t-h} - \bar{y}) \text{ when embedded missing values are present} \\ \text{CCF} & \quad \hat{\rho}_{x,y}(h) = \hat{\gamma}_{x,y}(h) / \sqrt{\hat{\gamma}_x(0)\hat{\gamma}_y(0)} \end{aligned}$$

CCFSTD	$Std(\hat{\rho}_{x,y}(h)) = 1/\sqrt{N_0}$
CCFNORM	$Norm(\hat{\rho}_{x,y}(h)) = \hat{\rho}_{x,y}(h)/Std(\hat{\rho}_{x,y}(h))$
CCFPROB	$Prob(\hat{\rho}_{x,y}(h)) = 2(1 - \Phi(Norm(\hat{\rho}_{x,y}(h))))$
CCFLPROB	$LogProb(\hat{\rho}_{x,y}(h)) = -\log_{10}(Prob(\hat{\rho}_{x,y}(h)))$
CCF2STD	$Flag(\hat{\rho}_{x,y}(h)) = \begin{cases} 1 & \hat{\rho}_{x,y}(h) > 2Std(\hat{\rho}_{x,y}(h)) \\ 0 & -2Std(\hat{\rho}_{x,y}(h)) < \hat{\rho}_{x,y}(h) < 2Std(\hat{\rho}_{x,y}(h)) \\ -1 & \hat{\rho}_{x,y}(h) < -2Std(\hat{\rho}_{x,y}(h)) \end{cases}$

Spectral Density Analysis

Spectral analysis can be performed on the working series by specifying the OUTSPECTRA= option or by specifying the PLOTS=PERIODOGRAM or PLOTS=SPECTRUM option in the PROC TIMESERIES statement. PROC TIMESERIES uses the finite Fourier transform to decompose data series into a sum of sine and cosine terms of different amplitudes and wavelengths. The finite Fourier transform decomposition of the series x_t is

$$x_t = \frac{a_0}{2} + \sum_{k=1}^{K-1} f_k(a_k \cos \omega_k t + b_k \sin \omega_k t)$$

$$f_k = \begin{cases} 1/2 & \text{if } T \text{ is even and } k = K - 1 \\ 1 & \text{otherwise} \end{cases}$$

where

t	is the time subscript, $t = 0, 1, 2, \dots, T - 1$
x_t	are the equally spaced time series data
T	is the number of observations in the time series
K	is the number of frequencies in the Fourier decomposition: $K = \frac{T+2}{2}$ if T is even, $K = \frac{T+1}{2}$ if T is odd
k	is the frequency subscript, $k = 0, 1, 2, \dots, K - 1$
a_0	is the mean term: $a_0 = 2\bar{x}$
a_k	are the cosine coefficients
b_k	are the sine coefficients
ω_k	are the Fourier frequencies: $\omega_k = \frac{2\pi k}{T}$

The Fourier decomposition is performed after the ACCUMULATE=, DIF=, SDIF= and TRANSFORM= options in the ID and VAR statements have been applied.

Functions of the Fourier coefficients a_k and b_k can be plotted against frequency or against wavelength to form *periodograms*. The amplitude periodogram I_k is defined as follows:

$$I_k = \frac{T}{2}(a_k^2 + b_k^2)$$

Since the Fourier transform is an even, periodic function of frequency which repeats every T ordinates the periodogram is also. Values of I_k for all k therefore can be mapped to the unique values $I_k : k = 0 \dots K-1$ using the equations

$$\begin{aligned} I_k &= I_{-k} && \text{for all } k \\ I_k &= I_{k+nT} && \text{for } n = \pm 1, \pm 2, \pm 3, \dots \\ I_k &= I_{T-k} && \text{for } 0 \leq k \leq K-1 \end{aligned}$$

The periodogram, I_k , is an estimate at the discrete frequencies ω_k of the spectral density function which characterizes the series x_t . By smoothing the periodogram an improved spectral density estimate with reduced variance and bias can be achieved at these points. Smoothing can be accomplished either through use of a spectral window smoothing function or by applying a lag window filter to the series autocovariance function.

When the SPECTRA statement's DOMAIN=FREQUENCY option is in effect spectral density estimates are computed by smoothing the periodogram ordinates using the equation

$$S_k(M) = \sum_{\tau=K-T}^{K-1} w\left(\frac{\tau}{M}\right) I_{k+\tau}$$

where $w(\theta)$ is the spectral window function whose form is specified by either the KERNEL= option or the WEIGHTS option. M is the kernel scale parameter which acts as a frequency scaling factor in the spectral window smoothing function. Values of $I_{k+\tau}$ that fall outside of $0 \leq k + \tau \leq K-1$ are mapped to values inside this range by the equations presented previously.

When the DOMAIN=TIME option is specified spectral density values are estimated by applying a lag window filter, $\lambda(h, M)$, to the series autocovariance function. The spectral density estimate then can be computed from the filtered autocovariance function using the equation

$$S_k(M) = \sum_{h=-(T-1)}^{T-1} \lambda(h, M) \hat{\gamma}(h) \cos h\omega_k.$$

In this case the kernel scale parameter, M , serves as a scale factor for the lag length, h , in the time domain. In the lag window formulation the spectral density estimate is a consistent estimator as $T, M \rightarrow \infty$ under the conditions $\lambda(h, M) = 0$ for $|h| > M$, and $\lim_{T \rightarrow \infty} M/T = 0$. These conditions lead to the following parameterization of M provided by the SPECTRA statement:

$$M = cK^e$$

where the values $c > 0$ and $0 < e < 1$ satisfy the consistency conditions. To specify the kernel scale parameter explicitly, set $c =$ to the desired scale factor and $e = 0$.

For uniformity and computational efficiency all spectral density estimates are calculated using a spectral window weighting function, $w(\theta)$, applied to the periodogram ordinates. In the case where the DOMAIN=TIME option is specified the effective spectral window weighting function is computed by the equation

$$w_{\text{TIME}}(\theta) = \sum_{h=-(T-1)}^{T-1} \lambda(h, M) \cos h\theta.$$

Because the kernel scale parameter, M , serves as a lag scale factor in the time domain and bandwidth scale factor in the frequency domain the impact of M on spectral density estimates depends on the value of the DOMAIN= option. When DOMAIN=FREQUENCY increasing values of M decrease variance and increase bias in the spectral density estimates whereas when DOMAIN=TIME increasing values of M increase variance and decrease bias.

Using Kernel Specifications

You can specify one of ten different kernel smoothing functions in the SPECTRA statement. Five smoothing functions are available as KERNEL= options and five complementary smoothing functions which correspond to lag window filters are available when the KERNEL= option is used in conjunction with the DOMAIN=TIME option.

For example, a Parzen kernel with a support of 11 periodogram ordinates in the frequency domain can be specified using the kernel option:

```
spectra / parzen c=5 expon=0;
```

The TIMESERIES procedure supports the following spectral window kernel functions in the frequency domain where $x = \tau/M$:

BARTLETT: Bartlett kernel

$$w(x) = \begin{cases} 1 - |x| & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

PARZEN: Parzen kernel

$$w(x) = \begin{cases} 1 - 6|x|^2 + 6|x|^3 & 0 \leq |x| \leq \frac{1}{2} \\ 2(1 - |x|)^3 & \frac{1}{2} \leq |x| \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

QS: quadratic spectral kernel

$$w(x) = \frac{3}{(2\pi x)^2} \left(\frac{\sin 2\pi x}{2\pi x} - \cos 2\pi x \right)$$

TUKEY: Tukey-Hanning kernel

$$w(x) = \begin{cases} (1 + \cos(\pi x))/2 & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

TRUNCAT: truncated kernel

$$w(x) = \begin{cases} 1 & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

When the DOMAIN=TIME option is specified the five kernel functions above are interpreted as lag window filters on the autocovariance function. The lag window kernel functions correspond to the following spectral window smoothing functions where $\theta = 2\pi\tau/T$:

BARTLETT: Bartlett equivalent lag window filter

$$w(\theta) = \frac{1}{2\pi M} \left(\frac{\sin(M\theta/2)}{\sin(\theta/2)} \right)^2$$

PARZEN: Parzen equivalent lag window filter

$$w(\theta) = \frac{6}{\pi M^3} \left(\frac{\sin(M\theta/4)}{\sin(\theta/2)} \right)^4 \left(1 - \frac{2}{3} \sin^2(\theta/2) \right)$$

QS: quadratic spectral equivalent lag window filter

$$w(\theta) = \begin{cases} \frac{3M}{4\pi} (1 - (M\theta/\pi)^2) & |\theta| \leq \pi/M \\ 0 & |\theta| > \pi/M \end{cases}$$

TUKEY: Tukey-Hanning equivalent lag window filter

$$w(\theta) = \frac{1}{4} D_M(\theta - \pi/M) + \frac{1}{2} D_M(\theta) + \frac{1}{4} D_M(\theta + \pi/M)$$

$$D_M(\theta) = \frac{1}{2\pi} \frac{\sin[(M + 1/2)\theta]}{\sin(\theta/2)}$$

TRUNC: truncated equivalent lag window filter

$$w(\theta) = D_M(\theta)$$

Using Specification of Weight Constants

Any number of weighting constants can be specified. The constants are interpreted symmetrically about the middle weight. The middle constant (or the constant to the right of the middle if an even number of weight constants is specified) is the relative weight of the current periodogram ordinate. The constant immediately following the middle one is the relative weight of the next periodogram ordinate, and so on. The actual

weights used in the smoothing process are the weights specified in the WEIGHTS option scaled so that they sum to 1.

The moving average calculation reflects at each end of the periodogram to accommodate the periodicity of the periodogram function.

For example, a simple triangular weighting can be specified using the following WEIGHTS option:

```
spectra / weights 1 2 3 2 1;
```

Computational Method

If the number of observations, T , factors into prime integers that are less than or equal to 23, and the product of the square-free factors of T is less than 210, then the procedure uses the fast Fourier transform developed by Cooley and Tukey (1965) and implemented by Singleton (1969). If T cannot be factored in this way, then the procedure uses a Chirp-Z algorithm similar to that proposed by Monro and Branch (1976).

Missing Values

Missing values are replaced with an estimate of the mean to perform spectral analyses. This treatment of a series with missing values is consistent with the approach used by Priestley (1981).

Singular Spectrum Analysis

Given a time series, y_t , for $t = 1, \dots, T$, and a window length, $2 \leq L < T/2$, singular spectrum analysis Golyandina, Nekrutkin, and Zhigljavsky (2001) decompose the time series into spectral groupings using the following steps:

Embedding Step

Using the time series, form a $K \times L$ trajectory matrix, \mathbf{X} , with elements

$$\mathbf{X} = \{x_{k,l}\}_{k=1,l=1}^{K,L}$$

such that $x_{k,l} = y_{k-l+1}$ for $k = 1, \dots, K$ and $l = 1, \dots, L$ and where $K = T - L + 1$. By definition $L \leq K < T$, because $2 \leq L < T/2$.

Decomposition Step

Using the trajectory matrix, \mathbf{X} , apply singular value decomposition to the trajectory matrix

$$\mathbf{X} = \mathbf{U}\mathbf{Q}\mathbf{V}$$

where \mathbf{U} represents the $K \times L$ matrix that contains the left-hand-side (LHS) eigenvectors, where \mathbf{Q} represents the diagonal $L \times L$ matrix that contains the singular values, and where \mathbf{V} represents the $L \times L$ matrix that contains the right-hand-side (RHS) eigenvectors.

Therefore,

$$\mathbf{X} = \sum_{l=1}^L \mathbf{X}^{(l)} = \sum_{l=1}^L \mathbf{u}_l q_l \mathbf{v}_l^T$$

where $\mathbf{X}^{(l)}$ represents the $K \times L$ principal component matrix, \mathbf{u}_l represents the $K \times 1$ left-hand-side (LHS) eigenvector, q_l represents the singular value, and \mathbf{v}_l represents the $L \times 1$ right-hand-side (RHS) eigenvector associated with the l th window index.

Grouping Step

For each group index, $m = 1, \dots, M$, define a group of window indices $I_m \subset \{1, \dots, L\}$. Let

$$\mathbf{X}_{I_m} = \sum_{l \in I_m} \mathbf{X}^{(l)} = \sum_{l \in I_m} \mathbf{u}_l q_l \mathbf{v}_l^T$$

represent the grouped trajectory matrix for group I_m . If groupings represent a spectral partition,

$$\bigcup_{m=1}^M I_m = \{1, \dots, L\} \quad \text{and} \quad I_m \cap I_n = \emptyset \quad \text{for} \quad m \neq n$$

then according to the singular value decomposition theory,

$$\mathbf{X} = \sum_{m=1}^M \mathbf{X}_{I_m}$$

Averaging Step

For each group index, $m = 1, \dots, M$, compute the diagonal average of \mathbf{X}_{I_m} ,

$$\tilde{x}_t^{(m)} = \frac{1}{n_t} \sum_{l=s_t}^{e_t} x_{t-l+1,l}^{(m)}$$

where

$$\begin{array}{llll} s_t = 1, & e_t = t, & n_t = t & \text{for} \quad 1 \leq t < L \\ s_t = 1, & e_t = L, & n_t = L & \text{for} \quad L \leq t \leq T - L + 1 \\ s_t = T - t - 1, & e_t = L, & n_t = T - t + 1 & \text{for} \quad T - L + 1 < t \leq T \end{array}$$

If the groupings represent a spectral partition, then by definition

$$y_t = \sum_{m=1}^M \tilde{x}_t^{(m)}$$

Hence, singular spectrum analysis additively decomposes the original time series, y_t , into m component series $\tilde{x}_t^{(m)}$ for $m = 1, \dots, M$.

Specifying the Window Length

You can explicitly specify the maximum window length, $2 \leq L \leq 1000$, using the LENGTH= option or implicitly specify the window length using the INTERVAL= option in the ID statement or the SEASONALITY= option in the PROC TIMESERIES statement.

Either way the window length is reduced based on the accumulated time series length, T , to enforce the requirement that $2 \leq L \leq T/2$.

Specifying the Groups

You can use the GROUPS= option to explicitly specify the composition and number of groups, $I_m \subset \{1, \dots, L\}$ or use the THRESHOLDPCT= option in the SSA statement to implicitly specify the grouping. The THRESHOLDPCT= option is useful for removing noise or less dominant patterns from the accumulated time series.

Let $0 < \alpha < 1$ be the cumulative percent singular value THRESHOLDPCT=. Then the last group, $I_M = \{l_\alpha, \dots, L\}$, is determined by the smallest value such that

$$\left(\sum_{l=1}^{l_\alpha-1} q_l / \sum_{l=1}^L q_l \right) \geq \alpha \quad \text{where } 1 < l_\alpha \leq L$$

Using this rule, the last group, I_M , describes the least dominant patterns in the time series and the size of the last group is at least one and is less than the window length, $L \geq 2$.

The magnitudes of the principal components which are plotted using the PLOT=SSA option and selected by the THRESHOLDPCT= option are based on the singular values which appear on the diagonal of \mathbf{Q} . Alternatively, each principal component's contribution to variation in the series can be quantified by using the squares of the singular values. The relative contributions of the principal components to variation in the series are included in the printed tabular output produced by the PRINT=SSA option.

Data Set Output

The TIMESERIES procedure can create the OUT=, OUTCORR=, OUTCROSSCORR=, OUTDECOMP=, OUTSEASON=, OUTSPECTRA=, OUTSSA=, OUTSUM=, and OUTTREND= data sets. In general, these data sets contain the variables listed in the BY statement. If an analysis step that is related to an output data step fails, the values of this step are not recorded or are set to missing in the related output data set and appropriate error and/or warning messages are recorded in the log.

OUT= Data Set

The OUT= data set contains the variables specified in the BY, ID, VAR, and CROSSVAR statements. If the ID statement is specified, the ID variable values are aligned and extended based on the ALIGN=

and INTERVAL= options. The values of the variables specified in the VAR and CROSSVAR statements are accumulated based on the ACCUMULATE= option, and missing values are interpreted based on the SETMISSING= option.

OUTCORR= Data Set

The OUTCORR= data set contains the variables specified in the BY statement as well as the variables listed below. The OUTCORR= data set records the correlations for each variable specified in a VAR statement (not the CROSSVAR statement).

When the CORR statement TRANSPOSE=NO option is omitted or specified explicitly, the variable *names* are related to correlation statistics specified in the CORR statement options and the variable *values* are related to the NLAG= or LAGS= option.

NAME	variable name
LAG	time lag
N	number of variance products
ACOV	autocovariances
ACF	autocorrelations
ACFSTD	autocorrelation standard errors
ACF2STD	an indicator of whether autocorrelations are less than (−1), greater than (1), or within (0) two standard errors of zero
ACFNORM	normalized autocorrelations
ACFPROB	autocorrelation probabilities
ACFLPROB	autocorrelation log probabilities
PACF	partial autocorrelations
PACFSTD	partial autocorrelation standard errors
PACF2STD	an indicator of whether partial autocorrelations are less than (−1), greater than (1), or within (0) two standard errors of zero
PACFNORM	partial normalized autocorrelations
PACFPROB	partial autocorrelation probabilities
PACFLPROB	partial autocorrelation log probabilities
IACF	inverse autocorrelations
IACFSTD	an indicator of whether inverse autocorrelations are less than (−1), greater than (1), or within (0) two standard errors of zero
IACF2STD	two standard errors beyond inverse autocorrelation
IACFNORM	normalized inverse autocorrelations
IACFPROB	inverse autocorrelation probabilities

IACFLPROB	inverse autocorrelation log probabilities
WN	white noise test Statistics
WNPROB	white noise test probabilities
WNLPROB	white noise test log probabilities

The preceding correlation statistics are computed for each specified time lag.

When the CORR statement TRANSPOSE=YES option is specified, the variable *values* are related to correlation statistics specified in the CORR statement and the variable *names* are related to the NLAG= or LAGS= options.

NAME	variable name
STAT	correlation statistic name
LABEL	correlation statistic label
LAG h	correlation statistics for lag h

OUTCROSSCORR= Data Set

The OUTCROSSCORR= data set contains the variables specified in the BY statement as well as the variables listed below. The OUTCROSSCORR= data set records the cross-correlations for each variable specified in a VAR and the CROSSVAR statements.

When the CROSSCORR statement TRANSPOSE=NO option is omitted or specified explicitly, the variable *names* are related to cross-correlation statistics specified in the CROSSCORR statement options and the variable *values* are related to the NLAG= or LAGS= option.

NAME	variable name
CROSS	cross variable name
LAG	time lag
N	number of variance products
CCOV	cross-covariances
CCF	cross-correlations
CCFSTD	cross-correlation standard errors
CCF2STD	an indicator of whether cross-correlations are less than (-1) , greater than (1) , or within (0) two standard errors of zero
CCFNORM	normalized cross-correlations
CCFPROB	cross-correlation probabilities
CCFLPROB	cross-correlation log probabilities

The preceding cross-correlation statistics are computed for each specified time lag.

When the CROSSCORR statement TRANSPOSE=YES option is specified, the variable *values* are related to cross-correlation statistics specified in the CROSSCORR statement and the variable *names* are related to the NLAG= or LAGS= options.

<code>_NAME_</code>	variable name
<code>_CROSS_</code>	cross variable name
<code>_STAT_</code>	cross-correlation statistic name
<code>_LABEL_</code>	cross-correlation statistic label
<code>LAGh</code>	cross-correlation statistics for lag <i>h</i>

OUTDECOMP= Data Set

The OUTDECOMP= data set contains the variables specified in the BY statement as well as the variables listed below. The OUTDECOMP= data set records the seasonal decomposition/adjustments for each variable specified in a VAR statement (not the CROSSVAR statement).

When the DECOMP statement TRANSPOSE=NO option is omitted or specified explicitly, the variable *names* are related to decomposition/adjustments specified in the DECOMP statement and the variable *values* are related to the ID statement INTERVAL= option and the PROC TIMESERIES statement SEASONALITY= option.

<code>_NAME_</code>	variable name
<code>_MODE_</code>	mode of decomposition
<code>_TIMEID_</code>	time ID values
<code>_SEASON_</code>	seasonal index
<code>ORIGINAL</code>	original series values
<code>TCC</code>	trend-cycle component
<code>SIC</code>	seasonal-irregular component
<code>SC</code>	seasonal component
<code>SCSTD</code>	seasonal component standard errors
<code>TCS</code>	trend-cycle-seasonal component
<code>IC</code>	irregular component
<code>SA</code>	seasonally adjusted series
<code>PCSA</code>	percent change seasonally adjusted series
<code>TC</code>	trend component
<code>CC</code>	cycle component

The preceding decomposition components are computed for each time period.

When the DECOMP statement TRANSPOSE=YES option is specified, the variable *values* are related to decomposition/adjustments specified in the DECOMP statement and the variable *names* are related to the ID statement INTERVAL= option, the PROC TIMESERIES statement SEASONALITY= option, and the DECOMP statement NPERIODS= option.

<code>_NAME_</code>	variable name
<code>_MODE_</code>	mode of decomposition name
<code>_COMP_</code>	decomposition component name
<code>_LABEL_</code>	decomposition component label
<code>PERIODt</code>	decomposition component value for time period t

OUTPROCINFO= Data Set

The OUTPROCINFO= data set contains information about the run of the TIMESERIES procedure. The following variables are present:

<code>_SOURCE_</code>	set to the name of the procedure, in this case TIMESERIES
<code>_NAME_</code>	name of the item being reported
<code>_LABEL_</code>	descriptive label for the item in <code>_NAME_</code>
<code>_STAGE_</code>	set to the current stage of the procedure; for TIMESERIES this is set to ALL
<code>_VALUE_</code>	value of the item specified in <code>_NAME_</code>

OUTSEASON= Data Set

The OUTSEASON= data set contains the variables specified in the BY statement as well as the variables listed below. The OUTSEASON= data set records the seasonal statistics for each variable specified in a VAR statement (not the CROSSVAR statement).

When the SEASON statement TRANSPOSE=NO option is omitted or specified explicitly, the variable *names* are related to seasonal statistics specified in the SEASON statement and the variable *values* are related to the ID statement INTERVAL= option or the PROC TIMESERIES statement SEASONALITY= option.

<code>_NAME_</code>	variable name
<code>_TIMEID_</code>	time ID values
<code>_SEASON_</code>	seasonal index
<code>NOBS</code>	number of observations

N	number of nonmissing observations
NMISS	number of missing observations
MINIMUM	minimum value
MAXIMUM	maximum value
RANGE	range value
SUM	summation value
MEAN	mean value
STDDEV	standard deviation
CSS	corrected sum of squares
USS	uncorrected sum of squares
MEDIAN	median value

The preceding statistics are computed for each season.

When the SEASON statement TRANSPOSE=YES option is specified, the variable *values* are related to seasonal statistics specified in the SEASON statement and the variable *names* are related to the ID statement INTERVAL= option or the PROC TIMESERIES statement SEASONALITY= option.

NAME	variable name
STAT	season statistic name
LABEL	season statistic name
SEASON s	season statistic value for season s

OUTSPECTRA= Data Set

The OUTSPECTRA= data set contains the variables that are specified in the BY statement in addition to the variables listed below. The OUTSPECTRA= data set records the frequency domain analysis for each variable specified in a VAR statement (not the CROSSVAR statement).

The following variable names are related to correlation statistics specified in the SPECTRA statement options.

NAME	variable name
FREQ	frequency in radians from 0 to π
PERIOD	period or wavelength
COS	cosine transform
SIN	sine transform
P	periodogram
S	spectral density estimates

OUTSSA= Data Set

The OUTSSA= data set contains the variables that are specified in the BY statement in addition to the variables listed below. The OUTSSA= data set records the singular spectrum analysis (SSA) for each variable specified in a VAR statement (not the CROSSVAR statement).

When the SSA statement TRANSPOSE=NO option is omitted or specified explicitly, the variable *names* are related to singular spectrum analysis specified in the SSA statement, and the variable *values* are related to the INTERVAL= option in the ID statement and the SEASONALITY= option in the PROC TIMESERIES statement.

NAME	variable name
TIMEID	time ID values
CYCLE	cycle index
SEASON	seasonal index
ORIGINAL	original series values
_GROUP i _	SSA result groups

The _GROUP i _ decomposition components are computed for each time period.

When the SSA statement TRANSPOSE=YES option is specified, the variable *values* are related to singular spectrum analysis specified in the SSA statement, and the variable *names* are related to the INTERVAL= option in the ID statement, the SEASONALITY= option in the PROC TIMESERIES statement, or the NPERIODS= option in the SSA statement. The following variables are written to a transposed OUTSSA= data set:

NAME	variable name
GROUP	group number
PERIOD t	SSA group value for time period t

OUTSUM= Data Set

The OUTSUM= data set contains the variables specified in the BY statement as well as the variables listed below. The OUTSUM= data set records the descriptive statistics for each variable specified in a VAR statement (not the CROSSVAR statement).

Variables related to descriptive statistics are based on the ACCUMULATE= and SETMISSING= options in the ID and VAR statements:

NAME	variable name
STATUS	status flag that indicates whether the requested analyses were successful
NOBS	number of observations

N	number of nonmissing observations
NMISS	number of missing observations
MINIMUM	minimum value
MAXIMUM	maximum value
AVG	average value
STDDEV	standard deviation

The OUTSUM= data set contains the descriptive statistics of the (accumulated) time series.

OUTTREND= Data Set

The OUTTREND= data set contains the variables specified in the BY statement as well as the variables listed below. The OUTTREND= data set records the trend statistics for each variable specified in a VAR statement (not the CROSSVAR statement).

When the TREND statement TRANSPOSE=NO option is omitted or explicitly specified, the variable *names* are related to trend statistics specified in the TREND statement and the variable *values* are related to the INTERVAL= option in the ID statement or the SEASONALITY= option in the PROC TIMESERIES statement.

NAME	variable name
TIMEID	time ID values
SEASON	seasonal index
NOBS	number of observations
N	number of nonmissing observations
NMISS	number of missing observations
MINIMUM	minimum value
MAXIMUM	maximum value
RANGE	range value
SUM	summation value
MEAN	mean value
STDDEV	standard deviation
CSS	corrected sum of squares
USS	uncorrected sum of squares
MEDIAN	median value

The preceding statistics are computed for each time period.

When the TREND statement TRANSPOSE=YES option is specified, the variable *values* related to trend statistics specified in the TREND statement and the variable *names* are related to the INTERVAL= option in

the ID statement, the SEASONALITY= option in the PROC TIMESERIES statement, or the NPERIODS= option in the TREND statement. The following variables are written to the OUTTREND= data set:

<code>_NAME_</code>	variable name
<code>_STAT_</code>	trend statistic name
<code>_LABEL_</code>	trend statistic name
<code>PERIODt</code>	trend statistic value for time period t

`_STATUS_` Variable Values

The `_STATUS_` variable that appears in the OUTSUM= data set contains a code that specifies whether the analysis has been successful or not. The `_STATUS_` variable can take the following values:

0	success
1000	transactional trend statistics failure
2000	transactional seasonal statistics failure
3000	accumulation failure
4000	missing value interpretation failure
6000	series is all missing
7000	transformation failure
8000	differencing failure
9000	unable to compute descriptive statistics
10000	seasonal decomposition failure
11000	correlation analysis failure
15000	singular spectrum analysis failure
16000	spectral analysis failure

Printed Output

The TIMESERIES procedure optionally produces printed output by using the Output Delivery System (ODS). By default, the procedure produces no printed output. All output is controlled by the PRINT= and PRINTDETAILS options associated with the PROC TIMESERIES statement. In general, if an analysis step related to printed output fails, the values of this step are not printed and appropriate error or warning messages or both are recorded in the log. The printed output is similar to the output data set, and these similarities are described below.

`PRINT=DECOMP` prints the seasonal decomposition similar to the OUTDECOMP= data set.

PRINT=DESCSTATS	prints a table of descriptive statistics for each variable.
PRINT=SEASONS	prints the seasonal statistics similar to the OUTSEASON= data set.
PRINT=SSA	prints the singular spectrum analysis similar to the OUTSSA= data set.
PRINT=SUMMARY	prints the summary statistics similar to the OUTSUM= data set.
PRINT=TRENDS	prints the trend statistics similar to the OUTTREND= data set.
PRINTDETAILS	prints each table with greater detail.

If PRINT=SEASONS and the PRINTDETAILS options are both specified, all seasonal statistics are printed.

ODS Table Names

Table 32.4 relates the PRINT= options to ODS tables:

Table 32.4 ODS Tables Produced in PROC TIMESERIES

ODS Table Name	Description	Statement	Option
SeasonalDecomposition	Seasonal decomposition	PRINT	DECOMP
DescStats	Descriptive statistics	PRINT	DESCSTATS
GlobalStatistics	Global statistics	PRINT	SEASONS
SeasonStatistics	Season statistics	PRINT	SEASONS
StatisticsSummary	Statistics summary	PRINT	SUMMARY
TrendStatistics	Trend statistics	PRINT	TRENDS
GlobalStatistics	Global statistics	PRINT	TRENDS
SSASingularValues	SSA singular values	PRINT	SSA
SSAResults	SSA results	PRINT	SSA

The tables are related to a single series within a BY group.

ODS Graphics Names

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#)” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the graphical output produced by the TIMESERIES procedure. PROC TIMESERIES assigns a name to each graph it creates. These names are listed in [Table 32.5](#).

Table 32.5 ODS Graphics Produced by PROC TIMESERIES

ODS Graph Name	Plot Description	Statement	Option
ACFPlot	Autocorrelation function	PLOTS	ACF
ACFNORMPlot	Normalized autocorrelation function	PLOTS	ACF
CCFNORMPlot	Normalized cross-correlation function	CROSSPLOTS	CCF
CCFPlot	Cross-correlation function	CROSSPLOTS	CCF

Examples: TIMESERIES Procedure

Example 32.1: Accumulating Transactional Data into Time Series Data

This example illustrates using the TIMESERIES procedure to accumulate time-stamped transactional data that has been recorded at no particular frequency into time series data at a specific frequency. After the time series is created, the various SAS/ETS procedures related to time series analysis, seasonal adjustment/decomposition, modeling, and forecasting can be used to further analyze the time series data.

Suppose that the input data set WORK.RETAIL contains variables STORE and TIMESTAMP and numerous other numeric transaction variables. The BY variable STORE contains values that break up the transactions into groups (BY groups). The time ID variable TIMESTAMP contains SAS date values recorded at no particular frequency. The other data set variables contain the numeric transaction values to be analyzed. It is further assumed that the input data set is sorted by the variables STORE and TIMESTAMP. The following statements form monthly time series from the transactional data based on the median value (AC-CUMULATE=MEDIAN) of the transactions recorded with each time period. Also, the accumulated time series values for time periods with no transactions are set to zero instead of to missing (SETMISS=0) and only transactions recorded between the first day of 1998 (START='01JAN1998'D) and last day of 2000 (END='31JAN2000'D) are considered and, if needed, extended to include this range.

```
proc timeseries data=retail out=mseries;
  by store;
  id timestamp interval=month
    accumulate=median
```

```

        setmiss=0
        start='01jan1998'd
        end   ='31dec2000'd;
    var item1-item8;
run;

```

The monthly time series data are stored in the data WORK.MSERIES. Each BY group associated with the BY variable STORE contains an observation for each of the 36 months associated with the years 1998, 1999, and 2000. Each observation contains the variable STORE, TIMESTAMP, and each of the analysis variables in the input data set.

After each set of transactions has been accumulated to form corresponding time series, accumulated time series can be analyzed using various time series analysis techniques. For example, exponentially weighted moving averages can be used to smooth each series. The following statements use the EXPAND procedure to smooth the analysis variable named STOREITEM.

```

proc expand data=mseries out=smoothed from=month;
    by store;
    id date;
    convert storeitem=smooth / transform=(ewma 0.1);
run;

```

The smoothed series are stored in the data set WORK.SMOOTHED. The variable SMOOTH contains the smoothed series.

If the time ID variable TIMESTAMP contains SAS datetime values instead of SAS date values, the INTERVAL=, START=, and END= options must be changed accordingly and the following statements could be used:

```

proc timeseries data=retail out=tseries;
    by store;
    id timestamp interval=dtmonth
        accumulate=median
        setmiss=0
        start='01jan1998:00:00:00'dt
        end   ='31dec2000:00:00:00'dt;
    var _numeric_;
run;

```

The monthly time series data are stored in the data WORK.TSERIES, and the time ID values use a SAS datetime representation.

Example 32.2: Trend and Seasonal Analysis

This example illustrates using the TIMESERIES procedure for trend and seasonal analysis of time-stamped transactional data.

Suppose that the data set SASHELP.AIR contains two variables: DATE and AIR. The variable DATE contains sorted SAS date values recorded at no particular frequency. The variable AIR contains the transaction values to be analyzed.

The following statements accumulate the transactional data on an average basis to form a quarterly time series and perform trend and seasonal analysis on the transactions.

```
proc timeseries data=sashelp.air
    out=series
    outtrend=trend
    outseason=season print=seasons;
    id date interval=qtr accumulate=avg;
    var air;
run;
```

The time series is stored in the data set WORK.SERIES, the trend statistics are stored in the data set WORK.TREND, and the seasonal statistics are stored in the data set WORK.SEASON. Additionally, the seasonal statistics are printed (PRINT=SEASONS) and the results of the seasonal analysis are shown in [Output 32.2.1](#).

Output 32.2.1 Seasonal Statistics Table

The TIMESERIES Procedure						
Season Statistics for Variable AIR						
Season Index	N	Minimum	Maximum	Sum	Mean	Standard Deviation
1	36	112.0000	419.0000	8963.00	248.9722	95.65189
2	36	121.0000	535.0000	10207.00	283.5278	117.61839
3	36	136.0000	622.0000	12058.00	334.9444	143.97935
4	36	104.0000	461.0000	9135.00	253.7500	101.34732

Using the trend statistics stored in the WORK.TREND data set, the following statements plot various trend statistics associated with each time period over time.

```
title1 "Trend Statistics";
proc sgplot data=trend;
    series x=date y=max / lineattrs=(pattern=solid);
    series x=date y=mean / lineattrs=(pattern=solid);
    series x=date y=min / lineattrs=(pattern=solid);
    yaxis display=(nolabel);
    format date year4.;
run;
```

The results of this trend analysis are shown in [Output 32.2.2](#).

Output 32.2.2 Trend Statistics Plot

Using the trend statistics stored in the WORK.TREND data set, the following statements chart the sum of the transactions associated with each time period for the second season over time.

```

title1 "Trend Statistics for 2nd Season";
proc sgplot data=trend;
  where _season_ = 2;
  vbar date / freq=sum;
  format date year4.;
  yaxis label='Sum';
run;

```

The results of this trend analysis are shown in [Output 32.2.3](#).

Output 32.2.3 Trend Statistics Bar Chart

Using the trend statistics stored in the WORK.TREND data set, the following statements plot the mean of the transactions associated with each time period by each year over time.

```
data trend;
  set trend;
  year = year(date);
run;

title1 "Trend Statistics by Year";
proc sgplot data=trend;
  series x=_season_ y=mean / group=year lineattrs=(pattern=solid);
  xaxis values=(1 to 4 by 1);
run;
```

The results of this trend analysis are shown in [Output 32.2.4](#).

Output 32.2.4 Trend Statistics

Using the season statistics stored in the WORK.SEASON data set, the following statements plot various season statistics for each season.

```

title1 "Seasonal Statistics";
proc sgplot data=season;
  series x=_season_ y=max / lineattrs=(pattern=solid);
  series x=_season_ y=mean / lineattrs=(pattern=solid);
  series x=_season_ y=min / lineattrs=(pattern=solid);
  yaxis display=(nolabel);
  xaxis values=(1 to 4 by 1);
run;

```

The results of this seasonal analysis are shown in [Output 32.2.5](#).

Output 32.2.5 Seasonal Statistics Plot**Example 32.3: Illustration of ODS Graphics**

This example illustrates the use of ODS graphics.

The following statements use the SASHELP.WORKERS data set to study the time series of electrical workers and its interaction with the simply differenced series of masonry workers. The series plot, the correlation panel, the seasonal adjustment panel, and all cross-series plots are requested. [Output 32.3.1](#) through [Output 32.3.4](#) show a selection of the plots created.

The graphical displays are requested by specifying the [PLOTS=](#) or [CROSSPLOTS=](#) options in the PROC TIMESERIES statement. For information about the graphics available in the TIMESERIES procedure, see the section “[ODS Graphics Names](#)” on page 2072.

```
title "Illustration of ODS Graphics";
proc timeseries data=sashelp.workers out=_null_
               plots=(series corr decomp)
               crossplots=all;
  id date interval=month;
```

```
var electric;  
crossvar masonry / dif=(1);  
run;
```

Output 32.3.1 Series Plot

Output 32.3.2 Correlation Panel

Output 32.3.3 Seasonal Decomposition Panel

Output 32.3.4 Cross-Correlation Plot

Example 32.4: Illustration of Spectral Analysis

This example illustrates the use of spectral analysis.

The following statements perform a spectral analysis on the SUNSPOT dataset. The periodogram is displayed as a function of the period and frequency in [Output 32.4.1](#). The estimated spectral density together with its 50% confidence limits are displayed in [Output 32.4.2](#).

```
title "Wolfer's Sunspot Data";

proc timeseries data=sunspot plot=(series periodogram spectrum);
  var wolfer;
  id year interval=year;
  spectra freq period p s / adjmean bart c=1.5 expon=0.2;
run;
```

Output 32.4.1 Periodogram

Output 32.4.2 Spectral Density Plot**Example 32.5: Illustration of Singular Spectrum Analysis**

This example illustrates the use of singular spectrum analysis.

The following statements extract two additive components from the SASHELP.AIR time series by using the THRESHOLDPCT= option to specify that the first component represent 80% of the variability in the series. The resulting groupings, consisting of the first three and remaining nine singular value components, are presented in [Output 32.5.1](#) through [Output 32.5.3](#).

```
title "SSA of AIR data";

proc timeseries data=sashelp.air plot=ssa;
  id date interval=month;
  var air;
  ssa / length=12 THRESHOLDPCT=80;
run;
```

Output 32.5.1 Singular Value Grouping #1 Plot

Output 32.5.2 Singular Value Grouping #2 Plot

Output 32.5.3 Singular Value Components Plot

Overview: The TSCSREG Procedure

The TSCSREG (time series cross section regression) procedure analyzes a class of linear econometric models that commonly arise when time series and cross-sectional data are combined. The TSCSREG procedure deals with panel data sets that consist of time series observations on each of several cross-sectional units.

The TSCSREG procedure is very similar to the PANEL procedure; for full description, syntax details, models, and estimation methods, see Chapter 20, “[The PANEL Procedure](#).” The TSCSREG procedure is no longer being updated, and it shares the code base with the PANEL procedure.

The original TSCSREG procedure was developed by Douglas J. Drummond and A. Ronald Gallant, and contributed to the Version 5 SUGI Supplemental Library in 1979. The original code was changed substantially over the years. Additional new methods as well as other new features are currently included in the PANEL PROCEDURE. SAS Institute would like to thank Dr. Drummond and Dr. Gallant for their contribution of the original version of the TSCSREG procedure.

Getting Started: The TSCSREG Procedure

Specifying the Input Data

The input data set used by the TSCSREG procedure must be sorted by cross section and by time within each cross section. Therefore, the first step in using PROC TSCSREG is to make sure that the input data set is sorted. Normally, the input data set contains a variable that identifies the cross section for each observation and a variable that identifies the time period for each observation.

To illustrate, suppose that you have a data set A that contains data over time for each of several states. You want to regress the variable Y on regressors X1 and X2. Cross sections are identified by the variable STATE, and time periods are identified by the variable DATE. The following statements sort the data set A appropriately:

```
proc sort data=a;  
    by state date;  
run;
```

The next step is to invoke the TSCSREG procedure and specify the cross section and time series variables in an ID statement. List the variables in the ID statement exactly as they are listed in the BY statement.

```
proc tscsreg data=a;  
    id state date;
```

Alternatively, you can omit the ID statement and use the CS= and TS= options on the PROC TSCSREG statement to specify the number of cross sections in the data set and the number of time series observations in each cross section.

Unbalanced Data

In the case of fixed-effects and random-effects models, the TSCSREG procedure is capable of processing data with different numbers of time series observations across different cross sections. You must specify the ID statement to estimate models that use unbalanced data. The missing time series observations are recognized by the absence of time series ID variable values in some of the cross sections in the input data set. Moreover, if an observation with a particular time series ID value and cross-sectional ID value is present in the input data set, but one or more of the model variables are missing, that time series point is treated as missing for that cross section.

Specifying the Regression Model

Next, specify the linear regression model with a MODEL statement, as shown in the following statements.

```
proc tscsreg data=a;
  id state date;
  model y = x1 x2;
run;
```

The MODEL statement in PROC TSCSREG is specified like the MODEL statement in other SAS regression procedures: the dependent variable is listed first, followed by an equal sign, followed by the list of regressor variables.

The reason for using PROC TSCSREG instead of other SAS regression procedures is that you can incorporate a model for the structure of the random errors. It is important to consider what kind of error structure model is appropriate for your data and to specify the corresponding option in the MODEL statement.

The error structure options supported by the TSCSREG procedure are FIXONE, FIXTWO, RANONE, RANTWO, FULLER, PARKS, and DASILVA. See “[Details: The TSCSREG Procedure](#)” on page 2102 for more information about these methods and the error structures they assume.

By default, the two-way random-effects error model structure is used while Fuller-Battese and Wansbeek-Kapteyn methods are used for the estimation of variance components in balanced data and unbalanced data, respectively. Thus, the preceding example is the same as specifying the RANTWO option, as shown in the following statements:

```
proc tscsreg data=a;
  id state date;
  model y = x1 x2 / rantwo;
run;
```

You can specify more than one error structure option in the MODEL statement; the analysis is repeated using each method specified. You can use any number of MODEL statements to estimate different regression models or estimate the same model by using different options.

In order to aid in model specification within this class of models, the procedure provides two specification test statistics. The first is an F statistic that tests the null hypothesis that the fixed-effects parameters are all zero. The second is a Hausman m -statistic that provides information about the appropriateness of the random-effects specification. It is based on the idea that, under the null hypothesis of no correlation between the effects variables and the regressors, OLS and GLS are consistent, but OLS is inefficient. Hence, a test can be based on the result that the covariance of an efficient estimator with its difference from an inefficient estimator is zero. Rejection of the null hypothesis might suggest that the fixed-effects model is more appropriate.

The procedure also provides the Buse R-square measure, which is the most appropriate goodness-of-fit measure for models estimated by using GLS. This number is interpreted as a measure of the proportion of the transformed sum of squares of the dependent variable that is attributable to the influence of the

independent variables. In the case of OLS estimation, the Buse R-square measure is equivalent to the usual R-square measure.

Estimation Techniques

If the effects are fixed, the models are essentially regression models with dummy variables that correspond to the specified effects. For fixed-effects models, ordinary least squares (OLS) estimation is equivalent to best linear unbiased estimation.

The output from TSCSREG is identical to what one would obtain from creating dummy variables to represent the cross-sectional and time (fixed) effects. The output is presented in this manner to facilitate comparisons to the least squares dummy variables estimator (LSDV). As such, the inclusion of a intercept term implies that one dummy variable must be dropped. The actual estimation of the fixed-effects models is not LSDV. LSDV is much too cumbersome to implement. Instead, TSCSREG operates in a two step fashion. In the first step, the following occurs:

- *One-way fixed-effects model:* In the one-way fixed-effects model, the data is transformed by removing the cross-sectional means from the dependent and independent variables. The following is true:

$$\tilde{y}_{it} = y_{it} - \bar{y}_{i\cdot}$$

$$\tilde{\mathbf{x}}_{it} = \mathbf{x}_{it} - \bar{\mathbf{x}}_{i\cdot}$$

- *Two-way fixed-effects model:* In the two-way fixed-effects model, the data is transformed by removing the cross-sectional and time means and adding back the overall means:

$$\tilde{y}_{it} = y_{it} - \bar{y}_{i\cdot} - \bar{y}_{\cdot t} + \bar{\bar{y}}$$

$$\tilde{\mathbf{x}}_{it} = \mathbf{x}_{it} - \bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{\cdot t} + \bar{\bar{\mathbf{x}}}$$

where the symbols:

y_{it} and \mathbf{x}_{it} are the dependent variable (a scalar) and the explanatory variables (a vector whose columns are the explanatory variables not including a constant), respectively

$\bar{y}_{i\cdot}$ and $\bar{\mathbf{x}}_{i\cdot}$ are cross section means

$\bar{y}_{\cdot t}$ and $\bar{\mathbf{x}}_{\cdot t}$ are time means

$\bar{\bar{y}}$ and $\bar{\bar{\mathbf{x}}}$ are the overall means

The second step consists of running OLS on the properly demeaned series, provided that the data are balanced. The unbalanced case is slightly more difficult, because the structure of the missing data must be retained. For this case, PROC TSCSREG uses a slight specialization on Wansbeek and Kapteyn.

The other alternative is to assume that the effects are random. In the one-way case, $E(v_i) = 0$, $E(v_i^2) = \sigma_v^2$, and $E(v_i v_j) = 0$ for $i \neq j$, and v_i is uncorrelated with ϵ_{it} for all i and t . In the two-way case, in addition to all of the preceding, $E(e_t) = 0$, $E(e_t^2) = \sigma_e^2$, and $E(e_t e_s) = 0$ for $t \neq s$, and the e_t are uncorrelated with

the v_i and the ϵ_{it} for all i and t . Thus, the model is a variance components model, with the variance components σ_v^2 , σ_e^2 , and σ_ϵ^2 , to be estimated. A crucial implication of such a specification is that the effects are independent of the regressors. For random-effects models, the estimation method is an estimated generalized least squares (EGLS) procedure that involves estimating the variance components in the first stage and using the estimated variance covariance matrix thus obtained to apply generalized least squares (GLS) to the data.

Introductory Example

The following example uses the cost function data from Greene (1990) to estimate the variance components model. The variable OUTPUT is the log of output in millions of kilowatt-hours, and COST is the log of cost in millions of dollars. Refer to Greene (1990) for details.

```

title1;
data greene;
    input firm year output cost @@;
    df1 = firm = 1;
    df2 = firm = 2;
    df3 = firm = 3;
    df4 = firm = 4;
    df5 = firm = 5;
    d60 = year = 1960;
    d65 = year = 1965;
    d70 = year = 1970;
datalines;

... more lines ...

```

Usually you cannot explicitly specify all the explanatory variables that affect the dependent variable. The omitted or unobservable variables are summarized in the error disturbances. The TSCSREG procedure used with the RANTWO option specifies the two-way random-effects error model where the variance components are estimated by the Fuller-Battese method, because the data are balanced and the parameters are efficiently estimated by using the GLS method. The variance components model used by the Fuller-Battese method is

$$y_{it} = \sum_{k=1}^K X_{itk} \beta_k + v_i + e_t + \epsilon_{it} \quad i = 1, \dots, N; t = 1, \dots, T$$

The following statements fit this model.

```

proc sort data=greene;
    by firm year;
run;

proc tscsreg data=greene;
    model cost = output / rantwo;
    id firm year;

```

```
run;
```

The TSCSREG procedure output is shown in Figure 33.1. A model description is printed first; it reports the estimation method used and the number of cross sections and time periods. The variance components estimates are printed next. Finally, the table of regression parameter estimates shows the estimates, standard errors, and t tests.

Syntax: The TSCSREG Procedure

The following statements are used with the TSCSREG procedure.

```
PROC TSCSREG options ;
  BY variables ;
  ID cross-section-id-variable time-series-id-variable ;
  MODEL dependent = regressor-variables / options ;
  TEST equation1 < ,equation2... > ;
```

Functional Summary

The statements and options used with the TSCSREG procedure are summarized in the following table.

Table 33.1 Functional Summary

Description	Statement	Option
Data Set Options		
specify the input data set	TSCSREG	DATA=
write parameter estimates to an output data set	TSCSREG	OUTEST=
include correlations in the OUTEST= data set	TSCSREG	CORROUT
include covariances in the OUTEST= data set	TSCSREG	COVOUT
specify number of time series observations	TSCSREG	TS=
specify number of cross sections	TSCSREG	CS=
Declaring the Role of Variables		
specify BY-group processing	BY	
specify the cross section and time ID variables	ID	
Printing Control Options		
print correlations of the estimates	MODEL	CORRB
print covariances of the estimates	MODEL	COVB
suppress printed output	MODEL	NOPRINT
perform tests of linear hypotheses	TEST	
Model Estimation Options		
specify the one-way fixed-effects model	MODEL	FIXONE
specify the two-way fixed-effects model	MODEL	FIXTWO
specify the one-way random-effects model	MODEL	RANONE
specify the two-way random-effects model	MODEL	RANTWO
specify Fuller-Battese method	MODEL	FULLER
specify PARKS	MODEL	PARKS
specify Da Silva method	MODEL	DASILVA

Description	Statement	Option
specify order of the moving-average error process for Da Silva method	MODEL	M=
print Φ matrix for Parks method	MODEL	PHI
print autocorrelation coefficients for Parks method	MODEL	RHO
suppress the intercept term	MODEL	NOINT
control check for singularity	MODEL	SINGULAR=

PROC TSCSREG Statement

PROC TSCSREG *options* ;

The following options can be specified in the PROC TSCSREG statement.

DATA=SAS-data-set

names the input data set. The input data set must be sorted by cross section and by time period within cross section. If you omit the DATA= option, the most recently created SAS data set is used.

TS=number

specifies the number of observations in the time series for each cross section. The TS= option value must be greater than 1. The TS= option is required unless an ID statement is used. Note that the number of observations for each time series must be the same for each cross section and must cover the same time period.

CS=number

specifies the number of cross sections. The CS= option value must be greater than 1. The CS= option is required unless an ID statement is used.

OUTEST=SAS-data-set

the parameter estimates. When the OUTEST= option is not specified, the OUTEST= data set is not created.

OUTCOV

COVOUT

writes the covariance matrix of the parameter estimates to the OUTEST= data set.

OUTCORR

CORROUT

writes the correlation matrix of the parameter estimates to the OUTEST= data set.

In addition, any of the following MODEL statement options can be specified in the PROC TSCSREG statement: CORRB, COVB, FIXONE, FIXTWO, RANONE, RANTWO, FULLER, PARKS, DASILVA, NOINT, NOPRINT, M=, PHI, RHO, and SINGULAR=. When specified in the PROC

TSCSREG statement, these options are equivalent to specifying the options for every MODEL statement.

BY Statement

BY *variables* ;

A BY statement can be used with PROC TSCSREG to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the input data set must be sorted by the BY variables as well as by cross section and time period within the BY groups.

When both an ID statement and a BY statement are specified, the input data set must be sorted first with respect to BY variables and then with respect to the cross section and time series ID variables. For example,

```
proc sort data=a;
    by byvar1 byvar2 csid tsid;
run;

proc tscsreg data=a;
    by byvar1 byvar2;
    id csid tsid;
    ...
run;
```

When both a BY statement and an ID statement are used, the data set might have a different number of cross sections or a different number of time periods in each BY group. If no ID statement is used, the CS= N and TS= T options must be specified and each BY group must contain $N \times T$ observations.

ID Statement

ID *cross-section-id-variable time-series-id-variable* ;

The ID statement is used to specify variables in the input data set that identify the cross section and time period for each observation.

When an ID statement is used, the TSCSREG procedure verifies that the input data set is sorted by the cross section ID variable and by the time series ID variable within each cross section. The TSCSREG procedure also verifies that the time series ID values are the same for all cross sections.

To make sure the input data set is correctly sorted, use PROC SORT with a BY statement with the variables listed exactly as they are listed in the ID statement to sort the input data set. For example,

```
proc sort data=a;
    by csid tsid;
run;
```

```
proc tscsreg data=a;
    id csid tsid;
    ... etc. ...
run;
```

If the ID statement is not used, the TS= and CS= options must be specified on the PROC TSCSREG statement. Note that the input data must be sorted by time within cross section, regardless of whether the cross section structure is given by an ID statement or by the options TS= and CS=.

If an ID statement is specified, the time series length T is set to the minimum number of observations for any cross section, and only the first T observations in each cross section are used. If both the ID statement and the TS= and CS= options are specified, the TS= and CS= options are ignored.

MODEL Statement

MODEL *response = regressors / options ;*

The MODEL statement specifies the regression model and the error structure assumed for the regression residuals. The response variable on the left side of the equal sign is regressed on the independent variables listed after the equal sign. Any number of MODEL statements can be used. For each model statement, only one response variable can be specified on the left side of the equal sign.

The error structure is specified by the FIXONE, FIXTWO, RANONE, RANTWO, FULLER, PARKS, and DASILVA options. More than one of these options can be used, in which case the analysis is repeated for each error structure model specified.

Models can be given labels up to 32 characters in length. Model labels are used in the printed output to identify the results for different models. If no label is specified, the response variable name is used as the label for the model. The model label is specified as follows:

label: **MODEL** *response = regressors / options ;*

The following options can be specified on the MODEL statement after a slash (/).

CORRB

CORR

prints the matrix of estimated correlations between the parameter estimates.

COVB

VAR

prints the matrix of estimated covariances between the parameter estimates.

FIXONE

specifies that a one-way fixed-effects model be estimated with the one-way model that corresponds to group effects only.

FIXTWO

specifies that a two-way fixed-effects model be estimated.

RANONE

specifies that a one-way random-effects model be estimated.

RANTWO

specifies that a two-way random-effects model be estimated.

FULLER

specifies that the model be estimated by using the Fuller-Battese method, which assumes a variance components model for the error structure.

PARKS

specifies that the model be estimated by using the Parks method, which assumes a first-order autoregressive model for the error structure.

DASILVA

specifies that the model be estimated by using the Da Silva method, which assumes a mixed variance-component moving-average model for the error structure.

M=number

specifies the order of the moving-average process in the Da Silva method. The M= value must be less than $T - 1$. The default is M=1.

PHI

prints the Φ matrix of estimated covariances of the observations for the Parks method. The PHI option is relevant only when the PARKS option is used.

RHO

prints the estimated autocorrelation coefficients for the Parks method.

NOINT**NOMEAN**

suppresses the intercept parameter from the model.

NOPRINT

suppresses the normal printed output.

SINGULAR=number

specifies a singularity criterion for the inversion of the matrix. The default depends on the precision of the computer system.

TEST Statement

TEST *equation* < , *equation* ... > < / *options* > ;

The TEST statement performs F tests of linear hypotheses about the regression parameters in the preceding MODEL statement. Each equation specifies a linear hypothesis to be tested. All hypotheses in one TEST statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding

MODEL statement, and each name represents the coefficient of the corresponding regressor. The keyword INTERCEPT refers to the coefficient of the intercept.

The following statements illustrate the use of the TEST statement:

```
proc tscsreg;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0;
  test_int: test intercept=0, x3 = 0;
```

Note that a test of the following form is not permitted:

```
test_bad: test x2 / 2 + 2 * x3 = 0;
```

Do not use the division sign in test/restrict statements.

Details: The TSCSREG Procedure

Models, estimators, and methods are covered in detail in Chapter 20, “The PANEL Procedure.”

ODS Table Names

PROC TSCSREG assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 33.2 ODS Tables Produced in PROC TSCSREG

ODS Table Name	Description	Option
ODS Tables Created by the MODEL Statement		
ModelDescription	Model description	default
FitStatistics	Fit statistics	default
FixedEffectsTest	<i>F</i> test for no fixed effects	FIXONE, FIXTWO, RANONE, RANTWO
ParameterEstimates	Parameter estimates	default
CovB	Covariance of parameter estimates	COVB
CorrB	Correlations of parameter estimates	CORRB

Table 33.2 continued

ODS Table Name	Description	Option
VarianceComponents	Variance component estimates	FULLER, DASILVA, M=, RANONE, RANTWO
RandomEffectsTest	Hausman test for random effects	FULLER, DASILVA, M=, RANONE, RANTWO
AR1Estimates	First order autoregressive parameter estimates	PARKS, RHO
EstimatedPhiMatrix	Estimated phi matrix	PARKS
EstimatedAutocovariances	Estimates of autocovariances	DASILVA, M=
ODS Tables Created by the TEST Statement		
TestResults	Test results

Overview: UCM Procedure

The UCM procedure analyzes and forecasts equally spaced univariate time series data by using an unobserved components model (UCM). The UCMs are also called *structural models* in the time series literature. A UCM decomposes the response series into components such as trend, seasonals, cycles, and the regression effects due to predictor series. The components in the model are supposed to capture the salient features of the series that are useful in explaining and predicting its behavior. Harvey (1989) is a good reference for time series modeling that uses the UCMs. Harvey calls the components in a UCM the “stylized facts” about the series under consideration. Traditionally, the ARIMA models and, to some limited extent, the exponential smoothing models have been the main tools in the analysis of this type of time series data. It is fair to say that the UCMs capture the versatility of the ARIMA models while possessing the interpretability of the smoothing models. A thorough discussion of the correspondence between the ARIMA models and the UCMs, and the relative merits of UCM and ARIMA modeling, is given in Harvey (1989). The UCMs are also very similar to another set of models, called the *dynamic models*, that are popular in the Bayesian time series literature (West and Harrison 1999). In SAS/ETS you can use PROC ARIMA for ARIMA modeling (see Chapter 7, “[The ARIMA Procedure](#)”), PROC ESM for exponential smoothing modeling (see Chapter 14, “[The ESM Procedure](#)”), and use the Time Series Forecasting System for a point-and-click interface to ARIMA and exponential smoothing modeling.

You can use the UCM procedure to fit a wide range of UCMs that can incorporate complex trend, seasonal, and cyclical patterns and can include multiple predictors. It provides a variety of diagnostic tools to assess the fitted model and to suggest the possible extensions or modifications. The components in the UCM provide a succinct description of the underlying mechanism governing the series. You can print, save, or plot the estimates of these component series. Along with the standard forecast and residual plots, the study of these component plots is an essential part of time series analysis using the UCMs. Once a suitable UCM is found for the series under consideration, it can be used for a variety of purposes. For example, it can be used for the following:

- forecasting the values of the response series and the component series in the model
- obtaining a model-based seasonal decomposition of the series
- obtaining a “denoised” version and interpolating the missing values of the response series in the historical period
- obtaining the full sample or “smoothed” estimates of the component series in the model

Getting Started: UCM Procedure

The analysis of time series using the UCMs involves recognizing the salient features present in the series and modeling them suitably. The UCM procedure provides a variety of models for estimating and forecasting the commonly observed features in time series. These models are discussed in detail later in the section “[An Introduction to Unobserved Component Models](#)” on page 2144. First the procedure is illustrated using an example.

A Seasonal Series with Linear Trend

The airline passenger series, given as Series G in Box and Jenkins (1976), is often used in time series literature as an example of a nonstationary seasonal time series. This series is a monthly series consisting of the number of airline passengers who traveled during the years 1949 to 1960. Its main features are a steady rise in the number of passengers from year to year and the seasonal variation in the numbers during any given year. It also exhibits an increase in variability around the trend. A log transformation is used to stabilize this variability. The following DATA step prepares the log-transformed passenger series analyzed in this example:

```
data seriesG;
    set sashelp.air;
    logair = log( air );
run;
```

The following statements produce a time series plot of the series by using the TIMESERIES procedure (see Chapter 32, “[The TIMESERIES Procedure](#)”). The trend and seasonal features of the series are apparent in the plot in [Figure 34.1](#).

```
proc timeseries data=seriesG plot=series;
    id date interval=month;
    var logair;
run;
```

Figure 34.1 Series Plot of Log-Transformed Airline Passenger Series

In this example this series is modeled using an unobserved component model called the basic structural model (BSM). The BSM models a time series as a sum of three stochastic components: a trend component μ_t , a seasonal component γ_t , and random error ϵ_t . Formally, a BSM for a response series y_t can be described as

$$y_t = \mu_t + \gamma_t + \epsilon_t$$

Each of the stochastic components in the model is modeled separately. The random error ϵ_t , also called the *irregular component*, is modeled simply as a sequence of independent, identically distributed (i.i.d.) zero-mean Gaussian random variables. The trend and the seasonal components can be modeled in a few different ways. The model for trend used here is called a *locally linear time trend*. This trend model can be written as follows:

$$\begin{aligned}\mu_t &= \mu_{t-1} + \beta_{t-1} + \eta_t, & \eta_t &\sim i.i.d. N(0, \sigma_\eta^2) \\ \beta_t &= \beta_{t-1} + \xi_t, & \xi_t &\sim i.i.d. N(0, \sigma_\xi^2)\end{aligned}$$

These equations specify a trend where the level μ_t as well as the slope β_t is allowed to vary over time. This variation in slope and level is governed by the variances of the disturbance terms η_t and ξ_t in their respective

equations. Some interesting special cases of this model arise when you manipulate these disturbance variances. For example, if the variance of ξ_t is zero, the slope will be constant (equal to β_0); if the variance of η_t is also zero, μ_t will be a deterministic trend given by the line $\mu_0 + \beta_0 t$. The seasonal model used in this example is called a trigonometric seasonal. The stochastic equations governing a trigonometric seasonal are explained later (see the section “[Modeling Seasons](#)” on page 2146). However, it is interesting to note here that this seasonal model reduces to the familiar regression with deterministic seasonal dummies if the variance of the disturbance terms in its equations is equal to zero. The following statements specify a BSM with these three components:

```
proc ucm data=seriesG;
  id date interval=month;
  model logair;
  irregular;
  level;
  slope;
  season length=12 type=trig print=smooth;
  estimate;
  forecast lead=24 print=decomp;
run;
```

The PROC UCM statement signifies the start of the UCM procedure, and the input data set, `seriesG`, containing the dependent series is specified there. The optional `ID` statement is used to specify a date, datetime, or time identification variable, `date` in this example, to label the observations. The `INTERVAL=MONTH` option in the `ID` statement indicates that the measurements were collected on a monthly basis. The model specification begins with the `MODEL` statement, where the response series is specified (`logair` in this case). After this the components in the model are specified using separate statements that enable you to control their individual properties. The irregular component ϵ_t is specified using the `IRREGULAR` statement and the trend component μ_t is specified using the `LEVEL` and `SLOPE` statements. The seasonal component γ_t is specified using the `SEASON` statement. The specifics of the seasonal characteristics such as the season length, its stochastic evolution properties, etc., are specified using the options in the `SEASON` statement. The seasonal component used in this example has a season length of 12, corresponding to the monthly seasonality, and is of the *trigonometric* type. Different types of seasonals are explained later (see the section “[Modeling Seasons](#)” on page 2146).

The parameters of this model are the variances of the disturbance terms in the evolution equations of μ_t , β_t , and γ_t and the variance of the irregular component ϵ_t . These parameters are estimated by maximizing the likelihood of the data. The `ESTIMATE` statement options can be used to specify the span of data used in parameter estimation and to display and save the results of the estimation step and the model diagnostics. You can use the estimated model to obtain the forecasts of the series as well as the components. The options in the individual component statements can be used to display the component forecasts—for example, `PRINT=SMOOTH` option in the `SEASON` statement requests the displaying of smoothed forecasts of the seasonal component γ_t . The series forecasts and forecasts of the sum of components can be requested using the `FORECAST` statement. The option `PRINT=DECOMP` in the `FORECAST` statement requests the printing of the smoothed trend μ_t and the trend plus seasonal component ($\mu_t + \gamma_t$).

The parameter estimates for this model are displayed in [Figure 34.2](#).

Figure 34.2 BSM for the Logair Series

The UCM Procedure					
Final Estimates of the Free Parameters					
Component	Parameter	Estimate	Approx Std Error	t Value	Approx Pr > t
Irregular	Error Variance	0.00023436	0.0001079	2.17	0.0298
Level	Error Variance	0.00029828	0.0001057	2.82	0.0048
Slope	Error Variance	8.47916E-13	6.2271E-10	0.00	0.9989
Season	Error Variance	0.00000356	1.32347E-6	2.69	0.0072

The estimates suggest that except for the slope component, the disturbance variances of all the components are significant—that is, all these components are *stochastic*. The slope component, however, appears to be deterministic because its error variance is quite insignificant. It might then be useful to check if the slope component can be dropped from the model—that is, if $\beta_0 = 0$. This can be checked by examining the significance analysis table of the components given in [Figure 34.3](#).

Figure 34.3 Component Significance Analysis for the Logair Series

Significance Analysis of Components (Based on the Final State)			
Component	DF	Chi-Square	Pr > ChiSq
Irregular	1	0.08	0.7747
Level	1	117867	<.0001
Slope	1	43.78	<.0001
Season	11	507.75	<.0001

This table provides the significance of the components in the model at the end of the estimation span. If a component is deterministic, this analysis is equivalent to checking whether the corresponding regression effect is significant. However, if a component is stochastic, then this analysis pertains only to the portion of the series near the end of the estimation span. In this example the slope appears quite significant and should be retained in the model, possibly as a deterministic component. Note that, on the basis of this table, the irregular component's contribution appears insignificant toward the end of the estimation span; however, since it is a stochastic component, it cannot be dropped from the model on the basis of this analysis alone. The slope component can be made deterministic by holding the value of its error variance fixed at zero. This is done by modifying the SLOPE statement as follows:

```
slope variance=0 noest;
```

After a tentative model is fit, its adequacy can be checked by examining different goodness-of-fit measures and other diagnostic tests and plots that are based on the model residuals. Once the model appears satisfactory, it can be used for forecasting. An interesting feature of the UCM procedure is that, apart from the series forecasts, you can request the forecasts of the individual components in the model. The plots of component

forecasts can be useful in understanding their contributions to the series. The following statements illustrate some of these features:

```
proc ucm data=seriesG;
  id date interval = month;
  model logair;
  irregular;
  level plot=smooth;
  slope variance=0 noest;
  season length=12 type=trig
    plot=smooth;
  estimate;
  forecast lead=24 plot=decomp;
run;
```

The table given in [Figure 34.4](#) shows the goodness-of-fit statistics that are computed by using the one-step-ahead prediction errors (see the section “[Statistics of Fit](#)” on page 2182). These measures indicate a good agreement between the model and the data. Additional diagnostic measures are also printed by default but are not shown here.

Figure 34.4 Fit Statistics for the Logair Series

The UCM Procedure	
Fit Statistics Based on Residuals	
Mean Squared Error	0.00147
Root Mean Squared Error	0.03830
Mean Absolute Percentage Error	0.54132
Maximum Percent Error	2.19097
R-Square	0.99061
Adjusted R-Square	0.99046
Random Walk R-Square	0.87288
Amemiya's Adjusted R-Square	0.99017
Number of non-missing residuals used for computing the fit statistics = 131	

The first plot, shown in [Figure 34.5](#), is produced by the PLOT=SMOOTH option in the LEVEL statement, it shows the smoothed level of the series.

Figure 34.5 Smoothed Trend in the Logair Series

The second plot (Figure 34.6), produced by the PLOT=SMOOTH option in the SEASON statement, shows the smoothed seasonal component by itself.

Figure 34.6 Smoothed Seasonal in the Logair Series

The plot of the sum of the trend and seasonal component, produced by the `PLOT=DECOMP` option in the `FORECAST` statement, is shown in [Figure 34.7](#). You can see that, at least visually, the model seems to fit the data well. In all these decomposition plots the component estimates are extrapolated for two years in the future based on the `LEAD=24` option specified in the `FORECAST` statement.

Figure 34.7 Smoothed Trend plus Seasonal in the Logair Series

Syntax: UCM Procedure

The UCM procedure uses the following statements:

```

PROC UCM < options > ;
  AUTOREG < options > ;
  BLOCKSEASON options ;
  BY variables ;
  CYCLE < options > ;
  DEPLAG options ;
  ESTIMATE < options > ;
  FORECAST < options > ;
  ID variable options ;
  IRREGULAR < options > ;
  LEVEL < options > ;
  MODEL dependent variable < = regressors > ;
  NLOPTIONS options ;
  OUTLIER options ;
  RANDOMREG regressors < / options > ;
  SEASON options ;
  SLOPE < options > ;
  SPLINEREG regressor < options > ;
  SPLINESEASON options ;

```

The **PROC UCM** and **MODEL** statements are required. In addition, the model must contain at least one component with nonzero disturbance variance.

Functional Summary

The statements and options controlling the UCM procedure are summarized in the following table. Most commonly needed scenarios are listed; see the individual statements for additional details. You can use the **PRINT=** and **PLOT=** options in the individual component statements for printing and plotting the corresponding component forecasts.

Table 34.1 Functional Summary

Description	Statement	Option
Data Set Options		
specify the input data set	PROC UCM	DATA=
write parameter estimates to an output data set	ESTIMATE	OUTEST=
write series and component forecasts to an output data set	FORECAST	OUTFOR=

Table 34.1 *continued*

Description	Statement	Option
Model Specification		
specify the dependent variable and simple predictors	MODEL	
specify predictors with time-varying coefficients	RANDOMREG	
specify a nonlinear predictor	SPLINEREG	
specify the irregular component	IRREGULAR	
specify the random walk trend	LEVEL	
specify the locally linear trend	LEVEL and SLOPE	
specify a cycle component	CYCLE	
specify a dummy seasonal component	SEASON	TYPE=DUMMY
specify a trigonometric seasonal component	SEASON	TYPE=TRIG
drop some harmonics from a trigonometric seasonal component	SEASON	DROPH=
specify a list of harmonics to keep in a trigonometric seasonal component	SEASON	KEEPH=
specify a spline-season component	SPLINESEASON	
specify a block-season component	BLOCKSEASON	
specify an autoreg component	AUTOREG	
specify the lags of the dependent variable	DEPLAG	
Controlling the Likelihood Optimization Process		
request optimization of the profile likelihood	ESTIMATE	PROFILE
request optimization of the usual likelihood	ESTIMATE	NOPROFILE
specify the optimization technique	NLOPTIONS	TECH=

specify a variable that provides the time index for the series values	ID	

PROC UCM Statement

PROC UCM *< options >* ;

The PROC UCM statement is required. The following options can be used in the PROC UCM statement:

DATA=SAS-data-set

specifies the name of the SAS data set containing the time series. If the DATA= option is not specified in the PROC UCM statement, the most recently created SAS data set is used.

NOPRINT

turns off all the printing for the procedure. The subsequent print options in the procedure are ignored.

PLOTS*< (global-plot-options) > < = plot-request < (options) > >*

PLOTS*< (global-plot-options) > < = (plot-request < (options) > < ... plot-request < (options) > > >*

controls the plots produced with ODS Graphics. When you specify only one plot request, you can omit the parentheses around the plot request.

Here are some examples:

```
plots=none
plots=all
plots=residuals(acf loess)
plots(noclm)=(smooth(decomp) residual(panel loess))
```

For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

```
proc ucm;
  model y = x;
  irregular;
  level;
run;

proc ucm plots=all;
  model y = x;
  irregular;
  level;
run;
```

The first PROC UCM step does not specify the PLOTS= option, so the default plot that displays the series forecasts in the forecast region is produced. The PLOTS=ALL option in the second PROC UCM step produces all the plots that are appropriate for the specified model.

In addition to the PLOTS= option in the PROC UCM statement, you can request plots by using the PLOT= option in other statements of the UCM procedure. This way of requesting plots provides finer control over the plot production. If you do not specify any specific plot request, then PROC UCM produces the plot of series forecasts in the forecast horizon by default.

Global Plot Options:

The *global-plot-options* apply to all relevant plots generated by the UCM procedure. The following *global-plot-option* is supported:

NOCLM

suppresses the confidence limits in all the component and forecast plots.

Specific Plot Options:

The following list describes the specific plots and their options:

ALL

produces all plots appropriate for the particular analysis.

NONE

suppresses all plots.

FILTER (< filter-plot-options >)

produces time series plots of the filtered component estimates. The following *filter-plot-options* are available:

ALL

produces all the filtered component estimate plots appropriate for the particular analysis.

LEVEL

produces a time series plot of the filtered level component estimate, provided the model contains the level component.

SLOPE

produces a time series plot of the filtered slope component estimate, provided the model contains the slope component.

CYCLE

produces time series plots of the filtered cycle component estimates for all cycle components in the model, if there are any.

SEASON

produces time series plots of the filtered season component estimates for all seasonal components in the model, if there are any.

DECOMP

produces time series plots of the filtered estimates of the series decomposition.

RESIDUAL (< residual-plot-options >)

produces the residuals plots. The following *residual-plot-options* are available:

ALL

produces all the residual diagnostics plots appropriate for the particular analysis.

ACF

produces the autocorrelation plot of residuals.

CUSUM

produces the plot of cumulative residuals against time.

CUSUMSQ

produces the plot of cumulative squared residuals against time.

HISTOGRAM

produces the histogram of residuals.

LOESS

produces a scatter plot of residuals against time, which has an overlaid loess-fit.

PACF

produces the partial-autocorrelation plot of residuals.

PANEL

produces a summary panel of the residual diagnostics consisting of the following:

- histogram of residuals
- normal quantile plot of residuals
- the residual-autocorrelation-plot
- the residual-partial-autocorrelation-plot

QQ

produces a normal quantile plot of residuals.

RESIDUAL

produces a needle plot of residuals against time.

WN

produces the plot of Ljung-Box white-noise test p -values at different lags (in log scale).

SMOOTH (< *smooth-plot-options* >)

produces time series plots of the smoothed component estimates. The following *smooth-plot-options* are available:

ALL

produces all the smoothed component estimate plots appropriate for the particular analysis.

LEVEL

produces time series plot of the smoothed level component estimate, provided the model contains the level component.

SLOPE

produces time series plot of the smoothed slope component estimate, provided the model contains the slope component.

CYCLE

produces time series plots of the smoothed cycle component estimates for all cycle components in the model, if there are any.

SEASON

produces time series plots of the smoothed season component estimates for all season components in the model, if there are any.

DECOMP

produces time series plots of the smoothed estimates of the series decomposition.

PRINTALL

turns on all the printing options for the procedure. The subsequent NOPRINT options in the procedure are ignored.

AUTOREG Statement

AUTOREG <options> ;

The AUTOREG statement specifies an autoregressive component in the model. An autoregressive component is a special case of cycle that corresponds to the frequency of zero or π . It is modeled separately for easier interpretation. A stochastic equation for an autoregressive component r_t can be written as follows:

$$r_t = \rho r_{t-1} + v_t, \quad v_t \sim i.i.d. \ N(0, \sigma_v^2)$$

The damping factor ρ can take any value in the interval $(-1, 1)$, including -1 but excluding 1 . If $\rho = 1$, the autoregressive component cannot be distinguished from the random walk level component. If $\rho = -1$, the autoregressive component corresponds to a seasonal component with a season length of 2, or a nonstationary cycle with period 2. If $|\rho| < 1$, then the autoregressive component is stationary. The following example illustrates the AUTOREG statement. This statement includes an autoregressive component in the model. The damping factor ρ and the disturbance variance σ_v^2 are estimated from the data.

autoreg;

NOEST=RHO

NOEST=VARIANCE

NOEST=(RHO VARIANCE)

fixes the values of ρ and σ_v^2 to those specified in the **RHO=** and **VARIANCE=** options.

PLOT=FILTER**PLOT=SMOOTH****PLOT=(< FILTER > < SMOOTH >)**

requests plotting of the filtered or smoothed estimate of the autoreg component.

PRINT=FILTER**PRINT=SMOOTH****PRINT=(< FILTER > < SMOOTH >)**

requests printing of the filtered or smoothed estimate of the autoreg component.

RHO=valuespecifies an initial value for the damping factor ρ during the parameter estimation process. The value of ρ must be in the interval $(-1, 1)$, including -1 but excluding 1 .**VARIANCE=value**specifies an initial value for the disturbance variance σ_v^2 during the parameter estimation process. Any nonnegative value, including zero, is an acceptable starting value.

BLOCKSEASON Statement

BLOCKSEASON *NBLOCKS* = integer *BLOCKSIZE* = integer < options > ;

The **BLOCKSEASON** or **BLOCKSEASONAL** statement is used to specify a seasonal component γ_t that has a special block structure. The seasonal γ_t is called a *block seasonal* of block size m and number of blocks k if its season length, s , can be factored as $s = m * k$ and its seasonal effects have a block form—that is, the first m seasonal effects are all equal to some number τ_1 , the next m effects are all equal to some number τ_2 , and so on.

This type of seasonal structure can be appropriate in some cases; for example, consider a series that is recorded on an hourly basis. Further assume that, in this particular case, the hour-of-the-day effect and the day-of-the-week effect are additive. In this situation the hour-of-the-week seasonality, having a season length of 168, can be modeled as a sum of two components. The hour-of-the-day effect is modeled using a simple seasonal of season length 24, while the day-of-the-week is modeled as a block seasonal component that has the days of the week as blocks. This day-of-the-week block seasonal component has seven blocks, each of size 24.

A block seasonal specification requires, at the minimum, the block size m and the number of blocks in the seasonal k . These are specified using the **BLOCKSIZE=** and **NBLOCKS=** option, respectively. In addition, you might need to specify the position of the first observation of the series by using the **OFFSET=** option if it is not at the beginning of one of the blocks. In the example just considered, this corresponds to a situation where the first series measurement is not at the start of the day. Suppose that the first measurement of the series corresponds to the hour between 6:00 and 7:00 a.m., which is the seventh hour within that day or at the seventh position within that block. This is specified as **OFFSET=7**.

The other options in this statement are very similar to the options in the **SEASON** statement; for example, a block seasonal can also be of one of the two types, **DUMMY** and **TRIG**. There can be more than one block seasonal component in the model, each specified using a separate **BLOCKSEASON** statement. No

two block seasonals in the model can have the same NBLOCKS= and BLOCKSIZE= specifications. The following example illustrates the use of the BLOCKSEASON statement to specify the additive, hour-of-the-week seasonal model:

```
season length=24 type=trig;
blockseason nblocks=7 blocksize=24;
```

BLOCKSIZE=integer

specifies the block size, m . This is a required option in this statement. The block size can be any integer larger than or equal to two. Typical examples of block sizes are 24, corresponding to the hours of the day when a day is being used as a block in hourly data, or 60, corresponding to the minutes in an hour when an hour is being used as a block in data recorded by minutes, etc.

NBLOCKS=integer

specifies the number of blocks, k . This is a required option in this statement. The number of blocks can be any integer greater than or equal to two.

NOEST

fixes the value of the disturbance variance parameter to the value specified in the **VARIANCE=** option.

OFFSET=integer

specifies the position of the first measurement within the block, if the first measurement is not at the start of a block. The OFFSET= value must be between one and the block size. The default value is one. The first measurement refers to the start of the estimation span and the forecast span. If these spans differ, their starting measurements must be separated by an integer multiple of the block size.

PLOT=FILTER

PLOT=SMOOTH

PLOT=F_ANNUAL

PLOT=S_ANNUAL

PLOT=(<plot request> ... <plot request>)

requests plots of the season component. When you specify only one plot request, you can omit the parentheses around the plot request. You can use the FILTER and SMOOTH options to plot the filtered and smoothed estimates of the season component γ_t . You can use the F_ANNUAL and S_ANNUAL options to get the plots of “annual” variation in the filtered and smoothed estimates of γ_t . The annual plots are useful to see the change in the contribution of a particular month over the span of years. Here “month” and “year” are generic terms that change appropriately with the interval type being used to label the observations and the season length. For example, for monthly data with a season length of 12, the usual meaning applies, while for daily data with a season length of 7, the days of the week serve as months and the weeks serve as years. The first period in each block is plotted over the years.

PRINT=FILTER

PRINT=SMOOTH

PRINT=(<FILTER> <SMOOTH>)

requests the printing of the filtered or smoothed estimate of the block seasonal component γ_t .

TYPE=DUMMY | TRIG

specifies the type of the block seasonal component. The default type is DUMMY.

VARIANCE=value

specifies an initial value for the disturbance variance, σ_{ω}^2 , in the γ_t equation at the start of the parameter estimation process. Any nonnegative value, including zero, is an acceptable starting value.

BY Statement

BY variables ;

A BY statement can be used in the UCM procedure to process a data set in groups of observations defined by the BY variables. The model specified using the MODEL and other component statements is applied to all the groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The variables are one or more variables in the input data set.

CYCLE Statement

CYCLE < options > ;

The CYCLE statement is used to specify a cycle component, ψ_t , in the model. The stochastic equation governing a cycle component of period p and damping factor ρ is as follows

$$\begin{bmatrix} \psi_t \\ \psi_t^* \end{bmatrix} = \rho \begin{bmatrix} \cos \lambda & \sin \lambda \\ -\sin \lambda & \cos \lambda \end{bmatrix} \begin{bmatrix} \psi_{t-1} \\ \psi_{t-1}^* \end{bmatrix} + \begin{bmatrix} v_t \\ v_t^* \end{bmatrix}$$

where v_t and v_t^* are independent, zero-mean, Gaussian disturbances with variance σ_v^2 and $\lambda = 2 * \pi / p$ is the angular frequency of the cycle. Any p strictly greater than two is an admissible value for the period, and the damping factor ρ can be any value in the interval (0, 1), including one but excluding zero. The cycles with frequency zero and π , which correspond to the periods equal to infinity and two, respectively, can be specified using the AUTOREG statement. The values of ρ less than one give rise to a stationary cycle, while $\rho = 1$ gives rise to a nonstationary cycle. As a default, values of ρ , p , and σ_v^2 are estimated from the data. However, if necessary, you can fix the values of some or all of these parameters.

There can be multiple cycles in a model, each specified using a separate CYCLE statement. The examples that follow illustrate the use of the CYCLE statement.

The following statements request including two cycles in the model. The parameters of each of these cycles are estimated from the data.

```
cycle;
cycle;
```

The following statement requests inclusion of a nonstationary cycle in the model. The cycle period p and the disturbance variance σ_v^2 are estimated from the data.

```
cycle rho=1 noest=rho;
```

In the following statement a nonstationary cycle with a fixed period of 12 is specified. Moreover, a starting value is supplied for σ_v^2 .

```
cycle period=12 rho=1 variance=4 noest=(rho period);
```

NOEST=PERIOD

NOEST=RHO

NOEST=VARIANCE

NOEST=(< RHO > < PERIOD > < VARIANCE >)

fixes the values of the component parameters to those specified in the **RHO=**, **PERIOD=**, and **VARIANCE=** options. This option enables you to fix any combination of parameter values.

PERIOD=value

specifies an initial value for the cycle period during the parameter estimation process. Period value must be strictly greater than 2.

PLOT=FILTER

PLOT=SMOOTH

PLOT=(< FILTER > < SMOOTH >)

requests plotting of the filtered or smoothed estimate of the cycle component.

PRINT=FILTER

PRINT=SMOOTH

PRINT=(< FILTER > < SMOOTH >)

requests the printing of a filtered or smoothed estimate of the cycle component ψ_t .

RHO=value

specifies an initial value for the damping factor in this component during the parameter estimation process. Any value in the interval (0, 1), including one but excluding zero, is an acceptable initial value for the damping factor.

VARIANCE=value

specifies an initial value for the disturbance variance parameter, σ_v^2 , to be used during the parameter estimation process. Any nonnegative value, including zero, is an acceptable starting value.

DEPLAG Statement

DEPLAG LAGS = order < PHI = value ... > < NOEST > ;

The DEPLAG statement is used to specify the lags of the dependent variable to be included as predictors in the model. The following examples illustrate the use of DEPLAG statement.

If the dependent series is denoted by y_t , the following statement specifies the inclusion of $\phi_1 y_{t-1} + \phi_2 y_{t-2}$ in the model. The parameters ϕ_1 and ϕ_2 are estimated from the data.

```
deplag lags=2;
```

The following statement requests including $\phi_1 y_{t-1} + \phi_2 y_{t-4} - \phi_1 \phi_2 y_{t-5}$ in the model. The values of ϕ_1 and ϕ_2 are fixed at 0.8 and -1.2.

```
deplag lags=(1) (4) phi=0.8 -1.2 noest;
```

The dependent lag parameters are not constrained to lie in any particular region. In particular, this implies that a UCM that contains only an irregular component and dependent lags, resulting in a traditional autoregressive model, is not constrained to be a stationary model. In the DEPLAG statement, if an initial value is supplied for any one of the parameters, the initial values must also be supplied for all other parameters.

LAGS=order

LAGS=(lag, ..., lag) ... (lag, ..., lag)

is a required option in this statement. $\text{LAGS}=(l_1, l_2, \dots, l_k)$ defines a model with specified lags of the dependent variable included as predictors. $\text{LAGS}=order$ is equivalent to $\text{LAGS}=(1, 2, \dots, order)$.

A concatenation of parenthesized lists specifies a factored model. For example, $\text{LAGS}=(1)(12)$ specifies that the lag values, 1, 12, and 13, corresponding to the following polynomial in the backward shift operator, be included in the model

$$(1 - \phi_{1,1}B)(1 - \phi_{2,1}B^{12})$$

Note that, in this case, the coefficient of the thirteenth lag is constrained to be the product of the coefficients of the first and twelfth lags.

NOEST

fixes the values of the parameters to those specified in **PHI=** option.

PHI=value ...

lists starting values for the coefficients of the lagged dependent variable. The order of the values listed corresponds with the order of the lags specified in the **LAGS=** option.

ESTIMATE Statement

```
ESTIMATE <options>;
```

The ESTIMATE statement is an optional statement used to control the overall model-fitting environment. Using this statement, you can control the span of observations used to fit the model by using the **SKIPFIRST=** and **BACK=** options. This can be useful in model diagnostics. You can request a variety of goodness-of-fit statistics and other model diagnostic information including different residual diagnostic plots. Note that the ESTIMATE statement is not used to control the nonlinear optimization process itself. That is done using the **NLOPTIONS** statement, where you can control the number of iterations, choose between the different optimization techniques, and so on. You can save the estimated parameters and other

related information in a data set by using the `OUTEST=` option. You can request the optimization of the profile likelihood, the likelihood obtained by concentrating out a disturbance variance, for parameter estimation by using the [PROFILE](#) option. The following example illustrates the use of this statement:

```
estimate skipfirst=12 back=24;
```

This statement requests that the initial 12 measurements and the last 24 measurements be excluded during the model-fitting process. The actual observation span used to fit the model is decided as follows: Suppose that n_0 and n_1 are the observation numbers of the first and the last nonmissing values of the response variable, respectively. As a result of `SKIPFIRST=12` and `BACK=24`, the measurements between observation numbers $n_0 + 12$ and $n_1 - 24$ form the estimation span. Of course, the model fitting might not take place if there are insufficient data in the resulting span. The model fitting does not take place if there are regressors in the model that have missing values in the estimation span.

BACK=integer

SKIPLAST=integer

indicates that some ending part of the data needs to be ignored during the parameter estimation. This can be useful when you want to study the forecasting performance of a model on the observed data. `BACK=10` results in skipping the last 10 measurements of the response series during the parameter estimation. The default is `BACK=0`.

EXTRADIFFUSE=k

enables continuation of the diffuse filtering iterations for k additional iterations beyond the first instance where the initialization of the diffuse state would have otherwise taken place. If the specified k is larger than the sample size, the diffuse iterations continue until the end of the sample. Note that one-step-ahead residuals are produced only after the diffuse state is initialized. Delaying the initialization leads to a reduction in the number of one-step-ahead residuals available for computing the residual diagnostic measures. This option is useful when you want to ignore the first few one-step-ahead residuals that often have large variance.

NOPROFILE

requests that the usual likelihood be optimized for parameter estimation. For more information, see the section [“Parameter Estimation by Profile Likelihood Optimization”](#) on page 2160.

OUTEST=SAS-data-set

specifies an output data set for the estimated parameters.

In the `ESTIMATE` statement, the `PLOT=` option is used to obtain different residual diagnostic plots. The different possibilities are as follows:

PLOT=ACF**PLOT=MODEL****PLOT=LOESS****PLOT=HISTOGRAM****PLOT=PACF****PLOT=PANEL****PLOT=QQ****PLOT=RESIDUAL****PLOT=WN****PLOT=(<plot request> ... <plot request>)**

requests different residual diagnostic plots. The different options are as follows:

ACF

produces the residual-autocorrelation plot.

CUSUM

produces the plot of cumulative residuals against time.

CUSUMSQ

produces the plot of cumulative squared residuals against time.

MODEL

produces the plot of one-step-ahead forecasts in the estimation span.

HISTOGRAM

produces the histogram of residuals.

LOESS

produces a scatter plot of residuals against time, which has an overlaid loess-fit.

PACF

produces the residual-partial-autocorrelation plot.

PANEL

produces a summary panel of the residual diagnostics consisting of

- histogram of residuals
- normal quantile plot of residuals
- the residual-autocorrelation-plot
- the residual-partial-autocorrelation-plot

QQ

produces a normal quantile plot of residuals.

RESIDUAL

produces a needle plot of residuals against time.

WN

produces a plot of p -values, in log-scale, at different lags for the Ljung-Box portmanteau white noise test statistics.

PRINT=NONE

suppresses all the printed output related to the model fitting, such as the parameter estimates, the goodness-of-fit statistics, and so on.

PROFILE

requests that the profile likelihood, obtained by concentrating out one of the disturbance variances from the likelihood, be optimized for parameter estimation. By default, the profile likelihood is not optimized if any of the disturbance variance parameters is held fixed to a nonzero value. For more information see the section “[Parameter Estimation by Profile Likelihood Optimization](#)” on page 2160.

SKIPFIRST=integer

indicates that some early part of the data needs to be ignored during the parameter estimation. This can be useful if there is a reason to believe that the model being estimated is not appropriate for this portion of the data. SKIPFIRST=10 results in skipping the first 10 measurements of the response series during the parameter estimation. The default is SKIPFIRST=0.

FORECAST Statement

FORECAST < options > ;

The FORECAST statement is an optional statement that is used to specify the overall forecasting environment for the specified model. It can be used to specify the span of observations, the historical period, to use to compute the forecasts of the future observations. This is done using the SKIPFIRST= and BACK= options. The number of periods to forecast beyond the historical period, and the significance level of the forecast confidence interval, is specified using the LEAD= and ALPHA= options. You can request one-step-ahead series and component forecasts by using the PRINT= option. You can save the series forecasts, and the model-based decomposition of the series, in a data set by using the OUTFOR= option. The following example illustrates the use of this statement:

```
forecast skipfirst=12 back=24 lead=30;
```

This statement requests that the initial 12 and the last 24 response values be excluded during the forecast computations. The forecast horizon, specified using the LEAD= option, is 30 periods; that is, multistep forecasting begins at the end of the historical period and continues for 30 periods. The actual observation span used to compute the multistep forecasting is decided as follows: Suppose that n_0 and n_1 are the observation numbers of the first and the last nonmissing values of the response variable, respectively. As a result of SKIPFIRST=12 and BACK=24, the historical period, or the forecast span, begins at $n_0 + 12$ and ends at $n_1 - 24$. Multistep forecasts are produced for the next 30 periods—that is, for the observation numbers $n_1 - 23$ to $n_1 + 6$. Of course, the forecast computations can fail if the model has regressor variables that have missing values in the forecast span. If the regressors contain missing values in the forecast horizon—that is, between the observations $n_1 - 23$ and $n_1 + 6$ —the forecast horizon is reduced accordingly.

ALPHA=value

specifies the significance level of the forecast confidence intervals; for example, ALPHA=0.05, which is the default, results in a 95% confidence interval.

BACK=integer**SKIPLAST=integer**

specifies the holdout sample for the evaluation of the forecasting performance of the model. For example, BACK=10 results in treating the last 10 observed values of the response series as unobserved. A post-sample-prediction-analysis table is produced for comparing the predicted values with the actual values in the holdout period. The default is BACK=0.

EXTRADIFFUSE=k

enables continuation of the diffuse filtering iterations for k additional iterations beyond the first instance where the initialization of the diffuse state would have otherwise taken place. If the specified k is larger than the sample size, the diffuse iterations continue until the end of the sample. Note that one-step-ahead forecasts are produced only after the diffuse state is initialized. Delaying the initialization leads to reduction in the number of one-step-ahead forecasts. This option is useful when you want to ignore the first few one-step-ahead forecasts that often have large variance.

LEAD=integer

specifies the number of periods to forecast beyond the historical period defined by the SKIPFIRST= and BACK= options; for example, LEAD=10 results in the forecasting of 10 future values of the response series. The default is LEAD=12.

OUTFOR=SAS-data-set

specifies an output data set for the forecasts. The output data set contains the ID variable (if specified), the response and predictor series, the one-step-ahead and out-of-sample response series forecasts, the forecast confidence intervals, the smoothed values of the response series, and the smoothed forecasts produced as a result of the model-based decomposition of the series.

PLOT=DECOMP**PLOT=DECOMPVAR****PLOT=FDECOMP****PLOT=FDECOMPVAR****PLOT=FORECASTS****PLOT=TREND****PLOT=(<plot request> ... <plot request>)**

requests forecast and model decomposition plots. The FORECASTS option provides the plot of the series forecasts, the TREND and DECOMP options provide the plots of the smoothed trend and other decompositions, the DECOMPVAR option can be used to plot the variance of these components, and the FDECOMP and FDECOMPVAR options provide the same plots for the filtered decomposition estimates and their variances.

PRINT=DECOMP**PRINT=FDECOMP****PRINT=FORECASTS****PRINT=NONE****PRINT=(< print request > ... < print request >)**

controls the printing of the series forecasts and the printing of smoothed model decomposition estimates. By default, the series forecasts are printed only for the forecast horizon specified by the LEAD= option; that is, the one-step-ahead predicted values are not printed. You can request forecasts for the entire forecast span by specifying the PRINT=FORECASTS option. Using PRINT=DECOMP, you can get smoothed estimates of the following effects: trend, trend plus regression, trend plus regression plus cycle, and sum of all components except the irregular. If some of these effects are absent in the model, then they are ignored. Similarly you can get filtered estimates of these effects by using PRINT=FDECOMP. You can use PRINT=NONE to suppress the printing of all the forecast output.

SKIPFIRST=integer

indicates that some early part of the data needs to be ignored during the forecasting calculations. This can be useful if there is a reason to believe that the model being used for forecasting is not appropriate for this portion of the data. SKIPFIRST=10 results in skipping the first 10 measurements of the response series during the forecast calculations. The default is SKIPFIRST=0.

ID Statement

ID *variable* **INTERVAL=**value < **ALIGN=**value > ;

The ID statement names a numeric variable that identifies observations in the input and output data sets. The ID variable's values are assumed to be SAS date, time, or datetime values. In addition, the ID statement specifies the frequency associated with the time series. The ID statement options also specify how the observations are aligned to form the time series. If the ID statement is specified, the INTERVAL= option must also be specified. If the ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID. The values of the ID variable are extrapolated for the forecast observations based on the values of the INTERVAL= option.

ALIGN=value

controls the alignment of SAS dates used to identify output observations. The ALIGN= option has the following possible values: BEGINNING | BEG | B, MIDDLE | MID | M, and ENDING | END | E. The default is BEGINNING. The ALIGN= option is used to align the ID variable with the beginning, middle, or end of the time ID interval specified by the INTERVAL= option.

INTERVAL=value

specifies the time interval between observations. This option is required in the ID statement. INTERVAL=value is used in conjunction with the ID variable to check that the input data are in order and have no gaps. The INTERVAL= option is also used to extrapolate the ID values past the end of the input data. For a complete discussion of the intervals supported, please see Chapter 4, “[Date Intervals, Formats, and Functions](#).”

IRREGULAR Statement

IRREGULAR <options> ;

The IRREGULAR statement includes an irregular component in the model. There can be at most one IRREGULAR statement in the model specification. The irregular component corresponds to the overall random error ϵ_t in the model. By default the irregular component is modeled as white noise—that is, as a sequence of independent, identically distributed, zero-mean, Gaussian random variables. However, you can also model it as an autoregressive moving average (ARMA) process. The options for specifying an ARMA model for the irregular component are given in a separate subsection: “[ARMA Specification](#)” on page 2132.

The options in this statement enable you to specify the model for the irregular component and to output its estimates. Two examples of the IRREGULAR statement are given next. In the first example the statement is in its simplest form, resulting in the inclusion of an irregular component that is white noise with unknown variance:

```
irregular;
```

The following statement provides a starting value for the white noise variance σ_ϵ^2 to be used in the nonlinear parameter estimation process. It also requests the printing of smoothed estimates of ϵ_t . The smoothed irregulars are useful in model diagnostics.

```
irregular variance=4 print=smooth;
```

NOEST

fixes the value of σ_ϵ^2 to the value specified in the **VARIANCE=** option. Also see the **NOEST=** option in the subsection “[ARMA Specification](#)” on page 2132.

PLOT=FILTER

PLOT=SMOOTH

PLOT=(<FILTER> <SMOOTH>)

requests plotting of the filtered or smoothed estimate of the irregular component.

PRINT=FILTER

PRINT=SMOOTH

PRINT=(<FILTER> <SMOOTH>)

requests printing of the filtered or smoothed estimate of the irregular component.

VARIANCE=value

specifies an initial value for σ_ϵ^2 during the parameter estimation process. Any nonnegative value, including zero, is an acceptable starting value.

ARMA Specification

This section details the options for specifying an ARMA model for the irregular component. The specification of ARMA models requires some notation, which is explained first.

Let B denote the backshift operator—that is, for any sequence ϵ_t , $B\epsilon_t = \epsilon_{t-1}$. The higher powers of B represent larger shifts (for example, $B^3\epsilon_t = \epsilon_{t-3}$). A random sequence ϵ_t follows a zero-mean $\text{ARMA}(p,q) \times (P,Q)_s$ model with nonseasonal autoregressive order p , seasonal autoregressive order P , nonseasonal moving average order q , and seasonal moving average order Q , if it satisfies the following difference equation specified in terms of the polynomials in the backshift operator where a_t is a white noise sequence and s is the season length:

$$\phi(B)\Phi(B^s)\epsilon_t = \theta(B)\Theta(B^s)a_t$$

The polynomials ϕ , Φ , θ , and Θ are of orders p , P , q , and Q , respectively, which can be any nonnegative integers. The season length s must be a positive integer. For example, ϵ_t satisfies an $\text{ARMA}(1,1)$ model (that is, $p = 1, q = 1, P = 0$, and $Q = 0$) if

$$\epsilon_t = \phi_1\epsilon_{t-1} + a_t - \theta_1a_{t-1}$$

for some coefficients ϕ_1 and θ_1 and a white noise sequence a_t . Similarly ϵ_t satisfies an $\text{ARMA}(1,1) \times (1,1)_{12}$ model if

$$\epsilon_t = \phi_1\epsilon_{t-1} + \Phi_1\epsilon_{t-12} - \phi_1\Phi_1\epsilon_{t-13} + a_t - \theta_1a_{t-1} - \Theta_1a_{t-12} + \theta_1\Theta_1a_{t-13}$$

for some coefficients ϕ_1 , Φ_1 , θ_1 , and Θ_1 and a white noise sequence a_t . The ARMA process is stationary and invertible if the defining polynomials ϕ , Φ , θ , and Θ have all their roots outside the unit circle—that is, their absolute values are strictly larger than 1.0. It is assumed that the ARMA model specified for the irregular component is stationary and invertible—that is, the coefficients of the polynomials ϕ , Φ , θ , and Θ are constrained so that the stationarity and invertibility conditions are satisfied. The unknown coefficients of these polynomials become part of the model parameter vector that is estimated using the data.

The notation for a closely related class of models, autoregressive integrated moving average (ARIMA) models, is also given here. A random sequence y_t is said to follow an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model if, for some nonnegative integers d and D , the differenced series $\epsilon_t = (1 - B)^d(1 - B^s)^D y_t$ follows an $\text{ARMA}(p,q) \times (P,Q)_s$ model. The integers d and D are called nonseasonal and seasonal differencing orders, respectively. You can specify ARIMA models by using the [DEPLAG](#) statement for specifying the differencing orders and by using the [IRREGULAR](#) statement for the ARMA specification. See [Example 34.8](#) for an example of $\text{ARIMA}(0,1,1) \times (0,1,1)_{12}$ model specification. Brockwell and Davis (1991) can be consulted for additional information about ARIMA models.

You can use options of the [IRREGULAR](#) statement to specify the desired ARMA model and to request printed and graphical output. A few examples of the [IRREGULAR](#) statement are given next.

The following statement specifies an irregular component that is modeled as an $\text{ARMA}(1,1)$ process. It also requests plotting its smoothed estimate.

```
irregular p=1 q=1 plot=smooth;
```

The following statement specifies an $\text{ARMA}(1,1) \times (1,1)_{12}$ model. It also fixes the coefficient of the first-order seasonal moving average polynomial to 0.1. The other coefficients and the white noise variance are estimated using the data.

```
irregular p=1 sp=1 q=1 sq=1 s=12 sma=0.1 noest=(sma);
```

AR= $\phi_1 \phi_2 \dots \phi_p$

lists the starting values of the coefficients of the nonseasonal autoregressive polynomial

$$\phi(B) = 1 - \phi_1 B - \dots - \phi_p B^p$$

where the order p is specified in the **P=** option. The coefficients ϕ_i must define a stationary autoregressive polynomial.

MA= $\theta_1 \theta_2 \dots \theta_q$

lists the starting values of the coefficients of the nonseasonal moving average polynomial

$$\theta(B) = 1 - \theta_1 B - \dots - \theta_q B^q$$

where the order q is specified in the **Q=** option. The coefficients θ_i must define an invertible moving average polynomial.

NOEST=(**<VARIANCE>** **<AR>** **<SAR>** **<MA>** **<SMA>**)

fixes the values of the ARMA parameters and the value of the white noise variance to those specified in the **AR=**, **SAR=**, **MA=**, **SMA=**, or **VARIANCE=** options.

P=integer

specifies the order of the nonseasonal autoregressive polynomial. The order can be any nonnegative integer; the default value is 0. In practice the order is a small integer such as 1, 2, or 3.

Q=integer

specifies the order of the nonseasonal moving average polynomial. The order can be any nonnegative integer; the default value is 0. In practice the order is a small integer such as 1, 2, or 3.

S=integer

specifies the season length used during the specification of the seasonal autoregressive or seasonal moving average polynomial. The season length can be any positive integer; for example, $S=4$ might be an appropriate value for a quarterly series. The default value is $S=1$.

SAR= $\Phi_1 \Phi_2 \dots \Phi_P$

lists the starting values of the coefficients of the seasonal autoregressive polynomial

$$\Phi(B^s) = 1 - \Phi_1 B^s - \dots - \Phi_P B^{sP}$$

where the order P is specified in the **SP=** option and the season length s is specified in the **S=** option. The coefficients Φ_i must define a stationary autoregressive polynomial.

SMA= $\Theta_1 \Theta_2 \dots \Theta_Q$

lists the starting values of the coefficients of the seasonal moving average polynomial

$$\Theta(B^s) = 1 - \Theta_1 B^s - \dots - \Theta_Q B^{sQ}$$

where the order Q is specified in the **SQ=** option and the season length s is specified in the **S=** option. The coefficients Θ_i must define an invertible moving average polynomial.

SP=integer

specifies the order of the seasonal autoregressive polynomial. The order can be any nonnegative integer; the default value is 0. In practice the order is a small integer such as 1 or 2.

SQ=integer

specifies the order of the seasonal moving average polynomial. The order can be any nonnegative integer; the default value is 0. In practice the order is a small integer such as 1 or 2.

LEVEL Statement

LEVEL < options > ;

The LEVEL statement is used to include a level component in the model. The level component, either by itself or together with a slope component (see the [SLOPE](#) statement), forms the trend component, μ_t , of the model. If the slope component is absent, the resulting trend is a random walk (RW) specified by the following equations:

$$\mu_t = \mu_{t-1} + \eta_t, \quad \eta_t \sim i.i.d. \ N(0, \sigma_\eta^2)$$

If the slope component is present, signified by the presence of a [SLOPE](#) statement, a locally linear trend (LLT) is obtained. The equations of LLT are as follows:

$$\begin{aligned} \mu_t &= \mu_{t-1} + \beta_{t-1} + \eta_t, & \eta_t &\sim i.i.d. \ N(0, \sigma_\eta^2) \\ \beta_t &= \beta_{t-1} + \xi_t, & \xi_t &\sim i.i.d. \ N(0, \sigma_\xi^2) \end{aligned}$$

In either case, the options in the LEVEL statement are used to specify the value of σ_η^2 and to request forecasts of μ_t . The SLOPE statement is used for similar purposes in the case of slope β_t . The following examples illustrate the use of the LEVEL statement. Assuming that a SLOPE statement is not added subsequently, a simple random walk trend is specified by the following statement:

```
level;
```

The following statements specify a locally linear trend with value of σ_η^2 fixed at 4. It also requests printing of filtered values of μ_t . The value of σ_ξ^2 , the disturbance variance in the slope equation, is estimated from the data.

```
level variance=4 noest print=filter;
slope;
```

CHECKBREAK

turns on the checking of breaks in the level component.

NOEST

fixes the value of σ_η^2 to the value specified in the [VARIANCE=](#) option.

PLOT=FILTER

PLOT=SMOOTH

PLOT=(< FILTER > < SMOOTH >)

requests plotting of the filtered or smoothed estimate of the level component.

PRINT=FILTER**PRINT=SMOOTH****PRINT=(< FILTER > < SMOOTH >)**

requests printing of the filtered or smoothed estimate of the level component.

VARIANCE=valuespecifies an initial value for σ_{η}^2 , the disturbance variance in the μ_t equation at the start of the parameter estimation process. Any nonnegative value, including zero, is an acceptable starting value.

MODEL Statement

MODEL *dependent* < = *regressors* > ;

The MODEL statement specifies the response variable and, optionally, the predictor or regressor variables for the UCM model. This is a required statement in the UCM procedure. The predictors specified in the MODEL statement are assumed to have a linear and time-invariant relationship with the response. The predictors that have time-varying regression coefficients are specified separately in the [RANDOMREG](#) statement. Similarly, the predictors that have a nonlinear effect on the response variable are specified separately in the [SPLINEREG](#) statement. Only one MODEL statement can be specified.

NLOPTIONS Statement

NLOPTIONS < *options* > ;

PROC UCM uses the nonlinear optimization (NLO) subsystem to perform the nonlinear optimization of the likelihood function during the estimation of model parameters. You can use the NLOPTIONS statement to control different aspects of this optimization process. For most problems the default settings of the optimization process are adequate. However, in some cases it might be useful to change the optimization technique or to change the maximum number of iterations. This can be done by using the TECH= and MAXITER= options in the NLOPTIONS statement as follows:

```
nloptions tech=dbldog maxiter=200;
```

This sets the maximum number of iterations to 200 and changes the optimization technique to DBLDOG rather than the default technique, TRUREG, used in PROC UCM. A discussion of the full range of options that can be used with the NLOPTIONS statement is given in Chapter 6, “[Nonlinear Optimization Methods](#).” In PROC UCM all these options are available except the options related to the printing of the optimization history. In this version of PROC UCM all the printed output from the NLO subsystem is suppressed.

OUTLIER Statement

OUTLIER < options > ;

The OUTLIER statement enables you to control the reporting of the additive outliers (AO) and level shifts (LS) in the response series. The AOs are searched by default. You can turn on the search for LSs by using the [CHECKBREAK](#) option in the LEVEL statement.

ALPHA=*significance-level*

specifies the significance level for reporting the outliers. The default is 0.05.

MAXNUM=*number*

limits the number of outliers to search. The default is MAXNUM=5.

MAXPCT=*number*

is similar to the MAXNUM= option. In the MAXPCT= option you can limit the number of outliers to search for according to a percentage of the series length. The default is MAXPCT=1. When both of these options are specified, the minimum of the two search numbers is used.

PRINT=SHORT | DETAIL

enables you to control the printed output of the outlier search. The PRINT=SHORT option, which is the default, produces an outlier summary table containing the most significant outliers, either AO or LS, discovered in the outlier search. The PRINT=DETAIL option produces, in addition to the outlier summary table, separate tables containing the AO and LS structural break chi-square statistics computed at each time point in the estimation span.

RANDOMREG Statement

RANDOMREG *regressors* < / options > ;

The RANDOMREG statement is used to specify regressors with time-varying regression coefficients. Each regression coefficient—say, β_t —is assumed to evolve as a random walk:

$$\beta_t = \beta_{t-1} + \eta_t, \quad \eta_t \sim i.i.d. \ N(0, \sigma^2)$$

Of course, if the random walk disturbance variance σ^2 is zero, then the regression coefficient is not time varying, and it reduces to the standard regression setting. There can be multiple RANDOMREG statements, and each statement can contain one or more regressors. The regressors in a given RANDOMREG statement form a group that is assumed to share the same disturbance variance parameter. The random walks associated with different regressors are assumed to be independent. For an example of using this statement see [Example 34.4](#). See the section “[Reporting Parameter Estimates for Random Regressors](#)” on page 2157 for additional information about the way parameter estimates are reported for this type of regressors.

NOEST

fixes the value of σ^2 to the value specified in the **VARIANCE=** option.

PLOT=FILTER**PLOT=SMOOTH****PLOT=(< FILTER > < SMOOTH >)**

requests plotting of filtered or smoothed estimate of the time-varying regression coefficient.

PRINT=FILTER**PRINT=SMOOTH****PRINT=(< FILTER > < SMOOTH >)**

requests printing of the filtered or smoothed estimate of the time-varying regression coefficient.

VARIANCE=value

specifies an initial value for σ^2 during the parameter estimation process. Any nonnegative value, including zero, is an acceptable starting value.

SEASON Statement

SEASON *LENGTH* = *integer* < *options* > ;

The **SEASON** or **SEASONAL** statement is used to specify a seasonal component, γ_t , in the model. A seasonal component can be one of the two types, **DUMMY** or **TRIG**. A **DUMMY** seasonal with season length s satisfies the following stochastic equation:

$$\sum_{i=0}^{s-1} \gamma_{t-i} = \omega_t, \quad \omega_t \sim i.i.d. \ N(0, \sigma_\omega^2)$$

The equations for a **TRIG** (short for trigonometric) seasonal component are as follows

$$\gamma_t = \sum_{j=1}^{[s/2]} \gamma_{j,t}$$

where $[s/2]$ equals $s/2$ if s is even and $(s-1)/2$ if it is odd. The sinusoids, also called *harmonics*, $\gamma_{j,t}$ have frequencies $\lambda_j = 2\pi j/s$ and are specified by the matrix equation

$$\begin{bmatrix} \gamma_{j,t} \\ \gamma_{j,t}^* \end{bmatrix} = \begin{bmatrix} \cos \lambda_j & \sin \lambda_j \\ -\sin \lambda_j & \cos \lambda_j \end{bmatrix} \begin{bmatrix} \gamma_{j,t-1} \\ \gamma_{j,t-1}^* \end{bmatrix} + \begin{bmatrix} \omega_{j,t} \\ \omega_{j,t}^* \end{bmatrix}$$

where the disturbances $\omega_{j,t}$ and $\omega_{j,t}^*$ are assumed to be independent and, for fixed j , $\omega_{j,t}$ and $\omega_{j,t}^* \sim N(0, \sigma_\omega^2)$. If s is even, then the equation for $\gamma_{s/2,t}^*$ is not needed and $\gamma_{s/2,t}$ is given by

$$\gamma_{s/2,t} = -\gamma_{s/2,t-1} + \omega_{s/2,t}$$

In the **TRIG** seasonal case, the option **KEEPH=** or **DROPH=** can be used to obtain *subset trigonometric* seasonals that contain only a subset of the full set of harmonics $\gamma_{j,t}$, $j = 1, 2, \dots, [s/2]$. This is particularly useful when the season length s is large and the seasonal pattern is relatively smooth.

Note that whether the seasonal type is DUMMY or TRIG, there is only one parameter, the disturbance variance σ_{ω}^2 , in the seasonal model.

There can be more than one seasonal component in the model, necessarily with different season lengths if the seasons are full. You can have multiple *subset* season components with the same season length, if you need to use separate disturbance variances for different sets of harmonics. Each seasonal component is specified using a separate SEASON statement. A model with multiple seasonal components can easily become quite complex and might need a large amount of data and computing resources for its estimation and forecasting. The examples that follow illustrate the use of SEASON statement.

The following statement specifies a DUMMY type (default) seasonal component with a season length of four, corresponding to the quarterly seasonality. The disturbance variance σ_{ω}^2 is estimated from the data.

```
season length=4;
```

The following statement specifies a trigonometric seasonal with monthly seasonality. It also provides a starting value for σ_{ω}^2 .

```
season length=12 type=trig variance=4;
```

DROPHARMONICS|DROPH=number-list | n TO m BY p

enables you to drop some harmonics $\gamma_{j,t}$ from the full set of harmonics used to obtain a trigonometric seasonal. The drop list can include any integer between 1 and $[s/2]$, s being the season length. For example, the following specification results in a specification of a trigonometric seasonal with a season length 12 that consists of only the first four harmonics $\gamma_{j,t}$, $j = 1, 2, 3, 4$:

```
season length=12 type=trig DROPH=5 6;
```

The last two *high* frequency harmonics are dropped. The **DROPH=** option cannot be used with the **KEEPH=** option.

KEEPHARMONICS|KEEPH=number-list | n TO m BY p

enables you to keep only the harmonics $\gamma_{j,t}$ listed in the option to obtain a trigonometric seasonal. The keep list can include any integer between 1 and $[s/2]$, s being the season length. For example, the following specification results in a specification of a trigonometric seasonal with a season length of 12 that consists of all the six harmonics $\gamma_{j,t}$, $j = 1, \dots, 6$:

```
season length=12 type=trig KEEPH=1 to 3;
season length=12 type=trig KEEPH=4 to 6;
```

However, these six harmonics are grouped into two groups, each having its own disturbance variance parameter. The **DROPH=** option cannot be used with the **KEEPH=** option.

LENGTH=integer

specifies the season length, s . This is a required option in this statement. The season length can be any integer greater than or equal to 2. Typical examples of season lengths are 12, corresponding to the monthly seasonality, or 4, corresponding to the quarterly seasonality.

NOEST

fixes the value of the disturbance variance parameter to the value specified in the **VARIANCE=** option.

PLOT=FILTER**PLOT=SMOOTH****PLOT=F_ANNUAL****PLOT=S_ANNUAL****PLOT=(<plot request> ... <plot request>)**

requests plots of the season component. When you specify only one plot request, you can omit the parentheses around the plot request. You can use the **FILTER** and **SMOOTH** options to plot the filtered and smoothed estimates of the season component γ_t . You can use the **F_ANNUAL** and **S_ANNUAL** options to get the plots of “annual” variation in the filtered and smoothed estimates of γ_t . The annual plots are useful to see the change in the contribution of a particular month over the span of years. Here “month” and “year” are generic terms that change appropriately with the interval type being used to label the observations and the season length. For example, for monthly data with a season length of 12, the usual meaning applies, while for daily data with a season length of 7, the days of the week serve as months and the weeks serve as years.

PRINT=HARMONICS

requests printing of the summary of harmonics present in the seasonal component. This option is valid only for the trigonometric seasonal component.

PRINT=FILTER**PRINT=SMOOTH****PRINT=(<print request> ... <print request>)**

requests printing of the filtered or smoothed estimate of the seasonal component γ_t .

TYPE=DUMMY | TRIG

specifies the type of the seasonal component. The default type is **DUMMY**.

VARIANCE=value

specifies an initial value for the disturbance variance, σ_ω^2 , in the γ_t equation at the start of the parameter estimation process. Any nonnegative value, including zero, is an acceptable starting value.

SLOPE Statement

SLOPE <options> ;

The **SLOPE** statement is used to include a slope component in the model. The slope component cannot be used without the level component (see the **LEVEL** statement). The level and slope specifications jointly define the trend component of the model. A **SLOPE** statement without the accompanying **LEVEL** statement is ignored. The equations of the trend, defined jointly by the level μ_t and slope β_t , are as follows:

$$\begin{aligned}\mu_t &= \mu_{t-1} + \beta_{t-1} + \eta_t, & \eta_t &\sim i.i.d. N(0, \sigma_\eta^2) \\ \beta_t &= \beta_{t-1} + \xi_t, & \xi_t &\sim i.i.d. N(0, \sigma_\xi^2)\end{aligned}$$

The SLOPE statement is used to specify the value of the disturbance variance, σ_{ξ}^2 , in the slope equation, and to request forecasts of β_t . The following examples illustrate this statement:

```
level;
slope;
```

The preceding statements fit a model with a locally linear trend. The disturbance variances σ_{η}^2 and σ_{ξ}^2 are estimated from the data. You can request a locally linear trend with fixed slope by using the following statements:

```
level;
slope variance=0 noest;
```

NOEST

fixes the value of the disturbance variance, σ_{ξ}^2 , to the value specified in the **VARIANCE=** option.

PLOT=FILTER

PLOT=SMOOTH

PLOT=(< FILTER > < SMOOTH >)

requests plotting of the filtered or smoothed estimate of the slope component.

PRINT=FILTER

PRINT=SMOOTH

PRINT=(< FILTER > < SMOOTH >)

requests printing of the filtered or smoothed estimate of the slope component β_t .

VARIANCE=value

specifies an initial value for the disturbance variance, σ_{ξ}^2 , in the β_t equation at the start of the parameter estimation process. Any nonnegative value, including zero, is an acceptable starting value.

SPLINEREG Statement

SPLINEREG *regressor* < options > ;

The SPLINEREG statement is used to specify a regressor that has a nonlinear relationship with the dependent series that can be approximated by a given B-spline. If the specified spline has degree d and is based on n internal knots, then it is known that it can be written as a linear combination of $(n + d + 1)$ regressors that are derived from the original regressor. The span of these $(n + d + 1)$ derived regressors includes constant; therefore, to avoid multicollinearity with the level component, one of these regressors is dropped. Specifying the SPLINEREG statement is equivalent to specifying a RANDOMREG statement with these derived regressors. There can be multiple SPLINEREG statements. You must specify at least one interior knot, either using the NKNOTS= option or the KNOTS= option. For additional information about splines, see Chapter 93, “[The TRANSREG Procedure](#)” (*SAS/STAT User's Guide*). For an example of using this statement, see [Example 34.6](#). See the section “[Reporting Parameter Estimates for Random Regressors](#)” on page 2157 for additional information about the way parameter estimates are reported for this type of regressors.

DEGREE=integer

specifies the degree of the spline. It can be any integer larger than or equal to zero. The default value is 3. The polynomial degree should be a small integer, usually 0, 1, 2, or 3. Larger values are rarely useful. If you have any doubt as to what degree to specify, use the default.

KNOTS=number-list | n TO m BY p

specifies the interior knots or break points. The values in the knot list must be nondecreasing and must lie between the minimum and the maximum of the spline regressor values in the input data set. The first time you specify a value in the knot list, it indicates a discontinuity in the n th (from DEGREE= n) derivative of the transformation function at the value of the knot. The second mention of a value indicates a discontinuity in the $(n - 1)$ th derivative of the transformation function at the value of the knot. Knots can be repeated any number of times for decreasing smoothness at the break points, but the values in the knot list can never decrease.

You cannot use the **KNOTS=** option with the **NKNOTS=** option. You should keep the number of knots small.

NKNOTS=m

creates m knots, the first at the $100/(m + 1)$ percentile, the second at the $200/(m + 1)$ percentile, and so on. Knots are always placed at data values; there is no interpolation. For example, if **NKNOTS=3**, knots are placed at the 25th percentile, the median, and the 75th percentile. The value specified for the **NKNOTS=** option must be ≥ 1 . You cannot use the **NKNOTS=** option with the **KNOTS=** option.

NOTE: Specifying knots by using the **NKNOTS=** option can result in different sets of knots in the estimation and forecast stages if the distributions of regressor values in the estimation and forecast spans differ. The estimation span is based on the **BACK=** and **SKIPFIRST=** options in the **ESTIMATE** statement, and the forecast span is based on the **BACK=** and **SKIPFIRST=** options in the **FORECAST** statement.

NOEST

fixes the value of the regression coefficient random walk disturbance variance to the value specified in the **VARIANCE=** option.

PLOT=FILTER**PLOT=SMOOTH****PLOT=(< FILTER > < SMOOTH >)**

requests plotting of filtered or smoothed estimate of the time-varying regression coefficient.

PRINT=FILTER**PRINT=SMOOTH****PRINT=(< FILTER > < SMOOTH >)**

requests printing of filtered or smoothed estimate of the time-varying regression coefficient.

VARIANCE=value

specifies an initial value for the regression coefficient random walk disturbance variance during the parameter estimation process. Any nonnegative value, including zero, is an acceptable starting value.

SPLINESEASON Statement

SPLINESEASON *LENGTH* = *integer* *KNOTS* = *integer*₁ *integer*₂ ... <options> ;

The SPLINESEASON statement is used to specify a seasonal pattern that is to be approximated by a given B-spline. If the specified spline has degree d and is based on n internal knots, then it can be written as a linear combination of $(n + d)$ regressors that are derived from the seasonal dummy regressors. The SPLINESEASON specification is equivalent to specifying a RANDOMREG specification with these derived regressors. Such approximation is useful only if the season length is relatively large, at least larger than $(n + d)$. For additional information about splines, see Chapter 93, “The TRANSREG Procedure” (*SAS/STAT User's Guide*). For an example of using this statement, see [Example 34.3](#).

DEGREE = *integer*

specifies the degree of the spline. It can be any integer greater than or equal to zero. The default value is 3.

KNOTS = *integer*₁ *integer*₂ ...

lists the *internal* knots. This list of values must be a nondecreasing sequence of integers within the range of 2 to $(s - 1)$, where s is the season length specified in the **LENGTH**= option. This is a required option in this statement.

LENGTH = *integer*

specifies the season length, s . This is a required option in this statement. The length can be any integer greater than or equal to three.

NOEST

fixes the value of the regression coefficient random walk disturbance variance to the value specified in the **VARIANCE**= option.

OFFSET = *integer*

specifies the position of the first measurement within the season, if the first measurement is not at the start of the season. The OFFSET= value must be between one and the season length. The default value is one. The first measurement refers to the start of the estimation span and the forecast span. If these spans differ, their starting measurements must be separated by an integer multiple of the season length.

PLOT = **FILTER**

PLOT = **SMOOTH**

PLOT = (< **FILTER** > < **SMOOTH** >)

requests plots of the season component. When you specify only one plot request, you can omit the parentheses around the plot request. You can use the FILTER and SMOOTH options to plot the filtered and smoothed estimates of the season component.

PRINT = **FILTER**

PRINT = **SMOOTH**

PRINT = (< **FILTER** > < **SMOOTH** >)

requests the printing of the filtered or smoothed estimate of the spline season component.

RKNOTS=(*knot*, ..., *knot*) ... (*knot*, ..., *knot*)

Experimental

specifies a grouping of knots such that the knots within the same group have identical seasonal values. The knots specified in this option must already be present in the list specified by the **KNOTS**= option. The knot groups must be non-overlapping and without any repeated knots.

VARIANCE=*value*

specifies an initial value for the regression coefficient random walk disturbance variance during the parameter estimation process. Any nonnegative value, including zero, is an acceptable starting value.

Details: UCM Procedure

An Introduction to Unobserved Component Models

A UCM decomposes the response series into components such as trend, seasons, cycles, and the regression effects due to predictor series. The following model shows a possible scenario:

$$y_t = \mu_t + \gamma_t + \psi_t + \sum_{j=1}^m \beta_j x_{jt} + \epsilon_t$$

$$\epsilon_t \sim i.i.d. N(0, \sigma_\epsilon^2)$$

The terms μ_t , γ_t , and ψ_t represent the trend, seasonal, and cyclical components, respectively. In fact the model can contain multiple seasons and cycles, and the seasons can be of different types. For simplicity of discussion the preceding model contains only one of each of these components. The regression term, $\sum_{j=1}^m \beta_j x_{jt}$, includes contribution of regression variables with *fixed* regression coefficients. A model can also contain regression variables that have *time varying* regression coefficients or that have a nonlinear relationship with the dependent series (see “[Incorporating Predictors of Different Kinds](#)” on page 2156). The disturbance term ϵ_t , also called the *irregular* component, is usually assumed to be Gaussian white noise. In some cases it is useful to model the irregular component as a stationary ARMA process. See the section “[Modeling the Irregular Component](#)” on page 2148 for additional information.

By controlling the presence or absence of various terms and by choosing the proper flavor of the included terms, the UCMs can generate a rich variety of time series patterns. A UCM can be applied to variables after transforming them by transforms such as *log* and *difference*.

The components μ_t , γ_t , and ψ_t model structurally different aspects of the time series. For example, the trend μ_t models the natural tendency of the series in the absence of any other perturbing effects such as seasonality, cyclical components, and the effects of exogenous variables, while the seasonal component γ_t models the correction to the level due to the seasonal effects. These components are assumed to be statistically independent of each other and independent of the irregular component. All of the component models can be thought of as stochastic generalizations of the relevant deterministic patterns in time. This way the deterministic cases emerge as special cases of the stochastic models. The different models available for these unobserved components are discussed next.

Modeling the Trend

As mentioned earlier, the trend in a series can be loosely defined as the natural tendency of the series in the absence of any other perturbing effects. The UCM procedure offers two ways to model the trend component μ_t . The first model, called the random walk (RW) model, implies that the trend remains roughly constant throughout the life of the series without any persistent upward or downward drift. In the second model the trend is modeled as a locally linear time trend (LLT). The RW model can be described as

$$\mu_t = \mu_{t-1} + \eta_t, \quad \eta_t \sim i.i.d. \ N(0, \sigma_\eta^2)$$

Note that if $\sigma_\eta^2 = 0$, then the model becomes $\mu_t = \text{constant}$. In the LLT model the trend is locally linear, consisting of both the *level* and *slope*. The LLT model is

$$\begin{aligned} \mu_t &= \mu_{t-1} + \beta_{t-1} + \eta_t, & \eta_t &\sim i.i.d. \ N(0, \sigma_\eta^2) \\ \beta_t &= \beta_{t-1} + \xi_t, & \xi_t &\sim i.i.d. \ N(0, \sigma_\xi^2) \end{aligned}$$

The disturbances η_t and ξ_t are assumed to be independent. There are some interesting special cases of this model obtained by setting one or both of the disturbance variances σ_η^2 and σ_ξ^2 equal to zero. If σ_ξ^2 is set equal to zero, then you get a linear trend model with fixed slope. If σ_η^2 is set to zero, then the resulting model usually has a smoother trend. If both the variances are set to zero, then the resulting model is the deterministic linear time trend: $\mu_t = \mu_0 + \beta_0 t$.

You can incorporate these trend patterns in your model by using the **LEVEL** and **SLOPE** statements.

Modeling a Cycle

A deterministic cycle ψ_t with frequency λ , $0 < \lambda < \pi$, can be written as

$$\psi_t = \alpha \cos(\lambda t) + \beta \sin(\lambda t)$$

If the argument t is measured on a continuous scale, then ψ_t is a periodic function with period $2\pi/\lambda$, amplitude $\gamma = (\alpha^2 + \beta^2)^{1/2}$, and phase $\phi = \tan^{-1}(\beta/\alpha)$. Equivalently, the cycle can be written in terms of the amplitude and phase as

$$\psi_t = \gamma \cos(\lambda t - \phi)$$

Note that when ψ_t is measured only at the integer values, it is not exactly periodic, unless $\lambda = (2\pi j)/k$ for some integers j and k . The cycles in their pure form are not used very often in practice. However, they are very useful as building blocks for more complex periodic patterns. It is well known that the periodic pattern of any complexity can be written as a sum of pure cycles of different frequencies and amplitudes. In time series situations it is useful to generalize this simple cyclical pattern to a stochastic cycle that has a fixed period but time-varying amplitude and phase. The stochastic cycle considered here is motivated by the following recursive formula for computing ψ_t :

$$\begin{bmatrix} \psi_t \\ \psi_t^* \end{bmatrix} = \begin{bmatrix} \cos \lambda & \sin \lambda \\ -\sin \lambda & \cos \lambda \end{bmatrix} \begin{bmatrix} \psi_{t-1} \\ \psi_{t-1}^* \end{bmatrix}$$

starting with $\psi_0 = \alpha$ and $\psi_0^* = \beta$. Note that ψ_t and ψ_t^* satisfy the relation

$$\psi_t^2 + \psi_t^{*2} = \alpha^2 + \beta^2 \quad \text{for all } t$$

A stochastic generalization of the cycle ψ_t can be obtained by adding random noise to this recursion and by introducing a damping factor, ρ , for additional modeling flexibility. This model can be described as follows

$$\begin{bmatrix} \psi_t \\ \psi_t^* \end{bmatrix} = \rho \begin{bmatrix} \cos \lambda & \sin \lambda \\ -\sin \lambda & \cos \lambda \end{bmatrix} \begin{bmatrix} \psi_{t-1} \\ \psi_{t-1}^* \end{bmatrix} + \begin{bmatrix} v_t \\ v_t^* \end{bmatrix}$$

where $0 \leq \rho \leq 1$, and the disturbances v_t and v_t^* are independent $N(0, \sigma_v^2)$ variables. The resulting stochastic cycle has a fixed period but time-varying amplitude and phase. The stationarity properties of the random sequence ψ_t depend on the damping factor ρ . If $\rho < 1$, ψ_t has a stationary distribution with mean zero and variance $\sigma_v^2/(1 - \rho^2)$. If $\rho = 1$, ψ_t is nonstationary.

You can incorporate a cycle in a UCM by specifying a **CYCLE** statement. You can include multiple cycles in the model by using separate **CYCLE** statements for each included cycle.

As mentioned before, the cycles are very useful as building blocks for constructing more complex periodic patterns. Periodic patterns of almost any complexity can be created by superimposing cycles of different periods and amplitudes. In particular, the seasonal patterns, general periodic patterns with integer periods, can be constructed as sums of cycles. This important topic of modeling the seasonal components is considered next.

Modeling Seasons

The seasonal fluctuations are a common source of variation in time series data. These fluctuations arise because of the regular changes in seasons or some other periodic events. The seasonal effects are regarded as corrections to the general trend of the series due to the seasonal variations, and these effects sum to zero when summed over the full season cycle. Therefore the seasonal component γ_t is modeled as a stochastic periodic pattern of an integer period s such that the sum $\sum_{i=0}^{s-1} \gamma_{t-i}$ is always zero in the mean. The period s is called the season length. Two different models for the seasonal component are considered here. The first model is called the *dummy* variable form of the seasonal component. It is described by the equation

$$\sum_{i=0}^{s-1} \gamma_{t-i} = \omega_t, \quad \omega_t \sim i.i.d. \ N(0, \sigma_\omega^2)$$

The other model is called the *trigonometric* form of the seasonal component. In this case γ_t is modeled as a sum of cycles of different frequencies. This model is given as follows

$$\gamma_t = \sum_{j=1}^{[s/2]} \gamma_{j,t}$$

where $[s/2]$ equals $s/2$ if s is even and $(s-1)/2$ if it is odd. The cycles $\gamma_{j,t}$ have frequencies $\lambda_j = 2\pi j/s$ and are specified by the matrix equation

$$\begin{bmatrix} \gamma_{j,t} \\ \gamma_{j,t}^* \end{bmatrix} = \begin{bmatrix} \cos \lambda_j & \sin \lambda_j \\ -\sin \lambda_j & \cos \lambda_j \end{bmatrix} \begin{bmatrix} \gamma_{j,t-1} \\ \gamma_{j,t-1}^* \end{bmatrix} + \begin{bmatrix} \omega_{j,t} \\ \omega_{j,t}^* \end{bmatrix}$$

where the disturbances $\omega_{j,t}$ and $\omega_{j,t}^*$ are assumed to be independent and, for fixed j , $\omega_{j,t}$ and $\omega_{j,t}^* \sim N(0, \sigma_\omega^2)$. If s is even, then the equation for $\gamma_{s/2,t}^*$ is not needed and $\gamma_{s/2,t}$ is given by

$$\gamma_{s/2,t} = -\gamma_{s/2,t-1} + \omega_{s/2,t}$$

The cycles $\gamma_{j,t}$ are called *harmonics*. If the seasonal component is deterministic, the decomposition of the seasonal effects into these harmonics is identical to its Fourier decomposition. In this case the sum of squares of the seasonal factors equals the sum of squares of the amplitudes of these harmonics. In many practical situations, the contribution of the high-frequency harmonics is negligible and can be ignored, giving rise to a simpler description of the seasonal. In the case of stochastic seasonals, the situation might not be so transparent; however, similar considerations still apply. Note that if the disturbance variance $\sigma_\omega^2 = 0$, then both the dummy and the trigonometric forms of seasonal components reduce to constant seasonal effects. That is, the seasonal component reduces to a deterministic function that is completely determined by its first $s - 1$ values.

In the UCM procedure you can specify a seasonal component in a variety of ways, the **SEASON** statement being the simplest of these. The dummy and the trigonometric seasonal components discussed so far can be considered as *saturated* seasonal components that put no restrictions on the $s - 1$ seasonal values. In some cases a more parsimonious representation of the seasonal might be more appropriate. This is particularly useful for seasonal components with large season lengths. In the UCM procedure you can obtain parsimonious representations of the seasonal components by one of the following ways:

- Use a *subset* trigonometric seasonal component obtained by deleting a few of the $[s/2]$ harmonics used in its sum. For example, a slightly smoother seasonal component of length 12, corresponding to the monthly seasonality, can be obtained by deleting the highest-frequency harmonic of period 2. That is, such a seasonal component will be a sum of five stochastic cycles that have periods 12, 6, 4, 3, and 2.4. You can specify such subset seasonal components by using the **KEEPH=** or **DROPH=** option in the **SEASON** statement.
- Approximate the seasonal pattern by a suitable spline approximation. You can do this by using the **SPLINESEASON** statement.
- A *block-seasonal* pattern is a seasonal pattern where the pattern is divided into a few blocks of equal length such that the season values within a block are the same—for example, a monthly seasonal pattern that has only four different values, one for each quarter. In some situations a long seasonal pattern can be approximated by the sum of block season and a simple season, the length of the simple season being equal to the block length of the block season. You can obtain such approximation by using a combination of **BLOCKSEASON** and **SEASON** statements.
- Consider a seasonal component of a large season length as a sum of two or more seasonal components that are each of much smaller season lengths. This can be done by specifying more than one **SEASON** statements.

Note that the preceding techniques of obtaining parsimonious seasonal components can also enable you to specify seasonal components that are more *general* than the simple saturated seasonal components. For example, you can specify a saturated trigonometric seasonal component that has some of its harmonics evolving according to one disturbance variance parameter while the others evolve with another disturbance variance parameter.

Modeling an Autoregression

An autoregression of order one can be thought of as a special case of a cycle when the frequency λ is either 0 or π . Modeling this special case separately helps interpretation and parameter estimation. The autoregression component r_t is modeled as follows

$$r_t = \rho r_{t-1} + v_t, \quad v_t \sim i.i.d. \ N(0, \sigma_v^2)$$

where $-1 \leq \rho < 1$. An autoregression can also provide an alternative to the **IRREGULAR** component when the model errors show some autocorrelation. You can incorporate an autoregression in your model by using the **AUTOREG** statement.

Modeling Regression Effects

A predictor variable can affect the response variable in a variety of ways. The UCM procedure enables you to model several different types of predictor-response relationships:

- The predictor-response relationship is *linear*, and the regression coefficient does not change with time. This is the simplest kind of relationship and such predictors are specified in the **MODEL** statement.
- The predictor-response relationship is *linear*, but the regression coefficient does change with time. Such predictors are specified in the **RANDOMREG** statement. Here the regression coefficient is assumed to evolve as a random walk.
- The predictor-response relationship is *nonlinear* and the relationship can change with time. This type of relationship can be approximated by an appropriate time-varying spline. Such predictors are specified in the **SPLINEREG** statement.

A response variable can depend on its own past values—that is, lagged dependent values. Such a relationship can be specified in the **DEPLAG** statement.

Modeling the Irregular Component

The components—such as trend, seasonal and regression effects, and nonstationary cycles—are used to capture the structural dynamics of a response series. In contrast, the stationary cycles and the autoregression are used to capture the transient aspects of the response series that are important for its short-range prediction but have little impact on its long-term forecasts. The irregular component represents the residual variation remaining in the response series that is modeled using an appropriate selection of structural and transient effects. In most cases, the irregular component can be assumed to be simply Gaussian white noise. In some other cases, however, the residual variation can be more complicated. In such situations, it might be necessary to model the irregular component as a stationary ARMA process. Moreover, you can use the ARMA irregular component together with the dependent lag specification (see the **DEPLAG** statement) to specify an $\text{ARIMA}(p, d, q) \times (P, D, Q)_s$ model for the response series. See the **IRREGULAR** statement for the explanation of the ARIMA notation. See [Example 34.8](#) for an example of modeling a series by using an $\text{ARIMA}(0, 1, 1) \times (0, 1, 1)_{12}$ model.

The Model Parameters

The parameter vector in a UCM consists of the variances of the disturbance terms of the unobserved components, the damping coefficients and frequencies in the cycles, the damping coefficient in the autoregression, and the regression coefficients in the regression terms. These parameters are estimated by maximizing the likelihood. It is possible to restrict the values of the model parameters to user-specified values.

Model Specification

A UCM is specified by describing the components in the model. For example, consider the model

$$y_t = \mu_t + \gamma_t + \epsilon_t$$

consisting of the irregular, level, slope, and seasonal components. This model is called the basic structural model (BSM) by Harvey (1989). The syntax for a BSM with monthly seasonality of trigonometric type is as follows:

```
model y;
irregular;
level;
slope;
season length=12 type=trig;
```

Similarly the following syntax specifies a BSM with a response variable y , a regressor x , and dummy-type monthly seasonality:

```
model y = x;
irregular;
level;
slope variance=0 noest;
season length=12 type=dummy;
```

Moreover, the disturbance variance of the slope component is restricted to zero, giving rise to a local linear trend with fixed slope.

A model can contain multiple cycle and seasonal components. In such cases the model syntax contains a separate statement for each of these multiple cycle or seasonal components; for example, the syntax for a model containing irregular and level components along with two cycle components could be as follows:

```
model y = x;
irregular;
level;
cycle;
cycle;
```

The UCMs as State Space Models

The UCMs considered in PROC UCM can be thought of as special cases of more general models, called (linear) Gaussian state space models (GSSM). A GSSM can be described as follows:

$$\begin{aligned} y_t &= Z_t \alpha_t \\ \alpha_{t+1} &= T_t \alpha_t + \zeta_{t+1}, \quad \zeta_t \sim N(0, Q_t) \\ \alpha_1 &\sim N(0, P) \end{aligned}$$

The first equation, called the *observation equation*, relates the response series y_t to a state vector α_t that is usually unobserved. The second equation, called the *state equation*, describes the evolution of the state vector in time. The system matrices Z_t and T_t are of appropriate dimensions and are known, except possibly for some unknown elements that become part of the parameter vector of the model. The noise series ζ_t consists of independent, zero-mean, Gaussian vectors with covariance matrices Q_t . For most of the UCMs considered here, the system matrices Z_t and T_t , and the noise covariances Q_t , are time invariant—that is, they do not depend on time. In a few cases, however, some or all of them can depend on time. The initial state vector α_1 is assumed to be independent of the noise series, and its covariance matrix P can be partially diffuse. A random vector has a partially diffuse covariance matrix if it can be partitioned such that one part of the vector has a properly defined probability distribution, while the covariance matrix of the other part is infinite—that is, you have no prior information about this part of the vector. The covariance of the initial state α_1 is assumed to have the following form:

$$P = P_* + \kappa P_\infty$$

where P_* and P_∞ are nonnegative definite, symmetric matrices and κ is a constant that is assumed to be close to ∞ . In the case of UCMs considered here, P_∞ is always a diagonal matrix that consists of zeros and ones, and, if a particular diagonal element of P_∞ is one, then the corresponding row and column in P_* are zero.

The state space formulation of a UCM has many computational advantages. In this formulation there are convenient algorithms for estimating and forecasting the unobserved states $\{\alpha_t\}$ by using the observed series $\{y_t\}$. These algorithms also yield the in-sample and out-of-sample forecasts and the likelihood of $\{y_t\}$. The state space representation of a UCM does not need to be unique. In the representation used here, the unobserved components in the UCM often appear as elements of the state vector. This makes the elements of the state interpretable and, more important, the sample estimates and forecasts of these unobserved components are easily obtained. For additional information about the computational aspects of the state space modeling, see Durbin and Koopman (2001). Next, some notation is developed to describe the essential quantities computed during the analysis of the state space models.

Let $\{y_t, t = 1, \dots, n\}$ be the observed sample from a series that satisfies a state space model. Next, for $1 \leq t \leq n$, let the one-step-ahead forecasts of the series, the states, and their variances be defined as follows, using the usual notation to denote the conditional expectation and conditional variance:

$$\begin{aligned} \hat{\alpha}_t &= E(\alpha_t | y_1, y_2, \dots, y_{t-1}) \\ \Gamma_t &= \text{Var}(\alpha_t | y_1, y_2, \dots, y_{t-1}) \\ \hat{y}_t &= E(y_t | y_1, y_2, \dots, y_{t-1}) \\ F_t &= \text{Var}(y_t | y_1, y_2, \dots, y_{t-1}) \end{aligned}$$

These are also called the *filtered* estimates of the series and the states. Similarly, for $t \geq 1$, let the following denote the full-sample estimates of the series and the state values at time t :

$$\begin{aligned}\tilde{\alpha}_t &= E(\alpha_t | y_1, y_2, \dots, y_n) \\ \Delta_t &= \text{Var}(\alpha_t | y_1, y_2, \dots, y_n) \\ \tilde{y}_t &= E(y_t | y_1, y_2, \dots, y_n) \\ G_t &= \text{Var}(y_t | y_1, y_2, \dots, y_n)\end{aligned}$$

If the time t is in the historical period— that is, if $1 \leq t \leq n$ — then the full-sample estimates are called the *smoothed* estimates, and if t lies in the future then they are called out-of-sample forecasts. Note that if $1 \leq t \leq n$, then $\tilde{y}_t = y_t$ and $G_t = 0$, unless y_t is missing.

All the filtered and smoothed estimates ($\hat{\alpha}_t, \tilde{\alpha}_t, \dots, G_t$, and so on) are computed by using the Kalman filtering and smoothing (KFS) algorithm, which is an iterative process. If the initial state is diffuse, as is often the case for the UCMs, its treatment requires modification of the traditional KFS, which is called the diffuse KFS (DKFS). The details of DKFS implemented in the UCM procedure can be found in de Jong and Chu-Chun-Lin (2003). Additional information on the state space models can be found in Durbin and Koopman (2001). The likelihood formulas described in this section are taken from the latter reference.

In the case of diffuse initial condition, the effect of the improper prior distribution of α_1 manifests itself in the first few filtering iterations. During these initial filtering iterations the distribution of the filtered quantities remains diffuse; that is, during these iterations the one-step-ahead series and state forecast variances F_t and Γ_t have the following form:

$$\begin{aligned}F_t &= F_{*t} + \kappa F_{\infty t} \\ \Gamma_t &= \Gamma_{*t} + \kappa \Gamma_{\infty t}\end{aligned}$$

The actual number of iterations—say, I — affected by this improper prior depends on the nature of the vectors Z_t , the number of nonzero diagonal elements of P_∞ , and the pattern of missing values in the dependent series. After I iterations, $\Gamma_{\infty t}$ and $F_{\infty t}$ become zero and the one-step-ahead series and state forecasts have proper distributions. These first I iterations constitute the *initialization* phase of the DKFS algorithm. The post-initialization phase of the DKFS and the traditional KFS is the same. In the state space modeling literature the pre-initialization and post-initialization phases are some times called *pre-collapse* and *post-collapse* phases of the diffuse Kalman filtering. In certain missing value patterns it is possible for I to exceed the sample size; that is, the sample information can be insufficient to create a proper prior for the filtering process. In these cases, parameter estimation and forecasting is done on the basis of this improper prior, and some or all of the series and component forecasts can have infinite variances (or zero precision). The forecasts that have infinite variance are set to missing. The same situation can occur if the specified model contains components that are essentially multicollinear. In these situations no residual analysis is possible; in particular, no residuals-based goodness-of-fit statistics are produced.

The log likelihood of the sample (L_∞), which takes account of this diffuse initialization step, is computed by using the one-step-ahead series forecasts as follows

$$L_\infty(y_1, \dots, y_n) = -\frac{(n-d)}{2} \log 2\pi - \frac{1}{2} \sum_{t=1}^I w_t - \frac{1}{2} \sum_{t=I+1}^n \left(\log F_t + \frac{v_t^2}{F_t} \right)$$

where d is the number of diffuse elements in the initial state α_1 , $v_t = y_t - Z_t \hat{\alpha}_t$ are the one-step-ahead residuals, and

$$\begin{aligned} w_t &= \log F_{\infty t} && \text{if } F_{\infty t} > 0 \\ &= \log F_{*t} + \frac{v_t^2}{F_{*t}} && \text{if } F_{\infty t} = 0 \end{aligned}$$

If y_t is missing at some time t , then the corresponding summand in the log likelihood expression is deleted, and the constant term is adjusted suitably. Moreover, if the initialization step does not complete—that is, if I exceeds the sample size—then the value of d is reduced to the number of diffuse states that are successfully initialized.

The portion of the log likelihood that corresponds to the post-initialization period is called the nondiffuse log likelihood (L_0). The nondiffuse log likelihood is given by

$$L_0(y_1, \dots, y_n) = -\frac{1}{2} \sum_{t=I+1}^n (\log F_t + \frac{v_t^2}{F_t})$$

In the case of UCMs considered in PROC UCM, it often happens that the diffuse part of the likelihood, $\sum_{t=1}^I w_t$, does not depend on the model parameters, and in these cases the maximization of nondiffuse and diffuse likelihoods is equivalent. However, in some cases, such as when the model consists of dependent lags, the diffuse part does depend on the model parameters. In these cases the maximization of the diffuse and nondiffuse likelihood can produce different parameter estimates.

In some situations it is convenient to reparameterize the nondiffuse initial state covariance P_* as $\sigma^2 P_*$ and the state noise covariance Q_t as $\sigma^2 Q_t$ for some common scalar parameter σ^2 . In this case the preceding log-likelihood expression, up to a constant, can be written as

$$L_\infty(y_1, \dots, y_n) = -\frac{1}{2} \sum_{t=1}^I w_t - \frac{1}{2} \sum_{t=I+1}^n \log F_t - \frac{1}{2\sigma^2} \sum_{t=I+1}^n \frac{v_t^2}{F_t} - \frac{(n-d)}{2} \log \sigma^2$$

Solving analytically for the optimum, the maximum likelihood estimate of σ^2 can be shown to be

$$\hat{\sigma}^2 = \frac{1}{(n-d)} \sum_{t=I+1}^n \frac{v_t^2}{F_t}$$

When this expression of σ^2 is substituted back into the likelihood formula, an expression called the *profile likelihood* ($L_{profile}$) of the data is obtained:

$$-2L_{profile}(y_1, \dots, y_n) = \sum_{t=1}^I w_t + \sum_{t=I+1}^n \log F_t + (n-d) \log \left(\sum_{t=I+1}^n \frac{v_t^2}{F_t} \right)$$

In some situations the parameter estimation is done by optimizing the profile likelihood (see the section “[Parameter Estimation by Profile Likelihood Optimization](#)” on page 2160 and the **PROFILE** option in the **ESTIMATE** statement).

In the remainder of this section the state space formulation of UCMs is further explained by using some particular UCMs as examples. The examples show that the state space formulation of the UCMs depends

on the components in the model in a simple fashion; for example, the system matrix T is usually a block diagonal matrix with blocks that correspond to the components in the model. The only exception to this pattern is the UCMs that consist of the lags of dependent variable. This case is considered at the end of the section.

In what follows, $Diag[a, b, \dots]$ denotes a diagonal matrix with diagonal entries $[a, b, \dots]$, and the transpose of a matrix T is denoted as T' .

Locally Linear Trend Model

Recall that the dynamics of the locally linear trend model are

$$\begin{aligned} y_t &= \mu_t + \epsilon_t \\ \mu_t &= \mu_{t-1} + \beta_{t-1} + \eta_t \\ \beta_t &= \beta_{t-1} + \xi_t \end{aligned}$$

Here y_t is the response series and ϵ_t , η_t , and ξ_t are independent, zero-mean Gaussian disturbance sequences with variances σ_ϵ^2 , σ_η^2 , and σ_ξ^2 , respectively. This model can be formulated as a state space model where the state vector $\alpha_t = [\epsilon_t \mu_t \beta_t]'$ and the state noise $\zeta_t = [\epsilon_t \eta_t \xi_t]'$. Note that the elements of the state vector are precisely the unobserved components in the model. The system matrices T and Z and the noise covariance Q corresponding to this choice of state and state noise vectors can be seen to be time invariant and are given by

$$Z = [1 \ 1 \ 0], \quad T = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{bmatrix} \quad \text{and} \quad Q = Diag[\sigma_\epsilon^2, \sigma_\eta^2, \sigma_\xi^2]$$
